Sublingual organic nitrates should be taken at the time of an anginal attack or in anticipation of exercise or stress. Such intermittent treatment provides reproducible cardiovascular effects. However, frequently repeated or continuous exposure to high doses of organic nitrates leads to a marked attenuation in the magnitude of most of their effects. The magnitude of tolerance is a function of dosage and frequency of use.

Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO (*i.e.*, true vascular tolerance), or to the activation of mechanisms extraneous to the vessel wall (*i.e.*, pseudotolerance). Multiple mechanisms are proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals. Inactivation of aldehyde dehydrogenase, a mitochondrial enzyme implicated in nitroglycerin biotransformation, is seen in models of nitrate tolerance. A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway; tolerance could involve endothelium-derived superoxide.

A more effective approach to restoring responsiveness is to interrupt therapy for 8–12 hours each day, which restores efficacy. It is usually convenient to omit dosing at night in patients with exertional angina, either by adjusting dosing intervals of oral or buccal preparations or by removing

cutaneous nitroglycerin. However, patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (*i.e.*, occurring in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Tolerance also has been seen with *isosorbide-5-mononitrate*; an eccentric twice-daily dosing schedule appears to maintain efficacy.

While these approaches often are effective, some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using nitroglycerin patches; such patients may require another class of antianginal agent during this period. Tolerance is not universal, and some patients develop only partial tolerance. The problem of anginal rebound during nitrate-free intervals is especially problematic in the treatment of unstable angina with intravenous nitroglycerin. As tolerance develops, increasing doses are required to achieve the same therapeutic effects; eventually, despite dose escalation, the drug loses efficacy.

Toxicity and Untoward Responses

Untoward responses to the organic nitrates are almost all secondary to cardiovascular actions. Headache is common and can be severe. It usually decreases over a few days if treatment is continued and often responds to decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and occasionally may progress to loss of consciousness. This reaction appears to be accentuated by *alcohol*, and also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All organic nitrates occasionally can produce rash.

INTERACTION OF NITRATES WITH PHOSPHODIESTERASE 5 INHIBITORS

Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of coronary artery disease. Thus, many men desiring therapy for erectile dysfunction already may be receiving antianginal therapy. The *phosphodiesterase 5 (PDE5) inhibitors sildenafil (VIAGRA), tadalafil (CIALIS), and vardenafil (LEVITRA)* have been developed and widely used for therapy of erectile dysfunction. In the presence of a PDE5 inhibitor, nitrates cause profound increases in cyclic GMP and can dramatically reduce blood pressure. Thus, all three PDE5 inhibitors are contraindicated in patients taking organic nitrate vasodilators, as indicated by a “black box” warning on product labeling. In the event that patients develop significant hypotension following combined administration of PDE5 inhibitor and a nitrate, fluids and α adrenergic receptor agonists, if needed, should be used for support.

Therapeutic Uses

ANGINA Diseases that predispose to angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute anxiety can precipitate anginal symptoms in many patients. The patient should be asked to stop smoking and overeating; hypertension and hyperlipidemia should be corrected (*see* Chapters 32 and 35); and daily aspirin (or clopidogrel or *ticlopidine* if aspirin is not tolerated) (*see* Chapter 54) should be prescribed. Exposure to sympathomimetic agents (*e.g.*, those in nasal decongestants) should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

CONGESTIVE HEART FAILURE The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 33.

UNSTABLE ANGINA PECTORIS AND NON-ST-SEGMENT-ELEVATION MYOCARDIAL INFARCTION The term *unstable angina pectoris* has been used to describe a broad spectrum of clinical entities characterized by an acute or subacute worsening in a patient’s anginal symptoms. The variable prognosis of unstable angina no doubt reflects the broad range of clinical entities subsumed by the term. More recently, efforts have been directed toward identifying patients with unstable angina on the basis of their risks for subsequent adverse outcomes (*e.g.*, myocardial infarction or death). The term *acute coronary syndrome* is useful in this context: common to most clinical presentations of acute coronary syndrome is disruption of a coronary plaque leading to local platelet aggregation and thrombosis at the arterial wall with subsequent partial or total occlusion of the vessel. There is some variability in the pathogenesis of unstable angina, with gradually progressive

atherosclerosis accounting for some cases of new-onset exertional angina. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for some cases where rest angina has not been preceded by symptoms of exertional angina. For the most part, the pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial oxygen demand—have limited efficacy in the treatment of acute coronary syndromes characterized by an insufficiency of myocardial oxygen (blood) supply.

Drugs that reduce myocardial oxygen consumption by reducing ventricular preload (nitrates) or by reducing heart rate and ventricular contractility (β adrenergic receptor antagonists) are efficacious, but additional therapies are directed at the atherosclerotic plaque itself and the consequences (or prevention) of its rupture. These therapies include combinations of (1) antiplatelet agents, including aspirin and clopidogrel; (2) antithrombin agents such as heparin and the thrombolytics; (3) anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein (GP)IIb/IIIa; (4) mechanopharmacological approaches with percutaneously deployed drug-delivering intracoronary stents; or (5) coronary bypass surgery for selected patients.

Along with nitrates and β adrenergic receptor antagonists, antiplatelet agents represent the cornerstone of therapy for acute coronary syndrome. Aspirin inhibits platelet aggregation and improves survival. Heparin (either unfractionated or low-molecular-weight) also appears to reduce angina and prevent infarction. These and related agents are discussed in detail in Chapters 26 and 54. Anti-integrin agents directed against the platelet integrin GPIIb/IIIa (including abciximab, tirofiban, and eptifibatid) are effective in combination with heparin, as discussed below. Nitrates are useful both in reducing vasospasm and in reducing myocardial oxygen consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca^{2+} channel blocker may be required to achieve complete control.

ACUTE MYOCARDIAL INFARCTION Therapeutic maneuvers in myocardial infarction (MI) are directed at reducing the size of the infarct; preserving or retrieving viable tissue by reducing the oxygen demand of the myocardium; and preventing ventricular remodeling that could lead to heart failure.

Nitroglycerin is commonly administered to relieve ischemic pain in patients presenting with MI, but evidence that nitrates improve mortality in MI is sparse. Because they reduce ventricular preload through vasodilation, nitrates are effective in relief of pulmonary congestion. A decreased ventricular preload should be avoided in patients with right ventricular infarction because higher right-sided heart filling pressures are needed in this clinical context. Nitrates are relatively contraindicated in patients with systemic hypotension. According to the American Heart Association/American College of Cardiology (AHA/ACC) guidelines, “nitrates should not be used if hypotension limits the administration of β blockers, which have more powerful salutary effects.”

Since the proximate cause of MI is intracoronary thrombosis, reperfusion therapies are critically important, employing, when possible, direct percutaneous coronary interventions (PCIs) for acute MI, usually using drug-eluting intracoronary stents. Thrombolytic agents are administered at hospitals where emergency PCI is not performed, but outcomes are better with direct PCI than with thrombolytic therapy.

VARIANT (PRINZMETAL) ANGINA

The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary vasoconstriction results in reduced blood flow and ischemic pain. Ca^{2+} channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina and should be included in therapy.

Ca^{2+} CHANNEL ANTAGONISTS

Voltage-sensitive Ca^{2+} channels (L-type or slow channels) mediate the entry of extracellular Ca^{2+} into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca^{2+} is a trigger for contraction. Ca^{2+} channel antagonists, also called *Ca^{2+} entry blockers*, inhibit Ca^{2+} channel function. In vascular smooth muscle, this leads to relaxation, especially in arterial beds. These drugs also may produce negative inotropic and chronotropic effects in the heart.

The Ca^{2+} channel antagonists approved for clinical use in the U.S. have diverse chemical structures, including: phenylalkylamines, dihydropyridines, benzothiazepines, diphenylpiperazines,

and a diarylamino-propylamine. Verapamil (a phenylalkylamine); diltiazem (a benzothiazepine); nifedipine, amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine (dihydropyridines); and bepridil (a diarylamino-propylamine ether) are approved. Their tissue specificities are shown in Table 31-1. All bind to the α_1 subunit of the L-type Ca^{2+} channels and reduce Ca^{2+} flux through the channel; however, there are fundamental differences amongst verapamil, diltiazem, and the dihydropyridines, especially with respect to pharmacologic characteristics, drug interactions, and toxicities.

All Ca^{2+} channel blockers relax arterial smooth muscle; they have little effect on most venous beds and hence do not affect cardiac preload significantly. In cardiac muscle, Ca^{2+} channel blockers can produce a negative inotropic effect. Although true for all classes of Ca^{2+} channel blockers, the marked peripheral vasodilation seen with the dihydropyridines is accompanied by a robust baroreflex-mediated increase in sympathetic tone that overcomes the negative inotropic effect.

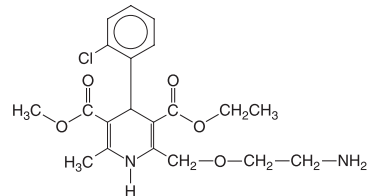

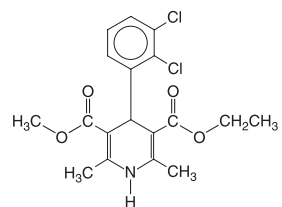

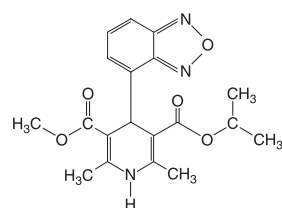

In the SA and AV nodes, depolarization largely depends on Ca^{2+} movement through the slow L-type channel. The effect of a Ca^{2+} channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether the agent delays the recovery of the slow channel. Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca^{2+} channel. The channel blockade caused by dihydropyridines also shows little dependence on the frequency of stimulation. Thus, at doses used clinically, nifedipine does not affect conduction through the node. In contrast, verapamil not only reduces the magnitude of the Ca^{2+} current through the slow channel but also decreases the rate of channel recovery. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as *frequency dependence* or *use dependence*. Thus, verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 34). Bepridil, like verapamil, inhibits both slow inward Ca^{2+} current and fast inward Na^+ current. It has a direct negative inotropic effect. Its electrophysiological properties lead to slowing of the heart rate, prolongation of the AV nodal effective refractory period, and importantly, prolongation of the Q-Tc interval. Particularly in the setting of hypokalemia, the last effect can be associated with *torsades de pointes*, a potentially lethal ventricular arrhythmia (see Chapter 34).

All Ca^{2+} channel blockers approved for clinical use decrease coronary vascular resistance and increase coronary blood flow. The dihydropyridines are more potent vasodilators than verapamil, which is more potent than diltiazem. The hemodynamic effects of these agents vary depending on the route of administration and the extent of left ventricular dysfunction.

Nifedipine, the prototypical dihydropyridine, selectively dilates arterial resistance vessels. The decrease in arterial blood pressure elicits sympathetic reflexes, with resulting tachycardia and positive inotropy. Thus, arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved, and heart rate and cardiac output are modestly increased. The other dihydropyridines—amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine—share many of the cardiovascular effects of nifedipine. There is less reflex tachycardia with amlodipine, possibly because its long $t_{1/2}$ (35–50 hours) produces minimal peaks and troughs in plasma concentrations. Felodipine may have even greater vascular specificity than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Nicardipine has antianginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. This inhibitory effect does not extend to the cardiac myocytes (no cardiodepressant effect is seen). Despite the negative chronotropic effect, isradipine appears to have little effect on the AV node, so it may be used in patients with AV block or combined with a β adrenergic receptor antagonist. In general, because of their lack of myocardial depression and, to a greater or lesser extent, lack of negative chronotropic effect, dihydropyridines are less effective as monotherapy in stable angina than are verapamil, diltiazem, or a β adrenergic receptor antagonist. Nisoldipine is >1000 times more potent in preventing contraction of human vascular smooth muscle than in preventing contraction of human cardiac muscle in vitro, suggesting a high degree of vascular selectivity. Although nisoldipine has a short elimination $t_{1/2}$, a sustained-release preparation is efficacious as an antianginal agent. Nimodipine has high lipid solubility and was developed as an agent to relax the cerebral vasculature. It is effective in inhibiting cerebral vasospasm and has been used primarily to treat patients with neurological defects associated with cerebral vasospasm after subarachnoid hemorrhage.

Table 31-1

Ca²⁺ Channel Blockers: Chemical Structures and Some Relative Cardiovascular Effects*

Chemical Structure (Nonproprietary and TRADE NAMES)	Vasodilation (Coronary Flow)	Suppression of Cardiac Contractility	Suppression of Automaticity (SA Node)	Suppression of Conduction (AV Node)

Bepridil reduces blood pressure and heart rate in patients with stable exertional angina and also produces an increase in left ventricular performance. Its side effects (see below) limit its use to truly refractory patients.

Verapamil is a less potent vasodilator than the dihydropyridines. Like the latter agents, verapamil causes little effect on venous resistance vessels at concentrations that produce arteriolar dilation. With doses of verapamil sufficient to produce peripheral arterial vasodilation, there are more direct negative chronotropic, dromotropic, and inotropic effects than with the dihydropyridines. Intravenous verapamil decreases arterial blood pressure owing to a decrease in vascular resistance, but the reflex tachycardia is blunted or abolished by the direct negative chronotropic effect of the drug. This intrinsic negative inotropic effect is partially offset by both a decrease in afterload and the reflex increase in adrenergic tone. Thus, in patients without congestive heart failure, ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. Oral administration of verapamil reduces peripheral vascular resistance and blood pressure, often with minimal changes in heart rate. The relief of pacing-induced angina seen with verapamil is due primarily to a reduction in myocardial oxygen demand.

Intravenous administration of diltiazem initially can result in a marked decrease in peripheral vascular resistance and arterial blood pressure, which elicits a reflex increase in heart rate and cardiac output. Heart rate then falls below initial levels because of the direct negative chronotropic effect of the agent. Oral administration of diltiazem decreases both heart rate and mean arterial blood pressure. While diltiazem and verapamil produce similar effects on the SA and AV nodes, the negative inotropic effect of diltiazem is more modest.

ABSORPTION, FATE, AND EXCRETION Although the absorption of these agents is nearly complete after oral administration, their bioavailability is reduced, sometimes markedly, by first-pass hepatic metabolism. The effects of these drugs are evident within 30–60 minutes of an oral dose, with the exception of the more slowly absorbed and longer-acting agents amlodipine, isradipine, and felodipine. For comparison, peak effects of verapamil occur within 15 minutes of its intravenous administration. These agents all are bound extensively to plasma proteins; their elimination half-lives vary widely (see Appendix II in the 11th edition of the parent text). During repeated oral administration, bioavailability and $t_{1/2}$ may increase because of saturation of hepatic metabolism. A major metabolite of diltiazem is desacetyldiltiazem, which has about one-half of diltiazem's potency as a vasodilator. *N*-Demethylation of verapamil results in production of norverapamil ($t_{1/2}$ ~10 hours), which is biologically active but much less potent than the parent compound. Metabolites of dihydropyridines are inactive or weakly active. In patients with cirrhosis, the bioavailabilities and half-lives of the Ca^{2+} channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients. Except for diltiazem and nifedipine, all of the Ca^{2+} channel blockers are administered as racemic mixtures.

TOXICITY AND UNTOWARD RESPONSES The most common side effects caused by the Ca^{2+} channel antagonists, particularly the dihydropyridines, are due to excessive vasodilation. Symptoms include dizziness, hypotension, headache, flushing, digital dysesthesia, and nausea. Patients also may experience constipation, peripheral edema, coughing, wheezing, and pulmonary edema. Nimodipine may produce muscle cramps when given in the large doses required for a beneficial effect in patients with subarachnoid hemorrhage. Less common side effects include rash, somnolence, and occasional minor elevations of liver function tests. These side effects usually are benign and may abate with time or with dose adjustment. Worsened myocardial ischemia has been reported with nifedipine in patients with angiographically demonstrable coronary collateral circulation. The worsening of angina may have resulted from excessive hypotension and decreased coronary perfusion, selective coronary vasodilation in nonischemic regions of the myocardium in a setting where vessels perfusing ischemic regions were already maximally dilated (*i.e.*, coronary steal), or an increase in oxygen demand owing to increased sympathetic tone and excessive tachycardia. Monotherapy with an immediate-release formulation of nisoldipine was associated with a trend toward an increased incidence of serious adverse events.

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration in patients with disease of the SA node or AV nodal conduction disturbances or in the presence of β adrenergic receptor blockade. The use of intravenous verapamil with a β adrenergic receptor antagonist is contraindicated because of the increased propensity for AV block and/or severe depression of

ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, or systolic blood pressures <90 mm Hg should not be treated with verapamil or diltiazem, particularly intravenously. Some Ca^{2+} channel antagonists can cause an increase in the concentration of digoxin in plasma, although toxicity from the cardiac glycoside rarely develops. The use of verapamil to treat digitalis toxicity is contraindicated, as AV nodal conduction disturbances may be exacerbated. Bepridil, because of its ability to prolong the QTc interval, can produce serious arrhythmias. Especially in the setting of hypokalemia and/or bradycardia, polymorphic ventricular tachycardia (*torsades de pointes*) can occur. Agranulocytosis also has been reported. Because of these serious side effects, bepridil should be reserved for patients refractory to all other appropriate medical and surgical therapy.

Several studies have raised concerns about the long-term safety of short-acting nifedipine. The proposed mechanism for this adverse effect lies in abrupt vasodilation with reflex sympathetic activation. There does not appear to be either significant reflex tachycardia or long-term adverse outcomes from treatment with sustained-release forms of nifedipine or with dihydropyridine Ca^{2+} blockers such as amlodipine or felodipine, which have more favorable (slower) pharmacokinetics.

Therapeutic Uses

VARIANT ANGINA Variant angina results from reduced flow rather than increased O_2 demand, and Ca^{2+} channel blockers have proven efficacy. In these patients, these drugs can attenuate *ergonovine*-induced vasospasm, suggesting that protection in variant angina is due to coronary dilation rather than to alterations in peripheral hemodynamics.

EXERTIONAL ANGINA Ca^{2+} channel antagonists also are effective in the treatment of exertional angina. Their utility may result from an increase in blood flow owing to coronary arterial dilation, from a decrease in myocardial O_2 demand (secondary to a decrease in arterial blood pressure, heart rate, or contractility), or both. These drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression.

Ca²⁺ channel antagonists, particularly the dihydropyridines, may aggravate anginal symptoms in some patients when used without a β adrenergic receptor antagonist. This adverse effect is not prominent with verapamil or diltiazem because of their limited ability to induce marked peripheral vasodilation and reflex tachycardia. Concurrent therapy with nifedipine and the β adrenergic receptor antagonist propranolol or with amlodipine and any of several β adrenergic receptor antagonists has proven more effective than either agent given alone in exertional angina, presumably because the β adrenergic receptor antagonist suppresses reflex tachycardia. This concurrent drug therapy is particularly attractive because the dihydropyridines, unlike verapamil and diltiazem, do not delay AV conduction and will not enhance the negative dromotropic effects associated with β adrenergic receptor blockade. Although concurrent administration of verapamil or diltiazem with a β adrenergic receptor antagonist also may reduce angina, the potential for AV block, severe bradycardia, and decreased left ventricular function requires that these combinations be used judiciously, especially if left ventricular function is compromised prior to therapy. Amlodipine produces less reflex tachycardia than does nifedipine, probably because of a flatter plasma concentration profile. Isradipine, approximately equivalent to nifedipine in enhancing exercise tolerance, also produces less rise in heart rate, possibly because of its slow onset of action.

UNSTABLE ANGINA Medical therapy for unstable angina involves the administration of aspirin (which reduces mortality), nitrates, β adrenergic receptor antagonists, and heparin, which are effective in controlling ischemic episodes and angina. Since vasospasm occurs in some patients with unstable angina, Ca^{2+} channel blockers offer an additional approach to this condition. However, there is insufficient evidence to assess whether such treatment decreases mortality except when the underlying mechanism is vasospasm. In contrast, therapy directed toward reducing platelet function and thrombotic episodes clearly decreases morbidity and mortality in patients with unstable angina (see Chapters 54).

MYOCARDIAL INFARCTION There is no evidence that Ca^{2+} channel antagonists are beneficial in the early treatment or secondary prevention of acute MI. In several trials, higher doses of the short-acting formulation of the dihydropyridine nifedipine had a detrimental effect on mortality. Diltiazem and verapamil may reduce the incidence of reinfarction in patients with a first non-ST segment elevation infarction who are not candidates for a β adrenergic receptor antagonist, but β blockers remain the preferred drugs.

OTHER USES

Ca^{2+} channel antagonists are also used as antiarrhythmic agents, for the treatment of hypertension, and for the treatment of heart failure. Clinical trials are under way to evaluate the capacity of Ca^{2+} channel blockers to slow the progression of renal failure and to protect the transplanted kidney. Verapamil has been demonstrated to improve left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy. Verapamil also has been used in the prophylaxis of migraine headaches. While the dihydropyridines may suppress the progression of mild atherosclerosis, there is no evidence that this alters mortality or reduces the incidence of ischemic events. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud's disease. The Ca^{2+} channel antagonists cause relaxation of the myometrium in vitro and may be effective in stopping preterm uterine contractions in preterm labor (see Chapter 55).

 β ADRENERGIC RECEPTOR ANTAGONISTS

β Adrenergic receptor antagonists are effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients after an MI. In contrast, these agents are not useful and may actually exacerbate vasospastic angina. Most β adrenergic receptor antagonists are equally effective in the treatment of exertional angina. *Timolol*, metoprolol, *atenolol*, and propranolol have been shown to exert cardioprotective effects. The effectiveness of β adrenergic receptor antagonists in the treatment of exertional angina is attributable primarily to a fall in myocardial O_2 consumption at rest and during exertion, although there also is some tendency for increased flow toward ischemic regions. The decrease in myocardial O_2 consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. Not all actions of β adrenergic receptor antagonists are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O_2 consumption. However, the net effect of β adrenergic receptor blockade is usually to decrease myocardial O_2 consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β adrenergic receptor blockade can profoundly decrease left ventricular function. Despite this, several β adrenergic receptor antagonists have been shown to reduce mortality in patients with congestive heart failure (see Chapter 33). Numerous β adrenergic receptor antagonists are approved for clinical use in the U.S. (see Chapter 10).

Therapeutic Uses**UNSTABLE ANGINA**

β Adrenergic receptor antagonists are effective in reducing recurrent episodes of ischemia and the risk of progression to acute MI. Clinical trials have lacked sufficient power to demonstrate beneficial effects of β adrenergic receptor antagonists on mortality. On the other hand, if the underlying pathophysiology is coronary vasospasm, nitrates and Ca^{2+} channel blockers may be effective, and β adrenergic receptor antagonists should be used with caution. In some patients, there is a combination of severe fixed disease and superimposed vasospasm; if adequate antiplatelet therapy and vasodilation have been provided by other agents and angina continues, the addition of a β adrenergic receptor antagonist may be helpful.

MYOCARDIAL INFARCTION

β Adrenergic receptor antagonists that lack intrinsic sympathomimetic activity improve mortality in MI. They should be given early and continued indefinitely in patients who can tolerate them.

OVERVIEW OF ANTIANGINAL THERAPEUTIC STRATEGIES

In evaluating trials in which different forms of antianginal therapy are compared, careful attention must be paid to the patient population studied and to the pathophysiology and stage of the disease. The efficacy of antianginal treatment will depend on the severity of angina, the presence of coronary vasospasm, and myocardial O_2 demand. Optimally, the dose of each agent should be titrated to maximum benefit.

Task forces from the ACC and the AHA have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris (www.americanheart.org). Patients with coronary artery disease should be treated with aspirin and a β adrenergic receptor antagonist (particularly if there is a history of prior MI). The guidelines also

note that solid data support the use of ACE inhibitors in patients with coronary artery disease who also have left ventricular dysfunction and/or diabetes. Therapy of hypercholesterolemia is also indicated. Nitrates, for treatment of angina symptoms, and Ca^{2+} antagonists also may be used. Table 31–2 summarizes the issues that the ACC/AHA task force considered to be relevant in choosing between β adrenergic receptor antagonists and Ca^{2+} channel blockers in patients with angina and other medical conditions. A meta-analysis comparison of β adrenergic receptor antagonists with Ca^{2+} channel blockers showed that β adrenergic receptor antagonists are associated with fewer episodes of angina per week and a lower rate of withdrawal because of adverse events. However, there were no differences in time to ischemia during exercise or in the frequency of adverse events when Ca^{2+} channel blockers other than nifedipine were compared with β adrenergic receptor antagonists. There were no significant differences in outcome between the studies comparing long-acting nitrates and Ca^{2+} channel blockers and the studies comparing long-acting nitrates with β adrenergic receptor antagonists.

COMBINATION THERAPY

Since the different categories of antianginal agents have different mechanisms of action, it has been suggested that combinations of these agents would allow the use of lower doses, increasing effectiveness and reducing the incidence of side effects. Despite the predicted advantages, combination therapy rarely achieves this potential and may be accompanied by serious side effects. Newer antianginal agents have distinct pharmacological mechanisms to reduce myocardial O_2 consumption (e.g., ranolazine); some studies have suggested that these compounds may have additional efficacy in combination with other antianginal agents. Ranolazine and related compounds (e.g., perhexiline, trimetazidine) are “metabolic” antianginal drugs that shift myocardial metabolism from free fatty acid oxidation to glucose metabolism, resulting in reduced myocardial O_2 consumption. These agents are not FDA-approved, although perhexiline is available in Australia and Europe.

Nitrates and β Adrenergic Receptor Antagonists

The concurrent use of organic nitrates and β adrenergic receptor antagonists can be very effective in the treatment of typical exertional angina. The additive efficacy is primarily a result of the blockade by one drug of a reflex effect elicited by the other. β Adrenergic receptor antagonists can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that are sometimes associated with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β adrenergic receptor blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors.

Ca^{2+} Channel Blockers and β Adrenergic Receptor Antagonists

Since there is a proven mortality benefit from the use of β adrenergic receptor antagonists in patients with heart disease, they represent the first line of therapy. However, when angina is controlled inadequately by a β adrenergic receptor antagonist plus nitrates, further improvement sometimes can be achieved by the addition of a Ca^{2+} channel blocker, especially if there is a component of coronary vasospasm. The differences among the chemical classes of Ca^{2+} channel blockers can lead to important adverse or salutary drug interactions with β adrenergic receptor antagonists. If the patient already is being treated with maximal doses of verapamil or diltiazem, it is difficult to demonstrate any additional benefit of β adrenergic receptor blockade, and excessive bradycardia, heart block, or heart failure may ensue. However, in patients treated with a dihydropyridine or with nitrates, substantial reflex tachycardia often limits the effectiveness of these agents. A β adrenergic receptor antagonist may be a helpful addition, resulting in a lower heart rate and blood pressure with exercise.

Relative contraindications to the use of β adrenergic receptor antagonists for treatment of angina—bronchospasm, Raynaud’s syndrome, or Prinzmetal’s angina—may favor initial therapy with a Ca^{2+} channel blocker. Fluctuations in coronary tone are important determinants of variant angina. It is likely that episodes of increased tone, such as those precipitated by cold and by emotion, superimposed on fixed disease have a role in the variable anginal threshold seen in some patients with otherwise chronic stable angina. Increased coronary tone also may be important in the anginal episodes occurring early after MI and after coronary angioplasty and probably accounts for those patients with unstable angina who respond to dihydropyridines. Atherosclerotic arteries have abnormal vasomotor responses to a number of stimuli, including exercise, other forms of sympathetic activation, and cholinergic agonists; in such vessels, stenotic segments actually may become more severely stenosed during exertion. This implies that the normal

Table 31–2

Recommended Drug Therapy for Angina in Patients with Other Medical Conditions

Condition	Recommended Treatment (and Alternatives) for Angina	Drugs to Avoid
<i>Medical Conditions</i>		
Systemic hypertension	β Adrenergic receptor antagonists (Ca ²⁺ channel antagonists)	
Migraine or vascular headaches	β Adrenergic receptor antagonists (Ca ²⁺ channel antagonists)	
Asthma or chronic obstructive pulmonary disease with bronchospasm	Verapamil or diltiazem	β Adrenergic receptor antagonists
Hyperthyroidism	β Adrenergic receptor antagonists	
Raynaud's syndrome	Long-acting, slow-release Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
Insulin-dependent diabetes mellitus	β Adrenergic receptor antagonists (particularly if prior MI) or long-acting, slow-release Ca ²⁺ channel antagonists	
Non-insulin-dependent diabetes mellitus	β Adrenergic receptor antagonists or long-acting, slow-release Ca ²⁺ channel antagonists	
Depression	Long-acting, slow-release Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
Mild peripheral vascular disease	β Adrenergic receptor antagonists or Ca ²⁺ channel antagonists	
Severe peripheral vascular disease with rest ischemia	Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists
<i>Cardiac Arrhythmias and Conduction Abnormalities</i>		
Sinus bradycardia	Dihydropyridine Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists, diltiazem, verapamil
Sinus tachycardia (not due to heart failure)	β Adrenergic receptor antagonists	
Supraventricular tachycardia	Verapamil, diltiazem, or β adrenergic receptor antagonists	
Atrioventricular block	Dihydropyridine Ca ²⁺ channel antagonists	β Adrenergic receptor antagonists, verapamil, diltiazem
Rapid atrial fibrillation (with digitalis)	Verapamil, diltiazem, or β adrenergic receptor antagonists	
Ventricular arrhythmias	β Adrenergic receptor antagonists	

Left Ventricular Dysfunction

Congestive heart failure

Mild (LVEF \geq 40%)

Moderate to severe (LVEF $<$ 40%)

Left-sided valvular heart disease

Mild aortic stenosis

Aortic insufficiency

Mitral regurgitation

Mitral stenosis

Hypertrophic cardiomyopathy

β Adrenergic receptor antagonists

Amlodipine or felodipine (nitrates)

β Adrenergic receptor antagonists

Long-acting, slow-release dihydropyridines

Long-acting, slow-release dihydropyridines

β Adrenergic receptor antagonists

β Adrenergic receptor antagonists, nondihydropyridine
 Ca^{2+} channel antagonists

Nitrates, dihydropyridine Ca^{2+} channel
antagonists

MI, myocardial infarction; LVEF, left ventricular ejection fraction.

exercise-induced increase in coronary flow is lost in atherosclerosis. Similar exaggerated vascular contractile responses are seen in hyperlipidemia, even before anatomic evidence of atherosclerosis develops. Because of this, coronary vasodilators (nitrates and/or Ca²⁺ channel blockers) are an important part of the therapeutic program in the majority of patients with ischemic heart disease.

Ca²⁺ Channel Blockers and Nitrates

In severe exertional or vasospastic angina, the combination of a nitrate and a Ca²⁺ channel blocker may provide additional relief over that obtained with either agent alone. Since nitrates primarily reduce preload, whereas Ca²⁺ channel blockers reduce afterload, the net effect on reduction of oxygen demand should be additive. However, excessive vasodilation and hypotension can occur. The concurrent administration of a nitrate and nifedipine has been advocated in particular for patients with exertional angina with heart failure, the sick-sinus syndrome, or AV nodal conduction disturbances, but excessive tachycardia may be seen.

Ca²⁺ Channel Blockers, β Adrenergic Receptor Antagonists, and Nitrates

In patients with exertional angina that is not controlled by the administration of two types of antianginal agents, the use of all three may provide improvement, although the incidence of side effects increases significantly. The dihydropyridines and nitrates dilate epicardial coronary arteries; the dihydropyridines decrease afterload; the nitrates decrease preload; and the β adrenergic receptor antagonists decrease heart rate and myocardial contractility. Therefore, there is theoretical, and sometimes real, benefit with their combination, although adverse drug interactions may lead to clinically important events. For example, combining verapamil or diltiazem with a β adrenergic receptor antagonist greatly increases the risk of conduction system and left ventricular dysfunction-related side effects and should be undertaken with extreme caution.

ANTIPLATELET, ANTI-INTEGRIN, AND ANTITHROMBOTIC AGENTS

Aspirin reduces the incidence of MI and death in patients with unstable angina. In addition, low doses of aspirin appear to reduce the incidence of MI in patients with chronic stable angina. Aspirin, given in doses of 160–325 mg at the onset of treatment, reduces mortality in patients presenting with unstable angina. The addition of clopidogrel to aspirin therapy reduces mortality in patients with acute coronary syndromes. Heparin, in its unfractionated form or as low-molecular-weight heparin, also reduces symptoms and prevents infarction in unstable angina. Thrombin inhibitors, such as *hirudin* or *bivalirudin*, are being investigated; these agents directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function independently of antithrombin III. Thrombolytic agents, on the other hand, are of no benefit in unstable angina. Intravenous inhibitors of the platelet GPIIb/IIIa receptor (abciximab, tirofiban, and eptifibatide) are effective in preventing the complications of PCIs and in the treatment of patients presenting with acute coronary syndromes.

TREATMENT OF CLAUDICATION AND PERIPHERAL VASCULAR DISEASE

Most patients with peripheral vascular disease also have coronary artery disease, and the therapeutic approaches for peripheral and coronary arterial diseases overlap. Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease, and treatment of coronary disease remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O₂ demand exceeding blood flow impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of coronary artery disease also have a salutary effect on progression of peripheral artery disease. Reductions in cardiovascular morbidity and mortality in patients with peripheral arterial disease have been documented with antiplatelet therapy using aspirin or with ADP antagonists such as clopidogrel or ticlopidine, administration of ACE inhibitors, and treatment of hyperlipidemia. Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication: Physical exercise, rehabilitation, and smoking cessation have proven efficacy. Drugs used specifically in the treatment of lower extremity claudication include *pentoxifylline* and *cilostazol*.

Pentoxifylline is a methylxanthine derivative that has been termed a rheologic modifier for its effects on increasing the deformability of red blood cells. The effects of pentoxifylline on lower extremity claudication appear to be modest. Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cyclic AMP in many cells, including blood platelets. Cilostazol-mediated increases in cyclic AMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important interactions with other drugs metabolized *via* this pathway (see Chapter 3). Cilostazol improves symptoms of claudication but has no effect on cardiovascular mortality. As a PDE3 inhibitor, cilostazol belongs to the same drug class as flosequinan, which was used as an inotropic agent for patients with heart failure. The latter drug was associated with an increase in sudden cardiac death, leading to withdrawal from the market. Cilostazol therefore is contraindicated in patients with heart failure, although it is not clear that it leads to increased mortality in such patients. Cilostazol has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect. Other treatments for claudication, including *naftidrofuryl*, *propionyl levocarnitine*, and *prostaglandins*, may also be efficacious.

MECHANOPHARMACOLOGICAL THERAPY: DRUG-ELUTING ENDOVASCULAR STENTS

Intracoronary stents can ameliorate angina and reduce adverse events in patients with acute coronary syndromes. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which occurs in a substantial fraction of patients. The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored, and the development of drug-eluting stents has had an important impact on clinical practice. Two drugs are currently used in intravascular stents: *paclitaxel* (TAXOL) and *sirolimus* (RAPAMYCIN). Paclitaxel inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12–sirolimus complex inhibits the protein kinase, mammalian target of RAPAMYCIN (mTOR), thereby inhibiting cell cycle progression (see Chapter 53). Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis; patients typically are treated with antiplatelet agents, including clopidogrel (for up to 6 months) and aspirin (indefinitely), sometimes in conjunction with intravenously administered GPIIb/IIIa inhibitors. The inhibition of cellular proliferation by paclitaxel and sirolimus not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery. Therefore, antiplatelet therapy (typically with clopidogrel) is continued for several months after intracoronary stenting with drug-eluting stents. The rate of restenosis with drug-eluting stents is reduced markedly compared with “bare metal” stents, possibly at the expense of increased risk of thrombosis, especially if antiplatelet therapy is stopped prematurely.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

THERAPY OF HYPERTENSION

Hypertension is the most common cardiovascular disease; its prevalence increases with advancing age. Elevated arterial pressure causes pathological changes in the vasculature and hypertrophy of the left ventricle. Hypertension is the principal cause of stroke, is a major risk factor for coronary artery disease and its complications, and is a major contributor to cardiac failure, renal insufficiency, and dissecting aortic aneurysm. Hypertension is defined as a sustained increase in blood pressure $\geq 140/90$ mm Hg, a criterion where risk of hypertension-related cardiovascular disease is high enough to merit medical attention. The risk of fatal and nonfatal cardiovascular disease in adults is lowest with systolic BP < 120 mm Hg and diastolic BP < 80 mm Hg and increases progressively with higher systolic and diastolic blood pressures. Recognition of this continuously increasing risk provides a simple classification of hypertension (Table 32–1). Isolated systolic hypertension (sometimes defined as systolic BP > 140 – 160 mm Hg with diastolic BP < 90 mm Hg) is largely confined to people > 60 years of age. At very high blood pressures (systolic ≥ 210 and/or diastolic ≥ 120 mm Hg), some patients develop fulminant arteriopathy characterized by endothelial injury and marked intimal proliferation, leading ultimately to arteriolar occlusion and the syndrome of immediately life-threatening hypertension. This is associated with rapidly progressive microvascular occlusive disease in the kidney (with renal failure), brain (hypertensive encephalopathy), congestive heart failure, and pulmonary edema, and typically requires emergent, in-hospital management for prompt lowering of blood pressure.

PRINCIPLES OF ANTIHYPERTENSIVE THERAPY Nonpharmacological therapy is an important component of treatment of all patients with hypertension. In some stage 1 hypertensives, blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake, increasing aerobic exercise, and moderating alcohol consumption. These lifestyle changes may also facilitate pharmacological control of blood pressure.

Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated by changes in peripheral resistance but also *via* effects on large artery stiffness.

Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 32–2). The hemodynamic effects of antihypertensive agents (Table 32–3) provide a rationale for potential complementary effects of concurrent therapy with two or more drugs. Concurrent use of drugs from different classes is an effective strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

DIURETICS

Diuretic agents (*see* Chapter 28) have antihypertensive effects when used alone and enhance the efficacy of virtually all other antihypertensive drugs; thus, these drugs are very important in the treatment of hypertension.

Benzothiadiazines and Related Compounds

Benzothiadiazines (“thiazides”) and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Thiazides block the $\text{Na}^+\text{-Cl}^-$ symporter and have the same pharmacological effects and are generally interchangeable with appropriate dose adjustment (*see* Chapter 28). Since their pharmacokinetics and pharmacodynamics differ, these drugs do not necessarily have the same clinical efficacy in treating hypertension.

The exact mechanism for reduction of arterial blood pressure by thiazide diuretics is not certain. The drugs decrease extracellular volume by inhibiting the Na-Cl symporter in the distal convoluted tubule, leading to a fall in cardiac output, but the hypotensive effect is maintained during long-term therapy because of reduced vascular resistance; presumably thiazides directly promote vasodilation. *Hydrochlorothiazide* may open Ca^{2+} -activated K^+ channels, leading to hyperpolarization of vascular smooth muscle cells, decreased Ca^{2+} entry through voltage-sensitive L-type Ca^{2+} channels, and ultimately reduced vasoconstriction.

REGIMEN FOR ADMINISTRATION OF THE THIAZIDE-CLASS DIURETICS IN HYPERTENSION When a thiazide diuretic is used as the sole antihypertensive drug (monotherapy), its dose-response curve for lowering blood pressure in patients with hypertension should be

Table 32-1

Criteria for Hypertension in Adults

Classification	Blood Pressure (mm Hg)	
	Systolic	Diastolic
Normal	<120	and <80
Pre-hypertension	120–139	or 80–89
Hypertension, stage 1	140–159	or 90–99
Hypertension, stage 2	≥160	or ≥100

kept in mind. Antihypertensive effects are achieved in many patients with as little as 12.5 mg of chlorthalidone (HYGROTON) or hydrochlorothiazide (HYDRODIURIL) daily. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses of these diuretics, higher doses generally are not more efficacious in patients with normal renal function. These doses of hydrochlorothiazide are not at the top of the dose-response curve for adverse effects such as K^+ wasting and inhibition of uric acid excretion (*see* below), emphasizing the importance of the dose-response relationships for both beneficial and adverse effects.

Urinary K^+ loss can be a problem with thiazides. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor antagonists will partly attenuate diuretic-induced loss of K^+ , and this is a consideration if a second drug is needed to adequately control blood pressure. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each drug. Administration of ACE inhibitors or angiotensin receptor antagonists together with other K^+ -sparing agents or with K^+ supplements requires great caution; combining K^+ -sparing agents with each other or with K^+ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the dose limitations when thiazide diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide diuretics. Hypertensive patients may become refractory to drugs that block the sympathetic nervous system or to vasodilator drugs because these drugs engender a state in which the blood pressure is very volume-dependent. It therefore is appropriate to consider the use of thiazide diuretics

Table 32-2

Classification of Antihypertensive Drugs by Their Primary Site or Mechanism of Action

Diuretics (Chapter 28)

1. Thiazides and related agents (hydrochlorothiazide, chlorthalidone, *etc.*)
2. Loop diuretics (furosemide, bumetanide, torsemide, ethacrynic acid)
3. K^+ -sparing diuretics (amiloride, triamterene, spironolactone)

Sympatholytic drugs (Chapters 9, 10, and 33)

1. β Adrenergic antagonists (metoprolol, atenolol, *etc.*)
2. α Adrenergic antagonists (prazosin, terazosin, doxazosin, phenoxybenzamine, phentolamine)
3. Mixed adrenergic antagonists (labetalol, carvedilol)
4. Centrally acting agents (methyldopa, clonidine, guanabenz, guanfacine)
5. Adrenergic neuron blocking agents (guanadrel, reserpine)

 Ca^{2+} channel blockers (Chapters 31 through 34)

(verapamil, diltiazem, nimodipine, felodipine, nicardipine, isradipine, amlodipine)

Angiotensin-converting enzyme inhibitors (Chapters 30 and 31)

(captopril, enalapril, lisinopril, quinapril, ramipril, benazepril, fosinopril, moexipril, perindopril, trandolapril)

Angiotensin II receptor antagonists (Chapters 30 and 33)

(losartan, candesartan, irbesartan, valsartan, telmisartan, eprosartan)

Vasodilators (Chapter 33)

1. Arterial (hydralazine, minoxidil, diazoxide, fenoldopam)
2. Arterial and venous (nitroprusside)

Table 32-3

Hemodynamic Effects of Long-Term Administration of Antihypertensive Agents

Drug Class	Heart Rate	Cardiac Output	Total Peripheral Resistance	Plasma Volume	Plasma Renin Activity
Diuretics	↔	↔	↓	↓	↑
Sympatholytic agents					
Centrally acting	↓	↓	↓	↑	↓
Adrenergic neuron blockers	↓	↓	↓	↑	↑
α Adrenergic antagonists	↑	↑	↓	↑	↔
β Adrenergic antagonists					
No ISA*	↓	↓	↓	↑	↓
ISA	↔	↔	↓	↑	↓
Arteriolar vasodilators	↑	↑	↓	↑	↑
Ca ²⁺ channel blockers	↓ or ↑	↓ or ↑	↓	↑	↑
ACE inhibitors	↔	↔	↓	↔	↑
AT ₁ receptor antagonists	↔	↔	↓	↔	↑

Changes are indicated as follows: ↑, increased; ↓, decreased; -↑, increased or no change; -↓, decreased or no change; ↔, unchanged.

*ISA, intrinsic sympathomimetic activity. ACE, angiotensin-converting enzyme; AT₁, the type 1 receptor for AngII.

in doses of 50 mg/day of hydrochlorothiazide or its equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate blood pressure control. Alternatively, higher-capacity diuretics such as *furosemide* may be needed, especially if renal function is impaired. Dietary Na⁺ restriction (e.g., 2 g daily) is a valuable adjunct in such refractory patients that minimizes the dose of diuretic that is required. Since the degree of K⁺ loss relates to the amount of Na⁺ delivered to the distal tubule, such restriction of Na⁺ can minimize the development of hypokalemia and alkalosis. The effectiveness of thiazides as diuretics or antihypertensive agents diminishes progressively when the glomerular filtration rate is <30 mL/min. One exception is *metolazone*, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within ~4 weeks, although a minority will not achieve maximum reduction in arterial pressure for up to 12 weeks. Therefore, doses should not be increased more often than every 4–6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension. Since the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. Diuretics also minimize the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

ADVERSE EFFECTS AND PRECAUTIONS Adverse effects of diuretics (see Chapter 28) determine tolerance and adherence. Erectile dysfunction is a troublesome adverse effect of thiazide diuretics; physicians should inquire specifically regarding its occurrence. Albeit uncommon, gout may be a consequence of the hyperuricemia induced by these diuretics. Either of these adverse effects is reason to consider alternative therapies. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca²⁺ excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca²⁺ excretion may be used therapeutically in patients with osteoporosis or hypercalciuria.

The effects of diuretic drugs on several *surrogate markers* merit consideration. The K⁺ depletion produced by thiazide diuretics is dose-dependent and variable among individuals, such that some patients may become substantially K⁺-depleted on diuretic drugs. Given chronically, even small doses lead to some K⁺ depletion. Two types of ventricular arrhythmias may be enhanced by K⁺ depletion. One of these is polymorphic ventricular tachycardia (*torsades de pointes*; see Chapter 34), which is initiated by abnormal ventricular repolarization. Because K⁺ currents normally mediate repolarization, drugs that produce K⁺ depletion potentiate polymorphic ventricular tachycardia. Accordingly, thiazide diuretics should not be given together with drugs that can cause polymorphic ventricular tachycardia (see Chapter 34). The more important concern regarding

K^+ depletion is its influence on ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. Diuretic dose is positively correlated with sudden cardiac death, while there is an inverse correlation between the use of K^+ -sparing agents and sudden cardiac death.

Thiazide diuretics have been associated with changes in plasma lipids and glucose tolerance. Nonetheless, clinical studies consistently demonstrate the efficacy of thiazide diuretics in reducing cardiovascular risk. All of the thiazide drugs cross the placenta, but they have not been shown to have direct adverse effects on the fetus. However, if administration of a thiazide is begun during pregnancy, there is a risk of transient volume depletion that may result in placental hypoperfusion. Since the thiazides appear in breast milk, they should be avoided by nursing mothers.

Other Diuretic Antihypertensive Agents

In patients who have normal renal function, the thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, (e.g. furosemide and bumetanide). This differential effect is most likely related to the short duration of action of loop diuretics, such that a single daily dose does not cause a significant net loss of Na^+ throughout the day. Indeed, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment of hypertension, congestive heart failure, and ascites. The spectacular efficacy of the loop diuretics in producing a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, excessive diuresis can lead to more side effects than occur with a slower-acting, thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

Amiloride is a K^+ -sparing diuretic that has some efficacy in lowering blood pressure in patients with hypertension. Spironolactone, a mineralocorticoid receptor antagonist, also lowers blood pressure but has some significant adverse effects, especially in men (e.g., impotence and gynecomastia). Triamterene is a K^+ -sparing diuretic that decreases the risk of hypokalemia in patients treated with a thiazide diuretic but does not have efficacy in lowering blood pressure by itself. These agents should be used cautiously with frequent measurements of K^+ concentrations in plasma in patients predisposed to hyperkalemia. Patients taking spironolactone, amiloride, or triamterene should be cautioned regarding the concurrent use of K^+ -containing salt substitutes. Renal insufficiency is a relative contraindication to the use of K^+ -sparing diuretics. Concomitant use of an ACE inhibitor or an angiotensin receptor antagonist magnifies the risk of hyperkalemia with these agents.

Diuretic-Associated Drug Interactions

Since the antihypertensive effects of diuretics are frequently additive with those of other antihypertensive agents, a diuretic commonly is combined with other drugs. The K^+ - and Mg^{2+} -depleting effects of the thiazides and loop diuretics also can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. All diuretics can decrease the clearance of Li^+ , resulting in increased plasma concentrations of Li^+ and potential toxicity. NSAIDs (see Chapter 26), including selective COX-2 inhibitors, that inhibit the synthesis of renal prostaglandins, reduce the antihypertensive effects of diuretics. NSAIDs, β adrenergic receptor antagonists, and ACE inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K^+ -sparing diuretic.

SYMPATHOLYTIC AGENTS

α and β adrenergic antagonists are mainstays of antihypertensive therapy (Table 32–2).

β Adrenergic Receptor Antagonists

β receptor antagonists have antihypertensive effects. The pharmacology of these drugs is discussed in Chapter 10. Antagonism of β adrenergic receptors affects blood pressure through a number of mechanisms, including reducing cardiac output. β Adrenergic receptor antagonists also act on the juxtaglomerular complex to reduce renin secretion and thereby diminish production of circulating angiotensin II. Other mechanisms by which β receptor antagonists may lower blood pressure include alteration of the control of the sympathetic nervous system at the level of the CNS, altered baroreceptor sensitivity, altered peripheral adrenergic neuron function, and increased prostacyclin biosynthesis.

PHARMACOLOGICAL EFFECTS The β blockers vary in their lipid solubility, selectivity for the β_1 adrenergic receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and membrane-stabilizing properties. While all of the β receptor antagonists are effective

as antihypertensive agents, these differences do influence the clinical pharmacokinetics and spectrum of adverse effects of the various drugs. Drugs without intrinsic sympathomimetic activity produce an initial reduction in cardiac output and a reflex-induced rise in peripheral resistance, generally with no net change in arterial pressure; peripheral resistance gradually returns to pretreatment values or less. Persistently reduced cardiac output and possibly decreased peripheral resistance account for the reduced arterial pressure. Drugs with intrinsic sympathomimetic activity produce lesser decreases in resting heart rate and cardiac output; the fall in arterial pressure correlates with a fall in vascular resistance below pretreatment levels, possibly because of stimulation of vascular β_2 adrenergic receptors that mediate vasodilation.

ADVERSE EFFECTS AND PRECAUTIONS The β adrenergic blocking agents should be avoided in patients with asthma, with sinoatrial or atrioventricular (AV) nodal dysfunction, or in combination with other drugs that inhibit AV conduction, such as *verapamil*. Patients with type 1 diabetes mellitus also are better treated with other drugs (e.g., ACE inhibitors).

β Receptor antagonists without intrinsic sympathomimetic activity increase concentrations of triglycerides in plasma and lower those of high-density lipoprotein (HDL) cholesterol. β Adrenergic blocking agents with intrinsic sympathomimetic activity have little or no effect on blood lipids. The long-term consequences of these effects are unknown.

Sudden discontinuation of β adrenergic blockers can produce a withdrawal syndrome that is likely due to up-regulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines; this can exacerbate the symptoms of coronary artery disease. The result, especially in active patients, can be rebound hypertension. Thus, β adrenergic blockers should be tapered over 10–14 days.

NSAIDs such as *indomethacin* can blunt the antihypertensive effect of propranolol and probably other β receptor antagonists. This effect may relate to inhibition of vascular synthesis of prostacyclin, as well as to Na^+ retention.

Epinephrine can produce severe hypertension when used with a nonselective β receptor antagonist due to the unopposed stimulation of α receptors when vascular β_2 receptors are blocked. Such paradoxical hypertensive responses to β adrenergic receptor antagonists have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from *clonidine*, following administration of Epi as a therapeutic agent, or in association with the illicit use of cocaine.

THERAPEUTIC USES β receptor antagonists provide effective therapy for all grades of hypertension. Despite marked differences in their pharmacokinetic properties, the antihypertensive effect of all the β blockers is of sufficient duration to permit once or twice daily administration. Populations that tend to have a lesser antihypertensive response to β -blocking agents include the elderly and African Americans. However, this should not discourage the use of these drugs in individual patients, as intraindividual differences in antihypertensive efficacy generally are much larger than differences between racial or age-related groups.

β receptor antagonists do not usually cause salt and water retention, and diuretic administration is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β receptor antagonist, a diuretic, and a vasodilator is effective for patients who require a third drug. β Adrenergic receptor antagonists are preferred drugs for hypertensive patients with conditions such as myocardial infarction, ischemic heart disease, or congestive heart failure.

α_1 Adrenergic Antagonists

Drugs that selectively block α_1 adrenergic receptors without affecting α_2 adrenergic receptors also are used in hypertension (Table 32–2). Prazosin (MINIPRESS), terazosin (HYTRIN), and doxazosin (CARDURA) are the agents approved in the U.S. for this indication.

PHARMACOLOGICAL EFFECTS Initially, α_1 adrenergic receptor antagonists reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During chronic therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal, and renal blood flow is unchanged. The α_1 adrenergic blockers variably cause postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients, which attenuates the postural hypotension. α_1 Receptor antagonists reduce plasma concentrations of triglycerides and total low-density lipoprotein (LDL) cholesterol and increase HDL cholesterol. These potentially favorable

effects on lipids persist when a thiazide diuretic is given concurrently. The long-term consequences of these changes in lipids are unknown.

ADVERSE EFFECTS The use of doxazosin as monotherapy for hypertension increases the risk of developing congestive heart failure. This may be an adverse effect of all of the α_1 adrenergic receptor antagonists.

An important precaution in the use of the α_1 receptor antagonists for hypertension is the so-called first-dose phenomenon, which may occur in up to 50% of patients, especially in patients who are already receiving a diuretic or α receptor antagonist. This effect is characterized by symptomatic orthostatic hypotension within 90 minutes of the initial dose of the drug or after a dosage increase; after the first few doses, patients become tolerant to this marked hypotensive response.

THERAPEUTIC USES α_1 Receptor antagonists are not recommended as monotherapy for hypertensive patients. They rather are used primarily in conjunction with diuretics, β blockers, and other antihypertensive agents. β Receptor antagonists enhance the efficacy of the α_1 blockers. α_1 Receptor antagonists are not the drugs of choice in patients with pheochromocytoma, because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α_2 adrenergic receptors. α_1 Receptor antagonists are attractive drugs for hypertensive patients with benign prostatic hyperplasia, since they also improve urinary symptoms.

Combined α_1 and β Adrenergic Receptor Antagonists

Labetalol (*NORMODYNE*, *TRANDATE*) (see Chapter 10) is a mixture of four stereoisomers. One isomer is an α_1 antagonist (like prazosin), another is a nonselective β antagonist with partial agonist activity (like pindolol), and the other two isomers are inactive. Because of its capacity to block α_1 adrenergic receptors, intravenous labetalol can reduce pressure sufficiently rapidly to be useful for the treatment of hypertensive emergencies. Labetalol has efficacy and side effects that would be expected with any combination of β and α_1 receptor antagonists; as with any fixed-dose combination, the relative extents of α receptor and β receptor antagonism vary from patient to patient.

Carvedilol (*COREG*) is a β receptor antagonist with α_1 receptor antagonist activity. The drug is approved for the treatment of hypertension and symptomatic heart failure. The ratio of α_1 to β receptor antagonist potency for carvedilol is ~1:10. Carvedilol is oxidized by hepatic CYP2D6 and then glucuronidated. Carvedilol reduces mortality in patients with systolic heart failure when used as an adjunct to therapy with diuretics and ACE inhibitors. It should not be given to those patients with decompensated heart failure who are dependent on sympathetic stimulation. As with labetalol, efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a β and α_1 adrenergic receptor antagonist.

Methyldopa

Methyldopa (*ALDOMET*) is a centrally acting antihypertensive agent that exerts its antihypertensive action via an active metabolite. Methyldopa's significant adverse effects currently limit its use in the U.S. to treatment of hypertension in pregnancy, where it has a record for safety. Methyldopa (α -methyl-3,4-dihydroxy-L-phenylalanine), an analog of 3,4-dihydroxyphenylalanine (DOPA), is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α -methyl-dopamine, which then is converted to α -methyl-NE. α -Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for NE. Thus, when adrenergic neurons discharge neurotransmitter, α -methyl-NE is released instead of NE. Because α -methyl-NE is as potent a vasoconstrictor as NE, its substitution for NE in peripheral adrenergic neurosecretory vesicles does not alter the vasoconstrictor response to peripheral adrenergic neurotransmission. Rather, α -methylnorepinephrine acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem. Methylnorepinephrine probably acts as an agonist at presynaptic α_2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

PHARMACOLOGICAL EFFECTS In younger patients with uncomplicated essential hypertension, methyldopa reduces vascular resistance without much change in cardiac output or heart rate. In older patients, cardiac output may be decreased as a result of decreased heart rate and stroke volume secondary to relaxation of veins and reduced preload. The fall in arterial pressure is maximal 6–8 hours after an oral or intravenous dose. Although the decrease in supine blood pressure is less than that in the upright position, symptomatic orthostatic hypotension is less common

with methyldopa than with drugs that act exclusively on peripheral adrenergic neurons or autonomic ganglia; this is because methyldopa attenuates but does not completely block baroreceptor-mediated vasoconstriction. It therefore is well tolerated during surgical anesthesia. Any severe hypotension is reversible with volume expansion. Renal blood flow is maintained and renal function is unchanged during treatment with methyldopa.

Plasma concentrations of NE fall in association with reduction in arterial pressure, reflecting decreased sympathetic tone. Renin secretion also is reduced, but this is not necessary for methyldopa's hypotensive effects. Salt and water often are gradually retained with prolonged use, blunting the antihypertensive effect. This effect, termed "pseudo-tolerance," can be overcome with concurrent use of a diuretic.

ABSORPTION, METABOLISM, AND EXCRETION When administered orally, methyldopa is absorbed by an active amino acid transporter. Peak plasma concentrations occur after 2–3 hours. The drug is eliminated with a $t_{1/2}$ of ~2 hours (prolonged to 4–6 hours in patients with renal failure). Methyldopa transport into the CNS apparently is an active process. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50–70%) and as the parent drug (25%). The remainder is excreted as other metabolites, including methyldopamine, methylnorepinephrine, and *O*-methylated products of these catecholamines.

In spite of its rapid absorption and short $t_{1/2}$, the peak effect of methyldopa is delayed for 6–8 hours, even after intravenous administration, and the duration of action of a single dose is usually ~24 hours; this permits once- or twice-daily dosing. The discrepancy between the effects and the measured concentrations of the drug in plasma is likely related to the time required for transport into the CNS, conversion to the active metabolite, storage of α -methyl-NE and its subsequent release in the vicinity of relevant α_2 receptors in the CNS.

ADVERSE EFFECTS AND PRECAUTIONS In addition to lowering blood pressure, the active metabolite of methyldopa acts on α_2 adrenergic receptors in the brainstem to inhibit the centers that are responsible for wakefulness and alertness, producing sedation that is largely transient. Decreased mental acuity and lassitude may persist in some patients, and depression occurs occasionally. Medullary centers that control salivation are inhibited by α adrenergic receptors, and methyldopa may produce dry mouth. Other side effects related to pharmacological effects in the CNS include decreased libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause galactorrhea. In individuals who have sinoatrial node dysfunction, methyldopa may precipitate severe bradycardia and sinus arrest, including that which occurs with carotid sinus hypersensitivity.

Methyldopa also produces adverse effects that are unrelated to its pharmacological action. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect. Prompt diagnosis of hepatotoxicity requires a low threshold for considering the drug as a cause for hepatitis-like symptoms (e.g., nausea, anorexia) and screening for hepatotoxicity (e.g., with determination of hepatic transaminases) after 3 weeks and again 3 months after initiation of treatment. The incidence of methyldopa-induced hepatitis is unknown, but ~5% of patients will have transient increases in hepatic transaminases in plasma. Hepatic dysfunction usually is reversible with prompt drug discontinuation but will recur if methyldopa is given again; a few cases of fatal hepatic necrosis have been reported. It is advisable to avoid the use of methyldopa in patients with hepatic disease.

Methyldopa can cause hemolytic anemia. At least 20% of patients who receive methyldopa for a year develop a positive Coombs test due to autoantibodies directed against the Rh antigen on erythrocytes. This does not necessitate drug discontinuation; 1–5% of these patients will develop a hemolytic anemia that mandates prompt drug discontinuation. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Rarer adverse effects include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus-like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

THERAPEUTIC USES Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus. The usual initial dose of methyldopa is 250 mg twice daily, and there is little additional effect with doses >2 g/day. Administration of a single daily dose of methyldopa at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

Clonidine, Guanabenz, and Guanfacine

The detailed pharmacology of the α_2 adrenergic agonists clonidine (CATAPRES), *guanabenz* (WYTENSIN), and *guanfacine* (TENEX) is discussed in Chapter 10. These drugs stimulate the α_{2A} subtype of α_2 adrenergic receptors in the brainstem, reducing sympathetic outflow from the CNS. Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α_{2A} receptors, these drugs can activate α_2 receptors of the α_{2B} subtype on vascular smooth muscle cells. This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken and may be responsible for the loss of therapeutic effect that is observed with high doses.

PHARMACOLOGICAL EFFECTS The α_2 adrenergic agonists lower arterial pressure by an effect on both cardiac output and peripheral resistance. In the supine position, when the vascular sympathetic tone is low, the major effect is to reduce both heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature normally increases, these drugs reduce vascular resistance and may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to reduced myocardial contractility and heart rate, possibly promoting congestive heart failure in susceptible patients.

ADVERSE EFFECTS AND PRECAUTIONS Many patients experience annoying and even intolerable adverse effects with these drugs. Sedation and xerostomia are prominent. The latter may be accompanied by dry nasal mucosa, dry eyes, and parotid gland swelling and pain. Postural hypotension and erectile dysfunction are prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. Less common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympathetic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the sinoatrial node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15–20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related α_2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. The arterial blood pressure may rise to levels above those that were present prior to treatment, but the syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18–36 hours after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines. The withdrawal syndrome is likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also is seen after discontinuation of transdermal administration of clonidine. Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, clonidine reinitiation may suffice. If a more rapid effect is needed, sodium nitroprusside or a combination of an α and β adrenergic blocker is appropriate. β Adrenergic blocking agents should not be used alone in this setting, since they can accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines. Because perioperative hypertension has been described when clonidine was withdrawn the night before surgery, surgical patients receiving an α_2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose and/or transdermal clonidine preoperatively. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly; poorly compliant patients should not be given α_2 adrenergic agonists for hypertension.

Adverse drug interactions with α_2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine by unknown mechanisms.

THERAPEUTIC USES The CNS effects prevent this class of drugs from being a leading option for monotherapy of hypertension. These drugs effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. Enthusiasm for these drugs is further diminished by the paucity of evidence demonstrating reduction in risk of adverse cardiovascular events.

Guanadrel

Guanadrel (HYLOREL) specifically inhibits the function of peripheral postganglionic adrenergic neurons. It is an exogenous false neurotransmitter that is accumulated, stored, and released like NE but is inactive at adrenergic receptors. The drug is actively transported into neurons by the same transporter (NET) that mediates NE reuptake (see Chapter 6). When given intravenously, guanadrel initially releases NE in an amount sufficient to increase arterial blood pressure. This is not noticeable with oral administration, since NE is released only slowly from the vesicles under this circumstance and is degraded within the neuron by monoamine oxidase. Nonetheless, because of the potential for NE release, guanadrel is contraindicated in patients with pheochromocytoma. During adrenergic neuron blockade with guanadrel, effector cells become supersensitive to NE. The supersensitivity is similar to that produced by postganglionic sympathetic denervation.

PHARMACOLOGICAL EFFECTS

Essentially all of the therapeutic and adverse effects of guanadrel result from functional sympathetic blockade. The antihypertensive effect is achieved by a reduction in peripheral vascular resistance that results from inhibition of α receptor-mediated vasoconstriction. Consequently, arterial pressure is reduced modestly in the supine position when sympathetic activity is usually low, but the pressure can fall considerably when reflex sympathetic activation is needed to maintain arterial pressure, such as assumption of the upright posture, exercise, and depletion of plasma volume. Plasma volume often expands, which may diminish the antihypertensive efficacy of guanadrel and require administration of diuretic to restore the antihypertensive effect.

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Guanadrel is rapidly absorbed, leading to maximal levels in plasma at 1–2 hours. Because guanadrel must be transported into and accumulate in adrenergic neurons, the maximum effect on blood pressure is not seen until 4–5 hours. Although the β phase of its elimination has a $t_{1/2}$ of ~5–10 hours, this almost certainly does not reflect the longer $t_{1/2}$ of drug stored at its site of action in the secretory vesicles of adrenergic neurons. The $t_{1/2}$ of the pharmacological effect of guanadrel is determined by the drug's persistence in this neuronal pool and is probably at least 10 hours. Guanadrel is administered in a regimen of twice-daily doses.

Guanadrel is cleared by both renal and nonrenal disposition. Its elimination is impaired in patients with renal insufficiency; total-body clearance is reduced by four- to fivefold in patients with severe renal dysfunction.

ADVERSE EFFECTS

Guanadrel produces undesirable effects that are related entirely to sympathetic blockade. The lack of sympathetic compensation results in symptomatic hypotension during standing, exercise, ingestion of alcohol, or hot weather. A general feeling of fatigue and lassitude is partially related to postural hypotension. Sexual dysfunction usually presents as delayed or retrograde ejaculation. Diarrhea also may occur.

Because guanadrel is actively transported to its site of action, drugs that block or compete for the catecholamine transporter on the presynaptic membrane will inhibit the effect of guanadrel. Such drugs include the tricyclic antidepressants, cocaine, chlorpromazine, ephedrine, phenylpropranolamine, and amphetamine (see Chapter 6).

THERAPEUTIC USES

Because of the availability of a number of drugs that lower blood pressure without producing this degree of orthostatic hypotension, guanadrel is not employed in the monotherapy of hypertension and only rarely is used as an additional agent in patients who have not achieved a satisfactory antihypertensive effect on multiple other agents. The usual starting dose is 10 mg/day; side effects can be minimized by not exceeding 20 mg/day.

Reserpine

Reserpine is an alkaloid that binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and inhibits the vesicular monoamine transporter (VMAT-2) that facilitates NE storage. Thus, nerve endings lose their capacity to concentrate and store NE and DA. Catecholamines leak into the cytoplasm, where they are metabolized by intraneuronal MAO, such that little or no active transmitter is discharged from nerve endings upon depolarization. The overall result is a pharmacological sympathectomy. A similar process occurs at storage sites for 5-hydroxytryptamine. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after drug discontinuation. Since reserpine depletes amines in the CNS

as well as in peripheral adrenergic neurons, its antihypertensive effects probably are related to both central and peripheral actions.

PHARMACOLOGICAL EFFECTS

Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with reserpine. Orthostatic hypotension may occur but does not usually cause symptoms. Heart rate and renin secretion fall. Salt and water are retained, which commonly results in “pseudotolerance.”

ABSORPTION, METABOLISM, AND EXCRETION

The amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action because of irreversible reserpine binding to storage vesicles. Reserpine is entirely metabolized, and none of the parent drug is excreted unchanged.

TOXICITY AND PRECAUTIONS

Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. Reserpine must be discontinued at the first sign of depression, which may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression appears to be uncommon, but not unknown, with doses of 0.25 mg/day or less. The drug should never be given to patients with a history of depression. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

THERAPEUTIC USES

With the availability of newer drugs that are both effective and well tolerated, the use of reserpine has diminished because of its CNS side effects. Nonetheless, there has been some interest in using reserpine at low doses, in combination with diuretics, in hypertension therapy, especially in the elderly. Reserpine is used once daily with a diuretic, and several weeks are necessary to achieve a maximum effect. The daily dose should be limited to 0.25 mg or less, and as little as 0.05 mg/day may be effective when a diuretic is also used. Reserpine is considerably less expensive than many other antihypertensive drugs; thus, it is still used in developing nations.

Metyrosine

Metyrosine (DEMSEK) is (–)- α -methyl-L-tyrosine. It inhibits tyrosine hydroxylase, the enzyme that catalyzes the conversion of tyrosine to DOPA, the rate-limiting step in catecholamine biosynthesis (see Chapter 6). At a dose of 1–4 g/day, metyrosine decreases catecholamine biosynthesis by 35–80% in patients with pheochromocytoma. The maximal decrease in synthesis occurs only after several days, as assessed by measurements of urinary catecholamines and their metabolites. Metyrosine is used as an adjunct to phenoxybenzamine and other α adrenergic blocking agents for the management of malignant pheochromocytoma and in the preoperative preparation of patients for resection of pheochromocytoma. Metyrosine carries a risk of crystalluria, which can be minimized by maintaining a daily urine volume of >2 L. Other adverse effects include orthostatic hypotension, sedation, extrapyramidal signs, diarrhea, anxiety, and psychic disturbances. Doses must be titrated carefully to achieve significant inhibition of catecholamine biosynthesis while minimizing these substantial side effects.

Ca²⁺ CHANNEL ANTAGONISTS

Ca²⁺ channel antagonists are important drugs for the treatment of hypertension. The pharmacology of these drugs is presented in Chapters 31, 33, and 34. The largest chemical class of calcium-channel blockers is the dihydropyridines: *amlodipine*, *felodipine*, *isradipine*, and *nifedipine*. *Diltiazem* and *verapamil* are non-dihydropyridine calcium-channel blockers. All Ca²⁺ channel blockers lower blood pressure by inhibiting Ca²⁺ influx through voltage-sensitive L-type calcium-channels in arteriolar smooth muscle, ultimately leading to smooth muscle relaxation and decreased peripheral vascular resistance. Due to decreased peripheral vascular resistance, the Ca²⁺ channel blockers evoke a baroreceptor-mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the sinoatrial node; this response is generally quite modest except when drug is administered rapidly. Tachycardia is typically minimal to absent with verapamil and diltiazem because of the direct negative chronotropic effect of these two drugs. All Ca²⁺ channel blockers are effective when used alone for the treatment of mild-to-moderate

hypertension; however, these drugs are not considered appropriate for hypertension monotherapy, except in certain situations such as isolated systolic hypertension (*see* below).

The Ca²⁺ channel blockers vary in their adverse reactions. Patients receiving immediate-release capsules of nifedipine develop headache, flushing, dizziness, and peripheral edema. Because of the oscillation in blood pressure and concurrent surges in sympathetic reflex activity within each dosage interval, nifedipine or other dihydropyridine Ca²⁺ channel blockers with short half-lives administered in immediate-release formulation are inappropriate in the long-term treatment of hypertension. Dizziness and flushing are much less of a problem with sustained-release formulations and with dihydropyridines having a long $t_{1/2}$ and relatively constant concentrations of drug in plasma. Peripheral edema is not the result of generalized fluid retention; it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction. Some other adverse effects of these drugs are due to actions in nonvascular smooth muscle. For example, Ca²⁺ channel blockers can cause or aggravate gastroesophageal reflux by inhibiting contraction of the lower esophageal sphincter. Constipation is a common side effect of verapamil but occurs less frequently with other Ca²⁺ channel blockers. Urinary retention is a rare adverse effect. Inhibition of sinoatrial node function by diltiazem and verapamil can lead to bradycardia and even sinoatrial node arrest, particularly in patients with sinoatrial node dysfunction; this effect is exaggerated by concurrent use of β adrenergic receptor antagonists.

Compared with other classes of antihypertensive agents, there is a greater frequency of achieving blood pressure control with Ca²⁺ channel blockers as monotherapy in elderly subjects and in African Americans, population groups in which the low renin status is more prevalent. Ca²⁺ channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension. Indeed, these drugs may be a preferred treatment in these patients.

Significant drug–drug interactions may be encountered when Ca²⁺ channel blockers are used to treat hypertension. Concurrent use of a β receptor antagonist with a nondihydropyridine drug may magnify negative chronotropic and inotropic effects of these drugs or cause heart block in susceptible patients. Verapamil blocks the P-glycoprotein drug transporter in kidney and liver and inhibits the elimination of digoxin and other drugs (*see* Chapter 2). When used with quinidine, Ca²⁺ channel blockers may cause excessive hypotension, particularly in patients with idiopathic hypertrophic subaortic stenosis.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The ability to reduce levels of angiotensin II (AngII) with orally effective inhibitors of angiotensin-converting enzyme (ACE) represents an important advance in the treatment of hypertension. *Captopril* (CAPOTEN), *enalapril* (VASOTEC), *lisinopril* (PRINIVIL), *quinapril* (ACCUPRIL), *ramipril* (ALTACE), *benazepril* (LOTENSIN), *moexipril* (UNIVASC), *fosinopril* (MONOPRIL), *trandolapril* (MAVIK), and *perindopril* (ACEON) have proven to be very useful for the treatment of hypertension because of their efficacy and their very favorable profile of adverse effects, which enhances patient adherence. Chapter 30 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes mellitus, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, and many of these patients also have hypertension. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors because administration of ACE inhibitors in the immediate post–myocardial infarction period has been shown to improve ventricular function and reduce morbidity and mortality (*see* Chapter 33).

The decreased biosynthesis of AngII impacts a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na⁺ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretics. Thus, even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors, while the use of high doses of diuretics together with ACE inhibitors may lead to excessive blood pressure reduction and volume depletion.

The attenuation of aldosterone production by ACE inhibitors also influences K⁺ homeostasis. There is only a very small and clinically unimportant rise in serum K⁺ when these agents are used alone in patients with normal renal function. However, substantial K⁺ retention can occur in patients

with renal insufficiency. Furthermore, the potential for developing hyperkalemia must be considered when ACE inhibitors are used with other drugs that can cause K^+ retention, including K^+ -sparing diuretics (amiloride, triamterene, and spironolactone), NSAIDs, K^+ supplements, and β receptor antagonists. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors. Angioedema is a rare but potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that must be communicated to women of childbearing age.

In most patients there is no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. In renovascular hypertension, however, the glomerular filtration rate generally is maintained by AngII-driven increased resistance in the postglomerular arteriole. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will substantially reduce glomerular filtration rate. Similar effects are seen in some patients with preexisting renal disease.

ACE inhibitors decrease blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, some patients exhibit a considerable fall in blood pressure that is a function of plasma renin activity prior to treatment. Because of this, therapy is initiated with low doses, especially in patients who may have a very active renin-angiotensin system supporting blood pressure (*e.g.*, diuretic-induced volume contraction or congestive heart failure). With continuing treatment, there usually is a progressive fall in blood pressure that often takes several weeks and is not strongly correlated with the pretreatment plasma renin activity. Younger Caucasian patients are more likely to respond to ACE inhibitors, while elderly African American patients generally are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients have a response that lasts for less than 24 hours and require twice-daily dosing for optimal blood pressure control.

AT₁ ANGIOTENSIN II RECEPTOR ANTAGONISTS

Nonpeptide antagonists of the AT₁ angiotensin II receptor approved for the treatment of hypertension include *losartan* (COZAAR), *candesartan* (ATACAND), *irbesartan* (AVAPRO), *valsartan* (DIOVAN), *telmisartan* (MICARDIS), and *eprosartan* (TEVETEN). By antagonizing the effects of AngII, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy (*see* Chapter 30).

Distinct subtypes of AngII receptors are designated as AT₁ and AT₂. The AT₁ receptor subtype is located predominantly in vascular and myocardial tissue and also in brain, kidney, and adrenal glomerulosa cells, which secrete aldosterone (*see* Chapter 30). Because the AT₁ receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT₁ receptor antagonism. The clinical consequences of increased AngII effects on an uninhibited AT₂ receptor are unknown; emerging data suggest that the AT₂ receptor may elicit antiproliferative responses.

ADVERSE EFFECTS AND PRECAUTIONS Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions also occur with AT₁ receptor antagonists, including hypotension, hyperkalemia, and reduced renal function (especially associated with renal artery stenosis). Hypotension most often occurs in patients in whom the blood pressure is highly dependent on AngII, including those with volume depletion (*e.g.*, with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients initiation of treatment with low doses and attention to volume status is essential. Hyperkalemia may occur in conjunction with other factors, such as renal insufficiency, ingestion of excess K^+ , and the use of drugs that promote K^+ retention. Cough is much less frequent with AngII receptor antagonists, and angioedema occurs very rarely. AT₁ receptor antagonists also should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

THERAPEUTIC USES When given in adequate doses, the AT₁ receptor antagonists appear to be as effective as ACE inhibitors in the treatment of hypertension. As with ACE inhibitors, these drugs may be less effective in African Americans and patients with low-renin hypertension. The full effect of AT₁ receptor antagonists on blood pressure typically is not observed until ~4 weeks after initiation of therapy. If blood pressure is not controlled by an AT₁ receptor antagonist alone, a low dose of a thiazide or other diuretic may be added. In patients with mild-to-severe hypertension, the

addition of an AT₁ receptor antagonist to a thiazide can produce significant additional reductions in blood pressure in patients who demonstrated an insufficient response to the first agent alone. A smaller initial dosage is preferred for patients who have already received diuretics and therefore have intravascular volume depletion, and for other patients whose blood pressure is highly dependent on AngII. Given their different mechanisms, there is no assurance that the effects of ACE inhibitors and antagonists of the AT₁ receptor will be equivalent in preventing target organ damage in patients with hypertension.

VASODILATORS

Hydralazine

Hydralazine (APRESOLINE) causes direct relaxation of arteriolar smooth muscle, possibly secondary to a fall in intracellular Ca²⁺ concentrations. The drug does not dilate epicardial coronary arteries or relax venous smooth muscle. Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, which results in increased heart rate and contractility, increased plasma renin activity, and fluid retention; all of these effects counteract the antihypertensive effect of hydralazine. Although most of the sympathetic activity is due to a baroreceptor-mediated reflex, hydralazine may stimulate NE release from sympathetic nerve terminals and augment myocardial contractility directly. Most of hydralazine's effects are confined to the cardiovascular system; the decrease in blood pressure after administration is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles, postural hypotension is not common, and hydralazine lowers blood pressure equally in the supine and upright positions.

ABSORPTION, METABOLISM, AND EXCRETION Hydralazine is well absorbed through the gastrointestinal (GI) tract but systemic bioavailability is low (16% in fast acetylators, 35% in slow acetylators). Hydralazine is *N*-acetylated in the bowel and/or the liver. The t_{1/2} of hydralazine is 1 hour, and systemic clearance of the drug is about 50 mL/kg/min. The rate of acetylation is genetically determined; ~half of all individual in the U.S. are rapid acetylators. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Since systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating α -keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer t_{1/2} than hydralazine but does not appear to be very active. The rate of acetylation is an important determinant of hydralazine bioavailability but does not play a role in the systemic elimination of the drug, probably because the hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow. The peak concentration of hydralazine in plasma and its peak hypotensive effect both occur within 30–120 minutes of ingestion. Although its t_{1/2} in plasma is ~1 hour, the duration of the hypotensive effect of hydralazine can last as long as 12 hours. There is no clear explanation for this discrepancy.

TOXICITY AND PRECAUTIONS Extensions of hydralazine's pharmacological effects include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia occurs because of the increased O₂ demand induced by the baroreceptor reflex-induced stimulation of the sympathetic nervous system and because hydralazine does not dilate the epicardial coronary arteries; thus, the arteriolar dilation it produces may cause a "steal" of blood flow away from the ischemic region. Following parenteral administration to patients with coronary artery disease, the myocardial ischemia may be sufficiently severe and protracted to cause frank myocardial infarction. For this reason, parenteral administration of hydralazine is not advised in hypertensive patients with coronary artery disease, hypertensive patients with multiple cardiovascular risk factors, or in older patients. In addition, if the drug is used alone, there may be salt retention with development of congestive heart failure. When combined with a β adrenergic receptor blocker and a diuretic, hydralazine is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

Other adverse effects are caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis; the mechanism of these autoimmune reactions is unknown. The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, sex,

acetylator phenotype, and race. After 3 years of treatment with hydralazine, drug-induced lupus occurs in 10% of patients who receive 200 mg/day and 5% who receive 100 mg/day. The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African Americans. The rate of conversion to a positive antinuclear antibody test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, since the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, hydralazine need not be discontinued unless clinical features of the syndrome appear. These features are similar to those of other drug-induced lupus syndromes, including arthralgia, arthritis, and fever. Pleuritis and pericarditis may be present, and pericardial effusion can occasionally cause cardiac tamponade. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome; symptoms may persist in a few patients and administration of glucocorticoids may be necessary. Hydralazine also can produce a pyridoxine-responsive polyneuropathy, apparently related to its ability to combine with pyridoxine to form a hydrazone. This side effect is rare with doses ≤ 200 mg/day.

THERAPEUTIC USES Due to its relatively unfavorable adverse-effect profile, hydralazine is no longer a first-line drug in the treatment of hypertension. It may have utility in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT₁ receptor antagonists), and in the treatment of hypertensive emergencies in pregnant women (especially preeclampsia) on account of extensive experience with the drug in that setting. Hydralazine should be used with great caution if at all in elderly patients and in hypertensive patients with coronary artery disease because of the possibility of precipitation of myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25–100 mg twice daily. Twice-daily administration is as effective as administration four times a day for blood pressure control, regardless of acetylator phenotype. The maximum recommended dose of hydralazine is 200 mg/day to minimize the risk of drug-induced lupus syndrome.

K_{ATP}⁺ Channel Openers: Minoxidil

Minoxidil (LONITEN) is efficacious in patients with the most severe and drug-resistant forms of hypertension. A small fraction of minoxidil is metabolized by hepatic sulfotransferase to the active molecule, minoxidil *N-O* sulfate. Minoxidil sulfate activates the ATP-modulated K⁺ channel in smooth muscle, causing hyperpolarization and relaxation of arteriolar smooth muscle. Minoxidil produces arteriolar vasodilation with essentially no effect on capacitance vessels. Minoxidil preferentially increases blood flow to skin, skeletal muscle, the GI tract, and the heart. The disproportionate increase in blood flow to the heart may have a metabolic basis, in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase by as much as three- to fourfold, primarily due to enhanced venous return to the heart. The increased venous return probably results from enhanced flow in vascular beds with a fast response for venous return to the heart. The adrenergic increase in myocardial contractility contributes to the increased cardiac output, but is not the predominant factor. The renal effects of minoxidil are complex; it dilates renal arteries, but systemic hypotension produced by the drug actually can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension. Minoxidil potently stimulates renin secretion, an effect mediated by renal sympathetic stimulation.

ABSORPTION, METABOLISM, AND EXCRETION Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 hour after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed. About 20% of the absorbed drug is excreted unchanged in the urine; the main route of elimination is by hepatic metabolism. The major metabolite of minoxidil is the glucuronide conjugate at the *N*-oxide position. This metabolite is less active than minoxidil but has a long $t_{1/2}$. Minoxidil has a $t_{1/2}$ in plasma of 3–4 hours, but its duration of action is 24 hours or longer.

ADVERSE EFFECTS AND PRECAUTIONS The adverse effects of minoxidil can be severe and are divided into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis.

Salt and water retention result from increased proximal tubular reabsorption due to reduced renal perfusion pressure and reflex stimulation of renal tubular α adrenergic receptors. Similar anti-natriuretic effects are observed with other arteriolar dilators (*e.g.*, diazoxide and hydralazine).

Although minoxidil causes increased secretion of renin and aldosterone, this is unimportant for retention of salt and water. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any renal dysfunction. Large doses of loop diuretics may be required to prevent edema formation in some patients.

The cardiac consequences of baroreceptor-mediated activation of the sympathetic nervous system with minoxidil are similar to those with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O_2 consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with coronary artery disease. The cardiac sympathetic responses are attenuated by concurrent administration of a β adrenergic blocker. The adrenergically-induced increase in renin secretion also can be ameliorated by a β receptor antagonist or an ACE inhibitor, with enhancement of blood pressure control.

Minoxidil has particularly adverse consequences in hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This likely contributes to the increased pulmonary artery pressure seen with minoxidil therapy in hypertensive patients and is compounded by the drug-induced retention of salt and water. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Although more commonly described in patients with cardiac failure and renal failure, pericardial effusion can occur in patients with normal cardiovascular and renal function. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K^+ channels; these drugs can accelerate myocardial repolarization, shorten the refractory period, and may lower the ventricular fibrillation threshold in ischemic myocardium. Hypertrichosis occurs in patients who receive minoxidil for extended periods, probably related to K^+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly upsetting to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil (ROGAINE) is used for male pattern baldness; it may have cardiovascular effects in some individuals.

Rare side effects of the drug include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

THERAPEUTIC USES Minoxidil is reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency. Minoxidil must be given concurrently with a diuretic to avoid fluid retention and with a sympatholytic drug (usually a β receptor antagonist) to control reflex cardiovascular effects. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Sodium Nitroprusside

Sodium nitroprusside is used for the short-term control of severe hypertension and can improve cardiac function in patients with left ventricular failure (see Chapter 34). Nitroprusside acts by releasing nitric oxide (NO). NO activates the guanylyl cyclase–cyclic GMP–PKG pathway, leading to vasodilation. The mechanism of release of NO likely involves both enzymatic and nonenzymatic pathways. Tolerance does not develop to nitroprusside. Nitroprusside dilates both arterioles and venules; the hemodynamic response results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output thus tends to fall. In patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance leads to a rise in cardiac output (see Chapter 33). Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In

general, renal blood flow and glomerular filtration are maintained, and plasma renin activity increases. Unlike other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O_2 demand.

ABSORPTION, METABOLISM, AND EXCRETION Sodium nitroprusside is unstable and decomposes under strongly alkaline conditions or when exposed to light. It must be given by continuous intravenous infusion to be effective. Its onset of action is within 30 seconds; the peak hypotensive effect occurs within 2 minutes, and the effect disappears within 3 minutes after the infusion is stopped.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, followed by the release of cyanide and then nitric oxide. Cyanide is further metabolized by liver rhodanase to thiocyanate, which is eliminated almost entirely in the urine. The mean elimination half-time for thiocyanate is 3 days in patients with normal renal function but can be much longer in patients with renal insufficiency.

TOXICITY AND PRECAUTIONS The short-term adverse effects of nitroprusside are due to excessive vasodilation. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will usually prevent an excessive hemodynamic response to the drug. Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate $>5 \mu\text{g}/\text{kg}/\text{min}$, but also can occur in some patients receiving doses of $2 \mu\text{g}/\text{kg}/\text{min}$ for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (mainly thiosulfate). The concomitant administration of *sodium thiosulfate* can prevent cyanide accumulation in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the nitroprusside is unchanged. The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for >24 – 48 hours, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged nitroprusside infusions and should not exceed $0.1 \text{ mg}/\text{mL}$. Excessive concentrations of thiocyanate rarely may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed by hemodialysis.

Nitroprusside can worsen hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and thereby promotes ventilation/perfusion mismatch.

THERAPEUTIC USES Sodium nitroprusside is used primarily to treat hypertensive emergencies but can also be used in many situations when short-term reduction of cardiac preload and/or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection, to improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 33), and to decrease myocardial oxygen demand after acute myocardial infarction. In addition, nitroprusside is used to induce controlled hypotension during anesthesia in order to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is essential to administer a β adrenergic receptor antagonist with nitroprusside, since reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2–3 mL of 5% dextrose in water. Addition of this solution to 250–1000 mL of 5% dextrose in water produces a concentration of 50–200 $\mu\text{g}/\text{mL}$. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. Most hypertensive patients respond to an infusion of 0.25–1.5 $\mu\text{g}/\text{kg}/\text{min}$. Higher infusion rates are needed to produce controlled hypotension in normotensive patients under surgical anesthesia. Infusion of nitroprusside at rates $>5 \mu\text{g}/\text{kg}/\text{min}$ over a prolonged period can cause cyanide and/or thiocyanate poisoning. Patients receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of $10 \mu\text{g}/\text{kg}/\text{min}$ do not produce adequate reduction of blood pressure within 10 minutes, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

Diazoxide

Diazoxide (HYPERSTAT IV) is used in the treatment of hypertensive emergencies only if accurate infusion pumps are not available and/or close monitoring of blood pressure is not feasible.

NONPHARMACOLOGICAL THERAPY OF HYPERTENSION

The indications and efficacy of various lifestyle modifications in hypertension are reviewed in a summary statement from the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (www.nhlbi.nih.gov/guidelines/hypertension).

SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL PATIENTS

Choice of an antihypertensive drug should be driven by likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost.

Consensus guidelines (www.nhlbi.nih.gov/guidelines/hypertension) recommend diuretics as preferred initial therapy for most patients with uncomplicated stage 1 hypertension who are unresponsive to nonpharmacological measures. Patients are also commonly treated with other drugs: β receptor antagonists, ACE inhibitors/AT₁ receptor antagonists, and Ca²⁺ channel blockers. Patients with uncomplicated stage 2 hypertension will likely require the early introduction of a diuretic and another drug from a different class. Subsequently, doses can be titrated upward and additional drugs added in order to achieve goals (blood pressure <140/90 mm Hg in uncomplicated patients). Some of patients may require four different drugs to reach their goal.

Some patients with hypertension have compelling indications for specific drugs on account of other underlying serious cardiovascular disease (heart failure, post–myocardial infarction, or with high risk for coronary artery disease), chronic kidney disease, or diabetes. For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β receptor antagonist, ACE inhibitor/AT₁ receptor antagonist, and spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension. Similarly, ACE inhibitors/AT₁ receptor antagonists should be first-line drugs in the treatment of diabetics with hypertension in view of their well-established benefits in diabetic nephropathy.

Other patients may have less serious underlying diseases that could influence choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α_1 receptor antagonist as part of this therapeutic program, since α_1 antagonists are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β receptor antagonist since a number of drugs in this class are efficacious in preventing migraine attacks.

Patients with isolated systolic hypertension (systolic blood pressure >160 mm Hg and diastolic blood pressure <90 mm Hg) benefit particularly from diuretics and also from Ca²⁺ channel blockers.

Different considerations are needed for patients in immediately life-threatening settings due to hypertension. Clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as patients with hypertensive encephalopathy or pulmonary edema due to severe hypertension. Rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation to aggressively treat patients merely on the basis of increased blood pressure should be resisted and therapy should encompass how well the patients' major organs are reacting to the very high blood pressures.

PHARMACOTHERAPY OF CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is a major contributor to morbidity and mortality worldwide. Drug therapies historically have focused on the endpoint components of this syndrome, volume overload (congestion) and myocardial dysfunction (heart failure), with treatment strategies emphasizing the use of diuretics and cardiac glycosides. While effective in relieving symptoms and in stabilizing patients with hemodynamic decompensation, such therapies have not improved survival. Recent work has provided new insights into the induction and propagation of CHF, building a conceptual framework in which heart failure is viewed as a consequence of disordered circulatory dynamics and pathologic cardiac remodeling. These developments have had a major positive impact on the treatment of CHF that has improved survival.

Pathophysiology of Heart Failure

Initially, myocardial dysfunction and the attendant reduction of forward cardiac output lead to expansion of intravascular volume and activation of neurohumoral systems, particularly the sympathetic nervous system and the renin–angiotensin system (Figure 33–1). These compensatory responses maintain perfusion to vital organs by increasing left ventricular preload, stimulating myocardial contractility, and increasing arterial tone. Acutely, these mechanisms help to sustain cardiac output by allowing the heart to operate at higher end-diastolic volumes, leading to increased stroke volume; concomitant peripheral vasoconstriction allows for regional redistribution of the cardiac output to critical organs. Unfortunately, each of these compensatory responses will also promote disease progression. Expansion of the intravascular volume and elevated ventricular chamber volumes lead to increased diastolic and systolic wall stress; these changes in turn impair myocardial energetics and induce hypertrophic remodeling. Neurohumoral activation leads to arterial and venous constriction; the former increases left ventricular afterload (thereby compromising left ventricular stroke volume) and the latter increases preload, thereby exacerbating both diastolic and systolic wall stress. In addition, the neurohumoral effectors (such as norepinephrine [NE] and angiotensin II [AngII]) may act directly on the myocardium to promote unfavorable remodeling by causing myocyte apoptosis, abnormal gene expression, and alterations in the extracellular matrix.

PHARMACOLOGICAL TREATMENT OF HEART FAILURE

The abnormalities of myocardial structure and function that underlie heart failure can activate biological responses that drive disease progression. Drugs that reduce ventricular wall stress or inhibit the renin–angiotensin system (*e.g.*, selected vasodilators, ACE inhibitors, and aldosterone antagonists) or the sympathetic nervous system (*e.g.*, β adrenergic antagonists) can decrease pathological ventricular remodeling, attenuate disease progression, and decrease mortality in patients with heart failure due to systolic dysfunction. As a result, these drugs have become mainstays in the long-term treatment of heart failure. Some of the drugs that slow progression afford an immediate beneficial impact on hemodynamic function and symptoms (*e.g.*, vasodilators and ACE inhibitors). Other agents that attenuate disease progression can adversely affect hemodynamic function and worsen symptoms in the short term and must therefore be used with caution (*e.g.*, β receptor antagonists). Figure 33–1 provides an overview of the pathophysiological mechanisms of heart failure and the sites of action of the major drug classes used in treatment.

The current approach to therapy for CHF involves preload reduction, afterload reduction, and enhancement of inotropic state. A variety of vasodilators will reduce preload and afterload (Table 33–1). Although a vasodilator's more prominent effect may be to reduce either preload or afterload, most agents affect both.

Diuretics

Diuretics retain a central role in the management of the “congestive” symptoms in patients with heart failure. The pharmacological properties of these agents are presented in detail in Chapter 28. Their importance in heart failure management reflects the central role of the kidney in the hemodynamic, hormonal, and autonomic responses to myocardial failure. The net effect of these responses is the retention of Na^+ and water and expansion of the extracellular fluid volume, allowing the heart to operate at higher end-diastolic volumes, and thereby to maintain LV stroke volume. However, this increase in end-diastolic volume results in higher end-diastolic filling pressures,

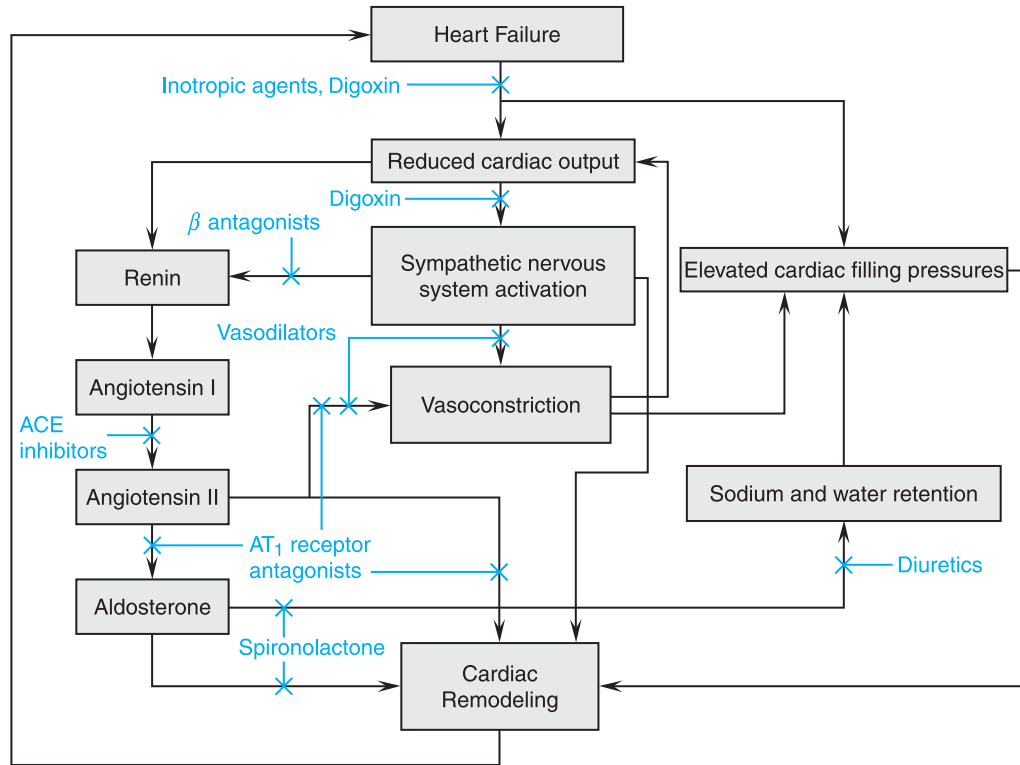

FIGURE 33-1 Pathophysiological mechanisms of heart failure and major sites of drug action. Heart failure is accompanied by compensatory neurohormonal responses including activation of the sympathetic nervous and renin–angiotensin systems. Although these responses initially help to maintain cardiovascular function by increasing ventricular preload and systemic vascular tone, with time they contribute to the progression of myocardial failure. Increased ventricular afterload, due to systemic vasoconstriction and chamber dilation, causes a depression in systolic function. In addition, increased afterload and the direct effects of angiotensin and NE on the ventricular myocardium cause pathological remodeling characterized by progressive chamber dilation and loss of contractile function. The figure illustrates several mechanisms that appear to play important roles in the pathophysiology of heart failure, and the sites of action of pharmacological therapies for heart failure.

Table 33–1

Vasodilator Drugs Used to Treat Heart Failure

Drug Class	Examples	Mechanism of Vasodilating Action	Preload Reduction	Afterload Reduction
Organic nitrates	Nitroglycerin, isosorbide dinitrate	NO-mediated vasodilation	+++	+
Nitric oxide donors	Nitroprusside	NO-mediated vasodilation	+++	+++
Angiotensin-converting enzyme inhibitors	Captopril, enalapril, lisinopril	Inhibition of AngII generation, decreased bradykinin degradation	++	++
Angiotensin receptor blockers	Losartan, candesartan	Blockade of AT ₁ receptors	++	++
Phosphodiesterase inhibitors	Milrinone, inamrinone	Inhibition of cyclic AMP degradation	++	++
Direct-acting K ⁺ -channel agonist	Hydralazine Minoxidil	Unknown Hyperpolarization of vascular smooth muscle cells	+ +	+++ +++
α ₁ Adrenergic antagonists	Doxazosin, prazosin	Selective α ₁ adrenergic receptor blockade	+++	++
Nonselective α adrenergic antagonists	Phentolamine	Nonselective α adrenergic receptor blockade	+++	+++
Vasodilating β/α ₁ adrenergic antagonists	Carvedilol, labetalol	Selective α ₁ adrenergic receptor blockade	++	++
Ca ²⁺ channel blockers	Amlodipine, nifedipine, felodipine	Inhibition of L-type Ca ²⁺ channels	+	+++
β Adrenergic agonists	Isoproterenol	Stimulation of vascular β ₂ adrenergic receptors	+	++

ABBREVIATIONS: AngII, angiotensin II; AT₁, type I AngII receptor; NO, nitric oxide.

increased ventricular chamber dimensions, and elevated wall stress. In turn, these changes result in pulmonary venous congestion and peripheral edema, ultimately limiting further augmentation of cardiac output. Elevated filling pressures are associated with enhanced activation of neurohumoral systems that can drive CHF progression.

Diuretics reduce extracellular fluid volume and ventricular filling pressure (or “preload”). Because patients with heart failure often operate on a “plateau” phase of the Starling curve, preload reduction can occur without concomitant reduction in cardiac output. Note that reduction in cardiac output can occur in patients who have had either sustained natriuresis and/or a rapid decline in intravascular volume. In this circumstance, diuretic therapy may augment neurohormonal activation due to volume depletion, with potentially deleterious effects on the progression of heart failure. It therefore is preferable to avoid the use of diuretics in the subset of patients with asymptomatic LV dysfunction and to use the minimal dose necessary to maintain euolemia in patients with symptoms related to volume retention. Despite the efficacy of diuretics in controlling congestive symptoms and improving exercise capacity, with the exception of aldosterone antagonists, they do not reduce mortality in heart failure.

DIETARY SODIUM RESTRICTION All patients with clinically significant ventricular dysfunction, regardless of symptom status, should be advised to limit dietary intake of NaCl. Most patients will tolerate moderate reductions in salt intake (2–3 g/day total intake). More stringent salt restriction is seldom necessary and may be counterproductive, as it can lead to hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis when combined with loop diuretics.

LOOP DIURETICS *Furosemide* (LASIX), *bumetanide* (BUMEX), and *torseamide* (DEMADEX) are widely used in the treatment of heart failure. Due to the increased risk of ototoxicity, *ethacrynic acid* (EDECRIN) should be reserved for patients who are allergic to sulfonamides or who have developed interstitial nephritis on alternative drugs.

Furosemide and bumetanide are short-acting drugs. The resultant postdose decline in renal tubular diuretic levels leads to avid renal Na^+ retention by all nephron segments. This can limit or prevent negative Na^+ balance and it is a common practice in CHF patients to administer two or more doses daily. In patients with decompensated heart failure of a severity that warrants hospital admission, it is generally desirable to initiate diuresis by intravenous administration of a loop diuretic. This typically provides a more rapid and predictable diuresis than does oral administration. The loop diuretic may be administered as repetitive boluses titrated to achieve the desired response, or by constant infusion. An advantage of infusion is that the same total daily dose of diuretic, given as a continuous infusion, results in a more sustained natriuresis due to maintenance of high drug levels within the lumen of renal tubules. In addition, the risk of ototoxicity is reduced by continuous infusion when compared to repetitive, intermittent intravenous dosing. When there is a poor response to monotherapy, coadministration of a thiazide agent is warranted. If the poor response is due to reduced renal perfusion, short-term administration of sympathomimetic drugs or phosphodiesterase inhibitors to increase cardiac output may be required.

THIAZIDE DIURETICS The thiazide diuretics (DIURIL, HYDRODIURIL, others) are most frequently used in the treatment of hypertension; they play a more restricted role in the treatment of CHF. Thiazides exhibit true synergism with loop diuretics: the natriuresis that follows coadministration exceeds the summed effects of the drugs administered individually. This synergism is the rationale for combination therapy in patients who appear refractory to loop diuretics. Thiazides are associated with a greater degree of K^+ wasting for comparable volume reduction than are loop diuretics.

K^+ -SPARING DIURETICS K^+ -sparing diuretics (*see* Chapter 28) act principally in the collecting duct of the nephron and either inhibit apical membrane Na^+ conductance channels in epithelial cells (*e.g.*, *amiloride*, *triamterene*) or act as aldosterone antagonists (*e.g.*, *spironolactone*, *eplerenone*). These agents are relatively weak diuretics and therefore are not effective for volume reduction. Historically, these agents have been used to limit renal K^+ and Mg^{2+} wasting and/or to augment the diuretic response to other agents. Aldosterone antagonists improve survival in patients with advanced heart failure *via* a mechanism that is independent of diuresis.

USE OF DIURETICS IN CLINICAL PRACTICE The majority of patients with heart failure will require chronic administration of a loop diuretic to maintain euvolemia. In patients with clinically evident fluid retention, furosemide typically is started at a dose of 40 mg once or twice/day and increased until an adequate diuresis is achieved. A larger initial dose may be required in patients with more advanced heart failure or with concurrent azotemia. Serum electrolytes and renal function should be monitored frequently in patients with preexisting renal insufficiency or those in whom a rapid diuresis is desirable. Once fluid retention has resolved, the diuretic dose should be reduced to the minimal level necessary to maintain euvolemia. Electrolyte abnormalities and/or worsening azotemia may supervene before euvolemia is achieved. Hypokalemia may be corrected by potassium supplementation or addition of a K -sparing diuretic.

Aldosterone Antagonists

*A principal feature of CHF is marked activation of the renin–angiotensin–aldosterone system. In heart failure patients, plasma aldosterone concentrations may increase to as high as 20 times the normal level. Aldosterone has a range of biological effects beyond salt retention (Table 33–2), and antagonism of aldosterone's actions may be beneficial in patients with heart failure. The beneficial effects of spironolactone on mortality appear to be additive to those of ACE inhibitors and β receptor antagonists in patients with symptomatic heart failure; the use of spironolactone should be considered in patients with NYHA Class III and IV heart failure. Caution should be exercised when significant renal impairment is present. Treatment is initiated at a dose of 12.5 or 25 mg daily, as higher doses may lead to hyperkalemia, particularly in patients receiving an ACE inhibitor. Serum K^+ levels and electrolytes should be checked after initiation of treatment, and vigilance is warranted for potential drug interactions and medical disorders that may elevate serum K^+ concentration (*e.g.*, potassium supplements, ACE inhibitors, and worsening renal function).*

DIURETIC RESISTANCE IN HEART FAILURE

The response to diuretics is often impaired in patients with CHF. This impaired response may itself be a manifestation of the Na^+ avidity and the volume retention that characterize advanced heart failure. While there may initially be a brisk response to once-daily dosing, a compensatory increase in Na^+ reabsorption during the remainder of the day may prevent effective diuresis; as a result, reduction of the dosing interval may be warranted. In advanced heart failure, edema,

Table 33–2

Potential Roles of Aldosterone in the Pathophysiology of Heart Failure

Mechanism	Pathophysiological Effect
Increased Na ⁺ and water retention K ⁺ and Mg ²⁺ loss	Edema, elevated cardiac filling pressures Arrhythmogenesis and risk of sudden cardiac death
Reduced myocardial norepinephrine uptake	Potentiation of norepinephrine effects: myocardial remodeling and arrhythmogenesis
Reduced baroreceptor sensitivity	Reduced parasympathetic activity and risk of sudden cardiac death
Myocardial fibrosis, fibroblast proliferation Alterations in Na ⁺ channel expression	Remodeling and ventricular dysfunction Increased excitability and contractility of cardiac myocytes

decreased motility of the bowel wall, and reduced splanchnic blood flow can delay or attenuate peak diuretic effect. Patients who have impaired renal function typically require higher doses of diuretic to ensure adequate delivery of the drug to its site of action. Following prolonged administration of a loop diuretic, a process of adaptation can occur in which there is a compensatory increase in Na⁺ reabsorption in the distal nephron and blunting of net Na⁺ and water loss. The more common causes of diuretic resistance are listed in Table 33–3 and discussed in Chapter 28.

The caveats about concomitant therapy merit particular emphasis when considering coadministration of diuretics and ACE inhibitors or AT₁ receptor antagonists. These inhibitors of the renin–angiotensin system can either augment or reduce the effectiveness of diuretics. A reduced response is observed most commonly in patients with decreased renal arterial perfusion pressure, due either to renal artery stenosis or to reduction of forward cardiac output. In such patients, a high level of AngII–mediated glomerular efferent arteriolar tone is necessary to maintain glomerular filtration pressure. Pharmacologic antagonism of this intrarenal autoregulation may be accompanied by a decline in creatinine clearance and a derivative rise in the serum creatinine. In general, this is readily distinguished from the modest and limited rise in serum creatinine levels that commonly accompanies administration of ACE inhibitors. Diuretic resistance that reflects poor forward cardiac output may require the use of positive inotropic agents (e.g., dobutamine) as vasodilator therapy is initiated.

Decreased responsiveness to loop diuretics in patients with known chronic heart failure should prompt an increase in the dose administered or the dosing frequency. If this is ineffective, a thiazide diuretic (e.g., hydrochlorothiazide or metolazone) administered with the loop diuretic is often effective. However, this combination can result in an unpredictable and sometimes excessive diuresis, leading to intravascular volume depletion and renal K⁺ wasting; the combination therefore should be used cautiously. Spironolactone also may be effective in these patients when combined with a loop diuretic.

Table 33–3

Causes of Diuretic Resistance in Heart Failure

Noncompliance with medical regimen; excess dietary Na ⁺ intake
Decreased renal perfusion and glomerular filtration rate due to: <ul style="list-style-type: none"> <i>Excessive intravascular volume depletion and hypotension due to aggressive diuretic or vasodilator therapy</i> <i>Decline in cardiac output due to worsening heart failure, arrhythmias, or other primary cardiac causes</i> <i>Selective reduction in glomerular perfusion pressure following initiation (or dose increase) of ACE inhibitor therapy</i>
Nonsteroidal anti-inflammatory drugs
Primary renal pathology (e.g., cholesterol emboli, renal artery stenosis, drug-induced interstitial nephritis, obstructive uropathy)
Reduced or impaired diuretic absorption due to gut wall edema and reduced splanchnic blood flow

METABOLIC CONSEQUENCES OF DIURETIC THERAPY

The side effects of diuretics are discussed in Chapter 28. With regard to diuretic use in heart failure, the most important adverse sequelae of diuretics are electrolyte abnormalities, including hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis. Both hypokalemia and renal Mg^{2+} wasting can be limited by administration of oral KCl supplements or a K^+ -sparing diuretic.

Vasodilators

The rationale for the use of oral vasodilator drugs in the pharmacotherapy of CHF derived from the experience with the parenteral agents *phentolamine* and *nitroprusside* in patients with severe heart failure and elevated systemic vascular resistance. Although a number of vasodilators may improve symptoms in heart failure, only the *hydralazine–isosorbide dinitrate* combination and antagonists of the renin–angiotensin system (ACE inhibitors and AT_1 receptor blockers) have been shown to improve survival in prospective randomized trials. Table 33–1 summarizes some properties of vasodilators used to treat heart failure.

Inhibitors of the Renin–Angiotensin System: ACE Inhibitors and AT_1 Receptor Antagonists

RENIN–ANGIOTENSIN SYSTEM ANTAGONISTS The renin–angiotensin system (Figure 33–1; see Chapter 30) plays a central role in the pathophysiology of heart failure. Angiotensinogen is cleaved by renin to form the decapeptide angiotensin I (AngI); ACE converts AngI to the octapeptide AngII. AngII is a potent arterial vasoconstrictor and an important mediator of Na^+ and water retention through its effects on glomerular filtration pressure and aldosterone secretion. In addition, AngII potentiates neural catecholamine release, stimulates catecholamine release from the adrenal medulla, is arrhythmogenic, promotes vascular hyperplasia and pathologic myocardial hypertrophy, and stimulates myocyte death. Consequently, the antagonism of AngII is a cornerstone of heart failure management.

ACE inhibitors suppress AngII and aldosterone production, decrease sympathetic nervous system activity, and potentiate the effects of diuretics in heart failure. However, AngII levels frequently return to baseline values following chronic treatment with ACE inhibitors, due in part to production of AngII through ACE-independent enzymes such as chymase, a tissue protease. The sustained clinical effectiveness of ACE inhibitors despite AngII “escape” suggests that there are alternate mechanisms that contribute to the clinical effects of ACE inhibitors in heart failure. ACE also degrades bradykinin and other kinins that stimulate production of NO, cyclic GMP, and vasoactive eicosanoids; these vasodilator substances seem to oppose the effects of AngII on growth of vascular smooth muscle and cardiac fibroblasts and on extracellular matrix production. Thus, increased levels of bradykinin resulting from ACE inhibition may play a role in the hemodynamic and anti-remodeling effects of ACE inhibitors.

ACE inhibitors are more potent arterial than venous dilators. In response to ACE inhibition, mean arterial pressure (MAP) may decrease or be unchanged; the change in MAP will be determined by the stroke volume response to afterload reduction. Heart rate typically is unchanged, even when there is a decrease in systemic arterial pressure, a response that likely reflects a decrease in sympathetic tone in response to ACE inhibition. The decrease in left ventricular afterload results in increased stroke volume and cardiac output. Venodilation results in decreases in right and left heart filling pressures and end-diastolic volumes.

An alternative means of attenuating the hemodynamic and vascular impact of the renin–angiotensin system is through inhibition of angiotensin receptors. Most of the known clinical actions of AngII, including its deleterious effects in heart failure, are mediated through the AT_1 angiotensin receptor. AT_2 angiotensin receptors, also present throughout the cardiovascular system, seem to mediate responses that counterbalance the biological effects of AT_1 receptor stimulation. Due to their more distal site of action, AT_1 receptor antagonists may provide more potent reduction of the effects of AngII than do ACE inhibitors. Furthermore, AT_1 receptor blockade may result in greater AT_2 receptor activation, as AngII levels rise as a consequence of AT_1 receptor blockade. Note that blockade of AT_1 receptors does not alter bradykinin metabolism, which ACE inhibitors reduce.

Angiotensin-Converting Enzyme Inhibitors Six ACE inhibitors—*captopril* (CAPOTEN), *enalapril* (VASOTEC), *ramipril* (ALTACE), *lisinopril* (PRINIVIL, ZESTRIL), *quinapril* (ACCUPRIL), and *fosinopril* (MONOPRIL)—are currently FDA-approved for the treatment of heart failure. Data from

numerous clinical trials support the use of ACE inhibitors for the treatment of patients with heart failure of any severity, including patients with asymptomatic left ventricular dysfunction.

ACE-inhibitor therapy should be initiated at a low dose (e.g., 6.25 mg of captopril or 5 mg of lisinopril), as some patients may experience an abrupt drop in blood pressure, particularly in the setting of volume contraction. It is therefore reasonable to consider initiation of these drugs while congestive symptoms are present. ACE-inhibitor doses are customarily increased over several days in hospitalized patients or a few weeks in ambulatory patients, with careful observation of blood pressure, serum electrolytes, and serum creatinine.

There is no precisely defined relationship between dose and long-term clinical effectiveness of these drugs, but it is reasonable to use doses comparable to those used in studies that established efficacy in patients with heart failure. On this basis, target doses of these drugs would be 50 mg three times/day for captopril; 10 mg twice daily for enalapril; 10 mg once daily for lisinopril; or 5 mg twice daily for ramipril. In patients who have not achieved an adequate clinical response at these doses, further increases, as tolerated, may be of value; high-dose lisinopril (32.5 or 35 mg) reduced the combined endpoint of mortality and hospitalization when compared to lower doses of this agent.

In patients with heart failure and reduced renal blood flow, ACE inhibitors limit the kidney's ability to autoregulate glomerular perfusion pressure due to their selective effects on efferent arteriolar tone. If this occurs, the dose of ACE inhibitor should be reduced or another class of vasodilator added or substituted. Rarely, renal function deteriorates following initiation of therapy with an ACE inhibitor, often in patients with bilateral renal artery stenosis. Preferably, the renal artery stenosis should be treated; if this is not feasible, another class of vasodilator should be substituted. Angioedema secondary to ACE inhibition mandates immediate cessation of therapy. A small rise in serum K^+ occurs frequently with ACE inhibitors; this rise can be substantial in patients with renal impairment or in diabetic patients with type IV renal tubular acidosis (hyporeninemic hypoaldosteronism). Mild hyperkalemia is best managed by institution of a low-potassium diet but may require dosage adjustment. A troublesome cough may occur that is likely related to the effects of bradykinin. Substitution of an AT_1 receptor antagonist often alleviates this problem. The inability to use ACE inhibitors as a consequence of cardiorenal side effects (e.g., excessive hypotension, progressive renal insufficiency, or hyperkalemia) is itself a marker of poor prognosis in CHF patients.

Myocardial infarction is the leading cause of heart failure due to systolic dysfunction in industrialized countries. ACE inhibitors prevent the development of clinically significant ventricular dysfunction and mortality following acute infarction, likely by preventing adverse ventricular remodeling. ACE inhibitors are proven effective in specific patient subgroups, including women, African Americans, and the elderly.

AT_1 Receptor Antagonists Activation of the AT_1 receptor mediates most of the deleterious effects of AngII. The receptor blockade provided by AT_1 antagonists provides a pharmacologic means by which to reduce the AngII “escape” that occurs with ACE inhibitors. AT_1 receptor antagonism might also be expected to avoid the bradykinin-mediated side effects of ACE inhibition, principally cough. This side effect, which occurs in >10% of patients, represents an important limitation to the use of ACE inhibitors in clinical practice. Angioedema has been reported with AT_1 receptor antagonists; caution is therefore warranted when prescribing these agents to patients with a history of ACE inhibitor–associated angioedema. AT_1 receptor antagonists provide an alternative to ACE inhibitors in the treatment of heart failure and provide comparable mortality benefits.

The combined use of ACE inhibitors and ARBs in the treatment of heart failure offers the intriguing possibility of additive therapeutic benefit by virtue of distinctive modes of angiotensin antagonism. Some experts suggest that the addition of an AT_1 blocker to a heart failure regimen that includes an ACE inhibitor can be considered in an effort to reduce hospitalizations. AT_1 antagonists also appear to reduce hospitalization in patients with diastolic heart failure.

NITROVASODILATORS Nitrovasodilators have long been used to treat heart failure and remain among the most widely used vasoactive medications. These drugs relax vascular smooth muscle by supplying NO and thereby activating soluble guanylyl cyclase. Thus, they mimic the actions of endogenous NO, an intracellular and paracrine autocoid synthesized from arginine by NO synthases in endothelial and smooth muscle cells throughout the vasculature.

Organic Nitrates Organic nitrates are available in a number of formulations that include rapid-acting nitroglycerin tablets or spray for sublingual administration, short-acting oral agents

such as isosorbide dinitrate (ISORDIL, SORBITRATE, others), long-acting oral agents such as *isosorbide mononitrate* (IMDUR), topical preparations such as nitroglycerin ointment and transdermal patches, and intravenous nitroglycerin. The nitrates are relatively safe and effective agents whose principal action in the treatment of congestive heart failure is reduction of left ventricular filling pressures. This preload reduction is due to an increase in peripheral venous capacitance. Nitrates will cause a decline in pulmonary and systemic vascular resistance, particularly at higher doses, although this response is less marked and less predictable than with nitroprusside. These drugs have a selective vasodilator effect on the epicardial coronary vasculature and may enhance both systolic and diastolic ventricular function by increasing coronary flow.

Isosorbide dinitrate when administered to patients with CHF is more effective than placebo in improving exercise capacity and reducing symptoms. However, the limited effects of these agents on the systemic vascular resistance and the development of tolerance limit the utility of organic nitrates as monotherapy in the treatment of CHF. An isosorbide dinitrate-hydralazine combination was proven effective in reducing overall mortality in patients with mild-to-moderate heart failure concurrently treated with digoxin and diuretics. The mononitrate formulation has not been studied in chronic heart failure; the transdermal formulations are infrequently used in the treatment of CHF, reflecting concerns related to perfusion-dependent drug absorption in such patients.

Tolerance can limit the long-term effectiveness of nitrates in the treatment of CHF. Blood levels of these drugs should be permitted to fall to negligible levels for at least 6–8 hours each day, which can be adjusted to the patient's symptoms. Patients with recurrent orthopnea or paroxysmal nocturnal dyspnea, for example, would likely benefit most by using nitrates at night. N-acetylcysteine (MUCOMYST) may diminish tolerance to the hemodynamic effects of nitrates in heart failure. Likewise, hydralazine may decrease nitrate tolerance by an antioxidant effect that attenuates superoxide formation, thereby increasing NO bioavailability.

HYDRALAZINE Hydralazine (APRESOLINE) is an effective antihypertensive drug (see Chapter 32), particularly when combined with agents that blunt compensatory increases in sympathetic tone and salt and water retention. In heart failure, hydralazine reduces right and left ventricular afterload by reducing pulmonary and systemic vascular resistance. This augments forward stroke volume and reduces ventricular systolic wall stress. Hydralazine also appears to have moderate “direct” positive inotropic activity in cardiac muscle unrelated to afterload reduction. Hydralazine is effective in reducing renal vascular resistance and in increasing renal blood flow to a greater degree than are most other vasodilators, with the exception of ACE inhibitors. Reflecting these aggregate effects, hydralazine may be useful in heart-failure patients with renal dysfunction who cannot tolerate an ACE inhibitor. Hydralazine has minimal effects on venous capacitance and therefore is most effective when combined with agents with venodilating activity (e.g., organic nitrates).

The combination of hydralazine (300 mg/day) and isosorbide dinitrate increased survival when compared to placebo or the α_1 adrenergic antagonist prazosin. Hydralazine, with or without nitrates, may provide additional hemodynamic improvement for patients with advanced heart failure who already are being treated with conventional doses of an ACE inhibitor, digoxin, and diuretics. A combination of isosorbide dinitrate-hydralazine (BIDIL) was most recently investigated in African Americans; when added to standard therapy that included neurohumoral blockade in patients with NYHA Class III or IV heart failure there was a significant reduction in all-cause mortality compared to placebo. This combination preparation is FDA-approved as adjunct to standard therapy for use in CHF patients self-identified as African American. It is the first race-based drug approved by the FDA.

Several important limitations constrain the use of hydralazine in the treatment of CHF. Although hydralazine therapy was associated with a greater increase in ejection fraction and exercise duration when compared to the ACE inhibitor enalapril, the latter was superior with respect to reduction of mortality. Side effects that may necessitate dose adjustment or withdrawal of hydralazine are common. The lupus-like side effects associated with hydralazine are relatively uncommon and may be more likely to occur in patients with the “slow-acetylator” phenotype (see Chapter 3). Finally, compliance with the multidosing regimen may be difficult in CHF patients who often are taking multiple concurrent medications.

The oral bioavailability and pharmacokinetics of hydralazine are not altered significantly by heart failure unless there is severe hepatic congestion or hypoperfusion. Intravenous hydralazine provides little practical advantage over oral formulations except for urgent use during pregnancy, a state in which relative or absolute contraindications exist for most other vasodilators.

β Adrenergic Receptor Antagonists

Heart failure is characterized by sympathetic hyperactivation. Sympathetic activation supports circulatory function by enhancing contractility (inotropy), augmenting ventricular relaxation and filling (lusitropy), and increasing heart rate (chronotropy). For many years, pharmacological approaches to the treatment of heart failure involved the use of drugs that would further stimulate sympathetic responses, reflecting the viewpoint that the fundamental abnormality in CHF is the reduction of stroke volume/cardiac output that occurs as a consequence of myocardial dysfunction. Paradoxically, many of these sympathomimetics increased mortality in CHF patients, while an unexpected mortality benefit was seen with the administration of β adrenergic blocking drugs. The recognition that sustained activation of sympathetic nerves in the context of myocardial injury contributes to the progression of contractile dysfunction is now well established and derives support from the demonstrable adverse consequences of long-term sympathetic stimulation (such as maladaptive proliferative signaling in the myocardium, direct cardiomyocyte toxicity, and myocyte apoptosis).

β Receptor antagonists improve symptoms, exercise tolerance, and measures of ventricular function over a period of several months in patients with heart failure due to idiopathic dilated cardiomyopathy. Serial measurements indicate that a decrease in systolic function does occur immediately after initiation of a β antagonist in CHF patients, but systolic function recovers and improves beyond baseline levels over the ensuing 2–4 months. Improved ventricular function with chronic β receptor antagonist therapy may be due to attenuation or prevention of the β adrenergic receptor-mediated adverse effects of catecholamines on the myocardium.

More important than improving symptoms, β receptor antagonists reduce hospitalization and decrease mortality in patients with mild-to-moderate CHF. A consistent finding is a reduction in the incidence of sudden death, presumably reflecting a decrease in malignant ventricular arrhythmias. Thus, an antiarrhythmic benefit seems likely, possibly reflecting a reduced propensity to develop hypokalemia in the face of systemic β adrenergic blockade, or perhaps a direct consequence of the anti-ischemic effects of these drugs. Another consistent finding with β adrenergic blockade is an improvement in left ventricular structure and function with a decrease in chamber size and an increase in ejection fraction.

METOPROLOL *Metoprolol* (LOPRESSOR, TOPROL XL, OTHERS) is a β_1 -selective antagonist. The 25-mg extended-release tablet formulation is FDA-approved for the management of mild-to-moderate heart failure. A number of clinical trials have demonstrated the beneficial effects of metoprolol therapy in heart failure, with decreased mortality due both to reductions in sudden death and to death from worsening heart failure. These beneficial effects were independent of age, sex, etiology of heart failure, or ejection fraction.

CARVEDILOL *Carvedilol* (COREG) is a nonselective β receptor antagonist and α_1 -selective antagonist that is FDA-approved for the management of mild-to-severe heart failure. Carvedilol, in combination with standard therapy, is associated with significant reductions in all-cause mortality and hospitalization for heart failure exacerbation.

BISOPROLOL *Bisoprolol* (ZEBETA) is a β_1 -selective antagonist that reduces all-cause mortality in CHF patients, due primarily to a decrease in sudden deaths and a lesser decrease in pump failure. The mortality benefit of bisoprolol was independent of the etiology of heart failure and the drug also significantly decreased hospitalizations for heart failure. In the U.S., heart failure is an off-label use for bisoprolol.

Clinical Use of β Adrenergic Receptor Antagonists in Heart Failure

The extensive body of data regarding the use of β receptor antagonists in chronic heart failure provides compelling evidence that β antagonists improve symptoms, reduce hospitalization, and decrease mortality in patients with mild and moderate heart failure. Accordingly, β receptor antagonists are now recommended for routine use in patients with an ejection fraction <35% and NYHA Class II or III symptoms in conjunction with ACE inhibitor or angiotensin receptor antagonist, and diuretics as required to palliate symptoms.

This general recommendation should be tempered by certain limitations in the experimental database. First, most of the data that underlie this recommendation were obtained in relatively stable patients with mild-to-moderate symptoms. Therefore, the role of β receptor antagonists in patients with more severe symptoms, or with recent decompensation, is not yet clear. Likewise, the utility

of β receptor blockade in patients with asymptomatic left ventricular dysfunction has not been studied. Finally, although it appears likely that the beneficial effects of these drugs are related to β receptor blockade, it cannot be assumed that all β receptor antagonists will exert similar effects. Since β antagonists have the potential to worsen both ventricular function and symptoms in patients with heart failure, several caveats should be considered. β Adrenergic receptor antagonists should be initiated at very low doses, generally less than one-tenth of the final target dose, and the dose should be increased slowly, over the course of weeks and under careful supervision. The rapid institution of the usual β adrenergic receptor–blocking doses used for hypertension or coronary artery disease may cause decompensation in many patients who otherwise would be able to tolerate a slower dose titration. Even when therapy is initiated with low doses of a β antagonist, there may be an increased tendency to retain fluid that will require adjustments in the diuretic regimen. Although limited data suggest that patients with NYHA Class IIIB and IV CHF may tolerate β blockers and benefit from their use, this group of patients should be approached with considerable caution. There is almost no experience in patients with new-onset, recently decompensated heart failure. Such patients should not be treated with β blockers until after they have stabilized for several days to weeks.

Parenteral Vasodilators

The failing left ventricle is characterized by depression of myocardial contractility and increased sensitivity to alterations of left ventricular afterload. This latter attribute of the failing ventricle is manifest by a greater proportional reduction of stroke volume as the impedance to ejection is increased. Conversely, afterload reduction in this setting can be associated with substantial increases in stroke volume. This increased afterload dependence underlies the beneficial effects of load reduction therapy in patients with heart failure due to systolic dysfunction.

SODIUM NITROPRUSSIDE *Sodium nitroprusside* (NITROPRESS) is a prodrug and potent vasodilator that reduces both ventricular filling pressures and systemic vascular resistance. It has a rapid onset (2–5 minutes) and offset (quickly metabolized to cyanide and NO, the active vasodilator) of action and its dose can be titrated expeditiously to achieve the desired hemodynamic effect. For these reasons, nitroprusside is commonly used in intensive-care settings for rapid control of severe hypertension and for the management of decompensated heart failure. The basic pharmacologic properties of this drug are described in Chapter 32.

Several mechanisms contribute to the reduction of ventricular filling pressures after treatment with nitroprusside. This agent directly increases venous capacitance, redistributing blood volume from the central to the peripheral venous circulation. Nitroprusside also causes a fall in peripheral vascular resistance as well as an increase in aortic wall compliance and improves ventricular–vascular coupling; left ventricular afterload is decreased and cardiac output is thereby increased. This combination of preload and afterload reduction improves myocardial energetics by reducing wall stress. This improvement in myocardial energetics is contingent upon maintenance of a mean arterial pressure sufficient to drive coronary perfusion during diastole. Following the rapid withdrawal of nitroprusside, a transient deterioration in ventricular function associated with a rebound increase in systemic vascular resistance occurs. Nitroprusside is particularly effective in patients with CHF due to elevations of systemic vascular resistance and/or mechanical complications that follow acute myocardial infarction (such as mitral regurgitation or left-to-right shunts through a ventricular septal defect).

The most common adverse effect of nitroprusside is hypotension. In general, nitroprusside initiation in patients with severe heart failure results in increased cardiac output and a parallel increase in renal blood flow, improving both glomerular filtration and diuretic effectiveness. However, excessive reduction of systemic arterial pressure may limit or prevent an increase in renal blood flow in patients with more severe contractile dysfunction. Cyanide produced during the biotransformation of nitroprusside is rapidly metabolized by the liver to thiocyanate, which is cleared by the kidney. Thiocyanate and/or cyanide toxicity is uncommon but may occur in the setting of hepatic or renal failure, or following prolonged, high-dose infusion of the drug. Typical symptoms include unexplained abdominal pain, mental status changes, convulsions, or lactic acidosis. Methemoglobinemia, another unusual complication of prolonged, high-dose nitroprusside infusion, is due to the oxidation of hemoglobin by NO.

INTRAVENOUS NITROGLYCERIN Intravenous nitroglycerin, like nitroprusside, is a vasoactive NO source that is commonly used in intensive care units. Its structure and basic pharmacology are described in Chapter 31. Unlike nitroprusside, nitroglycerin is relatively selective for

venous capacitance vessels, particularly at low infusion rates. In patients with CHF, intravenous nitroglycerin is most clearly indicated in the treatment of left heart failure due to acute myocardial ischemia. Parenteral nitroglycerin also is used in the treatment of nonischemic left heart failure when expeditious reduction of ventricular filling pressures is desired; nitroglycerin can be particularly useful in patients with symptomatic volume overload in whom effective diuresis has not been established. At higher infusion rates, this drug can also reduce systemic arterial resistance, although this effect is less predictable. Nitroglycerin therapy may be limited by headache and the development of nitrate tolerance, although the latter is generally overcome by uptitration of the infusion rate to maintain the desired response. Since nitroglycerin is administered in ethanol, high infusion rates can be associated with significant elevation of blood alcohol levels.

NESIRITIDE *Nesiritide* (NATRECOR), a recombinant form of human brain natriuretic peptide (BNP), is FDA-approved for treatment of dyspnea due to congestive heart failure. The natriuretic peptides—atrial natriuretic peptide (ANP), BNP, and C-type natriuretic peptide—are a family of endogenous hormones that possess potent natriuretic, diuretic, and vasodilator properties. BNP is secreted by ventricular cardiac myocytes in response to stretch; circulating levels of BNP correlate with the severity of heart failure. In the setting of heart failure, the effects of BNP counteract the effects of AngII and NE by producing vasodilation, natriuresis, and diuresis.

The BNP receptor is the extracellular domain of type A guanylyl cyclase, GC-A. The active receptor-cyclase complex is a homodimer. Activation of GC-A by nesiritide (BNP) increases cyclic GMP content in target tissues, including vascular, endothelial, and smooth muscle cells. As with nitrovasodilators, elevated cyclic GMP leads to relaxation of vascular smooth muscle and vasodilation in both the venous and arterial systems. BNP is metabolized by specific clearance receptors, which facilitate its internalization and enzymatic degradation. It is also inactivated by neutral endopeptidases (NEP). Dose adjustment is not required in patients with renal dysfunction.

Nesiritide lowers right and left side cardiac filling pressures without a direct chronotropic or inotropic action. The hemodynamic response to nesiritide is characterized by decreased right atrial, pulmonary arterial, and pulmonary capillary wedge pressures; systemic vascular resistance is reduced and cardiac index is increased. Improvement in global clinical status, attenuation of dyspnea and fatigue, and enhanced diuretic responsiveness have been reported. When compared to intravenous nitroglycerin and placebo in the treatment of decompensated heart failure, nesiritide was associated with greater reductions in pulmonary capillary wedge pressure and improvements in dyspnea were comparable to nitroglycerin and better than placebo. In contrast to the effects of parenteral inotropic agents, nesiritide is not associated with increased ventricular or atrial arrhythmias. Thus, nesiritide may be preferable to inotropic drugs when treating refractory heart failure in patients at risk for arrhythmia

Nesiritide therapy is initiated with a loading dose of 2 $\mu\text{g}/\text{kg}$ followed by an infusion rate of 0.01 $\mu\text{g}/\text{kg}/\text{min}$ that can be increased in increments of 0.005 $\mu\text{g}/\text{kg}/\text{min}$ to a maximum of 0.03 $\mu\text{g}/\text{kg}/\text{min}$. The primary side effect is hypotension that is reversible upon discontinuation of the drug. The $t_{1/2}$ of the drug is 18 minutes; however, hypotensive effects may persist for a longer period than would be predicted on the basis of the elimination $t_{1/2}$. Although there is no specific systolic blood pressure below which nesiritide therapy is contraindicated, studies have typically excluded patients with systolic blood pressure ≤ 90 mm Hg; inotropic support may be preferred in such patients. Also of concern, recent meta-analyses have suggested that nesiritide therapy of CHF is associated with an increased risk of renal dysfunction and death.

VASOPEPTIDASE INHIBITORS AND BNP

Vasopeptidase inhibitors are a novel group of drugs that simultaneously inhibit ACE and neutral endopeptidases (NEPs) and are effective antihypertensive agents. NEPs are responsible for the enzymatic degradation of atrial and brain natriuretic peptides. Inhibitors of NEPs therefore are expected to increase circulating levels of these natriuretic hormones and on this basis have been investigated as therapeutic agents in heart failure. Studies suggest that the vasopeptidase inhibitor omapatrilat is comparable to ACE inhibitors with respect to improving exercise capacity, decreasing symptoms, and reducing the risk of death and hospitalization in chronic heart failure, but is more frequently associated with symptomatic hypotension. Omapatrilat is not approved by the FDA.

Cardiac Glycosides

Beneficial effects of cardiac glycosides in the treatment of heart failure have been attributed to a positive inotropic effect on failing myocardium and efficacy in controlling the ventricular rate

response to atrial fibrillation. The cardiac glycosides also modulate autonomic nervous system activity, and it is likely that this mechanism contributes substantially to their efficacy in the management of heart failure. However, the advent of alternative therapies that both palliate symptoms and improve survival has led to a more limited role for the cardiac glycosides in the pharmacotherapy of congestive heart failure. Only digoxin (LANOXIN, LANOXICAPS) is widely used today.

MECHANISM OF THE POSITIVE INOTROPIC EFFECT

All cardiac glycosides are potent and highly selective inhibitors of the active transport of Na^+ and K^+ across cell membranes by their reversible binding to the α subunit of the Na^+ , K^+ -ATPase. Both Na^+ and Ca^{2+} ions enter cardiac muscle cells during each depolarization (Figure 33–2). Ca^{2+} entry triggers contraction; it then is resequenced by the sarcoplasmic reticular Ca^{2+} -ATPase (SERCA2) and also is removed from the cell by the Na^+ - Ca^{2+} exchanger (NCX) and by a sarcolemmal Ca^{2+} -ATPase. Inhibition of the Na^+ , K^+ -ATPase by cardiac glycosides results in a reduction in the rate of Na^+ extrusion and a rise in cytosolic Na^+ , which reduces the ability of the NCX to extrude Ca^{2+} during myocyte repolarization. With reduced Ca^{2+} efflux and repeated entry

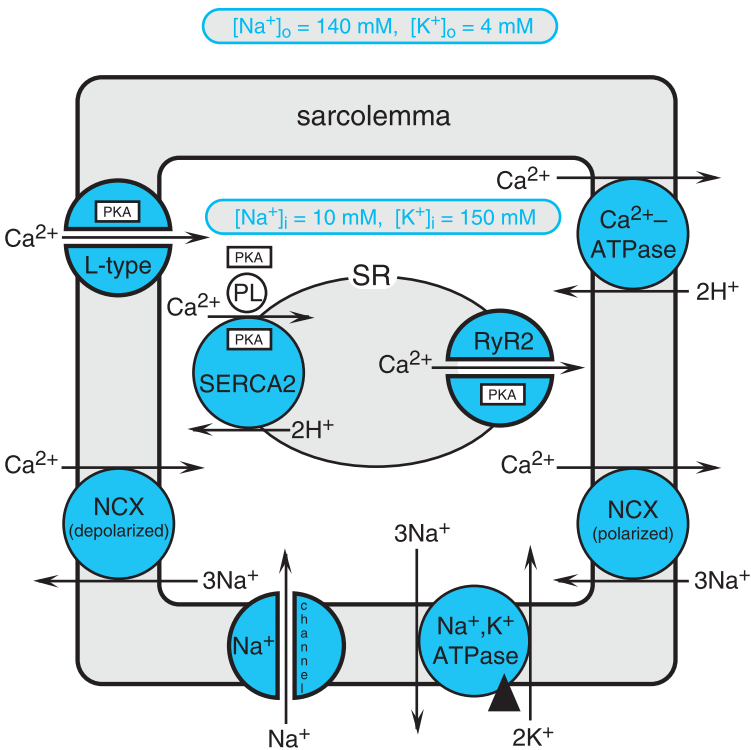

FIGURE 33–2 Sarcolemmal exchange of Na^+ and Ca^{2+} during cell depolarization and repolarization. Na^+ and Ca^{2+} enter the cardiac myocyte via the Na^+ channel and the L-type Ca^{2+} channel during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of Ca^{2+} from internal stores in the sarcoplasmic reticulum (SR). The resulting increase in intracellular Ca^{2+} interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for Na^+ across the sarcolemma is maintained by active transport of Na^+ out of the cell by the sarcolemmal Na^+ , K^+ -ATPase. The bulk of cytosolic Ca^{2+} is pumped back into the SR by a Ca^{2+} -ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal Ca^{2+} -ATPase or a high capacity Na^+ - Ca^{2+} exchange protein, NCX. NCX exchanges three Na^+ for every Ca^{2+} , using the electrochemical potential of Na^+ to drive Ca^{2+} extrusion. The direction of Na^+ - Ca^{2+} exchange may reverse briefly during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. β Receptor agonists and PDE inhibitors, by increasing cellular cyclic AMP levels, activate PKA, which phosphorylates target proteins, including phospholamban, the α subunit of the L-type Ca^{2+} channel and regulatory components of the RyR, as well as TnI, the inhibitory subunit of troponin (not shown). The effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. \blacktriangle indicates site of cardiac glycoside binding. See text for mechanism of positive inotropic effect of cardiac glycosides.

of Ca^{2+} , Ca^{2+} accumulates in the myocyte: Ca^{2+} uptake into the SR is increased; this increased Ca^{2+} becomes available for release from the SR during the next cycle of excitation-contraction coupling and is the penultimate effect by which cardiac glycosides enhance myocardial contractility (Figure 33–2).

ELECTROPHYSIOLOGICAL ACTIONS At therapeutic concentrations, digoxin decreases automaticity and increases maximal diastolic resting membrane potential in atrial and AV nodal tissues due to an increase in vagal tone and a decrease in sympathetic nervous system activity. This can cause sinus bradycardia and/or prolongation of AV conduction or higher-grade sinus arrest or AV block. At higher concentrations, cardiac glycosides can directly increase automaticity in cardiac tissue, actions that contribute to the genesis of atrial and ventricular arrhythmias. Increased intracellular Ca^{2+} loading and increased sympathetic tone increase the spontaneous (phase 4) rate of diastolic depolarization as well as delayed afterdepolarizations that may trigger generation of a propagated action potential. This simultaneous nonuniform increase in automaticity and depression of conduction in His-Purkinje and ventricular muscle fibers can predispose the heart to serious ventricular arrhythmias (see Chapter 34).

PHARMACOKINETICS The elimination $t_{1/2}$ for digoxin is 36 hours in patients with normal renal function. This permits once-a-day dosing; near steady-state blood levels are achieved one week after initiation of maintenance therapy. Digoxin is excreted by the kidney with a clearance rate that is proportional to the glomerular filtration rate. In patients with congestive heart failure and marginal cardiac reserve, an increase in cardiac output and renal blood flow with vasodilator therapy or sympathomimetic agents may increase renal digoxin clearance, necessitating dosage adjustment. Conversely, the $t_{1/2}$ is increased substantially in patients with advanced renal insufficiency (to ~3.5–5 days); both the volume of distribution and the clearance rate of the drug are decreased in the elderly. Because of its narrow therapeutic index, the drug must be used with caution in patients with renal insufficiency and in the elderly.

Liquid-filled capsules of digoxin (LANOXICAPS) have a higher bioavailability than do tablets (LANOXIN) and require dosage adjustment if a patient is switched from one dosage form to the other. Digoxin is available for intravenous administration, and maintenance doses can be given intravenously when oral dosing is impractical. A number of drug interactions and clinical conditions can alter the pharmacokinetics of digoxin or alter patient susceptibility to its toxic manifestations. For example, chronic renal failure decreases the volume of distribution of digoxin, and therefore requires a decrease in maintenance dosage of the drug. Electrolyte disturbances, especially hypokalemia, acid–base imbalances, and the specific type of underlying heart disease also may alter a patient's susceptibility to toxic manifestations of digoxin.

CLINICAL USE OF DIGOXIN IN HEART FAILURE There has been controversy surrounding the efficacy of cardiac glycosides in the treatment of patients with heart failure who are in sinus rhythm. It is now recommended that digoxin be reserved for patients with heart failure who are in atrial fibrillation, or for patients in sinus rhythm who remain symptomatic despite maximal therapy with ACE inhibitors and β adrenergic receptor antagonists. Although digoxin is no longer viewed as a first-line agent, it should be emphasized that digoxin—unlike most other inotropic agents—does not have an adverse impact on mortality in CHF. Digoxin may be unique among inotropic drugs by virtue of its neurohumoral effects, which include attenuation of sympathetic activation and reduction of renin release.

DIGOXIN TOXICITY The incidence and severity of digoxin toxicity have declined substantially, due in part to the development of alternative drugs for the treatment of supraventricular arrhythmias and heart failure, to the increased understanding of digoxin pharmacokinetics, to the monitoring of serum digoxin levels, and to the identification of important interactions between digoxin and other concomitantly administered drugs. Nevertheless, the recognition of digoxin toxicity remains an important consideration in the differential diagnosis of arrhythmias and neurological and GI symptoms in patients receiving cardiac glycosides. Immunotherapy with purified Fab fragments from ovine antidigoxin antisera (DIGIBIND) provides an effective antidote for life-threatening digoxin or *digitoxin* toxicity.

Parenteral Inotropic Agents

GENERAL CONSIDERATIONS Patients with heart failure are most commonly hospitalized because of fluid retention that results in dyspnea and peripheral edema. Accordingly, relief of

congestion through the use of diuretics and venodilators remains a therapeutic priority. A subset of these patients may present with clinical evidence of reduced forward cardiac output, including fatigue, azotemia, and alterations in mental status. Patients who present with more severe decompensation typically require intensive therapy that may include parenteral inotropic agents; in extreme circumstances assisted ventilation and mechanical circulatory support may be required. In the setting of severe decompensation, the principal focus of initial therapy is to increase cardiac output by administration of agents that increase myocardial contractility.

β Adrenergic and Dopaminergic Agonists

Dopamine and dobutamine are the positive inotropic agents most often used for the short-term support of the circulation in advanced heart failure. These drugs act *via* stimulation of the cardiac myocyte dopamine D_1 and β adrenergic receptors, leading to stimulation of the G_s -adenylyl cyclase-cyclic AMP-PKA pathway. *Isoproterenol*, *epinephrine*, and *norepinephrine*, although useful in specific circumstances, have little role in the treatment of heart failure (see Chapter 10).

DOPAMINE (DA) DA has limited utility in the treatment of most patients with cardiogenic circulatory failure. At *low doses* ($\leq 2 \mu\text{g}/\text{kg}$ lean body mass per minute), DA causes vasodilation by stimulating dopaminergic receptors on smooth muscle (causing cyclic AMP-dependent relaxation) and by stimulating presynaptic D_2 receptors on sympathetic nerves in the peripheral circulation (inhibiting NE release and reducing α adrenergic stimulation of vascular smooth muscle); these receptors are prominent in splanchnic and renal arterial beds. DA infusion at this rate may increase renal blood flow and thereby help to maintain the glomerular filtration rate in patients who are refractory to diuretics. DA also has direct effects on renal tubular epithelial cells that promote diuresis. At *intermediate* infusion rates ($2\text{--}5 \mu\text{g}/\text{kg}/\text{min}$), DA directly stimulates β receptors on the heart and vascular sympathetic neurons, enhancing cardiac contractility and neural NE release. At *higher* infusion rates ($5\text{--}15 \mu\text{g}/\text{kg}/\text{min}$), peripheral arterial and venous constriction occur, mediated by α adrenergic receptor stimulation (see above). This effect may be desirable for support of a critically reduced arterial pressure in selected patients in whom circulatory failure is the result of vasodilation (e.g., sepsis or anaphylaxis). However, high-dose DA infusion has little role in the treatment of patients with primary contractile dysfunction; in this setting, increased vasoconstriction will lead to increased afterload, further compromising left ventricular stroke volume and forward cardiac output. Tachycardia, which is more pronounced with DA than with dobutamine, may provoke ischemia in patients with coronary artery disease.

DOBUTAMINE Dobutamine (DOBUTREX) is the preferred β agonist for the management of patients with end-stage systolic dysfunction and CHF. Dobutamine is supplied as a racemic mixture that stimulates both β_1 and β_2 receptor subtypes. In addition, the (–) enantiomer is an agonist for α adrenergic receptors, whereas the (+) enantiomer is a very weak partial agonist. At infusion rates that have a positive inotropic effect in humans, the β_1 adrenergic effect in the myocardium predominates. In the vasculature, the α adrenergic agonist effect of the (–) enantiomer appears to be negated by the partial agonism of the (+) enantiomer and the vasodilator effects of β_2 receptor stimulation. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume due to its positive inotropic action. At doses that increase cardiac output, there is relatively little increase in heart rate. Dobutamine infusion generally causes a modest decrease in systemic resistance and intracardiac filling pressures. Dobutamine does not activate dopaminergic receptors. As such, the increase in renal blood flow that occurs in association with dobutamine is proportional to the increase in cardiac output.

Continuous infusion of dobutamine for up to several days in patients with severe clinical decompensation has been a common practice; pharmacological tolerance may limit efficacy during longer-term administration. Infusions are typically initiated at $2\text{--}3 \mu\text{g}/\text{kg}/\text{min}$, without a loading dose, and increased until the desired hemodynamic response is achieved. The blood pressure response to dobutamine is variable and is dependent on the relative effects of this agent on vascular tone and cardiac output. If cardiac output is significantly increased, heart rate may decline secondary to reflex withdrawal of sympathetic tone. The major side effects of dobutamine are excessive tachycardia and arrhythmias, which may require a reduction in dosage. Tolerance may occur after prolonged use, requiring substitution of an alternative drug such as a PDE3 inhibitor. In patients who have been receiving a β receptor antagonist, the initial response to dobutamine may be attenuated.

PHOSPHODIESTERASE INHIBITORS

The cyclic AMP–phosphodiesterase (PDE) inhibitors reduce the degradation of cellular cyclic AMP; the consequences are generally those of elevated cyclic AMP, much as would occur in response to a stimulator of adenyl cyclase activity. In the heart, the result is positive inotropism. In the peripheral vasculature, the result is dilation of both resistance and capacitance vessels, leading to reduction of both afterload and preload. These combined effects on the myocardium and in the periphery underlie the classification of these drugs as “inodilators”.

INAMRINONE AND MILRINONE Parenteral formulations of *inamrinone* (previous name: *amrinone*) and *milrinone* are approved for short-term support of the circulation in advanced heart failure. Both drugs are bipyridine derivatives and relatively selective inhibitors of PDE3, the cyclic GMP–inhibited cyclic AMP PDE. These drugs cause direct stimulation of myocardial contractility and acceleration of myocardial relaxation. In addition, they cause balanced arterial and venous dilation with a consequent fall in systemic and pulmonary vascular resistances, and left and right heart filling pressures. Cardiac output increases due to the stimulation of myocardial contractility and the decrease in left ventricular afterload. As a result of this dual mechanism of action, the increase in cardiac output with milrinone is greater than that seen with nitroprusside at doses that comparably reduce systemic resistance. Conversely, the arterial and venous dilator effects of milrinone are greater than those of dobutamine at doses that produce comparable increases in cardiac output.

Intravenous infusions of either drug should be initiated with a loading dose followed by a continuous infusion. For inamrinone, a 0.75-mg/kg bolus injection administered over 2–3 minutes is followed by a 2- to 20- μ g/kg/min infusion. The loading dose of milrinone is usually 50 μ g/kg, and the continuous infusion rate ranges from 0.25–1 μ g/kg/min. The elimination half-lives of inamrinone and milrinone in healthy subjects are 2–3 hours and 0.5–1 hour, respectively, and are approximately doubled in patients with severe heart failure. Clinically significant thrombocytopenia occurs in 10% of patients receiving inamrinone but is rare with milrinone. Because of its greater selectivity for PDE3 isoenzymes, shorter $t_{1/2}$, and more favorable side-effect profile, milrinone is preferred among currently available PDE inhibitors for short-term, parenteral inotropic support. The vasodilating effects of the drug and its relatively protracted $t_{1/2}$ limit use in patients with low systemic arterial pressure.

Diastolic Heart Failure

Approximately 30–40% of CHF cases occur in patients with normal or preserved left ventricular systolic function. Despite intact systolic function, such patients will present with typical signs and symptoms of heart failure, including dyspnea, impaired functional capacity, and pulmonary/systemic venous congestion. The pathogenesis of diastolic heart failure includes structural and functional abnormalities of the ventricle that are associated with impaired ventricular relaxation and impaired left ventricular distensibility (*i.e.*, abnormal LV compliance with increased chamber stiffness). Consonant with the definition of heart failure outlined above, the diagnosis of diastolic heart failure is made when the left ventricle is unable to fill to a volume that is sufficient to maintain normal cardiac output without exceeding the upper range of normal diastolic pressure. The underlying problem in diastolic heart failure is the inability to fill (rather than to empty) the ventricle.

There are no definitive trials to guide therapy in patients with diastolic heart failure, and one is therefore unable to initiate treatment in anticipation of attenuating disease progression or reducing mortality. It is, however, possible to make some general comments regarding mechanistic considerations in selecting treatment.

Patients with diastolic heart failure are typically dependent upon preload to maintain adequate cardiac output. While patients with symptomatic volume overload will benefit from careful modulation of intravascular volume, volume reduction should be accomplished gradually and treatment goals reassessed frequently. In addition to cautious volume management, it is important to maintain synchronous atrial contraction in such patients, which maintains adequate left ventricular filling during the latter phase of diastole. Cardiac function is often severely impaired if patients with diastolic heart failure develop atrial fibrillation, particularly in the context of suboptimal ventricular rate control. Meticulous control of the ventricular rate with drugs that slow AV conduction is mandatory (see Chapter 34) and restoration of sinus rhythm should be considered. It is also important to evaluate and treat conditions that are associated with dynamic abnormalities of diastolic function, such as myocardial ischemia and poorly controlled systemic hypertension.

CLINICAL SUMMARY

Heart failure is a chronic illness that begins with a primary myocardial insult (that leads to loss of cardiomyocyte number or function) and that is progressive (through a course that is characterized by a variety of functional and structural compensations). In fact, this temporal progression of disease provides the basis for a revised classification system that is replacing the standard New York Heart Association categories that are based on patient functional status. Under this new construct (Figure 33–3), patients progress from a stage in which they are at risk to develop heart failure (Stage A) to a phase in which structural heart disease is established and demonstrable (Stage B). From this point of asymptomatic ventricular dysfunction, patients progress to a stage in which symptoms of the heart failure syndrome are present (Stage C); a subset of Stage C patients will progress to end-stage status (Stage D) in which symptoms refractory to medical therapy are present. Given that the syndrome of heart failure begins with a primary insult to the myocardium (such as infarction, excessive hemodynamic load, or inflammation), treatment should begin with prevention *via* the identification and remediation of risk factors that predispose to the development of structural heart disease. For example, since coronary artery disease is the most common etiologic basis for systolic dysfunction and CHF, the prevention of myocardial infarction through risk factor modification (e.g., lipid lowering, control of hypertension, and smoking cessation) is a critical therapeutic strategy with substantial public health implications.

Once structural heart disease is established (Stage B), compensatory mechanisms are activated that support cardiovascular function, but that also set the stage for disease progression. This phase can be referred to as the stage of asymptomatic ventricular dysfunction. Treatment in Stage B is directed at attenuation of sustained neurohormonal activation, and target doses of β blockers, ACE inhibitors, or AT_1 receptor antagonists should be selected using the treatment guidelines applied in clinical trials that established the morbidity and mortality benefits of these agents. It is axiomatic that the specific agent selected and the dosing regimen must be individualized.

After an asymptomatic period, heart failure usually progresses to a symptomatic stage. Once symptoms ensue (Stage C), the goals of treatment include both relief of symptoms and prevention of disease progression. In addition to the relief of congestive symptoms with diuretics and load-reducing therapies, antagonism of the renin–angiotensin system and the sympathetic branch of the autonomic nervous system are indicated to prevent further myocardial injury. In the ambulatory patient in a compensated hemodynamic state, diuretics and organic nitrates are used to establish and maintain euvolemia; vasodilators are used to reduce the systemic vascular resistance and optimize forward cardiac output. While maintenance of forward cardiac output will help to attenuate neuro-humoral activation, agents that antagonize the effects of AngII and sympathetic stimulation are

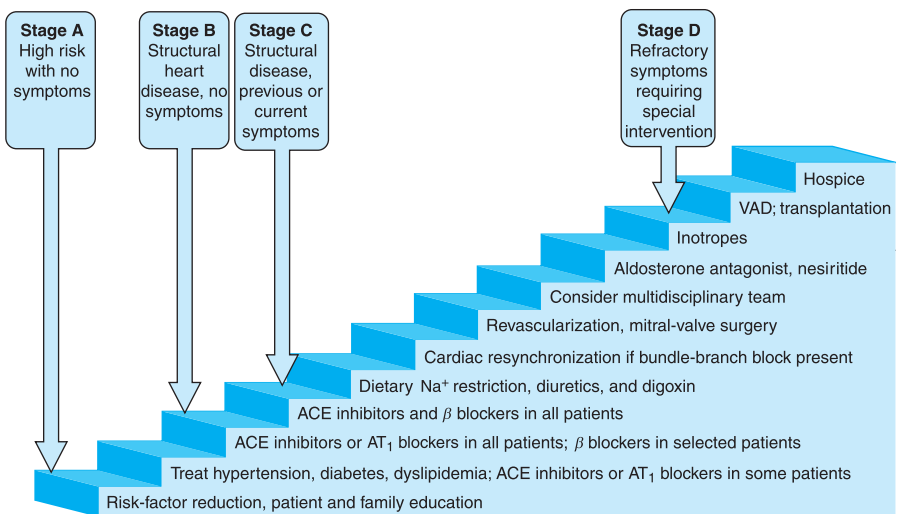

FIGURE 33–3 Stages of heart failure. ACE, Ang-converting enzyme; AT_1 , Type I Ang receptor; VAD, ventricular assist device.

indicated; ACE inhibitors and AT₁ receptor antagonists are preferred. If neither of these agents is tolerated, treatment with the hydralazine–isosorbide dinitrate combination should be initiated. Treatment with β blockers should be undertaken when hemodynamic stability is established and treatment with aldosterone antagonists considered in patients with preserved renal function. Digoxin is now primarily used for persistent symptoms in the ambulatory patient, and there are no data that cardiac glycosides decrease mortality.

In the symptomatic patient with hemodynamic decompensation, hospitalization may be required, since oral diuretic and vasodilator therapy alone may be inadequate to reestablish euvolemia and adequate peripheral perfusion. In such patients, parenteral vasodilators and inotropic agents may be required to restore forward cardiac output. In designing a treatment regimen, the clinician must consider the hemodynamic status of the individual patient. It is frequently possible to do so by qualitative assessment of the forward cardiac output (normal vs. low), systemic vascular resistance (normal vs. high), and intracardiac filling pressures (normal vs. high).

In patients with elevated systemic vascular resistance and normal-to-elevated systemic blood pressure, afterload reduction with nitroprusside is logical; it should be emphasized that nitroprusside also increases venous capacitance, thereby also decreasing preload. In the context of myocardial dysfunction, afterload reduction will typically lead to improved forward cardiac output. Nitroprusside may also be effective when the systemic vascular resistance is elevated and systemic blood pressure is reduced; the caveat in this more complex hemodynamic setting is that the load reduction produced by nitroprusside must be counterbalanced by an increase in stroke volume. This derivative increase in stroke volume may not occur in the patient with advanced heart failure; rather, the result will be a further reduction in mean arterial pressure and the potential risk of peripheral organ hypoperfusion. An alternative approach would be the use of an inotropic-dilator drug such as milrinone, which will provide both preload and afterload reduction; its concurrent positive inotropic effect may offset the reduction in mean arterial pressure that can occur from vasodilation alone.

In the decompensated patient who presents with heart failure and normal systemic vascular resistance, afterload reduction may be contraindicated, and treatment with a parenteral agent such as dobutamine may be preferable. The risk attendant to treatment with sympathomimetic drugs is related to the increase in myocardial O₂ consumption that may occur; this is of particular concern in patients with left heart failure that occurs as a direct consequence of myocardial ischemia. This clinical quandary has become less common in the era of aggressive myocardial revascularization; when it is encountered, coadministration of dobutamine with parenteral nitroglycerin should be considered.

Therapy in the patient with symptomatic pulmonary congestion generally should include diuresis to alleviate pulmonary and systemic vascular congestion. The administration of an oral or intravenous nitrate preparation may improve pulmonary congestion by increasing venous capacitance. This treatment goal is desirable to reduce patient discomfort; an important ancillary impact of such treatment is the attenuation of the neurohumoral activation that accompanies elevation of intracardiac filling pressures and the attendant dyspnea. Excessive preload reduction should be avoided given the dependence on preload that accompanies advanced myocardial dysfunction.

When advanced heart failure is unresponsive to these standard therapies, invasive hemodynamic monitoring may be required. Effective treatment of these patients is often complicated by concurrent renal insufficiency and hypotension, despite evidence of persistent elevation of intracardiac filling pressures. In patients who remain symptomatic and/or hemodynamically unstable (Stage D), referral to a specialized tertiary center with expertise in the evaluation and management of heart failure should be considered. At this advanced stage of disease, resource-intensive treatment (such as cardiac resynchronization therapy, mechanical assist devices, high-risk surgical interventions, or cardiac transplantation) or investigational therapies can be considered.

ANTIARRHYTHMIC DRUGS

Cardiac cells undergo depolarization and repolarization ~60 times/min. The shape and duration of each cardiac action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and each heartbeat results from the highly integrated electrophysiological behavior of multiple proteins on multiple cardiac cells. Ion channel function can be perturbed by acute ischemia, sympathetic stimulation, or myocardial scarring to create abnormalities of cardiac rhythm, or arrhythmias. Antiarrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function.

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. In some arrhythmias, precise mechanisms are known, and treatment can be targeted specifically against those mechanisms. In other cases, the choice of drugs is largely empirical. Antiarrhythmic drug therapy can prevent or terminate an arrhythmia. Unfortunately, antiarrhythmic drugs not only help to control arrhythmias but also can cause them (Table 34–1). Thus, prescribing antiarrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY

The normal cardiac cell at rest maintains a transmembrane potential ~80–90 mV negative to the exterior; this gradient is established by pumps, especially the Na^+ , K^+ -ATPase, and fixed anionic charges within cells. At rest, the normal cardiac cell is permeable to K^+ (because inward rectifier channels are open) and $[\text{K}]_o$ is the major determinant of resting potential.

If an atrial or ventricular cell at rest is depolarized above a threshold potential, Na^+ channels change conformation from the “closed” (resting) state to the “open” (conducting) state, allowing up to 10^7 Na^+ /second to enter each cell and moving the transmembrane potential toward the equilibrium potential for Na^+ , E_{Na} (+65 mV). This surge of Na^+ ions lasts only about a millisecond, after which the Na^+ channel protein rapidly changes conformation from the “open” state to an “inactivated,” nonconducting state. The changes in transmembrane potential generated by the inward Na^+ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 34–1). For example, when a cell from the epicardium or the His–Purkinje conducting system is depolarized, “transient outward” K^+ channels change conformation to enter an open, or conducting, state; since the transmembrane potential at the end of phase 0 is positive relative to E_{K} , the opening of transient outward channels results in an outward, or repolarizing, K^+ current (termed I_{TO}), which contributes to the phase 1 “notch” seen in action potentials from these tissues. Transient outward K^+ channels, like Na^+ channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through Ca^{2+} channels, are balanced by outward, repolarizing currents primarily through K^+ (“delayed rectifier”) channels. Delayed rectifier currents (collectively termed I_{K}) increase with time, whereas Ca^{2+} currents inactivate; as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na^+ channel opening.

A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is through inhibition of a specific delayed rectifier current, I_{Kr} , generated by expression of the human ether-a-go-go related gene (HERG). The ion channel protein generated by HERG expression differs from other ion channels in important structural features that make it much more susceptible to drug block. Avoiding I_{Kr} /HERG channel block has become a major issue in the development of new antiarrhythmic drugs.

Differing Action Potential Behaviors among Cardiac Cells

This general description must be modified for certain cell types (Figure 34–1) presumably because of variability in the ion channel proteins expressed in individual cells. Atrial cells have very short action potentials probably because I_{TO} is larger, and an additional repolarizing K^+ current, activated by acetylcholine, is present. As a result, vagal stimulation further shortens atrial action potentials. Cells of the sinus and atrioventricular (AV) nodes lack substantial Na^+ currents. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4, depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. Specialized K^+ channels underlie the pacemaker current in the heart.

Table 34-1

Drug-Induced Cardiac Arrhythmias

Arrhythmia	Drug	Likely Mechanism	Treatment*	Clinical Features
Digoxin	Sinus bradycardia	↑Vagal tone	Antidigoxin antibodies	Atrial tachycardia may also be present
Verapamil, Diltiazem, β-Blockers, Clonidine, Methyldopa β-Blocker withdrawal	AV block Sinus bradycardia, AV block Sinus bradycardia, AV block	Ca ²⁺ channel block Sympatholytic	Temporary pacing Ca ²⁺ Temporary pacing Isoproterenol Temporary pacing	
	Sinus tachycardia Any other tachycardia	Upregulation of β-receptors with chronic therapy; more receptors available for agonist after withdrawal of blocker	β-Blockade	Hypertension, angina also possible
Quinidine, Flecainide, Propafenone	↑ Ventricular rate in atrial flutter	Conduction slowing in atrium, with enhanced (quinidine) or unaltered AV conduction	AV nodal blockers	QRS complexes often widened at fast rates
Digoxin, Verapamil	↑ Ventricular rate in atrial fibrillation in patients with WPW syndrome	↓ Accessory pathway refractoriness	IV procainamide DC cardioversion	Ventricular rate can exceed 300/min
Theophylline	Multifocal atrial tachycardia	?↑ Intracellular Ca ²⁺ and DADs	Withdraw theophylline ?Verapamil	Often in advanced lung disease
Quinidine, Sotalol, Procainamide, Disopyramide, Dofetilide, Ibutilide, “Noncardioactive”, drugs (see text) Amiodarone (rare)	Polymorphic VT with ↑ QT interval (<i>torsades de pointes</i>)	EAD-related triggered activity	Cardiac pacing Isoproterenol Magnesium	Hypokalemia, bradycardia frequent Related to ↑ plasma concentrations, except for quinidine

(Continued)

Table 34-1

Drug-Induced Cardiac Arrhythmias (Continued)

Arrhythmia	Drug	Likely Mechanism	Treatment*	Clinical Features
Flecainide, Propafenone, Quinidine (rarer)	Frequent or difficult to terminate VT ("incessant" VT)	Conduction slowing in reentrant circuits	Na ⁺ bolus reportedly effective in some cases	Most often in patients with advanced myocardial scarring
Digoxin	Atrial tachycardia with AV block; ventricular bigeminy and others	DAD-related triggered activity (±↑ vagal tone)	Antidigoxin antibodies	Coexistence of abnormal impulses with abnormal sinus or AV nodal function
Inappropriate use of IV verapamil	Ventricular fibrillation	Severe hypotension and/or myocardial ischemia	Cardiac resuscitation (DC cardioversion)	Misdiagnosis of VT as PSVT → inappropriate use of verapamil

*In each of these cases, recognition and withdrawal of the offending drug(s) are mandatory.

ABBREVIATIONS: AV, atrioventricular; DAD, delayed afterdepolarization; DC, direct current; EAD, early afterdepolarization; WPW, Wolff–Parkinson–White supraventricular tachycardia; IV, intravenous; ↑, increase; ↓, decrease; ?, unclear.

FIGURE 34-1 Action potentials that occur during normal impulse propagation and the time course of the currents that generate them. Hypothetical action potentials from different regions of the heart are shown. The current magnitudes are not to scale. In atrial myocytes, Purkinje fibers, and ventricular myocytes the Na^+ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca^{2+} current, transient outward current (I_{TO}), and delayed rectifier (I_{K}) have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP (4-aminopyridine) is a widely used *in vitro* blocker of K^+ channels. I_{TO2} may be a Cl^- current in some species. Components of I_{K} have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultrarapidly (I_{Kur}). For all currents shown here (with the possible exception of I_{TO2}), the genes encoding the major pore-forming proteins have been cloned.

Maintenance of Intracellular Homeostasis

With each action potential, the cell interior gains Na^+ ions and loses K^+ ions. The Na^+, K^+ -ATPase is activated in most cells to maintain intracellular homeostasis, extruding 3 Na^+ ions for every 2 K^+ ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself generates a net outward (repolarizing) current.

Normally, intracellular Ca^{2+} is maintained at very low levels ($<100 \text{ nM}$). In cardiac myocytes, the entry of Ca^{2+} during each action potential is a signal to the sarcoplasmic reticulum to release its Ca^{2+} stores. The resulting increase in intracellular Ca^{2+} then triggers Ca^{2+} -dependent contraction. Removal of intracellular Ca^{2+} occurs by both an ATP-dependent Ca^{2+} pump (which moves Ca^{2+} ions back to storage sites in the sarcoplasmic reticulum) and an electrogenic $\text{Na}^+-\text{Ca}^{2+}$ exchange mechanism in the cell membrane, which usually exchanges 3 Na^+ ions from the exterior for each Ca^{2+} ion extruded. Abnormal regulation of intracellular Ca^{2+} , characterized by contractile dysfunction, may contribute to arrhythmias in the setting of heart failure. The initial rise in Ca^{2+} , which serves as the trigger for Ca^{2+} release from intracellular stores, results from the opening of Ca^{2+} channels in the cell membrane or from Ca^{2+} entry through $\text{Na}^+-\text{Ca}^{2+}$ exchange; i.e., in response to phase 0 entry of Na^+ , the $\text{Na}^+-\text{Ca}^{2+}$ exchange protein may transiently extrude Na^+ ions in exchange for Ca^{2+} ions (Figure 34–1).

Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the electrocardiogram (ECG; Figure 34–1). Propagation slows markedly through the AV node, where the inward current (through Ca^{2+} channels) is much smaller than the Na^+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output. Once impulses exit the AV node, they enter the conducting system, where Na^+ currents are larger than in any other tissue. Hence propagation is correspondingly faster, up to 0.75 m/s longitudinally, and manifests as the QRS complex on the ECG as impulses spread from the endocardium to the epicardium, stimulating coordinated ventricular contraction. Ventricular repolarization results in the T wave of the ECG.

The ECG can be used as a rough guide to some cellular properties of cardiac tissue: (1) Heart rate reflects sinus node automaticity, (2) PR-interval duration reflects AV nodal conduction time, (3) QRS duration reflects conduction time in the ventricle, and (4) the QT interval is a measure of ventricular action potential duration.

Refractoriness: Fast-Response versus Slow-Response Tissue

If a single action potential, such as that shown in Figure 34–1, is restimulated very early during the plateau, no Na^+ channels are available to open, no inward current results, and no action potential is generated: The cell is refractory. On the other hand, if a stimulus occurs after the cell has repolarized completely, Na^+ channels have recovered, and a normal Na^+ channel-dependent upstroke results. When a stimulus occurs during phase 3 of the action potential, the magnitude of the resultant Na^+ current depends on the number of Na^+ channels that have recovered, which depends on the voltage at which the extra stimulus was applied. Thus, in atrial, ventricular, and His–Purkinje cells (“fast-response” cells), refractoriness is determined by the voltage-dependent recovery of Na^+ channels from inactivation. The effective refractory period is the shortest interval at which a premature stimulus results in a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in Ca^{2+} channel-dependent (“slow-response”) tissue such as the AV node. The major factor controlling recovery from inactivation of Ca^{2+} channels is time. Thus, even after a Ca^{2+} channel-dependent action potential has repolarized to its initial resting potential, not all Ca^{2+} channels are available for reexcitation. Therefore, an extra stimulus applied shortly after repolarization is complete generates a reduced Ca^{2+} current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca^{2+} current and faster propagation. Thus, in Ca^{2+} channel-dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is time-dependent, and propagation occurs slowly. Slow conduction in the heart, a critical factor in the genesis of reentrant arrhythmias (see below), also can occur when Na^+ currents are depressed by disease or membrane depolarization (e.g., elevated $[\text{K}]_o$), resulting in decreased steady-state Na^+ channel availability.

MECHANISMS OF CARDIAC ARRHYTHMIAS

When the normal sequence of impulse initiation and propagation is perturbed, an arrhythmia occurs. Failure of impulse initiation may result in slow heart rates (bradyarrhythmias), whereas

failure of impulses to propagate normally from atrium to ventricle results in dropped beats (heart block) that usually reflect an abnormality in either the AV node or the His–Purkinje system. These abnormalities may be caused by drugs or by structural heart disease. Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with antiarrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and reentry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His–Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas acetylcholine reduces pacemaker rate both by decreasing phase 4 slope and by hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; e.g., depolarization of ventricular cells by ischemia) may produce such “abnormal” automaticity.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiological conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization. If this abnormal depolarization reaches threshold, it may give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and so are termed triggered rhythms.

Under conditions of intracellular Ca^{2+} overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, or heart failure), a normal action potential may be followed by a delayed afterdepolarization (DAD). If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. In a second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an early afterdepolarization (EAD). EAD-mediated triggering clinical arrhythmias are most common when the underlying heart rate is slow, extracellular K^+ is low, and certain drugs that prolong action potential duration are present. EAD-related triggered upstrokes probably reflect inward current through Na^+ or Ca^{2+} channels or Na^+ – Ca^{2+} exchange. When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, known as torsades de pointes, may occur. This arrhythmia is thought to be caused by EADs, which trigger “functionally defined” reentry owing to heterogeneity of action potential durations across the ventricular wall. Congenital long QT syndrome, a disease in which torsades de pointes is common, can be caused by mutations in the genes encoding the Na^+ or Ca^{2+} channels or, more commonly, the channels underlying the repolarizing currents I_{Kr} and I_{Ks} .

Reentry

ANATOMICALLY DEFINED REENTRY

Reentry can occur when impulses propagate by more than one pathway between two points in the heart, and those pathways have heterogeneous electrophysiological properties. Patients with Wolff–Parkinson–White (WPW) syndrome have accessory connections between the atrium and ventricle. With each sinus node depolarization, impulses can excite the ventricle via the normal structures (AV node) or the accessory pathway. However, the electrophysiological properties of the AV node and accessory pathways are different: Accessory pathways usually consist of fast-response tissue, whereas the AV node is composed of slow-response tissue. Thus, with a premature atrial beat, conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His–Purkinje system; there the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood that the accessory pathway is no longer refractory increases as AV nodal conduction slows. When the impulse reenters the atrium, it then can reenter the ventricle via the AV node, reenter the atrium via the accessory pathway, and so on. Reentry of this type, referred to as AV reentrant tachycardia, is determined by (1) the presence of an anatomically defined circuit, (2) heterogeneity in refractoriness among regions in the circuit, and (3) slow conduction in one part of the circuit. Similar “anatomically defined” reentry commonly occurs in the region of the AV node (AV nodal reentrant tachycardia) and in the atrium (atrial flutter). The term paroxysmal supraventricular tachycardia (PSVT) includes both AV reentry and AV nodal reentry, which share many clinical features. It now sometimes is possible to identify and ablate critical portions of reentrant pathways (or automatic foci), thus curing the patient and obviating the need for long-term drug therapy.

FUNCTIONALLY DEFINED REENTRY

Reentry also may occur in the absence of a distinct, anatomically defined pathway. If ischemia or other electrophysiological perturbations result in an area of sufficiently slow conduction in the ventricle, impulses exiting from that area may find the rest of the myocardium reexcitable, in which case fibrillation may ensue. Atrial or ventricular fibrillation is an extreme example of “functionally defined” (or “leading circle”) reentry: Cells are reexcited as soon as they are repolarized sufficiently to allow enough Na^+ channels to recover. In this setting, neither organized activation patterns nor coordinated contractile activity is present.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG. Table 34–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Some arrhythmias, notably ventricular fibrillation (VF), are best treated not with drugs but with direct current (dc) cardioversion—the application of a large electric current across the chest. Implantable cardioverter–defibrillators (ICDs), devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF.

MECHANISMS OF ANTIARRHYTHMIC DRUG ACTION

A single arrhythmia may result from multiple mechanisms. Drugs may be antiarrhythmic by suppressing the initiating mechanism or by altering a reentrant circuit. In some cases, drugs may suppress the initiator but nonetheless promote reentry (see below).

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge: increase maximum diastolic potential, decrease phase 4 slope, increase threshold potential, or prolong action potential duration. Adenosine and acetylcholine may increase maximum diastolic potential, and β adrenergic receptor antagonists (β blockers) may decrease phase 4 slope. Block of Na^+ or Ca^{2+} channels usually results in altered threshold, and block of cardiac K^+ channels prolongs the action potential.

Antiarrhythmic drugs may block arrhythmias owing to DADs or EADs by two major mechanisms: (1) inhibition of the development of afterdepolarizations and (2) interference with the inward current (usually through Na^+ or Ca^{2+} channels), which is responsible for the upstroke. Thus, arrhythmias owing to digitalis-induced DADs may be inhibited by verapamil (which blocks the development of DAD) or by quinidine (which blocks Na^+ channels, thereby elevating the threshold required to produce the abnormal upstroke). Similarly, two approaches are used in arrhythmias related to EAD-induced triggered beats (Tables 34–2 and 34–3). EADs can be inhibited by shortening action potential duration; in practice, heart rate is accelerated by isoproterenol infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg^{2+} without normalizing repolarization *in vitro* or QT interval. In patients with congenitally long QT syndrome, torsades de pointes often occurs with adrenergic stress; therapies include β adrenergic blockade (which does not shorten the QT interval) and pacing.

In anatomically determined reentry, drugs may terminate the arrhythmia by blocking propagation of the action potential. In the example of the WPW-related arrhythmia described above, drugs that prolong AV nodal refractoriness and slow AV nodal conduction (e.g., Ca^{2+} channel blockers, β adrenergic receptor antagonists, or digoxin) are likely to be effective but should be used with caution. On the other hand, slowing conduction in functionally determined reentrant circuits may change the pathway without extinguishing the circuit. Slow conduction generally promotes the development of reentrant arrhythmias, whereas the most likely approach for terminating functionally determined reentry is prolongation of refractoriness. In fast-response tissues, refractoriness is prolonged by delaying the recovery of Na^+ channels from inactivation. Drugs that block Na^+ channels generally shift the voltage dependence of recovery and so prolong refractoriness. Drugs that increase action potential duration without direct action on Na^+ channels (e.g., by blocking delayed rectifier currents) also will prolong refractoriness. In slow-response tissues, Ca^{2+} channel block prolongs refractoriness.

State-Dependent Ion Channel Block

A key concept is that ion channel–blocking drugs bind to specific sites on ion channel proteins to modify function (e.g., decrease current) and that the affinity of the ion channel protein for the drug on its target site varies as the ion channel protein shuttles among functional conformations (or ion

Table 34–2

A Mechanistic Approach to Antiarrhythmic Therapy

Arrhythmia	Common Mechanism	Acute Therapy ^a	Chronic Therapy ^a
Premature atrial, nodal, or ventricular depolarizations	Unknown	None indicated	None indicated
Atrial fibrillation	Disorganized “functional” reentry	1. Control ventricular response: AV nodal block ^b	1. Control ventricular response: AV nodal block ^b
Atrial flutter	Continual AV node stimulation → irregular, often rapid, ventricular rate Stable reentrant circuit in the right atrium Ventricular rate often rapid and irregular	2. Restore sinus rhythm: DC cardioversion Same as atrial fibrillation	2. Maintain normal rhythm: K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second Same as atrial fibrillation AV nodal blocking drugs especially desirable to avoid ↑ ventricular rate Ablation in selected cases ^c
Atrial tachycardia	Enhanced automaticity, DAD-related automaticity, or reentry within the atrium	Same as atrial fibrillation	Same as atrial fibrillation Ablation of tachycardia “focus” ^c
AV nodal reentrant tachycardia (PSVT)	Reentrant circuit within or near AV node	*Adenosine AV nodal block Less commonly: ↑ vagal tone (digitalis, edrophonium, phenylephrine)	*AV nodal block Flecainide Propafenone *Ablation ^c
Arrhythmias associated with WPW syndrome:			
1. AV reentry (PSVT)	Reentry	Same as AV nodal reentry	K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second Ablation ^c
2. Atrial fibrillation with atrioventricular conduction via accessory pathway	Very rapid rate due to nondecremental properties of accessory pathway	*DC cardioversion *Procainamide	Ablation ^c K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second (AV nodal blockers can be harmful)
VT in patients with remote myocardial infarction	Reentry near the rim of the healed myocardial infarction	Lidocaine Amiodarone Procainamide DC cardioversion	*ICD ^d *Amiodarone K ⁺ channel block Na ⁺ channel block

Table 34-2

A Mechanistic Approach to Antiarrhythmic Therapy (Continued)

Arrhythmia	Common Mechanism	Acute Therapy ^a	Chronic Therapy ^a
VT in patients without structural heart disease	DADs triggered by ↑ sympathetic tone	Adenosine ^e Verapamil ^e β-Blockers ^e	Verapamil ^e β-Blockers ^e
VF	Disorganized reentry	DC cardioversion *DC cardioversion Lidocaine Amiodarone Procainamide	*ICD ^d *Amiodarone K ⁺ channel block Na ⁺ channel block
<i>Torsades de pointes</i> , congenital or acquired; (often drug-related)	EAD-related triggered activity	Pacing Magnesium Isoproterenol	β-Blockade Pacing

*Indicates treatment of choice.

^aAcute drug therapy is administered intravenously; chronic therapy implies long-term oral use.

^bAV nodal block can be achieved clinically by adenosine, Ca²⁺ channel block, β adrenergic receptor blockade, or increased vagal tone (a major antiarrhythmic effect of digitalis glycosides).

^cAblation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart.

^dICD, implanted cardioverter/defibrillator. A device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm.

^eThese may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure.

ABBREVIATIONS: DAD, delayed afterdepolarization; EAD, early afterdepolarization; WPW, Wolff–Parkinson–White; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.

Table 34-3

Major Electrophysiological Actions of Antiarrhythmic Drugs

Drug	Na ⁺ Channel Block		↑APD	Ca ²⁺ Channel Block	Autonomic Effects	Other Effects
	τ_{RECOVERY} ¹ , Seconds	State Dependence ¹				
Lidocaine	0.1	I > O				
Phenytoin	0.2	I				
Mexiletine*	0.3					
Tocainide*	0.4	O > I				
Procainamide	1.8	O	✓		Ganglionic blockade (especially intravenous)	✓: Metabolite prolongs APD
Quinidine	3	O	✓	(x)	α-Blockade, vagolytic	
Disopyramide [†]	9	O	✓		Anticholinergic	
Moricizine	~10	O ≈ I				
Propafenone [†]	11	O ≈ I	✓		β-Blockade (variable clinical effect)	
Flecainide*	11	O	(x)	(x)		
β-Blockers: Propranolol [†]					β-Blockade	Na ⁺ channel block <i>in vitro</i>
Sotalol [†]			✓		β-Blockade	
Amiodarone	1.6	I	✓	(x)	Noncompetitive β-Blockade	Antithyroid action
Dofetilide			✓			
Ibutilide			✓			
Verapamil*				✓		
Diltiazem*				✓		
Digoxin					✓: Vagal stimulation	✓: Inhibition of Na ⁺ , K ⁺ -ATPase
Adenosine				✓	✓: Adenosine receptor activation	✓: Activation of outward K ⁺ current
Magnesium				?✓		Mechanism not well understood

¹indicates an effect that is important in mediating the clinical action of a drug.

(x)indicates a demonstrable effect whose relationship to drug action in patients is less well established.

*indicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiological effects.

[†]indicates racemates for which clinically relevant differences in the electrophysiological properties of individual enantiomers have been reported (*see text*).

One approach to classifying drugs is:

Class	Major action
I	Na ⁺ channel block
II	β-Blockade
III	action potential prolongation (usually by K ⁺ channel block)
IV	Ca ²⁺ channel block

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na⁺ channel blockers by their rates of recovery from drug-induced block (τ_{recovery}) under physiological conditions. Since this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, $\tau_{\text{recovery}} < 1$ s; class Ia, $\tau_{\text{recovery}} 1-10$ s; class Ic, $\tau_{\text{recovery}} > 10$ s. These class and subclass effects are associated with distinctive ECG changes, characteristic "class" toxicities, and efficacy in specific arrhythmia syndromes (*see text*).

[†]These data are dependent on experimental conditions, including species and temperature.

ABBREVIATIONS: O, Open state blocker; I, inactivated state blocker; APD, action potential duration.

channel “states”). Most useful antiarrhythmic agents that target Na^+ channels block the open and/or inactivated states and have very little affinity for channels in the resting state. Thus, with each action potential, drugs bind to Na^+ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. When heart rate increases, the time available for dissociation decreases, and steady-state Na^+ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na^+ channel blockers depress Na^+ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open versus inactivated-state block also may be important in determining the effects of some drugs. Increased action potential duration, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant (τ_{recovery} , the time required to complete ~63% of an exponentially determined process to be complete). In the case of drugs such as lidocaine, τ_{recovery} is so short ($\ll 1$ s) that recovery from block is very rapid, and substantial Na^+ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as *flecainide* have such long τ_{recovery} values (>10 s) that roughly the same number of Na^+ channels is blocked during systole and diastole. As a result, marked slowing of conduction occurs even in normal tissues at normal rates.

Classifying Antiarrhythmic Drugs

To the extent that the clinical actions of drugs can be predicted, classifying drugs by common electrophysiological properties is useful. However, differences in pharmacological effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 34–3). Another way of approaching therapy is to attempt to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiological mechanism most likely to terminate or prevent the arrhythmia (Table 34–2).

Na^+ CHANNEL BLOCK The extent of Na^+ channel block depends critically on heart rate, membrane potential, and on drug-specific physicochemical characteristics that determine τ_{recovery} . When Na^+ channels are blocked, threshold for excitability is decreased; *i.e.*, greater membrane depolarization is required to bring Na^+ channels from the rest to open states. This change in threshold probably contributes to the clinical finding that Na^+ channel blockers tend to increase both pacing threshold and the energy required for defibrillation. These deleterious effects may be important if antiarrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na^+ channel block decreases conduction velocity in fast-response tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with τ_{recovery} values greater than 10 s (*e.g.*, flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca^{2+} channel block (*see below*) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval, largely as a result of its vagolytic properties. Action potential duration is either unaffected or shortened by Na^+ channel block; some Na^+ channel-blocking drugs do prolong cardiac action potentials, but usually by K^+ channel block (Table 34–3).

Na^+ channel block decreases automaticity and can inhibit triggered activity arising from DADs or EADs. Many Na^+ channel blockers also decrease phase 4 slope. In anatomically defined reentry, Na^+ channel blockers may decrease conduction sufficiently to extinguish the propagating reentrant wavefront. However, as described earlier, conduction slowing owing to Na^+ channel block may exacerbate reentry. Thus, whether a given drug exacerbates or suppresses reentrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular reentrant circuit. Lidocaine and *mexiletine* have short τ_{recovery} values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, *propafenone*, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K^+ channels.

Na^+ Channel–Blocker Toxicity Conduction slowing in potential reentrant circuits can account for toxicity of drugs that block the Na^+ channel (Table 34–1). For example, Na^+ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV nodal function permits

a greater number of impulses to penetrate the ventricle, and heart rate actually may increase. Thus, atrial flutter rate may drop from 300/min, with 2:1 or 4:1 AV conduction (*i.e.*, a heart rate of 150 or 75 beats/min), to 220/min, with 1:1 transmission to the ventricle (*i.e.*, a heart rate of 220 beats/min), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common with quinidine because it also increases AV nodal conduction through its vagolytic properties; flecainide and propafenone also have been implicated. Therapy with Na⁺ channel blockers in patients with reentrant ventricular tachycardia after myocardial infarction can increase the frequency and severity of arrhythmic episodes. Slowed conduction allows the reentrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced ventricular tachycardia have been reported. In this setting, Na⁺ infusion may be beneficial.

ACTION POTENTIAL PROLONGATION Most drugs that prolong the action potential do so by blocking K⁺ currents, usually I_{Kr} , although enhanced inward Na⁺ current also can cause prolongation. Enhanced inward current may underlie QT prolongation (and arrhythmia suppression) by *ibutilide*. Block of cardiac K⁺ channels increases action potential duration and reduces normal automaticity. Increased action potential duration, seen as an increase in QT interval, increases refractoriness and therefore should be an effective way of treating reentry. Experimentally, K⁺ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of ventricular fibrillation owing to acute ischemia, and increased contractility. Most K⁺ channel blocking drugs also interact with β adrenergic receptors (*sotalol*) or other channels (*e.g.*, amiodarone and quinidine) (*see* Table 34–3). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na⁺ channel-blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential-prolonging drugs (*e.g.*, *dofetilide* and *ibutilide*) also are available.

Toxicity of Drugs That Prolong QT Interval Most of these agents disproportionately prolong cardiac action potentials when underlying heart rate is slow and can cause *torsades de pointes* (Table 34–1). While this effect usually is seen with QT-prolonging antiarrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the risk of *torsades de pointes* may become apparent only after widespread use postmarketing. For unknown reasons, drug-induced *torsades de pointes* associated with antiarrhythmic drugs is significantly more common in women.

Ca²⁺ CHANNEL BLOCK The major electrophysiological effects resulting from block of cardiac Ca²⁺ channels are in slow-response tissues, the sinus and AV nodes. Dihydropyridines such as *nifedipine*, which are used commonly in angina and hypertension, preferentially block Ca²⁺ channels in vascular smooth muscle; their cardiac effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, *diltiazem*, and *bepidil* block Ca²⁺ channels in cardiac cells at clinically used doses. These drugs generally slow heart rate, although hypotension can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction and increased AV nodal refractoriness, which form the basis for the use of Ca²⁺ channel blockers in reentrant arrhythmias whose circuit involves the AV node, such as AV reentrant tachycardia.

Another important indication for antiarrhythmic therapy is to reduce ventricular rate in atrial flutter or fibrillation. Rare forms of ventricular tachycardia appear to be DAD-mediated and respond to verapamil. Parenteral verapamil and diltiazem are approved for rapid conversion of PSVTs to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. Oral verapamil may be used in conjunction with digoxin to control ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β adrenergic receptor antagonists, Ca²⁺ channel blockers have not been shown to reduce mortality after myocardial infarction.

Toxicity of Ca²⁺ Channel Blockers The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This is a particular problem if the drugs are used mistakenly in patients with ventricular tachycardia misdiagnosed as AV nodal reentrant tachycardia. Hypotension also is frequent in patients receiving other vasodilators, including quinidine, and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in patients also receiving β blockers. With oral therapy, these adverse effects tend to be less severe.

Verapamil (CALAN, ISOPTIN, VERELAN, COVERA-HS) is prescribed as a racemate. L-Verapamil is a more potent calcium channel blocker than is D-verapamil. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally. *Diltiazem* (CARDIZEM, TIAZAC, DILACOR XR, and others) also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca²⁺ channel-blocking actions. Adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation. Constipation can occur with oral verapamil.

BLOCK OF β ADRENERGIC RECEPTORS β Adrenergic stimulation increases the magnitude of the Ca²⁺ current and slows its inactivation, increases the magnitude of repolarizing K⁺ and Cl⁻ currents, increases pacemaker current (thereby increasing sinus rate), and under pathophysiological conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma Epi associated with severe stress (e.g., acute myocardial infarction or resuscitation from cardiac arrest) lower serum K⁺, especially in patients receiving chronic diuretic therapy. β Adrenergic receptor antagonists inhibit these effects and can be antiarrhythmic by reducing heart rate, decreasing intracellular Ca²⁺ overload, and inhibiting afterdepolarization-mediated automaticity. Epi-induced hypokalemia appears to be mediated by β_2 adrenergic receptors and is blocked by “noncardioselective” antagonists such as *propranolol* (see Chapter 10). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an antiarrhythmic action. These effects may contribute to the reduced mortality observed in trials of acute and chronic therapy with β blockers after myocardial infarction.

As with Ca²⁺ channel blockers and digitalis, β blockers slow AV nodal conduction and prolong AV nodal refractoriness; hence, they are useful in terminating reentrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In some patients, including many with the congenital long QT syndrome, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases. β adrenergic receptor antagonists also reportedly are effective in controlling arrhythmias owing to Na⁺ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na⁺ channel block.

Selected β Adrenergic Receptor Blockers The β antagonists likely share antiarrhythmic properties. Some, such as propranolol, also exert Na⁺ channel-blocking (“membrane stabilizing”) effects at high concentrations, but the clinical significance of this effect is uncertain. Drugs with intrinsic sympathomimetic activity may be less useful as antiarrhythmics. Sotalol (see below) is more effective for many arrhythmias than are other β blockers probably because of its K⁺ channel-blocking actions. *Esmolol* is a β_1 selective agent that is metabolized by erythrocyte esterases and so has a very short elimination $t_{1/2}$ (9 minutes). Intravenous esmolol is useful when immediate β adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation). Because of esmolol’s very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly.

Toxicity of β Adrenergic Blockers Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients. In patients with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma or *clonidine* withdrawal), β blockers can cause unopposed α adrenergic stimulation, resulting in severe hypertension and/or α adrenergic-mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β adrenergic antagonists or with a drug such as *labetalol* that combines α and β blocking properties. Abrupt discontinuation of chronic β blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus, β receptor antagonist therapy is tapered over 2 weeks.

PRINCIPLES IN THE CLINICAL USE OF ANTIARRHYTHMIC DRUGS

Drugs that modify cardiac electrophysiology often have a narrow therapeutic index. Moreover, antiarrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacological

treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize antiarrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs (Table 34–1). For example, theophylline can cause multifocal atrial tachycardia, while torsades de pointes can arise not only during therapy with action potential–prolonging antiarrhythmics but also with other drugs, including erythromycin (see Chapter 46); pentamidine (see Chapter 40); and some antipsychotics, notably thioridazine (see Chapter 18).

2. Establish the Goals of Treatment

SOME ARRHYTHMIAS SHOULD NOT BE TREATED: THE CAST EXAMPLE

The mere detection of an abnormal cardiac rhythm does not equate with the need for therapy. In the CAST trial, patients convalescing from myocardial infarction whose ventricular ectopic beats were suppressed by the Na⁺ channel blockers encainide (no longer marketed) or flecainide were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was two- to threefold higher among patients treated with drugs than those treated with placebo. This pivotal trial reemphasized the concept that therapy should be initiated only when a clear benefit can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater. Among the antiarrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone have been shown to reduce mortality during long-term therapy.

SYMPTOMS DUE TO ARRHYTHMIAS

If patients with an arrhythmia are asymptomatic, establishing any benefit for treatment will be very difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. The sensation of irregular heartbeats (i.e., palpitations) can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate). Finally, arrhythmias in some patients may present with symptoms owing to decreased cardiac output. The most common symptom is breathlessness either at rest or on exertion. Rarely, sustained tachycardias may produce no “arrhythmia” symptoms (such as palpitations) but will depress contractile function; these patients may present with congestive heart failure that can be controlled by treating the arrhythmia.

CHOOSING AMONGST THERAPEUTIC APPROACHES

In choosing among therapeutic options, it is important to establish clear goals. For example, three options are available in patients with atrial fibrillation: (1) Reduce the ventricular response using AV nodal blocking agents such as digitalis, verapamil, diltiazem, or β adrenergic antagonists (Table 34–2); (2) restore and maintain normal rhythm using drugs such as quinidine, flecainide, or amiodarone; or (3) decide not to implement antiarrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms.

Factors contributing to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases. In the rare patient with the WPW syndrome and atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically by AV nodal blocking drugs such as digitalis or Ca²⁺ channel blockers; deaths owing to drug therapy have been reported.

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective: A marked decrease in the duration of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic even if an occasional episode still can be detected.

3. Minimize Risks

ANTIARRHYTHMIC DRUGS CAN CAUSE ARRHYTHMIAS

One well-recognized risk of antiarrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Antiarrhythmic drugs can provoke arrhythmias by different mechanisms (Table 34–1). These drug-provoked arrhythmias must be recognized because further treatment with antiarrhythmic drugs often exacerbates the problem. Targeting therapies at underlying mechanisms of the arrhythmias may be required.

MONITORING OF PLASMA CONCENTRATION

Some adverse effects of antiarrhythmic drugs result from excessive drug levels. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving antiarrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease.

PATIENT-SPECIFIC CONTRAINDICATIONS

Another way to minimize the adverse effects of antiarrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect.

ANTIARRHYTHMIC DRUGS

Ca²⁺ channel blockers and β adrenergic antagonists were considered above. The other antiarrhythmic drugs are presented below in alphabetical order, and some pharmacologic properties are summarized in Table 34–4.

ADENOSINE Adenosine (ADENOCARD) is a nucleoside that is administered as a rapid intravenous bolus for the acute termination of reentrant supraventricular arrhythmias. Rare cases of ventricular tachycardia in patients with otherwise normal hearts are thought to be DAD-mediated and can be terminated by adenosine. Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease.

Pharmacological Effects The effects of adenosine are mediated *via* specific GPCRs (*see* Chapter 11). Adenosine activates acetylcholine-sensitive K⁺ current in the atrium and sinus and AV nodes, resulting in shortening of action potential duration, hyperpolarization, and slowing of normal automaticity. Adenosine also inhibits the electrophysiological effects of increased cellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca²⁺ currents, it can be antiarrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation. Administration of an intravenous bolus of adenosine transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors; a continuous infusion can cause hypotension.

Adverse Effects A major advantage of adenosine therapy is that adverse effects are short-lived because the drug is transported into cells and deaminated so rapidly. Transient asystole is common but usually lasts less than 5 seconds and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6–12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate bronchospasm or atrial fibrillation.

Clinical Pharmacokinetics Adenosine is eliminated with a $t_{1/2}$ of seconds by carrier-mediated uptake in most cell types and subsequent metabolism by adenosine deaminase. Adenosine probably is the only antiarrhythmic drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration permits elimination of the drug prior to its arrival at the heart. The effects of adenosine are potentiated in patients receiving *dipyridamole*, an adenosine-uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (*e.g.*, theophylline and caffeine) block adenosine receptors; therefore, larger than usual doses are required to produce an antiarrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Table 34-4

Pharmacokinetic Characteristics and Doses of Antiarrhythmic Drugs

Drug	Bioavailability		Elimination			Elimination $t_{1/2}$ ^a	Active Metabolite(s)	Therapeutic [†] Plasma Concentration	Usual Doses [‡]	
	Reduced: 1st Pass Metabolism	Protein Binding >80%	Renal	Hepatic	Other				Loading Doses	Maintenance Doses
Adenosine [§]					✓	<10 s			6–12 mg (IV only)	
Amiodarone		✓		✓		Weeks	✓	0.5–2 µg/mL	800–1600 mg/day × 2–4 weeks (IV: 100–300 mg)	100–400 mg/day
Digoxin	~80%		✓			36 h		0.5–2.0 ng/mL	1 mg over 12–24 h	0.125–0.375 mg q24h
Digitoxin	>80%	✓		✓		7–9 days	(Digoxin)	10–30 ng/mL		0.05–0.3 mg q24h
Diltiazem	✓			✓		4 h	(x)		0.25–0.35 mg/kg over 10 min (IV)	5–15 mg/h (IV) 30–90 mg q6h 120–300 mg q24h [¶]
Disopyramide	>80%		✓	✓		4–10 h	(x)	2–5 µg/mL		100–200 mg q6h 200–400 mg q12h [¶]

(x): metabolite or route of elimination probably of minor clinical importance.

*The elimination half-life is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (Chapter 5: Principles of Therapeutics). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, *e.g.*, propranolol or verapamil. Formulations that allow slow release into the gastrointestinal tract of a rapidly eliminated compound (available for many drugs including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing.

[†]The therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely, and an upper concentration above which the risk of adverse effects increases. As discussed in the text, many serious adverse reactions to antiarrhythmic drugs can occur at “therapeutic” concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (Chapters 1: Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, and Elimination and 5: Principles of Therapeutics).

[‡]Oral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range, *i.e.*, for acute therapy (*e.g.*, lidocaine, verapamil, adenosine) or when the elimination half-life is extremely long (amiodarone).

[§]Bioavailability reduced by incomplete absorption.

[¶]Indicates suggested dosage using slow-release formulation.

^{¶¶}This drug is available only in a restricted distribution system (*see* text).

ABBREVIATIONS: IV, intravenous; q, every.

AMIODARONE *Amiodarone* (CORDARONE, PACERONE) exerts multiple pharmacological effects, none of which is clearly linked to its arrhythmia-suppressing properties. Amiodarone is a structural analog of thyroid hormone, and some of its antiarrhythmic actions and its toxicity may be attributable to interaction with thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or fibrillation resistant to other drugs. Oral amiodarone also is effective in maintaining sinus rhythm in patients with atrial fibrillation. An intravenous form is indicated for acute termination of ventricular tachycardia or fibrillation and is supplanting lidocaine as first-line therapy for out-of-hospital cardiac arrest. Oral amiodarone has a modest beneficial effect on mortality after acute myocardial infarction. Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone now is used very widely in the treatment of common arrhythmias such as atrial fibrillation.

Pharmacological Effects Amiodarone blocks inactivated Na^+ channels and has a relatively rapid rate of recovery ($\tau_{\text{recovery}} \sim 1.6$ s) from block. It also decreases Ca^{2+} current and transient outward delayed rectifier and inward rectifier K^+ currents and exerts a noncompetitive adrenergic blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs action potential duration. Amiodarone decreases conduction velocity by Na^+ channel block and by a poorly understood effect on cell–cell coupling that may be especially important in diseased tissue. Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na^+ channel block, delayed repolarization owing to K^+ channel block, and inhibition of cell–cell coupling all may contribute to this effect.

Adverse Effects Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone. While depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long-term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasional patients develop nausea during the loading phase, which responds to a decrease in daily dose. Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose (*i.e.*, duration of therapy), suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/day or more, and recent pulmonary insults such as pneumonia appear to be risk factors. Monitoring plasma concentrations has not been useful; serial chest x-rays or pulmonary function studies may detect early amiodarone toxicity. With low doses, such as 200 mg/day or less used in atrial fibrillation, pulmonary toxicity is unusual. Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (*e.g.*, peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. Treatment for life-threatening pulmonary toxicity consists of drug withdrawal and supportive measures, including glucocorticoids. Dose reduction may be sufficient if the drug is deemed necessary and the adverse effect is not life-threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, *torsades de pointes* and other drug-induced tachyarrhythmias are unusual.

Clinical Pharmacokinetics Amiodarone's oral bioavailability, $\sim 30\%$, must be considered when calculating equivalent dosing regimens in converting from intravenous to oral therapy. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacological effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacological effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a $t_{1/2}$ of weeks to months. The mechanism whereby amiodarone and desethyl-amiodarone are eliminated is not well established. A therapeutic plasma amiodarone concentration range of 0.5–2 $\mu\text{g}/\text{mL}$ has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity. Because of amiodarone's slow accumulation in tissue, a high-dose oral loading regimen (*e.g.*, 800–1600 mg/day) usually is administered for several weeks before maintenance therapy is started. Maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life-threatening, dosages of more than

300 mg/day normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of 200 mg/day or less are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation. Because of its very slow elimination, amiodarone is administered once daily, and omission of one or two doses during chronic therapy rarely results in recurrence of arrhythmia. Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potentially inhibits the hepatic metabolism or renal elimination of many drugs. Mechanisms include inhibition of CYP3A4, CYP2C9, and P-glycoprotein (see Chapter 3). Dosages of warfarin, other antiarrhythmics (e.g., flecainide, procainamide, and quinidine), or digoxin usually require reduction during amiodarone therapy.

CARDIAC GLYCOSIDES

Pharmacological Effects Cardiac glycosides exert positive inotropic effects and thus are also used in heart failure (see Chapter 33). Their inotropic action results from increased intracellular Ca^{2+} , which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if $[\text{K}]_o$ is low. They also exert prominent vagotonic actions, resulting in inhibition of Ca^{2+} currents in the AV node and activation of acetylcholine-mediated K^+ currents in the atrium. Thus, the major “indirect” electrophysiological effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The latter action accounts for the utility of digitalis in terminating reentrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the latter situation because many such patients have heart failure, which can be exacerbated by other AV nodal blocking drugs such as Ca^{2+} channel blockers or β adrenergic receptor antagonists. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure. Similarly, in other conditions in which high sympathetic tone drives rapid atrioventricular conduction (e.g., chronic lung disease and thyrotoxicosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance. The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects Because of the low therapeutic index of cardiac glycosides, toxicity is common, including arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision. Elevated serum concentrations of digitalis, hypoxia, and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, and hypercalcemia) predispose patients to digitalis-induced arrhythmias. While digitalis intoxication can cause virtually any arrhythmia, arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia, AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na^+, K^+ -ATPase and profound bradyarrhythmias are seen. In patients with elevated serum digitalis levels, the risk of precipitating ventricular fibrillation by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely. Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg^{2+} has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (DIGIBIND), which bind digoxin and digitoxin and greatly enhance their renal excretion. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, and mesenteric and coronary ischemia can occur, especially in patients with advanced atherosclerosis who receive intravenous drug.

Clinical Pharmacokinetics The most commonly used digitalis glycoside in the U.S. is *digoxin* (LANOXIN), although *digitoxin* (various generic preparations) also is used. Digoxin tablets are incompletely (75%) bioavailable, but capsules are >90% bioavailable. In some patients, intestinal

microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher than usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics such as *tetracycline* or erythromycin are administered because these drugs can destroy intestinal microflora. Inhibition of P-glycoprotein also may play a role. Digoxin is 20–30% protein-bound. The antiarrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable antiarrhythmic effects such as PR-interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of ~1–1.5 mg digoxin is administered over 24 hours. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.125–0.375 mg) to maintain concentrations of 0.5–2 ng/mL are useful during chronic therapy. Some patients may require and tolerate higher concentrations, but with an increased risk of adverse effects. The elimination $t_{1/2}$ of digoxin ordinarily is ~36 hours, so maintenance doses are administered once daily. Most digoxin is renally excreted as unchanged drug. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as *phenytoin* and *rifampin* that induce hepatic metabolism. Digitoxin's elimination $t_{1/2}$ is ~7 days; it is highly protein-bound, and its therapeutic range is 10–30 ng/mL. Amiodarone, quinidine, verapamil, diltiazem, *cyclosporine*, *itraconazole*, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination. New steady-state digoxin concentrations are approached in about a week. Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia will potentiate digitalis-induced arrhythmias.

DISOPYRAMIDE *Disopyramide* (NORPACE, others) exerts electrophysiological effects very similar to those of quinidine, but the drugs have different adverse effects. Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or ventricular fibrillation.

Pharmacological Actions and Adverse Effects Disopyramide is prescribed as a racemate. The *in vitro* electrophysiological actions of *S*(+)-disopyramide are similar to those of quinidine. The *R*(-)-enantiomer produces similar Na^+ channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide is not an α adrenergic receptor antagonist, but it does exert prominent anticholinergic actions that account for many of its adverse effects, including precipitation of glaucoma, constipation, dry mouth, and urinary retention. Disopyramide commonly depresses contractility, which can precipitate heart failure, and also can cause *torsades de pointes*.

Clinical Pharmacokinetics Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration. Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher than usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

DOFETILIDE *Dofetilide* (TIKOSYN) is a potent and “pure” I_{Kr} blocker that has virtually no extracardiac pharmacological effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. Dofetilide is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and treatment initiation.

Adverse Effects *Torsades de pointes* occurred in 1–3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. The incidence of this adverse effect during more widespread use of the drug postmarketing is unknown. Other adverse effects were no more common than with placebo in premarketing trials.

Clinical Pharmacokinetics Most dofetilide is excreted unchanged by the kidneys. In patients with mild-to-moderate renal failure, decreases in dosage based on creatinine clearance are used to

minimize the risk of *torsades de pointes*. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

FLECAINIDE The effects of flecainide (TAMBOCOR) are thought to be attributable to the drug's very long τ_{recovery} from Na^+ channel block. It is approved for the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, in whom structural heart disease is absent.

Pharmacological Effects Flecainide blocks Na^+ current, delayed rectifier K^+ current (I_{Kr}), and Ca^{2+} currents. Action potential duration is shortened in Purkinje cells, probably owing to block of late-opening Na^+ channels, but prolonged in ventricular cells, probably owing to block of delayed rectifier current. Flecainide does not cause EADs *in vitro* or *torsades de pointes*. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable antiarrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates. Flecainide prolongs the PR, QRS, and QT intervals even at normal heart rates.

Adverse Effects Flecainide usually produces few subjective complaints; dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate CHF in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of reentrant ventricular tachycardia, and increased mortality in patients convalescing from myocardial infarction. These effects likely result from Na^+ channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics Flecainide is well absorbed. The elimination $t_{1/2}$ (10–18 hours) is sufficiently long to allow dosing twice daily. Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6. However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (*i.e.*, quinidine and fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Some reports have suggested that plasma flecainide concentrations greater than $1 \mu\text{g}/\text{mL}$ should be avoided to minimize the risk of flecainide toxicity, but the adverse electrophysiological effects of flecainide therapy can occur at therapeutic plasma concentrations.

IBUTILIDE Ibutilide (CORVERT) is an I_{Kr} blocker that may also activate an inward Na^+ current. The action potential-prolonging effect of the drug may arise from either mechanism. Ibutilide is administered as a rapid infusion (1 mg over 10 minutes) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug's efficacy is higher in patients with atrial flutter (50–70%) than in those with atrial fibrillation (30–50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is *torsades de pointes*, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism and so is not used orally. It is eliminated by hepatic metabolism with a $t_{1/2}$ of 2–12 hours (mean, 6 hours).

LIDOCAINE Lidocaine (XYLOCAINE) is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias.

Pharmacological Effects Lidocaine blocks both open and inactivated cardiac Na^+ channels. Recovery from block is very rapid, so lidocaine exerts greater effects in depolarized (*e.g.*, ischemic) and/or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias, possibly because atrial action potentials are so short that the Na^+ channel is in the inactivated state only briefly compared with the long diastolic (recovery) times. Lidocaine can hyperpolarize Purkinje fibers depolarized by low $[\text{K}]_0$ or stretch; the resulting increased conduction velocity may inhibit reentry. Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. Action potential duration usually is unaffected or shortened; such shortening may be due to block of the few Na^+ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug

has little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported in patients with decreased left ventricular function.

Adverse Effects When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

CLINICAL PHARMACOKINETICS Lidocaine is well absorbed but undergoes extensive, though variable, first-pass hepatic metabolism; thus, oral use of the drug is inappropriate and the intravenous route is preferred. Lidocaine's metabolites—glycine xylidide (GX) and monoethyl GX—are less potent as Na⁺ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na⁺ channel, suggesting that lidocaine's efficacy may be diminished by GX accumulation. With infusions lasting longer than 24 hours, the clearance of lidocaine falls—which has been attributed to competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes. The initial drop in plasma lidocaine following intravenous administration occurs rapidly ($t_{1/2}$ of ~8 minutes), and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$, usually 100–120 minutes, represents drug elimination by hepatic metabolism. Lidocaine's efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3–4 mg/kg over 20–30 minutes is used—e.g., an initial 100 mg followed by 50 mg every 8 minutes for three doses. Subsequently, stable concentrations can be maintained in plasma with an infusion of 1–4 mg/min, which replaces drug removed by hepatic metabolism. Routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting maintenance infusion rate to maintain efficacy and avoid toxicities.

In heart failure, lidocaine clearance is reduced and the total loading dose and the rate of the maintenance infusion must be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β blockers, and during prolonged infusions. Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that the concentrations remain within the therapeutic range (1.5–5 $\mu\text{g/mL}$) are necessary to minimize toxicity. Lidocaine is bound to the acute-phase reactant α_1 -acid glycoprotein. Diseases such as acute myocardial infarction are associated with increases in α_1 -acid glycoprotein and hence a decreased proportion of free drug. These findings may explain why some patients require higher than usual total plasma lidocaine concentrations to maintain antiarrhythmic efficacy.

MEXILETINE *Mexiletine* (MEXITIL) is an analog of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy. The electrophysiological actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food. Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. *In vitro* studies and clinical anecdotes have suggested a role for mexiletine in correcting the molecular defect in the form of congenital long QT syndrome caused by abnormal Na⁺ channel inactivation.

MORICIZINE *Moricizine* (ETHMOZINE) is a phenothiazine analog with Na⁺ channel-blocking properties used in the chronic treatment of ventricular arrhythmias. Moricizine undergoes extensive first-pass hepatic metabolism; despite its short elimination $t_{1/2}$, its antiarrhythmic effect can persist for many hours after a single dose, suggesting that some of its metabolites may be active.

PROCAINAMIDE Procainamide (PROCAN SR, others) is an analog of the local anesthetic procaine. It exerts electrophysiological effects similar to those of quinidine but lacks quinidine's vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

Pharmacological Effects Procainamide is a blocker of open Na⁺ channels with an intermediate time constant of recovery from block. It also prolongs cardiac action potentials, probably by

blocking outward K^+ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. Its major metabolite, *N*-acetyl procainamide, lacks the Na^+ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Since the plasma concentrations of *N*-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS-interval prolongation. Hypotension may occur at high plasma concentrations, an effect usually attributable to ganglionic blockade rather than to any negative inotropic effect.

Adverse Effects Hypotension and marked slowing of conduction are major adverse effects of high concentrations ($>10 \mu\text{g/mL}$) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of *N*-acetyl procainamide. *Torsades de pointes* can occur, particularly when plasma concentrations of *N*-acetyl procainamide exceed $30 \mu\text{g/mL}$. Procainamide produces idiosyncratic and potentially fatal bone marrow aplasia in 0.2% of patients. During long-term therapy, most patients will develop circulating antinuclear antibodies. Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25–50% of patients eventually develop symptoms of a drug-induced lupus syndrome, typically rash and arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupus-like symptoms resolve on cessation of therapy or during treatment with *N*-acetyl procainamide (*see below*).

Clinical Pharmacokinetics Procainamide is eliminated rapidly ($t_{1/2}$, 3–4 hours) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by *N*-acetyl transferase, whose activity is determined genetically, to form *N*-acetyl procainamide. *N*-Acetyl procainamide is eliminated by renal excretion ($t_{1/2}$, 6–10 hours) and is not significantly converted back to procainamide. Oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide and/or *N*-acetyl procainamide can accumulate to potentially toxic plasma concentrations, and reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required. Because the parent drug and metabolite exert different pharmacological effects, the practice of using the sum of their concentrations to guide therapy is inappropriate. In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators. In addition, the symptoms of procainamide-induced lupus resolve during treatment with *N*-acetyl procainamide. Both these findings suggest that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome.

PROPAFENONE *Propafenone* (RHYTHMOL) is a Na^+ channel blocker with a relatively slow time constant for recovery from block. Like flecainide, propafenone may also block K^+ channels. Its major electrophysiological effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; while the enantiomers do not differ in their Na^+ channel-blocking properties, *S*-(+)-propafenone also is a β adrenergic receptor antagonist. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na^+ channel blockers, it also can be used in ventricular arrhythmias but with only modest efficacy. Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of reentrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm.

Clinical Pharmacokinetics Propafenone is well absorbed and is eliminated by both hepatic and renal routes. The activity of CYP2D6, functionally absent in ~7% of Caucasians and African Americans (*see Chapter 3*), is a major determinant of plasma propafenone concentration. In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as a Na^+ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, *N*-desalkyl propafenone, is formed by non-CYP2D6-mediated metabolism and is a less potent blocker of Na^+ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable; thus, small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizers” who lack functional CYP2D6, first-pass hepatic metabolism is much less, and

plasma propafenone concentrations are much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers. CYP2D6 activity can be inhibited by a number of drugs, including quinidine and fluoxetine. In extensive metabolizers receiving such drugs or in poor metabolizers, plasma propafenone concentrations of more than 1 $\mu\text{g/mL}$ are associated with clinical effects of β adrenergic receptor blockade, such as reduction of exercise heart rate. Patients with moderate-to-severe liver disease should receive ~20–30% of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

QUINIDINE Quinidine, a diastereomer of the antimalarial quinine, is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or ventricular fibrillation.

Pharmacological Effects Quinidine (various generic preparations) blocks Na^+ current and multiple cardiac K^+ currents. It is an open-state blocker of Na^+ channels, with a τ_{recovery} in the intermediate (~3 seconds) range; as a consequence, QRS duration increases modestly, usually by 10–20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval by up to 25%, but the effect is highly variable. At concentrations as low as 1 μM , quinidine blocks Na^+ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca^{2+} current. Quinidine's Na^+ channel-blocking properties result in an increased threshold for excitability and decreased automaticity. Due to its K^+ channel-blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when $[\text{K}]_o$ is low. Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of action potential duration and Na^+ channel blockade.

Quinidine also produces α adrenergic receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine's vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so its effect on the PR interval is variable. Moreover, quinidine's vagolytic effect can increase AV nodal transmission of atrial tachycardias such as atrial flutter (Table 34–1).

Adverse Effects

Noncardiac Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30–50% of patients, usually within the first several days of quinidine therapy but sometimes later. Diarrhea-induced hypokalemia may potentiate the risk of *torsades de pointes* due to quinidine. A number of immunological reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but resolves rapidly with drug discontinuation. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations. Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

Cardiac Between 2% and 8% of patients who receive quinidine therapy will develop marked QT-interval prolongation and *torsades de pointes*. In contrast to sotalolol, *N*-acetyl procainamide, and other drugs, quinidine-associated *torsades de pointes* usually occurs at therapeutic or subtherapeutic plasma concentrations. The reasons for individual susceptibility are not known. At high plasma concentrations of quinidine, marked Na^+ channel block can occur, with resulting ventricular tachycardia. Quinidine can exacerbate heart failure or conduction system disease but usually is well tolerated in patients with congestive heart failure, perhaps because of its vasodilating actions.

Clinical Pharmacokinetics Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and α_1 -acid glycoprotein. As with lidocaine, greater than usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute myocardial infarction. Quinidine undergoes extensive hepatic oxidative metabolism, and ~20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na^+ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. Other metabolites are less potent and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the

clinical effects of quinidine. There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2–5 $\mu\text{g/mL}$. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions Quinidine is a potent inhibitor of CYP2D6, and its administration to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of *codeine* to its active metabolite *morphine* results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β adrenergic receptor blockade. Quinidine reduces the clearance of digoxin and digitoxin; inhibition of P-glycoprotein-mediated digoxin transport has been implicated. Quinidine metabolism is induced by drugs such as *phenobarbital* and phenytoin. In patients receiving these agents, very high doses of quinidine may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

SOTALOL *Sotalol* (BETAPACE, BETAPACE AF) is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed rectifier and possibly other K^+ currents. Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K^+ channel blockers. Sotalol is FDA-approved for use in patients with both ventricular tachyarrhythmias and atrial fibrillation or flutter. Clinical trials suggest that it is at least as effective as most Na^+ channel blockers in ventricular arrhythmias. Sotalol prolongs the QT interval, decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K^+ channels and β adrenergic receptors; it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity *in vitro* and can cause *torsades de pointes*, especially when the serum K^+ concentration is low. Unlike quinidine, the incidence of *torsades de pointes* depends on the dose of sotalol. Because sotalol is eliminated by renal excretion, occasional cases occur at low dosage in patients with renal dysfunction. Other adverse effects of sotalol therapy are those associated with β adrenergic receptor blockade.

MAGNESIUM The intravenous administration of 1–2 g MgSO_4 reportedly is effective in preventing recurrent episodes of *torsades de pointes*, even with normal serum Mg^{2+} . The mechanism of action is unknown but may reflect an effect on the inward current, possibly a Ca^{2+} current, responsible for the triggered upstroke arising from EADs. Intravenous Mg^{2+} also has been used successfully in arrhythmias related to digitalis intoxication.

DRUG THERAPY FOR HYPERCHOLESTEROLEMIA AND DYSLIPIDEMIA

Hyperlipidemia is a major cause of atherosclerosis and atherosclerosis-associated conditions, such as coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral vascular disease. These conditions account for most morbidity and mortality among middle-aged and older adults. Dyslipidemias, including hyperlipidemia (hypercholesterolemia) and low levels of high-density-lipoprotein cholesterol (HDL-C), are major causes of increased atherogenesis; both genetic disorders and lifestyle (sedentary behavior and diets high in calories, saturated fat, and cholesterol) contribute to the dyslipidemias seen in developed countries.

PLASMA LIPOPROTEIN METABOLISM

Lipoproteins are macromolecular assemblies that contain proteins and lipids, including free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins, provide structural stability to the lipoproteins, and also may function as ligands in lipoprotein–receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. In all lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) are located on the surface. The major classes of lipoproteins and their properties are presented in Table 35–1. Table 35–2 describes apoproteins that have well-defined roles in plasma lipoprotein metabolism.

CHYLOMICRONS Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed from the small intestine by epithelial cells. Intestinal cholesterol absorption is mediated by Niemann-Pick C1–like 1 (NPC1L1) protein, which appears to be the target of ezetimibe (*see* below). Dietary cholesterol is esterified by the type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase (ACAT). ACAT-2 is found in the intestine and the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins (chylomicrons and very-low-density lipoproteins [VLDL]) are assembled. Chylomicrons are the largest and lowest density plasma lipoproteins. In normal individuals, chylomicrons are present in plasma for 3–6 hours after a fat-containing meal; no chylomicrons remain after 10–12 hours. After entering the circulation *via* the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize the triglyceride hydrolase lipoprotein lipase (LPL; Figure 35–1), including adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. As triglycerides are hydrolyzed by LPL, the resulting free fatty acids are taken up and utilized by adjacent tissues. The interaction of chylomicrons and LPL absolutely requires apolipoprotein (apo) C-II as a cofactor. The absence of functional LPL or functional apoC-II prevents the hydrolysis of triglycerides in chylomicrons and results in severe hypertriglyceridemia and pancreatitis during childhood or even infancy (chylomicronemia syndrome). The chylomicrons can be decreased only by reducing dietary fat consumption. Insulin has a “permissive” effect on LPL-mediated triglyceride hydrolysis.

CHYLOMICRON REMNANTS After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, which still contain all of the dietary cholesterol, detach from the capillary surface and are removed within minutes from the circulation by the liver in a process mediated by apoE (Figure 35–1). First, the remnants are sequestered by the interaction of apoE with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apoE mediates remnant uptake by interacting with the hepatic low-density lipoproteins (LDL) receptor or the LDL receptor–related protein (LRP). Inherited deficiency of either functional HL (very rare) or functional apoE impedes remnant clearance by the LDL receptor, increasing triglyceride- and cholesterol-rich remnant lipoproteins in the plasma (type III hyperlipoproteinemia).

During the initial hydrolysis of chylomicron triglycerides by LPL, apoA-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor–mediated catabolism of LDL by the liver.

VERY-LOW-DENSITY LIPOPROTEINS VLDL are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased hepatic

Table 35-1

Characteristics of Plasma Lipoproteins

Lipoprotein Class	Density of Flotation, g/mL	Major Lipid Constituent	TG:Chol Ratio	Significant Apoproteins	Site of Synthesis	Mechanism(s) of Catabolism
Chylomicrons and remnants	<<1.006	Dietary triglycerides and cholesterol	10:1	B-48, E, A-I, A-IV, C-I, C-II, C-III	Intestine	Triglyceride hydrolysis by LPL ApoE-mediated remnant uptake by liver
VLDL	<1.006	“Endogenous” or hepatic triglycerides	5:1	B-100, E, C-I, C-II, C-III	Liver	Triglyceride hydrolysis by LPL
IDL	1.006–1.019	Cholesteryl esters and “endogenous” triglycerides	1:1	B-100, E, C-II, C-III	Product of VLDL catabolism	50% converted to LDL mediated by HL, 50% apoE-mediated uptake by liver
LDL	1.019–1.063	Cholesteryl esters	NS	B-100	Product of VLDL catabolism	50% apoE-mediated uptake by liver ApoB-100-mediated uptake by LDL receptor (~75% in liver)
HDL	1.063–1.21	Phospholipids, cholesteryl esters	NS	A-I, A-II, E, C-I, C-II, C-III	Intestine, liver, plasma	Complex: Transfer of cholesteryl ester to VLDL and LDL Uptake of HDL cholesterol by hepatocytes
Lp(a)	1.05–1.09	Cholesteryl esters	NS	B-100, apo(a)	Liver	Unknown

ABBREVIATIONS: apo, apolipoprotein; CHOL, cholesterol; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; Lp(a), lipoprotein(a); LDL, low-density lipoproteins; NS, not significant (triglyceride is less than 5% of LDL and HDL); TG, triglyceride; VLDL, very-low-density lipoproteins; HL, hepatic lipase; LPL, lipoprotein lipase.

Table 35–2

Apolipoproteins

Apolipoprotein	Average Concentration, mg/dL	Chromosome	Molecular Mass, kDa	Sites of Synthesis	Functions
ApoA-I	130	11	~29	Liver, intestine	Structural in HDL; LCAT cofactor; ligand of ABCA1 receptor; reverse cholesterol transport
ApoA-II	40	1	~17	Liver	Forms –S–S– complex with apoE-2 and E-3, which inhibits E-2 and E-3 binding to lipoprotein receptors
ApoA-V	<1	11	~40	Liver	Modulates triglyceride incorporation into hepatic VLDL; activates LPL
ApoB-100	85	2	~513	Liver	Structural protein of VLDL, IDL, LDL; LDL receptor ligand
ApoB-48	Fluctuates according to dietary fat intake	2	~241	Intestine	Structural protein of chylomicrons
ApoC-I	6	19	~6.6	Liver	LCAT activator; modulates receptor binding of remnants
ApoC-II	3	19	8.9	Liver	Lipoprotein lipase cofactor
ApoC-III	12	11	8.8	Liver	Modulates receptor binding of remnants
ApoE	5	19	34	Liver, brain, skin, gonads, spleen	Ligand for LDL receptor and receptors binding remnants; reverse cholesterol transport (HDL with apoE)
Apo(a)	Variable (under genetic control)	6	Variable	Liver	Modulator of fibrinolysis

ABBREVIATIONS: ABCA1, ATP-binding cassette transporter A1; apo, apolipoprotein; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; kDa, kilodaltons; LCAT, lecithin:cholesterol acyltransferase; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

synthesis of fatty acids. ApoB-100, apoE, and several other lipoproteins are synthesized constitutively by the liver and incorporated into VLDL (Table 35–2). If triglycerides are unavailable, the newly synthesized apoB-100 is degraded by hepatocytes. Small amounts of apoE and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of the VLDL apoproteins are acquired from plasma HDL after the VLDL are secreted by the liver.

Without the enzyme microsomal triglyceride transfer protein (MTP), hepatic triglycerides cannot be transferred to apoB-100. Patients with dysfunctional MTP fail to make any of the apoB-containing lipoproteins (VLDL, IDL, or LDL). MTP also plays a key role in the synthesis of chylomicrons in the intestine, and mutations of MTP that result in the inability of triglycerides to be transferred to either apoB-100 in the liver or apoB-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder abetalipoproteinemia.

FIGURE 35-1 The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LDL receptor-related protein (LRP), LDL, and perhaps other receptors. FFA released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue. FFA, free fatty acid; HL, hepatic lipase; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

Plasma VLDL is catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (Figure 35-1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed intermediate-density lipoproteins (IDL), are released from the capillary endothelium and reenter the circulation. ApoB-100 containing small VLDL and IDL, which have a $t_{1/2}$ of <30 minutes, have two potential fates: 40–60% are cleared from the plasma by the liver via apoB-100- and apoE-mediated interaction with LDL receptors and LRP; the remainder are converted to LDL by LPL and HL and the C apoproteins and apoE redistribute to HDL. Virtually all LDL particles in the plasma are derived from VLDL.

ApoE plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDL, and IDL) and in the local redistribution of lipids among cells. About half of the plasma apoE in fasting subjects is associated with triglyceride-rich lipoproteins; the other half is a constituent of HDL.

LOW-DENSITY LIPOPROTEINS The LDL particles arising from the catabolism of IDL have a $t_{1/2}$ of 1.5–2 days, which accounts for the higher plasma concentration of LDL than of VLDL and IDL. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL particles is mediated primarily by LDL receptors. Mutations of the LDL receptor gene cause familial hypercholesterolemia. ApoB-100, the only apoprotein of LDL, is the ligand that binds LDL to its receptor. Mutations in apoB-100 disrupt binding and are a cause of hypercholesterolemia (familial defective apoB-100). Autosomal recessive hypercholesterolemia closely resembles familial hypercholesterolemia, but is not caused by LDL receptor mutations but by mutations in a protein that is required for internalization of LDL receptor complexes on the surface of hepatocytes.

The liver expresses a large complement of LDL receptors and removes ~75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor expression is a most effective way to modulate plasma LDL-C levels. Thyroxine and estrogen enhance LDL receptor gene expression, which explains their LDL-C-lowering effects. The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression. LDL become atherogenic when they are modified by oxidation, a required step for LDL uptake by the scavenger receptors of macrophages. This process leads to foam-cell formation in arterial lesions. Despite the large body

of evidence implicating LDL oxidation as a requisite step during atherogenesis, controlled clinical trials have failed to show efficacy of antioxidant vitamins in preventing vascular disease.

HIGH-DENSITY LIPOPROTEINS

The metabolism of HDL is complex because of the multiple mechanisms by which HDL particles are synthesized and modified plasma. Many factors, including genetic variation, can alter HDL levels and affect CHD risk. ApoA-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level. Mutations in the apoA-I gene that cause HDL deficiency are variable in their clinical expression and often are associated with accelerated atherogenesis. The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL. When ABCA1 is defective, the acquisition of cholesterol by HDL is greatly diminished, and HDL levels are markedly reduced. Loss-of-function mutations of ABCA1 cause Tangier disease, a genetic disorder characterized by extremely low levels of HDL and cholesterol accumulation in the liver, spleen, tonsils, and peripheral nerves.

Mature HDL can be separated by ultracentrifugation into HDL₂, which are larger, more cholesterol-rich lipoproteins, and HDL₃, which are smaller and denser. Newly formed HDL₃ particles are converted to HDL₂ by accepting more free cholesterol, which is then esterified by lecithin: cholesterol acyltransferase (LCAT). As the cholesteryl ester content of the HDL₂ increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDL, remnant lipoproteins, and LDL). This exchange is mediated by the cholesteryl ester transfer protein (CETP), which in humans accounts for the removal of about two-thirds of the cholesterol associated with HDL. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. The triglyceride transferred into HDL₂ is hydrolyzed in the liver by HL, regenerating smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol.

HDL are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion.

HYPERLIPIDEMIA AND ATHEROSCLEROSIS

The major conventional risk factors for CHD are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature (men <55 years; women <65 years) CHD events in a first-degree relative. Control of the modifiable risk factors, which account for 85% of excess risk, is especially important in preventing premature CHD. When total cholesterol levels are <160 mg/dL, CHD risk is markedly attenuated, even in the presence of additional risk factors. This pivotal role of hypercholesterolemia in atherogenesis gave rise to the almost universally accepted cholesterol-diet-CHD hypothesis: elevated plasma cholesterol levels cause CHD; diets rich in saturated fat and cholesterol raise cholesterol levels; and lowering cholesterol levels reduces CHD risk.

Clinical trials with effective cholesterol-lowering drugs, the statins, have documented the safety and efficacy of cholesterol-lowering therapy in preventing CHD. Patients benefit from lowering plasma cholesterol levels regardless of gender, age, or baseline lipid values whether or not they have a prior history of vascular disease. Guidelines based on these clinical trials and were developed in 2001 by the National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III and revised in 2004 (www.nhlbi.nih.gov/guidelines/cholesterol). The key features of the revision include abandoning the concept of a threshold LDL-C level that must be exceeded before initiating cholesterol-lowering drug therapy in CHD or CHD equivalent patients; adopting a new target LDL-C level (<70 mg/dL) for very high-risk patients; and employing a “standard statin dose” (a dosage sufficient to lower LDL-C by 30–40%) as a minimum therapy when initiating cholesterol-lowering therapy with statins (see Table 35–3). Clinical trials suggest that CHD risk is reduced by 1% for every 1% reduction in LDL-C. Current recommendations for statin therapy are that LDL-C levels should be lowered by 30–40% from baseline as well as achieving a specific LDL-C goal.

National Cholesterol Education Program (NCEP) Guidelines for Treatment: Managing Patients with Dyslipidemia

The NCEP guidelines for patient management are of two types. One is a population-based approach to reduce CHD risk, which includes recommendations to increase exercise (to expend ~2000 calories/week)

Table 35-3

Treatment Based on LDL-C Levels (2004 Revision of NCEP Adult Treatment Panel III Guidelines)

Risk Category	LDL-C Goal	Adults	
		Therapeutic Lifestyle Change	Drug Therapy
<i>Very high risk</i> Atherosclerosis-induced CHD plus one of: (a) multiple risk factors, (b) diabetes mellitus, (c) a poorly controlled single factor, (d) acute coronary syndrome, (e) metabolic syndrome	<70 mg/dL*	No threshold	No threshold
<i>High risk</i> CHD or CHD equivalent	<100 mg/dL*	No threshold	No threshold
<i>Moderately high risk</i> 2+ risk factors 10-year risk: 10–20%	<130 mg/dL (Optional <100 mg/dL)	≥100 mg/dL	≥130 mg/dL (100–129 mg/dL)†
<i>Moderate risk</i> 2+ risk factors 10-year risk <10%	<130 mg/dL	≥130 mg/dL	>160 mg/dL
<i>0–1 risk factor</i>	<160 mg/dL	≥160 mg/dL	≥190 mg/dL (Optional: 160–189 mg/dL)‡

*If pretreatment LDL-C is near or below LDL-C goal value, then a statin dose sufficient to lower LDL-C by 30%–40% should be prescribed.

†Patients in this category include those with a 10-year risk of 10%–20% and one of the following: (a) age >60 years; (b) three or more risk factors; (c) a severe risk factor; (d) triglycerides >200 mg/dL and HDL-C <40 mg/dL; (e) metabolic syndrome; (f) highly sensitive C-reactive protein (CRP) >3 mg/L; (g) coronary calcium score (age/gender adjusted) >75th percentile.

‡Patients include those with: (a) any severe single risk factor; (b) multiple major risk factors; (c) 10-year risk >8%.

ABBREVIATIONS: CHD, coronary heart disease; CHD equivalent, peripheral vascular disease, abdominal aortic aneurysm, symptomatic carotid artery disease, >20% 10-year CHD risk, or diabetes mellitus; LDL-C, low-density-lipoprotein cholesterol; NCEP, National Cholesterol Education Program.

and to lower blood cholesterol by dietary recommendations: reduce total calories from fat to <30% and from saturated and trans fats to <10%; consume less than 300 mg of cholesterol per day; eat a variety of oily fish twice a week and oils/foods rich in α -linolenic acid (canola, flaxseed, and soybean oils, flaxseed, and walnuts); and maintain desirable body weight. The second is the patient-based approach that focuses on lowering LDL-C levels as the primary goal of therapy.

According to guidelines, all adults >20 years old should have a complete fasting lipoprotein profile (total cholesterol, LDL-C, HDL-C, and triglycerides). The classification of lipid levels is shown in Table 35-4. If the values for total cholesterol, LDL-C, and triglycerides are in the lowest category and the HDL-C level is not low, lifestyle recommendations (diet and exercise) should be made to ensure maintenance of a normal lipid profile. Other vascular disease risk factors (Table 35-5), if present, should be assessed and treated individually. For patients with elevated levels of total cholesterol, LDL-C, or triglycerides, or reduced HDL-C values, further treatment is based on the patient's risk-factor status (Table 35-5), LDL-C levels (Table 35-3), and calculation of the Framingham risk score (Table 35-6) of primary prevention patients with two or more risk factors. A high risk or CHD equivalent status is defined as >20% chance of sustaining a CHD event in the next 10 years.

All patients who meet the criteria for lipid-lowering therapy should receive instruction about therapeutic lifestyle change. Dietary restrictions include <7% of calories from saturated and trans fatty acids, <200 mg of cholesterol daily, up to 20% of calories from monounsaturated fatty acids,

Table 35–4

Classification of Plasma Lipid Levels*

Total cholesterol

<200 mg/dL	Desirable
200–239 mg/dL	Borderline high
≥240 mg/dL	High

HDL-C

<40 mg/dL	Low (consider <50 mg/dL as low for women)
>60 mg/dL	High

LDL-C

<70 mg/dL	Optimal for very high risk (minimal goal for CHD equivalent patients)
<100 mg/dL	Optimal
100–129 mg/dL	Near optimal
130–159 mg/dL	Borderline high
160–189 mg/dL	High
≥190 mg/dL	Very high

Triglycerides

<150 mg/dL	Normal
150–199 mg/dL	Borderline high
200–499 mg/dL	High
≥500 mg/dL	Very high

ABBREVIATIONS: HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol.

*2001 National Cholesterol Education Program guidelines.

up to 10% of calories from polyunsaturated fat, and total fat calories ranging between 25–35% of all calories. Two meals of oily fish per week are especially important for patients after myocardial infarction due to a substantial reduction in sudden cardiac death. Patients with CHD or a CHD equivalent (symptomatic peripheral or carotid vascular disease, abdominal aortic aneurysm, >20% 10-year CHD risk, or diabetes mellitus) should immediately start appropriate lipid-lowering drug therapy irrespective of their baseline LDL-C level. Patients without CHD or CHD equivalent

Table 35–5

Risk Factors for Coronary Heart Disease*

Age

Male >45 years or female >55 years

Family history of premature CHD

A first-degree relative (male below 55 years or female below 65 years when the first CHD clinical event occurs)

Current cigarette smoking

Defined as smoking within the preceding 30 days

Hypertension

Blood pressure ≥140/90 or use of antihypertensive medication, irrespective of blood pressure

Low HDL-C

<40 mg/dL (consider <50 mg/dL as “low” for women)

Obesity[†]

Body mass index >25 kg/m² and waist circumference above 40 inches (men) or 35 inches (women)

ABBREVIATIONS: CHD, coronary heart disease; HDL-C, high-density-lipoprotein cholesterol.

[†]Diabetes mellitus is considered to be a CHD-equivalent disorder; therefore, the lipid management of diabetes patients is the same as that for patients with established vascular disease (American Diabetes Association, 1999).

[‡]Obesity was returned to the list of CHD risk factors in 1998, although it was not included as a risk factor in the 2001 NCEP guidelines.

Table 35–6

Guidelines Based on LDL-C and Total Cholesterol:HDL-C Ratio for Treatment of Low HDL-C Patients

Risk Category	Goals		Lifestyle Change Initiated for		Drug Therapy Initiated for	
	LDL-C	TC:HDL-C	LDL-C	TC:HDL-C	LDL-C	TC:HDL-C
CHD or equivalent	<100	and <3.5	≥100	or ≥3.5	≥100	or ≥3.5
2+ risk factors	<130	and <4.5	≥130	or ≥4.5	≥130	or ≥6.0
0–1 risk factor	<160	and <5.5	≥160	or ≥5.5	≥160	or ≥7.0

ABBREVIATIONS: CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; TC, total cholesterol.

should be managed with lifestyle advice (diet, exercise, weight management) for 3–6 months before drug therapy is implemented.

Before drug therapy is initiated, secondary causes of hyperlipidemia should be excluded. Most secondary causes (*e.g.*, diabetes mellitus, nephrotic syndrome, alcohol use, estrogen use, glucocorticoid excess, hypothyroidism, and obstructive liver disease) can be excluded by ascertaining the patient's medication history and by measuring serum creatinine, liver function tests, fasting glucose, and thyroid-stimulating hormone levels. Treatment of the disorder causing secondary dyslipidemia may preclude the necessity of treatment with hypolipidemic drugs.

WHOM AND WHEN TO TREAT Large-scale trials with statins have provided new insights into which patients with dyslipidemia should be treated and when treatment should be initiated.

Sex Both men and women benefit from lipid-lowering therapy. Statins are the recommended first-line drug therapy for lowering lipids in postmenopausal women.

Age Age >45 years in men and >55 years in women is considered to be a CHD risk factor. The statin trials have shown that patients >65 years of age benefit from therapy as much as do younger patients. Thus, old age *per se* is not a reason to withhold drug therapy in an otherwise healthy person.

Cerebrovascular Disease Patients Plasma cholesterol levels correlate positively with the risk of ischemic stroke and statins reduce stroke and transient ischemic attacks in patients with and without CHD.

Peripheral Vascular Disease Patients Statins are beneficial in patients with peripheral vascular disease.

Hypertensive Patients and Smokers The risk reduction for coronary events in hypertensive patients and in smokers is similar to that in subjects without these risk factors.

Type 2 Diabetes Mellitus Patients with type 2 diabetes benefit very significantly from aggressive lipid lowering (*see* "Treatment of Type 2 Diabetes," below).

Post–Myocardial Infarction or Revascularization Patients

As soon as CHD is diagnosed, it is essential to begin lipid-lowering therapy (NCEP guidelines: LDL-C goal <70 mg/dL for very high-risk patients). Compliance with drug therapy is greatly enhanced if treatment is initiated in the hospital. Statin therapy improves the long-term outcome after bypass surgery; the lower the LDL-C, the better.

CAN CHOLESTEROL LEVELS BE LOWERED TOO MUCH?

There are no significant risks associated with low cholesterol levels.

Treatment of Type 2 Diabetes

Diabetes mellitus is an independent predictor of high risk for CHD. Glucose control is essential but provides only minimal benefit with respect to CHD prevention. Diabetic dyslipidemia typically includes high triglycerides, low HDL-C, and moderate elevations of total cholesterol and LDL-C.

Aggressive treatment of diabetic dyslipidemia through diet, weight control, and drugs is critical in reducing risk. Diabetics without diagnosed CHD have the same level of risk as nondiabetics with established CHD. Thus, the dyslipidemia treatment guidelines for diabetic patients are the same as for patients with CHD, irrespective of whether the diabetic patient has had a CHD event. The first line of treatment for diabetic dyslipidemia usually should be a statin.

Metabolic Syndrome

There is an increased CHD risk associated with the insulin-resistant, prediabetic state described under the rubric of “metabolic syndrome,” a constellation of abdominal obesity, hypertension, insulin resistance, hypertriglyceridemia, and low HDL. Treatment should focus on weight loss and increased physical activity, since being overweight or obese usually precludes optimal risk factor reduction. Specific treatment of lipid abnormalities should also be undertaken.

Treatment of Hypertriglyceridemia

There is increased CHD risk associated with the presence of triglyceride levels >150 mg/dL. Three categories of hypertriglyceridemia are recognized (Table 35–4), and treatment depends on the degree of elevation. Weight loss, increased exercise, and alcohol restriction are important for all hypertriglyceridemic patients. The LDL-C goal should be ascertained based on each patient’s risk factors or CHD status (Table 35–3). If triglycerides remain >200 mg/dL after the LDL-C goal is reached, further reduction in triglycerides may be achieved by increasing the dose of a statin or of niacin. Combination therapy (statin plus niacin or statin plus fibrate) may be required, but caution is necessary with these combinations to avoid myopathy (*see below*).

TREATMENT OF LOW HDL-C The most frequent risk factor for premature CHD is low HDL-C. In patients with low HDL-C, the total cholesterol:HDL-C ratio is a particularly useful predictor of CHD risk. A favorable ratio is ≤ 3.5 and a ratio of >4.5 is associated with increased risk. Patients with low HDL-C may have what are considered to be “normal” total and LDL cholesterol levels; however, because of their low HDL-C levels, such patients may be at high risk based on the total cholesterol:HDL-C ratio (*e.g.*, a total cholesterol, 180 mg/dL; HDL-C, 30 mg/dL; ratio, 6). A desirable total cholesterol level in low-HDL-C patients may be considerably lower than 200 mg/dL, especially since low-HDL-C patients may also have moderately elevated triglycerides, which may reflect increased levels of atherogenic remnant lipoproteins. Patients with average or high LDL-C, low HDL-C, and high total cholesterol:HDL-C ratios have benefited from treatment.

The treatment of low HDL-C patients focuses on lowering LDL-C to the target level based on the patient’s risk factor or CHD status (Table 35–4) and a reduction of VLDL cholesterol to below 30 mg/dL. Satisfactory treatment results are a ratio of total cholesterol:HDL-C that is 3.5 or less. Patients with total cholesterol:HDL-C ratios >4.5 are at risk even if their “non-HDL-C” levels (LDL-C and VLDL cholesterol) are at the goal values recommended by the NCEP guidelines. Consequently, it is useful to base treatment of patients with low HDL-C levels on both LDL-C levels and the total cholesterol:HDL-C ratio (Table 35–6).

DRUG THERAPY OF DYSLIPIDEMIA

Statins

The statins are the most effective and best-tolerated agents for treating dyslipidemia. These drugs are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (*e.g.*, atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Some statins also are indicated for raising HDL-C levels, although the benefits of these effects on HDL-C remain to be proven.

The efficacy and safety of the statins in reducing fatal and nonfatal CHD events, strokes, and total mortality are well established. Rates of non-CHD adverse events in clinical trials were the same in the placebo groups and in the groups receiving the drug, both with regard to noncardiac illness and two laboratory tests, hepatic transaminases and creatine kinase (CK), commonly monitored in patients taking statins.

Pravastatin and simvastatin are chemically modified derivatives of lovastatin. Atorvastatin, fluvastatin, and rosuvastatin are structurally distinct synthetic compounds. Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit

hepatic cholesterol biosynthesis. In response to the reduced free cholesterol content within hepatocytes, synthesis of LDL receptors is increased and their degradation is reduced. The greater number of LDL receptors on the surface of hepatocytes increases removal of LDL from the blood, thereby lowering LDL-C levels. Statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. This mechanism likely accounts for the triglyceride-lowering effect of statins and may account for the reduction (~25%) of LDL-C levels in patients with homozygous familial hypercholesterolemia treated with 80 mg of atorvastatin or simvastatin.

Triglyceride levels >250 mg/dL are reduced substantially by statins, and the percent reduction achieved is similar to that in LDL-C. Accordingly, hypertriglyceridemic patients taking the highest doses of the most potent statins (simvastatin and atorvastatin, 80 mg/day; rosuvastatin, 40 mg/day) experience a 35–45% reduction in LDL-C and a comparable reduction in fasting triglyceride levels. If baseline triglyceride levels are <250 mg/dL, reductions in triglycerides are <25% irrespective of the dose or statin used. Similar reductions (35–45%) in triglycerides can be accomplished with doses of fibrates or niacin (see below), although these drugs do not reduce LDL-C to the same extent as atorvastatin or simvastatin at the 80-mg dose.

Statins lower LDL-C by 20–55%, depending on the dose and statin (Table 35–7). The fractional reductions achieved with the various doses are the same regardless of the absolute value of the baseline LDL-C level. Efficacy of LDL-C lowering is log-linear; LDL-C is reduced by ~6% (from baseline) with each doubling of the dose. Maximal effects on plasma cholesterol levels are achieved within 7–10 days. The statins are effective in almost all patients with high LDL-C levels. Patients with homozygous familial hypercholesterolemia have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene encode dysfunctional LDL receptors; the partial response in these patients is due to a reduction in hepatic VLDL synthesis.

Although the statins clearly exert their major effects on CHD by lowering LDL-C and improving the lipid profile (Figure 35–2), a multitude of potentially cardioprotective effects are also ascribed to these drugs. It is not known whether these potential pleiotropic effects represent a class-action effect, differ amongst statins, or are biologically or clinically relevant.

Absorption, Metabolism, and Excretion

After oral administration, intestinal absorption of the statins varies between 30% and 85%. All of the statins, except simvastatin and lovastatin, are administered as active β-hydroxy acids. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids. There is extensive first-pass hepatic uptake of all statins, but they enter the liver by different mechanisms. Uptake of atorvastatin, pravastatin, and rosuvastatin is mediated by the organic anion transporter 2 (OATP2). The lipophilic lactone forms of simvastatin and lovastatin are thought to enter the liver by simple diffusion. Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. Except for fluvastatin and pravastatin, the metabolites of all statins have some HMG-CoA reductase inhibitory activity. Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. In the plasma, >95% of statins and their metabolites are protein bound with the exception of pravastatin and its metabolites (50% bound).

After oral dosing, plasma concentrations of statins peak in 1–4 hours. The half-lives of the parent compounds are 1–4 hours, except for atorvastatin and rosuvastatin, which have half-lives of ~20 hours, which may contribute to their greater cholesterol-lowering efficacy. The liver biotransforms all

Table 35–7

Doses (mg) of Statins Required to Achieve Various Reductions in Low-Density-Lipoprotein Cholesterol from Baseline

	20%–25%	26%–30%	31%–35%	36%–40%	41%–50%	51%–55%

Pravastatin	10	20	40			
Rosuvastatin	—	—	—	5	10	20, 40
Simvastatin	—	10	20	40	80	

FIGURE 35–2 Reduction in coronary heart disease events in clinical trials is associated with the extent of plasma cholesterol lowering. As more potent cholesterol-reducing agents become available, will it be possible to reduce events by 50% or more in a typical 5-year trial? AFCAPS, Air Force/Texas Coronary Atherosclerosis Prevention Study; CARE, Cholesterol and Recurrent Events trial; LIPID, Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) study; LRC, Lipid Research Clinics Coronary Primary Prevention Trial; POSCH, Program on the Surgical Control of the Hyperlipidemias; 4S, Scandinavian Simvastatin Survival Study; WOS, West of Scotland Coronary Prevention Study. (Adapted from Thompson and Barter, 1999, and used by permission of Lippincott Williams & Wilkins.)

statins, and >70% of statin metabolites are excreted by the liver with subsequent elimination in the feces.

ADVERSE EFFECTS AND DRUG INTERACTIONS

Hepatotoxicity

Serious hepatotoxicity is very rare (~one case per million person-years of use); nonetheless, it is reasonable to measure alanine aminotransferase (ALT) at baseline and thereafter when clinically indicated. Patients taking 80-mg doses (or 40 mg of rosuvastatin) should have their ALT checked after 3 months. If the ALT values are normal, it is not necessary to repeat the ALT test unless clinically indicated.

MYOPATHY

The most significant adverse effect associated with statin use is myopathy. The incidence of myopathy is quite low (~0.01%), but the risk of myopathy and rhabdomyolysis increases in proportion to plasma statin concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, multisystem disease (especially in association with diabetes mellitus), small body size, and untreated hypothyroidism. Concomitant use of drugs that diminish statin catabolism is associated with myopathy and rhabdomyolysis in ~50% of cases. The most common statin interactions occurred with fibrates, especially gemfibrozil, 38%; cyclosporine, 4%; digoxin, 5%; warfarin, 4%; macrolide antibiotics, 3%; mibefradil, 2%; and azole antifungals, 1%. Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, amiodarone, and nefazodone.

There are a variety of pharmacokinetic mechanisms by which these drugs increase myopathy risk when coadministered with statins. Gemfibrozil, the drug most commonly associated with statin-induced myopathy, inhibits uptake of the active hydroxy acid forms of statins into hepatocytes by OATP2 and interferes with the transformation of most statins by CYPs and glucuronidases. Primarily due to inhibition of OATP2-mediated hepatic uptake, coadministration of gemfibrozil nearly doubles the plasma concentration of rosuvastatin. Other fibrates, especially fenofibrate, do not interfere with the glucuronidation of statins and pose less risk of myopathy when combined with statin therapy. Concomitant therapy with simvastatin, 80 mg daily, and fenofibrate, 160 mg daily, results in no clinically significant pharmacokinetic interaction. Similar results were obtained in a study of low-dose rosuvastatin, 10 mg daily, plus fenofibrate, 67 mg three times a day. When statins are administered with niacin, the myopathy is probably caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction).

Other drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4, including certain macrolide antibiotics (e.g., erythromycin); azole antifungals (e.g., itraconazole); cyclosporine; the antidepressant nefazodone; and HIV protease inhibitors. These pharmacokinetic interactions are associated with increased plasma concentrations of statins and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYP3A4. Fluvastatin is mostly (50–80%) metabolized to inactive metabolites by CYP2C9, but CYP3A4 and CYP2C8 also contribute to its metabolism. Pravastatin is not metabolized to any appreciable extent by CYPs and is excreted unchanged in the urine. Because they are not extensively metabolized by CYP3A4, pravastatin, fluvastatin, and rosuvastatin may be less likely to cause myopathy when used with one of the predisposing drugs. However, because myopathy has occurred with all statins, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy.

The myopathy syndrome is characterized by intense myalgia, first in the arms and thighs and then in the entire body, along with weakness and fatigue. Symptoms progress as long as the statin is continued. Myoglobinuria, renal failure, and death have been reported. Serum CK levels in affected patients typically are tenfold higher than the upper limit of normal. If myopathy is suspected, a blood sample should be drawn to document the presence of a significantly elevated CK level, since many patients complain of muscle pain unrelated to true statin-induced myopathy. The statin, and any other drug suspected of contributing to myopathy, should be discontinued if true myopathy is suspected, even if it is not possible to measure CK activity to confirm the diagnosis. Rhabdomyolysis should be excluded and renal function monitored.

Since myopathy rarely occurs in the absence of combination therapy, routine CK monitoring is not recommended unless the statins are used with a predisposing drug. Such monitoring is not sufficient to protect patients, as myopathy can occur months to years after combined therapy is initiated. As a rule, statins may be combined with one of these predisposing drugs with reduced risk of myopathy if the statin is administered at no more than 25% of its maximal dose (e.g., 10 mg for rosuvastatin and 20 mg for all other statins).

PREGNANCY

The safety of statins during pregnancy has not been established. Women wishing to conceive should not take statins. During their childbearing years, women taking statins should use highly effective contraception (see Chapter 57). Nursing mothers also are advised to avoid statins.

THERAPEUTIC USES Each statin has a recommended starting dose that reduces LDL-C by 20–30%. Dyslipidemic patients frequently remain on their initial dose and thus remain undertreated. For this reason, it is advisable to start each patient on a dose that will achieve the patient's target goal for LDL-C lowering. For example, a patient with a baseline LDL-C of 150 mg/dL and a goal of 100 mg/dL requires a 33% reduction in LDL-C and should be started on a dose expected to provide it (Table 35–7). Hepatic cholesterol synthesis is maximal between midnight and 2:00 AM. Thus, statins with half-lives of 4 hours or less (all but atorvastatin and rosuvastatin) should be taken in the evening.

The manufacturer's initial recommended dose of lovastatin (MEVACOR) is 20 mg and is slightly more effective if taken with the evening meal than if it is taken at bedtime. The dose of lovastatin may be increased every 3–6 weeks up to a maximum of 80 mg/day. The 80-mg dose is slightly (2–3%) more effective if given as 40 mg twice daily. Lovastatin, at 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (ADVICOR). Few patients are appropriate candidates for this fixed-dose combination. Alternate-day statin therapy has been associated with nearly equivalent efficacy (as judged by serum lipid profiles) and reduced cost, and has been proposed as a means to enhance compliance; clinical trials are needed to evaluate the efficacy of alternate-day dosing with regard to reducing clinical events.

The approved starting dose of simvastatin (ZOCOR) for most patients is 20 mg at bedtime unless the required LDL-C reduction exceeds 45% or the patient is a high-risk secondary prevention patient, in which case a 40-mg starting dose is indicated. The maximal dose is 80 mg, and the drug should be taken at bedtime. In patients taking cyclosporine, fibrates, or niacin, the daily dose should not exceed 20 mg.

Pravastatin (PRAVACHOL) therapy is started with a 20- or 40-mg dose that may be increased to 80 mg; it should be taken at bedtime. Since pravastatin is a hydroxy acid, it is bound by bile-acid sequestrants, which reduce its absorption. This is rarely a problem since the resins should be taken before meals and pravastatin should be taken at bedtime. Pravastatin is also marketed in combination with buffered aspirin (PRAVIGARD). The small advantage of combining these two drugs should be weighed against disadvantages inherent in fixed-dose combinations.

The starting dose of fluvastatin (LESCOL) is 20 or 40 mg, and the maximum is 80 mg/day. Like pravastatin, it is administered as a hydroxy acid and should be taken at bedtime, several hours after ingesting a bile-acid sequestrant (if the combination is used).

Atorvastatin (LIPITOR) has a long $t_{1/2}$, which allows dosing at any time of the day. The starting dose is 10 mg, and the maximum is 80 mg/day. Atorvastatin is marketed in combination with the Ca^{2+} -channel blocker amlodipine (CADUET), for patients with hypertension or angina as well as hypercholesterolemia. The physician should weigh any advantage of combination against the associated risks and disadvantages.

Rosuvastatin (CRESTOR) is available in doses ranging between 5 and 40 mg. It has a $t_{1/2}$ of 20–30 hours and may be taken at any time of day. Since experience with rosuvastatin is more limited, treatment should be initiated with 5–10 mg daily, increasing stepwise if needed. If the combination of gemfibrozil with rosuvastatin is used, the dose of rosuvastatin should not exceed 10 mg. Rosuvastatin at a dose of 80 mg (dose not approved by the FDA) was noted to cause proteinuria and hematuria and isolated cases of renal failure. Other statins have also been observed to cause proteinuria, apparently by inhibiting tubular protein reabsorption. Whether statin-induced proteinuria is harmful or beneficial, especially in patients with chronic kidney disease, remains to be determined.

The choice of statins should be based on efficacy (reduction of LDL-C) and cost. Three drugs (lovastatin, simvastatin, and pravastatin) have been used safely in clinical trials involving thousands of subjects for 5 or more years. The documented safety records of these statins should be considered, especially when initiating therapy in younger patients. Once drug treatment is initiated, it almost always is lifelong. Baseline determinations of alanine aminotransferase (ALT) and repeat testing at 3–6 months are recommended. If ALT is normal after the initial 3–6 months, then it need not be repeated more than once every 6–12 months. CK measurements are not done routinely unless the patient also is taking a drug that enhances the risk of myopathy.

STATIN USE BY CHILDREN Some statins are approved for children with heterozygous familial hypercholesterolemia. Atorvastatin, lovastatin, and simvastatin are indicated for children age 11 or older. Pravastatin is approved for children age 8 or older.

STATINS IN COMBINATION WITH OTHER LIPID-LOWERING DRUGS Statins, in combination with the bile acid-binding resins *cholestyramine* and *colestipol*, produce 20–30% greater reductions in LDL-C than statins alone achieve. Preliminary data indicate that *colesevelam hydrochloride* plus a statin lowers LDL-C by 8–16% more than statins alone. Niacin also can enhance the effect of statins, but the occurrence of myopathy increases when statin doses greater than 25% of maximum are used with niacin. The combination of a fibrate (*clofibrate*, gemfibrozil, or fenofibrate) with a statin is particularly useful in patients with hypertriglyceridemia and high LDL-C levels. This combination increases the risk of myopathy but usually is safe with a fibrate at its usual maximal dose and a statin at no more than 25% of its maximal dose. Fenofibrate, which is least likely to interfere with statin metabolism, appears to be the safest fibrate to use with statins. Triple therapy with resins, niacin, and statins can reduce LDL-C by up to 70%. VYTORIN, a fixed combination of simvastatin (10, 20, 40, or 80 mg) and ezetimibe (10 mg), decreased LDL-C levels by up to 60% at 24 weeks.

Bile-Acid Sequestrants

The two established bile-acid sequestrants or resins (*cholestyramine* and *colestipol*) are most often used as second agents if statin therapy does not lower LDL-C levels sufficiently. When used with a statin, *cholestyramine* and *colestipol* usually are prescribed at submaximal doses. Maximal doses can reduce LDL-C by up to 25% but are associated with unacceptable gastrointestinal (GI) side effects (bloating and constipation) that limit compliance. *Colesevelam* is a newer bile-acid sequestrant that is prepared as an anhydrous gel and taken as a tablet. It lowers LDL-C by 18% at its maximum dose. The safety and efficacy of *colesevelam* have not been studied in children or pregnant women.

MECHANISM OF ACTION The bile-acid sequestrants are highly positively charged and bind negatively charged bile acids. The resins are not absorbed, and the bound bile acids are excreted in the stool. Since >95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids and increases hepatic bile-acid synthesis. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins.

The resin-induced increase in bile-acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride >250 mg/dL). In such patients, bile-acid sequestrant therapy may increase triglyceride levels; until this issue is resolved, use of colestevlam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1–2 weeks) monitoring of fasting triglyceride levels until the triglyceride level is stable, or colestevlam should be avoided in these patients.

EFFECTS ON LIPOPROTEIN LEVELS

The reduction in LDL-C by resins is dose-dependent. Doses of 8–12 g of cholestyramine or 10–15 g of colestipol are associated with 12–18% reductions in LDL-C. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25%, but will cause GI side effects that are poorly tolerated by most patients. One to two weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. HDL-C levels increase 4–5%. Statins plus resins or niacin plus resins can reduce LDL-C by as much as 40–60%. Colestevlam, in doses of 3–3.75 g, reduces LDL-C levels by 9–19%.

ADVERSE EFFECTS AND DRUG INTERACTIONS

The resins are generally safe, as they are not systemically absorbed. Since they are administered as chloride salts, rare instances of hyperchloremic acidosis have occurred. Since they increase triglyceride levels, severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol. At present, there are insufficient data on the effect of colestevlam on triglyceride levels.

Cholestyramine and colestipol both are available as a powder that must be mixed with water and drunk as a slurry. The gritty sensation is unpleasant to patients initially but can be tolerated. Colestipol is available in a tablet that reduces the complaint of grittiness but not the GI symptoms. Colestevlam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for GI irritation.

Patients taking cholestyramine and colestipol complain of bloating and dyspepsia, which can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion. Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium, if necessary. Colestevlam may be less likely to cause the dyspepsia, bloating, and constipation observed in patients treated with cholestyramine or colestipol.

Cholestyramine and colestipol interfere with the absorption of many drugs, including some thiazides, furosemide, propranolol, l-thyroxine, digoxin, warfarin, and some of the statins. It is wise to administer all drugs either 1 hour before or 3–4 hours after a dose of cholestyramine or colestipol. Colestevlam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, metoprolol, quinidine, and valproic acid. The maximum concentration and the AUC of sustained-release verapamil are reduced by 31% and 11%, respectively, when the drug is coadministered with colestevlam. The effect of colestevlam on the absorption of other drugs has not been tested; prudence suggests that patients take other medications 1 hour before or 3–4 hours after a dose.

THERAPEUTIC USES

The powdered forms of cholestyramine (4 g/dose) and colestipol (5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with one scoop or packet twice daily, and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than two doses (scoops or packets) twice a day.

Colestevlam hydrochloride (WELCHOL) is available as a solid tablet containing 0.625 g of colestevlam. The starting dose is either three tablets taken twice daily with meals or all six tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

Niacin (Nicotinic Acid)

Niacin, *nicotinic acid* favorably affects virtually all lipid parameters. Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after its conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally for its functions as a vitamin but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are

required for its vitamin effects. Niacin is the best agent available for increasing HDL-C (increments of 30–40%); it also lowers triglycerides by 35–45% (as effectively as fibrates and the more potent statins) and reduces LDL-C levels by 20–30%. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly, by ~40%; however, this is unnecessary because adequate control of other lipid abnormalities mitigates the atherogenic effects of elevated Lp(a). Despite its salutary effect on lipids, niacin use is limited by side effects (*see below*).

In adipose tissue, niacin inhibits the lipolysis of triglycerides by hormone-sensitive lipase, which reduces transport of free fatty acids to the liver and decreases hepatic triglyceride synthesis. Niacin may exert its effects on lipolysis by stimulating a GPCR that couples to G_i to inhibit adenylyl cyclase in adipocytes. In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and esterification of fatty acids, effects that increase apoB degradation. Reduced triglyceride synthesis decreases hepatic VLDL production, which reduces LDL levels. Niacin also enhances LPL activity, promoting the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing fractional clearance of apoA-I in HDL rather than by enhancing HDL synthesis.

Regular or crystalline niacin in doses of 2–6 g/day reduces triglycerides by 35–50%, and the maximal effect occurs within 4–7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5–6 g/day, but 3–6 weeks are required for maximal effect. Average increases in HDL-C of 15–30% occur in patients with low HDL-C levels; greater increases may occur in patients with normal HDL-C levels at baseline. Combination therapy with resins can reduce LDL-C levels by as much as 40–60%.

ABSORPTION, FATE, AND EXCRETION

The doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations are achieved within 30–60 minutes. The $t_{1/2}$ is ~60 minutes, which accounts for the necessity of twice- or thrice-daily dosing. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of drug is excreted in the urine as unchanged nicotinic acid.

ADVERSE EFFECTS

Niacin's side effects limit patient compliance. Cutaneous effects include flushing and pruritus of the face and upper trunk, rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin-mediated. Flushing is worse when therapy is initiated or the dosage is increased, but ceases in most patients after 1–2 weeks of a stable dose. Aspirin alleviates the flushing in many patients. Flushing recurs if only one or two doses are missed and is more likely to occur when niacin is consumed with hot beverages (coffee, tea) or with ethanol-containing beverages. Flushing is minimized if therapy is initiated with low doses (100–250 mg twice daily) and if the drug is taken after breakfast or supper. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions or creams containing salicylic acid. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin because it can reactivate ulcer disease.

The most common serious side effects are hepatotoxicity, manifested as elevated serum transaminases and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin have been reported to cause severe liver toxicity, and sustained-release niacin can cause fulminant hepatic failure. An extended-release niacin (NIASPAN), appears to be less likely to cause severe hepatotoxicity, perhaps because it is administered only once daily. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take >2 g of sustained-release, over-the-counter preparations. Affected patients experience flu-like fatigue and weakness. Usually, serum transaminases are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially.

In patients with diabetes mellitus, niacin should be used cautiously, since niacin-induced insulin resistance can cause severe hyperglycemia. Niacin use in patients with diabetes mellitus often mandates a change to insulin therapy. If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels; a history of gout is a relative contraindication for niacin use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. Niacin, at doses used in humans, has been associated with birth defects in animal models and should not be taken by pregnant women.

THERAPEUTIC USES

Niacin is indicated for hypertriglyceridemia and elevated LDL-C; it is especially useful in patients with both hypertriglyceridemia and low HDL-C levels. Crystalline niacin (immediate-release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6–8 hours after ingestion. NIASPAN is the only preparation of niacin that is FDA-approved for treating dyslipidemia; it requires a prescription.

Crystalline niacin tablets are available over the counter in a variety of strengths. To minimize the flushing and pruritus, it is best to start with a low dose (e.g., 100 mg twice daily taken after breakfast and supper). The dose may be increased stepwise every 7 days by 100–200 mg to a total daily dose of 1.5–2 g. After 2–4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. Lipid levels should be checked and the dose increased further until the desired effect on plasma lipids is achieved. After a stable dose is attained, blood should be drawn every 3–6 months to monitor for the various toxicities.

Since concurrent use of niacin and a statin can cause myopathy, the statin should be administered at no more than 25% of its maximal dose. Patients also should be instructed to discontinue therapy if myalgias occur. Routine measurement of CK in patients taking niacin and statins does not assure that severe myopathy will be detected before onset of symptoms, as patients have developed myopathy after several years of concomitant use of niacin with a statin.

Over-the-counter, sustained-release niacin preparations and NIASPAN are effective up to a total daily dose of 2 g/day. All doses of sustained-release niacin, but particularly those >2 g/day, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use. The potential for severe liver damage should preclude its use in most patients. NIASPAN may be less likely to cause hepatotoxicity.

Fibric Acid Derivatives: PPAR Activators

Clofibrate is a halogenated fibric acid derivative. Gemfibrozil is a nonhalogenated compound that is distinct from the halogenated fibrates. A number of fibric acid analogs (e.g., fenofibrate, bezafibrate, and ciprofibrate) have been developed and are used in Europe and elsewhere. The mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Many of their effects on blood lipids are mediated by their interaction with peroxisome proliferator activated receptors (PPARs), which regulate gene transcription. Fibrates bind to PPAR α , which is expressed primarily in the liver and brown adipose tissue and to a lesser extent in kidney, heart, and skeletal muscle. Fibrates reduce triglycerides through PPAR α -mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apoC-III.

LDL levels rise in many patients treated with gemfibrozil, especially those with hypertriglyceridemia. However, LDL levels are unchanged or fall in others, especially those whose triglyceride levels are not elevated or who are taking a second-generation agent e.g., fenofibrate, bezafibrate, or ciprofibrate. The decrease in LDL levels may partly be due to changes in the cholesterol and triglyceride contents of LDL that are mediated by CETP; such changes can alter the affinity of LDL for the LDL receptor.

The effects of the fibrates on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used. Patients with type III hyperlipoproteinemia (dysbetalipoproteinemia) are among the most sensitive responders to fibrates. Elevated triglyceride and cholesterol levels are dramatically lowered, and xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridemia (e.g., triglycerides <400 mg/dL), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations ~15%; LDL-C levels may be unchanged or increase. The second-generation agents, such as fenofibrate, bezafibrate, and ciprofibrate, lower VLDL levels to a degree similar to that produced by gemfibrozil, but they also are more likely to decrease LDL levels by 15–20%. In patients with more marked hypertriglyceridemia (e.g., 400–1000 mg/dl), a similar fall in triglycerides occurs, but LDL increases of 10–30% are seen frequently. Normotriglyceridemic patients with heterozygous familial hypercholesterolemia usually experience little change in LDL levels with gemfibrozil; with the other fibric acid agents, reductions as great as 20% may occur.

Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and as much fat from the diet as possible, fibrates help both by increasing triglyceride clearance and by decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

ABSORPTION, FATE, AND EXCRETION

All of the fibrates are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. The ester bond is hydrolyzed rapidly, and peak plasma concentrations are attained within 1–4 hours. More than 95% of these drugs are bound to plasma protein, mainly to albumin. The half-lives of fibrates differ significantly, ranging from 1 hour (gemfibrozil) to 20 hours (fenofibrate). The drugs distribute widely throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates; 60–90% of an oral dose is excreted in the urine, with smaller amounts appearing in the feces. Excretion is impaired in renal failure and fibrates are contraindicated in such patients.

ADVERSE EFFECTS AND DRUG INTERACTIONS

Fibric acid compounds usually are well tolerated. Side effects, most often GI-related, may occur in 5–10% of patients but most often are not sufficient to cause drug discontinuation. Other infrequent side effects include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate reportedly can potentiate the action of oral anticoagulants by displacing them from their binding sites on albumin; thus, monitoring of the prothrombin time and reduction in anticoagulant dosage may be appropriate.

Myopathy occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate, and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. Statin doses therefore should be reduced when a statin plus a fibrate are combined. Several drug interactions may contribute to this adverse response. Gemfibrozil inhibits hepatic uptake of statins by OATP2 and also competes for the same glucuronosyl transferases that metabolize most statins. Thus, levels of both drugs may increase with coadministration. Patients taking this combination should be told about potential symptoms and followed at 3-month intervals with careful history and determination of CK values until a stable pattern is established. Until there is more experience, patients taking fibrates with rosuvastatin should be followed especially closely even at low doses (5–10 mg) of rosuvastatin. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation; thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All fibrates increase the lithogenicity of bile. Clofibrate has been associated with increased risk of gallstone formation; gemfibrozil and fenofibrate reportedly do not increase biliary tract disease. Renal failure and hepatic dysfunction are relative contraindications to fibrate therapy. Combined statin-fibrate therapy should be avoided in patients with impaired renal function. Gemfibrozil should be used with caution and at a reduced dosage to treat the hyperlipidemia of renal failure. Fibrates should not be used by children or pregnant women.

THERAPEUTIC USES Clofibrate is available for oral administration and may be useful in patients who do not tolerate gemfibrozil or fenofibrate. The usual dose is 2 g/day in divided doses. Gemfibrozil (LOPID) is usually administered as a 600-mg dose taken twice a day, 30 minutes before the morning and evening meals. The TRICOR brand of fenofibrate is available in tablets of 48 and 145 mg. The usual daily dose is 145 mg. Generic fenofibrate (LOFIBRA) is available in capsules containing 67, 134, and 200 mg. TRICOR, 145 mg, and LOFIBRA, 200 mg, are equivalent doses.

Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia and for subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dL) who are at risk for pancreatitis. Fibrates appear to have an important role in subjects with high triglycerides and low HDL-C levels associated with the metabolic syndrome or type 2 diabetes mellitus. In these settings, the LDL levels should be monitored; if LDL levels rise, the addition of a low dose of a statin may be needed. Many experts now treat such patients first with a statin, and then add a fibrate, based on the reported benefit of gemfibrozil therapy. If this combination is used, there should be careful monitoring for myopathy.

Ezetimibe and the Inhibition of Dietary Cholesterol Uptake

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by 15–20% and is used primarily as adjunctive therapy with statins. Ezetimibe does not affect intestinal triglyceride absorption. In human subjects, ezetimibe reduced cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis, which can be inhibited with a cholesterol synthesis inhibitor such as a statin. The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons. The reduced cholesterol content

of chylomicrons diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins.

Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma.

As monotherapy, ezetimibe is limited to the small group of statin-intolerant patients. The actions of ezetimibe, which inhibits intestinal cholesterol absorption and enhances cholesterol biosynthesis, are complementary to those of statins, and there is a further reduction of 15–20% in LDL-C when ezetimibe is combined with any statin at any dose. Increasing statin dosages from the usual starting dose of 20–80 mg normally yields only an additional 12% reduction in LDL-C, whereas adding ezetimibe, 10 mg daily, to 20 mg of a statin will reduce LDL-C by an additional 18–20%. A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) is available (VYTORIN). At the highest simvastatin dose (80 mg), plus ezetimibe (10 mg), average LDL-C reduction was 60%, exceeding that attained with any statin as monotherapy.

ABSORPTION, FATE, AND EXCRETION

Ezetimibe is highly water insoluble. After ingestion, it is glucuronidated in the intestinal epithelium, absorbed, and enters an enterohepatic recirculation. Pharmacokinetic studies indicate that ~70% is excreted in the feces and ~10% in the urine (as a glucuronide conjugate). Bile acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be coadministered. Otherwise, no significant drug interactions have been reported.

ADVERSE EFFECTS AND DRUG INTERACTIONS

Ezetimibe rarely can cause allergic reactions. It has been associated with myopathy, more commonly in association with statins but also when used as monotherapy. The mechanism for this adverse effects is unknown. The safety of ezetimibe during pregnancy has not been established. Since all statins are contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.

THERAPEUTIC USES

Ezetimibe (ZETIA) is available as a 10-mg tablet that may be taken at any time of day irrespective of food.

SECTION VI

DRUGS AFFECTING GASTROINTESTINAL FUNCTION

36

PHARMACOTHERAPY OF GASTRIC ACIDITY, PEPTIC ULCERS, AND GASTROESOPHAGEAL REFLUX DISEASE

The acid-peptic diseases are those disorders in which gastric acid and pepsin are necessary, but usually not sufficient, pathogenic factors. Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia and/or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the lower esophageal sphincter pressure, or stimulating esophageal motility (see Chapter 37). In the stomach, mucus and bicarbonate, stimulated by the local generation of prostaglandins, protect the gastric mucosa. If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of these acid-related disorders are accomplished either by decreasing the level of gastric acidity or by enhancing mucosal protection. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases has stimulated new approaches to prevention and therapy.

PHYSIOLOGY OF GASTRIC SECRETION

The regulation of gastric acid secretion is shown in Figure 36-1.

GASTRIC DEFENSES AGAINST ACID

The high $[H^+]$ in the gastric lumen requires defense mechanisms to protect the esophagus and the stomach. The primary esophageal defense is the lower esophageal sphincter, which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow, perhaps because of the high metabolic activity and oxygen requirements of the gastric mucosa. One key defense is the secretion of a mucus layer that protects gastric epithelial cells. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by prostaglandins E_2 and I_2 , which also directly inhibit gastric acid secretion by parietal cells. Thus, alcohol, aspirin, and other drugs that inhibit prostaglandin formation decrease mucus secretion and predispose to the development of acid-peptic disease. A second important part of the normal mucosal defense is the secretion of bicarbonate ions by superficial gastric epithelial cells. Bicarbonate neutralizes the acid in the region of the mucosal cells, thereby raising pH and preventing acid-mediated damage.

PROTON PUMP INHIBITORS

CHEMISTRY, MECHANISM OF ACTION, AND PHARMACOLOGY The most potent suppressors of gastric acid secretion are inhibitors of the gastric H^+,K^+ -ATPase (proton pump) (Figure 36-2A). In typical doses, these drugs diminish the daily production of acid (basal and stimulated) by 80–95%. Five proton pump inhibitors are available for clinical use: *omeprazole* (PRILOSEC, RAPINEX, ZEGERID) and its S-isomer, *esomeprazole* (NEXIUM), *lansoprazole* (PREVACID), *rabeprazole* (ACIPHEX), and *pantoprazole* (PROTONIX). These drugs have different substitutions on their pyridine and/or benzimidazole groups but are remarkably similar in their pharmacological properties. Omeprazole is a racemate; the S-isomer, esomeprazole (S-omeprazole), is eliminated less rapidly than R-omeprazole, which theoretically provides a therapeutic advantage because of the increased $t_{1/2}$. All proton pump inhibitors have equivalent efficacy at comparable doses.

Proton pump inhibitors are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (Figure 36-2), trapping the drug so that it cannot diffuse back across the

FIGURE 36-1 *Physiological and pharmacological regulation of gastric secretion: the basis for therapy of acid-peptic disorders.* Shown are the interactions among an enterochromaffin-like (ECL) cell that secretes histamine, a parietal cell that secretes acid, and a superficial epithelial cell that secretes cytoprotective mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (-). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers, while 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include: acetylcholine (ACh), muscarinic (M), and nicotinic (N) receptors; gastrin, cholecystokinin receptor 2 (CCK₂); histamine (HIST), H₂ receptor; and prostaglandin E₂ (PGE₂), EP₃ receptor. Drug actions are indicated by dashed lines. A blue X indicates targets of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in blue are drugs used to treat acid-peptic disorders. NSAIDs are nonsteroidal antiinflammatory drugs and are ulcerogenic.

canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H⁺,K⁺-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24–48 hour) suppression of acid secretion, despite the much shorter plasma half-lives (0.5–2 hours) of the parent compounds. Because they block the final step in acid production, the proton pump inhibitors are effective in acid suppression regardless of other stimulating factors.

To prevent degradation of proton pump inhibitors by acid in the gastric lumen, oral dosage forms are supplied in different formulations: (1) enteric-coated drugs contained inside gelatin capsules (omeprazole, esomeprazole, and lansoprazole); (2) enteric-coated granules supplied as a powder for suspension (lansoprazole); (3) enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole); and (4) powdered drug combined with sodium bicarbonate (omeprazole). The delayed-release and enteric-coated tablets dissolve only at alkaline pH, while admixture of omeprazole with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. In patients for whom the oral route of administration is not available and those requiring immediate acid suppression can be treated parenterally with pantoprazole or lansoprazole. A single intravenous bolus of 80 mg of pantoprazole inhibits acid production by 80–90% within an hour, and this inhibition persists for up to 21 hours, permitting once-daily dosing to achieve the desired degree of hypochlorhydria. The dose of intravenous pantoprazole for gastroesophageal reflux disease is 40 mg daily for up to 10 days. Higher doses (e.g., 160–240 mg in divided doses) are used to manage hypersecretory conditions such as the Zollinger-Ellison syndrome. An intravenous formulation of esomeprazole is available in Europe but not in the U.S.

FIGURE 36-2 Proton pump inhibitors. **A.** Inhibitors of gastric H^+,K^+ -ATPase (proton pump). **B.** Conversion of omeprazole to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. The other three proton pump inhibitors undergo analogous conversions.

PHARMACOKINETICS

Since an acidic pH in the parietal cell acid canaliculi is required for drug activation, and since food stimulates acid production, these drugs ideally should be given about 30 minutes before meals.

Once in the small bowel, proton pump inhibitors are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Several polymorphic variants of CYP2C19 have been identified. Asians are more likely than Caucasians or African Americans to have the CYP2C19 genotype that correlates with slow metabolism of proton pump inhibitors (23% vs. 3%, respectively), which may contribute to heightened efficacy and/or toxicity in this ethnic group.

It may take 2–5 days of therapy with once-daily dosing to achieve the 70% inhibition of proton pumps that is seen at steady state. Since proton pump inhibition is irreversible, acid secretion is suppressed for 24–48 hours, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells.

Chronic renal failure does not lead to accumulation of the proton pump inhibitors with once-a-day dosing. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole; thus, in patients with severe hepatic disease, dose reduction is recommended for esomeprazole and should be considered for lansoprazole.

ADVERSE EFFECTS AND DRUG INTERACTIONS

Proton pump inhibitors generally cause remarkably few adverse effects. The most common are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, and rashes also have been reported. Proton pump inhibitors can interact with warfarin (esomeprazole, lansoprazole, omeprazole, and rabeprazole), diazepam (esomeprazole and omeprazole), and cyclosporine (omeprazole and rabeprazole). Omeprazole inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsychotic drugs, tacrine, and theophylline).

Loss of gastric acidity from chronic proton pump inhibitor treatment may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic therapy, with proton pump inhibitors has been linked to increased frequency of hip fractures, possibly secondary to decreased absorption of calcium.

Hypergastrinemia is more frequent and more severe with proton pump inhibitors than with H₂ receptor antagonists, and gastrin levels of >500 ng/L occur in ~5–10% of users with chronic omeprazole administration. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid upon drug discontinuation (see below). The proton pump inhibitors have a long record of use worldwide without the emergence of major safety concerns.

THERAPEUTIC USES Proton pump inhibitors are used principally to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, that is either complicated or unresponsive to treatment with H₂ receptor antagonists. Proton pump inhibitors also are the mainstay in the treatment of pathological hypersecretory conditions, such as the Zollinger-Ellison syndrome. Lansoprazole is FDA-approved for treatment and prevention of recurrence of nonsteroidal anti-inflammatory drug (NSAID)-associated gastric ulcers in patients who continue NSAID use and for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections.

In children, omeprazole is safe and effective for treatment of erosive esophagitis and GERD. Younger patients generally have increased metabolic capacity, resulting in the need for higher dosages of omeprazole per kilogram in children compared to adults.

H₂ RECEPTOR ANTAGONISTS

The H₂ receptor antagonists were the first truly effective drugs for the therapy of acid-peptic disease, and their long history of safety and efficacy with the eventually led to their availability without a prescription. Increasingly, proton pump inhibitors (some also available OTC) are replacing the H₂ receptor antagonists in clinical practice.

CHEMISTRY; MECHANISM OF ACTION; PHARMACOLOGY The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells. Four different H₂ receptor antagonists, which differ mainly in their pharmacokinetics and propensity to cause drug interactions, are available in the U.S. (Figure 36–3): *cimetidine* (TAGAMET), *ranitidine* (ZANTAC), *famotidine* (PEPCID), and *nizatidine* (AXID). These drugs are less potent than proton pump inhibitors but still suppress 24-hour gastric acid secretion by ~70%. The H₂ receptor antagonists predominantly inhibit basal acid secretion, which accounts for their efficacy in suppressing nocturnal acid secretion. Because the most important determinant of duodenal ulcer healing is the level of nocturnal acidity, evening dosing of H₂ receptor antagonists is adequate therapy in most instances.

All four H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available. When the oral or nasogastric routes are not an option, these drugs can be given in intermittent intravenous boluses or by continuous intravenous infusion.

PHARMACOKINETICS

The H₂ receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations within 1–3 hours. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4–5 hours (cimetidine), 6–8 hours (ranitidine), or 10–12 hours (famotidine). Unlike proton pump inhibitors, only a small percentage of H₂ receptor antagonists are protein-bound. Liver disease per se is not an indication for dose adjustment. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce doses of H₂ receptor antagonists in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of the drugs.

ADVERSE REACTIONS AND DRUG INTERACTIONS

The H₂ receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects; including diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less common adverse effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration or in elderly subjects. Long-term use of cimetidine at high doses decreases testosterone binding to the androgen receptor and inhibits a CYP that hydroxylates estradiol. Clinically, these effects can cause galactorrhea in women and gynecomastia, reduced sperm count, and impotence in men. Several reports have associated H₂ receptor antagonists with various blood dyscrasias, including thrombocytopenia. H₂ receptor antagonists cross the placenta and are excreted in breast milk.

FIGURE 36-3 Histamine and H₂ receptor antagonists.

THERAPEUTIC USES The major therapeutic indications for H₂ receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers.

TOLERANCE AND REBOUND WITH ACID-SUPPRESSING MEDICATIONS

Tolerance to the acid-suppressing effects of H₂ receptor antagonists may account for a diminished therapeutic effect with continued drug administration. Tolerance can develop within 3 days of starting treatment and may be resistant to increased doses. Diminished sensitivity may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells. Proton pump inhibitors, despite even greater elevations of endogenous gastrin, do not cause this phenomenon, probably because their site of action is distal to the action of histamine on acid release. Rebound increases in gastric acidity can occur when either of these drug classes is discontinued, possibly reflecting changes in function and justifying a gradual drug taper or the substitution of alternatives (*e.g.*, antacids) in at-risk patients.

AGENTS THAT ENHANCE MUCOSAL DEFENSE

Prostaglandin Analogs: Misoprostol

CHEMISTRY; MECHANISM OF ACTION; PHARMACOLOGY PGE₂ and PGI₂ are the major prostaglandins synthesized by the gastric mucosa. They bind to the EP₃ receptor on parietal cells (*see* Chapter 26) and stimulate the G_i pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Since NSAIDs diminish prostaglandin formation by inhibiting cyclooxygenase, synthetic prostaglandin analogs offer a logical approach to reducing NSAID-induced mucosal damage (*see* below). *Misoprostol* (15-deoxy-16-hydroxy-16-methyl-PGE₁; CYTOTEC) is a synthetic analog of PGE₁. The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100–200 μg significantly inhibit basal acid secretion (up to 95% inhibition) or food-stimulated acid secretion (up to 85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg four times a day.

PHARMACOKINETICS

Misoprostol is rapidly absorbed after oral administration and then is rapidly and extensively de-esterified to form misoprostol acid, the principal and active metabolite of the drug. Some of this conversion may occur in the parietal cells. A single dose inhibits acid production within 30 minutes; the therapeutic effect peaks at 60–90 minutes and lasts for up to 3 hours. Food and antacids decrease the rate of misoprostol absorption, resulting in delayed and decreased peak plasma concentrations of the active metabolite. The free acid is excreted mainly in the urine, with an elimination t_{1/2} of about 20–40 minutes.

ADVERSE EFFECTS

*Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose-related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe or protracted cases may necessitate drug discontinuation. Misoprostol can cause clinical exacerbations of inflammatory bowel disease (*see* Chapter 38) and should be avoided in patients with this disorder. Misoprostol is contraindicated during pregnancy because it can increase uterine contractility.*

THERAPEUTIC USE Misoprostol is FDA-approved to prevent NSAID-induced mucosal injury. However, adverse effects and the inconvenience of four-times-daily dosing limit its use.

SUCRALFATE

CHEMISTRY; MECHANISM OF ACTION; PHARMACOLOGY In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. *Sucralfate* (CARAFATE) consists of the octasulfate of sucrose to which Al(OH)₃ has been added. In an acid environment (pH <4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 hours after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have additional cytoprotective effects, including stimulation of local production of prostaglandins and epidermal growth factor.

THERAPEUTIC USES Because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over proton pump inhibitors and H₂ receptor antagonists for the prophylaxis of stress ulcers (*see* below). Due to its unique mechanism of action, sucralfate also has been used in several other conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers.

Since it is activated by acid, sucralfate should be taken on an empty stomach 1 hour before meals. The use of antacids within 30 minutes of a dose of sucralfate should be avoided. The usual dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy).

ADVERSE EFFECTS

The most common side effect of sucralfate is constipation (~2%). As some aluminum can be absorbed, sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload. Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketoconazole, and fluoroquinolone antibiotics.

Sucralfate therefore should be taken at least 2 hours after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may lead to the formation of bezoars in some patients, particularly in those with underlying gastroparesis.

ANTACIDS

Antacids continue to be used by patients for a variety of indications. Many factors, including palatability, determine the effectiveness and choice of antacid (Table 36–1). Although sodium bicarbonate effectively neutralizes acid, it is very water-soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. Depending on particle size and crystal structure, CaCO_3 rapidly and effectively neutralizes gastric H^+ , but the release of CO_2 from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration.

Combinations of Mg^{2+} (rapidly reacting) and Al^{3+} (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. *Magaldrate* is a hydroxymagnesium aluminate complex that is converted rapidly in gastric acid to $\text{Mg}(\text{OH})_2$ and $\text{Al}(\text{OH})_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of magnesium and aluminum theoretically counteract the adverse effects of each other on the bowel (Al^{3+} delays gastric emptying and may cause constipation, while Mg^{2+} exerts the opposite effects), such balance is not always achieved in practice.

Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations that are marketed for “acid indigestion”, particularly those with aspirin, are potentially unsafe in patients predisposed to gastroduodenal ulcers and should not be used.

The relative effectiveness of antacid preparations is expressed as milliequivalents of acid-neutralizing capacity, but antacid doses in practice are titrated simply to relieve symptoms. For uncomplicated ulcers, antacids are given orally 1 and 3 hours after meals and at bedtime. This regimen, providing ~120 mEq of a Mg-Al combination per dose, may be almost as effective as conventional

Table 36–1

Composition and Neutralizing Capacities of Popular Antacid Preparations

Product	milligrams per tablet or per 5 mL				Acid Neutralizing Capacity [†]
	$\text{Al}(\text{OH})_3$	$\text{Mg}(\text{OH})_2$	CaCO_3	Simethicone

[†]Acid-neutralizing capacity, milliequivalents per tablet or per 5 mL.

*magaldrate, a magnesium aluminum hydroxide complex.

The current trend of “reusing” well-known brand names to introduce new products that contain an active ingredient different from expected is a source of confusion that can present a danger to patients.

dosing with an H₂ receptor antagonist. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30–60 minutes. Antacids generally should be administered in suspension form, as this probably has a greater neutralizing capacity than do powder or tablet dosage forms. If tablets are used, they should be thoroughly chewed for maximum effect.

Antacids are cleared from the empty stomach in ~30 minutes. However, the presence of food is sufficient to elevate gastric pH to about 5 for ~1 hour and to prolong the neutralizing effects of antacids for 2–3 hours.

Antacids vary in the extent to which they are absorbed, and hence in their systemic effects. In general, most antacids can elevate urinary pH by about one pH unit. Antacids that contain Al³⁺, Ca²⁺, or Mg²⁺ are absorbed less completely than are those that contain NaHCO₃. With normal renal function, the modest accumulations of Al³⁺ and Mg²⁺ do not pose a problem; with renal insufficiency, however, absorbed Al³⁺ can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca²⁺ is absorbed, causing a transient hypercalcemia. Although this is not a problem in normal patients, the hypercalcemia from as little as 3–4 g of CaCO₃ per day can be problematic in patients with uremia. In the past, when large doses of NaHCO₃ and CaCO₃ were administered with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca²⁺ (five to forty 500-mg tablets per day of calcium carbonate) taken with milk. Patients may be asymptomatic or may present with the insidious onset of hypercalcemia, reduced secretion of parathyroid hormone, retention of phosphate, precipitation of Ca²⁺ salts in the kidney, and renal insufficiency.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals), by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al³⁺ and Mg²⁺ antacids also are notable for their propensity to chelate other drugs present in the gastrointestinal (GI) tract, forming insoluble complexes that pass through the GI tract without absorption. Thus, it generally is prudent to avoid concurrent administration of antacids and drugs intended for systemic absorption. Most interactions can be avoided by taking antacids 2 hours before or after ingestion of other drugs.

OTHER ACID SUPPRESSANTS AND CYTOPROTECTANTS

Rebamipide (2-(4-chlorobenzoylamino)-3-[2(1*H*)-quinolinon-4-yl]-propionic acid) is used for ulcer therapy in parts of Asia. It appears to exert a cytoprotective effect both by increasing prostaglandin generation in gastric mucosa and by scavenging reactive oxygen species. *Ecabet* (GASTROM; 12-sulfodehydroabietic acid monosodium), which appears to increase the formation of PGE₂ and PGI₂, also is used for ulcer therapy, mostly in Japan. *Carbenoxolone*, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Its exact mechanism of action is not clear, but it may alter the composition and quantity of mucin. Unfortunately, carbenoxolone inhibits the type 2 isozyme of 11β-hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 59). *Bismuth compounds* (see Chapter 37) may be as effective as cimetidine in patients with peptic ulcers and are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects. Bismuth compounds are an important component of many anti-*Helicobacter* regimens (see below); however, bismuth compounds seldom are used alone as cytoprotective agents.

SPECIFIC ACID-PEPTIC DISORDERS AND THERAPEUTIC STRATEGIES

The success of acid-suppressing agents in a variety of conditions is critically dependent upon their ability to keep intragastric pH above a certain target, generally pH 3–5; this target varies to some extent with the disease being treated.

Gastroesophageal Reflux Disease

In the U.S., GERD is common, and it is estimated that one in five adults has symptoms of heartburn or gastroesophageal regurgitation at least once a week. Although most cases follow a relatively benign course, GERD in some individuals can cause severe erosive esophagitis; serious sequelae include stricture formation and Barrett's metaplasia (replacement of squamous by intestinal columnar epithelium), which, in turn, is associated with a small but significant risk of adenocarcinoma. Most of the

symptoms of GERD reflect injurious effects of the refluxed gastric content on the esophageal epithelium, providing the rationale for suppression of gastric acid. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis. Proton pump inhibitors clearly are more effective than H_2 receptor antagonists in achieving these goals. Healing rates after 4 weeks and 8 weeks of therapy with proton pump inhibitors are ~80% and 90%, respectively, while the corresponding healing rates with H_2 receptor antagonists are 50% and 75%, respectively. Indeed, proton pump inhibitors are so effective that their empirical use is advocated as a therapeutic trial in patients in whom GERD is suspected to play a role in the pathogenesis of symptoms. Because of the wide clinical spectrum associated with GERD, the therapeutic approach is best tailored to the level of severity in the individual patient (Figure 36–4). In general, the optimal dose for each patient is determined based upon symptom control, and routine measurement of esophageal pH to guide dosing is not recommended. Strictures associated with GERD also respond better to proton pump inhibitors than to H_2 receptor antagonists. Unfortunately, one of the other complications of GERD, Barrett's esophagus, appears to be more refractory to therapy, as neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia or to decrease the incidence of tumors.

Regimens for the treatment of GERD with proton pump inhibitors and histamine H_2 receptor antagonists are listed in Table 36–2. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H_2 receptor antagonists, twice-daily dosing usually is required. Antacids are recommended only for the patient with mild, infrequent episodes of heartburn. Prokinetic agents (*see* Chapter 37) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications.

GERD AND PREGNANCY

Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H_2 receptor antagonists can be used, with ranitidine having the most established track record in this setting. Proton pump inhibitors are reserved for women with intractable symptoms or complicated reflux disease. In these situations, lansoprazole is preferred based on animal data and available experience in pregnant women.

Peptic Ulcer Disease

The pathophysiology of peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, prostaglandin, nitric oxide, and other peptides and growth factors) and injurious factors (acid and pepsin). On average, patients with duodenal ulcers produce more acid

Severity of GERD

Stage I

Sporadic uncomplicated heartburn, often in setting of known precipitating factor. Often not the chief complaint. Less than 2–3 episodes per week. No additional symptoms.

Medical Management

Lifestyle modification, including diet, positional changes, weight loss, *etc.* Antacids and/or histamine H_2 receptor antagonists as needed.

Stage II

Frequent symptoms, with or without esophagitis. Greater than 2–3 episodes per week.

Proton pump inhibitors more effective than histamine H_2 receptor antagonists.

Stage III

Chronic, unrelenting symptoms; immediate relapse off therapy. Esophageal complications (*e.g.*, stricture, Barrett's metaplasia)

Proton pump inhibitor either once or twice daily.

FIGURE 36–4 General guidelines for the medical management of gastroesophageal reflux disease (GERD). Only medications that suppress acid production or that neutralize acid are shown.

Table 36–2

Antisecretory Drug Regimens for Treatment and Maintenance of GERD

Drug	Dosage
<i>H₂ Receptor Antagonists</i>	
Cimetidine	400*/800* mg <i>bid</i>
Famotidine	20/40 mg <i>bid</i>
Nizatidine	150*/300* mg <i>bid</i>
Ranitidine	150/300 mg <i>bid</i>
<i>Proton Pump Inhibitors</i>	
Esomeprazole	20/40 mg daily/40* mg <i>bid</i>
Lansoprazole	30*/60* mg daily/30* mg <i>bid</i>
Omeprazole	20/40* mg daily/20* mg <i>bid</i>
Pantoprazole	40/80* mg daily/40* mg <i>bid</i>
Rabeprazole	20/40* mg daily/20* mg <i>bid</i>

bid, twice daily.

*Indicates unlabeled use.

than do control subjects, particularly at night (basal secretion). Although patients with gastric ulcers have normal or even diminished acid production, ulcers rarely if ever occur in the complete absence of acid. Presumably, a weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. *H. pylori* and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by Δ cells, and in time, decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production.

NSAIDs also are very frequently associated with peptic ulcers (in up to 60% of patients, particularly those with complications such as bleeding). Topical injury by the luminal presence of the drug appears to play a minor role in the pathogenesis of these ulcers, as evidenced by the fact that ulcers can occur with very low doses of aspirin (10 mg) or with parenteral administration of NSAIDs. The effects of these drugs are instead mediated systemically; the critical element is suppression of COX-1 in the mucosa and decreased production of the cytoprotective prostaglandins PGE₂ and PGI₂.

Table 36–3 summarizes recommendations for drug therapy of gastroduodenal ulcers. Proton pump inhibitors relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂ receptor antagonists, although both classes of drugs are very effective. Peptic ulcer is a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation that *H. pylori* plays a major role in the majority of peptic ulcers (*see below*), prevention of relapse is focused on eliminating this organism from the stomach. Chronic acid suppression, once the mainstay of ulcer prevention, now is used mainly in patients who are *H. pylori*-negative or, in some cases, for maximum prevention of recurrence in patients who have had life-threatening complications.

Intravenous pantoprazole or lansoprazole clearly is the preferred therapy in patients with acute bleeding ulcers. The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

TREATMENT OF HELICOBACTER PYLORI INFECTION *H. pylori*, a gram-negative bacillus, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma. Eradication of this infection is standard care in patients with gastric or duodenal ulcers. Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of *H. pylori* also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment.

Many regimens for *H. pylori* eradication have been proposed. The ideal regimen in this setting should achieve a cure rate of >80%. Five important considerations influence the selection of an eradication regimen (*see Table 36–4*).

Table 36–3

Recommendations for Treatment of Gastroduodenal Ulcers

Drug	Active Ulcer	Maintenance Therapy
<i>H₂ Receptor Antagonists</i>		
Cimetidine	800 mg at bedtime/400 mg twice daily	400 mg at bedtime
Famotidine	40 mg at bedtime	20 mg at bedtime
Nizatidine/ranitidine	300 mg after evening meal or at bedtime/150 mg twice daily	150 mg at bedtime
<i>Proton Pump Inhibitors</i>		
Lansoprazole	15 mg (DU; NSAID risk reduction) daily 30 mg (GU including NSAID-associated) daily	
Omeprazole	20 mg daily	
Rabeprazole	20 mg daily	
<i>Prostaglandin Analogs</i>		
Misoprostol	200 μ g four times daily (NSAID-associated ulcer prevention)*	

DU, duodenal ulcer; GU, gastric ulcer.

*Only misoprostol 800 μ g/day has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction.

The emergence of resistance to clarithromycin and *metronidazole* increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. Clarithromycin resistance is related to mutations that prevent binding of the antibiotic to the ribosomes of the pathogen and is an all-or-none phenomenon. In contrast, metronidazole resistance is relative rather than absolute and may involve several adaptations by the bacteria. In the presence of *in vitro* evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day, quadruple-drug regimen (three antibiotics combined with a proton pump inhibitor) generally is effective therapy.

NSAID-RELATED ULCERS

Chronic NSAID users have a 2–4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens

Table 36–4

Therapy of *Helicobacter pylori* Infection

Triple therapy \times 14 days: [Proton pump inhibitor + clarithromycin 500 mg + (metronidazole 500 mg or amoxicillin 1 g)] twice a day. (Tetracycline 500 mg can be substituted for amoxicillin or metronidazole.)

Quadruple therapy \times 14 days: Proton pump inhibitor twice a day + metronidazole 500 mg three times daily + (bismuth subsalicylate 525 mg + tetracycline 500 mg four times daily)

or

H₂ receptor antagonist twice a day + (bismuth subsalicylate 525 mg + metronidazole 250 mg + tetracycline 500 mg) four times daily

Dosages:

Proton pump inhibitors:	<i>H₂ receptor antagonists:</i>
Omeprazole: 20 mg	Cimetidine: 400 mg
Lansoprazole: 30 mg	Famotidine: 20 mg
Rabeprazole: 20 mg	Nizatidine: 150 mg
Pantoprazole: 40 mg	Ranitidine: 150 mg
Esomeprazole: 40 mg	

(e.g., 8 weeks or longer). Again, proton pump inhibitors are superior to H_2 receptor antagonists and misoprostol in promoting the healing of active ulcers (healing rates of 80–90% for proton pump inhibitors versus 60–75% for the H_2 receptor antagonists) and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration.

STRESS-RELATED ULCERS

Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care. The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H_2 receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of proton pump inhibitors are available, it is likely that they will prove to be equally beneficial.

ZOLLINGER-ELLISON SYNDROME

Patients with this syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid. This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. Proton pump inhibitors are the drugs of choice, usually given at twice the routine dosage for peptic ulcers with the therapeutic goal of reducing acid secretion to 1–10 mmol/h.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

TREATMENT OF DISORDERS OF BOWEL MOTILITY AND WATER FLUX; ANTIEMETICS; AGENTS USED IN BILIARY AND PANCREATIC DISEASE

The gastrointestinal (GI) tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle itself, local nerves (*i.e.*, the enteric nervous system, ENS), the central nervous system (CNS), and humoral pathways. Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 37–1), which is an autonomous collection of nerves within the wall of the GI tract, organized into two connected networks of neurons: the *myenteric (Auerbach's) plexus*, found between the circular and longitudinal muscle layers, and the *submucosal (Meissner's) plexus*, found below the epithelium. The former is responsible for motor control, while the latter regulates secretion, fluid transport, and vascular flow.

OVERVIEW OF FUNCTIONAL AND MOTILITY DISORDERS OF THE BOWEL

GI motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), myopathic, and neuropathic forms of intestinal dysmotility. These disorders can be congenital, idiopathic, or secondary to systemic diseases (*e.g.*, diabetes mellitus or scleroderma). For most of these disorders, treatment remains empirical and symptom-based, reflecting our ignorance of the specific derangements in pathophysiology involved.

PROKINETIC AGENTS AND OTHER STIMULANTS OF GI CONTRACTILITY

Prokinetic agents enhance coordinated GI motility and transit of material in the GI tract. Although ACh, when released from primary motor neurons in the myenteric plexus, is the principal immediate mediator of muscle contractility, most clinically useful prokinetic agents act “upstream” of ACh, at receptor sites on the motor neuron itself, or even more indirectly, on neurons one or two orders removed. These agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. Coordination of activity among the segments of the gut, necessary for propulsion of luminal contents, therefore is maintained.

Cholinergic Agents

CHOLINE DERIVATIVES

ACh itself is not used pharmacologically because it affects all classes of cholinergic receptors (nicotinic and muscarinic; see Chapters 6 and 7) and is degraded rapidly by acetylcholinesterase. Modification of the ACh structure has yielded drugs such as bethanechol that have increased receptor selectivity and that resist enzymatic hydrolysis. In addition to its lack of real prokinetic efficacy, bethanechol has significant side effects resulting from its broad muscarinic effects on contractility and secretion in the GI tract and other organs, including bradycardia, flushing, diarrhea and cramps, salivation, and blurred vision.

ACETYLCHOLINESTERASE INHIBITORS

These drugs inhibit the degradation of ACh by its esterase (see Chapter 8), thereby allowing ACh to accumulate at sites of release. Unlike muscarinic receptor agonists, these parasympathomimetic drugs do not stimulate muscle directly, but rather accelerate GI transit times by enhancing the contractile effects of ACh released at synaptic and neuromuscular junctions. Among these cholinergic muscle stimulants, neostigmine methylsulfate has been used off-label for some GI disorders, particularly those associated with acute colonic pseudo-obstruction (Ogilvie's syndrome) and paralytic ileus. The usual dose in the acute setting is 2–2.5 mg of neostigmine administered intravenously over 3 minutes with continuous monitoring of ECG, blood pressure, and O₂ saturation. Atropine should be available in case of severe bradycardia.

Dopamine Receptor Antagonists

Dopamine is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which apparently result from suppression of ACh release from myenteric motor neurons, are mediated by D₂ receptors. By antagonizing the inhibitory effect of dopamine on myenteric motor neurons,

FIGURE 37-1 The neuronal network that initiates and generates the peristaltic response. Mucosal stimulation leads to release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neuron (1), which then communicates with ascending (2) and descending (3) interneurons in the local reflex pathways. The reflex results in contraction at the oral end via the excitatory motor neuron (6) and aboral relaxation via the inhibitory motor neuron (5). The migratory myoelectric complex (see text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). MP, myenteric plexus; CM, circular muscle; LM, longitudinal muscle; SM, submucosa; Muc, mucosa. (Adapted from Kunze and Furness, 1999, with permission.)

dopamine receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of dopamine receptors in the chemoreceptor trigger zone (see below). Examples of such agents are *metoclopramide* and *domperidone*.

METOCLOPRAMIDE

Chemistry, Mechanism of Action, and Pharmacological Properties The chemical structure of metoclopramide (REGLAN) is:

METOCLOPRAMIDE

The mechanisms of action of metoclopramide involve 5-HT₄ receptor agonism, vagal and central 5-HT₃ antagonism, possible sensitization of muscarinic receptors on smooth muscle, and dopamine receptor antagonism. Metoclopramide, one of the oldest true prokinetic agents, stimulates coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Metoclopramide has no clinically significant effects on large-bowel motility.

Therapeutic Use and Pharmacokinetics Metoclopramide is indicated in symptomatic patients with gastroparesis, in whom it may modestly improve gastric emptying. Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as intestinal intubation or contrast radiography of the GI tract. Although it has been used in patients with postoperative ileus, its ability to improve transit in disorders of small-bowel motility is limited. In general, its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes.

Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a $t_{1/2}$ of 4–6 hours. Peak concentrations occur within 1 hour after a single oral dose; the duration of action is 1–2 hours.

Metoclopramide is available for oral and parenteral use. The usual initial oral dose range is 10 mg, 30 minutes before each meal and at bedtime. The onset of action is within 30–60 minutes after an oral dose. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10–15 minutes) or intravenously (onset of action 1–3 minutes). For prevention of chemotherapy-induced emesis, metoclopramide can be infused at 1–2 mg/kg of body weight, administered over at least 15 minutes, beginning 30 minutes before the chemotherapy is begun and repeated as needed every 2–3 hours. Alternatively, a continuous intravenous infusion may be given (3 mg/kg of body weight before chemotherapy, followed by 0.5 mg/kg of body weight per hour for 8 hours). The usual pediatric dose for gastroparesis is 0.1–0.2 mg/kg of body weight per dose, given 30 minutes before meals and at bedtime.

Adverse Effects The major side effects of metoclopramide include extrapyramidal effects. Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and are reversible upon metoclopramide discontinuation. Tardive dyskinesia also can occur with chronic treatment (months to years) and may be irreversible. Metoclopramide can elevate prolactin levels by blocking the inhibitory effect of dopamine on pituitary lactotropes. Methemoglobinemia has been reported in premature and full-term neonates receiving metoclopramide.

Domperidone; D₂ Receptor Antagonists

In contrast to metoclopramide, domperidone predominantly antagonizes the dopamine D₂ receptor without major involvement of other receptors. It is not available in the U.S. but has been used elsewhere (MOTILUM, others) and has modest prokinetic activity in doses of 10–20 mg three times a day. Although it does not readily cross the blood–brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release.

5-HT Receptor Modulators

5-HT plays an important role in the normal motor and secretory function of the gut (*see* Chapter 11). Indeed, >90% of the total 5-HT in the body exists in the GI tract. The enterochromaffin cell, a specialized cell lining the mucosa of the gut, produces most of this 5-HT and rapidly releases 5-HT in response to chemical and mechanical stimulation (*e.g.*, food boluses; noxious agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5-HT triggers the peristaltic reflex (Figure 37–1) by stimulating intrinsic sensory neurons in the myenteric plexus (*via* variant 5-HT receptors, 5-HT_{1p}, and *via* 5-HT₄ receptors), as well as extrinsic vagal and spinal sensory neurons (*via* 5-HT₃ receptors). Additionally, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes resulting in epithelial secretion. 5-HT receptors also are found on other neurons in the ENS, where they can be either stimulatory (5-HT₃ and 5-HT₄) or inhibitory (5-HT_{1a}). In addition, serotonin also stimulates the release of other neurotransmitters, depending upon the receptor subtype. Thus, 5-HT₁ stimulation of the gastric fundus results in release of nitric oxide and reduces smooth muscle tone. 5-HT₄ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5-HT₃ and 5-HT₄ receptors facilitate interneuronal signaling. Developmentally, 5-HT acts as a neurotrophic factor for enteric neurons *via* the 5-HT_{2B} and 5-HT₃ receptors.

Reuptake of serotonin by enteric neurons and epithelium is mediated by the same mechanism as 5-HT reuptake by serotonergic neurons in the CNS. This reuptake therefore also is blocked by selective serotonin reuptake inhibitors (*see* Chapter 17), which explains the common side effect of diarrhea that accompanies the use of these agents.

TEGASEROD MALEATE

Chemistry, Mechanism of Action, and Pharmacological Properties Tegaserod (ZELNORM), an aminoguanidine indole, is structurally related to serotonin and is a partial 5-HT₄ agonist with negligible affinity for other receptor subtypes. Tegaserod has multiple effects on the GI tract. It stimulates motility and accelerates transit in the esophagus, stomach, small bowel, and ascending colon. It also stimulates chloride secretion. The clinical efficacy of tegaserod has been shown for male and female

patients with constipation-predominant irritable bowel syndrome (see below). In patients with constipation, tegaserod results in mild-to-moderate improvement in stool frequency, with less consistent effects on other parameters such as stool form, bloating, and pain. The absolute improvement is modest at best. It is not clear that the drug has any greater efficacy in this regard than other agents used for constipation.

Tegaserod is available for oral administration in 2-mg and 6-mg tablets and is approved for use in women with constipation-dominant irritable bowel syndrome at a dose of 6 mg twice daily. Tegaserod also is approved for the treatment of chronic constipation.

After oral administration, tegaserod is partially absorbed from the gut, reaching peak plasma levels after ~1 hour. Absorption of tegaserod is best on an empty stomach. Once in circulation, tegaserod is ~98% bound to plasma proteins. Tegaserod is degraded by acid hydrolysis before absorption from the stomach, and by oxidation and glucuronidation in the liver to three inactive N-glucuronide metabolites. Approximately two-thirds of the orally administered dose of tegaserod is excreted unchanged in feces, with the remainder excreted in urine; the drug has a $t_{1/2}$ of ~11 hours.

Diarrhea and headache are the most common side effects of tegaserod, occurring in ~10% of patients. Tegaserod does not appear to have any clinically relevant drug-drug interactions. No dosage adjustment is required in elderly patients or those with mild-to-moderate hepatic or renal impairment, but tegaserod should not be used in patients with severe hepatic or renal impairment.

MOTILIN AGONISTS: MACROLIDES AND ERYTHROMYCIN CHEMISTRY, PHARMACOLOGICAL EFFECTS, AND MECHANISM OF ACTION

Motilin, a 22-amino acid peptide hormone found in the GI M cells and some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. The effects of motilin can be mimicked by erythromycin and by other macrolide antibiotics (see Chapter 46), including oleandomycin, azithromycin, and clarithromycin.

THERAPEUTIC USE

The best-established use of erythromycin as a prokinetic agent is in patients with diabetic gastroparesis, where erythromycin can improve gastric emptying in the short term. Erythromycin-stimulated gastric contractions can be intense and result in “dumping” of relatively undigested food into the small bowel. This potential disadvantage is exploited clinically to clear the stomach of indigestible residue such as plastic tubes or bezoars. Rapid development of tolerance to erythromycin, possibly by down-regulation of the motilin receptor, and undesirable (in this context) antibiotic effects have limited the use of this drug as a prokinetic agent.

A standard dose of erythromycin for gastric stimulation is 3 mg/kg intravenously or 200–250 mg orally every 8 hours. For small-bowel stimulation, a smaller dose (e.g., 40 mg intravenously) may be more useful, as higher doses may actually retard small-bowel motility.

MISCELLANEOUS AGENTS FOR STIMULATING MOTILITY

The GI hormone cholecystokinin (CCK) is released from the intestine in response to meals and delays gastric emptying. Dexloxiglumide is a CCK_1 (or CCK_A)–receptor antagonist that can improve gastric emptying and is being investigated as a treatment for gastroparesis and constipation-dominant irritable bowel syndrome. Clonidine also may be of benefit in patients with gastroparesis. Octreotide acetate (SANDOSTATIN), a somatostatin analog, also is used in some patients with intestinal dysmotility (see below).

OTHER AGENTS THAT SUPPRESS MOTILITY

Smooth muscle relaxants such as organic nitrates and Ca^{2+} channel antagonists (see Chapter 31) often produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in a functional obstruction to the passage of food and severe difficulty in swallowing. Another approach relies on the use of botulinum toxin, injected in doses of 80–200 units directly into the lower esophageal sphincter via an endoscope. This agent inhibits ACh release from nerve endings (see Chapter 9) and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance. However, its effects dissipate over a period of several months, requiring repeated injections. Botulinum toxin also is being used increasingly in other GI conditions such as chronic anal fissures.

LAXATIVES, CATHARTICS, AND THERAPY FOR CONSTIPATION

OVERVIEW OF GI WATER AND ELECTROLYTE FLUX Fluid content is the principal determinant of stool volume and consistency; water normally accounts for 70–85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion and secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge

for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste material *via* the process of defecation. Normally ~8–9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 37–2). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only ~1–1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving ~100 mL of fecal water daily.

Under normal circumstances, these quantities are well within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4–5 L). Neurohumoral mechanisms, pathogens, and drugs can alter these processes, resulting in changes in either secretion or absorption of fluid by the intestinal epithelium. Altered motility also contributes to this process, as the extent of absorption parallels transit time. With decreased motility and excess fluid removal, feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea will occur.

CONSTIPATION: GENERAL PRINCIPLES OF PATHOPHYSIOLOGY AND TREATMENT

Patients use the term constipation not only for decreased frequency, but also for difficulty in initiation or passage, passage of firm or small-volume feces, or a feeling of incomplete evacuation. Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation will have normal colonic transit. These patients either have irritable bowel syndrome or define constipation in terms other than stool frequency. In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility, or less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the recto-anal region. Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions. In any given patient, the predominant factor underlying constipation (propulsive vs. nonpropulsive colonic motility) often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and nonspecific.

Constipation can be corrected by adherence to a fiber-rich (20–30 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs. Constipation related to medications can be corrected by use of alternative drugs where possible, or adjustment of dosage. If nonpharmacological measures alone are inadequate, they may be supplemented with bulk-forming agents or osmotic laxatives. When stimulant laxatives are used, they should be

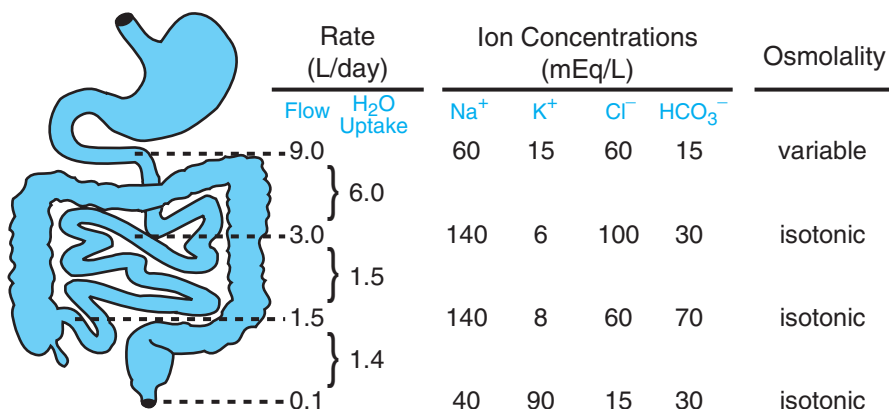

FIGURE 37–2 The approximate volume and composition of fluid that traverses the small and large intestines daily. Of the 9 L of fluid presented to the small intestine each day, 2–3 L are from the diet and the remainder are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4–5 L/day.

administered at the lowest effective dosage and for the shortest period of time to avoid abuse. Habitual use of laxatives may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported.

Laxatives are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable.

The terms *laxatives*, *cathartics*, *purgatives*, *aperients*, and *evacuants* often are used interchangeably. There is a distinction, however, between *laxation* (the evacuation of formed fecal material from the rectum) and *catharsis* (the evacuation of unformed, usually watery fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are cathartics that act as laxatives at low doses.

Laxatives act by: (1) enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms, (2) decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport, or (3) altering motility by either inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions. Based on their actions, laxatives can be classified as shown in Table 37–1; their known effects on motility and secretion are listed in Table 37–2. A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor in the gut. Platelet-activating factor is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility. Nitric oxide also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, and bisacodyl (but not senna), as well as magnesium sulfate.

Laxatives also can be classed by the pattern of effects produced by the usual clinical dosage (Table 37–3).

Dietary Fiber and Supplements

Bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber produces short-chain fatty acids that are trophic for colonic epithelium and increases bacterial mass. Although fermentation of fiber generally decreases stool water, short-chain fatty acids also may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. Fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 37–4). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereals, contains >40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight. Fruits and vegetables contain more *pectins* and *hemicelluloses*, which are more readily fermentable and have less effect on stool transit. *Psyllium husk*, derived from the seed of the plantago herb, is a component of many commercial products for constipation (METAMUCIL, others). Psyllium husk contains a hydrophilic mucilloid that undergoes significant fermentation in the colon, leading to an increase in colonic

Table 37–1

Classification of Laxatives

1. Luminally active agents

- a. Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.)
- b. Osmotic agents (nonabsorbable inorganic salts or sugars)
- c. Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)

2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility)

- Diphenylmethanes (bisacodyl)
- Anthraquinones (senna and cascara)
- Castor oil

3. Prokinetic agents (acting primarily on motility)

- 5-HT₄ receptor agonists
- Opioid receptor antagonists

Table 37–2

Summary of Effects of Some Laxatives on Bowel Function

Agent	Small Bowel		Colon		
	Transit Time	Mixing Contractions	Propulsive Contractions	Mass Actions	Stool Water
Dietary fiber	↓	?	↑	?	↑↑
Magnesium	↓	—	↑	↑	↑↑
Lactulose	↓	?	?	?	↑↑
Metoclopramide	↓	?	↑	?	—
Cisapride	↓	?	↑	?	↑
Erythromycin	↓	?	?	?	?
Naloxone	↓	↓	—	—	↑
Anthraquinones	↓	↓	↑	↑	↑↑
Diphenylmethanes	↓	↓	↑	↑	↑↑
Docusates	—	?	?	?	—

KEY: ↑, increased; ↓, decreased; ?, no data available; —, no effect on this parameter.

Modified from Kreek, 1994, with permission.

bacterial mass. The usual dose is 2.5–4 g (1–3 teaspoonfuls in 250 mL of fruit juice), titrated upwards until the desired goal is reached. A variety of semisynthetic celluloses—*e.g.*, *methylcellulose* (CITRUCEL, others) and the hydrophilic resin *calcium polycarbophil* (FIBERCON, FIBERALL, others), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk.

Osmotically Active Agents

SALINE LAXATIVES Laxatives containing magnesium cations or phosphate anions commonly are called *saline laxatives*: magnesium sulfate, magnesium hydroxide, magnesium citrate, sodium phosphate. Their cathartic action is believed to result from osmotically mediated water retention, which then stimulates peristalsis. Magnesium-containing laxatives may stimulate the release of cholecystokinin, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. For every additional mEq of Mg^{2+} in the intestinal lumen, fecal weight increases by ~7 g. The usual dose of magnesium salts contains 40–120 mEq of Mg^{2+} and produces 300–600 mL of stool within 6 hours.

Table 37–3

Classification and Comparison of Representative Laxatives

Laxative Effect and Latency in Usual Clinical Dosage		
Softening of Feces, 1–3 Days	Soft or Semifluid Stool, 6–8 Hours	Watery Evacuation, 1–3 Hours
<i>Bulk-forming laxatives</i>	<i>Stimulant laxatives</i>	<i>Osmotic laxatives*</i>
Bran	Diphenylmethane derivatives	Sodium phosphates
Psyllium preparations	Bisacodyl	Magnesium sulfate
Methylcellulose		Milk of magnesia
Calcium polycarbophil		Magnesium citrate
<i>Surfactant laxatives</i>	<i>Anthraquinone derivatives</i>	<i>Castor oil</i>
Docusates	Senna	
Poloxamers	Cascara sagrada	
Lactulose		

*Employed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.

Table 37-4

Properties of Different Dietary Fibers

Type of Fiber	Water Solubility	% Fermented
<i>Nonpolysaccharides</i>		
Lignin	Poor	0
Cellulose	Poor	15
<i>Noncellulose polysaccharides</i>		
Hemicellulose	Good	56-87
Mucilages and gums	Good	85-95
Pectins	Good	90-95

Phosphate salts are better absorbed than magnesium-based agents and therefore need to be given in larger doses to induce catharsis. The most frequently employed preparation of sodium phosphate is an oral solution (FLEET PHOSPHO-SODA), which contains 1.8 g of dibasic sodium phosphate and 4.8 g of monobasic sodium phosphate in 10 mL. The usual adult dose is 20–30 mL taken with ample water. For colonic preparation before a procedure, larger doses are used, typically in the form of two doses of 45 mL each, a few hours apart, the evening before the procedure. A newer preparation of phosphate salts (VISICOL) is available in tablet form, containing 1.5 g total sodium phosphate per tablet. For colon preparation, two doses of 20 tablets each (30 g sodium phosphate) are recommended. Adequate fluid intake (1–3 L) is essential for any oral sodium phosphate regimen used for colonic preparation. Sodium phosphate also can be given as an enema for laxative purposes (*see* below).

Magnesium- and phosphate-containing preparations are tolerated reasonably well by most patients. However, they must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities, and in patients on diuretic therapy. Patients taking >45 mL of oral sodium phosphate as a prescribed bowel preparation may experience electrolyte shifts that pose a risk for the development of symptomatic dehydration, renal failure, metabolic acidosis, hypocalcemic tetany, and even death in medically vulnerable populations.

NONDIGESTIBLE SUGARS AND ALCOHOLS *Lactulose* (CEPHULAC, CHRONULAC, others) is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other nonabsorbable sugars such as *sorbitol* and *mannitol* are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and *vincristine*, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15–30 mL at night, with increases as needed up to 60 mL/day in divided doses. Effects may not be seen for 24–48 hours after dosing is begun. Abdominal discomfort or distention and flatulence are relatively common in the first few days of treatment but usually subside with continued administration.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia produced by bacterial metabolism of urea in the colon. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal is to give sufficient lactulose (usually 20–30 g, 3–4 times/day) to produce two to three soft stools a day with a pH of 5–5.5.

POLYETHYLENE GLYCOL-ELECTROLYTE SOLUTIONS Long-chain *polyethylene glycols* (PEGs; molecular weight ~3350) are poorly absorbed, and PEG solutions are retained in the lumen by virtue of their high osmotic nature. When used in high volume, aqueous solutions of PEGs (COLYTE, GOLYTELY, others) produce an effective catharsis and are used widely for colonic cleansing for radiological, surgical, and endoscopic procedures (4 L of this solution taken over 3 hours, beginning at least 4 hours before the procedure). To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride.

Stool-Wetting Agents and Emollients

Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool, and permitting easier defecation. However, these agents also stimulate intestinal fluid and electrolyte secretion and alter intestinal mucosal permeability. *Docusate sodium* (dioctyl sodium sulfosuccinate; COLACE, DOXINATE, others) and *docusate calcium* (dioctyl calcium sulfosuccinate; SURFAK, others), are available in several dosage forms. Despite their widespread use, these agents have marginal, if any, efficacy in most cases of constipation.

Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2–3 days, it penetrates and softens the stool and may interfere with water resorption. The side effects of mineral oil preclude its regular use and include: interference with absorption of fat-soluble vitamins, elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

Stimulant (Irritant) Laxatives

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle and probably induce a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. Included in this group are *diphenylmethane derivatives*, *anthraquinones*, and *ricinoleic acid*.

DIPHENYLMETHANE DERIVATIVES *Sodium picosulfate* (LUBRILAX, SUR-LAX) is widely available outside of the U.S. It is hydrolyzed by colonic bacteria to its active form, and hence acts locally only in the colon. Effective doses vary as much as four- to eightfold in individual patients. Consequently, recommended doses may be ineffective in some patients but may produce cramps and excessive fluid secretion in others.

Bisacodyl is the only diphenylmethane derivative available in the U.S. It is marketed as an enteric-coated preparation (DULCOLAX, CORRECTOL, others) and as a suppository for rectal administration. The usual oral daily dose of bisacodyl is 10–15 mg for adults and 5–10 mg for children 6–12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, and so the laxative effects after an oral dose usually are not produced in <6 hours; taken at bedtime, it will produce its effect the next morning. Suppositories work within 30–60 minutes. Due to the possibility of developing an atonic nonfunctioning colon, bisacodyl should not be used for more than 10 consecutive days.

ANTHRAQUINONE LAXATIVES These derivatives of plants such as *aloe*, *cascara*, and *senna* share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones. For use, monoanthrones are converted to dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms. *Senna* (SENOKOT, EX-LAX) is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia*. *Cascara sagrada* (“sacred bark”; COLAMIN, SAGRADA-LAX) is obtained from the bark of the buckthorn tree. *Aloe* and *cascara sagrada* products sold as laxatives have been withdrawn from the U.S. market.

CASTOR OIL An age-old home remedy seldom recommended now, *castor oil* (PURGE, NEOLOID, others) is derived from the bean of the castor plant, *Ricinus communis*, which contains two well-known noxious ingredients: an extremely toxic protein, *ricin*, and an oil composed chiefly of the triglyceride of ricinoleic acid. The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1–3 hours; however, the usual dose for a cathartic effect is 15–60 mL for adults.

Enemas and Suppositories

Enemas commonly are employed, either by themselves or as adjuncts to bowel preparation regimens, to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that either are osmotically active or irritant; however, their safety and efficacy have not been studied in a rigorous manner. Repeated enemas with tap water or other hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate-containing solution can cause hypocalcemia.

Glycerin is a trihydroxy alcohol that acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5–15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. Some glycerin suppositories contain sodium stearate, which can cause local irritation.

ANTIDIARRHEAL AGENTS

DIARRHEA: GENERAL PRINCIPLES AND APPROACH TO TREATMENT Diarrhea is defined as excessive fluid weight, with 200 g/day representing the upper limit of normal stool water weight for healthy adults. Since stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

Diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. In severe cases, dehydration and electrolyte imbalances are the principal risks, particularly in infants, children, and frail elderly patients. *Oral rehydration therapy* therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This is of particular importance in developing countries, where the use of such therapy saves thousands of lives every year. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Sodium and chloride absorption is linked to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea should be reserved for patients with significant or persistent symptoms. Nonspecific antidiarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea; their principal utility is to provide symptomatic relief in mild cases of acute diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms; they also may induce local complications such as toxic megacolon.

BULK-FORMING AND HYDROSCOPIC AGENTS Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarbophil absorb water and increase stool bulk. They usually are used for constipation (*see above*) but are sometimes useful in mild chronic diarrhea in patients suffering with irritable bowel syndrome. Clays such as *kaolin* (a hydrated aluminum silicate) and other silicates such as *attapulgit* (magnesium aluminum disilicate; DIASORB) bind water avidly and also may bind enterotoxins. However, this effect is not selective and may involve other drugs and nutrients; hence, these agents are best avoided within 2–3 hours of taking other medications. A mixture of kaolin and pectin (a plant polysaccharide) is a popular over-the-counter remedy (KAOPECTOLIN) and may provide useful symptomatic relief of mild diarrhea.

BILE ACID SEQUESTRANTS *Cholestyramine*, *colestipol*, and *colesevalam* effectively bind bile acids and some bacterial toxins. Cholestyramine is useful in the treatment of bile salt–induced diarrhea, as in patients with resection of the distal ileum. In these patients, there is partial interruption of the normal enterohepatic circulation of bile salts, resulting in excessive concentrations reaching the colon and stimulating water and electrolyte secretion (*see below*). Patients with extensive ileal resection (usually >100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine will aggravate the diarrhea.

In patients suspected of having bile salt–induced diarrhea, a trial of cholestyramine can be given at a dose of 4 g of the dried resin (contained in either 9 g [QUESTRAN, others] or 5 g [QUESTRAN LIGHT, others] of powder) four times a day. If successful, the dose may be titrated down to achieve the desired stool frequency.

Cholestyramine resin also is helpful for the relief of pruritus associated with partial biliary obstruction and in conditions such as primary biliary cirrhosis. Cholestyramine increases fecal excretion of bile acids and reduces circulating and eventually systemic levels with relief of pruritus in ~1–3 weeks.

BISMUTH Bismuth compounds have been used to treat a variety of GI diseases and symptoms for centuries. PEPTO-BISMOL (*bismuth subsalicylate*) is an over-the-counter preparation estimated to be used by 60% of U.S. households. It is a crystal complex consisting of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. While 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, caution should be used in patients taking salicylates for other indications.

Bismuth is thought to have antisecretory, anti-inflammatory, and antimicrobial effects. Nausea and abdominal cramps also are relieved by bismuth. Today, the most common antibacterial use of this agent is in the treatment of Helicobacter pylori (see Chapter 36). A recommended dose of the bismuth subsalicylate (30 mL of regular strength PEPTO-BISMOL liquid or 2 tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30–60 minutes, as needed, up to eight times a day. Bismuth products have a long track record of safety at recommended doses, although impaction may occur in infants and debilitated patients. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract.

Antimotility and Antisecretory Agents

OPIOIDS Opioids continue to be widely used in the treatment of diarrhea. They act principally through either μ - or δ -opioid receptors on enteric nerves, epithelial cells, and muscle (see Chapter 21). These mechanisms include effects on intestinal motility (μ receptors), intestinal secretion (δ receptors), or absorption (μ and δ receptors). Commonly used antidiarrheals such as *diphenoxylate*, *difenoxin*, and *loperamide* act principally via peripheral μ -opioid receptors and are preferred over opioids that penetrate the CNS.

Loperamide Loperamide (IMODIUM, IMODIUM A-D, others), a piperidine butyramide derivative with μ -receptor activity, is an orally active antidiarrheal agent. The drug is 40–50 times more potent than morphine as an antidiarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone, an effect that may be of therapeutic value in some patients who suffer from anal incontinence. In addition, loperamide has antisecretory activity against cholera toxin and some forms of *Escherichia coli* toxin.

Because of its effectiveness and safety, loperamide is marketed for over-the-counter distribution and is available in capsule, solution, and chewable forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3–5 hours. It has a $t_{1/2}$ of ~11 hours and undergoes extensive hepatic metabolism. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg/day. If clinical improvement in acute diarrhea does not occur within 48 hours, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2–5 years, 4 mg for ages 6–8 years, and 6 mg for ages 8–12 years. Loperamide is not recommended for use in children younger than 2 years of age.

Diphenoxylate and Difenoxin Diphenoxylate and its active metabolite difenoxin (diphenoxylate acid) are related structurally to meperidine. As antidiarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1–2 hours. Diphenoxylate is rapidly deesterified to difenoxin, which is eliminated with a $t_{1/2}$ of ~12 hours. Both drugs can produce CNS effects when used in higher doses (40–60 mg/day) and thus have potential for abuse and/or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdosage: 25 μ g of *atropine sulfate* per tablet with either 2.5 mg diphenoxylate hydrochloride (LOMOTIL) or 1 mg of difenoxin hydrochloride (MOTOFEN). The usual dosage is two tablets initially, then one tablet every 3–4 hours. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (e.g., dry mouth, blurred vision) (see Chapter 7).

OCTREOTIDE AND SOMATOSTATIN Octreotide (SANDOSTATIN) (see Chapter 55) is an octapeptide analog of somatostatin that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. Its mechanism of action appears to involve inhibition of hormone secretion, including serotonin and various other GI peptides (*e.g.*, gastrin, vasoactive intestinal polypeptide, insulin, secretin, *etc.*). Octreotide has been used, with varying success, in other forms of secretory diarrhea such as chemotherapy-induced diarrhea, diarrhea associated with human immunodeficiency virus (HIV), and diabetes-associated diarrhea. Its greatest utility is in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty; octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects.

Standard initial therapy with octreotide is 50–100 µg, given subcutaneously two or three times a day, with titration to a maximum dose of 500 µg three times a day based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres (SANDOSTATIN LAR DEPOT) is available for monthly use in the treatment of diarrheas associated with carcinoid tumors and vasoactive intestinal peptide-secreting tumors, as well as in the treatment of acromegaly (see Chapter 55). Short-term therapy leads to transient nausea, bloating, or pain at sites of injection. Long-term therapy can lead to gallstone formation and hypo- or hyperglycemia.

Use in Variceal Bleeding

Somatostatin and octreotide reduce hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. These agents can control bleeding acutely and decrease bleeding-related mortality, with an efficacy comparable to endoscopic therapy or balloon tamponade. The major advantage of somatostatin and octreotide over vasopressin is their safety. For patients with variceal bleeding, octreotide therapy usually is initiated while the patient awaits endoscopy. After a bolus of 100 µg, it is given intravenously as an infusion of 25–50 µg/h for 48 hours. Some clinicians give 100 µg subcutaneously every 6–8 hours for an additional 72 hours until the patient has had the second endoscopic treatment.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a condition that affects up to 15% of the U.S. population. Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. IBS appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders. The disturbances in bowel function can be either constipation or diarrhea or both at different times. Considerable evidence suggests a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological stimuli in this syndrome.

Many patients can be managed with dietary restrictions and fiber supplementation. Despite these measures, a significant proportion of patients remain plagued by severe symptoms, and drug therapy is attempted almost invariably. However, there are very few effective pharmacological options, a situation that in part reflects our limited understanding of the pathogenesis of this syndrome.

Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific using agents discussed above.

In recent years, increased emphasis has been placed on the pharmacological treatment of visceral sensitivity in IBS patients. A possible role for serotonin in IBS has been suggested based on its known involvement in sensitization of nociceptor neurons in inflammatory conditions. This has led to the development of specific receptor modulators, such as tegaserod (see above).

*The most effective drugs in this regard are the tricyclic antidepressants (see Chapter 17), which have neuromodulatory and analgesic properties. Tricyclic antidepressants have a proven track record in the management of chronic “functional” visceral pain. Effective analgesic doses of these drugs (*e.g.*, 25–75 mg/day of nortryptiline) are significantly lower than those required to treat depression. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns.*

α₂ Adrenergic receptor agonists, such as clonidine (see Chapter 10), also can increase visceral compliance and reduce distention-induced pain. The somatostatin analog octreotide has selective inhibitory effects on peripheral afferent nerves projecting from the gut to the spinal cord and has been shown to blunt the perception of rectal distention in patients with irritable bowel syndrome.

Alosetron and Other 5-HT₃ Antagonists

The 5-HT₃ receptor participates in several important processes in the gut, including sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. The clinical effect of 5-HT₃ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. In general, effects of these antagonists oppose those seen with 5-HT₄ agonists such as tegaserod. The 5-HT₃ antagonist alosetron (LOTRONEX) was initially removed from the U.S. market due to an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. The mechanism of this effect is not fully established, but may result from the drug's ability to suppress intestinal relaxation, thereby causing severe spasm in segments of the colon in susceptible individuals. The FDA has reapproved alosetron for diarrhea-predominant irritable bowel syndrome under a limited distribution system. The manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent before dispensing.

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 hours) is longer than expected from its $t_{1/2}$ of 1.5 hours. It is metabolized by hepatic CYPs. The drug should be started at 1 mg/day for the first 4 weeks, and advanced to a maximum of 1 mg twice daily if an adequate response is not achieved.

Other 5-HT₃ antagonists currently available in the U.S. are approved for nausea and vomiting (see below).

ANTISPASMODICS AND OTHER AGENTS

Anticholinergic agents ("spasmolytics" or "antispasmodics") often are used in patients with irritable bowel syndrome. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (see Chapter 7) and include the tertiary amines dicyclomine (BENTYL) and hyoscyamine (LEVSIN, others) and the quaternary ammonium compounds glycopyrrolate (ROBINUL) and methscopolamine (PAMINE). The advantage of the latter two compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as light-headedness, drowsiness, or nervousness. These agents typically are given either on an as-needed basis (with the onset of pain) or before meals to prevent the pain and fecal urgency that predictably occur in some patients with irritable bowel syndrome.

Dicyclomine is given in doses of 10–20 mg orally every 4–6 hours as necessary. Hyoscyamine is available in many forms, including oral capsules, tablets, elixir, drops, a nonaerosol spray (0.125–0.25 mg every 4 hours as needed), and an extended-release form for oral use (0.375 mg every 12 hours as needed). Glycopyrrolate also comes in extended-release tablets (2 mg once or twice a day), in addition to a standard-release form (1 mg up to three times a day). Methscopolamine is provided as 2.5-mg tablets and the dose is 1 or 2 tablets, three to four times a day.

ANTIEMETIC AGENTS

Nausea and Vomiting

Nausea and vomiting are protective reflexes that serve to rid the stomach and intestine of toxic substances and prevent their further ingestion. Vomiting is complex, consisting of a preejection phase (gastric relaxation and retroperistalsis), retching (rhythmic action of respiratory muscles preceding vomiting and consisting of contraction of abdominal and intercostal muscles and diaphragm against a closed glottis), and ejection (intense contraction of the abdominal muscles and relaxation of the upper esophageal sphincter). This is accompanied by multiple autonomic phenomena including salivation, shivering, and vasomotor changes. The process appears to be coordinated by a central emesis center in the lateral reticular formation of the mid-brainstem adjacent to both the chemoreceptor trigger zone (CTZ) in the area postrema (AP) at the bottom of the fourth ventricle and the solitary tract nucleus (STN) of the vagus nerve. The lack of a blood-brain barrier allows the CTZ to monitor blood and cerebrospinal fluid constantly for toxic substances and to relay information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the STN) but also by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). In turn, the center sends out efferents to the nuclei responsible for respiratory, salivary, and vasomotor activity, as well as to striated and smooth muscle involved in the act. The CTZ has high concentrations of receptors for serotonin (5-HT₃), dopamine (D₂), and opioids, while the STN is rich in receptors for enkephalin, histamine, and ACh, and also contains 5-HT₃ receptors. A variety of these neurotransmitters

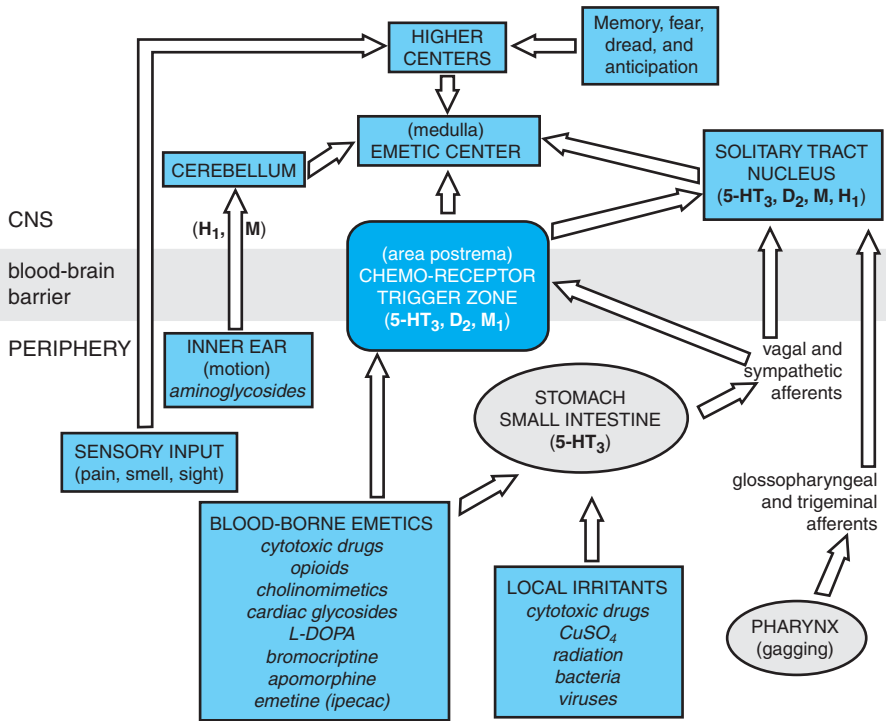

FIGURE 37-3 Pharmacologist's view of emetic stimuli. Myriad signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in *italics*. These pathways involve specific neurotransmitters and their receptors (**bold** type). Receptors are shown for dopamine (D₂), acetylcholine (muscarinic, M), histamine (H₁), and 5-hydroxytryptamine (5-HT₃). Some of these receptors also may mediate signaling in the emetic center.

are involved in nausea and vomiting (Figure 37-3), and an understanding of their nature has allowed a rational approach to pharmacological treatment.

Antiemetics generally are classified according to the predominant receptor on which they are proposed to act (Table 37-5). However, these mechanisms overlap considerably, particularly for the older agents (Table 37-6). For treatment and prevention of the nausea and emesis associated with

Table 37-5
General Classification of Antiemetic Agents

Antiemetic Class	Examples	Type of Vomiting Most Effective Against
5-HT ₃ receptor antagonists*	Ondansetron	Cytotoxic drug-induced emesis
Centrally acting dopamine receptor antagonists	Metoclopramide*†	Cytotoxic drug-induced emesis
Histamine H ₁ receptor antagonists	Promethazine‡	Vestibular (motion sickness)
Muscarinic receptor antagonists	Cyclizine	Motion sickness
Neurokinin receptor antagonists	Hyoscine (scopolamine)	Cytotoxic drug-induced emesis (delayed vomiting)
Cannabinoid receptor agonists	Investigational	Cytotoxic drug-induced emesis
	Dronabinol	Cytotoxic drug-induced emesis

*The most effective agents for chemotherapy-induced nausea and vomiting are the 5-HT₃ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy as well as reduce the incidence of side effects.

†Also has some peripheral activity at 5-HT₃ receptors.

‡Also has some antihistaminic and anticholinergic activity.

cancer chemotherapy, several antiemetic agents from different pharmacological classes may be combined (Table 37–7).

5-HT₃-Receptor Antagonists

CHEMISTRY, PHARMACOLOGICAL EFFECTS, AND MECHANISM OF ACTION

The 5-HT₃-receptor antagonists are the most widely used drugs for chemotherapy-induced emesis. Ondansetron (ZOFRAN) is the prototypical drug in this class; other agents include granisetron (KYTRIL), dolasetron (ANZEMET), palonosetron (ALOXI; intravenous use only) and tropisetron (available in some countries but not in the U.S.). Differences among these agents relate mainly to their chemical structures, 5-HT₃ receptor affinities, and pharmacokinetic profiles (Table 37–8).

PHARMACOKINETICS

The antiemetic effects of these drugs persist long after they disappear from the circulation, suggesting continued interaction at the receptor level. In fact, all of these drugs can be administered effectively once daily.

These agents are absorbed well from the GI tract. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Although ondansetron clearance also is reduced in elderly patients, no adjustment in dosage for age is recommended. Granisetron also is metabolized predominantly by the liver. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver, while about one-third is excreted unchanged in the urine. Palonosetron is metabolized principally by CYP2D6 and excreted in the urine as the metabolized and the unchanged form in about equal proportions.

THERAPEUTIC USE All three agents appear to be equally efficacious in chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation. They also are

Table 37-7

A. Some Antiemetic Regimens Used in Cancer Chemotherapy

Antiemetic Agent	Initial Dose
<i>For Severe Chemotherapy-Induced Emesis (Several Antiemetic Agents Used in Combination)</i>	
Dexamethasone	20 mg IV
Metoclopramide	3 mg/kg body weight IV every 2 h × 2
Diphenhydramine	25–50 mg IV every 2 h × 2
Lorazepam	1–2 mg IV
Dexamethasone	20 mg IV
Ondansetron	32 mg IV daily, in divided doses
<i>For Moderate Chemotherapy-Induced Emesis (Antiemetic Agents Used Singly)</i>	
Prochlorperazine	5–10 mg orally or IV, or 25 mg by rectal suppository
Thiethylperazine	10 mg orally, IM, or by rectal suppository
Dexamethasone	10–20 mg IV
Ondansetron	8 mg orally or 10 mg IV
Dronabinol	10 mg orally

B. Useful Combinations of Antiemetic Agents for Improved Antiemetic Effect

Primary Agent	Supplemental Agent
5-HT ₃ receptor antagonist	Glucocorticoid, phenothiazine, butyrophenone
Substituted benzamide	Glucocorticoid ± muscarinic receptor antagonist
Phenothiazine/butyrophenone	Glucocorticoid
Glucocorticoid	Benzodiazepine
Cannabinoid	Glucocorticoid

C. Useful Combinations of Antiemetic Agents Providing Decreased Toxicity of the Primary Agent

Primary Agent	Supplemental Agent
Substituted benzamide	H ₁ receptor antagonist, glucocorticoid, benzodiazepine
Phenothiazine/butyrophenone	H ₁ receptor antagonist
Cannabinoid	Phenothiazine

ABBREVIATIONS: H, histamine, 5-HT, serotonin; IV, intravenous; IM, intramuscular.
 SOURCE: All combination regimens are from Grunberg and Hesketh, 1993, with permission.

effective against hyperemesis of pregnancy, and to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron also may be helpful in delayed emesis (*see below*).

These agents are available as tablets, oral solution, and intravenous preparations for injection. For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 37-8)

Table 37-8

5-HT₃ Antagonists in Chemotherapy-Induced Nausea/Emesis

Drug	Chemical Nature	Receptor Interactions	t _{1/2}	Dose (IV)
Ondansetron	Carbazole derivative	5-HT ₃ antagonist and weak 5-HT ₄ antagonist	3.9 hours	0.15 mg/kg
Granisetron	Indazole	5-HT ₃ antagonist	9–11.6 hours	10 μg/kg
Dolasetron	Indole moiety	5-HT ₃ antagonist	7–9 hours	0.6–3 mg/kg
Palonosetron	Isoquinoline	5-HT ₃ antagonist; highest affinity for 5-HT ₃ receptor in this class	40 hours	0.25 mg
Ramosetron	Benzidazolyl derivative	5-HT ₃ antagonist	5.8 hours	300 μg/kg

infused over 15 minutes, beginning 30 minutes before chemotherapy, or in two to three divided doses, with the first usually given 30 minutes before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly or orally.

These drugs generally are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and light-headedness.

Dopamine Receptor Antagonists

Phenothiazines such as *prochlorperazine*, *thiethylperazine*, and chlorpromazine (see Chapter 18) are among the most commonly used antiemetics. Their principal mechanism of action is dopamine D₂ receptor antagonism at the CTZ. Compared to metoclopramide or ondansetron (see above), these drugs do not appear to be as uniformly effective in cancer chemotherapy-induced emesis. On the other hand, they also possess antihistaminic and anticholinergic activities, which are of value in other forms of nausea, such as motion sickness.

Antihistamines

Histamine H₁-receptor antagonists (see Chapter 24) are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. *Cyclizine*, *hydroxyzine*, *promethazine*, and *diphenhydramine* are examples of this class of agents. Cyclizine has additional anticholinergic effects that may be useful for patients with abdominal cancer.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist is *scopolamine* (hyoscine), which usually is administered as the free base in the form of a transdermal patch (TRANSDERM-SCOP). Its principal utility is in the prevention and treatment of motion sickness, although it also has some activity in postoperative nausea and vomiting. In general, anticholinergic agents have no role in chemotherapy-induced nausea.

DRONABINOL

Dronabinol (delta-9-tetrahydrocannabinol; MARINOL) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The antiemetic action of dronabinol probably relates to stimulation of the CB₁ subtype of cannabinoid receptors on neurons in and around the vomiting center.

PHARMACOKINETICS

Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2–4 hours. It undergoes extensive first-pass hepatic metabolism with limited systemic bioavailability after single doses (only 10–20%). Metabolites are excreted primarily via the biliary-fecal route, with only 10–15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

THERAPEUTIC USE Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. It also can stimulate appetite and has been used in patients with AIDS and anorexia. As an antiemetic agent, it is administered at an initial dose of 5 mg/m² given 1–3 hours before chemotherapy and then every 2–4 hours afterward for a total of four to six doses. If this is not adequate, incremental increases in dose can be made up to a maximum of 15 mg/m². For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to 20 mg a day.

ADVERSE EFFECTS Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity that can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and thinking abnormalities. After abrupt withdrawal of dronabinol, an abstinence syndrome manifest by irritability, insomnia, and restlessness can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse because it also may be abused by these patients.

Substance P Receptor Antagonists

APREPITANT

The nausea and vomiting associated with cisplatin (see Chapter 51) has two components: an acute phase within 24 hours after chemotherapy that universally is experienced and a delayed phase on days 2–5 that affects only some patients. 5-HT receptor antagonists are not very effective against delayed emesis. Antagonists of the NK₁ receptors for substance P, such as *aprepitant* (EMEND), have antiemetic effects in delayed nausea and improve the efficacy of standard antiemetic regimens in patients receiving multiple cycles of chemotherapy. Substance P belongs to the tachykinin family of neurotransmitters and is in vagal afferent fibers innervating the STN and area postrema.

After absorption, aprepitant is bound extensively to plasma proteins (>95%); it is extensively metabolized, primarily by hepatic CYP3A4, and is excreted in the stool; its $t_{1/2}$ is 9–13 hours. Aprepitant has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin. Aprepitant is contraindicated in patients on cisapride (see above) or pimozide, in whom life-threatening ventricular tachyarrhythmias has been reported.

Aprepitant is supplied in 80- and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy along with a 5-HT₃-receptor antagonist and a glucocorticoid. The recommended adult dosage of aprepitant is 125 mg administered 1 hour before chemotherapy on day one, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

AGENTS USED FOR MISCELLANEOUS GASTROINTESTINAL DISORDERS

Chronic Pancreatitis and Steatorrhea

PANCREATIC ENZYMES Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). The goals of pharmacological therapy are prevention of malabsorption and palliation of pain. The cornerstone of therapy for malabsorption is the use of pancreatic enzymes.

ENZYME FORMULATIONS

*The two common preparations of pancreatic enzymes for replacement therapy are obtained from the pancreas of the hog (*Sus scrofa* Linne var. domesticus Gray). Pancreatin (DONNAZYME, others) contains amylase, lipase, and protease and has one-twelfth of the lipolytic activity of pancrelipase, on a weight-by-weight basis. Pancrelipase is more commonly used and is available in uncoated forms, as well as capsules containing enteric-coated microspheres and enteric-coated microtablets, which withstand gastric acid (lipase is inactivated by acid) and disintegrate at pH >6 (Table 37–9).*

REPLACEMENT THERAPY FOR MALABSORPTION

Fat malabsorption (steatorrhea) and protein maldigestion occur when the pancreas loses >90% of its ability to produce digestive enzymes. The resultant diarrhea and malabsorption can be managed reasonably well if 30,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-hour period with and after meals; this represents ~10% of the normal pancreatic output. Alternatively, the dose can be titrated to the fat content of the diet, with ~8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes (Table 37–10) contain up to 20,000 units of lipase and 75,000 units of protease, and the typical dose of pancrelipase is 1–3 capsules or tablets with or just before meals and snacks, adjusted until a satisfactory symptomatic response is obtained. The loss of pancreatic amylase does not present a problem because of other sources of this enzyme (e.g., salivary glands). Patients using uncoated preparations require concomitant pharmacological control of gastric acid production with a proton pump inhibitor (see Chapter 36).

Table 37-9

Comparison of Uncoated and Enteric-Coated Pancreatic Enzyme Preparations*

	Uncoated Preparations	Enteric-Coated Preparations
Number of tablets or capsules required per dose	2-8	2-3
Acid suppression required	Yes	No
Site of delivery	Duodenum	More distal small bowel and beyond
Symptoms relieved	Pain; malabsorption	Malabsorption

*The major components of these preparations are a lipase and a protease (see Table 37-10).

ENZYMES FOR PAIN

Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative feedback inhibition of the pancreas by the presence of duodenal proteases. The evidence supporting this practice is equivocal at best.

In general, pancreatic enzyme preparations are well tolerated by patients. For patients with hypersensitivity to pork protein, bovine enzymes are available. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

BILE ACIDS

Bile acids and their conjugates are essential components of bile that are synthesized from cholesterol in the liver. The major bile acids in human adults are depicted in Figure 37-4. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the dispersion and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine (mainly in the terminal ileum), returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids, while lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called *bile salts*. Colonic bacteria convert primary bile acids (cholic and chenodeoxycholic acid) to secondary acids (mainly deoxycholic and lithocholic acid) by sequential deconjugation and dehydroxylation. These secondary bile acids also are absorbed in the colon and join the primary acids in the enterohepatic pool.

Table 37-10

Ursodeoxycholic acid	-OH	-OH	-H	

FIGURE 37-4 Major bile acids in adults.

Ursodeoxycholic acid (UDCA; *ursodiol*, *ACTIGALL*) (Figure 37-4) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of chenodeoxycholic acid (CDCA; *chenodiol*) in the gut by intestinal bacteria; it comprises ~1–3% of the total bile acid pool. When administered orally, litholytic bile acids such as *chenodiol* and *ursodiol* can alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. *Ursodiol* also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

Use of bile acids for gallstone dissolution requires a functional gallbladder because the modified bile must enter the gallbladder to interact with gallstones. To be amenable to dissolution, the gallstones must be composed of cholesterol monohydrate crystals and generally must be <15 mm in diameter. The overall efficacy of litholytic bile acids in the treatment of gallstones has been disappointing (partial dissolution occurs in 40–60% of patients completing therapy and complete dissolution in only 33–50%). *Ursodiol* is preferred as a single agent because of its greater efficacy and less-frequent side effects (e.g., hepatotoxicity).

Primary biliary cirrhosis is a chronic, progressive, cholestatic liver disease of unknown etiology that typically affects middle-aged to elderly women. *Ursodiol* (administered at 13–15 mg/kg/day in two divided doses) reduces the concentration of primary bile acids and improves biochemical and histological features of primary biliary cirrhosis.

ANTIFLATULENCE AGENTS

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation, but also bloating or fullness. Although few if any symptoms can be directly attributable to excessive intestinal gas, over-the-counter and herbal preparations that are touted as antifatulent are very popular. One of these is *simethicone*, a mixture of siloxane polymers stabilized with silicon dioxide.

For a complete Bibliographical listing see Goodman & Gilman’s *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

PHARMACOTHERAPY OF INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a spectrum of chronic idiopathic inflammatory intestinal conditions. IBD causes significant GI symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD also is associated with a spectrum of extraintestinal manifestations, including arthritis, ankylosing spondylitis, sclerosing cholangitis, uveitis, iritis, pyoderma gangrenosum, and erythema nodosum.

IBD is divided into two major subtypes: ulcerative colitis and Crohn's disease. Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis). Crohn's disease, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn's disease is not necessarily confluent, frequently leaving "skip areas" of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or, alternatively, fistula formation.

Therapy for IBD seeks to dampen the generalized inflammatory response; however, no agent can reliably accomplish this, and the response of an individual patient to a given medicine may be limited and unpredictable. Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications such as fistulas. Specific drugs may be better suited for one or the other of these aims (Table 38–1). For example, *glucocorticoids* remain the treatment of choice for moderate-to-severe flares but are inappropriate for long-term use because of side effects and their inability to maintain remission.

For many years, glucocorticoids and *sulfasalazine* were the mainstays of medical therapy for IBD. More recently, medicines used in other immune/inflammatory conditions, such as azathioprine and *cyclosporine*, have been adapted for IBD therapy. Biological agents have been developed that can target single steps in the immune cascade. Drug delivery to the appropriate site(s) along the GI tract also has been a major challenge, and second-generation agents have been created with improved drug delivery, increased efficacy, and decreased side effects.

PATHOGENESIS OF IBD

A summary of proposed pathogenic events and potential sites of therapeutic intervention in IBD is shown in Figure 38–1. While Crohn's disease and ulcerative colitis share a number of GI and extraintestinal manifestations and can respond to a similar array of drugs, emerging evidence suggests that they result from distinct pathogenetic mechanisms. Histologically, the transmural lesions in Crohn's disease exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates. Within the diseased bowel in Crohn's disease, the cytokine profile includes increased levels of interleukin-12 (IL-12), interferon- γ , and tumor necrosis factor- α (TNF- α), findings characteristic of T-helper 1 (T_H1)-mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles more closely that mediated by the T_H2 pathway.

MESALAMINE (5-ASA)-BASED THERAPY

CHEMISTRY, MECHANISM OF ACTION, AND PHARMACOLOGICAL PROPERTIES First-line therapy for mild-to-moderate ulcerative colitis generally involves *mesalamine* (5-aminosalicylic acid, or 5-ASA). The archetype for this class of medications is sulfasalazine (AZULFIDINE), which consists of 5-ASA linked to *sulfapyridine* by an azo bond. Sulfasalazine represents one of the first examples of an oral drug that is delivered effectively to the distal GI tract. The azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated for absorption until colonic bacteria cleave the bond. 5-ASA is now regarded as the therapeutic agent, with little, if any, contribution by sulfapyridine.

Although mesalamine is a salicylate, its therapeutic effect does not appear to be related to cyclooxygenase inhibition; indeed, traditional nonsteroidal anti-inflammatory drugs actually may exacerbate IBD. Specific mechanisms of action have not been identified, although a myriad of effects on immune function and inflammation have been shown *in vitro*.

Although not active therapeutically, sulfapyridine causes many of the side effects associated with sulfasalazine. To preserve the therapeutic effect of 5-ASA without the side effects of sulfapyridine, several second-generation 5-ASA compounds have been developed. They are divided into two

ABBREVIATIONS: 6-MP, 6-mercaptopurine; AZA, azathioprine.

FIGURE 38–1 Proposed pathogenesis of inflammatory bowel disease and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the endothelial barrier is impaired, bacterial antigens (dark circles) can gain access to antigen-presenting cells (APCs) in the lamina propria. These cells then present the antigen(s) to $CD4^+$ lymphocytes and also secrete IL-12, thereby inducing the differentiation of T_H1 cells in Crohn's disease (or type 2 helper T cells in ulcerative colitis). The T_H1 cells produce a characteristic array of lymphokines, including $IFN-\gamma$, which in turn activates macrophages. Macrophages positively regulate T_H1 cells by secreting additional IL-12 and $TNF-\alpha$. In addition to general immunosuppressants that affect multiple sites of inflammation (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine), more specific sites for therapeutic intervention involve the intestinal bacteria (antibiotics and probiotics) and therapy directed at $TNF-\alpha$ (see text for further details).

groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (*olsalazine*, DIPENTUM) or an inert compound (*balsalazide*, COLAZIDE). Thus, these compounds act at similar sites along the GI tract as does sulfasalazine. The alternative approaches employ either a delayed-release formulation (PENTASA) or a pH-sensitive coating (ASACOL). Delayed-release mesalamine is released throughout the small intestine and colon, whereas pH-sensitive mesalamine is released in the terminal ileum and colon. These different distributions of drug delivery have potential therapeutic implications (see Figure 38–2).

Oral sulfasalazine is of proven value in patients with mild or moderately active ulcerative colitis, with response rates of 60–80%. The usual dose is 4 g/day in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to

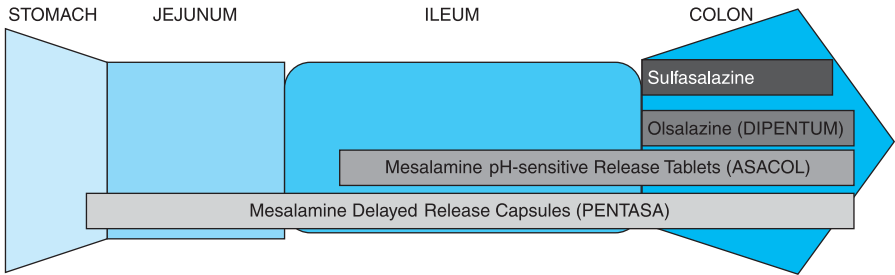

FIGURE 38–2 Sites of release of mesalamine (5-ASA) in the GI tract from different oral formulations.

systemic glucocorticoids. Regardless of disease severity, the drug plays a useful role in preventing relapses once remission has been achieved. Because they lack the dose-related side effects of sulfapyridine, the newer formulations can be used to provide higher doses of mesalamine with some improvement in disease control. The usual doses to treat active disease are 800 mg three times a day for ASACOL and 1 g four times a day for PENTASA. Lower doses are used for maintenance (e.g., ASACOL, 800 mg twice a day).

The efficacy of 5-ASA preparations (e.g., sulfasalazine) in Crohn's disease is less striking, with modest benefit at best. Sulfasalazine has not been shown to be effective in maintaining remission and has been replaced by newer 5-ASA preparations. Some studies have reported that both ASACOL and PENTASA are more effective than placebo in inducing remission in patients with Crohn's disease (particularly colitis), although higher doses than those typically used in ulcerative colitis are required. The role of mesalamine in maintenance therapy for Crohn's disease is controversial, and there is no clear benefit of continued 5-ASA therapy in patients who achieve medical remission. Because they largely bypass the small intestine, the second-generation 5-ASA prodrugs such as olsalazine and balsalazide do not have a significant effect in small bowel Crohn's disease.

Topical preparations of mesalamine suspended in a wax matrix suppository (ROWASA) or in a suspension enema (CANASA) are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75–90%. Mesalamine enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 hours; the suppository (500 mg) should be used two to three times a day with the objective of retaining it for at least 3 hours. Response to local therapy with mesalamine may occur within 3–21 days; however, the usual course of therapy is from 3–6 weeks. Once remission has occurred, lower doses are used for maintenance.

PHARMACOKINETICS

Approximately 20–30% of orally administered sulfasalazine is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine, which is highly lipid-soluble, is absorbed rapidly from the colon. It undergoes extensive hepatic metabolism, including acetylation and hydroxylation, conjugation with glucuronic acid, and excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of adverse effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. By contrast, only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. Intraluminal concentrations of mesalamine therefore are very high (around 1500 µg/mL or 10 mM in patients taking a typical dose of 3 g/day).

The pH-sensitive coating of ASACOL (EUDAGRIT-S) limits gastric and small intestinal absorption of 5-ASA. The pharmacokinetics of PENTASA differ somewhat. The ethylcellulose-coated microgranules are released in the upper GI tract as discrete, prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, but some intact microgranules also can be detected in the colon. Because it is released in the small bowel, a greater fraction of PENTASA is absorbed systemically compared with the other 5-ASA preparations.

ADVERSE EFFECTS

Side effects of sulfasalazine occur in 10–45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose-related, including headache, nausea, and fatigue. These reactions can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfasalazine reversibly decreases the number and motility of sperm but does not impair female fertility. It also inhibits intestinal folate absorption; therefore, folate usually is given with sulfasalazine.

The newer mesalamine formulations generally are well tolerated, and side effects are relatively infrequent and minor. Headache, dyspepsia, and rash are the most common. Diarrhea appears to be particularly common with olsalazine (occurring in 10–20% of patients); this may be related to its ability to stimulate chloride and fluid secretion in the small bowel. Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; while its pathogenic role is controversial, renal function should be monitored in all patients receiving these drugs. Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. Although not studied as thoroughly, the newer formulations also appear to be safe in pregnancy. The risks to the fetus from the consequences of uncontrolled IBD in pregnant women are believed to outweigh the risks associated with the therapeutic use of these agents (see below).

GLUCOCORTICOIDS

The effects of glucocorticoids on the inflammatory response are numerous and well documented (see Chapter 59). Although glucocorticoids are universally recognized as effective in acute exacerbations, their use in either ulcerative colitis or Crohn's disease involves considerable challenges and pitfalls, and they are indicated only for moderate-to-severe IBD. Because the same issues impact steroid use in both ulcerative colitis and Crohn's disease, they are discussed together.

The response to glucocorticoids in individual patients with IBD divides them into three general classes: steroid-responsive, steroid-dependent, and steroid-unresponsive. Steroid-responsive patients improve clinically, generally within 1–2 weeks, and remain in remission as the steroids are tapered and then discontinued. Steroid-dependent patients also respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered. Steroid-unresponsive patients do not improve even with prolonged high-dose glucocorticoids. Approximately 40% of patients are steroid-responsive, 30–40% have only a partial response or become steroid-dependent, and 15–20% of patients do not respond to steroid therapy.

Glucocorticoids sometimes are used for prolonged periods to control symptoms in steroid-dependent patients, but the failure to respond to glucocorticoids with prolonged remission (*i.e.*, a disease relapse) should prompt consideration of alternative therapies, including immunosuppressives and *infliximab* (see below). Glucocorticoids are not effective in maintaining remission in either ulcerative colitis or Crohn's disease; thus, their significant side effects have led to increased emphasis on limiting the duration and cumulative dose of steroids in IBD.

Initial doses in IBD are between 40–60 mg prednisone or equivalent per day; higher doses generally are no more effective. The glucocorticoid is tapered over weeks to months. Even with these slow tapers, however, efforts should be made to minimize the duration of steroid therapy. Most patients improve substantially within 5 days of initiating treatment; others require treatment for several weeks before remission occurs. For more severe cases, glucocorticoids (typically methylprednisolone or hydrocortisone) are given intravenously.

Glucocorticoid enemas are useful in patients whose disease is limited to the rectum (proctitis) and left colon. Hydrocortisone is available as a retention enema (100 mg/60 mL), and the usual dose is one 60-mL enema per night for 2 or 3 weeks. When administered optimally, the drug can reach up to or beyond the descending colon. Patients with distal disease usually respond within 3–7 days. Hydrocortisone also can be given once or twice daily as a 10% foam suspension (CORTIFOAM) that delivers 80 mg hydrocortisone per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty in retaining fluid.

Budesonide (ENTOCORT ER) is an enteric-release form of a synthetic glucocorticoid that is used for ileocecal Crohn's disease. It is proposed to deliver glucocorticoid therapy to a specific portion of inflamed gut while minimizing systemic side effects owing to extensive first-pass hepatic metabolism to inactive derivatives. Topical therapy (e.g., enemas and suppositories) also is effective in treating colitis limited to the left side of the colon. Budesonide (9 mg/day for 10–12 weeks) is effective in the acute management of mild-to-moderate exacerbations of Crohn's disease.

A significant number of patients with IBD fail to respond adequately to glucocorticoids and are either steroid-resistant or steroid-dependent.

IMMUNOSUPPRESSIVE AGENTS

Thiopurine Derivatives

The cytotoxic thiopurine derivatives *mercaptopurine* (6-MP, PURINETHOL) and azathioprine (IMMURAN) (see Chapters 51 and 52) are used to treat patients with severe IBD or those who are steroid-resistant or steroid-dependent. These thiopurine antimetabolites impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: Azathioprine is converted to mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides that are the presumed active moiety. These drugs generally are used interchangeably with appropriate dose adjustments, typically azathioprine (2–2.5 mg/kg) or mercaptopurine (1.5 mg/kg). These drugs are considered equally effective in Crohn's disease and ulcerative colitis and can effectively maintain remission in both diseases; they also may prevent (or, more typically, delay) recurrence of Crohn's disease after surgical resection. Finally, they are used successfully to treat fistulas in Crohn's disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, such that other drugs with a more rapid onset of action (e.g., mesalamine, glucocorticoids, or infliximab) are preferred in the acute setting.

PHARMACOGENETICS Favorable responses to azathioprine–mercaptopurine are seen in up to two-thirds of patients. Mercaptopurine has three metabolic fates: (1) conversion by xanthine oxidase to 6-thiouric acid; (2) metabolism by thiopurine methyltransferase (TPMT) to 6-methyl-mercaptopurine (6-MMP); and (3) conversion by hypoxanthine–guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides and other metabolites. The relative activities of these different pathways may explain, in part, individual variations in efficacy and side effects of these immunosuppressives. The plasma $t_{1/2}$ of mercaptopurine is limited by its relatively rapid (*i.e.*, within 1–2 hours) uptake into erythrocytes and other tissues. Following this uptake, differences in thiopurine methyltransferase (TPMT) activity determine the drug's fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals has minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-methyl-mercaptopurine and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, they will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, ~10% of the population are rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Pharmacogenetic typing can guide therapy (see Chapter 4).

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which is inactive as an immunosuppressive. Inhibition of xanthine oxidase by allopurinol diverts mercaptopurine to more active metabolites such as 6-thioguanine and increases both immunosuppressive and potential toxic effects. Thus, patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

Methotrexate

Methotrexate generally is reserved for patients whose IBD is either steroid-resistant or steroid-dependent. In Crohn's disease, it both induces and maintains remission, generally with a more rapid response than that seen with mercaptopurine or azathioprine. Only limited studies have examined the role of methotrexate in ulcerative colitis.

Therapy of IBD with methotrexate differs somewhat from its use in other autoimmune diseases. Most important, higher doses (e.g., 15–25 mg/week) are given parenterally. The increased efficacy with parenteral administration may reflect the unpredictable intestinal absorption at higher doses of methotrexate.

Cyclosporine

Cyclosporine is effective in severe ulcerative colitis that has failed to respond adequately to glucocorticoid therapy. Between 50% and 80% of these severely ill patients improve significantly (generally within 7 days) in response to intravenous cyclosporine (2–4 mg/kg/day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level in whole blood of 300–400 ng/mL.

Oral cyclosporine is less effective as maintenance therapy in IBD, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with NEORAL (a microemulsion formu-

lation of cyclosporine with increased oral bioavailability) may be more effective. Cyclosporine can be used to treat fistulous complications of Crohn's disease. A significant, rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus, calcineurin inhibitors generally are used to treat specific problems over a short term while providing a bridge to longer-term therapy.

ANTI-TNF THERAPY

Infliximab (REMICADE, cA2) is a chimeric immunoglobulin (25% mouse, 75% human) that binds to and neutralizes TNF- α , one of the principal cytokines mediating the T_H1 immune response characteristic of Crohn's disease (see Figure 38–1).

Infliximab (5 mg/kg infused intravenously at intervals of several weeks to months) decreases the frequency of acute flares in approximately two-thirds of patients with moderate-to-severe Crohn's disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn's disease. Its role in Crohn's disease is evolving, but emerging evidence supports its efficacy in maintaining remission and in preventing recurrence of fistulas.

The use of infliximab as a biologic response modifier raises several important considerations. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion. Anti–double-stranded DNA antibodies develop in 9% of patients, but a frank lupus-like syndrome occurs only rarely. Antibodies to infliximab can decrease its clinical efficacy; strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy for either recurrent or chronic therapy.

Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or other granulomatous infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy should be tested for latent tuberculosis with purified protein derivative, and patients who test positive should be treated prophylactically with isoniazid. However, anergy with a false-negative skin test has been noted in some patients with Crohn's disease, and some experts routinely perform chest radiographs to look for active or latent pulmonary disease. Infliximab also is contraindicated in patients with severe congestive heart failure. The significant cost of infliximab is an important consideration in some patients.

ANTIBIOTICS

An emerging concept is that a balance in the GI tract normally exists among the mucosal epithelium, the normal gut flora, and the immune response. Some data suggest that colonic bacteria may either initiate or perpetuate the inflammation of IBD, and specific bacterial antigens in the pathogenesis of Crohn's disease. Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used to this end, most prominently in Crohn's disease. More recently, probiotics have been used to treat specific clinical situations in IBD.

Antibiotics can be used as either (1) adjunctive treatment along with other medications for active IBD; (2) treatment for a specific complication of Crohn's disease; or (3) prophylaxis for recurrence in postoperative Crohn's disease. *Metronidazole*, *ciprofloxacin*, and *clarithromycin* are the antibiotics used most frequently. They are more beneficial in Crohn's disease involving the colon than in disease restricted to the ileum. Specific Crohn's disease–related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small bowel bacterial overgrowth secondary to partial small bowel obstruction, secondary infections with organisms such as *Clostridium difficile*, and postoperative complications. Metronidazole may be particularly effective for the treatment of perianal disease. Postoperatively, a 3-month course of metronidazole (20 mg/kg/day) can prolong the time to both endoscopic and clinical recurrence.

Supportive Therapy in IBD

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. These drugs should be individualized based on a patient's symptoms and are supplementary to anti-inflammatory drugs. Oral iron, folate, and vitamin B₁₂ should be administered as indicated. Loperamide or diphenoxylate (see Chapter 37) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease; these agents are contraindicated in severe disease because they may predispose to the development of toxic megacolon.

Cholestyramine can be used to prevent bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; see Chapter 7) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected. Care should be taken to differentiate exacerbation of IBD from symptoms that may be related to coexistent functional bowel disease (see Chapter 37).

THErapy OF IBD DURING PREGNANCY

IBD is a chronic disease that affects women in their reproductive years. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease.

Mesalamine and glucocorticoids are FDA category B drugs that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is clearly contraindicated in pregnant patients. The use of thiopurine immunosuppressives is more controversial. Because these medications are given long term, both their initiation and discontinuation are major management decisions. Although there are no controlled trials of these medications in pregnancy, considerable experience has emerged over the last several years. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives. Nonetheless, decisions regarding the use of these medications in patients contemplating pregnancy are complex and necessarily must involve consideration of the risks and benefits involved.

SECTION VII

CHEMOTHERAPY OF PARASITIC INFECTIONS

39

CHEMOTHERAPY OF PROTOZOAL INFECTIONS

Malaria

BIOLOGY OF MALARIAL INFECTION

Malaria afflicts nearly 500 million people and causes 2 million deaths each year. Infection with *Plasmodium falciparum* is responsible for nearly all this mortality. Human malaria is caused by four species of obligate intracellular protozoa of the genus *Plasmodium*. Infection usually is transmitted by the bite of infected female *Anopheline* mosquitoes. Sporozoites rapidly enter the circulation and localize to hepatocytes, where they transform, multiply, and develop into tissue schizonts (Figure 39–1). This primary asymptomatic stage (pre-erythrocytic or exoerythrocytic) lasts for 5–15 days, depending on the *Plasmodium* species. Tissue schizonts then rupture, releasing merozoites that enter the circulation, invade erythrocytes, and initiate the erythrocytic cycle. Once the tissue schizonts burst in *P. falciparum* and *P. malariae* infections, no parasites remain in the liver. In *P. vivax* and *P. ovale* infections, tissue parasites (hypnozoites) persist and can produce relapses years after the primary attack. Once plasmodia enter the erythrocytic cycle, they cannot reinvade the liver; thus, there is no tissue stage of infection for malaria contracted by transfusion. In erythrocytes, most parasites undergo asexual development from young forms to trophozoites and finally to mature schizonts. Schizont-containing erythrocytes rupture, producing febrile clinical attacks. The merozoites invade more erythrocytes to continue the cycle. The periodicity of parasitemia and fever depends on the timing of generation of erythrocytic parasites. For *P. falciparum*, *P. vivax*, and *P. ovale*, it takes ~48 hours to complete this process; *P. malariae* requires ~72 hours.

Merozoites bind to ligands on the red cell surface. P. falciparum recognizes a number of molecules and invades all stages of erythrocytes; it therefore can achieve high parasitemia. P. vivax recognizes reticulocyte-specific proteins; thus, it only invades reticulocytes and rarely exceeds 1% parasitemia in the bloodstream. P. ovale resembles P. vivax in its predilection for young red blood cells. P. malariae recognizes only senescent red cells, maintains a very low parasitemia, and causes an indolent infection. P. falciparum assembles cytoadherence proteins into structures called knobs on the erythrocyte surface, allowing the parasitized erythrocyte to bind the vascular endothelium. This can result in microvascular blockage in the brain and organ beds and local release of vascular mediators, leading to cerebral malaria.

Some erythrocytic parasites differentiate into sexual forms known as gametocytes. After a female mosquito ingests infected blood, exflagellation of the male gametocyte is followed by fertilization of the female gametocyte in the insect gut. The resulting zygote, which develops as an oocyst in the gut wall, eventually gives rise to sporozoites, which invade the salivary gland of the mosquito. The insect then can infect a human host by taking a blood meal.

Malaria is typified by high spiking fevers, chills, headache, myalgias, malaise, and gastrointestinal (GI) symptoms. Each Plasmodium species causes a distinct illness: (1) P. falciparum is the most dangerous. By invading erythrocytes of any age, sequestering in the vasculature, and producing vasoactive products, this species can cause an overwhelming parasitemia, hypoglycemia, and shock with multiorgan failure. Treatment delay may lead to death. If treated early, the infection usually responds within 48 hours. If treatment is inadequate, recrudescence of infection may result. (2) P. vivax infection has a low mortality rate in untreated adults and is characterized by relapses due to reactivation of latent tissue forms. (3) P. ovale causes infection with a periodicity and relapses similar to those of P. vivax but is milder. (4) P. malariae causes a generally indolent infection. Clinical attacks may occur years or decades after infection.

CLASSIFICATION OF ANTIMALARIAL AGENTS

The various stages of the malaria life cycle differ in their drug sensitivity. Thus, the antimalarial drugs are best classified in the context of the life cycle (Figure 39–2). Two generalizations can be made. *Since none of the drugs kills sporozoites, it is not truly possible to prevent infection but only*

to prevent the development of symptomatic malaria caused by the asexual erythrocytic forms. Also, none of the antimalarials is effective against all liver and red cell stages of the life cycle that may coexist in a patient. Complete cure therefore may require more than one drug.

Class I agents are directed against the asexual erythrocytic forms and are not reliable against primary or latent liver stages or against *P. falciparum* gametocytes. These drugs will treat, or prevent, clinically symptomatic malaria. When used prophylactically, the class I drugs must be taken for several weeks after exposure until parasites complete the liver phase and become susceptible to therapy. The spectrum is somewhat expanded for the class II agents, which target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure prophylaxis. Finally, primaquine is unique in its spectrum of activity, which includes reliable efficacy against primary and latent liver stages as well as gametocytes. Primaquine has no place in the treatment of symptomatic malaria but rather is used most commonly to eradicate the hypnozoites of *P. vivax* and *P. ovale*, which are responsible for relapsing infections.

The use of drugs for prophylaxis or therapy is dictated by their pharmacokinetics and safety. Thus, quinine and primaquine, which have short half-lives and common toxicities, are reserved for

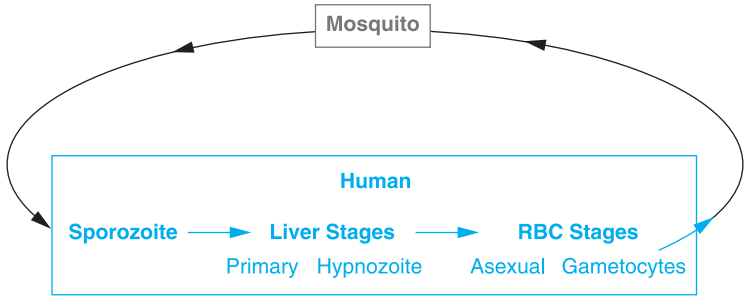

FIGURE 39-1 Life cycle of malaria parasites. See text for details.

Class I

	Chloroquine	-	-	-	+	(±)
	Mefloquine	-	-	-	+	-
	Quinine, Quinidine	-	-	-	+	(±)
FANSIDAR	Pyrimethamine	-	±	-	+	-
	Sulfadoxine	-	±	-	+	-
	Tetracyclines	-	-	-	±	-

Class II

--	------------	---	---	---	---	---

FIGURE 39–2 Spectrum of clinically useful activity for antimalarial drugs. For atovaquone and proguanil, reliable activity against the primary liver stage has been shown for *P. falciparum* only; for the class I agents, activity against gametocytes does not include *P. falciparum*.

treatment of established infection and not used for prophylaxis in healthy travelers. Chloroquine is relatively safe and has a 1-week $t_{1/2}$ that is convenient for prophylaxis (in those few areas where chloroquine-sensitive malaria persists).

Causal prophylactics act on the initial hepatic stages, drugs for terminal prophylaxis and radical cure target hypnozoites, and agents for suppressive prophylaxis or cure target the asexual red cell forms. Regimens currently recommended for *prophylaxis* in nonimmune individuals are given in Table 39–1, and regimens for the *treatment* of malaria are given in Table 39–2.

ARTEMISININ AND DERIVATIVES

The artemisinins are potent antimalarials with no clinical evidence of resistance. They are particularly well suited for the treatment of severe P. falciparum malaria and play a key role in combination therapy of drug-resistant infections. They are not FDA approved, and inactive counterfeits are common.

ANTIPARASITIC ACTIVITY Extensive structure–activity studies have confirmed the requirement for an endoperoxide moiety for antimalarial activity. These drugs act rapidly against the asexual erythrocytic stages of *P. vivax* and *P. falciparum*. Their potency *in vivo* is 10- to 100-fold greater than that of other antimalarials. They are not cross-resistant with other drugs; indeed, sensitivity to the artemisinins may be increased in chloroquine-resistant parasites. When used alone, the artemisinins are associated with a high level of parasite recrudescence, which may be related to their rapid metabolism. They have gametocytocidal activity but do not affect either primary or

ARTEMISININ

DIHYDROARTEMISININ

ARTEMETHER

ARTESUNATE

latent liver stages.

Artemisinin acts in two steps. Heme iron within the parasite catalyzes cleavage of the endoperoxide bridge, followed by rearrangement to produce a carbon-centered radical that alkylates and damages macromolecules in the parasite. Artemisinin and its derivatives exhibit antiparasitic activity against other protozoa, including *Leishmania major* and *Toxoplasma gondii*, and have been used alone or in combination in patients with schistosomiasis.

ABSORPTION, FATE, AND EXCRETION

The semisynthetic artemisinins are available for oral (dihydroartemisinin, artesunate, and artemether), intramuscular (artesunate and artemether), intravenous (artesunate), and rectal (artesunate) dosing. Absorption after oral dosing typically is <30%. Peak plasma levels occur within minutes with artesunate and at 2–6 hours with artemether. The endoperoxides are not highly bound to plasma proteins. Both artesunate and artemether are converted extensively to dihydroartemisinin, which provides much of their antimalarial activity and has a plasma $t_{1/2}$ of 1–2 hours; its major urinary metabolite is a glucuronide. With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, which may enhance clearance by up to fivefold.

THERAPEUTIC USES Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the initial treatment of severe *P. falciparum* infections. The artemisinins generally are not used alone because of their incomplete efficacy and to avoid selection of resistant parasites. Artemisinin combination treatment (ACT) is preferred because the endoperoxides rapidly and substantially reduce parasite burden, reduce the likelihood of resistance, and may decrease disease transmission by reducing gametocyte carriage. Artemisinins should not be used for prophylaxis because of their short $t_{1/2}$, incompletely characterized safety in healthy subjects, and unreliability when used alone.

TOXICITY AND CONTRAINDICATIONS

The artemisinins enjoy a deserved reputation of safety. The principal targets of toxicity are brain, liver, bone marrow, and fetus. The neurological changes that occur in severe malaria confound the evaluation of neurotoxicity; however, no systematic changes were attributable to treatment in patients >5 years of age. Dose-related and reversible changes also have been seen in reticulocyte and neutrophil counts and in transaminase levels. About 1 in 3000 patients develops an allergic reaction. The artemisinins are potent embryotoxins in animals. Only a few small studies have monitored the outcome of pregnancies in women treated with endoperoxides, but there are no reported increases in congenital or developmental abnormalities. Given the current state of safety information, the artemisinins should be used with caution in very young children and pregnant women.

Table 39-1

Regimens for Malaria Chemoprophylaxis and Self-Treatment in Nonimmune Individuals*

These regimens, based on CDC recommendations current at the time of writing, may change over time. Up-to-date information should be obtained from the CDC at www.cdc.gov/travel/. Recommendations and available treatments vary in other countries.

Prophylaxis for infections with chloroquine-sensitive *P. falciparum*,[†] *P. vivax*, *P. malariae*, and *P. ovale*

Chloroquine phosphate (ARALEN) is available for oral administration. Adults take 500 mg chloroquine phosphate (300 mg base) weekly starting 1–2 weeks before entering an endemic area and continuing for 4 weeks after leaving. The pediatric dosage is 8.3 mg/kg chloroquine phosphate (5 mg base per kg, up to the maximum adult dose) taken orally by the same schedule. *Note:* *Primaquine phosphate* is used to eradicate latent tissue forms of *P. vivax* and *P. ovale* and effect a radical cure after individuals leave areas endemic for these infections (see Table 39-2 and text).

Prophylaxis for infections with drug-resistant strains of *P. falciparum*[‡] or *P. vivax*. *Note:* The choice of regimen depends on the local geographic profile of drug resistance and other factors (see text).

Preferred regimens:

Atovaquone-proguanil (MALARONE) is available for oral dosing only as a fixed-combination tablet containing 250 mg atovaquone and 100 mg proguanil hydrochloride (adult tablet) or 62.5 mg atovaquone and 25 mg proguanil hydrochloride (pediatric tablet). Adults and children >40 kg should take one adult tablet per day beginning 1–2 days prior to exposure and continuing for 7 days after exposure. Smaller children should be dosed on the same schedule: 11–20 kg, 1 pediatric tablet daily; 21–30 kg, 2 pediatric tablets; 31–40 kg, 3 pediatric tablets. *Note:* For *P. vivax* malaria, atovaquone-proguanil may not be as effective as mefloquine. Atovaquone-proguanil is not recommended for children <11 kg, pregnant women, or those breast-feeding infants. Contraindicated in persons with severe renal impairment.

Mefloquine hydrochloride (LARIAM) is available for oral administration only. Tablets marketed in the U.S. contain 250 mg mefloquine hydrochloride, equivalent to 228 mg mefloquine base (this may vary in Canada and elsewhere). The dosing below is expressed in mg salt. Adults and children >45 kg body weight take 250 mg weekly starting 1–2 weeks before entering an endemic area and ending 4 weeks after leaving. Pediatric doses, taken by the same schedule, are 5 mg/kg for children up to 15 kg (may have to be prepared by a pharmacist); 62.5 mg ($1/4$ tablet) for 15–19 kg; 125 mg ($1/2$ tablet) for 20–30 kg; 187.5 mg ($3/4$ tablet) for 31–45 kg. *Note:* Mefloquine is *not* recommended for children weighing <5 kg or individuals with a history of seizures, severe neuropsychiatric disturbances, sensitivity to quinoline antimalarials, or cardiac conduction abnormalities.

Doxycycline hyclate (VIBRAMYCIN, others). Formulations of doxycycline are available in capsules, coated tablets, and liquid preparations for oral administration. The adult dose of doxycycline is 100 mg daily. For children >8 years of age, the dosage is 2 mg/kg given once daily, up to the adult dose. Prophylaxis with doxycycline should begin 1 day before travel to an endemic area and end 4 weeks after leaving. This regimen is used in geographical areas where highly multidrug-resistant strains of *P. falciparum* are prevalent. *Note:* Doxycycline should not be given to children <8 years of age or to pregnant women. Doxycycline is contraindicated in individuals who are hypersensitive to any tetracycline. Prophylaxis with doxycycline can be combined with the chloroquine phosphate regimen shown above for chloroquine-sensitive malaria. This strategy often is used in geographic areas where infection with more than one *Plasmodium* species is likely.

Primaquine phosphate USP. Tablets marketed in the U.S. contain 15 mg primaquine base per tablet (this may vary elsewhere); doses below are expressed as primaquine base. Primaquine may be used in special circumstances, such as when preferred agents cannot be tolerated or for multidrug-resistant *P. falciparum*. This should be done with caution and in consultation with malaria experts, such as those available through the CDC. The adult dose is 30 mg base (2 tablets) daily starting several days before exposure and continued for 7 days after exposure. The same regimen at a dose of 0.6 mg/kg base is used for children. Primaquine is contraindicated in G6PD deficiency or pregnancy (see text).

(Continued)

Table 39–1

Regimens for Malaria Chemoprophylaxis and Self-Treatment in Nonimmune Individuals* (Continued)

Other regimens:

The mefloquine, doxycycline, or chloroquine prophylactic regimens listed above may be used together with a self-treatment regimen. The latter should be used for prompt treatment of presumed malaria if, for example, the traveler is in a very remote area. *Medical attention should be sought immediately.* The preferred regimen is *atovaquone–proguanil* (MALARONE). Adults and children >41 kg should take 4 adult tablets as a single daily dose for three consecutive days; smaller children also should take adult tablets once daily for three consecutive days: 11–20 kg, 1 tablet; 21–30 kg, 2 tablets; 31–40 kg, 3 tablets.

*No chemoprophylactic regimen is always effective in preventing malaria. Recommended drug regimens always should be used in conjunction with other protective measures to avoid mosquito bites (*see text*).

†These strains now exist only in Mexico, Central America west of the Panama Canal Zone, the Caribbean, and parts of South America and the Middle East.

‡These strains exist in other geographical areas endemic for *P. falciparum* malaria.

§Papua New Guinea and Indonesia are the two areas where chloroquine-resistant *P. vivax* are highly prevalent, resulting in a high failure rate with prophylaxis. Resistant *P. vivax* also has been found sporadically in India, Burma, and Central and South America.

ATOVAQUONE

Atovaquone (MEPRON) has potent activity against *Plasmodium* species and the opportunistic pathogens *Pneumocystis jirovici* and *Toxoplasma gondii*; it is FDA approved for treatment of *P. jirovici* pneumonia in patients intolerant of trimethoprim–sulfamethoxazole. In patients with uncomplicated *P. falciparum* malaria, combination therapy with proguanil and atovaquone evoked high cure rates with few relapses and minimal toxicity. A fixed combination of atovaquone with proguanil (MALARONE) is available in the U.S. for malaria prophylaxis and treatment.

ANTIPARASITIC EFFECTS, MECHANISM, AND RESISTANCE Atovaquone is a lipophilic drug that has potent activity against blood stages of plasmodia, tachyzoite and cyst forms of *T. gondii*, the fungus *P. jirovici*, and *Babesia* species. It is active against liver stages of *P. falciparum* but not against *P. vivax* hypnozoites. Atovaquone is highly potent against *P. falciparum*. It inhibits electron transport and collapses the mitochondrial membrane potential. Synergism between proguanil and atovaquone may reflect proguanil's action to enhance membrane-potential collapse.

Resistance to atovaquone in P. falciparum develops readily. Mutations in resistant organisms have been mapped to the mitochondrially encoded cytochrome b gene. Resistance can be prevented by combining proguanil with atovaquone, but it remains to be seen how long this will be effective.

ABSORPTION, FATE, AND EXCRETION

Absorption is slow and variable after a single oral dose, increased two- to threefold by fatty food, and dose-limited >750 mg. More than 99% of the drug is bound to plasma protein, and cerebrospinal fluid (CSF) levels are <1% of those in plasma. Plasma level–time profiles often show a double peak; the first peak appears in 1–8 hours, whereas the second occurs 1–4 days after a single dose and possibly reflects enterohepatic circulation. Atovaquone has a $t_{1/2}$ of 1.5–3 days and is excreted in bile; >94% of drug is recovered unchanged in feces; its clearance varies among ethnic populations.

THERAPEUTIC USES Atovaquone is used with a biguanide for prophylaxis and treatment of malaria to obtain optimal results and avoid emergence of drug resistance. An oral tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride has been highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of drug-resistant *P. falciparum* malaria. The same regimen followed by primaquine appears to be effective in treatment of *P. vivax* malaria. Experience in treatment of non-*P. falciparum* malaria is limited and should be reserved for chloroquine-resistant *P. vivax* cases in which quinine and mefloquine cannot be used. Atovaquone–proguanil also is useful for malaria prophylaxis, which can be discontinued 1 week after leaving the endemic area because both components have hepatic-phase activity.

Opportunistic infections owing to the fungus P. jiroveci or the protozoan T. gondii are serious threats to patients with acquired immune deficiency syndrome (AIDS). Atovaquone remains an alternative for prophylaxis and treatment of pulmonary P. jirovecii infection in patients who can take oral medication but cannot tolerate trimethoprim–sulfamethoxazole or parenteral pentami-

Table 39–2

Regimens for Treatment of Malaria in the U.S.

These regimens, modified from CDC recommendations current at the time of writing, may change over time. Up-to-date information should be obtained from the CDC at www.cdc.gov/travel/. Recommendations and available treatments vary in other countries.

Treatment of severe malarial infections *Note:* Infections with *P. falciparum* in nonimmune or pregnant patients constitute medical emergencies because they can progress rapidly to a fatal outcome.* Chemotherapy should be initiated promptly and not await parasitological confirmation. Parenteral therapy with *quinidine gluconate* is advised for severely ill patients who cannot take oral medication; the regimen is identical for all species of *Plasmodium*. Exchange transfusion may benefit some patients.

Preferred regimen:

Quinidine gluconate is given intravenously to both adults and children starting with a loading dose of 10 mg of the salt per kg dissolved in 300 mL of normal saline and infused over 1–2 hours (maximum dose 600 mg of the salt). This is followed by continuous infusion at the rate of 0.02 mg of the salt per kg per minute for at least 24 hours and until oral therapy with quinine sulfate is feasible. During administration of quinidine gluconate, blood pressure (for hypotension) and ECG (for widening of the QRS complex and lengthening of the QT interval) should be monitored continuously and total blood glucose (for hypoglycemia) periodically. These complications, if severe, may warrant temporary discontinuation of the drug.

Quinine sulfate can be substituted for quinidine gluconate once patients can take oral medication. The dose for adults is 650 mg of the salt given every 8 hours. The pediatric dose is 10 mg of the salt per kg given every 8 hours. Therapy with quinidine/quinine usually is given for 3–7 days depending on the species of *Plasmodium* and geographical profile of drug resistance (7 days for *P. falciparum* in Southeast Asia). Previous use of mefloquine may mandate dosage reduction (*see text*).

Adjunctive therapy:

For optimal clinical response, any one of the following regimens should be used together with oral quinine sulfate therapy. The particular choice depends on the geographical profile of anti-malarial drug resistance.

Doxycycline hyclate (VIBRAMYCIN, others). The adult dose is 100 mg taken orally twice a day for 7 days. For children >8 years of age, the dosage is 2 mg/kg, increasing up to the adult dose and given by the same schedule. *Tetracycline* may be substituted if doxycycline hyclate is unavailable. Adults receive 250 mg every 6 hours for 7 days, whereas the pediatric dosage is 6.25 mg/kg every 6 hours for 7 days. *Note:* Because of adverse effects on bones and teeth, tetracyclines should not be given to children <8 years of age or to pregnant women. These drugs are contraindicated in individuals who are hypersensitive to any tetracycline.

Clindamycin. The adult or pediatric dosage is 20 mg (base)/kg/day, orally, divided into 3–4 doses, for 7 days.

Pyrimethamine–sulfadoxine (FANSIDAR). This combination is available for oral use only in tablets containing 25 mg pyrimethamine and 500 mg sulfadoxine. One dose is taken by mouth on the last day of quinine sulfate therapy: Adults take 3 tablets; children 5–10 kg, 0.5 tablet; 11–14 kg, 0.75 tablet; 15–20 kg, 1 tablet; 21–30 kg, 1.5 tablets; 31–40 kg, 2 tablets; 41–50 kg, 2.5 tablets; over 50 kg, 3 tablets. Owing to extensive drug resistance, pyrimethamine–sulfadoxine should be used as an adjunct treatment primarily in young children or women who are not able to tolerate clindamycin.

Other oral treatment regimens for infections with chloroquine-resistant *P. vivax*[†] and drug-resistant strains of *P. falciparum*

If quinine-based therapy cannot be used, mefloquine currently is the preferred alternative (except for Southeast Asia) but could be supplanted in this role by atovaquone–proguanil once more experience is obtained.

Mefloquine hydrochloride (LARIAM, MEPHAQUINE). The adult dose is 750 mg of the salt taken by mouth followed 6–12 hours later by 500 mg. The corresponding pediatric dose for children weighing less than 45 kg is 15 mg of the salt per kg followed 6–12 hours later by 10 mg of the salt per kg. (*Note:* The pediatric dosage is not approved by the FDA.) The initial dose should be

(Continued)

Table 39-2

Regimens for Treatment of Malaria in the U.S. (Continued)

repeated *only* if vomiting occurs within the first hour. Therapeutic doses of mefloquine may induce gastrointestinal and neuropsychiatric symptoms. Because of its long $t_{1/2}$ and potential for serious drug interactions, extreme caution is advised in using certain antimalarial agents (e.g., quinine or halofantrine) with or shortly after mefloquine. (See text for further details).

Atovaquone–proguanil hydrochloride (MALARONE). A fixed-dose combination of these drugs is available in tablets containing 250 mg atovaquone and 100 mg proguanil hydrochloride. The dose for adults is 1000 mg atovaquone plus 400 mg proguanil hydrochloride taken by mouth once each day for 3 days. The pediatric dose for children weighing 11–20 kg is 250 mg atovaquone plus 100 mg proguanil hydrochloride; 21–30 kg, 500 mg atovaquone plus 200 mg proguanil hydrochloride; 31–40 kg, 750 mg atovaquone plus 300 mg proguanil hydrochloride. These doses are given once daily for 3 days with food to increase drug bioavailability. If vomiting occurs within 30 minutes, the dose should be repeated. If nausea is severe, the dose may be split in half and given twice daily. Experience with children weighing <11 kg is limited, but if necessary, pediatric tablets are available. Consult CDC recommendations for dosages.

Oral treatment of infections with *P. vivax*, *P. malariae*, *P. ovale*, and chloroquine-sensitive *P. falciparum*

Chloroquine phosphate (ARALEN) is available in 250- and 500-mg tablets (equivalent to 150 and 300 mg base, respectively) for oral administration. The adult dosage is two 500-mg tablets immediately, followed by one 500-mg tablet at 6, 24, and 48 hours. The dosage for children is 16.7 mg/kg (10 mg base per kg) immediately, followed by 8.3 mg/kg (5 mg base per kg) at 6, 24, and 48 hours, not to exceed the adult dosage.

Prevention of relapse:

To eradicate latent tissue forms of *P. vivax* and *P. ovale* that persist to cause relapses of infection, primaquine phosphate is supplied in tablets containing either 13.2 or 26.3 mg of the salt (7.5 or 15 mg base, respectively) for oral administration only. Therapy with primaquine is started after the acute attack (about day 4) at doses of 52.6 mg (30 mg base) daily for 14 days. Pediatric doses are 1.06 mg/kg (0.6 mg base per kg) daily, also for 14 days. The same primaquine regimen also can be used during the last 2 weeks of chloroquine phosphate prophylaxis for individuals who have left areas endemic for *P. vivax* or *P. ovale* infection. Alternatively, adults using chloroquine for prophylaxis against *P. vivax* or *P. ovale* may take 500 mg chloroquine phosphate (300 mg base) together with 78.9 mg primaquine phosphate (45 mg base) weekly for 8 weeks starting after leaving an endemic area to achieve a “radical” cure. Primaquine is contraindicated in pregnancy and in severe G6PD deficiency (see text).

*Emergency advice is available from the Division of Parasitic Diseases, Centers for Disease Control and Prevention (telephone: 770-488-7788).

[†]Papua New Guinea and Indonesia are the two areas where chloroquine-resistant *P. vivax* are highly prevalent, resulting in a high failure rate. Resistant *P. vivax* also has been found sporadically in India, Burma, and Central and South America. Currently, patients acquiring *P. vivax* infections from regions other than Papua New Guinea and Indonesia should be treated with chloroquine.

dine. *T. gondii* infections in these patients, especially cerebral lesions, have shown only limited dose-related positive responses to prolonged regimens of atovaquone. Toxoplasma chorioretinitis in immunocompetent patients probably responds better to this drug. Atovaquone also is used in combination with azithromycin for infections owing to Babesia species.

TOXICITY

The most common adverse reactions are abdominal pain, nausea, vomiting, diarrhea, headache, and rash. Vomiting and diarrhea may result in therapeutic failure owing to decreased drug absorption. However, readministration of this drug within an hour of vomiting may still evoke a positive therapeutic response in patients with *P. falciparum* malaria. Patients treated with atovaquone occasionally exhibit abnormalities of serum transaminase or amylase levels.

PRECAUTIONS AND CONTRAINDICATIONS

While atovaquone seems remarkably safe, the drug needs further evaluation in pediatric patients weighing <11 kg, pregnant women, and lactating mothers and is not recommended in

these individuals. Atovaquone may compete with certain drugs for binding to plasma proteins, and therapy with rifampin, a potent inducer of CYP-mediated drug metabolism, can substan-

tially reduce plasma levels of atovaquone, whereas plasma levels of rifampin are raised. Co-administration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

DIAMINOPYRIMIDINES

ANTIPROTOZOAL EFFECTS

Antimalarial Actions Pyrimethamine is a slow-acting blood schizonticide with antimalarial effects *in vivo* similar to those of proguanil (*see below*). However, pyrimethamine has greater antimalarial potency, and its $t_{1/2}$ is much longer than that of cycloguanil, the active metabolite of proguanil. Pyrimethamine's efficacy against hepatic forms of *P. falciparum* is less than that of proguanil, and at therapeutic doses, pyrimethamine fails to eradicate the latent tissue forms of *P. vivax* or gametocytes of any plasmodial species.

Action Against Other Protozoa

High doses of pyrimethamine given concurrently with sulfadiazine is the preferred therapy for infection with *T. gondii* in infants and immunosuppressed individuals.

MECHANISMS OF ANTIMALARIAL ACTION AND RESISTANCE The 2,4-diaminopyrimidines inhibit dihydrofolate reductase of plasmodia at concentrations far lower than those required to inhibit the mammalian enzymes. The dihydrofolate reductase in malaria resides on the same polypeptide chain as thymidylate synthase and is not upregulated in the face of inhibition, which contributes to the selective toxicity of the antifolates. Synergism between pyrimethamine and the sulfonamides or sulfones has been attributed to inhibition of two steps in an essential metabolic pathway.

Several factors affect the response to antifolates, including host immunity and dietary p-aminobenzoic acid or folate, which can reduce efficacy substantially. Pyrimethamine resistance is seen in regions of prolonged or extensive drug use and results from mutations in dihydrofolate reductase–thymidylate synthetase. Several mutations in *P. falciparum* introduce single-amino-acid changes linked to resistance by decreasing the drug's binding affinity for its active site in dihydrofolate reductase.

ABSORPTION, FATE, AND DISTRIBUTION

Given orally, pyrimethamine is slowly but completely absorbed; it reaches peak plasma levels in about 2–6 hours. The compound binds to plasma proteins and accumulates in kidneys and other organs. Its elimination $t_{1/2}$ in plasma is ~80–95 hours. Concentrations that suppress responsive plasmodial strains remain in the blood for 2 weeks. Pyrimethamine also is excreted in the milk of nursing mothers.

THERAPEUTIC USES Pyrimethamine is almost always given with either a sulfonamide or sulfone to enhance its antifolate activity. It acts slowly relative to the quinoline blood schizonticides, and its prolonged elimination encourages the selection of resistant parasites. The use of pyrimethamine is restricted to the treatment of chloroquine-resistant *P. falciparum* malaria in areas where resistance to antifolates has not yet fully developed. Pyrimethamine together with a short-acting sulfonamide such as sulfadiazine also may be used as an adjunct to quinine to treat an acute malarial attack. Dosage regimens for this indication are given in Table 39–2. Pyrimethamine–sulfadoxine is no longer recommended for prophylaxis because of toxicity owing to the accompanying sulfonamide (*see below*).

High doses of pyrimethamine plus sulfadiazine are the treatment of choice for infections with *T. gondii* in immunocompromised adults; without treatment, these infections progress rapidly to death. Initial therapy consists of an oral loading dose of 200 mg followed by 50–75 mg pyrimethamine

daily for 4–6 weeks along with 4–6 g sulfadiazine daily in four divided doses. Leucovorin (folic acid), 10–15 mg daily, should also be taken to prevent bone marrow toxicity. For subsequent long-term suppressive therapy, lower doses of pyrimethamine (25–50 mg daily) and sulfadiazine (2–4 g daily) may suffice. Infants with congenital toxoplasmosis usually respond positively to oral pyrimethamine (0.5–1.0 mg/kg daily) and oral sulfadiazine (100 mg/kg daily) given for 1 year.

TOXICITY, PRECAUTIONS, AND CONTRAINDICATIONS

Antimalarial doses of pyrimethamine alone cause little toxicity except occasional rashes and depression of hematopoiesis. Excessive doses produce a megaloblastic anemia that responds to drug withdrawal or treatment with folic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans, trimethoprim–sulfamethoxazole therapy is associated with birth defects, but such toxicity has not been studied systematically for pyrimethamine in humans.

Sulfonamides or sulfones usually account for most toxicity associated with coadministration of these antifolate drugs (see Chapter 43). The combination of pyrimethamine (25 mg) and sulfadoxine (500 mg) (FANSIDAR) causes severe and even fatal cutaneous reactions in up to 1 in 5000 people. This combination also has been associated with serum sickness–type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine–sulfadoxine is contraindicated in individuals with previous reactions to sulfonamides, lactating mothers, and infants <2 months of age. Administration of pyrimethamine with dapsone (MALOPRIM, unavailable in the U.S.), occasionally has been associated with agranulocytosis. Higher doses of pyrimethamine (75 mg daily) used along

with sulfadiazine (4–6 g daily) to treat toxoplasmosis produce skin rashes, bone marrow suppression, and renal toxicity in ~40% of immunocompromised patients. Much of this toxicity probably is due to sulfadiazine.

PROGUANIL

Proguanil and its triazine metabolite cycloguanil have the following structures:

Proguanil has the widest margin of safety of a large series of antimalarial biguanide analogs examined. Dihalogen substitution in positions 3 and 4 of the benzene ring yields chlorproguanil (LAPUDRINE), a more potent prodrug that also is used clinically. Cycloguanil is structurally related to pyrimethamine.

ANTIMALARIAL ACTIONS In sensitive *P. falciparum* malaria, proguanil exerts activity against both the primary liver stages and the asexual red cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil also is active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after drug withdrawal. Proguanil treatment does not destroy gametocytes, but fertilized gametes in the gut of the mosquito fail to develop normally.

MECHANISMS OF ANTIMALARIAL ACTION AND RESISTANCE The active triazine metabolite of proguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, inhibiting DNA synthesis and depleting folate cofactors. Certain amino acid changes near the dihydrofolate reductase–binding site are linked to resistance to either cycloguanil, pyrimethamine, or both. Resistance to cycloguanil (and chlorcycloguanil) can be linked to mutations in plasmodial dihydrofolate reductase. This pattern differs from that typically observed for pyrimethamine resistance, but overlapping resistance to cycloguanil and pyrimethamine indicates that resistance mechanisms may be quite complex.

The mechanism of the antimalarial activity of proguanil or chlorproguanil is unknown. Proguanil as the biguanide accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against P. falciparum but displays no such activity by itself (see “Atovaquone,” above). In contrast to cycloguanil, resistance to the intrinsic antimalarial activity of proguanil itself, either alone or in combination with atovaquone, has yet to be documented.

ABSORPTION, FATE, AND EXCRETION

Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations of the drug usually are attained within 5 hours. The mean plasma elimination $t_{1/2}$ is ~12–20 hours. Metabolism of proguanil cosegregates with CYP2C isoforms that control mephenytoin oxidation. Only ~3% of Caucasians are deficient in this oxidation versus 20% of Asians and Kenyans. Proguanil is oxidized to two major metabolites, cycloguanil and an inactive 4-chlorophenylbiguanide. On a 200-mg daily dosage regimen, extensive metabolizers develop plasma levels of cycloguanil that are above the therapeutic range, whereas poor metabolizers may not. Proguanil does not accumulate appreciably in tissues during long-term administration, except in erythrocytes, where its concentration is about three times that in plasma. The inactive 4-chlorophenyl-biguanide metabolite appears in increased quantities in the urine of poor proguanil metabolizers. In humans, from 40% to 60% of absorbed proguanil is excreted in urine either as the parent drug or as active metabolite.

THERAPEUTIC USES Proguanil as a single agent is not available in the U.S. but is prescribed in Europe for nonimmune travelers to malarious areas. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections also may result from deficient conversion of this compound to its active antimalarial metabolite.

Proguanil is effective and well tolerated when given orally once daily for 3 days in combination with atovaquone for the treatment of malarial attacks owing to chloroquine- and multidrug-resistant strains of *P. falciparum* and *P. vivax* (see “Atovaquone,” above). Indeed, this drug combination (MALARONE) has been successful in Southeast Asia, where highly drug-resistant strains of *P. falciparum* prevail. *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone, but resistance to the combination is uncommon unless the strain is initially resistant to atovaquone. In contrast, some strains resistant to proguanil do respond to proguanil plus atovaquone.

TOXICITY AND SIDE EFFECTS

In prophylactic doses of 200–300 mg/day, proguanil causes few side effects except occasional nausea and diarrhea. Large doses (1 g or more daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and transient appearance of epithelial cells and casts in the urine. Overdose (up to 15 g) has been followed by complete recovery. Doses as high as 700 mg twice daily have been taken for >2 weeks without serious toxicity. Proguanil is considered safe during pregnancy. It is remarkably safe when coadministered with other antimalarial drugs.

QUINOLINES AND RELATED COMPOUNDS

Chloroquine and Hydroxychloroquine

*The structure of chloroquine is shown in Figure 39–3. A chlorine atom attached to position 7 of the quinoline ring confers the greatest antimalarial activity. Hydroxychloroquine (PLAQUENIL) is essentially equivalent to chloroquine against *P. falciparum* malaria.*

PHARMACOLOGICAL EFFECTS

Antimalarial Actions Chloroquine is highly effective against erythrocytic forms of *P. vivax*, *P. ovale*, *P. malariae*, and chloroquine-sensitive strains of *P. falciparum* and is the prophylaxis and treatment of choice for these organisms. It exerts activity against gametocytes of the first three plasmodial species but not against those of *P. falciparum*. The drug has no activity against latent tissue forms of *P. vivax* or *P. ovale*.

Other Effects

Chloroquine or its analogs are used to treat hepatic amebiasis and are secondary drugs for variety of chronic inflammatory diseases, including rheumatoid arthritis, systemic lupus erythematosus, discoid lupus, sarcoidosis, and photosensitivity diseases such as porphyria cutanea tarda.

MECHANISMS OF ANTIMALARIAL ACTION AND RESISTANCE TO CHLOROQUINE AND OTHER ANTIMALARIAL QUINOLINES

Asexual malaria parasites flourish in erythrocytes by digesting hemoglobin; this generates free radicals and heme as highly reactive by-products. Heme is sequestered as an insoluble malarial

FIGURE 39-3 Chemical structure of antimalarial quinolines and related compounds.

pigment termed hemozoin, and quinolines likely interfere with heme handling. Failure to inactivate heme or even enhanced toxicity of drug–heme complexes is thought to kill the parasites via oxidative damage to membranes.

Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially chloroquine, now is common. Chloroquine resistance results from mutations in the gene encoding a chloroquine resistance transporter, designated crt. Multiple mutations are needed to confer resistance. Chloroquine-resistant *P. vivax* isolates do not have alterations in their crt ortholog and may have a different resistance mechanism. P-glycoprotein and other transporters may modulate chloroquine resistance.

ABSORPTION, FATE, AND EXCRETION

Chloroquine is well absorbed after oral, intramuscular, and subcutaneous administration. It distributes relatively slowly into a very large apparent volume (over 100 L/kg) and is extensively sequestered in tissues, particularly liver, spleen, kidney, lung, and to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins and is biotransformed via hepatic CYPs to two active metabolites, desethylchloroquine and bisdesethylchloroquine. Renal clearance of chloroquine is about half of total clearance. Unchanged chloroquine and its major metabolites account for >50% and 25% of urinary drug products, respectively, and their renal excretion is increased by urine acidification.

Plasma levels of chloroquine shortly after dosing are determined primarily by the rate of distribution rather than the rate of elimination. Because of extensive tissue binding, a loading dose is used to achieve effective concentrations in plasma. After parenteral administration, rapid entry together with slow exit of chloroquine from a small central compartment can result transiently in potentially lethal drug concentrations in plasma. Hence, parenteral chloroquine is given either by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched; peak plasma levels are achieved in ~3–5 hours after dosing by this route. The $t_{1/2}$ of chloroquine increases from a few days to weeks as plasma levels decline, reflecting the transition from slow distribution to even slower elimination from extensive tissue stores. The terminal $t_{1/2}$ ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

THERAPEUTIC USES Chloroquine is inexpensive and safe, but its usefulness has declined in those parts of the world where strains of *P. falciparum* are resistant. Except in areas where resistant strains of *P. vivax* are reported (Table 39–2), chloroquine is very effective in prophylaxis or treatment of acute attacks of malaria caused by *P. vivax*, *P. ovale*, and *P. malariae*. Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, primaquine can be given either with chloroquine or reserved for use until after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become afebrile within 24–48 hours after receiving therapeutic doses. If patients fail to respond by the second day of chloroquine therapy, resistance of *P. falciparum* should be suspected and therapy instituted with quinine or another rapidly acting blood schizonticide. Although parenteral chloroquine can be given safely to comatose or vomiting patients until it can be taken orally, quinidine gluconate usually is given in the U.S. In comatose children, chloroquine is well absorbed when given *via* nasogastric tube. Tables 39–1 and 39–2 provide information about recommended prophylactic and therapeutic dosage regimens for chloroquine.

TOXICITY AND SIDE EFFECTS

Taken in proper doses, chloroquine is an extraordinarily safe drug; however, its safety margin is narrow, and a single dose of 30 mg/kg may be fatal. Acute chloroquine toxicity is encountered most frequently with too rapid administration of parenteral doses. Cardiovascular effects include hypotension, vasodilation, depressed myocardial function, cardiac arrhythmias, and cardiac arrest. Confusion, convulsions, and coma denote central nervous system (CNS) dysfunction. Chloroquine doses of >5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs, most commonly among dark-skinned persons. Prolonged medication with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes.

Irreversible retinopathy and ototoxicity can result from high daily doses (>250 mg) of chloroquine or hydroxychloroquine that lead to cumulative total doses of more than 1 g of base per kilogram body weight, such as those used for treatment of diseases other than malaria. Retinopathy can be avoided if the daily dose is ≤ 250 mg. Prolonged therapy with high doses of 4-aminoquinoline also can cause toxic myopathy, cardiopathy, and peripheral neuropathy; these reactions improve if the drug is withdrawn promptly. Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

PRECAUTIONS AND CONTRAINDICATIONS

Chloroquine is not recommended for treating individuals with epilepsy or myasthenia gravis. The drug should be used cautiously if at all in the presence of hepatic disease or severe GI, neurological, or blood disorders. The dose must be adjusted in renal failure. In rare cases, chloroquine can cause hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Chloroquine should not be used in patients with psoriasis or other exfoliative skin conditions because it causes severe reactions. It should not be used for malaria in patients with porphyria cutanea tarda but is used in smaller doses for treatment of the underlying disease (see Chapter 63). Chloroquine inhibits CYP2D6 and interacts with a variety of drugs. It should not be given with mefloquine because of increased risk of seizures. Most important, this antimalarial opposes the action of anti-convulsants and increases the risk of ventricular arrhythmias from coadministration with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine can increase the risk of their toxicity. For patients receiving long-term, high-dose therapy, ophthalmological and neurological evaluations are recommended every 3–6 months.

QUININE AND QUINIDINE

Quinine remains a mainstay for treating attacks of chloroquine- and multidrug-resistant *P. falciparum* malaria (Table 39–2). Multidrug therapy with other antimalarials is supplanting quinine regimens because of increasing resistance of *P. falciparum* to quinine together with its toxicity. Both quinine and quinidine are obtained from natural sources and contain a quinoline group attached through a secondary alcohol linkage to a quinuclidine ring (Figure 39–3). A methoxy side chain is attached to the quinoline ring and a vinyl to the quinuclidine. They differ only in the steric configuration at two of the three asymmetrical centers. Quinidine is both somewhat more potent as an antimalarial and more toxic than quinine.

PHARMACOLOGICAL EFFECTS

Antimalarial Actions Quinine acts primarily against asexual erythrocytic forms and has little effect on hepatic forms of malarial parasites. The alkaloid also is gametocidal for *P. vivax* and *P. malariae* but not for *P. falciparum*. Quinine is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. However, quinine, along with its stereoisomer quinidine, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*, even though these strains have become more resistant to both agents in certain parts of Southeast Asia and South America. Because of its toxicity and short $t_{1/2}$, quinine generally is not used for prophylaxis.

Quinine resistance in P. falciparum more closely resembles resistance to mefloquine and halofantrine than to chloroquine. A number of different transporter genes may confer resistance to quinine.

Action on Skeletal Muscle Quinine increases the tension response to a single maximal stimulus delivered to muscle, but it also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive stimulation and to acetylcholine are reduced. Thus, quinine can antagonize the actions of *physostigmine* on skeletal muscle. Quinine also may produce respiratory distress and dysphagia in patients with myasthenia gravis.

ABSORPTION, FATE, AND EXCRETION

Quinine is readily absorbed when given orally or intramuscularly. Oral absorption occurs mainly from the upper small intestine and exceeds 80%, even in patients with marked diarrhea. After an oral dose, plasma levels of quinine reach a maximum in 3–8 hours and, after distributing into an apparent volume of ~ 1.5 L/kg, decline with a $t_{1/2}$ of ~ 11 hours after termination of therapy. Quinine pharmacokinetics may change according to the severity of malarial infection. Values for both the apparent volume of distribution and the systemic clearance of quinine decrease, the latter more than the former, so that the average elimination $t_{1/2}$ increases from 11 to 18 hours. After standard therapeutic doses, peak plasma levels of quinine may reach 15–20 mg/L in severely ill patients without causing major toxicity (see below); in contrast, levels >10 mg/L produce severe

drug reactions in self-poisoning. The high levels of plasma α_2 -acid glycoprotein in severe malaria may prevent toxicity by binding the drug and reducing its free fraction. Concentrations of quinine are lower in erythrocytes (33–40%) and CSF (2–5%) than in plasma, and the drug readily reaches fetal tissues.

The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4, so only ~20% of a dose is excreted unaltered in the urine. The major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

THERAPEUTIC USES

Treatment of Malaria Quinine is the drug of choice for drug-resistant *P. falciparum* malaria. In severe illness, the prompt use of loading doses of intravenous quinine (or quinidine, where IV quinine is not available, as in the U.S.) can be lifesaving. Oral medication to maintain therapeutic concentrations then is given as soon as tolerated and continued for 5–7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizontocides such as a sulfonamide or a tetracycline are given concurrently to enhance the efficacy of quinine. Formulations of quinine and quinidine and specific regimens for the treatment of *P. falciparum* malaria are shown in Table 39–2.

The therapeutic range for “free” quinine is 0.2–2.0 mg/L. Regimens to achieve this target may vary based on patient age, severity of illness, and the drug responsiveness of *P. falciparum*. Lower doses are more effective in treating children in Africa than adults in Southeast Asia because quinine pharmacokinetics differ in these populations, as does the susceptibility of *P. falciparum* to the drug. Regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger volume of distribution, greater systemic clearance, and shorter terminal elimination $t_{1/2}$ than quinine. The dose of quinidine currently recommended by the Centers for Disease Control and Prevention (CDC), 10 mg salt per kilogram initially, followed by 0.02 mg salt per kilogram per minute, perhaps should be modified to 10 and 0.02 mg of base (60% of the salt is base).

TOXICITY AND SIDE EFFECTS

The fatal oral dose of quinine for adults is ~2–8 g. Quinine is associated with a triad of dose-related toxicities when it is given at full therapeutic or excessive doses. These are cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism—consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension—occur very frequently and disappear soon after the drug is withdrawn. Hypoglycemia can be life-threatening if not treated promptly with intravenous glucose. Hypotension is rare and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and dermal manifestations.

Hearing and vision are particularly affected. Functional impairment of the eighth nerve results in tinnitus, decreased auditory acuity, and vertigo. Visual symptoms also are common. The visual and auditory effects probably reflect direct neurotoxicity, although secondary vascular changes may have a role. Marked spastic constriction of the retinal vessels occurs. In severe cases, optic atrophy results.

GI symptoms (e.g., nausea, vomiting, abdominal pain, and diarrhea) result from the local irritant action of quinine; the nausea and emesis also have a central basis. The skin often is hot and flushed, and sweating is prominent. Rashes appear frequently. Angioedema, especially of the face, is observed occasionally.

Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells. Despite treatment with glucose infusions, this complication can be life threatening, especially in pregnancy and prolonged severe infection.

Quinine rarely causes cardiovascular complications unless target plasma concentrations are exceeded. QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. However, severe hypotension is predictable when quinine is administered too rapidly intravenously. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias. Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

Toxic manifestations of small doses of cinchona alkaloids usually result from drug hypersensitivity. Flushing and pruritus, often accompanied by rashes, fever, gastric distress, dyspnea, ringing in the ears, and visual impairment, are the usual expressions. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and even death—is a rare hypersensitivity

reaction to quinine. Quinine occasionally may cause milder hemolysis, especially in people with G6PD deficiency. Immune thrombocytopenic purpura also is rare but can occur even in response to ingestion of tonic water, which has about one-twenty-fifth the therapeutic oral dose per 12 oz. Other rare reactions to the drug include hypoprothrombinemia, leukopenia, and agranulocytosis.

PRECAUTIONS, CONTRAINDICATIONS, AND INTERACTIONS

Quinine must be used with considerable caution, if at all, in patients who manifest drug hypersensitivity. Quinine should be discontinued immediately if evidence of hemolysis appears. The drug should not be used in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be fairly safe and is used commonly for treatment of malaria during pregnancy, but caution must be used to avoid hypoglycemia.

Concentrated solutions of quinine may cause abscesses when injected intramuscularly or thrombophlebitis when infused intravenously. GI absorption of quinine can be delayed by antacids containing aluminum. Quinine and quinidine can elevate plasma levels of digoxin. Likewise, the alkaloid may raise plasma levels of warfarin. The action of quinine at neuromuscular junctions will enhance the effect of neuromuscular blocking agents and oppose the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinine's cardiotoxicity, as can halofantrine. The clearance of quinine is decreased by cimetidine and increased by acidification of the urine and by rifampin.

Mefloquine

Mefloquine (LARIAM) is 4-quinoline methanol (Figure 39–3) that emerged from clinical trials as safe and highly effective against drug-resistant strains of *P. falciparum*. Mefloquine was first used to treat chloroquine-resistant *P. falciparum* malaria in a coformulation with pyrimethamine-sulfadoxine (FANSIMEF) to delay development of resistance. This strategy failed, largely because slow elimination of mefloquine fostered the selection of resistant parasites at subtherapeutic drug concentrations. Mefloquine is used for prophylaxis and chemotherapy of drug-resistant *P. falciparum* and *P. vivax* malaria.

ANTIMALARIAL ACTIONS Mefloquine is a highly effective blood schizontocide but has no activity against early hepatic stages and mature gametocytes of *P. falciparum* or latent tissue forms of *P. vivax*. The drug may have some sporontocidal activity but is not used clinically for this purpose.

Mechanisms of Antimalarial Action and Resistance

The mechanism of action of mefloquine is unknown but may be similar to that of chloroquine. Certain isolates of *P. falciparum* exhibit resistance to mefloquine via unknown mechanisms. Chloroquine-resistant alleles of the *crt* gene actually confer increased sensitivity to mefloquine and some other quinolines. Amplification of the *pfmdr1* gene is associated with resistance to mefloquine and quinine.

Absorption, Fate, and Excretion

Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is well absorbed, a process enhanced by food. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise biphasically to peak in ~17 hours. The drug is widely distributed, highly bound (~98%) to plasma proteins, and slowly eliminated with a terminal $t_{1/2}$ of ~20 days. Several mefloquine metabolites are formed. Plasma levels of the inactive mefloquine 4-carboxylic acid exceed those of mefloquine itself and decline at about the same rate. Excretion is mainly by the fecal route; ~10% of mefloquine appears unchanged in the urine.

Therapeutic Uses

Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*. The drug is especially useful as a prophylactic agent for nonimmune travelers who stay for only brief periods in areas where these infections are endemic (Table 39–1). In areas where malaria is due to drug-resistant strains of *P. falciparum*, mefloquine is more effective when used in combination with an artemisinin compound.

TOXICITY AND SIDE EFFECTS

Mefloquine given orally usually is well tolerated, particularly at prophylaxis dosages. Vomiting occurs more frequently at treatment dosages. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour. Nausea, vomiting, dizziness, and neuropsychiatric side effects are increased at treatment dosages. CNS manifestations approach 0.5% and include seizures, confusion or decreased sensorium, acute psychosis, and vertigo. Such symptoms generally remit on drug discontinuation. At prophylactic doses, the risk of serious neuropsychiatric effects is ~0.01%. Milder toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Adverse effects usually appear after the first to third doses and often abate even with continued treatment. Cardiac abnormalities, hemolysis, and agranulocytosis are rare.

CONTRAINDICATIONS AND INTERACTIONS

At very high doses, mefloquine causes teratogenesis and developmental abnormalities in rodents. Mefloquine is approved for use during pregnancy by the CDC and after the first trimester by the World Health Organization (WHO). However, there have been studies suggesting an increased rate of fetal loss with mefloquine use, especially during the first trimester. The evidence for mefloquine's safety in pregnancy is not fully convincing, and alternatives should be sought. Pregnancy also should be avoided for 3 months after mefloquine use because of its prolonged $t_{1/2}$. The drug is contraindicated for patients with a history of seizures, severe neuropsychiatric disturbances, or adverse reactions to quinoline antimalarials. Although mefloquine can be taken safely 12 hours after a last dose of quinine, taking quinine shortly after mefloquine can be very hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated. Mefloquine reportedly increases the risk of seizures in epileptic patients controlled by valproate and may compromise adequate immunization by live typhoid vaccine. Caution is advised for use of mefloquine along with drugs that can perturb cardiac conduction. The WHO advises against mefloquine use for patients in occupations that require great dexterity, such as pilots.

Primaquine

Primaquine, in contrast with other antimalarials, acts on tissue stages (exoerythrocytic) of plasmodia in the liver to prevent and cure relapsing malaria. The structure of primaquine is shown in Figure 39-3.

ANTIMALARIAL ACTIONS Primaquine destroys primary and latent hepatic stages of *P. vivax* and *P. ovale* and thus has great clinical value for preventing relapses of *P. vivax* or *P. ovale* malaria. The drug will not treat ongoing attacks of malaria, even though it displays some activity against the erythrocytic stages. The 8-aminoquinolines exert a marked gametocidal effect against all four species of plasmodia that infect humans, especially *P. falciparum*. Some strains of *P. vivax* exhibit partial resistance to the action of primaquine, which makes it imperative that strict adherence to drug regimen be maintained.

MECHANISM OF ANTIMALARIAL ACTION Little is known about the antimalarial action of the 8-aminoquinolines. Primaquine may be converted to electrophiles that act as oxidation-reduction mediators, which may be the toxic moiety.

ABSORPTION, FATE, AND EXCRETION

Primaquine is only given orally. Absorption from the GI tract is nearly complete. After a single dose, the plasma concentration peaks within 3 hours and then falls with an elimination $t_{1/2}$ of 6 hours. The apparent volume of distribution is several times that of total-body water. Primaquine is metabolized rapidly; only a small fraction is excreted as the parent drug. The major metabolite in human plasma is 8-(3-carboxyl-1-methylpropylamino)-6-methoxyquinoline, which is eliminated more slowly and accumulates with multiple doses.

THERAPEUTIC USES Primaquine is used primarily for the terminal prophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) malarias because of its high activity against their latent tissue forms. The compound is given together with a blood schizontocide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal prophylaxis, primaquine regimens are initiated shortly before or immediately after leaving an endemic area (Table 39-1). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during the long-term latent period of infection or during an acute attack. Studies also have shown efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine is taken prophylactically. The drug generally is well tolerated when taken for up to 1

year.

TOXICITY AND SIDE EFFECTS

Primaquine is fairly innocuous when given to most Caucasians in the usual therapeutic doses. Primaquine can cause mild-to-moderate abdominal distress, which can be alleviated by taking the drug with food. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60–240 mg/day) accentuate the abdominal symptoms and cause methemoglobinemia in most subjects. Methemoglobinemia can be severe in individuals with congenital deficiency of nicotinamide adenine dinucleotide (NADH) methemoglobin reductase. Chloroquine and dapsone may be synergistic with primaquine in producing methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Also rare are hypertension, arrhythmias, and symptoms referable to the CNS.

Therapeutic or higher doses of primaquine may cause hemolytic anemia in humans with G6PD deficiency. This condition affects >200 million people worldwide. About 11% of African Americans have a G6PD variant that makes them vulnerable to hemolysis caused by oxidant drugs such as primaquine. Erythrocyte sensitivity to primaquine can be more severe in Sardinians, Sephardic Jews, Greeks, and Iranians. Because primaquine sensitivity is X-linked, hemolysis is of intermediate severity in heterozygous females who have two red cell populations, one normal and the other deficient in G6PD.

PRECAUTIONS AND CONTRAINDICATIONS

Patients should be tested for G6PD deficiency before they receive primaquine. Primaquine has been used cautiously in African American subjects with G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks, but should not be used in patients with more severe deficiency. The CDC recommends use only when a normal G6PD level has been documented. If a daily dose >30 mg of primaquine base (>15 mg in possibly sensitive patients) is given, repeated blood counts and at least gross examination of the urine for hemoglobin should be undertaken. Primaquine should not be used in pregnant women and can be used only in lactating mothers whose infants have a normal G6PD level.

Primaquine is contraindicated in acutely ill patients with diseases that predispose to granulocytopenia (e.g., rheumatoid arthritis and systemic lupus erythematosus). Primaquine should not be given to patients receiving other potentially hemolytic drugs or agents capable of depressing the myelopoiesis.

SULFONAMIDES AND SULFONES

The sulfonamides and sulfones have antimalarial activity. The sulfonamides are used together with pyrimethamine and often in addition to quinine to treat chloroquine-resistant *P. falciparum* malaria, especially in parts of Africa. The sulfonamides and sulfones are slow-acting blood schizontocides that are more active against *P. falciparum* than *P. vivax*. The sulfonamides are used together with inhibitors of parasite dihydrofolate reductase to enhance their antiparasitic action. The synergistic “antifolate” combination of sulfadoxine, a long-acting sulfonamide, with pyrimethamine (FANSIDAR) is used to treat malarial attacks. The sulfone dapsone given with the biguanide chlorproguanil also has been effective for therapy of chloroquine-resistant *P. falciparum* malaria.

TETRACYCLINES

The tetracyclines are slow-acting blood schizontocides that are used for short-term prophylaxis in areas with chloroquine and mefloquine resistance. Tetracyclines are particularly useful for the treatment of the acute malarial attack owing to multidrug-resistant strains of *P. falciparum* that also show partial resistance to quinine. Their relative slowness of action makes them ineffective as single agents for malaria treatment. *Tetracycline* or *doxycycline* usually is recommended. Tetracyclines have marked activity against primary tissue schizonts of chloroquine-resistant *P. falciparum*. Doxycycline is used by travelers for short-term prophylaxis of multidrug-resistant strains. Regimens for tetracycline and doxycycline are listed in Tables 39–1 and 39–2. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or children <8 years of age. Photosensitivity reactions or drug-induced superinfections may mandate their discontinuation.

PRINCIPLES AND GUIDELINES FOR PROPHYLAXIS AND CHEMOTHERAPY OF MALARIA

Pharmacological control of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Fortunately, chloroquine still is effective against malarias caused by *P. ovale*, *P. malariae*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* now prevail in most endemic areas. Extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine–sulfadoxine, a combination of antifolate drugs used widely for the treatment of *P. falciparum* malaria. Multidrug-resistant *P. falciparum* malaria, especially prevalent and severe in Southeast Asia and Oceania, now is well established in many areas. These infections may not respond adequately even to mefloquine or quinine.

Isolates of P. falciparum from patients in highly endemic areas contain many parasite clones with different drug-resistance phenotypes. A patient with severe malaria may have 10¹² parasites, so it is easy to understand how mutations conferring resistance can arise in virtually every patient and double mutations can arise occasionally. Therefore, drugs or drug combinations must not be susceptible to single-point-mutation resistance. Intense chloroquine use for decades preceded development of resistance to this agent, likely because multiple mutations are necessary to confer resistance. Resistance also can be promoted by free radicals generated by atovaquone treatment in the mitochondria of the parasite; this is thought to promote development of resistance to this drug. Drugs with a long t_{1/2} are more likely to select out resistant parasites. On a population level, the fitness of resistant parasites is an important parameter—if mutation causes a reduced ability to survive or grow, the parasites are less likely to spread. In the case of antifolates, treatment actually induces gametocytogenesis, which promotes propagation and may explain the sweep of resistance alleles across Africa. These considerations strongly suggest using regimens with two or more agents to treat drug-resistant P. falciparum malaria; such regimens include artemisinin combination treatment and proguanil together with atovaquone. Recommendations for the prophylaxis and therapy of malaria in nonimmune individuals are shown in Tables 39–1 and 39–2. These should serve only as general guidelines. Importantly, drugs should not replace simple, inexpensive measures for malaria prevention. Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites.

A number of regimens are available for malaria chemoprophylaxis. Dosing should be started before exposure, ideally before the traveler leaves home, to establish therapeutic blood levels and to detect early signs of intolerance so that the regimen can be modified before departure. The duration of postexposure dosing is dictated by the spectrum of drug action (Figure 39–2). In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine still is suitable for prophylaxis. It remains the drug of choice for prophylaxis and control of infections due to *P. vivax*, *P. ovale*, and *P. malariae*. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone–proguanil are preferred for prophylaxis. There is more experience with mefloquine and more evidence for its efficacy against *P. vivax* but also more contraindications and perhaps more toxicity. Doxycycline is an alternative chemoprophylactic agent. In cases where mefloquine, atovaquone–proguanil, and doxycycline all are contraindicated, primaquine is a possibility for prophylaxis. Primaquine, like atovaquone–proguanil, is active against liver stages and can be discontinued shortly after leaving the endemic area. Attempts at radical cure of *P. vivax* malaria with primaquine should be delayed until the patient leaves an endemic area.

A malarial attack is a medical emergency, especially for nonimmune travelers, pregnant women, and young children. Treatment with a rapidly acting blood schizontocide must be instituted promptly if P. falciparum malaria is suspected from travel history and clinical findings. One should not wait for a definitive parasitological diagnosis because the clinical status may deteriorate rapidly. Moreover, the clinical presentation may be atypical, and thick blood smears may fail to reveal plasmodia in early stages of this infection. Chloroquine is the drug of choice for P. vivax, P. ovale, P. malariae, and chloroquine-sensitive strains of P. falciparum. Oral administration is used whenever possible, but chloroquine can be given intramuscularly or even intravenously with suitable precautions, although quinine and quinidine usually are the parenteral drugs of choice. Within 48–72 hours of initiating therapy, patients should show marked clinical improvement and a substantial decrease in parasitemia. Lack of such a response or failure to clear parasites from the blood by 7 days is indicative of drug resistance. If chloroquine-resistant P. falciparum malaria is suspected, either from the travel history or from lack of response to chloroquine, the preferred treatment is quinine. For multidrug-resistant P. falciparum malaria, quinine is given together with other

effective but slower-acting blood schizontocides such as antifolates or tetracyclines (Table 39–2). Again, the oral route is preferred, but intravenous preparations should be given until oral medication can be taken. For parenteral therapy in the U.S., quinidine gluconate must be substituted for quinine dihydrochloride. Exchange transfusion may be of value in severe *P. falciparum* malaria.

Malarial attacks may recur during or after a course of chemotherapy, even in the absence of reinfection. Recurrent attacks by P. vivax, P. ovale, or P. malariae usually are well controlled by another course of chloroquine combined with or followed by a course of primaquine in the case of P. vivax or P. ovale. Some patients with P. vivax infection may require more than one course of primaquine for cure. Recrudescence of P. falciparum malarial attacks or parasitemia after appropriate treatment with chloroquine usually denotes infection with chloroquine-resistant plasmodia. Quinine together with a slower-acting drug such as doxycycline in Southeast Asia or with antifolate antimalarials (e.g., pyrimethamine–sulfadoxine) in Africa has been successful (Table 39–2). However, the 7-day course of treatment that often is required, the toxic doses of quinine needed to overcome increasingly drug-resistant parasites, and poor patient compliance compromise the utility of these regimens. Mefloquine is a good alternative to quinine in geographical areas where resistance is lacking but cannot be given parenterally. Moreover, toxic doses of mefloquine may be needed to eradicate parasites that exhibit cross-resistance to quinine. Especially promising compounds for treatment of multidrug-resistant P. falciparum malaria are the artemisinin compounds. As the most rapidly acting and potent blood schizontocides, these drugs markedly reduce parasite burden in a single life cycle and, when used to initiate therapy, make ideal partners for other drugs such as quinolines or antifolates. Parasite resistance has not yet been seen, probably because of their rapid action and very short half-lives. Success against multidrug-resistant P. falciparum malaria also has been achieved with atovaquone–proguanil. This combination is relatively expensive, and treatment failure owing to resistance already is being reported.

Malarial infection, especially with *P. falciparum*, is a severe threat to children and pregnant women. With appropriate adjustments and safety precautions, the treatment of children generally is the same as for adults. Tetracyclines should not be given except in an emergency to children <8 years of age, and atovaquone–proguanil has been approved only for children weighing >11 kg. Pregnant women should be urged to avoid endemic areas if possible. While chloroquine and proguanil may be used during pregnancy, safety documentation is incomplete. Antifolates, tetracyclines, the artemisinins, atovaquone, and primaquine should be avoided. Quinine and quinidine can be used with appropriate caution given to the frequently accompanying hypoglycemia. Mefloquine can be used if necessary, but safety data are not quite reassuring.

In lactating mothers, atovaquone–proguanil is not recommended. Also, the infant must be shown to have a normal G6PD level before using primaquine. For prophylaxis in long-term travelers, chloroquine is safe at the doses used, but may necessitate yearly retinal examinations. Mefloquine and doxycycline are well tolerated. Atovaquone–proguanil has been studied for up to 20 weeks but probably is acceptable for years based on experience with the individual components.

CHEMOTHERAPY OF PROTOZOAL INFECTIONS

Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

INTRODUCTION TO HUMAN PROTOZOAL INFECTIONS

AMEBIASIS

Amebiasis affects ~10% of the world's population. In the U.S., amebiasis is usually seen in those living in crowded, unsanitary conditions. Entamoeba dispar accounts for ~90% of human infections and E. histolytica for only 10%, but only E. histolytica causes human disease. Humans are the only known hosts for these protozoa, which are transmitted almost exclusively by the fecal-oral route. E. histolytica cysts ingested from contaminated food or water transform into trophozoites that reside in the large intestine. Many individuals infected with E. histolytica are asymptomatic but excrete infectious cysts, making them a source for further infections. In others, E. histolytica trophozoites invade the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). Rarely, E. histolytica trophozoites invade through the colonic mucosa and reach the liver via the portal circulation, where they establish an amebic liver abscess.

Metronidazole or its analogs tinidazole and ornidazole are the cornerstone of therapy. Metronidazole and tinidazole are the drugs of choice for amebic colitis, amebic liver abscess, and other extraintestinal form of amebiasis. Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen, and it is less effective against cysts. Patients with amebiasis (amebic colitis or amebic liver abscess) therefore also should receive a luminal agent to eradicate any residual trophozoites. Luminal agents are also used to treat asymptomatic individuals infected with E. histolytica. The nonabsorbed aminoglycoside paromomycin and the 8-hydroxyquinoline compound iodoquinol are effective luminal agents. Nitazoxanide (ALNIA), a drug approved in the U.S. for the treatment of cryptosporidiosis and giardiasis, is also active against E. histolytica.

GIARDIASIS

Giardiasis, caused by Giardia intestinalis, is the most commonly reported intestinal protozoal infection in the U.S. Infection results from ingestion of cysts in fecally contaminated water or food. Human-to-human transmission via the fecal-oral route is especially common among children in day-care centers and nurseries, institutionalized individuals, and male homosexuals.

Infection with Giardia results in an asymptomatic carrier state, acute self-limited diarrhea, or chronic diarrhea. Asymptomatic infection is most common; these individuals excrete Giardia cysts and are a source for new infections. Most adults with symptoms develop an acute self-limited illness, with watery, foul-smelling stools and abdominal distension. Some individuals develop a chronic diarrhea syndrome with malabsorption and weight loss.

The diagnosis of giardiasis is made by identification of cysts or trophozoites in fecal specimens or of trophozoites in duodenal contents. Chemotherapy with a 5-day course of metronidazole usually is successful, although therapy may need to be repeated or prolonged. A single dose of tinidazole (TINDAMAX) probably is superior to metronidazole for giardiasis. Paromomycin has been used to treat pregnant women to avoid any possible mutagenic effects of the other drugs. Nitazoxanide and tinidazole are FDA-approved for the treatment of giardiasis in immune-competent adults and children >1 year of age.

TRICHOMONIASIS

Trichomoniasis is caused by Trichomonas vaginalis, which inhabits the genitourinary tract and causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is sexually transmitted, with more than 200 million people infected worldwide and ~3 million women infected in the U.S. annually. The lack of symptoms in many men hinders effort to eradicate the disease.

Only trophozoite forms of T. vaginalis are found in infected secretions. Metronidazole is the drug of choice for trichomoniasis, but treatment failures owing to resistant organisms are increasing. Tinidazole has been used successfully at higher doses to treat metronidazole-resistant T. vaginalis. Nitazoxanide shows activity against T. vaginalis but is not approved for trichomoniasis.

TOXOPLASMOSIS

Toxoplasmosis is caused by the obligate intracellular protozoan Toxoplasma gondii. Although cats are the natural hosts, tissue cysts have been recovered from all mammalian species examined. Common routes of human infection are (1) ingestion of undercooked meat containing tissue cysts; (2) ingestion of vegetable matter contaminated with soil containing infective oocysts; (3) direct

oral contact with feces of cats shedding oocysts; and (4) transplacental fetal infection with tachyzoites from acutely infected mothers.

Primary infection with *T. gondii* produces clinical symptoms in ~10% of immunocompetent individuals. The acute illness is usually self-limiting and rarely requires treatment. It can cause serious disease in pregnant women, often leading to abortion. Immunocompromised individuals may develop toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain. Toxoplasmic encephalitis typically is seen in patients with AIDS and can be fatal. Clinical manifestations of congenital toxoplasmosis vary widely, but chorioretinitis is the most common finding. The primary treatment for toxoplasmic encephalitis is the antifolates pyrimethamine and sulfadiazine. Therapy must be discontinued in ~40% of cases because of toxicity, primarily of the sulfa drug; clindamycin can be substituted for sulfadiazine without loss of efficacy. Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine and folinic acid are less toxic but also less effective than the combination of pyrimethamine and sulfadiazine.

Spiramycin, which concentrates in placental tissue, is used to treat acute acquired toxoplasmosis in pregnancy to prevent transmission to the fetus. If fetal infection is detected, the combination of pyrimethamine and sulfadiazine is administered to the mother (only after the first 12–14 weeks of pregnancy) and to the newborn in the postnatal period.

CRYPTOSPORIDIOSIS

Cryptosporidia are protozoan parasites that cause diarrhea in many species, including humans. *Cryptosporidium parvum* and *C. hominis* account for almost all human infections. Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies. Groups at risk include travelers, children in day-care facilities, male homosexuals, animal handlers, veterinarians, and other healthcare personnel. Immunocompromised individuals are especially vulnerable. After ingestion, the mature oocyte releases sporozoites that invade host epithelial cells. Infection usually is self-limited. In AIDS patients and other immunocompromised individuals, severe secretory diarrhea may require hospitalization and supportive therapy.

The most effective therapy for cryptosporidiosis in AIDS patients is immune restoration with highly active antiretroviral therapy (HAART). Nitazoxanide has shown activity in treating cryptosporidiosis in immunocompetent children and may also be effective in adults. Its efficacy in children and adults with AIDS is not clearly established; the lower the CD4 count, the less likely a patient is to respond. Nevertheless, nitazoxanide is the only drug approved for cryptosporidiosis in the U.S.

TRYPANOSOMIASIS

African trypanosomiasis, or “sleeping sickness,” is caused by *Trypanosoma brucei* subspecies that are transmitted by tsetse flies. It causes serious human illness that is fatal unless treated. An estimated 300,000–500,000 Africans carry the infection, and over 60 million people are at risk. It is extremely rare in the U.S. The parasite is entirely extracellular, and early infection is characterized by the presence of replicating parasites in the bloodstream or lymph without central nervous system (CNS) involvement (stage 1). Manifestations of early stage disease include fever, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. Stage 2 is characterized by CNS involvement. There are two types of African trypanosomiasis, the East African and West African, caused by *T. brucei rhodesiense* and *T. brucei gambiense*, respectively. *T. brucei rhodesiense* produces a progressive, rapidly fatal disease marked by early CNS involvement and frequent terminal cardiac failure; *T. brucei gambiense* causes illness that is characterized by later CNS involvement and a prolonged course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, poor coordination, sensory deficits, an array of psychiatric signs, and eventual progression to coma and death.

Standard therapy for early-stage disease is pentamidine for *T. brucei gambiense* and suramin for *T. brucei rhodesiense*. These agents are not effective against late-stage disease, and standard treatment of the CNS phase is melarsoprol. All three compounds must be given parenterally over long periods. Eflornithine offers the only alternative for the treatment of late-stage disease; it has marked efficacy against early and late stages of human *T. brucei gambiense* infection. It has significantly fewer side effects than melarsoprol but is expensive, difficult to administer, and ineffective as monotherapy for infections of *T. brucei rhodesiense*.

American trypanosomiasis, or Chagas’ disease, is caused by *Trypanosoma cruzi*. It affects ~20 million people from Mexico to South America, where the chronic form of the disease is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Bloodsucking triatomid bugs most commonly transmit this infection to young children; transplacental transmission also may occur in endemic areas.

Reactivation also may occur in patients who are immunosuppressed after organ transplantation or because of other conditions (e.g., AIDS, leukemia, and other neoplasias). Occurrences of *T. cruzi* infection in transplant patients or through blood transfusions have been reported in the U.S. Acute infection is evidenced by a raised tender skin nodule (chagoma) at the site of inoculation; other signs may range from fever, adenitis, skin rash, and hepatosplenomegaly to, rarely, acute myocarditis and death. Invading metacyclic trypomastigotes penetrate host cells, especially macrophages, where they proliferate as amastigotes and then differentiate into trypomastigotes that enter the bloodstream. After recovery from the acute infection, individuals usually remain asymptomatic for years despite sporadic parasitemia. An increasing fraction of adults develops overt cardiac and GI chronic disease as they age. Progressive destruction of myocardial cells and neurons of the myenteric plexus results from the tropism of *T. cruzi* for muscle cells. Two nitroheterocyclic drugs, nifurtimox and benznidazole, are used to treat this infection. Both agents suppress parasitemia and can cure the acute phase of Chagas' disease in 60–80% of cases. Current recommendations are that patients with either acute- or recent chronic-phase disease should be treated. For patients with late chronic-phase disease (>10 years), parasitological cure is less likely, and there is no consensus on management. Both drugs are toxic and must be taken for long periods. Isolates vary with respect to their susceptibility to nifurtimox and benznidazole. In the absence of new drugs, alternative measures such as improved vector control and housing accommodations have reduced the transmission of Chagas' disease substantially.

LEISHMANIASIS

Leishmaniasis is caused by ~20 different species of protozoa of the genus *Leishmania*. Small mammals and canines serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of female sandflies. Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free promastigotes, regurgitated by feeding flies, enter the host, where they are phagocytized by tissue macrophages and transform into amastigotes, which multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the life cycle. The particular localized or systemic disease syndrome caused by *Leishmania* depends on the species of infecting parasite, the distribution of infected macrophages, and especially the host's immune response. In increasing order of severity, human leishmaniasis has been classified into cutaneous, mucocutaneous, diffuse cutaneous, and visceral forms. Leishmaniasis increasingly occurs as an AIDS-associated infection.

Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring within 3–18 months after infection, but can leave disfiguring scars. The mucocutaneous, diffuse cutaneous, and visceral forms of the disease do not resolve without therapy. Visceral leishmaniasis caused by *L. donovani* is fatal unless treated. The classic therapy for all species of *Leishmania* is pentavalent antimony, but increasing resistance to this compound has been encountered. Liposomal amphotericin B is highly effective for visceral leishmaniasis, and is currently the drug of choice for antimony-resistant disease. Miltefosine, an orally active agent, shows considerable promise for the treatment of leishmaniasis. Paromomycin and pentamidine both have been used successfully as parenteral agents for visceral disease, although pentamidine's usefulness is limited by toxicity. Topical formulations of paromomycin, recently combined with gentamicin, also have been effective for cutaneous disease.

OTHER PROTOZOAL INFECTIONS

Babesiosis is a tick-borne zoonosis caused by parasites that invade erythrocytes, producing a febrile illness, hemolysis, and hemoglobinuria. Infection usually is self-limiting but can be severe or even fatal in asplenic or severely immunocompromised individuals. Standard therapy is a combination of clindamycin and quinine, but azithromycin plus atovaquone was as effective with fewer adverse effects.

Microsporidia are unicellular eukaryotic fungal parasites that cause a number of disease syndromes, including diarrhea in immunocompromised individuals. Infections with microsporidia have been treated successfully with albendazole. Immunocompromised individuals with intestinal microsporidiosis owing to *E. bienersi* (which does not respond to albendazole) have been treated with fumagillin.

AMPHOTERICIN

Liposomal amphotericin B (AMBISOME) cures nearly 100% of cases of visceral leishmaniasis and has become the drug of choice for antimonial-resistant disease. Likely due to pharmacokinetic considerations, it is not useful against cutaneous or mucosal leishmaniasis. The recommended

dose for the treatment of visceral leishmaniasis is 3 mg/kg/day intravenously for days 1–5, 14, and 21, with the dose being increased to 4 mg/kg and extended to days 1–5, 10, 17, 24, 31, and 38 for immunosuppressed patients. Shorter courses of the drug provide a lower-cost alternative. Cure rates are ~90% with either regimen.

CHLOROQUINE

Chloroquine is directly toxic to *E. histolytica* trophozoites and is highly concentrated within the liver, making it effective for amebic liver abscess. It is used only when metronidazole or another nitroimidazole is either contraindicated or unavailable. Chloroquine is not effective against intestinal amebiasis because it only attains low concentrations in the colon; patients receiving chloroquine for amebic liver abscess also should receive paromomycin or iodoquinol to eliminate intestinal colonization.

The conventional course of treatment with chloroquine for extraintestinal amebiasis in adults is 1 g/day for 2 days, followed by 500 mg/day for at least 2–3 weeks. Because of its low toxicity, this dose can be increased or the schedule can be repeated if necessary.

EFLORNITHINE

Eflornithine (α -difluoromethylornithine, DFMO, ORNIDYL) is an irreversible suicide inhibitor of ornithine decarboxylase, which catalyzes the rate-limiting step in the biosynthesis of polyamines. Polyamines are required for cell division and normal cell differentiation. In trypanosomes, spermidine also is required for the synthesis of trypanothione, a conjugate of spermidine and glutathione that replaces many functions of glutathione in the parasite. Eflornithine is used to treat trypanosomiasis caused by *T. brucei gambiense*. The drug usually is curative even for late CNS stages of infection resistant to arsenicals but is largely ineffective for East African trypanosomiasis. Its high cost, production shortages, and difficult treatment regimen have limited use. Eflornithine is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request. The structure of eflornithine is:

ANTITRYPANOSOMAL EFFECTS

Eflornithine inhibits ornithine decarboxylase; it irreversibly inhibits both mammalian and trypanosomal enzymes, thereby preventing the synthesis of polyamines needed for cell division. The parasite and human enzymes are equally susceptible to eflornithine, but the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable. *T. brucei rhodesiense* cells are less sensitive to eflornithine inhibition than *T. brucei gambiense* cells, and effective levels generally cannot be achieved clinically.

ABSORPTION, FATE, AND EXCRETION

Eflornithine is given intravenously. Peak plasma levels are achieved ~4 hours after an oral dose, and the elimination $t_{1/2}$ averages 200 minutes. The drug does not bind to plasma proteins. It is well distributed and readily penetrates into the cerebrospinal fluid (CSF), which is especially important in late-stage West African trypanosomiasis. Over 80% of eflornithine is cleared by the kidney, largely in unchanged form.

THERAPEUTIC USES In patients with West African trypanosomiasis due to *T. brucei gambiense*, the preferred regimen for adult patients is 100 mg/kg given intravenously every 6 hours for 14 days as a 2-hour infusion. Response rates exceed 90% even in late-stage patients. A higher risk of treatment failure overall was found in patients who were stuporous on admission or were older. Children younger than 12 years of age required higher doses of eflornithine, probably because they clear the drug more rapidly such that the drug does not reach the CNS. To avoid early convulsions,

a proposed regimen uses the current intravenous dosage (400 mg/kg/day) in the first few days, followed by an increase for the second part of therapy. Eflornithine and melarsoprol may act synergistically.

Eflornithine has been less successful for AIDS patients with West African trypanosomiasis, presumably because host defenses play a critical role in clearing drug-treated pathogen from the bloodstream. Eflornithine failed to improve treatment of East African trypanosomiasis owing to *T. brucei rhodesiense*, consistent with the relatively short $t_{1/2}$ and high activity of ornithine decarboxylase in these parasites.

TOXICITY AND SIDE EFFECTS Eflornithine causes adverse effects that are generally reversible on drug withdrawal. Anemia (48%), diarrhea (39%), and leukopenia (27%) are the most common complications in patients receiving intravenous drug. Diarrhea is both dose-related and dose-limiting, especially after oral administration. Convulsions occur early in ~7% of treated patients but do not recur despite continuation of therapy. Other complications—such as thrombocytopenia, alopecia, vomiting, abdominal pain, dizziness, fever, anorexia, and headache—occur in <10% of treated patients. Reversible hearing loss can occur after prolonged therapy. Therapeutic doses of eflornithine require coadministration of substantial volumes of intravenous fluid, which poses practical limitations in remote settings and causes fluid overload in susceptible patients.

Fumagillin

Fumagillin (FUMIDIL B, others) is an acyclic polyene macrolide.

Fumagillin is toxic to microsporidia and also has some activity against E. histolytica. Fumagillin is used topically to treat keratoconjunctivitis caused by E. hellem at a dose of 3–10 mg/mL in suspension. For intestinal microsporidiosis caused by E. bienersi, fumagillin was used at a dose of 20 mg orally three times daily for 2 weeks. Adverse effects of fumagillin include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported. Fumagillin is not approved for the systemic treatment of microsporidia infection in the U.S.

8-Hydroxyquinolines

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and clioquinol (iodochlorhydroxyquin) have been used to eliminate intestinal colonization with E. histolytica. Iodoquinol (YODOXIN) is safer and is available for oral use in the U.S. Adverse effects are unusual when used at appropriate doses (never to exceed 2 g/day) and duration of therapy (<20 days in adults). The use of these drugs, especially at doses >2 g/day, for long periods is associated with significant risk. The most important toxic reaction, ascribed primarily to clioquinol, is subacute myelo-optic neuropathy. Peripheral neuropathy is a milder manifestation of neurotoxicity. Administration of iodoquinol in high doses to children has been associated with optic atrophy and permanent loss of vision. Because of its superior safety, paromomycin is preferred as the luminal agent for amebiasis; however, iodoquinol is a reasonable alternative. Iodoquinol is used in combination with metronidazole to treat individuals with amebic colitis or amebic liver abscess but may be used as a single agent for asymptomatic individuals found to be infected with E. histolytica. For adults, the recommended dose of iodoquinol is 650 mg orally three times daily for 20 days, whereas children receive 10 mg/kg of body weight orally three times a day (not to exceed 2 g/day) for 20 days.

MELARSOPROL

Melarsoprol (Mel B; ARSOBAL) is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

MELARSOPROL

ANTIPROTOZOAL EFFECTS Melarsoprol is a prodrug that is metabolized rapidly ($t_{1/2}$ of 30 minutes) to melarsen oxide, the active form. Arsenoxides react avidly and reversibly with sulfhydryl groups and thereby inactivate many enzymes. Melarsoprol reacts with trypanothione to form melarsen oxide–trypanothione adduct, which potently inhibits trypanothione reductase. Both the sequestering of trypanothione and the inhibition of trypanothione reductase are expected to have lethal consequences to the cell, but this remains unproven.

The number of treatment failures has risen sharply and some resistant strains are tenfold less sensitive to the drug than sensitive strains. It is not clear that the lack of patient response to the drug correlates with reduced sensitivity of the parasite in most cases.

Melarsoprol resistance likely involves transport defects. The P2 adenine–adenosine transporter has activity on melarsoprol as well as pentamidine and berenil; point mutations in this transporter are found in melarsoprol-resistant isolates.

ABSORPTION, FATE, AND EXCRETION

Melarsoprol is always administered intravenously. A small but therapeutically significant amount of the drug enters the CSF and has a lethal effect on CNS trypanosomes. The compound is excreted rapidly, with 70–80% of the arsenic appearing in the feces.

THERAPEUTIC USES Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis. Melarsoprol treatment of East African trypanosomiasis is initiated soon after diagnosis because CNS involvement occurs early in this aggressive infection. Melarsoprol is not used for prophylaxis because of its toxicity and rapid elimination.

The pattern of resistance to melarsoprol differs between the two subspecies of *T. brucei*. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug but often respond to eflornithine.

Melarsoprol is administered by slow intravenous injection, with care to avoid tissue extravasation. A typical course of treatment is three 3- to 4-day courses of 2–3.6 mg/kg with 7-day intervals between courses. Lesser doses should be given to children and debilitated patients. A continuous 10-day course of 2.2 mg/kg/day also is effective and will likely become standard. Unless contraindicated, glucocorticoids should be given to decrease the incidence of reactive encephalopathy.

TOXICITY AND SIDE EFFECTS Toxicity is common during treatment with melarsoprol. A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. Reactive encephalopathy occurs in ~5–10% of patients, leading to fatality in perhaps half of these. Encephalopathy, when it occurs, typically develops between the two courses of therapy. It is more common in East African than in West African trypanosomiasis and is more likely to develop in patients whose CSF contains many cells and trypanosomes. Manifestations include convulsions associated with acute cerebral edema, rapidly progressive coma, and acute mental disturbances; this likely represents a reaction to trypanosomal antigens. Coadministration of glucocorticoids reduces the frequency of reactive encephalopathy and also can help to control hypersensitivity reactions during the second or subsequent courses of therapy. Peripheral neuropathy, noted in ~10% of patients, probably is a direct toxic effect of the drug. Hypertension and myocardial damage are not

uncommon, although shock is rare. Proteinuria occurs frequently, and evidence of renal or hepatic dysfunction may necessitate treatment modification. Vomiting and abdominal colic are reduced by injecting melarsoprol slowly into the supine, fasting patient.

PRECAUTIONS AND CONTRAINDICATIONS Melarsoprol should be given to patients only under hospital supervision. The initial dose must be based on clinical assessment rather than body weight. Initiation of therapy during a febrile episode is associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprosy patients may precipitate erythema nodosum. The drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with glucose-6-phosphate dehydrogenase deficiency.

METRONIDAZOLE

ANTIPARASITIC AND ANTIMICROBIAL EFFECTS Metronidazole and related nitroimidazoles are active *in vitro* against a wide variety of anaerobic protozoal parasites and anaerobic bacteria. The drug also has potent amebicidal activity against *E. histolytica*.

Metronidazole has antibacterial activity against all anaerobic cocci and both anaerobic gram-negative bacilli, including *Bacteroides* spp., and anaerobic spore-forming gram-positive bacilli. Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis, and in a variety of infections caused by obligate anaerobic bacteria, including *Bacteroides*, *Clostridium*, and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp.

MECHANISM OF ACTION AND RESISTANCE

Metronidazole is a prodrug that is activated by reduction of the nitro group by susceptible organisms. Unlike their aerobic counterparts, anaerobic and microaerophilic pathogens such as *T. vaginalis*, *E. histolytica*, and *G. lamblia* and anaerobic bacteria contain electron transport components that have a sufficiently negative redox potential to donate electrons to metronidazole. Electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA. Metronidazole is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O_2 inhibit metronidazole-induced cytotoxicity because O_2 competes with metronidazole for electrons generated by energy metabolism. Thus, O_2 can both decrease reductive activation of metronidazole and increase recycling of activated drug. In susceptible organisms, pyruvate decarboxylation, catalyzed by pyruvate:ferredoxin oxidoreductase (PFOR), produces electrons that reduce ferredoxin, which then catalytically donates electrons to biological electron acceptors or to metronidazole.

Clinical resistance to metronidazole is well documented for *T. vaginalis*, *G. lamblia*, and a variety of anaerobic and microaerophilic bacteria. Resistance correlates with impaired oxygen-scavenging capabilities, leading to higher local O_2 concentrations, decreased metronidazole activation, and futile recycling of the activated drug. Other resistant strains have lowered but detectable levels of PFOR and ferredoxin, perhaps explaining why they may still respond to higher levels of drug. In the case of *Bacteroides* spp., metronidazole resistance is linked to a family of nitroimidazole (nim) resistance genes that can be encoded chromosomally or episomally. These nim genes encode nitroimidazole reductases capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus blocking formation of the reactive nitroso group responsible for microbial killing.

ABSORPTION, FATE, AND EXCRETION

Metronidazole is supplied for oral, intravenous, intravaginal, and topical administration. It usually is absorbed completely after oral intake. A linear relationship between dose and plasma concentration pertains for doses of 200–2000 mg. Repeated doses every 6–8 hours result in some drug accumulation. The $t_{1/2}$ of metronidazole in plasma is ~8 hours, and its volume of distribution is approximately that of total-body water. Less than 20% of the drug is bound to plasma proteins. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, and breast milk. Therapeutic concentrations also are achieved in CSF.

After an oral dose, >75% of labeled metronidazole is eliminated in the urine largely as metabolites; only ~10% is recovered as unchanged drug. The liver accounts for >50% of the systemic clearance of metronidazole. Two principal metabolites result from side-chain oxidation: a hydroxy derivative and an acid. The hydroxy metabolite has a longer $t_{1/2}$ (~12 hours) and contains nearly 50% of the antitrichomonal activity of metronidazole. Glucuronidation also is observed. Small amounts of reduced metabolites, including ring-cleavage products, are formed by gut flora. The urine of some patients may be reddish brown due to pigments derived from the drug. Oxidative metabolism of metronidazole is induced by phenobarbital, prednisone, rifampin, and possibly ethanol and is inhibited by cimetidine.

THERAPEUTIC USES Metronidazole cures genital infections with *T. vaginalis* in >90% of cases. The preferred regimen is 2 g metronidazole as a single oral dose for both males and females. For patients who cannot tolerate a single 2-g dose, an alternative is a 250-mg dose given three times daily or a 375-mg dose given twice daily for 7 days. When repeated courses or higher doses of the drug are required for uncured or recurrent infections, it is recommended that intervals of 4–6 weeks elapse between courses. In such cases, leukocyte counts should be carried out before, during, and after each course of treatment.

Treatment failures owing to metronidazole-resistant strains of T. vaginalis are increasingly common. Most cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a topical gel containing 0.75% metronidazole or a 500- to 1000-mg vaginal suppository may be beneficial in refractory cases.

Metronidazole is the agent of choice for all symptomatic forms of amebiasis, including colitis and liver abscess. The recommended dose is 500–750 mg metronidazole taken orally three times daily for 7–10 days. The daily dose for children is 35–50 mg/kg, given in three divided doses, for 7–10 days.

While standard recommendations are for 7–10 days' duration of therapy, amebic liver abscess has been treated successfully by short courses (2.4 g daily as a single oral dose for 2 days) of metronidazole or tinidazole. E. histolytica persist in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide.

Metronidazole is not approved for treatment of giardiasis in the U.S., but favorable responses have been noted with doses similar to or lower than those used for trichomoniasis; the usual regimen is 250 mg given three times daily for 5 days for adults and 15 mg/kg given three times a day for 5 days for children. A daily dose of 2 g for 3 days also has been used successfully.

Metronidazole is used for the treatment of serious infections owing to susceptible anaerobic bacteria, including Bacteroides, Clostridium, Fusobacterium, Peptococcus, Peptostreptococcus, Eubacterium, and Helicobacter. The drug is also given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole achieves clinically effective levels in bones, joints, and the CNS and can be given intravenously when oral administration is not possible. A loading dose of 15 mg/kg is followed 6 hours later by a maintenance dose of 7.5 mg/kg every 6 hours, usually for 7–10 days. Metronidazole is used as a component of prophylaxis of postoperative mixed bacterial infections and is used as a single agent to treat bacterial vaginosis.

Metronidazole is used increasingly as primary therapy for pseudomembranous colitis due to Clostridium difficile infection. At doses of 250–500 mg orally three times daily for 7–14 days, metronidazole is effective and less expensive than oral vancomycin. Metronidazole also is used in patients with Crohn's disease who have perianal fistulas or significant colonic disease (see Chapter 38).

TOXICITY, CONTRAINDICATIONS, AND DRUG INTERACTIONS Side effects rarely are severe enough to discontinue therapy. The most common are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Neurotoxic side effects (e.g., dizziness, vertigo, and very rarely, encephalopathy, convulsions, incoordination, and ataxia) mandate metronidazole discontinuation. The drug also should be withdrawn if numbness or paresthesias occur. Reversal of serious sensory neuropathies may be slow or incomplete. Urticaria, flushing, and pruritus are indications of drug sensitivity. Metronidazole rarely causes toxic epidermal necrolysis, which may be more common in individuals receiving high doses of metronidazole and concurrent therapy with *mebendazole*.

Dysuria, cystitis, and a sense of pelvic pressure have been reported. Metronidazole has a disulfiram-like effect, and some patients will experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy. Metronidazole and *disulfiram* or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur.

Metronidazole should be used with caution in patients with active CNS disease because of its potential neurotoxicity. The drug also may precipitate CNS signs of *lithium* toxicity in patients receiving this agent. Metronidazole can prolong the prothrombin time of patients receiving *coumadin* anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease.

There are conflicting data about the teratogenicity of metronidazole in animals. While metronidazole has been taken during all stages of pregnancy with no apparent adverse effects, its use during the first trimester generally is not advised.

MILTEFOSINE

MILTEFOSINE

ANTIPROTOZOAL EFFECTS Miltefosine is the first orally available therapy for leishmaniasis. It is safe and effective treatment for visceral leishmaniasis and has also shown >95% efficacy against cutaneous leishmaniasis. In *Leishmania*, the drug may alter ether–lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis. Mutations in a P-type ATPase of the aminophospholipid translocase subfamily apparently decrease drug uptake and thereby confer resistance.

ABSORPTION, FATE, AND EXCRETION

Miltefosine is well absorbed orally and distributed throughout the body. Plasma concentrations are proportional to the dose.

THERAPEUTIC USES Oral miltefosine is registered in India for use in the treatment of visceral leishmaniasis in adults at a dose of 100 mg/kg daily (for patients weighing more than 25 kg) for 28 days. A similar dosing schedule has shown efficacy against cutaneous disease. Children should be given 2.5 mg/kg/day. The compound cannot be given intravenously because of hemolysis.

TOXICITY AND SIDE EFFECTS Vomiting and diarrhea have been reported in up to 60% of patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These are typically mild and resolve quickly once the drug is withdrawn. The drug is contraindicated in pregnant women. Women should receive a negative pregnancy test prior to treatment, and birth control is required during and for at least 2 months after treatment.

NIFURTIMOX

ANTIPROTOZOAL EFFECTS Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi*. Nifurtimox also has activity against *T. brucei* and can cure early- and late-stage disease.

The trypanocidal action of nifurtimox derives from its ability to undergo activation by partial reduction to nitro radical anions. Transfer of electrons from the activated drug then forms superoxide radical anions and other reactive oxygen species. Reaction of free radicals results in lipid peroxidation and membrane injury, enzyme inactivation, and DNA damage. Benznidazole also requires a one-electron transfer that generates nitro anion radicals, leading to cellular damage that kills the parasites.

ABSORPTION, FATE, AND EXCRETION

Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after ~3.5 hours. Less than 0.5% of the dose is excreted in urine. The elimination $t_{1/2}$ is ~3 hours. High concentrations of several unidentified metabolites are found, and nifurtimox undergoes rapid biotransformation, probably via a presystemic first-pass effect. Whether the metabolites have any trypanocidal activity is unknown.

THERAPEUTIC USES

*Nifurtimox and benznidazole are used to treat American trypanosomiasis (Chagas' disease) caused by *T. cruzi*. Because of toxicity, benznidazole is preferred. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas' disease, producing parasitological cures*

in 80% of cases. In the chronic disease, parasitological cures are still possible in up to 50% of patients. Even without a complete parasitological cure, treatment also reduces clinical symptoms. Treatment with nifurtimox or benznidazole has no effect on irreversible organ lesions. While part of tissue destruction may be autoimmune in nature, the continued presence of parasites in the infected organs of patients with chronic disease argues that Chagas' disease should be treated as a parasitic disease. The clinical response of the acute illness to drug therapy varies with geographical region. Treatment of all seropositive individuals is recommended and should be initiated as soon as possible. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or blood transfusions.

Both drugs are given orally. For nifurtimox, adults with acute infection should receive 8–10 mg/kg/day in four divided doses for 90–120 days. Children 1–10 years of age with acute Chagas' disease should receive 15–20 mg/kg/day in four divided doses for 90 days; for individuals 11–16 years old, the daily dose is 12.5–15 mg/kg given according to the same schedule. For benznidazole, the recommended treatment is 5–7 mg/kg/day in two divided doses for 30–90 days, with children up to 12 years receiving 10 mg/kg/day. Gastric upset and weight loss can occur during treatment. If the latter occurs, dosage should be reduced. The ingestion of alcohol should be avoided.

TOXICITY AND SIDE EFFECTS Drug-related side effects range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications of the GI tract and the peripheral and CNS. Nausea and vomiting, myalgia, and weakness are common. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment. Headache, psychiatric disturbances, paresthesias, polyneuritis, and CNS excitability are less frequent. Leukopenia and decreased sperm counts also have been reported. Because of the seriousness of Chagas' disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

NITAZOXANIDE

NITAZOXANIDE

ANTIMICROBIAL EFFECTS

Nitazoxanide and its active metabolite tizoxanide inhibit the growth of sporozoites and oocysts of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* in vitro. Nitazoxanide also demonstrated activity against intestinal helminths.

MECHANISM OF ACTION AND RESISTANCE

Nitazoxanide appears to interfere with the PFOR enzyme-dependent electron-transfer reaction, which is essential in anaerobic metabolism. No resistance to nitazoxanide in infectious agents previously known to be susceptible to the drug has yet been reported.

ABSORPTION, FATE, AND EXCRETION

Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite tizoxanide, which undergoes conjugation primarily to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum plasma concentrations of metabolites are detected within 1–4 hours of administration of the parent compound. Tizoxanide is >99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces, whereas tizoxanide glucuronide is excreted in urine and bile.

THERAPEUTIC USES In the U.S., nitazoxanide (ALINIA) is available as an oral suspension and as tablets. It is approved for the treatment of *G. intestinalis* infections in adults and in children and for the treatment of diarrhea in children under 12 caused by cryptosporidia. The efficacy of nitazoxanide in children (or adults) with cryptosporidia infection and AIDS is not clearly established. For children between the ages of 12 and 47 months, the recommended dose is 100 mg every 12 hours for 3 days; for children between 4 and 11 years of age, the dose is 200 mg every 12 hours for 3 days. A 500-mg nitazoxanide tablet, suitable for adult dosing (every 12 hours), is not available in the U.S.

Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). Effective parasite clearance after nitazoxanide treatment was shown for *G. intestinalis*, *E. histolytica*/*E. dispar*, *B. hominis*, *C. parvum*, *C. cayetanensis*, *I. belli*, *H. nana*, *T. trichura*, *A. lumbricoides*, and *E. vermicularis*, although more than one course of therapy was sometimes required. Nitazoxanide has been used to treat infections with *G. intestinalis* that are resistant to metronidazole and albendazole.

TOXICITY AND SIDE EFFECTS Adverse effects are rare with nitazoxanide. A greenish tint to the urine is seen in most individuals taking nitazoxanide. Nitazoxanide is a category B agent for use in pregnancy based on animal studies, but there is no clinical experience with its use in pregnant women or nursing mothers.

PAROMOMYCIN

Paromomycin (aminosidine, *HUMATIN*) is an aminoglycoside given orally to treat *E. histolytica*, cryptosporidiosis, and giardiasis. A topical formulation is used to treat trichomoniasis and cutaneous leishmaniasis, and parenteral administration has been used for visceral leishmaniasis.

Paromomycin shares the same mechanism of action as other aminoglycosides and has the same spectrum of antibacterial activity and toxicity (see Chapter 45). Paromomycin is available only for oral use in the U.S. Following oral administration, 100% of the drug is recovered in the feces, even with compromised gut integrity.

Paromomycin is the drug of choice for intestinal colonization with *E. histolytica* and is used in combination with metronidazole to treat amebic colitis and amebic liver abscess. Dosing for adults and children is 25–35 mg/kg/day orally in three divided doses. Adverse effects are rare, but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Paromomycin has been used to treat cryptosporidiosis in AIDS patients both as a single agent (oral doses of 500 mg three times daily or 1 g orally twice daily for 14–28 days followed by 500 mg orally twice daily) and in combination with azithromycin (paromomycin 1 g orally twice daily plus azithromycin 600 mg orally once daily for 4 weeks, followed by paromomycin alone for 8 weeks). Paromomycin has been advocated as a treatment for giardiasis in pregnant women, especially during the first trimester when metronidazole is contraindicated, and as an alternative agent for metronidazole-resistant isolates of *G. intestinalis*. Response rates of 55–90% have been reported. Dosing in adults is 500 mg orally three times daily for 10 days, whereas children have been treated with 25–30 mg/kg/day in three divided oral doses. Paromomycin formulated as a 6.25% cream has been used to treat vaginal trichomoniasis in patients who failed or could not receive metronidazole therapy. Cures have been reported, but vulvovaginal ulcerations and pain have complicated treatment.

Paromomycin as a topical formulation containing 15% paromomycin in combination with either a patented base or 12% methylbenzoniun chloride has shown variable efficacy for the treatment of cutaneous leishmaniasis. Paromomycin has been administered parenterally (doses of 16–18 mg/kg/day) alone or in combination with antimony to treat visceral leishmaniasis. In one study, cure rates of 89% with paromomycin alone were reported, and cure rates of 94% were seen with combination therapy. These results compared favorably with those with antimony alone in areas where antimony resistance is common.

PENTAMIDINE

Pentamidine is a positively charged aromatic diamidine:

Pentamidine isethionate is marketed for injection (*PENTAM 300*) or for use as an aerosol (*NEBUPENT*). One milligram of pentamidine base is equivalent to 1.74 mg of the pentamidine isethionate. The isethionate salt is highly water soluble. Solutions should be used promptly because pentamidine is unstable in solution.

ANTIPROTOZOAL EFFECTS The diamidines are effective for the treatment of *T. brucei gambiense* sleeping sickness but not *T. brucei rhodesiense* or *T. cruzi* infections. They also are useful for treating antimony-resistant leishmania.

MECHANISM OF ACTION AND RESISTANCE

The diamidines display multiple effects on any given parasite and act by disparate mechanisms in different parasites. In *T. brucei*, for example, the diamidines are concentrated via an energy-dependent uptake system to millimolar concentrations that are essential for efficacy. The best-characterized diamidine transporter is a purine (P2) adenine and adenosine transporter that also is used by the melamine-based arsenicals, which explains the cross-resistance to diamidines exhibited by certain arsenical-resistant strains of *T. brucei*. Multiple transporters mediate pentamidine uptake, which may account for the fact that little resistance to this drug is observed despite years of prophylactic use. The diamidines may exert their trypanocidal effects by reacting with a variety of negatively charged intracellular targets such as membrane phospholipids, enzymes, RNA, and DNA. In *Leishmania*, pentamidine accumulates within mitochondria and causes early disintegration of the kinetoplast and collapse of the mitochondrial membrane potential. Moreover, pentamidine resistance is linked to decreased drug concentration within mitochondria, again implicating this organelle in drug action.

ABSORPTION, FATE, AND EXCRETION

The pharmacokinetics and biodisposition of pentamidine isethionate have been studied most extensively in AIDS patients with *P. jiroveci* infections. Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent $t_{1/2}$ of several minutes to a few hours and maximum plasma concentrations after intramuscular injection occur at 1 hour. The drug is highly protein bound and has an elimination $t_{1/2}$ of weeks to months. This highly charged compound does not cross the blood-brain barrier, explaining why it is ineffective against late-stage trypanosomiasis.

Inhalation of pentamidine aerosols is used for prophylaxis of *Pneumocystis pneumonia*; delivery of drug by this route results in little systemic absorption and decreased toxicity compared with intravenous administration in both adults and children.

THERAPEUTIC USES For sleeping sickness, pentamidine isethionate usually is given by intramuscular injection in single daily doses of 4 mg/kg/day for a series of 7 days. Because of failure to penetrate the CNS, pentamidine is ineffective against late stage disease and appears to have reduced efficacy against *T. brucei rhodesiense*. Thus, pentamidine is limited to use in early stage *T. brucei gambiense* infections.

Pentamidine has been used successfully in courses of 12–15 intramuscular doses of 2–4 mg/kg either daily or every other day to treat visceral leishmaniasis. It provides an alternative to antimonials or lipid formulations of amphotericin B for patients who cannot tolerate these agents.

*Pentamidine is one of several drugs used to treat or prevent Pneumocystis infection. Pneumocystis pneumonia (PCP) is a major cause of mortality in individuals with AIDS and can occur in patients who are immunosuppressed by other mechanisms. Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of PCP (see Chapter 43). Pentamidine given intravenously as a 4 mg/kg single daily dose for 21 days is used to treat severe PCP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agents such as atovaquone or the combination of clindamycin and primaquine. Pentamidine has been recommended as a “salvage” agent for individuals with PCP who failed to respond to initial therapy (usually trimethoprim-sulfamethoxazole) but may be less effective than the combination of clindamycin and primaquine or atovaquone for this indication. Pentamidine administered as an aerosol preparation is used to prevent PCP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not deemed candidates for either dapsone (alone or in combination with pyrimethamine) or atovaquone. Candidates for PCP prophylaxis are individuals with HIV infection and a CD4 count of <200 per mm³ and individuals with HIV infection and persistent unexplained fever or oropharyngeal candidiasis. Secondary prophylaxis is recommended after any documented PCP episode. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5–10% nebulized solution over 30–45 minutes. Although convenient, aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens, and a slightly increased risk for pneumothorax. For individuals who receive HAART and achieve CD4 counts persistently >200 per mm³ for 3 months, primary or secondary PCP prophylaxis can be stopped.*

TOXICITY AND SIDE EFFECTS Approximately 50% of individuals given pentamidine at recommended doses will show some adverse effect. Intravenous administration may be associated with hypotension, tachycardia, and headache, probably secondary to the ability of pentamidine to bind imidazoline receptors, which can be ameliorated by slowing the infusion rate. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment. Careful monitoring

of blood glucose is the key. Paradoxically, pancreatitis, hyperglycemia, and insulin-dependent diabetes also may occur. Pentamidine is nephrotoxic (~25% of treated patients will show signs of renal dysfunction), and if the serum creatinine concentration rises significantly, it may be necessary to withhold the drug temporarily or change to an alternative agent. Individuals developing pentamidine-induced renal dysfunction are at higher risk for hypoglycemia. Other adverse effects include rashes, thrombophlebitis, anemia, neutropenia, and elevated hepatic enzymes. Intramuscular administration of pentamidine can cause sterile abscesses at the injection site, and most authorities prefer intravenous administration. Aerosolized pentamidine has few adverse events.

SODIUM STIBOGLUCONATE

Sodium stibogluconate (*sodium antimony gluconate*, *PENTOSTAM*) is a pentavalent antimonial that has been a mainstay for the treatment of leishmaniasis. In the U.S., sodium stibogluconate is no longer available. Increasing resistance to antimonials has reduced their efficacy, and both lipid-based amphotericin and miltefosine are increasingly used.

The relatively nontoxic pentavalent antimonials are prodrugs that are reduced to the more toxic Sb^{3+} species within the phagolysosomes of macrophages. Following reduction, the drug interferes with the trypanothione redox system, inducing a rapid efflux of trypanothione and glutathione from the cells, and inhibiting trypanothione reductase to deplete the thiol reduction potential.

Most of a single dose of sodium stibogluconate is excreted in the urine within 24 hours. The agent is absorbed rapidly, distributed in an apparent volume of ~0.22 L/kg, and eliminated in two phases. The first has a short $t_{1/2}$ of ~2 hours, and the second is much slower. The prolonged terminal elimination phase ($t_{1/2} = 33\text{--}76$ hours) may reflect conversion of the pentavalent antimonial (Sb^{5+}) to the more toxic trivalent (Sb^{3+}) form that is slowly released from tissues.

Sodium stibogluconate is given parenterally. The standard course is 20 mg/kg/day for 20 days for cutaneous disease and for 28 days for visceral disease. Increased resistance has compromised the effectiveness of these drugs, and treatment failure rates of up to 60% have been observed in India. Amphotericin B is the recommended alternative for treatment of either visceral leishmaniasis in India or mucosal leishmaniasis in general, although the newly approved orally active compound miltefosine is likely to see much wider use.

Children usually tolerate the drug well, and the dose per kilogram is the same as for adults. Patients who respond favorably show clinical improvement within 1–2 weeks of initiation of therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals. Patients infected with HIV typically relapse after successful initial therapy with either pentavalent antimonials or amphotericin B.

Adverse effects noted most commonly include pain at the injection site; chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminases; bone marrow suppression manifested by decreased red cell, white cell, and platelet counts in the blood; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and rashes. Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of toxicity, as are shock and sudden death.

SURAMIN

Suramin (BAYER 205) is used primarily for treatment of African trypanosomiasis.

Suramin is a relatively slowly acting trypanocide (>6 hours *in vitro*) with high clinical activity against both *T. brucei gambiense* and *T. brucei rhodesiense*. Selective toxicity likely results from the ability of the parasite to take up the drug by receptor-mediated endocytosis of the protein-bound drug, especially low-density lipoproteins. Suramin inhibits many trypanosomal and mammalian enzymes and receptors unrelated to its antiparasitic effects. The synergism between eflornithine and suramin has led to speculation that it may inhibit polyamine biosynthesis. Suramin is the only microfilaricide used clinically, albeit rarely now, for the treatment of human onchocerciasis.

Suramin is given intravenously. The drug is highly protein bound and has a terminal elimination $t_{1/2}$ of ~90 days. Renal clearance accounts for elimination of ~80% of the compound. Very little suramin penetrates the CSF, consistent with its lack of efficacy once the CNS has been invaded by trypanosomes.

Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection but generally is not used for early-stage *T. brucei gambiense*. Because only small amounts of the drug enter the brain, suramin is used primarily to treat early stages (before CNS involvement) of African trypanosomiasis.

For therapy of early West African infections, this drug is more effective when given by intravenous regimens that also include intramuscular injections of pentamidine. In contrast, suramin alone is superior for therapy of early East African disease. Suramin will clear the hemolymphatic system of trypanosomes even in late-stage disease, so it is often administered before initiating melarsoprol to reduce the risk of reactive encephalopathy associated with arsenical administration (*see* above). For adults with *T. brucei rhodesiense*, a test dose of 200 mg is given initially to detect sensitivity, after which the normal 1 g dose is given on days 1, 3, 7, 14, and 21. The pediatric dose is 20 mg/kg, given on the same schedule. Debilitated patients should be treated with lower doses during the first week. A serious immediate reaction consisting of nausea, vomiting, shock, and loss of consciousness occurs rarely. Malaise, nausea, and fatigue are more common immediate reactions. Parasite destruction may cause febrile episodes and rash; concomitant onchocerciasis optimally should be treated first with ivermectin to minimize these reactions (*see* Chapter 41). The most common problems encountered after several doses of suramin are renal toxicity and delayed neurological complications, including headache and peripheral neuropathy; these usually disappear despite continued therapy. The drug should be employed with great caution in individuals with renal insufficiency or if significant proteinuria develops.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

CHEMOTHERAPY OF HELMINTH INFECTIONS

Infections with helminths, or parasitic worms, affect more than two billion people worldwide. Pathogenic worms are classified into roundworms (nematodes) and two types of flatworms, flukes (trematodes) and tapeworms (cestodes). Immature forms invade humans *via* the skin or gastrointestinal (GI) tract and mature into adult worms with characteristic tissue distributions. With few exceptions, such as *Strongyloides* and *Echinococcus*, they cannot complete their life cycle and replicate themselves within the human host.

Anthelmintics are drugs that act locally to expel worms from the GI tract or systemically to eradicate adult helminths or developmental forms that invade organs and tissues. Because metazoan parasites generally are long-lived and have relatively complex life cycles, acquired resistance to anthelmintics in humans is not a major factor limiting clinical efficacy. The extensive use of anthelmintics in veterinary medicine ensures that the potential of drug resistance among helminths in humans cannot be discounted.

TREATMENT OF HELMINTH INFECTIONS

Nematodes (Roundworms)

The major nematode parasites of humans include the soil-transmitted helminths (STHs) and the filarial nematodes. The STH infections, which include ascariasis, trichuriasis, and hookworm infection, are among the most prevalent infections in developing countries. Eradication programs use schools to administer broad-spectrum anthelmintics on a periodic and frequent basis. The most widely used agents for reducing morbidity are the benzimidazole anthelmintics (BZAs), either *albendazole* (ALBENZA and ZENTEL) or *mebendazole* (VERMOX) (see Table 41–1).

In addition to targeting STH infections among school-aged children, there is an ongoing attempt to employ anthelmintics that eliminate lymphatic filariasis (LF) and onchocerciasis (river blindness). The goal is to interrupt arthropod-borne transmission by administering combination therapy with either *diethylcarbamazine* and *albendazole* (in LF-endemic regions such as India and Egypt), or *ivermectin* and *albendazole* (in LF regions where onchocerciasis and/or loiasis are co-endemic). These drugs target the microfilarial stages of the parasite, which circulate in blood and are taken up by arthropod vectors where further parasite development occurs.

ASCARIS LUMBRICOIDES AND TOXOCARA CANIS

A. lumbricoides, known as the “roundworm,” affects up to 90% of persons in some tropical regions but also is seen in temperate climates.

Mebendazole, *albendazole*, and *pyrantel pamoate* (ANTIMINTH, others) are preferred drugs; all infected persons should be treated. *Mebendazole* and *albendazole* are preferred for therapy of asymptomatic-to-moderate ascariasis. Both compounds should be used with caution to treat heavy *Ascaris* infections, alone or with hookworms. Rarely, hyperactive ascarids may migrate to cause complications such as appendicitis, biliary or intestinal obstruction, and intestinal perforation—sometimes requiring surgery. *Pyrantel* is safe for use in pregnancy, whereas BZAs should be avoided during the first trimester (see below).

Toxocariasis is common in North America and Europe. Major syndromes caused by *T. canis* infection are visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (CT). Treatment of VLM is reserved for patients with severe, persistent, or progressive symptoms. *Albendazole* is the drug of choice. The role of anthelmintic drugs for OLM and CT is controversial and surgical management often is indicated, sometimes accompanied by glucocorticoids.

HOOKWORM

Necator americanus, *Ancylostoma duodenale*

Hookworm species infect 740 million people. *N. americanus* is the predominant hookworm worldwide, whereas *A. duodenale* is focally endemic in Egypt, India, and China. Hookworm larvae live in the soil and penetrate exposed skin. After reaching the lungs, larvae migrate to the oral cavity and are swallowed. After attaching to the jejunal mucosa, the adult worms feed on host blood. There is a direct correlation between the hookworm burden and fecal blood loss. Unlike heavy *Ascaris* and *Trichuris* infections, which occur mostly in children, heavy hookworm infections also occur in adults.

The major treatment goal is to remove blood-feeding adult hookworms from the intestines. *Albendazole* and *mebendazole* are preferred agents against both *A. duodenale* and *N. americanus*.

Table 41-1

Structure of the Benzimidazoles

R ₁	R ₂	Derivative
	H—	Thiabendazole
—NHCO ₂ CH ₃		Mebendazole
—NHCO ₂ CH ₃	CH ₃ CH ₂ CH ₂ S—	Albendazole

As a single dose, albendazole is superior to mebendazole at removing adult hookworms from the GI tract. Oral albendazole is the drug of choice for treating cutaneous larva migrans or “creeping eruption,” due most often to skin migration by larvae of the dog hookworm.

Strongyloides Stercoralis

S. stercoralis, sometimes called the threadworm, can replicate and cause cycles of larval reinfection entirely within the human host. The organism infects more than 200 million people worldwide, most frequently in the tropics. In the U.S., strongyloidiasis is endemic in Appalachia and also is found in institutionalized individuals living in unsanitary conditions and in immigrants, travelers, and military personnel who lived in endemic areas. Infective larvae in contaminated soil penetrate the skin or mucous membranes, travel to the lungs, and ultimately mature into adult worms in the small intestine, where they reside. Most infected individuals are asymptomatic, while some experience rash and GI symptoms. Life-threatening disease due to massive larval hyperinfection can occur in immunosuppressed persons, even decades after the initial infection. Most deaths caused by parasites in the U.S. probably are due to *Strongyloides* hyperinfection. Ivermectin is the best drug for treating intestinal strongyloidiasis.

Enterobius Vermicularis

Enterobius, probably the most common helminth infections in temperate climates, typically causes pruritus in the perianal and perineal regions. Because the infection is easily spread, the clinician must decide whether to treat all close contacts and more than one course of therapy may be required.

Pyrantel, mebendazole, and albendazole are highly effective. Single oral doses of each should be repeated after 2 weeks. When combined with fastidious personal hygiene, a high cure rate can be obtained.

Trichinella Spiralis

T. spiralis infection results from eating insufficiently cooked flesh of infected animals, especially pigs. When released, encysted larvae mature into adult worms in the intestine, which then produce infectious larvae that invade tissues, especially skeletal muscle and heart. Severe infection cause marked muscle pain and cardiac complications.

Albendazole and mebendazole appear to be effective against the intestinal forms of *T. spiralis* that are present early in infection. Their efficacy on larvae that have migrated to muscle is questionable. Glucocorticoids are of considerable value in controlling the acute manifestations of infection.

Wuchereria Bancrofti and Brugia Species (Lymphatic Filariasis)

Adult worms that cause human filariasis dwell either in the lymphatics or other tissues. Spread by the bites of infected mosquitoes, lymphatic filariasis (LF) affects ~120 million people in sub-Saharan Africa, India, Southeast Asia, the Pacific region, and tropical America. In LF, host reactions to adult worms initially cause lymphatic inflammation manifested by fever, lymphangitis, and

lymphadenitis; this can progress to lymphatic obstruction. A reaction to microfilariae, tropical pulmonary eosinophilia, may occur. In most countries, the World Health Organization (WHO) recommends yearly combined therapy with albendazole and diethylcarbamazine, which clears circulating microfilariae from infected subjects, thereby reducing the likelihood that mosquitoes will transmit LF to other individuals.

Diethylcarbamazine is the drug of choice for the treatment of LF adult worms, but the effect is variable; best results are achieved if therapy is started before lymphatic obstruction has occurred.

Loa Loa (Loiasis)

L. loa is a tissue-migrating filarial parasite found in river regions of Central and West Africa. Adult worms in subcutaneous tissues typically cause episodic swellings and allergic reactions. Rarely, encephalopathy, cardiomyopathy, or nephropathy occurs. Diethylcarbamazine is the best single drug for the treatment of loiasis, initially in small initial doses to diminish host reactions that result from destruction of microfilariae. Glucocorticoids often are required to control acute reactions.

Onchocerca Volvulus (Onchocerciasis or River Blindness)

Transmitted by blackflies, *O. volvulus* infects ~17 million people in sub-Saharan Africa, and <100,000 people in parts of Mexico, Guatemala, and South America. Inflammatory reactions, primarily to microfilariae rather than adult worms, affect the subcutaneous tissues, lymph nodes, and eyes. Onchocerciasis is a leading cause of infectious blindness worldwide. Ivermectin is the best single drug for control and treatment of onchocerciasis. It kills only microfilariae of *O. volvulus*, while producing few if any ocular complications.

Cestodes (Flatworms)

Taenia Saginata

Humans are the definitive hosts for *T. saginata*, the beef tapeworm. This most common tapeworm usually is detected after passage of proglottids from the intestine. It is cosmopolitan, occurring most commonly in sub-Saharan Africa and the Middle East, where undercooked beef is consumed. Praziquantel is the drug of choice for *T. saginata* infection.

Taenia Solium

T. solium, or pork tapeworm, causes two types of infection. The intestinal form with adult tapeworms results from eating undercooked meat containing cysticerci. Invasive larval forms cause Cysticercosis, the more dangerous systemic infection. Invasion of the brain (neurocysticercosis) can result in epilepsy, meningitis, and increased intracranial pressure. Praziquantel is preferred for intestinal infections with *T. solium*, while albendazole is the drug of choice for cysticercosis. Chemotherapy is appropriate only when it is directed at live cysticerci causing pathology; pretreatment with glucocorticoids is advised.

Diphyllobothrium Latum

D. latum, the fish tapeworm, is acquired by eating inadequately cooked, infested fish. Most infected individuals are asymptomatic; frequent manifestations include abdominal symptoms and weight loss; megaloblastic anemia may occur due to vitamin B₁₂ deficiency. Praziquantel eliminates the worm.

Hymenolepis Nana

H. nana, the dwarf tapeworm, is the most common tapeworm parasitizing humans. Infection is more prevalent in tropical than temperate climates and most common among institutionalized children, including those in the southern U.S. Cysticerci develop in the villi of the intestine and then regain access to the intestinal lumen where larvae mature into adults. Praziquantel is effective against *H. nana* infections; relatively high doses usually are required, and therapy may need to be repeated.

Echinococcus Species

Humans are one of several intermediate hosts for larval forms of *Echinococcus* species that cause "cystic" (*E. granulosus*) and "alveolar" (*E. multilocularis* and *E. vogeli*) hydatid disease. Parasite eggs from canine stools are a major source in associated livestock (e.g., sheep and goats). *E. granulosus* produces unilocular, slowly growing cysts, most often in liver and lung, and *E. multilocularis* creates multilocular invasive cysts in the same organs. Surgical removal of the cyst is the preferred treatment, but leakage may spread disease to other organs. Prolonged regimens of albendazole, either alone or combined with surgery, may be beneficial, but some patients are not cured despite multiple courses of therapy. Adjunct treatment with BZAs is the cornerstone of the interdisciplinary approach to controlling cystic echinococcosis.

Trematodes (Flukes)**Schistosoma Haematobium, Schistosoma Mansoni, Schistosoma Japonicum**

These are the main species of blood flukes that cause human schistosomiasis, which affects about 200 million people. Schistosomiasis is widely distributed over South America (*S. mansoni*), much of Africa and the Arabian Peninsula (*S. mansoni* and *S. haematobium*), and China and Southeast Asia (*S. japonicum*). Infected snails are intermediate hosts for freshwater transmission. Schistosomiasis primarily involves the liver, spleen, and GI tract (*S. mansoni* and *S. japonicum*) or the lower genitourinary tract (*S. haematobium*). Heavy infections with *S. haematobium* are associated with bladder carcinoma. Chronic infections can cause portosystemic shunting due to periportal fibrosis in the liver.

Praziquantel is the drug of choice for schistosomes. The artemisinin derivative artemether (see Chapter 39) targets the larval schistosomula stages of the parasite. Combined treatment of animals harboring juvenile and adult schistosome worms with artemether and praziquantel resulted in significantly higher worm burden reductions than either drug administered singly.

Paragonimus westermani and Other Paragonimus Species

Called lung flukes, a number of *Paragonimus* species, of which *P. westermani* is the most common, are pathogenic for humans. Found in the Far East and on the African and South American continents, these parasites have two intermediate hosts: snails and crustaceans. Humans become infected by eating raw or undercooked crabs or crayfish. Disease is caused by reactions to adult worms. Although these flukes are rather refractory to praziquantel, the drug is effective when used clinically. Bithionol is considered a second-line agent. Triclabendazole also recently was shown to be efficacious.

Clonorchis sinensis, Opisthorchis viverrini, Opisthorchis felineus

These closely related trematodes exist in the Far East (*C. sinensis*, “the Chinese liver fluke,” and *O. viverrini*) and parts of Eastern Europe (*O. felineus*). Metacercariae released from poorly cooked infected fish mature into adult flukes that inhabit the human biliary system. Heavy infections can cause obstructive liver disease, inflammatory gallbladder pathology associated with cholangiocarcinoma, and obstructive pancreatitis. One-day therapy with praziquantel is highly effective.

ANTHELMINTIC DRUGS**Benzimidazoles (BZAs)**

The BZAs have been developed as broad-spectrum anthelmintic agents. The most useful have modifications at the 2 and/or 5 positions of the benzimidazole ring system (Table 41–1). Thiabendazole, mebendazole, and albendazole have been used extensively for the treatment of human helminth infections.

Thiabendazole is active against a wide range of nematodes that infect the GI tract, but its clinical use has declined markedly because of its toxicity relative to other equally effective drugs. Mebendazole has supplanted thiabendazole for the treatment of intestinal roundworm infections. Albendazole is used primarily against a variety of intestinal and tissue nematodes but also against larval forms of certain cestodes. Albendazole is the drug of choice for cysticercosis and cystic hydatid disease. When used yearly in conjunction with either ivermectin or diethylcarbamazine, single doses of albendazole have shown considerable promise for global control of LF and other filarial infections.

ANTHELMINTIC ACTION

The BZAs inhibit microtubule polymerization by binding to β -tubulin. The selective toxicity of these agents likely results because the BZAs bind parasite β -tubulin with much higher affinity than they do the mammalian protein. Drug resistance in nematodes may involve expression of a mutated β -tubulin. There is no evidence of emerging resistance among human nematodes.

The BZAs are versatile anthelmintic agents, particularly against GI nematodes, where their action is not dictated by systemic drug concentration. Mebendazole and albendazole are highly effective in treating the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes, and they are ovicidal for *Ascaris* and *Trichuris*. Immobilization and death of susceptible GI parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment.

Albendazole is more effective than mebendazole against strongyloidiasis, cystic hydatid disease caused by *E. granulosus*, and neurocysticercosis caused by larval forms of *T. solium*. The BZAs probably are active against the intestinal stages of *T. spiralis*, but likely do not affect the larval stages in tissues. Albendazole is highly effective against the migrating forms of dog and cat

hookworms that cause cutaneous larval migrans. Regimens in which albendazole with either ivermectin or diethylcarbamazine are given as single annual doses show great promise for the elimination of LF. Certain microsporidia that cause intestinal infections in human immunodeficiency virus (HIV)-infected individuals respond partially (*Enterocytozoon bieneusi*) or completely (*Enterocytozoon intestinalis* and related species) to albendazole.

ABSORPTION, FATE, AND EXCRETION Thiabendazole is absorbed rapidly after oral ingestion and reaches peak plasma concentrations after 1 hour. Most of the drug is excreted in the urine within 24 hours as 5-hydroxythiabendazole, conjugated either as the glucuronide or the sulfate. Tablet formulations of mebendazole are poorly and erratically absorbed, and plasma concentrations are low. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Mebendazole is ~95% bound to plasma proteins and is extensively metabolized. The major metabolites have lower rates of clearance than does mebendazole and apparently are inactive. Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole is variably absorbed after oral administration. A fatty meal enhances absorption. After a 400-mg oral dose, albendazole cannot be detected in plasma, because the drug is rapidly metabolized in the liver to its sulfoxide, which has potent anthelmintic activity. Both the (+) and (-) enantiomers of albendazole sulfoxide are formed; the (+) enantiomer reaches much higher peak plasma concentrations and is cleared much more slowly. Albendazole sulfoxide is ~70% bound to plasma proteins and has a variable plasma $t_{1/2}$ (~4–15 hours). It is well distributed into various tissues including hydatid cysts, probably explaining its greater efficacy for tissue-dwelling helminths. Formation of albendazole sulfoxide is catalyzed by both microsomal flavin monooxygenase and CYP isoforms in the liver. Albendazole metabolites are excreted mainly in the urine.

THERAPEUTIC USES Thiabendazole (MINTEZOL) generally has been replaced by newer agents. Mebendazole is highly effective against GI nematodes and is particularly valuable for mixed infections. Mebendazole always is taken orally, and the same dosage schedule applies to adults and children >2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken, repeated after 2 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of mebendazole taken in the morning and evening for 3 consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. The 3-day mebendazole regimen is more effective than single doses of either mebendazole (500 mg) or albendazole (400 mg).

Like mebendazole, albendazole provides safe and effective therapy against infections with GI nematodes, including mixed infections of *Ascaris*, *Trichuris*, and hookworms. For treatment of enterobiasis, ascariasis, trichuriasis, and hookworm, albendazole is taken as a single oral 400-mg dose by adults and children >2 years of age. In children between the ages of 12 and 24 months, the WHO recommends a reduced dose of 200 mg. Cure rates for light-to-moderate *Ascaris* infections typically are >97%, although heavy infections may require therapy for 2–3 days. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections.

Albendazole is the drug of choice for cystic hydatid disease due to *E. granulosus*. While the drug provides only a modest cure rate when used alone, it produces superior results when used in conjunction with either surgery to remove cysts or aspiration/injection of cysts with protoscolicidal agents. A typical dosage regimen for adults is 400 mg given twice a day (for children 15 mg/kg/day with a maximum of 800 mg) for 1–6 months. While the best drug available, albendazole is only marginally effective for alveolar echinococcosis caused by *E. multilocularis*, and surgical intervention often is needed.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of *T. solium*. The recommended dose is 400 mg given twice a day for adults for 8–30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg/day (maximum 800 mg) in two doses for 8–30 days. The course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. To reduce inflammatory side effects, glucocorticoids are usually given for several days before initiating albendazole therapy. Such pretreatment also increases plasma levels of albendazole sulfoxide. Therapy with either albendazole or praziquantel should include consideration of anticonvulsant therapy, the possible development of complications of arachnoiditis, vasculitis, or cerebral edema, and the need for surgical intervention should obstructive hydrocephalus occur. Albendazole, 400 mg/day, also has shown efficacy for therapy of microsporidial intestinal infections in patients with AIDS.

Albendazole is combined with either diethylcarbamazine or ivermectin in programs directed toward controlling LF. By annual dosing with combination therapy for 4–6 years, the goal is to maintain the microfilaremia at such low levels that transmission cannot occur for a period that corresponds to the duration of fecundity of adult worms. Albendazole is given with diethylcarbamazine to control LF in most parts of the world. To avoid serious reactions to dying microfilariae, an albendazole/ivermectin combination is recommended in locations where filariasis coexists with either onchocerciasis or loiasis.

TOXICITY, SIDE EFFECTS, PRECAUTIONS, AND CONTRAINDICATIONS The BZAs generally have excellent safety profiles. Side effects, primarily mild GI symptoms, occur in ~1% of treated children.

The clinical utility of thiabendazole in adults is compromised by its toxicity, which has diminished its clinical use. Frequent side effects include GI upset, fatigue, drowsiness, and headache. Occasional fever, rash, erythema multiforme, hallucinations, and sensory disturbances have been reported. Angioedema, shock, tinnitus, convulsions, and intrahepatic cholestasis, and crystalluria are rare complications. Transient leukopenia has been noted. Thiabendazole is hepatotoxic and should be used with caution in patients with hepatic disease. The effects of thiabendazole in pregnant women have not been studied adequately, so it should be used in pregnancy only when the potential benefit justifies the risk.

Mebendazole does not routinely cause significant systemic toxicity, even in the presence of anemia and malnutrition. Transient symptoms of abdominal pain, distention, and diarrhea have occurred with massive infestation and expulsion of GI worms. Rare side effects in patients treated with high doses of mebendazole include allergic reactions, alopecia, reversible neutropenia, agranulocytosis, and oligospermia. Reversible elevation of serum transaminases may occur. Mebendazole may be associated with occipital seizures. It should not be used in patients who have experienced allergic reactions to the agent.

Albendazole also produces few side effects when used for short-term therapy of GI helminthiasis, even in patients with heavy worm burdens. Transient mild GI symptoms (epigastric pain, diarrhea, nausea, and vomiting) occur in ~1% of treated individuals. Dizziness and headache occur on occasion. In school-age mass treatments, the incidence of side effects with albendazole is very low. Allergic phenomena rarely occur and usually resolve after 48 hours.

Even in long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is an increase in serum aminotransferases, which return to normal upon drug cessation; rarely jaundice or cholestasis may occur. Liver function tests should be monitored during protracted albendazole therapy, and the drug is not recommended for patients with cirrhosis. Especially if not pretreated with glucocorticoids, some patients with neurocysticercosis may experience serious neurological sequelae. Other side effects during extended therapy include GI pain, severe headaches, fever, fatigue, alopecia, leukopenia, and thrombocytopenia.

The BZAs display remarkably few interactions with other drugs. The most versatile member of this family, albendazole, probably induces its own metabolism, and plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly praziquantel. Caution is advised when using high doses of albendazole together with general inhibitors of hepatic CYPs.

Use in Pregnancy Both albendazole and mebendazole are embryotoxic and teratogenic in rats. In postmarketing surveys of women who inadvertently consumed mebendazole during the first trimester, the incidence of spontaneous abortion and malformations did not exceed that of the general population; comparable studies with albendazole are not available. A review of the risk of congenital abnormalities from BZAs concluded that their use during pregnancy is not associated with an increased risk of major congenital defects; nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy.

Use in Young Children The WHO concluded that the BZAs may be used to treat children past the first year who are at risk for adverse consequences caused by STHs; a reduced dose of albendazole (200 mg) is used in children between the ages of 12–24 months.

DIETHYLCARBAMAZINE Diethylcarbamazine is a first-line agent for control and treatment of lymphatic filariasis and for therapy of tropical pulmonary eosinophilia caused by *W. bancrofti* and *Brugia malayi*. Although partially effective against onchocerciasis and loiasis, it can cause serious reactions to affected microfilariae. For this reason, ivermectin has replaced diethylcarbamazine for onchocerciasis. Despite its toxicity, diethylcarbamazine remains the best drug available to treat loiasis.

Annual single doses of both diethylcarbamazine and albendazole show considerable promise for the control of lymphatic filariasis in regions where onchocerciasis and loiasis are not endemic.

Diethylcarbamazine (HETRAZAN) is formulated as the water-soluble citrate salt.

DIETHYLCARBAMAZINE

ANTHELMINTIC ACTION

Microfilarial forms of susceptible species are most affected by diethylcarbamazine, which elicits rapid disappearance from blood for W. bancrofti, B. malayi, and L. loa. The drug kills microfilariae of O. volvulus in skin but not in nodules that contain the adult (female) worms. It does not affect the microfilariae of W. bancrofti in a hydrocele. Diethylcarbamazine appears to exert a direct toxic effect on W. bancrofti microfilariae; it also kills worms of adult L. loa and probably adult W. bancrofti and B. malayi. Diethylcarbamazine may impair intracellular processing and transport of certain macromolecules to the helminth plasma membrane. The drug also may affect specific immune responses of the host.

ABSORPTION, FATE, AND EXCRETION Diethylcarbamazine is absorbed rapidly from the GI tract. Peak plasma levels occur within 1–2 hours, and the plasma $t_{1/2}$ varies from 2 to 10 hours, depending on urinary pH. Metabolism is rapid and extensive. A major metabolite, diethylcarbamazine-N-oxide, is bioactive. Diethylcarbamazine is excreted by both urinary and extraurinary routes. Alkalinizing the urine can elevate plasma levels, prolong the plasma $t_{1/2}$, and increase both therapeutic effect and toxicity of diethylcarbamazine. Dosage reduction may be required in people with renal dysfunction or sustained alkaline urine.

THERAPEUTIC USES Recommended regimens for filarial infections differ according to whether the drug is used for population-based chemotherapy, control of filarial disease, or prophylaxis against infection.

W. Bancrofti, B. Malayi, and B. Timori The standard regimen for LF has been a 12-day, 72-mg/kg (6 mg/kg/day) course of diethylcarbamazine. A single dose of 6 mg/kg had comparable macrofilaricidal and microfilaricidal efficacy to previous regimens. Single-dose therapy may be repeated every 6–12 months, as necessary.

Although diethylcarbamazine does not usually reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent progression. Repeat treatment sometimes is recommended if microfilariae remain in the circulation or adult worms are seen on ultrasound. During acute episodes of lymphangitis, diethylcarbamazine is not recommended until acute symptoms subside. Supportive treatment is critical, including prevention of secondary bacterial infections by attention to hygiene, wearing shoes to prevent foot injury, and avoidance of lymphostasis by exercise and limb elevation.

For mass treatment programs, the introduction of diethylcarbamazine into table salt (0.2–0.4% by weight of the base) has markedly reduced the prevalence, severity, and transmission of lymphatic filariasis in many endemic areas. Diethylcarbamazine given annually as a single oral dose of 6 mg/kg is most effective in reducing microfilaremia when coadministered with either albendazole (400 mg) or ivermectin (0.2–0.4 mg/kg). Adverse reactions to microfilarial destruction usually are well tolerated. However, mass chemotherapy with diethylcarbamazine should not be used in regions where onchocerciasis or loiasis coexist because it may induce severe reactions related to parasite burden in these infections.

O. Volvulus and L. Loa Diethylcarbamazine is contraindicated for onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions. For purposes of LF control, ivermectin is preferred in areas where onchocerciasis is endemic. Diethylcarbamazine remains the best drug for therapy of loiasis. Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2–3 days, escalating as tolerated to daily doses of 9 mg/kg in three doses for a total of 2–3 weeks.

Low test doses are used, often with glucocorticoid or antihistamine pretreatment to minimize reactions to dying microfilariae and adult worms. Repeated courses of diethylcarbamazine treatment, separated by 3–4 weeks, may be required. Ivermectin is not a good alternative for treatment of

loiasis, but albendazole may prove to be useful in patients who either fail therapy with diethylcarbamazine or who cannot tolerate the drug.

TOXICITY AND SIDE EFFECTS At <8–10 mg/kg/day, direct toxic reactions to diethylcarbamazine, including anorexia, nausea, headache, and vomiting, are rarely severe and usually disappear within a few days despite continued therapy. Major adverse effects result from host response to destruction of parasites, primarily microfilariae.

Reactions typically are most severe in patients heavily infected with *O. volvulus*, less serious in *B. malayi* or *L. loa* infections, and mild in bancroftian filariasis, but the drug occasionally induces retinal hemorrhages and severe encephalopathy in patients heavily infected with *L. loa*. In patients with onchocerciasis, reactions typically occur within a few hours after the first dose and include intense itching, tender lymphadenitis, and sometimes a papular rash, fever, tachycardia, arthralgias, and headache. This reaction persists for 3–7 days and then subsides, after which high doses sometimes can be tolerated. Ocular complications include limbitis, keratitis, uveitis, and atrophy of the retinal pigment epithelium. In patients with bancroftian or brugian filariasis, nodular swellings may occur along the course of the lymphatics, often with an accompanying lymphadenitis that also subsides within a few days. Almost all patients receiving therapy exhibit a leukocytosis. Reversible proteinuria may occur, and the eosinophilia so frequently observed in patients with filariasis can be intensified by diethylcarbamazine. Delayed reactions include lymphangitis, swelling and lymphoid abscesses in bancroftian and brugian filariasis, and small skin wheals in loiasis. Diethylcarbamazine appears to be safe during pregnancy.

PRECAUTIONS AND CONTRAINDICATIONS Population-based therapy with diethylcarbamazine should be avoided in areas where onchocerciasis or loiasis is endemic, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is given to minimize indirect reactions to diethylcarbamazine that result from dying microfilariae.

Ivermectin

The avermectins are a novel class of 16-membered lactones. Ivermectin (MECTIZAN; STROMECTOL; 22,23-dihydroavermectin B_{1a}) is FDA-approved for treatment of onchocerciasis and for therapy of intestinal strongyloidiasis. Ivermectin taken as a single oral dose every 6–12 months continues to serve as the mainstay of major programs to control onchocerciasis. In addition, annual oral doses of ivermectin, either taken alone or combined with annual oral doses of albendazole, markedly reduce microfilaremia in lymphatic filariasis due to *W. bancrofti* or *B. malayi*. Current recommendations advocate diethylcarbamazine (6 mg/kg) plus albendazole (400 mg). The two-drug regimen is preferred in regions where LF coexists with either onchocerciasis or loiasis. Ivermectin is the drug of choice against intestinal strongyloidiasis and is effective against several other human infections caused by intestinal nematodes.

IVERMECTIN (R = CH₃ or C₂H₅)

ANTIPARASITIC ACTIVITY AND RESISTANCE

Ivermectin is effective and highly potent against at least some stages of many parasitic nematodes that affect animals and humans. Avermectins affect a group of glutamate-gated Cl⁻ channels found in nematode nerve or muscle cells, causing hyperpolarization and paralysis by increasing Cl⁻ permeability

of the cell membrane. Alterations in genes encoding P-glycoprotein transporters that bind avermectins and in those encoding components of the glutamate-gated Cl^- channel have been associated with the development of resistance. Avermectins also interact with γ -aminobutyric acid (GABA) receptors in mammalian brain, but their affinity for invertebrate receptors is ~100-fold higher.

In humans infected with *O. volvulus*, ivermectin causes a rapid, marked decrease in microfilarial counts in the skin and ocular tissues that lasts for 6–12 months. The drug has little discernible effect on adult parasites, even at doses as high as 800 μ g/kg, but affects developing larvae and blocks egress of microfilariae from the uterus of adult female worms. Regular treatment with ivermectin also may act prophylactically against the development of *Onchocerca* infection.

Ivermectin also is effective against microfilaria but not adult worms of *W. bancrofti*, *B. malayi*, *L. loa*, and *M. ozzardi*. It exhibits excellent efficacy against *A. lumbricoides*, *S. stercoralis*, and cutaneous larva migrans.

ABSORPTION, FATE, AND EXCRETION Peak plasma levels of ivermectin are achieved within 4–5 hours after oral administration. The long terminal $t_{1/2}$ of ~57 hours primarily reflects a low systemic clearance and a large apparent volume of distribution. Ivermectin is ~93% bound to plasma proteins. The drug is extensively converted by hepatic CYP3A4 to at least 10 metabolites, mostly hydroxylated and demethylated derivatives. Virtually no ivermectin appears in human urine in either unchanged or conjugated form. Highest tissue concentrations occur in liver and fat. Extremely low levels are found in brain; a P-glycoprotein efflux pump in the blood–brain barrier prevents ivermectin from entering the central nervous system (CNS).

THERAPEUTIC USES

Onchocerciasis Single oral doses of ivermectin (150 μ g/kg) given every 6–12 months are considered effective, safe, and practical for reducing the number of circulating microfilariae in adults and children 5 years of age or older; widespread use of ivermectin is a mainstay of onchocerciasis control programs. Equally important, such therapy reverses lymphadenopathy and acute inflammatory changes in ocular tissues and arrests the progression of ocular pathology. Marked reduction of microfilariae in the skin and ocular tissues is noted within a few days and lasts for 6–12 months; the dose then should be repeated. Cure is not attained, because ivermectin has little effect on adult *O. volvulus*. Ivermectin has been widely used for onchocerciasis control programs in Africa, the Middle East, and Latin America.

Lymphatic Filariasis Single annual doses of ivermectin (400 μ g/kg) are effective and safe for mass therapy of infections with *W. bancrofti* and *B. malayi*. Ivermectin is as effective as diethylcarbamazine for controlling lymphatic filariasis and can be used in regions where onchocerciasis, loiasis, or both are endemic. Although ivermectin as a single agent can reduce *W. bancrofti* microfilaremia, the duration of treatment required to eliminate LF presumably would be >6 years. A single dose of ivermectin (200 μ g/kg) and a single dose of albendazole (400 mg) annually are even more effective in controlling lymphatic filariasis. The duration of treatment is for at least 5 years based on the estimated fecundity of the adult worms. This dual-drug regimen also reduces infections with intestinal nematodes.

Infections with Intestinal Nematodes The finding that a single dose of 150–200 μ g/kg of ivermectin can cure strongyloidiasis is encouraging, because this drug also is effective against coexisting ascariasis, trichuriasis, and enterobiasis. A single dose of 100 μ g/kg of ivermectin is as effective as traditional treatment of intestinal strongyloidiasis with thiabendazole, and less toxic. In Japan, almost all *S. stercoralis*-infected patients were cured by 200 μ g/kg of ivermectin orally twice at an interval of 2 weeks. In *Strongyloides* hyperinfection syndrome, ivermectin has been used successfully, including cases unresponsive to thiabendazole.

Other Indications

Taken as a single 200- μ g/kg oral dose, ivermectin is a first-line drug for treatment of cutaneous larva migrans. Similar doses also are safe and highly effective against human head lice and scabies, even in HIV-infected individuals.

Toxicity, Side Effects, and Precautions Ivermectin generally is well tolerated. In infected humans, ivermectin toxicity nearly always results from reactions to dying microfilariae; the intensity and nature of these reactions relate to the microfilarial burden and the duration and type of filarial infection.

After treatment of *O. volvulus* infections with ivermectin, side effects usually are limited to pruritus and swollen, tender lymph nodes, these occur in 5–35% of people, last a few days, and are

relieved by aspirin and antihistamines. Rarely, more severe reactions include high fever, tachycardia, hypotension, prostration, dizziness, headache, myalgia, arthralgia, diarrhea, and edema; these may respond to glucocorticoids. Ivermectin induces milder side effects than does diethylcarbamazine, and unlike the latter, seldom exacerbates ocular lesions in onchocerciasis. Serious side effects include marked disability and encephalopathies in patients coinfecting with heavy burdens of *L. loa microfilaria*. *Loa* encephalopathy is associated with ivermectin treatment of individuals with high levels of *Loa* microfilaremia ($\geq 30,000$ microfilariae). There is little evidence that ivermectin is teratogenic or carcinogenic.

Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). Caution also is advised about coadministration of ivermectin with other CNS depressants, but epileptics should not be excluded from onchocerciasis treatment programs. Possible adverse interactions of ivermectin with other substrates for CYP3A4 have yet to be evaluated. Ivermectin is not approved for use in children <5 years old or in pregnant women, but both populations undoubtedly have been exposed to the drug in mass treatment programs. Lactating women taking the drug secrete low levels in their milk; the consequences for nursing infants are unknown.

Metrifonate

Metrifonate (trichlorfon; BILARCIL) is an organophosphorus compound used as an insecticide and then as an anthelmintic, especially for *S. haematobium*. Metrifonate is a prodrug that is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethyl phosphate, DDVP), a potent cholinesterase inhibitor.

Oxamniquine

Oxamniquine (VANSIL) is a second-line drug to praziquantel for the treatment of schistosomiasis. Most strains of *S. mansoni* are highly susceptible to oxamniquine, but *S. haematobium* and *S. japonicum* are virtually unaffected by therapeutic doses. Because of a low incidence of mild side effects together with normally high efficacy after a single oral dose, oxamniquine continues to be used in *S. mansoni* control programs, especially in South America.

PIPERAZINE

Piperazine

A number of substituted piperazine derivatives have anthelmintic activity, but none apart from diethylcarbamazine has found a place in human therapeutics.

Piperazine is highly effective against *A. lumbricoides* and *E. vermicularis*. The predominant effect of piperazine on *Ascaris* is a temporary paralysis that results in expulsion of the worm by peristalsis. Piperazine acts as a GABA-receptor agonist. By increasing Cl^- conductance of the *Ascaris* muscle membrane, the drug produces hyperpolarization that leads to flaccid paralysis.

PRAZIQUANTEL

Praziquantel

Praziquantel (BILTRICIDE, DISTOCIDE) is a pyrazinoisoquinoline derivative. Infections with many different cestodes and trematodes respond favorably to this agent, whereas nematodes generally are unaffected. Praziquantel treatment of patients coinfectd with schistosomes and hookworms reduces hookworm prevalence and infection intensities (egg counts) significantly.

ANTHELMINTIC ACTION

After rapid and reversible uptake, praziquantel has two major effects on adult schistosomes. At low concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls, resulting in a rapid shift from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage, which exposes a number of tegumental antigens. The tegument of schistosomes seems to be the primary site of action; the drug causes an influx of Ca^{2+} across the tegument via unknown mechanisms.

ABSORPTION, FATE, AND EXCRETION Praziquantel is readily absorbed after oral administration, and maximal levels in human plasma occur in 1–2 hours. Extensive first-pass metabolism to inactive hydroxylated and conjugated products limits drug bioavailability and results in plasma concentrations of metabolites at least 100-fold higher than that of praziquantel. The drug is ~80% bound to plasma proteins. Its plasma $t_{1/2}$ is 1–3 hours but may be prolonged in patients with severe liver disease, including those with hepatosplenic schistosomiasis. About 70% of an oral dose of praziquantel is recovered as metabolites in the urine within 24 hours; most of the remainder is metabolized in the liver and eliminated in the bile.

THERAPEUTIC USES Praziquantel is FDA approved for therapy of schistosomiasis and liver fluke infections, but also is used to treat infections with many other trematodes and cestodes. Praziquantel is the drug of choice for schistosomiasis caused by all *Schistosoma* species. Although dosage regimens vary, a single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4–6 hours apart, generally produce cure rates of 70–95% and consistent reductions (>85%) in egg counts. Tablets of 600 mg are available.

*Decreased clinical efficacy of praziquantel against infections with *S. mansoni* has been reported. However, praziquantel-tolerant or -resistant schistosomes currently do not limit its clinical usefulness.*

*Three doses of 25 mg/kg taken 4–8 hours apart on the same day yield high cure rates of infections with either the liver flukes *C. sinensis* and *O. viverrini*, or the intestinal flukes *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen used for 2 days is highly effective against lung fluke infections. Infections with *Fasciola hepatica* are unresponsive to high doses, even though praziquantel penetrates this trematode.*

*Low doses of praziquantel can be used successfully to treat intestinal infections with adult cestodes (e.g., a single oral dose of 25 mg/kg for *H. nana* and 10–20 mg/kg for *D. latum*, *T. saginata*, or *T. solium*). Retreatment after 7–10 days is advised for individuals heavily infected with *H. nana*. While albendazole is preferred for therapy of human cysticercosis, the tissue infection with intermediate cyst larvae of *T. solium*, prolonged high-dose therapy with praziquantel remains an alternative treatment. Neither the “cystic” nor “alveolar” hydatid diseases caused by larval stages of *Echinococcus* tapeworms respond to praziquantel; here, too, albendazole is effective.*

TOXICITY, PRECAUTIONS, AND INTERACTIONS Abdominal discomfort, nausea, diarrhea, headache, dizziness, and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose-related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally and are related to parasite burden. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, mental changes, and CSF pleocytosis. These effects usually are delayed in onset, last 2–3 days, and respond to symptomatic therapy such as analgesics and anticonvulsants.

Praziquantel is considered safe in children >4 years of age, who probably tolerate the drug better than do adults. Low levels of the drug appear in breast milk. High doses of praziquantel increase abortion rates in rats, but one study showed that treatment of pregnant women resulted in no significant differences between treated and untreated women in the rates of abortion or preterm deliveries. No congenital abnormalities were noted by clinical examination in any of the babies born to either group.

Inducers of hepatic CYPs such as carbamazepine and phenobarbital reduce the bioavailability of praziquantel. Dexamethasone reduces the bioavailability of praziquantel, but the mechanism is not understood. Under certain conditions, praziquantel may increase the bioavailability of albendazole.

PYRANTEL

Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Tasks requiring mental alertness (e.g., driving, operating machinery) should be avoided shortly after taking the drug. The $t_{1/2}$ of praziquantel can be prolonged in patients with severe hepatic disease, and dosage adjustment may be required.

Pyrantel Pamoate

Pyrantel is a broad-spectrum anthelmintic directed against pinworm, roundworm, and hookworm infections. Pyrantel is given as the pamoate salt and has the following structure:

Pyrantel is a depolarizing neuromuscular blocking agent that opens nonselective cation channels and induces marked, persistent activation of nicotinic acetylcholine receptors, which results in spastic paralysis of the worm. Pyrantel is effective against hookworm, pinworm, and roundworm; unlike its analog oxantel, it is ineffective against Trichuris trichiura.

Pyrantel pamoate is poorly absorbed from the GI tract, a property that contributes to its selective action on GI nematodes. Less than 15% is excreted in the urine as parent drug and metabolites. Most of an administered dose is recovered in the feces.

*Pyrantel pamoate is an alternative to mebendazole in the treatment of ascariasis and enterobiasis. High cure rates have been achieved after a single oral dose of 11 mg/kg (maximum of 1 g). Pyrantel also is effective against hookworm infections caused by *A. duodenale* and *N. americanus*, although repeated doses are needed to cure heavy infections with the latter organism. The drug is combined with oxantel for mixed infections with *T. trichiura*. For pinworm, treatment should be repeated after an interval of 2 weeks. In the U.S., pyrantel is sold over-the-counter for pinworm treatment (PIN-X).*

Transient and mild GI symptoms occasionally are observed, as are headache, dizziness, rash, and fever. Pyrantel pamoate use in pregnant patients and children <2 years of age is not recommended. Because pyrantel pamoate and piperazine are mutually antagonistic in their neuromuscular effects on parasites, they should not be used together.

SECTION VIII

CHEMOTHERAPY OF MICROBIAL DISEASES

42

GENERAL PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial agents are among the most commonly used and misused of all drugs. The inevitable consequence of their widespread use has been the emergence of antibiotic-resistant pathogens, fueling an ever-increasing need for new drugs at a time when the pace of antimicrobial drug development has slowed dramatically. Reducing inappropriate antibiotic use is thought to be the best way to control resistance.

CLASSIFICATION AND MECHANISM OF ACTION Antimicrobial agents are classified based on proposed mechanism of action as follows: (1) agents that inhibit synthesis of bacterial cell walls, including the β -lactam class and other agents such as *vancomycin*; (2) agents that act directly on the cell membrane to increase permeability and cause leakage of intracellular compounds; (3) agents that disrupt function of ribosomal subunits to reversibly inhibit protein synthesis (e.g., *chloramphenicol*, the *tetracyclines*, *erythromycin*, and *clindamycin*); (4) agents that bind to the 30S ribosomal subunit and alter protein synthesis (e.g., the *aminoglycosides*); (5) agents that affect bacterial nucleic acid metabolism by inhibiting RNA polymerase (e.g., *rifampin*) or topoisomerase (e.g., the *quinolones*); (6) the antimetabolites, including *trimethoprim* and the *sulfonamides*, which block essential enzymes of folate metabolism. Classes of antiviral agents include: (1) nucleic acid analogs that selectively inhibit viral DNA polymerase or HIV reverse transcriptase; (2) nonnucleoside HIV reverse transcriptase inhibitors; (3) inhibitors of other essential viral enzymes; (4) fusion inhibitors.

FACTORS THAT DETERMINE THE SUSCEPTIBILITY AND RESISTANCE OF MICROORGANISMS TO ANTIMICROBIAL AGENTS Successful antimicrobial therapy of an infection ultimately depends on the concentration of the antibiotic at the site of infection, which must be sufficient to inhibit growth of the offending microorganisms. If host defenses are intact, agents that interfere with growth or replication of the microorganism but do not kill it (i.e., *bacteriostatic* agents) may suffice. If host defenses are impaired, antibiotic-mediated killing (i.e., a *bactericidal* effect) may be required. The drug concentration at the site of infection must inhibit the organism but also must remain below the level that is toxic to human cells. If this can be achieved, the microorganism is considered sensitive; if not, the microorganism is considered resistant to the drug.

The achievable serum concentration for an antibiotic generally is used to guide decisions on sensitivity or resistance of a microorganism to that drug. However, the concentration at the infection site may be considerably lower than serum concentrations. Local factors (e.g., low pH, high protein concentration, anaerobic conditions) also may impair drug activity.

The emergence of antibiotic resistance in bacterial pathogens is a serious development that threatens the end of the antibiotic era. More than 70% of the bacteria associated with hospital-acquired infections in the U.S. are resistant to one or more of the drugs previously used to treat them. This rampant spread of antibiotic resistance mandates a more responsible approach to antibiotic use. The Centers for Disease Control and Prevention (CDC) has outlined a series of steps to diminish antibiotic resistance, including appropriate use of vaccination, judicious and proper use of indwelling catheters, early involvement of infectious disease experts, antibiotic selection based on local patterns of susceptibility, proper antiseptic technique to ensure infection rather than contamination, appropriate use of prophylactic antibiotics in surgical procedures, infection control procedures to isolate the pathogen, and strict compliance to hand hygiene.

To be effective, an antibiotic must reach its target in an active form, bind to the target, and interfere with its function. Bacterial resistance to an antimicrobial agent is attributable to three general mechanisms: (1) the drug does not reach its target; (2) the drug is not active; or (3) the target is altered.

Failure of the drug to reach its target. The outer membrane of gram-negative bacteria is a barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called porins. Absence of, mutation in, or loss of a favored porin can slow drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at its active site. If the target is intracellular and the drug requires active transport across the

FIGURE 42–1 Model depicting the interaction among components mediating resistance to β -lactam antibiotics in *Pseudomonas aeruginosa*. (Courtesy of Hiroshi Nikaïdo.) Most β -lactam antibiotics are hydrophilic and must cross the outer membrane barrier of the cell *via* outer membrane protein (Omp) channels, or porins. The channel has size and charge selectivity such that some Omps slow or block transit of the drug. If an Omp permitting drug entry is altered by mutation, is missing, or is deleted, then drug entry is slowed or prevented. β -Lactamase concentrated between the inner and outer membranes in the periplasmic space constitutes an enzymatic barrier that works in concert with the porin permeability barrier. If the antibiotic is a good substrate for β -lactamase, it will be destroyed rapidly even if the outer membrane is relatively permeable to the drug. If the rate of drug entry is slow, then a relatively inefficient β -lactamase with a slow turnover rate can hydrolyze just enough drug that an effective concentration cannot be achieved. If the target (PBP, penicillin-binding protein) has low binding affinity for the drug or is altered, then the minimum concentration for inhibition is elevated, further contributing to resistance. Finally, β -lactam antibiotics (and other polar antibiotics) that enter the cell and avoid β -lactamase destruction can be taken up by an efflux transporter system (*e.g.*, MexA, MexB, and OprF) and pumped across the outer membrane, further reducing the intracellular concentration of active drug.

cell membrane, resistance can result from mutations that inhibit this transport mechanism. For example, gentamicin, which targets the ribosome, is actively transported across the cell membrane using energy provided by the membrane electrochemical gradient. This gradient is generated by respiratory enzymes that couple electron transport and oxidative phosphorylation. A mutation in this pathway or anaerobic conditions slows entry of gentamicin into the cell, resulting in resistance. Bacteria also have efflux pumps that can transport drugs out of cells. Resistance to numerous drugs (*e.g.*, tetracycline, chloramphenicol, fluoroquinolones, macrolides, and β -lactam antibiotics) is mediated by an efflux pump mechanism. Figure 42–1 depicts the multiple membrane and periplasm components that reduce the intracellular concentrations of β -lactam antibiotics and cause resistance.

Drug inactivation. Bacterial resistance to aminoglycosides and β -lactam antibiotics usually results from production of enzymes that modify or destroy the antibiotic, respectively. A variation in this mechanism—the failure of bacteria to activate a prodrug—commonly underlies resistance of *Mycobacterium tuberculosis* to isoniazid.

Target alteration. This can include mutation of the natural target (*e.g.*, fluoroquinolone resistance), target modification (*e.g.*, ribosomal protection from macrolides and tetracyclines), or acquisition of a resistant form of the susceptible target (*e.g.*, staphylococcal resistance to methicillin caused by production of a low-affinity variant of penicillin-binding protein).

ACQUISITION OF DRUG RESISTANCE Drug resistance may be acquired by *mutation and selection*, with passage of the trait vertically to daughter cells, or by *horizontal transfer* of resistance determinants. For mutation and selection to generate resistance, the mutation cannot be lethal, should not appreciably impair virulence, and the cell carrying the mutation must disseminate and replicate. Resistance acquired by horizontal transfer of resistance determinants can disseminate rapidly either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. Horizontal transfer offers several advantages over mutation-selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes; the gene can be mobilized and rapidly amplified within a population by transfer to susceptible cells; and the resistance gene can be eliminated when no longer required.

Mutation-Selection. Mutation and antibiotic selection of the resistant mutant are the molecular basis for resistance to *streptomycin* (ribosomal mutation) quinolones (gyrase or topoisomerase IV mutations) rifampin (RNA polymerase mutation), and *linezolid* (ribosomal RNA mutation). This mechanism underlies all drug resistance in *M. tuberculosis*. The mutations are not caused by drug exposure *per se*, but are random events that confer a survival advantage when the drug is present. High-level resistance can either emerge from a sequential series of mutations that alter susceptibility incrementally (more commonly) or from a mutation that confers high-level resistance in a single step.

Horizontal Gene Transfer. Horizontal gene transfer of resistance genes is greatly facilitated by and is largely dependent on mobile genetic elements. Of these, plasmids play the most important role, with lesser importance of transposable elements, integrons, and gene cassettes. Other mechanisms may play important roles in the horizontal transfer of resistance in certain bacteria. Conjugation, the direct transfer of genes by cell-to-cell contact through a sex pilus or bridge, is an extremely important mechanism because multiple resistance genes can be transferred in a single event. Genetic transfer by conjugation is common among gram-negative bacilli and resistance is conferred on a susceptible cell in a single event. Enterococci and staphylococci are gram-positive bacteria that also transfer antibiotic resistance by conjugative transfer.

Selection of an Antimicrobial Agent

Optimal selection of antimicrobial agents requires clinical judgment and detailed knowledge of pharmacological and microbiological factors. Antibiotics have three general uses: empirical therapy, definitive therapy, and prophylactic therapy. When used as empirical therapy, the antibiotic(s) should cover all the likely pathogens, because the infecting organism has not been identified. Either combination therapy or, preferably, treatment with a single broad-spectrum agent may be employed. Once the infecting microorganism is identified, the course is completed with a narrow-spectrum, low-toxicity drug. Failures to identify the infecting microorganism and to narrow the antibiotic spectrum thereafter are common misuses of antibiotics.

The first consideration in selecting an antibiotic is whether it is even indicated. *The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.* The diagnosis may be masked if therapy is started before appropriate cultures are obtained. Antibiotics are potentially toxic, and may promote selection of resistant microorganisms. Of course, definitive identification of a bacterial infection before treatment is initiated often is not possible. In the absence of a clear indication, antibiotics often may be used if disease is severe and it seems likely that withholding therapy will result in failure to manage a serious or life-threatening infection.

Initiation of optimal empiric antibiotic therapy requires knowledge of the most likely infecting organisms and their antibiotic susceptibilities. Selection of an antibiotic regimen should rely on the clinical presentation, which may suggest a specific microorganism, and knowledge of the microorganisms most likely to cause a specific infection in a given host. In addition, simple and rapid laboratory tests may provide important clues to the possible infectious microorganism (*e.g.*, Gram's stain of infected secretion or body fluid), thereby permitting more rational selection of initial antibiotic therapy. In many situations, it is not possible to arrive at a specific bacteriological diagnosis, and the selection of a single narrow-spectrum antibiotic may be inappropriate, particularly if the infection is severe. Broad-spectrum antibiotic coverage is then indicated, pending isolation and identification of the microorganism. *Whenever the clinician is faced with initiating therapy on a presumptive bacteriological diagnosis, cultures of the presumed site of infection and blood should be taken prior to the institution of drug therapy.* For definitive therapy, the regimen should be changed to a more specific and narrow-spectrum antibiotic once an organism has been identified and its susceptibility is known.

TESTING FOR MICROBIAL SENSITIVITY TO ANTIMICROBIAL AGENTS Bacterial strains, even from the same species, may vary widely in sensitivity to antibiotics. Information about the antibiotic sensitivity of the infecting microorganism is important for appropriate drug selection. Various methods are used to assess susceptibility, including disk-diffusion, dilution test, and automated broth dilution. The results are either reported on a semi-quantitative scale (*i.e.*, resistant, intermediate, or susceptible) or in terms of the minimal inhibitory concentration (MIC).

PHARMACOKINETIC FACTORS *In vitro* activity, although critical, is only a guide to whether an antibiotic is likely to be effective, and successful therapy also depends on achieving a drug concentration sufficient to inhibit or kill bacteria at the site of infection without harming the host.

The location of the infection may dictate the choice of drug and the route of administration. The minimal drug concentration achieved at the infected site should be approximately equal to the MIC for the infecting organism, although it usually is advisable to achieve multiples of the MIC if possible. Even subinhibitory concentrations of antibiotics may be effective, perhaps by enhancing phagocytosis. Nonetheless, the aim of antibiotic therapy always should be to produce antibacterial concentrations of the drug at the site of the infection during the dosing interval.

Antibiotic access to sites of infection depends on multiple factors. If the infection is in the central nervous system (CNS), the drug must pass the blood–brain barrier. Antibiotics that are polar at physiological pH generally penetrate poorly; some, such as penicillin G, are actively transported out of the cerebrospinal fluid (CSF) by an anion transport mechanism in the choroid plexus. The concentrations of penicillins in the CSF usually are only 0.5–5% of those determined simultaneously in plasma. If the integrity of the blood–brain barrier is diminished by active bacterial infection, antibiotic penetration is increased considerably, permitting the use of penicillins in infectious meningitis. As the inflammatory reactions subside, penetration returns to normal; the drug dosage therefore should not be decreased as the patient improves. In a similar manner, antibiotics that are highly protein bound may penetrate less well into the site of infection than those that are largely unbound.

The dose and dosing frequency of antibiotics traditionally have been selected to achieve antibacterial activity at the site of infection for most of the dosing interval. This may not always be necessary, and superior results may even be obtained with high peak concentrations followed by periods of subinhibitory activity. For example, aminoglycosides are at least as efficacious and less toxic when given in a single large daily dose than when given more frequently in divided doses.

Knowledge of an individual patient's renal and hepatic function also is essential, as the dose of certain antibiotics must be adjusted to avoid toxicity when their elimination is impaired.

HOST FACTORS A critical determinant of antibiotic efficacy is the status of the host humoral and cellular defense mechanisms. In the immunocompetent host, merely halting the multiplication of the microorganism with a bacteriostatic agent frequently is sufficient to cure the infection. If host defenses are impaired, bacteriostatic activity may be inadequate and a bactericidal agent is required for cure. Examples where this applies include bacterial endocarditis, bacterial meningitis, and disseminated bacterial infections in neutropenic patients. Patients with HIV-1 infection and acquired immunodeficiency syndrome have impaired cellular immune responses. Therapy for opportunistic infection therefore often is suppressive but not curative; disseminated infections with *Salmonella* or atypical mycobacteria typically require prolonged antibiotic therapy to prevent relapse.

LOCAL FACTORS Antibiotic activity may be reduced significantly in pus, which contains phagocytes, cellular debris, and proteins that can bind drugs or create conditions unfavorable to drug action. The low pH that is characteristically found in abscesses and many confined infected sites can markedly reduce the activity of some agents, particularly the aminoglycosides.

The presence of a foreign body in an infected site markedly reduces the likelihood for successful antibiotic therapy. Prosthetics such as cardiac valves, artificial joints, pacemakers, vascular grafts, and various shunts promote the formation of a bacterial biofilm that impairs phagocytosis; within the film, the slower growth of bacteria may also reduce antibiotic activity and favor bacterial persistence. Infections associated with foreign bodies thus are characterized by frequent relapses and failure, even with long-term antibiotic therapy. Successful therapy usually requires removal of the foreign material.

Intracellular pathogens (e.g., *Salmonella*, *Brucella*, *Toxoplasma*, *Listeria*, and *M. Tuberculosis*) are protected from the action of antibiotics that penetrate into cells poorly. Certain antibiotics (e.g., fluoroquinolones, isoniazid, trimethoprim-sulfamethoxazole, and rifampin) penetrate cells well and can achieve intracellular concentrations that inhibit or kill pathogens residing within cells.

OTHER FACTORS Age may play an important role in antibiotic therapy; newborn babies and the elderly often have impaired mechanisms of elimination of antibiotics and thus are uniquely susceptible to certain drug toxicities. *Genetic polymorphisms* that affect drug metabolism are increasingly appreciated as important factors in interindividual differences in toxic effects of many drugs, including antibiotics. *Pregnancy* may impose an increased risk of reaction to antibiotics for both mother and fetus. Similarly, lactating females can pass antibiotics to nursing babies, sometimes with adverse effects. *Drug allergy* is a common event with many antibiotics, especially β -lactam antibiotics.

Therapy with Combined Antimicrobial Agents

The simultaneous use of two or more antibiotics is recommended in specifically defined situations based on pharmacological rationale. Such combination therapy requires an understanding of the potential for interaction between the antibiotics. For example, vancomycin given alone typically has minimal nephrotoxicity, but it may be nephrotoxic when combined with an aminoglycoside.

To determine the antimicrobial activity of drug combinations, bacteria are incubated in broth with serial dilutions of antibiotics, either individually or in combination. *Synergism* of the antibiotics is defined as inhibition of growth by the drug combination at concentrations less than or equal to 25% of the MIC of each drug acting alone. This finding implies that one drug is affecting the microorganism so as to increase the susceptibility to the other antibiotic. If one half of the inhibitory concentration of each drug is required to produce inhibition, the result is called additive, suggesting that the two drugs are working independently of each other. If more than one-half of the MIC of each drug is necessary to produce an inhibitory effect, the drugs are said to be antagonistic.

Bacteriostatic antibiotics (*e.g.*, tetracyclines, erythromycin, and chloramphenicol) frequently antagonize the action of bactericidal drugs (*e.g.*, β -lactam antibiotics, vancomycin, and aminoglycosides); this probably is because they inhibit cell division and protein synthesis, which are required for the effect of most bactericidal drugs. Bactericidal drugs from different classes in combination tend to be additive or synergistic. For example, an inhibitor of cell wall synthesis and an aminoglycoside are synergistic against many bacterial species, and such combinations are frequently used. It is important to remember that these antibiotic sensitivities are determined *in vitro*, and the clinical relevance of synergy and antagonism *in vivo* is often much less clearly defined.

INDICATIONS FOR THE CLINICAL USE OF COMBINATIONS OF ANTIMICROBIAL AGENTS Use of antibiotics in combination may be justified: (1) for empirical therapy of an infection for which the cause is unknown; (2) for treatment of polymicrobial infections; (3) to enhance antimicrobial activity for a specific infection (*i.e.*, for synergy); or (4) to prevent emergence of resistance.

Empirical Therapy of Severe Infections in Which a Cause is Unknown. Empirical therapy of infection is the most common reason for using a combination of antibiotics. Severe illness and less certainty as to the particular infection or causative agent may mandate broad coverage initially, and more than one agent may be required to ensure that the regimen includes a drug that is active against the potential pathogens. In the treatment of community-acquired pneumonia, a macrolide may be used for atypical organisms such as *Mycoplasma* in combination with *cefuroxime* for pneumococci and gram-negative pathogens. Prolonged administration of empirical broad-spectrum coverage or multiple antibiotics should be avoided because it often is unnecessary, is expensive, may select for antibiotic resistance against multiple agents, and may cause additional adverse effects due to the multiple agents. Inappropriately broad coverage often is continued because adequate cultures were not obtained prior to the initiation of therapy or because of the misconception that a broad-spectrum regimen is superior to a narrow-spectrum regimen. Although reluctance to narrow therapy after a favorable initial response has occurred is understandable, *the goal should be to use the most selectively active drug that produces the fewest adverse effects, which includes adverse effects on normal host flora.*

Treatment of Polymicrobial Infections. Treatment of intra-abdominal, hepatic, and brain abscesses, and some genital tract infections may require the use of a drug combination to eradicate these typically mixed aerobic-anaerobic infections. These and other mixed infections may be caused by two or more different microorganisms that are sufficiently different in antibiotic sensitivity that no single agent can provide the required coverage.

Enhancement of Antibacterial Activity in the Treatment of Specific Infections. Antibiotics administered together may produce a synergistic effect. Such synergistic combinations have been shown to be better than single-agent therapy in relatively few infections. Perhaps the best-documented example of the utility of synergistic combinations is in the treatment of enterococcal endocarditis. The clinical outcome clearly is better in patients treated with a combination of penicillin and streptomycin or gentamicin *versus* treatment with penicillin alone. The same combination has shown clinical benefit in the treatment of endocarditis caused by strains of *viridans* streptococci, with more rapid eradication of bacteria. Combinations of β -lactam antibiotics and aminoglycosides also have been recommended for the treatment of serious infections with gram-negative rods, especially *Pseudomonas aeruginosa*; the benefits of these combinations *in vivo* are less well established.

Another frequently employed combination is that of a sulfonamide and an inhibitor of dihydrofolate reductase, such as trimethoprim; this combination is synergistic because the drugs block sequential steps in microbial folate synthesis.

Finally, the combination of flucytosine and amphotericin B is synergistic against *Cryptococcus neoformans* and is often employed in AIDS patients with cryptococcal meningitis.

Prevention of the Emergence of Resistant Microorganisms. The theoretical basis for combination therapy of tuberculosis is to prevent the emergence of resistant mutants that might result from monotherapy; clinical experience amply documents the utility of concomitant use of two or more agents in this setting. Combination therapy to prevent the emergence of resistance also frequently is used when rifampin is used in other infections.

DISADVANTAGES OF COMBINATIONS OF ANTIMICROBIAL AGENTS Disadvantages of antibiotic combinations include increased risk of toxicity, selection of multiple-drug-resistant microorganisms, eradication of normal host flora with subsequent superinfection, and increased cost. Although antibiotic antagonism is frequently observed *in vitro*, well-documented clinical examples are relatively rare; the most notable is pneumococcal meningitis, where penicillin alone is much more effective than a penicillin-tetracycline combination. Concerns of antagonism are most important in situations where achieving a bactericidal effect is critical for cure of the infection (*e.g.*, meningitis, endocarditis, and gram-negative infections in neutropenic patients).

Antibiotic Prophylaxis

In general, if a single, effective, nontoxic drug is used to prevent infection by a specific microorganism or to eradicate an early infection, then chemoprophylaxis frequently is successful. On the other hand, if the aim of prophylaxis is to prevent colonization or infection by any or all organisms present in the environment of the patient, then prophylaxis often fails.

Prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in close contacts of a known case, prevention of gonorrhea or syphilis after contact with an infected person, and the intermittent use of trimethoprim-sulfamethoxazole to prevent recurrent urinary tract infections.

Antibiotic prophylaxis, often with an oral fluoroquinolone, is used to prevent a variety of infections in patients undergoing organ transplantation or receiving cancer chemotherapy. Prophylaxis is recommended for primary and secondary prevention of opportunistic infections in AIDS patients whose CD4 counts are below certain thresholds (*e.g.*, <200 cell/mm³ for the prevention of *Pneumocystis pneumonia* and <50 cells/mm³ for prevention of atypical mycobacterial infections).

Chemoprophylaxis against endocarditis is recommended for patients with valvular or other structural lesions of the heart who are undergoing dental, surgical, or other procedures that may produce a high incidence of bacteremia. Therapy, generally as a single dose, should begin 1 hour before the procedure for oral drugs and 30 minutes before for parenteral drugs. Criteria are established for the selection of specific drugs and patients who should receive prophylaxis for various procedures (Table 42–1).

The most extensive and probably best-studied use of chemoprophylaxis is to prevent wound infections after various surgical procedures (Table 42–1). Wound infections occur when a critical number of bacteria are present in the wound at the time of closure; factors that influence the size of inoculum needed include: virulence of the bacteria, the presence of devitalized or poorly vascularized tissue, the presence of a foreign body, and the status of the host. Antibiotic agents directed against the invading microorganism may prevent infection by reducing the number of viable bacteria below the critical level.

Several factors are important for effective chemoprophylaxis in surgical procedures. Antimicrobial activity must be present at the wound site at the time of closure. Thus, the drug should be given preoperatively (and perhaps intraoperatively for prolonged procedures) to ensure that therapeutic levels are maintained throughout the procedure. The antibiotic, often a cephalosporin, must be active against the most likely contaminating microorganisms. Prolonged administration of the drug after the surgical procedure is unwarranted, and no data support a lower incidence of wound infections if antibiotics are continued after the day of surgery. Clinical trials support chemoprophylaxis for dirty or contaminated surgical procedures (*e.g.*, resection of the colon) but not for clean surgical procedures. When the surgery involves insertion of a prosthetic implant (*e.g.*, prosthetic valve, vascular graft, prosthetic joint), cardiac surgery, or neurosurgical procedures, the complications of infection are so drastic that most authorities currently advocate antibiotic prophylaxis.

Table 42-1

Guidelines for Prophylactic Antibiotics in Surgical Procedures

Antibiotics should be administered 30–60 minutes prior to incision and may need to be readministered to maintain effective serum drug concentrations during prolonged procedures. A single preoperative antibiotic dose is usually sufficient prophylaxis. Continuation of antibiotics for up to 24 hours may be considered in some cases (e.g., contaminated cases, surgery of long duration, implantation of prosthetic material).

Nature of Surgery	Probable Pathogen(s)	Recommended Drug(s) (Adult Dosage)	Time of Administration
<i>I. Clean</i>			
A. Thoracic, cardiac, vascular, and orthopedic; neurosurgery B. Ophthalmic	<i>S. aureus</i> *, coagulase-negative staphylococci, gram-negative bacilli, <i>Pseudomonas</i>	Cefazolin (1 g IV) Vancomycin* (1 g IV) Gentamicin or neomycin-gramicidin-polymyxin B ophthalmic drops; multiple drugs at intervals for first 24 hours	At induction of anesthesia
<i>II. Clean-Contaminated</i>			
713 A. Head and neck (potentially entering esophageal lumen)	<i>S. aureus</i> and oral anaerobes	Cefazolin (1–2 g IV) or clindamycin (600 mg IV) ± gentamicin (1.5 mg/kg IV)	At induction of anesthesia
B. Abdominal—cholecystectomy and high-risk gastroduodenal or biliary		Cefazolin (1 g IV)	At induction of anesthesia
C. Abdominal—appendectomy		Cefoxitin or cefotetan (1 g IV)	At induction of anesthesia
D. Colorectal Preoperative lavage recommended, plus antimicrobial treatment		Go-Lytely electrolyte solution (4 liters)	Preoperative day
1. Oral antimicrobial prophylaxis		Erythromycin stearate (1 g PO) or metronidazole (500 mg PO) plus neomycin (1 g PO)	At 1 PM, 2 PM, and 11 PM on the preoperative day
2. Parenteral antimicrobial prophylaxis	Patients who have not received lavage and oral prophylaxis should receive parenteral antibiotics for ≤24 hours to cover enteric aerobes (including <i>Escherichia coli</i> , <i>Klebsiella</i> spp.) and enteric anaerobes (including <i>Bacteroides fragilis</i> , <i>Clostridium</i> spp., anaerobic cocci, and <i>Fusobacterium</i> spp.)	Cefotetan (1 g every 12 hours for 2 doses) Ceftizoxime (1 g every 12 hours for 2 doses) Cefoxitin (1 g every 4–8 hours for 3 doses)	

(Continued)

Table 42-1

Guidelines for Prophylactic Antibiotics in Surgical Procedures (Continued)

Nature of Surgery	Probable Pathogen(s)	Recommended Drug(s) (Adult Dosage)	Time of Administration
<i>II. Clean-Contaminated</i>			
E. Gynecological			
1. Vaginal or abdominal hysterectomy and high-risk cesarean section (following labor or ruptured membrane only)		Cefazolin (1 g IV)	At induction of anesthesia or postcord clamp
2. High-risk abortion, first trimester		Penicillin G (2 million units IV) or doxycycline (300 mg PO)	
3. High-risk abortion, second trimester		Cefazolin (1 g IV)	
F. Urology		Prophylactic antibiotics not shown to reduce incidence of wound infection after urological procedures. Bacteriuria is most common postoperative complication; only patients with evidence of infected urine should be treated with antibiotics directed against the specific pathogens isolated.	
<i>III. Trauma-Contaminated Wounds</i>			
A. Extremity	Antimicrobial coverage for Group A streptococci, staphylococci, and <i>Clostridium</i> spp.	Cefazolin (1 g every 8 hours IV) Vancomycin (1 g every 12 hours IV) [†]	
B. Ruptured viscus—abdomen/bowel injury		Cefotetan (1 g every 12 hours) or ceftizoxime (1 g every 12 hours) or cefoxitin (1 g every 6 hours) or clindamycin (600 mg IV every 8 hours) + gentamicin (1.5 mg/kg IV every 8 hours) [†] for ≤ 5 days	
C. Bites (cats and human)	Aerobic and anaerobic streptococci from skin and oral flora. Infection of animal bites additionally may be caused by <i>Pasteurella multocida</i> , which is penicillin-sensitive	Amoxicillin/clavulanate (750/125 mg twice a day for 5 days) or doxycycline 100 mg PO twice a day for 5 days)	

^{*}Recommended for hospitals with a high prevalence of infections caused by methicillin-resistant staphylococci or for serious allergy to β -lactams.

[†]For serious β -lactam allergy.

ABBREVIATIONS: IV, intravenous administration; PO, oral administration.

Superinfections

All individual who receive therapeutic doses of antibiotics undergo alterations in the normal microbial population of the GI, upper respiratory, and genitourinary tracts; as a result, some develop *superinfection*, or the appearance of bacteriological and clinical evidence of a new infection during the chemotherapy of a primary one. Such superinfection is due to the removal of the normal flora, which produces antibacterial substances and competes for essential nutrients. Of concern, the microorganisms responsible for the new infection can be drug-resistant strains of bacteria or fungi. The broader the spectrum and the longer the period of antibiotic treatment, the greater the risk of superinfection. *The most specific and narrowest spectrum antibiotics should be chosen to treat infections whenever feasible.*

Misuses of Antibiotics

TREATMENT OF NONRESPONSIVE INFECTIONS Most viral diseases are self-limited and do not respond to any of the currently available anti-infective compounds. Thus, antibiotic therapy of at least 90% of infections of the upper respiratory tract and many GI infections is ineffective.

THERAPY OF FEVER OF UNKNOWN ORIGIN Fever of short duration in the absence of localizing signs usually is associated with undefined viral infections. Antimicrobial therapy is unnecessary, and resolution of fever usually occurs spontaneously within a week. Fever persisting for 2 or more weeks, commonly referred to as *fever of unknown origin*, has a variety of causes; only about one quarter of these are infections. Moreover, some of these infections (*e.g.*, tuberculosis, disseminated fungal infections) may require antibiotics that are not typically used for bacterial infections. Inappropriately administered antibiotics may mask an underlying infection, delay the diagnosis, and prevent the identification of the infectious pathogen by culture.

IMPROPER DOSAGE Dosing errors with antibiotics are common. Excessive dosing can result in significant toxicities, while too low a dose may result in treatment failure and is most likely to select for antibiotic resistance.

INAPPROPRIATE RELIANCE ON CHEMOTHERAPY ALONE Infections complicated by abscess formation or the presence of necrotic tissue or a foreign body often cannot be cured by antibiotic therapy alone. Drainage, debridement, and removal of the foreign body are at least as important as the choice of antibiotic agent. As a general rule, when an appreciable quantity of pus, necrotic tissue, or a foreign body is present, the most effective therapy is an antimicrobial agent given in adequate dose plus a properly performed surgical procedure.

LACK OF ADEQUATE BACTERIOLOGICAL INFORMATION Antibiotic therapy too often is given in the absence of supporting microbiological data. Bacterial cultures and Gram stains of infected material are obtained too infrequently, and, when available, the results often are disregarded in the selection and application of drug therapy. *Frequent use of drug combinations or drugs with broadest spectra is a cover for diagnostic imprecision.*

SULFONAMIDES, TRIMETHOPRIM–SULFAMETHOXAZOLE, QUINOLONES, AND AGENTS FOR URINARY TRACT INFECTIONS

SULFONAMIDES

CHEMISTRY

Sulfonamides are derivatives of para-aminobenzenesulfonamide (sulfanilamide); the structures of selected members are shown in Figure 43–1. Most are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are embodied in sulfanilamide itself. The sulfur must be linked directly to the benzene ring. The para- NH_2 group (the N of which is designated N4) can be replaced only by moieties that can be converted in vivo to a free amino group. Substitutions in the amide NH_2 group (N1) have variable effects on antibacterial activity of the molecule, but substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds.

Effects on Microbes

Sulfonamides have wide antimicrobial activity, but their usefulness has diminished as resistant strains have emerged. These drugs are bacteriostatic, and host defenses are essential for eradication of the infection.

ANTIBACTERIAL SPECTRUM

MECHANISM OF ACTION

Sulfonamides competitively inhibit dihydropteroate synthase, the bacterial enzyme responsible for the incorporation of para-aminobenzoic acid (PABA) into dihydropteroic acid, the immediate precursor of folic acid (Figure 43–2). Sensitive microorganisms must synthesize their own folic acid, while bacteria that can use preformed folate are not affected. Mammalian cells require preformed folic acid and are not affected by sulfonamides.

SYNERGISTS OF SULFONAMIDES

Trimethoprim exerts a synergistic effect with sulfonamides. It potently and selectively inhibits microbial dihydrofolate reductase, the enzyme that reduces dihydrofolate to tetrahydrofolate—the form required for one-carbon transfer reactions. Coadministration of a sulfonamide and trimethoprim thus introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate (Figure 43–2).

ACQUIRED BACTERIAL RESISTANCE TO SULFONAMIDES

Bacterial resistance to sulfonamides can originate by random mutation and selection or by plasmid transfer of resistance; it usually does not confer cross-resistance to other classes of antibiotics. Resistance to sulfonamide results from altered constitution of the bacterial cell that causes (1) a lower affinity for sulfonamides by dihydropteroate synthase, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) an increased production of an essential metabolite or drug antagonist. Plasmid-mediated resistance is due to plasmid-encoded, drug-resistant dihydropteroate synthetase.

Absorption, Fate, and Excretion

Except for drugs especially designed for local gastrointestinal (GI) effects (see Chapter 38), the sulfonamides are absorbed rapidly and well from the GI tract. Peak plasma levels are achieved in 2–6 hours, depending on the drug. Absorption from sites such as the vagina, respiratory tract, or abraded skin is unreliable, but sufficient drug may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly albumin. The extent is determined by the hydrophobicity of a particular drug and its pK_a ; at physiological pH, drugs with a high pK_a exhibit a low degree of protein binding and *vice versa*.

Sulfonamides are widely distributed. The diffusible fraction of sulfadiazine is distributed uniformly throughout the total-body water, whereas *sulfisoxazole* is confined largely to the extracellular space. The sulfonamides readily enter body fluids and may reach concentrations therein that are 50–80% of the simultaneously determined serum concentration. Since the protein content of such fluids usually is low, the drug is present in the unbound active form.

FIGURE 43-1 Structural formulas of selected sulfonamides and para-aminobenzoic acid. The N of the *para*-NH₂ group is designated as N4; that of the amide NH₂, as N1.

After systemic administration, *sulfadiazine* and *sulfisoxazole* attain concentrations in cerebrospinal fluid (CSF) that may be effective in meningitis. Sulfonamides readily cross the placenta to reach the fetal circulation, potentially exerting both antibacterial and toxic effects.

The sulfonamides are metabolized in the liver. The major derivative is the N4-acetylated sulfonamide. Acetylation, which occurs to a varying extent with each agent, is disadvantageous because the resulting products have no antibacterial activity yet retain the toxic potential of the parent substance. Sulfonamides are eliminated partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the $t_{1/2}$ of sulfonamides in the body thus

FIGURE 43-2 Steps in folate metabolism blocked by sulfonamides and trimethoprim.

depends on renal function. In acid urine, the older sulfonamides are insoluble and crystalluria may result. Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

The sulfonamides are classed based on the extent or rapidity with which they are absorbed and excreted: (1) agents that are absorbed and excreted rapidly, such as sulfisoxazole and sulfadiazine; (2) agents that are absorbed very poorly when administered orally and hence are active in the bowel lumen, such as *sulfasalazine*; (3) agents that are used mainly topically, such as *sulfacetamide*, *mafenide*, and *silver sulfadiazine*; and (4) long-acting sulfonamides, such as *sulfadoxine*, that are absorbed rapidly but excreted slowly.

RAPIDLY ABSORBED AND ELIMINATED SULFONAMIDES

Sulfisoxazole

Sulfisoxazole (GANTRISIN, others) is rapidly absorbed and excreted. Its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides. Sulfisoxazole is bound extensively to plasma proteins. From 28% to 35% of sulfisoxazole in the blood and ~30% in the urine is in the acetylated form. It has a serum $t_{1/2}$ of 5–6 hours and ~95% of a single dose is excreted by the kidney in 24 hours. Drug concentrations in urine greatly exceed those in blood and may be bactericidal. The CSF concentration is ~33% of that in the blood. Sulfisoxazole acetyl is tasteless and hence preferred for oral use in children; it is marketed in combination with erythromycin (*PEDIAZOLE, others*) for use in children with otitis media.

The untoward effects of sulfisoxazole are similar to those of other sulfonamides. Because of its relatively high solubility, sulfisoxazole rarely produces hematuria or crystalluria (0.2–0.3%). Patients still should ingest an adequate quantity of water. Sulfisoxazole must be used with caution in patients with impaired renal function. Like all sulfonamides, sulfisoxazole may produce hypersensitivity reactions, some of which are potentially lethal. Sulfisoxazole generally is preferred over other sulfonamides when a rapidly absorbed and excreted sulfonamide is indicated.

Sulfamethoxazole

Sulfamethoxazole is a close congener of sulfisoxazole, but its rates of enteric absorption and urinary excretion are slower; it has a serum $t_{1/2}$ of 11 hours. It is administered orally and employed for both systemic and urinary tract infections. Precautions must be observed to avoid crystalluria because of the high percentage of the acetylated, relatively insoluble form of the drug in urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. It also is marketed in fixed-dose combinations with trimethoprim (see below).

Sulfadiazine

Sulfadiazine given orally is absorbed rapidly, and peak blood concentrations are reached within 3–6 hours after a single dose; the serum $t_{1/2}$ is 10 hours. About half of the drug is bound to plasma protein. Therapeutic concentrations are attained in CSF within 4 hours of a single oral dose.

Sulfadiazine is readily excreted by the kidney in both the free and acetylated forms, rapidly at first and then more slowly over a period of 2–3 days. About 15–40% of the excreted sulfadiazine is acetylated. This form is excreted more readily than the free fraction, and alkalization of the urine accelerates the renal clearance of both forms by further diminishing their tubular reabsorption.

In adults and children who are treated with sulfadiazine, every precaution must be taken to ensure fluid intake adequate to produce a urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may reduce the risk of crystalluria.

POORLY ABSORBED SULFONAMIDES

Sulfasalazine (AZULFIDINE) is very poorly absorbed from the GI tract and is used in the therapy of ulcerative colitis and Crohn's disease (see Chapter 38).

SULFONAMIDES FOR TOPICAL USE

Sulfacetamide

Sulfacetamide is the *N*-1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility is ~90 times that of sulfadiazine. This drug (*ISOPTO-CETAMIDE, others*) is employed extensively for ophthalmic infections. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. The drug penetrates readily into ocular fluids and tissues. Sensitivity reactions to sulfacetamide are rare, but it should not be used in patients with known sulfonamide hypersensitivity.

Silver Sulfadiazine

Silver sulfadiazine (SILVADENE, others) inhibits the growth of nearly all pathogenic bacteria and fungi, including some species resistant to sulfonamides. The compound is used topically to reduce microbial colonization and the incidence of infections in burn patients. It is not used to treat an established deep infection. Silver is released slowly in concentrations that are selectively toxic to microorganisms. However, bacteria may develop resistance to silver sulfadiazine. The plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered one of the agents of choice for the prevention of burn infection.

Mafenide

*This sulfonamide (α -amino-*p*-toluene-sulfonamide) is marketed as mafenide acetate (SULFAMY-LON). It is used topically to prevent colonization of burns by a large variety of gram-negative and gram-positive bacteria. It is associated with significant adverse effects, including intense pain at sites of application, allergic reactions, loss of fluid by evaporation from the burn surface, and metabolic acidosis secondary to inhibition of carbonic anhydrase.*

LONG-ACTING SULFONAMIDES

*Sulfadoxine has a particularly long $t_{1/2}$ (7–9 days). In combination with pyrimethamine (500 mg sulfadoxine plus 25 mg pyrimethamine as FANSIDAR), it is used for prophylaxis and treatment of malaria caused by mefloquine-resistant strains of *Plasmodium falciparum* (see Chapter 39). Because of severe adverse reactions (e.g., Stevens-Johnson syndrome), the drug should be used for prophylaxis only where the risk of resistant malaria is high.*

Sulfonamide Therapy**URINARY TRACT INFECTIONS**

Many urinary tract infections are caused by sulfonamide-resistant microorganisms. Trimethoprim-sulfamethoxazole, a quinolone, trimethoprim, fosfomycin, or ampicillin are the preferred agents. Sulfisoxazole may be used in areas where the prevalence of resistance is not high or when the organism is known to be sensitive. The usual dose is 2–4 g initially, followed by 1–2 g, orally four times a day for 5–10 days. Patients with acute pyelonephritis should not be treated with a sulfonamide.

Nocardiosis

*Sulfonamides are of value in treating infections due to *Nocardia* spp. Sulfisoxazole or sulfadiazine may be given in dosages of 6–8 g daily and is continued for several months after all manifestations have resolved. The administration of a sulfonamide together with a second antibiotic has been recommended, especially for advanced cases, and ampicillin, erythromycin, and streptomycin have been suggested for this purpose. The clinical response and the results of sensitivity testing may be helpful in choosing a companion drug. Some experts consider trimethoprim-sulfamethoxazole to be the drug of choice.*

TOXOPLASMOSIS

The combination of pyrimethamine and sulfadiazine is the treatment of choice for toxoplasmosis (see Chapter 40). Pyrimethamine is given as a loading dose of 75 mg followed by 25 mg orally per day, with sulfadiazine 1 g orally every 6 hours, plus folic acid 10 mg orally each day for at least 3–6 weeks. Patients should receive at least 2 L of fluid intake daily to prevent crystalluria.

USE OF SULFONAMIDES FOR PROPHYLAXIS

The sulfonamides are as efficacious as oral penicillin in preventing streptococcal infections and recurrence of rheumatic fever in susceptible subjects and are used in patients who are hypersensitive to penicillin. Untoward responses usually occur during the first 8 weeks; serious reactions after this time are rare. White blood cell counts should be checked weekly during the first 8 weeks.

Untoward Reactions to Sulfonamides**DISTURBANCES OF THE URINARY TRACT**

*The incidence of crystalluria is low with more soluble agents (e.g., sulfisoxazole). Crystalluria has occurred in volume-depleted patients with the acquired immune deficiency syndrome (AIDS) who were given sulfadiazine for *Toxoplasma* encephalitis. Fluid intake should be sufficient to ensure a daily urine volume of at least 1.2 L (in adults). Urinary alkalization may be helpful if urine volume or pH is unusually low.*

DISORDERS OF THE HEMATOPOIETIC SYSTEM

Although rare, acute hemolytic anemia can occur. This may reflect an immune reaction or may be due to glucose-6-phosphate dehydrogenase deficiency. Agranulocytosis occurs in ~0.1% of patients who receive sulfadiazine and also can occur with other sulfonamides. Although neutropenia may persist for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care. Pancytopenia with complete suppression of bone-marrow activity is extremely rare. It probably results from a direct myelotoxic effect and may be fatal. Reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

HYPERSENSITIVITY REACTIONS

The sulfonamides are associated with a number of skin and mucous membrane manifestations attributed to sensitization to sulfonamide, including various rashes, erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet's syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions usually occur after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is ~2% with sulfisoxazole, although a higher frequency is seen in patients with AIDS. A syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever occurs in ~3% of patients treated with sulfisoxazole.

Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in <0.1% of patients and rarely may progress to fulminant hepatic failure and death. Hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3–5 days after sulfonamide administration is started.

MISCELLANEOUS REACTIONS

Anorexia, nausea, and vomiting occur in 1–2% of persons receiving sulfonamides. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from albumin, potentially causing kernicterus. Sulfonamides should not be given to pregnant women near term because these drugs cross the placenta and are secreted in milk.

DRUG INTERACTIONS

Important drug interactions of the sulfonamides are seen with the oral anticoagulants, the sulfonylureas, and phenytoin. In each case, sulfonamides can potentiate the effects of the other drug, either by inhibiting its metabolism or by displacing it from albumin. Dosage adjustment may be necessary.

TRIMETHOPRIM–SULFAMETHOXAZOLE

The introduction of trimethoprim in combination with sulfamethoxazole constitutes an important advance in the development of clinically effective antimicrobial agents. In addition to its combination with sulfamethoxazole (BACTRIM, SEPTRA, others), trimethoprim also is available as a single-entity preparation (PROLOPRIM, others). It is a diaminopyrimidine.

ANTIBACTERIAL SPECTRUM

The antibacterial spectrum of trimethoprim resembles that of sulfamethoxazole. Most gram-negative and gram-positive microorganisms are sensitive to trimethoprim, but there is significant regional variation in the susceptibility of Enterobacteriaceae to trimethoprim because of the spread of resistance.

Efficacy of Trimethoprim–Sulfamethoxazole in Combination

A synergistic interaction between these drugs is apparent even when microorganisms are resistant to sulfonamide, but maximal synergism occurs when microorganisms are sensitive to both drugs.

MECHANISM OF ACTION

The antimicrobial activity of the trimethoprim/sulfamethoxazole combination results from actions on two steps of the biosynthetic pathway for tetrahydrofolic acid. Trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (Figure 43–2). Mammalian cells use preformed folates from the diet and do not synthesize the compound. Trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms; ~100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. This relative selectivity is vital because the enzyme is essential to all species.

The synergistic interaction between sulfonamide and trimethoprim is predictable from their respective mechanisms. The most effective ratio of these two drugs for the greatest number of

microorganisms is 20 parts sulfamethoxazole to 1 part trimethoprim. The combination thus is formulated to achieve a sulfamethoxazole concentration in vivo that is 20 times greater than that of trimethoprim.

BACTERIAL RESISTANCE

Bacterial resistance increasingly complicates treatment and often results from the acquisition of a plasmid that encodes an altered dihydrofolate reductase. Emergence of trimethoprim-sulfamethoxazole-resistant *Staphylococcus aureus* and Enterobacteriaceae is a special problem in AIDS patients receiving the drug for prophylaxis of *Pneumocystis jiroveci* (formerly called *Pneumocystis carinii*) pneumonia.

ABSORPTION, DISTRIBUTION, AND EXCRETION The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely but not perfectly matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. The ratio in blood is often greater than 20:1, while that in tissues is frequently less. After a single oral dose of the combined preparation, peak blood concentrations of trimethoprim usually occur by 2 hours, whereas peak concentrations of sulfamethoxazole require 4 hours. The half-lives of trimethoprim and sulfamethoxazole are ~11 and 10 hours, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (the conventional 5:1 ratio) twice daily, the peak concentrations of the drugs in plasma approximate the optimal ratio. Peak concentrations are similar after intravenous infusion of 800 mg sulfamethoxazole/160 mg trimethoprim over a period of 1 hour.

Trimethoprim is distributed and concentrated rapidly in tissues, and ~40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters CSF and sputum. High concentrations of each component also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein.

About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 hours. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

THERAPEUTIC USES

Urinary Tract Infections

Treatment of uncomplicated lower urinary tract infections with trimethoprim-sulfamethoxazole often is highly effective for sensitive bacteria, usually for a minimum of 3 days. The combination is especially useful in chronic and recurrent infections of the urinary tract. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for bacterial prostatitis.

Bacterial Respiratory Tract Infections

Trimethoprim-sulfamethoxazole is effective for acute exacerbations of chronic bronchitis. Administration of 800–1200 mg sulfamethoxazole plus 160–240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should not be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults caused by susceptible strains of *Haemophilus influenzae* and *Streptococcus pneumoniae*.

Gastrointestinal Infections

The combination is an alternative to fluoroquinolone for treatment of shigellosis, but resistance to trimethoprim-sulfamethoxazole is increasingly common.

Trimethoprim-sulfamethoxazole appears to be effective in the management of carriers of sensitive strains of *Salmonella typhi* and other *Salmonella* spp., but failures have occurred. Chronic disease of the gallbladder may be associated with a high incidence of failure to clear the carrier state. Acute diarrhea owing to sensitive strains of enteropathogenic *Escherichia coli* can be treated or prevented with either trimethoprim or trimethoprim plus sulfamethoxazole. However, antibiotic treatment (either trimethoprim-sulfamethoxazole or cephalosporin) of diarrheal illness due to enterohemorrhagic *E. coli* O157:H7 may increase the risk of hemolytic-uremic syndrome, perhaps by increasing the release of Shiga toxin.

Infection by *Pneumocystis jiroveci*

High-dose therapy (trimethoprim 15 mg/kg/day plus sulfamethoxazole 100 mg/kg/day in three or four divided doses) is effective for this severe infection in patients with AIDS. Adjunctive glucocorticoids

should be given in patients with a P_{O_2} of <70 mm Hg or an alveolar–arterial gradient of >35 mm Hg. The incidence of side effects is high. Lower-dose oral therapy with 800 mg sulfamethoxazole plus 160 mg trimethoprim (given twice daily) has been used successfully in AIDS patients with less severe pneumonia ($P_{O_2} >70$ mm Hg). Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or three times a week is effective in preventing pneumonia caused by this organism in patients with AIDS. Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim–sulfamethoxazole. The most common problems are rash, fever, leukopenia, and hepatitis.

Prophylaxis in Neutropenic Patients

Low-dose therapy (i.e., 150 mg/m² of body surface area of trimethoprim and 750 mg/m² of body surface area of sulfamethoxazole) is effective for the prophylaxis of infection by *P. jiroveci*. Significant protection against sepsis caused by gram-negative bacteria also was noted when 800 mg sulfamethoxazole and 160 mg trimethoprim were given twice daily to severely neutropenic patients. The emergence of resistant bacteria may limit the usefulness of trimethoprim–sulfamethoxazole for prophylaxis.

Miscellaneous Infections

Nocardia infections have been treated successfully, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin is considered the treatment of choice for brucellosis, trimethoprim–sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim–sulfamethoxazole also has been used successfully for Whipple's disease, *Stenotrophomonas maltophilia* infection, and infection by the intestinal parasites *Cyclospora* and *Isospora*.

UNTOWARD EFFECTS The margin between toxicity for bacteria and that for human beings may be narrowed when the patient is folate deficient. In such cases, trimethoprim–sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. About 75% of the untoward effects involve the skin. Trimethoprim–sulfamethoxazole has been reported to cause up to three times as many dermatological reactions as does sulfisoxazole when given alone (5.9% vs. 1.7%). Severe dermatologic reactions primarily occur in older individuals. Nausea and vomiting constitute the bulk of GI reactions; diarrhea is rare. Glossitis and stomatitis are relatively common. Transient jaundice with histological features of allergic cholestatic hepatitis has been noted. CNS reactions consist of headache, depression, and hallucinations. Hematological reactions include various anemias (including aplastic, hemolytic, and macrocytic), coagulation disorders, granulocytopenia, agranulocytosis, purpura, and sulfhemoglobinemia. Permanent impairment of renal function may follow the use of trimethoprim–sulfamethoxazole in patients with renal disease, and a reversible decrease in creatinine clearance has been noted in patients with normal renal function.

Patients with AIDS frequently have hypersensitivity reactions to trimethoprim–sulfamethoxazole, including rash, neutropenia, Stevens-Johnson syndrome, Sweet's syndrome, and pulmonary infiltrates. It may be possible to continue therapy in such patients following rapid oral desensitization.

THE QUINOLONES

The fluorinated 4-quinolones, such as *ciprofloxacin* (CIPRO), *moxifloxacin* (AVELOX), and *gatifloxacin* (TEQUIN), are orally effective for the treatment of a wide variety of infectious diseases (Table 43–1) and have relatively few side effects.

CHEMISTRY

Compounds available in the U.S. contain a carboxylic acid moiety at position 3 of the primary ring structure. Many newer fluoroquinolones also contain a fluorine substituent at position 6 and a piperazine moiety at position 7 (Table 43–1).

MECHANISM OF ACTION

The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV. For many gram-positive bacteria, topoisomerase IV is the primary target. For many gram-negative bacteria, DNA gyrase is the primary quinolone target, as illustrated in Figure 43–3. The quinolones inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with their effective antibacterial actions. Mutations of *gyrA* can confer resistance to these drugs. Topoisomerase IV separates catenated DNA molecules that result from DNA replication, and also is a target for quinolones.

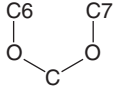

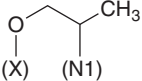

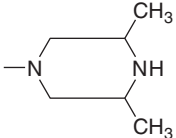

ANTIBACTERIAL SPECTRUM

The fluoroquinolones are potent bactericidal agents against a broad variety of microorganisms, as outlined under Therapeutic Uses. Fluoroquinolones have good activity against staphylococci but

FIGURE 43–3 Model of the formation of negative DNA supercoils by DNA gyrase. The enzyme binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and also block the decatenating activity of topoisomerase IV.

not against methicillin-resistant strains. Activity against streptococci is limited to a subset of the quinolones, including levofloxacin (*LEVAQUIN*), gatifloxacin (*TEQUIN*), and moxifloxacin (*AVELOX*). Several intracellular bacteria are inhibited by fluoroquinolones; these include species of *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*). *Ciprofloxacin*, ofloxacin (*FLOXIN*), and pefloxacin inhibit *M. fortuitum*, *M. kansasii*, and *M. tuberculosis*.

Resistance to quinolones may develop via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria. No quinolone-inactivating mechanisms have been identified. Resistance has increased, especially in *Pseudomonas* and *staphylococci*. Fluoroquinolone resistance also is increasing in *C. jejuni*, *Salmonella*, *Neisseria gonorrhoeae*, and *S. pneumoniae*.

ABSORPTION, FATE, AND EXCRETION The quinolones are well absorbed after oral administration and are widely distributed. Peak serum levels of the fluoroquinolones occur within 1–3 hours of an oral dose of 400 mg. Relatively low serum levels are reached with norfloxacin and limit its usefulness to the treatment of urinary tract infections. Food does not impair oral absorption but may delay the time to peak serum concentrations. Oral doses in adults are 200–400 mg every 12 hours for ofloxacin, 400 mg every 12 hours for norfloxacin and pefloxacin, and 250–750 mg every 12 hours for ciprofloxacin. Bioavailability of the fluoroquinolones exceeds 50% for all agents and 95% for several. The serum half-lives range from 3 to 5 hours for norfloxacin and ciprofloxacin to 20 hours for sparfloxacin. The volume of distribution of quinolones is high, with concentrations in urine, kidney, lung and prostate tissue, stool, bile, and macrophages and neutrophils higher than serum levels. Quinolone concentrations in CSF, bone, and prostatic fluid are lower than in serum. Pefloxacin and ofloxacin levels in ascites fluid approach serum levels, and ciprofloxacin, ofloxacin, and pefloxacin have been detected in human breast milk.

Most quinolones are cleared predominantly by the kidney, and dose must be adjusted for renal failure. Pefloxacin and moxifloxacin are metabolized predominantly by the liver and should not be used in patients with hepatic failure. None is removed efficiently by peritoneal or hemodialysis.

THERAPEUTIC USES

Urinary Tract Infections

Norfloxacin is approved for use in the U.S. only for urinary tract infections. The fluoroquinolones are more efficacious than trimethoprim-sulfamethoxazole for the treatment of urinary tract infections.

Prostatitis

Norfloxacin, *ciprofloxacin*, and *ofloxacin* are effective for the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4–6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

Sexually Transmitted Diseases

The quinolones are contraindicated in pregnancy. Fluoroquinolones lack activity for *Treponema pallidum* but have activity in vitro against *N. gonorrhoeae*, *Chlamydia trachomatis*, and *Haemophilus ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin or sparfloxacin is an alternative to a 7-day course with doxycycline or a single dose of azithromycin. A single oral dose of a fluoroquinolone such as ofloxacin or ciprofloxacin is effective treatment for sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has made

ceftriaxone the first-line agent. Pelvic inflammatory disease has been treated effectively with a 14-day course of ofloxacin combined with an antibiotic with activity against anaerobes (clindamycin or metronidazole). Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

Gastrointestinal and Abdominal Infections

For traveler's diarrhea (frequently caused by enterotoxigenic *E. coli*), the quinolones are equal to trimethoprim-sulfamethoxazole in effectiveness. Norfloxacin, ciprofloxacin, and ofloxacin given for 5 days all are effective in the treatment of patients with shigellosis, with even shorter courses effective in many cases. Norfloxacin is superior to tetracyclines in decreasing the duration of diarrhea in cholera. Ciprofloxacin and ofloxacin cure most patients with enteric fever caused by *S. typhi*, as well as bacteremic nontyphoidal infections in AIDS patients. Shigellosis is treated effectively with either ciprofloxacin or azithromycin. The *in vitro* ability of the quinolones to induce the Shiga toxin (the cause of the hemolytic-uremic syndrome) in *E. coli* suggests that the quinolones should not be used for Shiga toxin-producing *E. coli*. Ciprofloxacin and ofloxacin are less effective in treating episodes of peritonitis occurring in patients on chronic ambulatory peritoneal dialysis, likely owing to their higher MICs for coagulase-negative staphylococci commonly seen in this setting.

Respiratory Tract Infections

The major limitation to the use of quinolones for the treatment of community-acquired pneumonia and bronchitis was the poor activity against *S. pneumoniae* and anaerobic bacteria. Many of the newer fluoroquinolones, including gatifloxacin and moxifloxacin, have excellent activity against *S. pneumoniae* and have shown efficacy comparable to β -lactam antibiotics. The fluoroquinolones have activity against the rest of the common respiratory pathogens, including *H. influenzae*, *Moraxella catarrhalis*, *S. aureus*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila*. Either a fluoroquinolone (ciprofloxacin or levofloxacin) or azithromycin is the antibiotic of choice for *L. pneumophila*. Fluoroquinolones can effectively eradicate both *H. influenzae* and *M. catarrhalis* from sputum. Mild-to-moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolones.

Bone, Joint, and Soft Tissue Infections

The treatment of chronic osteomyelitis requires prolonged antimicrobial therapy with agents active against *S. aureus* and gram-negative rods. The fluoroquinolones, by virtue of their oral administration and antibacterial spectrum, may appropriately be used in some cases; recommended doses are 500 mg every 12 hours or, if severe, 750 mg twice daily. Bone and joint infections may require treatment for 4–6 weeks or more. Dosage should be reduced for patients with severely impaired renal function. Ciprofloxacin should not be given to children or pregnant women. Clinical cures have been as high as 75% in chronic osteomyelitis in which gram-negative rods predominated. Failures have been associated with the development of resistance in *S. aureus*, *P. aeruginosa*, and *Serratia marcescens*. In diabetic foot infections, which commonly are polymicrobial, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice. Ciprofloxacin as sole therapy is effective in ~50% of diabetic foot infections.

Other Infections

Ciprofloxacin received wide usage for the prophylaxis of anthrax and is effective for the treatment of tularemia. The quinolones may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and for the treatment of atypical mycobacterial infections and *Mycobacterium avium* complex infections in AIDS (see Chapter 47). In neutropenic cancer patients with fever, the combination of a quinolone with an aminoglycoside is comparable to β -lactam-aminoglycoside combinations; quinolones are less effective when used alone. Quinolones, when used prophylactically in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias. Ciprofloxacin plus amoxicillin-clavulanate is effective as an oral empirical therapy for fever in low-risk patients with granulocytopenia secondary to cancer chemotherapy.

ADVERSE EFFECTS

The most common adverse reactions involve the GI tract, with 3–17% of patients reporting mostly mild nausea, vomiting, and/or abdominal discomfort. Diarrhea and antibiotic-associated colitis have been unusual. CNS side effects, predominately mild headache and dizziness, have been seen in 1–10% of patients. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who also were receiving theophylline or a nonsteroidal anti-inflammatory drug. Ciprofloxacin and pefloxacin inhibit the metabolism of theophylline and may induce toxic levels. Nonsteroidal anti-inflammatory drugs may augment displacement of γ -aminobutyric acid (GABA) from its receptors by the quinolones. Rashes, including photosensitivity reactions, also can occur.

Achilles tendon rupture or tendinitis has occurred rarely. Renal disease, hemodialysis, and glucocorticoid use may be predisposing factors. Traditionally, the use of quinolones in children has been contraindicated because they have produced arthropathy in animal models. However, children with cystic fibrosis given ciprofloxacin, norfloxacin, and nalidixic acid have had few, and reversible, joint symptoms. Therefore, the benefits may outweigh the risks in some children.

Leukopenia, eosinophilia, and mild elevations in serum transaminases occur rarely. Prolongation of the QT_c interval has been observed with sparfloxacin and to a lesser extent with gatifloxacin and moxifloxacin. Quinolones probably should be used only with caution in patients who are taking certain antiarrhythmics, including amiodarone, quinidine, and procainamide (see Chapter 34).

The prescribing information for gatifloxacin includes a contraindication in diabetic patients due to serious reports of hypoglycemia and hyperglycemia. Risk factors for this adverse effect include older age, renal insufficiency, and concomitant therapy with glucose-altering medications.

ANTISEPTIC AND ANALGESIC AGENTS FOR URINARY TRACT INFECTIONS

The urinary tract antiseptics inhibit the growth of many species of bacteria and can be used therapeutically because they are concentrated in the renal tubules. Effective antibacterial concentrations also reach the renal pelves and bladder.

METHENAMINE

Methenamine is a urinary tract antiseptic and prodrug that owes its activity to its capacity to generate formaldehyde. It is bactericidal for gram-positive and gram-negative microorganisms and is more effective in an acid urine.

NITROFURANTOIN

Nitrofurantoin (*FURADANTIN*, *MACROBID*, others) is a synthetic nitrofuran that is used to prevent and treat urinary tract infections. Bacteria reduce nitrofurantoin to toxic products that apparently mediate cell damage. The antibacterial activity is higher in acidic urine.

Pharmacology and Toxicity

Nitrofurantoin is absorbed rapidly and completely from the GI tract. Antibacterial concentrations are not achieved in plasma at recommended doses because the drug is eliminated rapidly. The plasma $t_{1/2}$ is <1 hour; ~40% is excreted unchanged in the urine. The urine should not be alkalinized because this reduces antimicrobial activity. Nitrofurantoin colors the urine brown.

The most common side effects are anorexia, nausea and vomiting, and diarrhea. Hypersensitivity reactions occur occasionally, including fever, leukopenia, granulocytopenia, hemolytic anemia associated with glucose-6-phosphate dehydrogenase deficiency, cholestatic jaundice, and hepatitis. Acute pneumonitis may occur acutely; the symptoms usually resolve quickly after drug discontinuation. Subacute reactions also may occur, including interstitial pulmonary fibrosis. Elderly patients are especially susceptible to the pulmonary toxicity. Severe polyneuropathies affecting both sensory and motor nerves also have been reported, most often in patients with impaired renal function and in persons on long-term treatment.

The oral dosage of nitrofurantoin for adults is 50–100 mg four times a day with meals and at bedtime. A single 50- to 100-mg dose at bedtime may be sufficient to prevent recurrences. A course of therapy should not exceed 14 days. Pregnant women, individuals with impaired renal function (creatinine clearance <40 mL/min), and children <1 month of age should not receive nitrofurantoin.

Nitrofurantoin is approved only for the treatment of urinary tract infections caused by microorganisms known to be susceptible to the drug. Nitrofurantoin is not recommended for treatment of pyelonephritis or prostatitis but is effective for prophylaxis of recurrent urinary tract infections.

PENICILLINS, CEPHALOSPORINS, AND OTHER β -LACTAM ANTIBIOTICS

PENICILLINS

Penicillins consist of a thiazolidine ring (A) connected to a β -lactam ring (B), to which is attached a side chain (R) (Figure 44-1). The penicillin nucleus itself is the chief structural requirement for biological activity. The discovery that 6-aminopenicillanic acid could be obtained from cultures that were depleted of side-chain precursors led to the development of the semisynthetic penicillins, which have side chains that alter the susceptibility of the resulting compounds to inactivating enzymes (β -lactamases) and that change the antibacterial activity and pharmacological properties of the drug (Table 44-1).

The international unit of penicillin is the specific penicillin activity contained in 0.6 μ g of the crystalline sodium salt of penicillin G. Doses of semisynthetic penicillins are expressed by weight.

MECHANISM OF ACTION OF THE PENICILLINS AND CEPHALOSPORINS

Peptidoglycan is a heteropolymer that provides rigid mechanical stability to the bacterial cell wall by virtue of its highly cross-linked structure (Figure 44-2). In gram-positive bacteria, the cell wall is 50–100 molecules thick; it is only 1 or 2 molecules thick in gram-negative bacteria (Figure 44-3). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (N-acetylglucosamine and N-acetylmuramic acid) cross-linked by peptide chains.

Penicillin precursor formation takes place in the cytoplasm. The synthesis of UDP-acetylmuramyl-pentapeptide is completed with the addition of the dipeptide, D-Ala-D-Ala (formed by racemization and condensation of L-Ala). UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked to form a long polymer. The cross-link is completed by a transpeptidation reaction that occurs outside the cell membrane (Figure 44-2). The β -lactam antibiotics inhibit this last step in peptidoglycan synthesis, presumably by acylating the transpeptidase via cleavage of the—CO—N—bond of the β -lactam ring.

Although inhibition of the transpeptidase is demonstrably important, there are additional targets for the actions of penicillins and cephalosporins; these collectively are termed penicillin-binding proteins (PBPs). The transpeptidase responsible for peptidoglycan synthesis is one of these PBPs. Other PBPs are necessary for cell division and cell shape and other essential processes; thus, the lethality of penicillin for bacteria involves both lytic and nonlytic mechanisms.

MECHANISMS OF BACTERIAL RESISTANCE TO PENICILLINS AND CEPHALOSPORINS A sensitive strain may acquire resistance by mutations that decrease the affinity of PBPs for the antibiotic. Because β -lactam antibiotics inhibit many different PBPs, their affinity for several PBPs must decrease to confer resistance. Methicillin-resistant *S. aureus* are resistant via acquisition of an additional high-molecular-weight PBP (via a transposon) with a very low affinity for all β -lactam antibiotics; this mechanism is responsible for methicillin resistance in the coagulase-negative staphylococci.

Bacterial resistance to β -lactam antibiotics also results from the inability of the drug to penetrate to its site of action (Figure 44-3). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface and antibiotic penetration is not a problem. In gram-negative bacteria, the inner membrane is covered by the outer membrane, lipopolysaccharide, and capsule, which block access of some antibiotics. Some small hydrophilic antibiotics, including β -lactam antibiotics, diffuse through aqueous channels in the outer membrane formed by proteins called porins. These porins vary among different gram-negative bacteria, thereby providing greater or lesser antibiotics access to site of action. Active efflux pumps also can remove the antibiotic before it can act.

Bacteria also can destroy β -lactam antibiotics enzymatically via the actions of β -lactamases (Figures 44-1 and 44-3). The substrate specificities of some of these enzymes are relatively narrow; such enzymes are sometimes referred to as penicillinases or cephalosporinases. Other “extended-spectrum” enzymes can hydrolyze a variety of β -lactam antibiotics.

In general, gram-positive bacteria produce and secrete large amounts of β -lactamase (Figure 44-3). Most of these enzymes are penicillinases. The staphylococcal penicillinase is encoded in a plasmid that may be transferred to other bacteria and is inducible by substrate. In gram-negative bacteria, β -lactamases are strategically located in the periplasmic space between the inner and outer cell membranes for maximal protection of the microbe (Figure 44-3). β -lactamases of gram-negative bacteria are encoded either in chromosomes or plasmids, and may be constitutive or inducible. The

FIGURE 44-1 Structure of penicillins and products of their enzymatic hydrolysis.

plasmids can be transferred between bacteria by conjugation. These enzymes can hydrolyze penicillins, cephalosporins, or both.

OTHER FACTORS THAT INFLUENCE THE ACTIVITY OF β -LACTAM ANTIBIOTICS

Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves) produce biofilms. Bacteria in biofilms are much less sensitive to antibiotic therapy, in part owing to decreased growth rates. The β -lactam antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase. Similarly, intracellular bacteria that survive inside host cells generally are protected from the action of the β -lactam antibiotics.

Classification of the Penicillins and Summary of Their Pharmacological Properties

Penicillins are classified according to their spectra of antimicrobial activity (Table 44-1).

1. *Penicillin G* and its close congener *penicillin V* are highly active against sensitive strains of gram-positive cocci but are readily hydrolyzed by penicillinase and therefore ineffective against most strains of *S. aureus*.
2. The penicillinase-resistant penicillins (*methicillin* [discontinued in the U.S.], *nafcillin*, *oxacillin*, *cloxacillin* [not marketed in the U.S.], and *dicloxacillin*) have less potent antimicrobial activity against microorganisms that are sensitive to penicillin G but are the agents of first choice for treatment of penicillinase-producing *S. aureus* and *S. epidermidis* that are not methicillin-resistant.
3. *Ampicillin*, *amoxicillin*, and others comprise a group of penicillins whose antimicrobial activity is extended to include such gram-negative microorganisms as *Haemophilus influenzae*, *Escherichia coli*, and *Proteus mirabilis*. Frequently these drugs are administered with a β -lactamase inhibitor to prevent hydrolysis by broad-spectrum β -lactamases that are found with increasing frequency in clinical isolates of these gram-negative bacteria.
4. The antimicrobial activity of *carbenicillin* (discontinued in the U.S.), its indanyl ester (*carbenicillin indanyl*), and *ticarcillin* includes *Pseudomonas*, *Enterobacter*, and *Proteus* spp. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin against *Pseudomonas*.
5. *Mezlocillin*, *azlocillin* (both discontinued in the U.S.), and *piperacillin* have excellent antimicrobial activity against *Pseudomonas*, *Klebsiella*, and certain other gram-negative microorganisms. Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes*.

Certain useful generalizations can be made. Following oral or parenteral administration, these agents distribute widely throughout the body. Therapeutic concentrations of penicillins are achieved

Table 44-1

Chemical Structures and Major Properties of Various Penicillins

Penicillins are substituted 6-aminopenicillanic acids

Major Properties

R	Nonproprietary Name	Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Penicillin G	Variable (poor)	No	<p><i>Streptococcus</i> species, * <i>Enterococci</i>,* <i>Listeria</i>, <i>Neisseria meningitidis</i>, many anaerobes (not <i>Bacteroides fragilis</i>),* spirochetes, <i>Actinomyces</i>, <i>Erysipelothrix</i> spp., <i>Pasteurella multocida</i>**</p>
	Penicillin V	Good	No	
	Methicillin	Poor (not given orally)	Yes	
	Oxacillin (R ₁ = R ₂ = H)	Good	Yes	
	Cloxacillin (R ₁ = Cl; R ₂ = H)			
	Dicloxacillin (R ₁ = R ₂ = Cl)			

Indicated only for non-methicillin-resistant strains of *Staphylococcus aureus* and *Staphylococcus epidermidis*. Compared to other penicillins, these penicillinase-resistant penicillins lack activity against *Listeria monocytogenes* and *Enterococcus* spp.

Nafcillin

Variable

Yes

Ampicillin[†]
(R₁ = H)Amoxicillin
(R₁ = OH)

Good

No

Carbenicillin
(R₁ = H)Carbenicillin indanyl
(R₁ = 5-indanol)

Good

No

Ticarcillin

Poor (not given orally)

No

Mezlocillin

Poor (not given orally)

No

Excellent

Extends spectrum of penicillin to include sensitive strains of Enterobacteriaceae*** *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella*, *Haemophilus influenzae*,*** and *Helicobacter pylori*.

Superior to penicillin for treatment of *Listeria monocytogenes* and sensitive enterococci. Amoxicillin most active of all oral β -lactams against penicillin-resistant *Streptococcus pneumoniae*

Poor (not given orally)

Less active than ampicillin against *Streptococcus* species, *Enterococcus faecalis*, *Klebsiella*, and *Listeria monocytogenes*. Activity against *Pseudomonas aeruginosa* is inferior to that of mezlocillin and piperacillin

(Continued)

Table 44-1

Chemical Structures and Major Properties of Various Penicillins (Continued)

Penicillins are substituted 6-aminopenicillanic acids

Major Properties

R	Nonproprietary Name	Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Piperacillin	Poor (not given orally)	No	Extends spectrum of ampicillin to include <i>Pseudomonas aeruginosa</i> , [‡] Enterobacteriaceae, ^{**} Bacteroides species ^{**}

*Many strains are resistant due to altered penicillin-binding proteins.

**Many strains are resistant due to production of β -lactamases.

†There are other congeners of ampicillin; see the text.

‡Some strains are resistant due to decreased entry or active efflux.

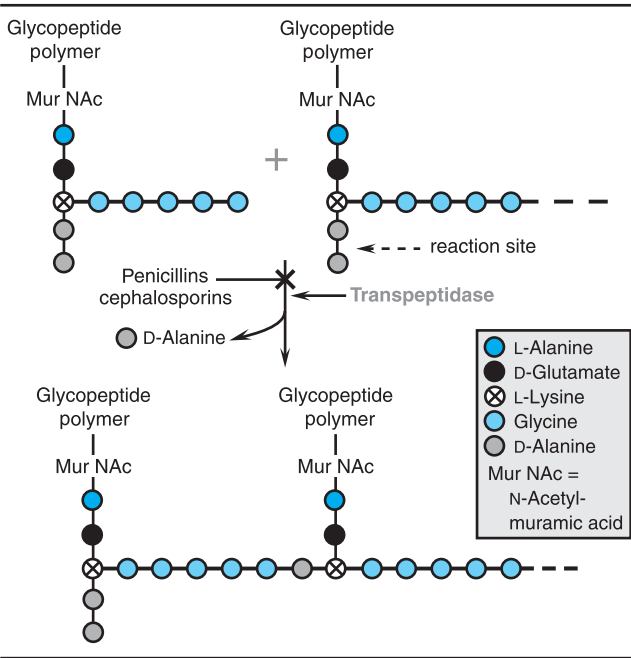

FIGURE 44-2 Action of β -lactam antibiotics in *Staphylococcus aureus*. The bacterial cell wall consists of glycopeptide polymers linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)₅-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit.

readily in tissues and in many secretions. Penicillins do not significantly penetrate living phagocytic cells, and only low concentrations are found in prostatic secretions, brain, and intraocular fluid. Concentrations of penicillins in cerebrospinal fluid (CSF) are <1% of those in plasma when the meninges are normal. With inflammation, CSF concentrations may increase to 5% of the plasma value. Penicillins are eliminated rapidly by the kidney; their half-lives in the body are short (typically 30–90 minutes) and their urine concentrations are high.

FIGURE 44-3 Comparison of the structure and composition of gram-positive and gram-negative cell walls.

Penicillin G and Penicillin V

ANTIMICROBIAL ACTIVITY The antimicrobial spectra of penicillin G (*benzylpenicillin*) and penicillin V (the phenoxyethyl derivative) are very similar for aerobic gram-positive microorganisms. Penicillin G is 5–10 times more active against *Neisseria* spp. and certain anaerobes.

Most streptococci (but not enterococci) are very susceptible to the drug. However, penicillin-resistant *viridans* streptococci and *S. pneumoniae* are increasingly seen. Penicillin-resistant pneumococci also are resistant to third-generation cephalosporins and are especially common in children. More than 90% of staphylococcal isolates are now resistant to penicillin G, as are most strains of *S. epidermidis* and many strains of gonococci. With rare exceptions, meningococci are quite sensitive to penicillin G.

Most anaerobic microorganisms, including Clostridium spp., are highly sensitive. Bacteroides fragilis is generally resistant to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Actinomyces israelii, Streptobacillus moniliformis, Pasteurella multocida, and L. monocytogenes are inhibited by penicillin G. Most species of Leptospira are moderately susceptible to the drug. Treponema pallidum is exquisitely sensitive. Borrelia burgdorferi, the organism responsible for Lyme disease, also is susceptible.

ABSORPTION

Oral Administration About one-third of an oral dose of penicillin G is absorbed from the GI tract under favorable conditions. Gastric juice at pH 2 rapidly destroys the antibiotic. Absorption is rapid, and maximal concentrations in blood are attained within 1 hour. Ingestion of food may interfere with GI absorption. Thus, oral penicillin G should be administered at least 30 minutes before or 2 hours after a meal, and oral therapy should be used only for infections in which clinical experience has proven its efficacy. The virtue of penicillin V in comparison with penicillin G is that it is better absorbed from the GI tract, yielding plasma concentrations two to five times greater than those provided by penicillin G.

Parenteral Administration of Penicillin G After intramuscular injection, peak concentrations in plasma are reached within 15–30 minutes. This value declines rapidly ($t_{1/2}$ of 30 minutes). Repository preparations of penicillin G increase the duration of its effect. Such compounds include *penicillin G procaine* (WYCILLIN, others) and *penicillin G benzathine* (BICILLIN L-A, PERMAPEN), which produce relatively low but persistent levels of penicillin in the blood.

Penicillin G procaine suspension combines procaine with penicillin in equimolar ratios; a dose of 300,000 units contains ~120 mg procaine, which exerts local anesthetic effects when injected. If the patient is believed to be hypersensitive to procaine, a test dose of 0.1 mL of 1% solution of procaine should be injected first.

Penicillin G benzathine suspension is the aqueous suspension of the salt obtained by combining 1 mol of an ammonium base and 2 mol of penicillin G; this provides a very slow release. The persistence of penicillin in the blood after an intramuscular dose reduces cost, need for repeated injections, and local trauma. The average duration of demonstrable antimicrobial activity in the plasma is 26 days.

DISTRIBUTION Penicillin G is distributed widely, but the concentration differs in various fluids and tissues. Its apparent volume of distribution is ~0.35 L/kg. Approximately 60% of penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, and lymph.

Cerebrospinal Fluid Penicillin does not readily enter the CSF but penetrates more easily with meningeal inflammation. The concentration attained usually reaches 5% of the value in plasma and thus is therapeutically effective against susceptible microorganisms. Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. In uremia, other organic acids compete with penicillin for secretion; the drug occasionally reaches toxic CNS concentrations that can produce convulsions.

EXCRETION Normally, penicillin G is eliminated rapidly from the body, mainly by the kidney. Approximately 60–90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid. The $t_{1/2}$ for elimination of penicillin G is ~30 minutes in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion.

Clearance values are considerably lower in neonates and infants because of incomplete development of renal function; thus, penicillin persists in the blood for several times as long in premature infants as in children and adults. After renal function is fully established in young children, renal excretion is considerably more rapid than in adults.

Anuria increases the $t_{1/2}$ of penicillin G to ~10 hours. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If hepatic insufficiency also is present, the $t_{1/2}$ is prolonged even further.

THERAPEUTIC USES

Pneumococcal Infections

Penicillin G is the drug of choice for infections caused by sensitive strains of S. pneumoniae, but resistance is an increasing problem. Thus, for pneumococcal pneumonia, a third-generation cephalosporin or high-dose penicillin G (i.e., 20–24 million units daily by continuous intravenous infusion or in divided boluses every 2–3 hours) should be used until sensitivities are determined. For parenteral therapy of sensitive isolates, penicillin G or penicillin G procaine is favored. Therapy should be continued for 7–10 days, including 3–5 days after the patient is afebrile. Similarly, pneumococcal meningitis initially should be treated with a combination of vancomycin and a third-generation cephalosporin until it is established that the infecting pneumococcus is penicillin-sensitive. Recommended therapy is 20–24 million units of penicillin G daily by constant intravenous infusion or divided into boluses given every 2–3 hours for 14 days.

Streptococcal Infections

Pharyngitis is the most common disease produced by S. pyogenes. Penicillin-resistant isolates of this organism have yet to be observed. The preferred oral therapy is with penicillin V, 500 mg every 6 hours for 10 days. Equal results are produced by the administration of 600,000 units of penicillin G procaine intramuscularly once daily for 10 days or by a single injection of 1.2 million units of penicillin G benzathine. Parenteral therapy is preferred if there are questions of patient compliance. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever but not of post-streptococcal glomerulonephritis.

Streptococcal Toxic Shock and Necrotizing Fasciitis

These life-threatening infections are best treated with penicillin plus clindamycin (to decrease toxin synthesis).

Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis

These uncommon conditions should be treated with penicillin G; daily doses of 12–20 million units are administered intravenously for 2–4 weeks (4 weeks for endocarditis).

Infections Caused by Other Streptococci

Viridans streptococci, the leading cause of infectious endocarditis, increasingly are resistant to penicillin G; quantitative microbial sensitivities therefore should be determined in patients with endocarditis. Patients with penicillin-sensitive S. viridans endocarditis are treated successfully with 1.2 million units of procaine penicillin G four times daily for 2 weeks or with daily doses of 12–20 million units of intravenous penicillin G for 2 weeks, both regimens in combination with streptomycin or gentamicin.

Recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 20 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with low-dose gentamicin. Therapy usually should be continued for 6 weeks, but selected patients with a short duration of illness (<3 months) have been treated successfully in 4 weeks.

Infections with Anaerobes

Many anaerobic infections are polymicrobial, and most of the organisms are sensitive to penicillin G. An exception is the B. fragilis group, 75% of which may be resistant. Pulmonary and periodontal infections usually respond well to penicillin G. Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 400,000 units four times daily). More severe infections should be treated with 12–20 million units of penicillin G intravenously. Brain abscesses also frequently contain several species of anaerobes, and most experts use high doses of penicillin G (20 million units per day) plus metronidazole or chloramphenicol.

Staphylococcal Infections

The vast majority of staphylococcal infections involve penicillinase-producing organisms. Patients with staphylococcal infection should receive penicillinase-resistant penicillins

(e.g., nafcillin or oxacillin). Staphylococcal infections increasingly involve methicillin-resistant staphylococci, which are resistant to penicillin G, all the penicillinase-resistant penicillins, and the cephalosporins. Vancomycin, linezolid, quinupristin–dalfopristin, and daptomycin are active against these bacteria (see Chapter 46).

Meningococcal Infections

Penicillin G is the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously (see above). The rare penicillin-resistant strains should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state and is ineffective for prophylaxis.

Syphilis

Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of <1 year's duration may be treated with penicillin G procaine (2.4 million units per day intramuscularly), plus probenecid (1.0 g/day orally) to prolong the $t_{1/2}$, for 10 days or with 1–3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine (three doses in patients with HIV infection). Patients with neurosyphilis or cardiovascular syphilis typically receive intensive therapy with 20 million units of penicillin G daily for 10 days. Since there are no proven alternatives for treating syphilis in pregnant women, penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis.

Infants with congenital syphilis discovered at birth or during the postnatal period should be treated for at least 10 days with 50,000 units per kg daily of aqueous penicillin G in two divided doses or 50,000 units per kg of procaine penicillin G in a single daily dose.

Most patients with secondary syphilis develop the Jarisch-Herxheimer reaction, including chills, fever, headache, myalgias, and arthralgias occurring several hours after the first dose of penicillin. This is likely due to release of spirochetal antigens that induce a host reaction. Reactions usually persist for a few hours to days but do not recur with subsequent penicillin injections; penicillin therapy should not be stopped.

Other Infections

Penicillin G is the drug of choice for all forms of actinomycosis. The dose should be 12–20 million units of penicillin G intravenously per day for 6 weeks. Surgical drainage also may be needed.

Neither penicillin nor any other antibiotic alters the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. Penicillin G can eliminate the carrier state. The parenteral administration of 2–3 million units per day in divided doses for 10–12 days eliminates the diphtheria bacilli from the pharynx and other sites in ~100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

Penicillin G is the drug of choice for gas gangrene due to clostridia; the dose is 12–20 million units per day given parenterally. Adequate débridement of the infected areas is essential. Antibiotics probably have no effect on the outcome of tetanus. Débridement and administration of human tetanus immune globulin may be indicated.

Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and fusospirochetes that are present in the mouth, is readily treatable with penicillin. For simple “trench mouth,” 500 mg penicillin V given every 6 hours for several days is usually sufficient.

The two microorganisms responsible for rat-bite fever, *Spirillum minor* and *Streptobacillus moniliformis*, are sensitive to penicillin G, the drug of choice. Since most cases due to *Streptobacillus* are complicated by bacteremia and often by infections of the synovia and endocardium, a daily dose of 12–15 million units given parenterally for 3–4 weeks is used.

Ampicillin (with gentamicin for immunosuppressed patients with meningitis) and penicillin G are the drugs of choice for infections with *L. monocytogenes*. The dose of penicillin G is 15–20 million units parenterally per day for at least 2 weeks. With endocarditis, treatment is for at least 4 weeks.

Severe Lyme disease may be treated with 20 million units of intravenous penicillin G daily for 14 days. The causative agent of erysipeloid, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. Uncomplicated infection responds to a single injection of 1.2 million units of penicillin G benzathine. If endocarditis is present, penicillin G, 12–20 million units per day for 4–6 weeks is required.

PROPHYLACTIC USES OF THE PENICILLINS

Streptococcal Infections

The administration of penicillin to individuals exposed to *S. pyogenes* protects against infection. The oral ingestion of 200,000 units of penicillin G or penicillin V twice a day or a single injection of 1.2 million units of penicillin G benzathine is effective. Indications for prophylaxis include

outbreaks of streptococcal disease in closed populations (e.g., boarding schools or military bases).

The oral administration of 200,000 units of penicillin G or penicillin V every 12 hours markedly decreases the incidence of recurrences of rheumatic fever in susceptible individuals. Intramuscular injection of 1.2 million units of penicillin G benzathine once monthly also yields excellent results. Because acute rheumatic fever has been observed in the fifth decade, some advocate that prophylaxis should be continued for life.

Syphilis

Prophylaxis for a contact with syphilis consists of a course of therapy as described for primary syphilis. Serologies for syphilis should be tested monthly for at least 4 months thereafter.

Penicillinase-Resistant Penicillins

These penicillins resist hydrolysis by staphylococcal penicillinase. Their appropriate use is restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme, including the vast majority of strains that are encountered clinically. These drugs are much less active than penicillin G against other penicillin-sensitive microorganisms.

The role of the penicillinase-resistant penicillins for most staphylococcal disease is decreasing with the increasing frequency of so-called methicillin-resistant microorganisms. Both *S. aureus* and *S. epidermidis* increasingly are resistant. Vancomycin is the drug of choice for serious infection caused by methicillin-resistant variants of these strains; rifampin is given concurrently when a foreign body is present.

ISOXAZOLYL PENICILLINS: OXACILLIN, CLOXACILLIN, AND DICLOXACILLIN These semisynthetic penicillins are similar structurally and pharmacologically (Table 44–1). All are relatively stable in an acid medium and are absorbed adequately after oral administration. All are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it and are not active against enterococci or *Listeria*. Oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections.

Pharmacological Properties

The isoxazolyl penicillins potently inhibit the growth of most penicillinase-producing staphylococci. Dicloxacillin is the most active. They are less effective against microorganisms susceptible to penicillin G and are not useful against gram-negative bacteria.

These agents are rapidly but incompletely absorbed from the GI tract (30–80%). As absorption is more efficient on an empty stomach, they ideally are administered 1 hour before or 2 hours after meals. Peak concentrations in plasma are attained by 1 hour. They all are highly bound to plasma albumin (>90%); none is removed from the circulation to a significant degree by hemodialysis.

The isoxazolyl penicillins are excreted rapidly by the kidney. Normally, ~50% of these drugs are excreted in the urine within 6 hours of an oral dose. They also are eliminated in the bile. Their half-lives are between 30 and 60 minutes. Intervals between doses are unchanged for patients with renal failure.

NAFCILLIN

Nafcillin (see Table 44–1) is highly resistant to penicillinase and has proven effective against infections caused by penicillinase-producing strains of *S. aureus*.

Pharmacological Properties

Nafcillin is slightly more active than oxacillin against penicillin G-resistant *S. aureus*. While it is the most active of the penicillinase-resistant penicillins for most microorganisms, it is not as potent as penicillin G.

Oral absorption of nafcillin is irregular, and injectable preparations should be used. Nafcillin is ~90% bound to plasma protein. Peak concentrations of nafcillin in bile exceed those found in plasma. Drug concentrations in CSF are adequate for therapy of staphylococcal meningitis.

Aminopenicillins: Ampicillin, Amoxicillin, and Their Congeners

ANTIMICROBIAL ACTIVITY

Ampicillin and the related aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The meningococci and *L. monocytogenes* are sensitive to this class of drugs.

Many pneumococcal isolates have varying levels of resistance to ampicillin. Penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. *H. influenzae* and the viridans group of streptococci exhibit varying degrees of resistance. Enterococci are twice as sensitive to ampicillin as they are to penicillin. From 30% to 50% of *E. coli*, a significant number of *P. mirabilis*, and practically all species of Enterobacter are insensitive. Resistant strains of *Salmonella* are recovered with increasing frequency. Most strains of *Shigella*, *Pseudomonas*, *Klebsiella*, *Serratia*, *Acinetobacter*, and indole-positive *Proteus* are resistant to this group of penicillins; these antibiotics are less active against *B. fragilis* than is penicillin G. Concurrent administration of β -lactamase inhibitors markedly expands their spectrum of activity (see below).

AMPICILLIN This drug is the prototype of the group (see structure in Table 44–1).

Pharmacological Properties Ampicillin (PRINCIPEN, others) is well absorbed after oral administration. Intake of food prior to ampicillin ingestion diminishes absorption. Severe renal impairment markedly prolongs the $t_{1/2}$ of ampicillin in the plasma. Peritoneal dialysis does not remove the drug from the blood, but hemodialysis removes ~40% of the body store in 7 hours. Ampicillin doses must be decreased in the setting of renal dysfunction. Ampicillin undergoes enterohepatic circulation and is excreted in appreciable quantities in the feces.

AMOXICILLIN This penicillinase-susceptible penicillin is closely related to ampicillin (Table 44–1). The drug is absorbed more rapidly and completely from the GI tract than is ampicillin. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, except that amoxicillin is less effective for shigellosis.

Peak plasma concentrations of amoxicillin (AMOXIL, others) are twice those of ampicillin after oral administration of the same dose. Food does not interfere with absorption. Perhaps because of its more complete absorption, the incidence of diarrhea with amoxicillin is less than that with ampicillin. The incidence of other adverse effects is similar. While the $t_{1/2}$ of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin because of its more complete absorption. About 20% of amoxicillin is protein-bound in plasma. Most of the antibiotic is excreted in an active form in the urine.

THERAPEUTIC INDICATIONS FOR THE AMINOPENICILLINS

Upper Respiratory Infections Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*, which are major upper respiratory pathogens. The drugs are effective for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of the oral β -lactam antibiotics against both penicillin-sensitive and penicillin-resistant *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40–45 to 80–90 mg/kg/day) for empirical treatment of acute otitis media in children is recommended. Ampicillin-resistant *H. influenzae* also is a problem in many areas. The addition of a β -lactamase inhibitor (amoxicillin–clavulanate or ampicillin–sulbactam) extends the spectrum to β -lactamase-producing *H. influenzae* and Enterobacteriaceae. Bacterial pharyngitis should be treated with penicillin G or penicillin V because *S. pyogenes* is the major pathogen.

Urinary Tract Infections Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species; ampicillin often is an effective agent, although resistance is increasing. Enterococcal urinary tract infections are treated effectively with ampicillin alone.

Meningitis Ampicillin is not indicated for single-agent treatment of acute bacterial meningitis in children. Ampicillin has excellent activity against *L. monocytogenes*, which causes meningitis in immunocompromised persons. Thus, the combination of ampicillin and vancomycin plus a third-generation cephalosporin is a rational regimen for empirical treatment of suspected bacterial meningitis.

Salmonella Infections High doses of ampicillin (12 g/day for adults) are often effective, but resistance is common. The typhoid carrier state has been eliminated successfully in patients without gallbladder disease with ampicillin.

Antipseudomonal Penicillins: Carboxypenicillins and Ureidopenicillins

The carboxypenicillins, *carbenicillin* and *ticarcillin*, are active against some isolates of *P. aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners. They are ineffective against most strains of *S. aureus*, *Enterococcus faecalis*, *Klebsiella*, and

L. monocytogenes. *B. fragilis* is susceptible to high concentrations of these drugs, but penicillin G is more active. The ureidopenicillins, *mezlocillin* and *piperacillin*, have superior activity against *P. aeruginosa* compared with carbenicillin and ticarcillin. Mezlocillin and piperacillin also are useful for *Klebsiella* infections. The carboxypenicillins and the ureidopenicillins are sensitive to destruction by β -lactamases.

CARBENICILLIN INDANYL (GEOCILLIN)

This indanyl ester of carbenicillin is excreted rapidly in the urine; its only use is for the management of urinary tract infections caused by Proteus spp. other than P. mirabilis and by P. aeruginosa.

TICARCILLIN (TICAR)

This semisynthetic penicillin (Table 44–1) is similar to carbenicillin but two to four times more active against P. aeruginosa. Ticarcillin is inferior to piperacillin for serious infections caused by Pseudomonas.

MEZLOCILLIN

This ureidopenicillin is more active against Klebsiella than is carbenicillin; its activity against Pseudomonas is similar to that of ticarcillin. It is more active than ticarcillin against E. faecalis. Mezlocillin sodium (MEZLIN) has been discontinued in the U.S.

PIPERACILLIN (PIPRACIL) Piperacillin (PIPRACIL) extends the spectrum of ampicillin to include most strains of *P. aeruginosa*, Enterobacteriaceae (non- β -lactamase-producing), many *Bacteroides* spp. and *E. faecalis*. In combination with a β -lactamase inhibitor (*piperacillin-tazobactam*, ZOSYN), it has the broadest antibacterial spectrum of the penicillins. Pharmacokinetic properties are reminiscent of the other ureidopenicillins. High biliary concentrations are achieved.

THERAPEUTIC INDICATIONS Piperacillin and related agents are important drugs for the treatment of serious infections caused by gram-negative bacteria, including infections acquired in the hospital. These penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to penicillin G and ampicillin; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. Since *Pseudomonas* infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β -lactam antibiotic such as piperacillin with good activity against these bacteria.

Untoward Reactions to Penicillins

HYPERSENSITIVITY REACTIONS Hypersensitivity reactions complicate 0.7–4% of all treatment courses: rash, urticaria, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, and anaphylaxis. Allergy to one penicillin increases the risk of reaction if another penicillin is given. Hypersensitivity reactions may appear in the absence of previous known exposure to the drug. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin is required. In a few instances, it is necessary to interdict the future use of penicillin because of the risk of death, and the patient should be so warned.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl (major) moiety. A large percentage of IgE-mediated reactions are to this derivative, but at least 25% of reactions are to other breakdown products. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to form rather than the severity of the reaction that may result, and anaphylactic reactions to penicillin usually are mediated by IgE antibodies against minor determinants.

Antipenicillin antibodies are detectable in virtually all patients who have received the drug (and in many who deny previous exposure). Immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant-specific skin-sensitizing antibodies. Some reactions may be due to toxic antigen-antibody complexes of major-determinant-specific IgM antibodies.

Rashes of all types may be caused by allergy to penicillin. Henoch-Schönlein purpura with renal involvement has been a rare complication. Contact dermatitis is observed occasionally in pharmacists, nurses, and physicians who prepare penicillin solutions. Fixed-drug reactions also have occurred. More severe reactions involving the skin are exfoliative dermatitis and exudative erythema multiforme. The incidence of rashes appears to be highest following the use of ampicillin (~9%); rash follows the administration of ampicillin in nearly all patients with infectious mononucleosis.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Acute anaphylactic or anaphylactoid reactions to the penicillins constitute the most important immediate danger connected with their use. *Among all drugs, the penicillins are most often responsible for this type of untoward effect.* Anaphylactoid reactions to penicillins may occur at any age; their incidence is thought to be 0.004–0.04%. About 0.001% of patients treated with these agents die from anaphylaxis. Anaphylaxis most often has followed parenteral use but also has been observed after oral or intradermal administration. The most dramatic reaction is sudden hypotension and death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.

Serum sickness reactions mediated by IgG antibodies can rarely appear after penicillin treatment has been continued for 1 week or more; they may be delayed until 1 or 2 weeks after the drug has been stopped and may persist for a week or longer.

Vasculitis may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy, but hemolytic anemia is rare. Reversible neutropenia has been noted, occurring in up to 30% of patients treated with 8–12 g nafcillin for longer than 21 days. Eosinophilia occasionally accompanies other allergic reactions to penicillin.

Fever may be the only evidence of a hypersensitivity reaction to the penicillins. The febrile reaction usually disappears within 24–36 hours after drug administration is stopped but may persist for days. Penicillins rarely cause interstitial nephritis; methicillin has been implicated most frequently.

MANAGEMENT OF THE PATIENT POTENTIALLY ALLERGIC TO PENICILLIN

Evaluation of the patient's history is the most practical way to identify patients at greatest risk of allergic reaction. Most patients with a history of penicillin allergy should be treated with another antibiotic. There is no totally reliable means to confirm a history of penicillin allergy. Skin testing using major and minor penicillin determinants is useful if available. Occasionally, *desensitization* is recommended for penicillin-allergic patients who must receive the drug. Gradually, increasing doses of penicillin are administered in the hope of binding all of the IgE without provoking anaphylaxis. When full doses are reached, penicillin should not be stopped and then restarted, as immediate reactions may recur. This procedure should be performed only in an intensive care setting, and its efficacy is unproven.

Patients with life-threatening infections (*e.g.*, endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antibiotics should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. Rarely, exfoliative dermatitis, with or without vasculitis, develops in these patients if therapy with penicillin is continued.

OTHER ADVERSE REACTIONS

Apparent toxic effects include bone marrow depression, granulocytopenia, and hepatitis; the latter is rare but is seen most commonly following the administration of oxacillin and nafcillin. Penicillin G, carbenicillin, piperacillin, or ticarcillin has been associated with impaired hemostasis due to defective platelet aggregation.

Most common among the irritative responses to penicillin are pain and sterile inflammation at sites of intramuscular injection. Phlebitis or thrombophlebitis develops in some individuals who receive penicillin intravenously. Many persons who take various penicillin preparations orally experience nausea, with or without vomiting, and some have mild-to-severe diarrhea. These manifestations often are dose related. Injection of penicillin G procaine may result in an immediate procaine reaction, with dizziness, tinnitus, headache, hallucinations, and sometimes seizures. Accidental injection of penicillin into the sciatic nerve causes severe local pain and dysfunction. Intrathecal injection of penicillin may produce arachnoiditis or encephalopathy and should be avoided. The parenteral administration of large doses of penicillin G (>20 million units per day, or less with renal insufficiency) may produce lethargy, confusion, twitching, multifocal myoclonus, or localized or generalized epileptiform seizures. These are most apt to occur in the presence of renal insufficiency, localized lesions of the CNS, or hyponatremia. When the CSF concentration of penicillin G exceeds 10 µg/mL, significant CNS dysfunction is frequent. The injection of 20 million units of penicillin G potassium, which contains 34 mEq of K⁺, may lead to severe hyperkalemia in persons with renal dysfunction.

REACTIONS UNRELATED TO HYPERSENSITIVITY OR TOXICITY

Penicillin changes the composition of the microflora. This phenomenon is usually of no clinical significance, and the normal microflora are reestablished shortly after therapy is stopped. In some

persons, superinfection results. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

CEPHALOSPORINS

CHEMISTRY

Cephalosporins are produced from 7-aminocephalosporanic acid by the addition of different side chains (Table 44–2). Modifications at position 7 of the β -lactam ring alter antibacterial activity, while substitutions at position 3 of the dihydrothiazine ring alter the metabolism and pharmacokinetic properties. The cephamycins are similar to the cephalosporins but have a methoxy group at position 7 of the β -lactam ring of the 7-aminocephalosporanic acid nucleus.

MECHANISM OF ACTION

Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

CLASSIFICATION Cephalosporins are classified by generations. The *first-generation* cephalosporins (e.g., *cephalothin* and *cefazolin*) have good activity against gram-positive bacteria and relatively modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, methicillin-resistant *S. aureus*, and *S. epidermidis*) are susceptible. Most mouth anaerobes are sensitive, but the *B. fragilis* group is resistant. *Second-generation* cephalosporins have somewhat increased activity against gram-negative microorganisms but are much less active than the third-generation agents. A subset of second-generation drugs (e.g., *cefoxitin*, *cefotetan*, and *cefmetazole*) also is active against *B. fragilis*. *Third-generation* cephalosporins generally are less active than first-generation agents against gram-positive cocci but are much more active against the Enterobacteriaceae, including β -lactamase-producing strains. A subset of third-generation agents (e.g., *ceftazidime* and *cefoperazone*) also is active against *P. aeruginosa* but less active than other third-generation agents against gram-positive cocci. *Fourth-generation* cephalosporins, such as *cefepime*, have an extended activity spectrum compared with the third generation and resist hydrolysis by β -lactamases. Fourth-generation drugs are particularly useful for the empirical treatment of serious infections in hospitalized patients when gram-positive microorganisms, Enterobacteriaceae, and *Pseudomonas* all are potential etiologies. None of the cephalosporins has reliable activity against penicillin-resistant *S. pneumoniae*, methicillin-resistant *S. aureus*, methicillin-resistant *S. epidermidis*, and other coagulase-negative staphylococci, *Enterococcus*, *L. monocytogenes*, *Legionella pneumophila*, *L. micdadei*, *C. difficile*, *Xanthomonas maltophilia*, *Campylobacter jejuni*, and *Acinetobacter* spp.

MECHANISMS OF BACTERIAL RESISTANCE TO THE CEPHALOSPORINS

Cephalosporin resistance may be related to the inability of the antibiotic to reach its sites of action or to alterations in the PBPs that are their targets. Alterations in two PBPs that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three PBPs have inherently low affinity.

*Cephalosporin resistance usually reflects hydrolysis of the β -lactam ring. The cephalosporins are variably susceptible to β -lactamase. Of the first-generation agents, cefazolin is more susceptible to hydrolysis by β -lactamase from *S. aureus* than is cephalothin. Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β -lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded β -lactamases. Induction of β -lactamases by treatment of infections owing to aerobic gram-negative bacilli with second- or third-generation cephalosporins and/or imipenem may result in resistance to all third-generation cephalosporins. Fourth-generation cephalosporins (e.g., cefepime) are poor inducers of β -lactamases and are less susceptible to hydrolysis than the third-generation agents.*

GENERAL FEATURES OF THE CEPHALOSPORINS Cephalosporins are excreted primarily by the kidney, and dosage should be decreased in patients with renal insufficiency. *Cefpiramide* (not available in U.S.) and cefoperazone are excreted predominantly in the bile. *Cefotaxime* is deacetylated to a metabolite with less antimicrobial activity than the parent compound and excreted by the kidneys. The other cephalosporins do not undergo appreciable metabolism.

Several cephalosporins (e.g., cefotaxime, ceftriaxone, and cefepime) penetrate into CSF in sufficient concentration to be useful for the treatment of meningitis. Cephalosporins also cross the pla-

 $t_{1/2} = 2$ hours

*T, tablet; C, capsule; O, oral suspension; I, injection.

†Cefoxitin, a cephamycin, has a $-OCH_3$ group at position 7 of cephem nucleus.

‡Cefuroxime axetil is the acetyloxyethyl ester of cefuroxime.

§Loracarbef, a carbacephem, has a carbon instead of sulfur at position 1 of cephem nucleus.

§Cefpodoxime proxetil has a $-COOCH(CH_3)OCOCH(CH_3)_2$ group at position 4 of cephem nucleus.

centa and are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Concentrations sufficient for therapy of ocular infections owing to gram-positive and certain gram-negative microorganisms likely can be achieved after systemic administration. Concentrations in bile usually are high, especially with cefoperazone and cefpiramide.

Specific Agents

FIRST-GENERATION CEPHALOSPORINS

The antibacterial spectrum of cefazolin is typical of first-generation cephalosporins except that it has activity against some Enterobacter spp. Cefazolin is relatively well tolerated; it is excreted by glomerular filtration and is ~85% bound to plasma proteins. Cefazolin usually is preferred among the first-generation cephalosporins because it can be administered less frequently owing to its longer $t_{1/2}$.

Cephalexin has the same antibacterial spectrum as the other first-generation cephalosporins. It is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin provides peak plasma concentrations adequate to inhibit many gram-positive and gram-negative pathogens. The drug is not metabolized and 70–100% is excreted in the urine.

Cephadrine is similar in structure to cephalexin and almost identical in its clinical use. Cephadrine is not metabolized and, after rapid absorption from the GI tract, is excreted unchanged in the urine. Because cephadrine is so well absorbed, concentrations in plasma are nearly equivalent after oral or intramuscular administration.

Cefadroxil is the para-hydroxy analog of cephalexin. Concentrations of cefadroxil in plasma and urine are somewhat higher than are those of cephalexin. The drug is given orally once or twice a day for the treatment of urinary tract infections. Its activity is similar to that of cephalexin.

SECOND-GENERATION CEPHALOSPORINS

Second-generation cephalosporins have a broader spectrum than first-generation agents and are active against Enterobacter spp., indole-positive Proteus spp., and Klebsiella spp. Their serum half-lives are generally ~1–2 hours.

Cefoxitin is resistant to some β -lactamases produced by gram-negative rods. This antibiotic is less active than the first-generation cephalosporins against gram-positive bacteria, but is more active against anaerobes, especially B. fragilis. Cefoxitin's special role is for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as pelvic inflammatory disease and lung abscess.

Cefaclor's concentration in plasma after oral administration is ~50% of that achieved after an equivalent oral dose of cephalexin. However, cefaclor is more active against H. influenzae and Moraxella catarrhalis, although some β -lactamase-producing strains may be resistant. Loracarbef is similar in activity to cefaclor, which is more stable against some β -lactamases.

Cefuroxime is similar to loracarbef with broader gram-negative activity against some Citrobacter and Enterobacter spp. Unlike cefoxitin, cefmetazole, and cefotetan, cefuroxime lacks activity against B. fragilis. The drug can be given every 8 hours. Concentrations in CSF are ~10% of those in plasma; the drug is effective (but inferior to ceftriaxone) for treatment of meningitis owing to H. influenzae (including strains resistant to ampicillin), N. meningitidis, and S. pneumoniae.

Cefuroxime axetil is the 1-acetyloxyethyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed and then hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

Cefotetan, like cefoxitin, has good activity against B. fragilis and several other species of Bacteroides and is slightly more active than cefoxitin against gram-negative aerobes. Hypoprotrombinemia and inhibition of vitamin K activation with bleeding have occurred in malnourished patients receiving cefotetan; this is preventable if vitamin K is also administered.

Cefprozil is an orally administered agent that is more active than first-generation cephalosporins against penicillin-sensitive streptococci, E. coli, P. mirabilis, Klebsiella spp., and Citrobacter spp.

THIRD-GENERATION CEPHALOSPORINS

Cefotaxime is highly resistant to many β -lactamases and has good activity against many bacteria; activity against B. fragilis is poor compared with clindamycin or metronidazole. Cefotaxime should be administered every 4–8 hours for serious infections. The drug is metabolized in vivo to desacetylcefotaxime, which is less active against most microorganisms than the parent compound but acts synergistically with the parent compound against certain microbes. Cefotaxime has been used effectively for meningitis caused by H. influenzae, penicillin-sensitive S. pneumoniae, and N. meningitides.

Ceftizoxime has a spectrum of activity that is very similar to that of cefotaxime, except that it is less active against S. pneumoniae and more active against B. fragilis. The drug can be administered every 8–12 hours for serious infections. Ceftizoxime is not metabolized, and 90% is recovered in urine.

Ceftriaxone has activity very similar to that of ceftizoxime and cefotaxime but a $t_{1/2}$ of ~8 hours. Administration of the drug once or twice daily has been effective for patients with meningitis, and dosage once a day is effective for other infections. About half the drug can be recovered in the urine; the remainder is eliminated by biliary secretion. A single dose of ceftriaxone (125–250 mg) is effective in the treatment of urethral, cervical, rectal, or pharyngeal gonorrhea, including penicillinase-producing microorganisms.

Cefpodoxime proxetil is an orally administered third-generation agent that is very similar in activity to the fourth-generation agent cefepime (see below) except that it is not more active against Enterobacter or Pseudomonas spp.

Cefditoren pivoxil is a prodrug that is hydrolyzed by esterases during absorption to the active drug, cefditoren. Cefditoren is eliminated unchanged in the urine. The drug is active against methicillin-susceptible strains of S. aureus, penicillin-susceptible strains of S. pneumoniae, S. pyogenes, H. influenzae, H. parainfluenzae, and Moraxella catarrhali. Cefditoren pivoxil is only indicated for the treatment of mild-to-moderate pharyngitis, tonsillitis, uncomplicated skin and skin structure infections, and acute exacerbations of chronic bronchitis.

Cefibuten is an orally effective drug that is less active against gram-positive and gram-negative organisms than cefixime, with activity limited to S. pneumoniae and S. pyogenes, H. influenzae, and M. catarrhalis. Cefibuten is only indicated for acute bacterial exacerbations of chronic bronchitis, acute bacterial otitis media, pharyngitis, and tonsillitis.

Cefdinir is effective orally; it is eliminated primarily unchanged in the urine. Cefdinir has a spectrum of activity similar to cefixime. It is inactive against Pseudomonas and Enterobacter spp.

Third-Generation Cephalosporins with Good Activity Against Pseudomonas

Ceftazidime is one-quarter to one-half as active against gram-positive microorganisms as cefotaxime. Its activity against the Enterobacteriaceae is very similar; its major distinguishing feature is excellent activity against Pseudomonas and other gram-negative bacteria. Ceftazidime has poor activity against B. fragilis. The drug is not metabolized.

FOURTH-GENERATION CEPHALOSPORINS

Cefepime and ceftiprome (not available in U.S.) are fourth-generation cephalosporins. Cefepime resists hydrolysis by many of the plasmid-encoded β -lactamases. It is a poor inducer of, and is relatively resistant to, chromosomally encoded and some extended-spectrum β -lactamases. Thus, it is active against many Enterobacteriaceae that are resistant to other cephalosporins via induction of β -lactamases but remains susceptible to many bacteria expressing extended-spectrum β -lactamases. Against H. influenzae, N. gonorrhoeae, and N. meningitidis, cefepime has comparable or greater activity than cefotaxime. For P. aeruginosa, cefepime has comparable activity to ceftazidime, although it is less active for other Pseudomonas spp. and X. maltophilia. Cefepime has higher activity than ceftazidime and is comparable to cefotaxime for streptococci and methicillin-sensitive S. aureus. It is inactive against methicillin-resistant S. aureus, penicillin-resistant pneumococci, enterococci, B. fragilis, L. monocytogenes, Mycobacterium avium complex, or M. tuberculosis. Cefepime is excreted renally, and doses should be adjusted for renal failure. Cefepime has excellent penetration into the CSF. The recommended dosage for adults is 2 g intravenously every 12 hours.

ADVERSE REACTIONS Hypersensitivity reactions are the most common side effects of cephalosporins; they are identical to those caused by the penicillins, perhaps related to their shared β -lactam structure. Patients who are allergic to one drug class may manifest cross-reactivity to a member of the other class. There is no skin test that can reliably predict whether a patient will manifest an allergic reaction to the cephalosporins.

Patients with a history of a mild or a temporally distant penicillin reaction appear to be at low risk of allergic reaction following cephalosporin administration. However, patients who have had a recent severe, immediate reaction to a penicillin should be given a cephalosporin with great caution, if at all. A positive Coombs' reaction appears frequently in patients who receive large doses of a cephalosporin, but hemolysis is rare. Cephalosporins rarely have produced bone marrow depression characterized by granulocytopenia.

Acute tubular necrosis has followed the administration of *cephaloridine* in doses greater than 4 g/day; this agent is no longer available in the U.S. Other cephalosporins, when used by themselves in recommended doses, rarely produce significant renal toxicity. High doses of cephalothin

(no longer available in U.S.) have produced acute tubular necrosis, and usual doses (8–12 g/day) have caused nephrotoxicity in patients with preexisting renal disease. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. Intolerance to alcohol has been noted. Serious bleeding related either to hypoprothrombinemia, thrombocytopenia, and/or platelet dysfunction has been reported.

THERAPEUTIC USES First-generation cephalosporins are excellent agents for skin and soft tissue infections owing to *S. aureus* and *S. pyogenes*. A single dose of ceftazidime just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens. For colorectal surgery, where prophylaxis for intestinal anaerobes is desired, the second-generation agents, cefoxitin or cefotetan, are preferred.

Second-generation cephalosporins generally have been displaced by third-generation agents. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are inferior to amoxicillin for treatment of penicillin-resistant *S. pneumoniae* pneumonia and otitis media. Cefoxitin and cefotetan both are effective in situations where facultative gram-negative bacteria and anaerobes are involved (e.g., intra-abdominal infections, pelvic inflammatory disease, and diabetic foot infection).

Third-generation cephalosporins are the drugs of choice for serious infections caused by *Klebsiella*, *Enterobacter*, *Providencia*, *Serratia*, and *Haemophilus* spp. Ceftriaxone is the drug of choice for all forms of gonorrhea and for severe forms of Lyme disease. Third-generation cephalosporins (e.g., cefotaxime or ceftriaxone) are used for initial treatment of meningitis in immunocompetent adults and children older than 3 months of age (in combination with vancomycin and ampicillin until the causative agent is identified). They are the drugs of choice for meningitis caused by *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria. Cefotaxime has failed in the treatment of meningitis owing to resistant *S. pneumoniae*; thus, vancomycin should be added. Ceftazidime plus an aminoglycoside is the treatment of choice for *Pseudomonas* meningitis. Third-generation cephalosporins lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectrum of cefotaxime and ceftriaxone is excellent for the treatment of community-acquired pneumonia.

The fourth-generation cephalosporins are indicated for the empirical treatment of nosocomial infections where antibiotic resistance owing to extended-spectrum β -lactamases or chromosomally induced β -lactamases is anticipated. For example, cefepime is superior to ceftazidime and piperacillin for nosocomial isolates of *Enterobacter*, *Citrobacter*, and *Serratia* spp.

OTHER β -LACTAM ANTIBIOTICS

Carbapenems

Carbapenems are β -lactams that have a broader spectrum of activity than most other β -lactam antibiotics.

IMIPENEM

Source and Chemistry

Imipenem is an N-formimidoyl derivative of thienamycin. Its structure is:

IMIPENEM

Antimicrobial Activity

Imipenem, like other β -lactam antibiotics, binds to PBPs, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β -lactamases.

*The activity of imipenem is excellent for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*), enterococci (excluding *E. faecium* and non- β -lactamase-producing penicillin-resistant strains), staphylococci (including*

penicillinase-producing strains), and *Listeria* are all susceptible. Although some strains of methicillin-resistant staphylococci are susceptible, many are not. Activity is excellent against the Enterobacteriaceae, including organisms that are cephalosporin-resistant by virtue of expression of extended-spectrum β -lactamases. Most strains of *Pseudomonas* and *Acinetobacter* are inhibited. Anaerobes, including *B. fragilis*, are highly susceptible.

Pharmacokinetics and Adverse Reactions

Imipenem is hydrolyzed by a dipeptidase found in the brush border of the proximal tubule. To prolong drug activity, imipenem is combined with cilastatin, an inhibitor of the dehydropeptidase; the combined formulation is available as PRIMAXIN. Both imipenem and cilastatin have a $t_{1/2}$ of ~1 hour. When administered with cilastatin, ~70% of administered imipenem is recovered in the urine as the active drug. Dosage should be reduced for patients with renal insufficiency.

Nausea and vomiting are the most common side effects. Seizures have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions or with renal insufficiency. Patients who are allergic to other β -lactam antibiotics may have hypersensitivity reactions to imipenem.

Therapeutic Uses

Imipenem–cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The combination appears to be especially useful for the treatment of serious infections caused by cephalosporin-resistant nosocomial bacteria, as may be seen in hospitalized patients who have recently received other β -lactam antibiotics. Imipenem should not be used as monotherapy for infections with *P. aeruginosa* because of the risk of developing resistance during therapy.

MEROPENEM Meropenem (MERREM IV) is a derivative of thienamycin that does not require coadministration with cilastatin because it is not sensitive to renal dipeptidase. Its toxicity and clinical efficacy are similar to imipenem, except that it may be less likely to cause seizures.

ERTAPENEM Ertapenem (INVANZ) differs from imipenem and meropenem by having a longer serum $t_{1/2}$ that allows once-daily dosing and by having inferior activity against *P. aeruginosa* and *Acinetobacter* spp. Its spectrum of activity against gram-positive organisms, Enterobacteriaceae, and anaerobes makes it attractive for use in intra-abdominal and pelvic infections.

AZTREONAM Aztreonam (AZACTAM) is a monocyclic β -lactam. Its structural formula is:

Aztreonam is resistant to the β -lactamases that are elaborated by most gram-negative bacteria. The antimicrobial activity of aztreonam differs from those of other β -lactam antibiotics and resembles that of an aminoglycoside. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. Activity against Enterobacteriaceae is excellent, as is that against *P. aeruginosa*. It is also highly active against *H. influenzae* and gonococci.

Aztreonam is administered intramuscularly or intravenously. The elimination $t_{1/2}$ is 1.7 hours, and most drug is excreted unaltered in the urine. The $t_{1/2}$ is prolonged to 6 hours in anephric patients. The usual dose of aztreonam for severe infections is 2 g every 6–8 hours (reduced in patients with renal insufficiency). A notable feature is that there is little cross-reactivity with most other β -lactam antibiotics. Aztreonam is therefore used to treat gram-negative infections that normally would be treated with a β -lactam antibiotic were it not for a prior allergic reaction.

β -LACTAMASE INHIBITORS

Certain molecules can inactivate β -lactamases, thereby protecting β -lactam antibiotics that are their substrates. These β -lactamase inhibitors are most active against plasmid-encoded β -lactamases (including those that hydrolyze ceftazidime and cefotaxime) but are inactive against the chromosomal β -lactamases induced in gram-negative bacilli (such as *Enterobacter*, *Acinetobacter*, and *Citrobacter*) by treatment with second- and third-generation cephalosporins.

Clavulanic acid is a “suicide” inhibitor that irreversibly binds β -lactamases from a wide range of gram-positive and gram-negative microorganisms. It is combined with amoxicillin for oral administration (AUGMENTIN) and with ticarcillin for parenteral administration (TIMENTIN).

Amoxicillin plus clavulanate is effective for β -lactamase-producing strains of staphylococci, H. influenzae, gonococci, and E. coli. It also is effective in the treatment of acute otitis media in children, sinusitis, animal or human bite wounds, cellulitis, and diabetic foot infections. The addition of clavulanate to ticarcillin (TIMENTIN) extends its spectrum to include aerobic gram-negative bacilli, S. aureus, and Bacteroides spp. There is no increased activity against Pseudomonas spp. The combination is especially useful for mixed nosocomial infections and often is used with an aminoglycoside. The dosage should be adjusted in patients with renal insufficiency.

Sulbactam is combined with ampicillin for intravenous or intramuscular use (UNASYN). The combination has good activity against gram-positive cocci, including β -lactamase-producing strains of S. aureus, gram-negative aerobes (but not Pseudomonas), and anaerobes; it has been used for the treatment of mixed intra-abdominal and pelvic infections. Dosage must be adjusted in patients with impaired renal function.

Tazobactam is a penicillanic acid sulfone β -lactamase inhibitor that has good activity against many of the plasmid β -lactamases, including some of the extended-spectrum class. It has been combined with piperacillin as a parenteral preparation (ZOSYN).

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

AMINOGLYCOSIDES

The aminoglycosides are first-line therapy for a limited number of very specific, often historically prominent infections, such as plague, tularemia, and tuberculosis; they also are frequently used to treat infections caused by aerobic gram-negative bacteria. Their clinical roles have diminished as less toxic alternatives have become available. Unlike most inhibitors of microbial protein synthesis, which are bacteriostatic, the aminoglycosides are bactericidal. Resistance most commonly arises from acquisition of plasmids or transposons encoding genes for aminoglycoside-metabolizing enzymes or from impaired transport of drug into the cell; cross-resistance is common.

These agents are polycations whose polarity affects their shared pharmacokinetic properties: none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. All members of the group also share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity.

The aminoglycosides consist of two or more amino sugars joined in glycosidic linkage to a hexose nucleus (Figure 45-1). Different aminoglycosides are distinguished by the amino sugars attached to the aminocyclitol. Streptomycin differs from the other aminoglycoside antibiotics in that it contains streptidine rather than 2-deoxystreptamine, and the aminocyclitol is not in a central position.

MECHANISM OF ACTION The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration-dependent, but residual bactericidal activity persists even after the serum concentration has fallen below the minimum inhibitory concentration. These properties account for the efficacy of once-daily dosing regimens.

Driven by the membrane electrical potential (interior negative), aminoglycosides diffuse through aqueous channels formed by porin proteins in the outer membrane of gram-negative bacteria and enter the periplasmic space. This rate-limiting process (and thus the antimicrobial efficacy of aminoglycosides) can be blocked or inhibited by a reduction in pH or anaerobic conditions, as in an abscess. Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation (Figure 45-2). The resulting aberrant proteins may be inserted into the cell membrane, altering permeability and further stimulating aminoglycoside transport.

FIGURE 45-1 Sites of activity of various plasmid-mediated enzymes capable of inactivating aminoglycosides. The symbol X indicates regions of the molecules that are protected from the designated enzyme. In gentamicin C₁, R₁=R₂=CH₃; in gentamicin C₂, R₁=CH₃, R₂=H; in gentamicin C_{1a}, R₁=R₂=H.

The primary site of action of the aminoglycosides is the 30S ribosomal subunit; some aminoglycosides also bind to several sites on the 50S ribosomal subunit. Aminoglycosides disrupt the normal cycle of ribosomal function by interfering with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes (Figure 45-2). Aminoglycosides also cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains. Aminoglycosides vary in their capacity to cause misreading, presumably owing to differences in their affinities for specific ribosomal proteins; bactericidal activity and the ability to induce misreading are strongly correlated.

MICROBIAL RESISTANCE TO THE AMINOGLYCOSIDES Bacteria may be resistant to aminoglycosides because of failure of the antibiotic to penetrate intracellularly, low affinity of the drug for the bacterial ribosome, or—most commonly—drug inactivation by modifying enzymes acquired by conjugative transfer of resistance plasmids. These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (Figure 45-1), preventing binding to ribosomes. Amikacin is modified by only a few of these inactivating enzymes; thus, strains that are resistant to other aminoglycosides may remain susceptible to amikacin.

FIGURE 45–2 Effects of aminoglycosides on protein synthesis. **A.** Aminoglycoside (represented by closed circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S–50S ribosomal complex at the start codon (AUG) of mRNA. As 30S–50S complexes downstream complete translation of mRNA and detach, the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to **B.** premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or **C.** incorporation of incorrect amino acids (indicated by the X), resulting in the production of abnormal or non-functional proteins.

Many clinical isolates of *Enterococcus faecalis* and *E. faecium* are highly resistant to all aminoglycosides. Infections caused by aminoglycoside-resistant strains of enterococci can be especially difficult to treat because of the loss of the synergistic bactericidal activity between a penicillin or vancomycin and an aminoglycoside and because these strains often also are cross-resistant to vancomycin and penicillin. Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because one enzyme inactivates all of these drugs; this enzyme does not modify streptomycin, which is inactivated by another enzyme; consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin. Natural resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Penetration of drug across the outer membrane of gram-negative microorganisms into the periplasmic space can be slow, but resistance on this basis is unimportant clinically. Transport of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent active process. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system. Similarly, facultative bacteria are resistant when grown under anaerobic conditions. Resistance owing to mutations that alter ribosomal structure is relatively uncommon. Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent streptomycin binding. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, only 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. It has been estimated that ~50% of the streptomycin-resistant strains of enterococci are ribosomally resistant. Because ribosomal resistance usually is specific for streptomycin, these strains remain sensitive to a combination of penicillin and gentamicin.

ANTIBACTERIAL SPECTRUM OF THE AMINOGLYCOSIDES The antibacterial activity of most aminoglycosides is directed primarily against aerobic gram-negative bacilli. Kanamycin, like streptomycin, has a more limited spectrum than the other aminoglycosides. Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. They should not be used as single agents for infections caused by gram-positive bacteria. Combined with a cell wall-active agent, such as a penicillin or vancomycin, aminoglycosides produce synergistic bactericidal effects against enterococci, streptococci, and staphylococci.

Aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides. Tobramycin and gentamicin exhibit similar activity against most gram-negative bacilli, although tobramycin usually is more active against *P. aeruginosa* and some *Proteus* spp. Many gram-negative bacilli that are resistant to gentamicin because of plasmid-mediated inactivating enzymes also are resistant to tobramycin. Amikacin, and in some instances netilmicin, retain their activity against gentamicin-resistant strains because they are a poor substrate for many of the aminoglycoside-inactivating enzymes.

ABSORPTION, DISTRIBUTION, DOSING, AND ELIMINATION OF THE AMINOGLYCOSIDES

ABSORPTION

The aminoglycosides are highly polar and, thus, poorly absorbed from the gastrointestinal (GI) tract. Instillation of these drugs into body cavities with serosal surfaces may result in rapid absorption and unexpected toxicity (e.g., neuromuscular blockade). Toxic levels also may result from sustained topical application to large wounds, burns, or cutaneous ulcers, particularly with renal insufficiency. Long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment.

Aminoglycosides are absorbed rapidly after intramuscular injection. In critically ill patients, especially those in shock, drug absorption from intramuscular sites may be reduced by poor perfusion.

DISTRIBUTION

These polar drugs do not penetrate into most cells, central nervous system (CNS), and the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma proteins. The volume of distribution of these drugs approximates the volume of extracellular fluid.

Concentrations of aminoglycosides in secretions and tissues are low. High concentrations are found only in the renal cortex and the inner ear, likely contributing to the aminoglycosides' nephrotoxicity and ototoxicity. Due to active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route. Penetration into respiratory secretions is poor. Diffusion into pleural and synovial fluid is relatively slow, but concentrations that approximate those in the plasma may be achieved after repeated administration. Inflammation increases aminoglycoside penetration into peritoneal and pericardial cavities.

Aminoglycoside concentrations in CSF following parenteral administration are <10% of those in plasma (~25% with meningitis). Thus, CSF levels are usually subtherapeutic unless delivered intrathecally. Similarly, effective therapy of bacterial endophthalmitis requires periocular and intraocular injections.

Administration of aminoglycosides to pregnant women may result in drug accumulation in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Aminoglycosides should be used with caution during pregnancy and only in the absence of suitable alternatives.

DOSING

Current practice is to administer the total daily dose as a single injection, which is associated with less toxicity and equal efficacy as multiple-dose regimens. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. Despite the higher peak concentration, a once-daily dosing regimen provides a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (12 hours vs. less than 3 hours total in Figure 45-3), accounting for its lower toxicity. Aminoglycoside bactericidal activity, on the other hand, is related directly to the peak concentration achieved because of concentration-dependent killing and a concentration-dependent postantibiotic effect.

Once-daily regimens are safer with equal efficacy, cost less, and are administered more easily. Exceptions include use in pregnancy, neonatal and pediatric infections, and low-dose combination therapy of bacterial endocarditis. Once-daily dosing also should be avoided in patients with creatinine clearances of <20–25 mL/min, where dosing every 48 hours is more appropriate.

Whether once-daily or multiple-daily dosing is used, the dose must be adjusted for patients with creatinine clearances of <80–100 mL/min, and plasma concentrations must be monitored. Nomograms may be helpful in selecting initial doses, but variability in aminoglycoside clearance among patients is too large for these to be relied on for more than a few days. If a patient likely will be treated with an aminoglycoside for more than 3–4 days, then plasma concentrations should be monitored.

For twice- or thrice-daily dosing regimens, both peak (30 minutes after dosing) and trough (immediately before the next dose) plasma concentrations are determined. The peak concentration documents that the dose produces therapeutic concentrations, while the trough concentration is used to avoid toxicity. With once-daily regimens, the trough concentration is either measured directly or estimated using various nomograms; a trough concentration >2 µg/mL predicts toxicity.

ELIMINATION

The aminoglycosides are excreted almost entirely by glomerular filtration, and urine concentrations of 50–200 µg/mL are achieved. The plasma half-lives of the aminoglycosides vary between 2 and 3 hours in patients with normal renal function.

FIGURE 45-3 Plasma concentrations ($\mu\text{g/mL}$) after administration of 5.1 mg/kg of gentamicin intravenously to a hypothetical patient either as a single dose (q24h) or as three divided doses (q8h). The threshold for toxicity has been chosen to correspond to a plasma concentration of 2 $\mu\text{g/mL}$, the maximum recommended. The once-daily regimen produces a threefold higher plasma concentration, which enhances efficacy that otherwise might be compromised due to prolonged sub-MIC concentrations later in the dosing interval compared with the every-8-hours regimen. The once-daily regimen provides a 12-hour period during which plasma concentrations are below the threshold for toxicity, thereby minimizing the toxicity that otherwise might result from the high plasma concentrations early on. The every-8-hours regimen, in contrast, provides only a brief period during which plasma concentrations are below the threshold for toxicity.

Since aminoglycoside elimination depends almost entirely on the kidney, a linear relationship exists between the serum creatinine and the $t_{1/2}$ of all aminoglycosides in patients with moderately compromised renal function. Because the incidence of nephrotoxicity and ototoxicity is related to the concentration to which an aminoglycoside accumulates, it is critical to reduce the maintenance dosage of these drugs in patients with impaired renal function. The size of the individual dose, the interval between doses, or both can be altered. Determination of drug concentration in plasma is essential for the proper administration of aminoglycosides. In patients with life-threatening systemic infections, aminoglycoside concentrations should be determined several times per week (more frequently if renal function is changing) and should be determined within 24–48 hours of a change in dosage.

Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis. Approximately 50% of the administered dose is removed in 12 hours by hemodialysis. As a general rule, a dose equal to half the loading dose administered after each hemodialysis should maintain the plasma concentration in the desired range, but a number of variables make this a rough approximation at best. The amount of aminoglycoside removed can be replaced by administering ~15–30% of the maximum daily dose (Table 45-1) each day. Frequent monitoring of plasma drug concentrations is crucial.

Table 45-1

Algorithm for Dose Reduction of Aminoglycosides Based on Calculated Creatinine Clearance

Creatinine Clearance, mL/min	% of Maximum Daily Dose*	Frequency of Dosing
100	100	Every 24 hours
75	75	
50	50	
25	25	
20	80	
10	60	Every 48 hours
<10	40	

*The maximum adult daily dose for amikacin, kanamycin, and streptomycin is 15 mg/kg; for gentamicin and tobramycin, 5.5 mg/kg; and for netilmicin, 6.5 mg/kg.

Peritoneal dialysis is less effective than hemodialysis in removing aminoglycosides. Clearance rates are ~5–10 mL/min but highly variable. If a patient who requires dialysis has bacterial peritonitis, the antibiotic can be added to the dialysate to achieve concentrations equal to those desired in plasma. For intermittent dosing via peritoneal dialysate, 2 mg/kg of amikacin is added to the bag once a day. The corresponding dose for gentamicin, netilmicin, or tobramycin is 0.6 mg/kg. For continuous dosing, the dose for amikacin is 12 mg/L (25 mg/L loading dose in the first bag), and the dose for gentamicin, netilmicin, or tobramycin is 4 mg/L in each bag (8 mg/L loading dose). This should be preceded by a loading dose, either parenterally or in dialysis fluid.

Although excretion of aminoglycosides is similar in adults and children >6 months of age, half-lives of the drugs may be prolonged significantly in the newborn. Thus, it is critically important to monitor concentrations of aminoglycosides during treatment of neonates.

Aminoglycosides can be inactivated by various penicillins in vitro and in patients with end-stage renal failure, further complicating dosage recommendations. Amikacin is least affected by this interaction.

UNTOWARD EFFECTS OF THE AMINOGLYCOSIDES

All aminoglycosides can produce reversible and irreversible vestibular, cochlear, and renal toxicity.

OTOTOXICITY Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides. Aminoglycosides progressively accumulate in the inner ear, and toxicity is more likely to occur in patients with persistently elevated plasma drug concentrations. Ototoxicity is largely irreversible and results from progressive destruction of vestibular or cochlear sensory cells, which are highly sensitive to damage by aminoglycosides. The degree of permanent dysfunction correlates with the number of damaged sensory hair cells. Repeated courses of aminoglycosides, each probably resulting in the loss of more cells, are more likely to cause deafness. Loop diuretics such as *ethacrynic acid* and *furosemide* may potentiate the ototoxic effects of the aminoglycosides and should be avoided when possible. Hearing loss following exposure to aminoglycosides is more likely to develop in patients with preexisting auditory impairment. Neomycin, kanamycin, and amikacin are most likely to cause hearing loss; streptomycin and gentamicin are the most vestibulotoxic aminoglycosides. Since the initial symptoms may be reversible, patients receiving high doses and/or prolonged courses of aminoglycosides should be monitored carefully, but deafness may occur even after therapy is discontinued.

Clinical Symptoms of Cochlear Toxicity

A high-pitched tinnitus often is the first symptom of toxicity and can persist for days to weeks. It is followed in a few days by auditory impairment. Since high-frequency hearing is lost first, the patient may be unaware of the difficulty unless audiometric examination is performed.

Clinical Symptoms of Vestibular Toxicity

Headache may precede the onset of labyrinthine dysfunction, followed immediately by nausea, vomiting, and difficulty with balance, which develop acutely and persist for 1–2 weeks. The acute stage is followed by manifestations of chronic labyrinthitis, in which the patient has difficulty when attempting to walk or make sudden movements; ataxia is prominent. The chronic phase persists for ~2 months. Recovery may require 12–18 months; most patients have some permanent residual damage. Although there is no specific treatment for the vestibular deficiency, early drug discontinuation may permit recovery before irreversible damage of the hair cells.

NEPHROTOXICITY Approximately 8–26% of patients who receive an aminoglycoside for more than several days will develop mild renal impairment that almost always is reversible. The most nephrotoxic aminoglycosides are neomycin, gentamicin, and tobramycin. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells. The initial manifestation is excretion of enzymes of the renal tubular brush border, followed by a defect in renal concentrating ability, mild proteinuria, and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days. The nonoliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron that reduce sensitivity to endogenous vasopressin. While severe acute tubular necrosis may occur rarely, the most common finding is a mild rise in plasma creatinine. The impairment in renal function is almost always reversible because the proximal tubular cells can regenerate.

Toxicity correlates with the total amount of drug administered and is more likely to be encountered with longer courses of therapy. Constantly elevated concentration of drug in plasma above a critical level (*i.e.*, an elevated trough concentration) correlates with toxicity. The most important result of

this toxicity may be reduced excretion of the drug, which, in turn, predisposes to ototoxicity. Other drugs, such as *amphotericin B*, *vancomycin*, *angiotensin-converting enzyme inhibitors*, *cisplatin*, and *cyclosporine*, may potentiate aminoglycoside-induced nephrotoxicity. Volume depletion and hypokalemia also have been implicated.

NEUROMUSCULAR BLOCKADE

Acute neuromuscular blockade and apnea have been attributed to the aminoglycosides; patients with myasthenia gravis are particularly susceptible. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside, but the reaction can follow intravenous, intramuscular, and even oral administration. Neuromuscular blockade may be reversed with calcium gluconate infusion.

OTHER EFFECTS ON THE NERVOUS SYSTEM

The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot, and (rarely) peripheral neuritis. Paresthesia occasionally follows streptomycin use, usually within 30–60 minutes, and can persist for several hours.

OTHER ADVERSE EFFECTS

In general, aminoglycosides have little allergenic potential; anaphylaxis and rash are unusual. Parenterally administered aminoglycosides are not associated with pseudomembranous colitis.

STREPTOMYCIN

Streptomycin is used for the treatment of certain unusual infections usually in combination with other antimicrobial agents. Because it is less active than other members of the class against aerobic gram-negative rods, it has fallen into disuse. Streptomycin may be administered by deep intramuscular injection or intravenously. The dose of streptomycin is 15 mg/kg/day for patients with creatinine clearances above 80 mL/min. It typically is administered as a 1000-mg single daily dose or 500 mg twice daily. The daily dose should be reduced in proportion to creatinine clearance for creatinine clearances >30 mL/min (Table 45–1).

THERAPEUTIC USES

Bacterial Endocarditis Streptomycin and penicillin in combination are synergistically bactericidal *in vitro* against strains of enterococci, group D streptococci, and the various oral streptococci of the *viridans* group. A combination of penicillin G and streptomycin may be indicated for treatment of streptococcal or enterococcal endocarditis. Streptomycin largely has been replaced by gentamicin but may still be used when the strain is resistant to gentamicin and susceptible to streptomycin.

Tularemia Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1 g (15–25 mg/kg) streptomycin per day (in divided doses) for 7–10 days. Fluoroquinolones and tetracyclines also are effective.

Plague Streptomycin is effective for the treatment of all forms of plague. The recommended dose is 2 g/day in two divided doses for 7–10 days. Gentamicin is probably as efficacious.

Tuberculosis In the treatment of tuberculosis, streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible (*see* Chapter 47).

GENTAMICIN

Gentamicin is an important drug for the treatment of many serious gram-negative bacillary infections and usually is the aminoglycoside of first choice because of its low cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin is given parenterally, ophthalmically, and topically.

THERAPEUTIC USES OF GENTAMICIN AND OTHER AMINOGLYCOSIDES Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for most infections; gentamicin usually is the preferred agent. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to life-threatening infections and those for which a less toxic agent is contraindicated or less effective.

The recommended intramuscular or intravenous dose of gentamicin sulfate (GARAMYCIN) for adults is a loading dose of 2 mg/kg and then 3–5 mg/kg/day, one-third being given every 8 hours when

administered as a multiple-daily-dosing regimen. The once-daily dose is 5–7 mg/kg given over 30–60 minutes for patients with normal renal function (lower if renal function is impaired). The upper limit of this dose range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, and others in whom drug clearance is more rapid or volume of distribution is larger than normal. Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns <35 weeks' gestation; 4 mg/kg once daily for newborns older than 35 weeks' gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2–2.5 mg/kg every 8 hours for children up to 2 years of age. Peak plasma concentrations range from 4–10 µg/mL (dosing: 1.7 mg/kg every 8 hours) and 16–24 µg/mL (dosing: 5.1 mg/kg once daily). It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of the plasma concentration of aminoglycosides are recommended strongly; trough concentrations consistently >2 µg/mL are associated with toxicity.

Aminoglycosides often are combined with a penicillin or cephalosporin for the therapy of proven or suspected serious gram-negative infections, especially those due to *P. aeruginosa*, *Enterobacter*, *Klebsiella*, *Serratia*, and other species resistant to less toxic antibiotics, including urinary tract infections, bacteremia, infected burns, osteomyelitis, pneumonia, peritonitis, and otitis. With few exceptions (e.g., enterococcal endocarditis), the superiority of aminoglycoside combination therapy over an effective single drug has not been demonstrated. Because of their toxicity, aminoglycosides should not be used for more than a few days unless deemed essential. Aminoglycosides should never be mixed in the same solution with penicillins because they are inactivated by penicillin. Similar incompatibilities exist in vitro to different degrees between gentamicin and heparin, amphotericin B, and the cephalosporins.

Urinary Tract Infections

Aminoglycosides usually are not indicated for the treatment of uncomplicated urinary tract infections, although a single intramuscular dose of gentamicin (5 mg/kg) can cure more than 90% of uncomplicated infections of the lower urinary tract. As strains of *E. coli* acquire resistance to other drugs, aminoglycoside use may increase. In the seriously ill patient with pyelonephritis, an aminoglycoside alone or in combination with a β -lactam antibiotic offers broad and effective initial coverage. Once the microorganism is isolated and its antibiotic sensitivities determined, the aminoglycoside is discontinued if the infecting microorganism is sensitive to less toxic drugs.

Pneumonia

Organisms that cause community-acquired pneumonia will be susceptible to broad-spectrum β -lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Gentamicin (or other aminoglycosides) never should be used as the sole agent to treat pneumonia acquired in the community or as the initial treatment for pneumonia acquired in the hospital.

An aminoglycoside in combination with a β -lactam antibiotic may be used for empirical therapy of hospital-acquired pneumonia in which multiple-drug-resistant gram-negative aerobes are a likely causative agent. However, provided the companion drug is active against the causative agent, there is generally no benefit from adding an aminoglycoside. One exception may be the treatment of pneumonia caused by *P. aeruginosa*, for which combination therapy generally is recommended, with the goal of preventing the emergence of resistance.

Meningitis

The availability of third-generation cephalosporins has reduced the need for aminoglycoside treatment in most cases of meningitis, except for infections caused by gram-negative organisms that are resistant to β -lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If therapy with an aminoglycoside is necessary, in adults, 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) is administered intrathecally once daily.

Peritoneal Dialysis–Associated Peritonitis

Patients who develop peritonitis during peritoneal dialysis may be treated with an aminoglycoside diluted into the dialysis fluid to a concentration of 4–8 mg/L for gentamicin, netilmicin, or tobramycin or 6–12 mg/L for amikacin.

Bacterial Endocarditis

“Synergistic” or low-dose gentamicin (3 mg/kg/day in three divided doses) in combination with a penicillin or vancomycin has been recommended in some circumstances for treating bacterial endocarditis. There is good evidence that penicillin and gentamicin in combination are effective

as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. In cases of enterococcal endocarditis, concomitant administration of penicillin and gentamicin for 4–6 weeks has been recommended because of an unacceptably high relapse rate with penicillin alone. A 2-week regimen of gentamicin or tobramycin in combination with nafcillin is effective for selected cases of staphylococcal tricuspid valve endocarditis in injection drug users, although the benefit of including an aminoglycoside is unproven.

Aminoglycosides have no clinically proven benefit in treatment of staphylococcal mitral or aortic valve endocarditis. Because of toxicity and limited clinical benefit, aminoglycoside combination therapy has fallen from favor as a first-line regimen for treatment of endocarditis.

Sepsis

In febrile patients with granulocytopenia and in infections suspected to be caused by *P. aeruginosa*, numerous studies using potent broad-spectrum β -lactams (e.g., carbapenems and antipseudomonal cephalosporins) have demonstrated no benefit of adding an aminoglycoside to the regimen. Most experts recommend combination therapy of documented non-urinary tract *P. aeruginosa* infections, particularly pneumonia with bacteremia. If there is concern that an infection may be caused by a multiple-drug-resistant organism that may be susceptible only to an aminoglycoside, then adding this antibiotic to the regimen is reasonable. Evidence that aminoglycosides are beneficial for other gram-negative infections is weak. To avoid toxicity, aminoglycosides should be used briefly and sparingly as long as other alternatives are available.

Topical Applications

Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface (e.g., in burn patients), plasma concentrations can reach 4 $\mu\text{g/mL}$, and 2–5% of the drug may appear in the urine.

UNTOWARD EFFECTS

The most important and serious side effects of gentamicin are nephrotoxicity and irreversible ototoxicity. Intrathecal or intraventricular administration may cause local inflammation and can result in radiculitis and other complications.

TOBRAMYCIN

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin (NEBCIN) are very similar to those of gentamicin. Dosages and serum concentrations are identical with those for gentamicin. Tobramycin (TOBREX) also is available in ophthalmic ointments and solutions.

THERAPEUTIC USES

Indications for tobramycin are the same as those for gentamicin. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections caused by this organism, usually in conjunction with an antipseudomonal β -lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against enterococci.

UNTOWARD EFFECTS

Tobramycin causes nephrotoxicity and ototoxicity.

AMIKACIN

The spectrum of antimicrobial activity of amikacin (AMIKIN) is the broadest of the group. Because of its resistance to many aminoglycoside-inactivating enzymes, it has a special role in hospitals where gentamicin- and tobramycin-resistant organisms are prevalent.

The recommended dose of amikacin is 15 mg/kg/day as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection but is usually given intravenously.

THERAPEUTIC USES

Amikacin is preferred for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where gentamicin and tobramycin resistance is prevalent. Amikacin is active against the vast majority of aerobic gram-negative bacilli, including most strains of *Serratia*, *Proteus*, and *P. aeruginosa*. It is active against nearly all strains of *Klebsiella*, *Enterobacter*, and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found among strains of *Acinetobacter*, *Providencia*, and *Flavobacter* and strains of *Pseudomonas* other

than *P. aeruginosa*; these all are unusual pathogens. Amikacin is less active than gentamicin against enterococci and should not be used. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis*, including streptomycin-resistant strains, and atypical mycobacteria. It has been used in the treatment of disseminated atypical mycobacterial infection in acquired immunodeficiency syndrome (AIDS) patients.

UNTOWARD EFFECTS

Amikacin causes ototoxicity and nephrotoxicity. Auditory deficits are produced most commonly.

NETILMICIN

Netilmicin (NETROMYCIN) is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage. Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes and therefore may be active against certain bacteria that are resistant to gentamicin.

The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5–2 mg/kg every 12 hours. For other serious systemic infections, a total daily dose of 4–7 mg/kg is given as a single dose or two to three divided doses. Children should receive 3–7 mg/kg/day in two to three divided doses; neonates receive 3.5–5 mg/kg/day as a single daily dose.

THERAPEUTIC USES

Netilmicin is useful for serious infections owing to susceptible *Enterobacteriaceae* and other aerobic gram-negative bacilli. It is effective against some gentamicin-resistant pathogens, with the exception of enterococci.

UNTOWARD EFFECTS

Netilmicin produces ototoxicity and nephrotoxicity. It may be less toxic than other aminoglycosides.

KANAMYCIN

The use of kanamycin has declined markedly because its spectrum of activity is limited compared with other aminoglycosides, and it is among the most toxic.

NEOMYCIN

Neomycin is a broad-spectrum antibiotic. Gram-negative species that are highly sensitive are *E. coli*, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and *Proteus vulgaris*. Gram-positive microorganisms that are inhibited include *S. aureus* and *E. faecalis*. *M. tuberculosis* also is sensitive to neomycin. Strains of *P. aeruginosa* are resistant to neomycin.

Neomycin sulfate is available for topical and oral administration. Neomycin and polymyxin B have been used for irrigation of the bladder. For this purpose, 1 mL of a preparation (NEOSPORIN G.U. IRRIGANT) containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% NaCl solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The goal is to prevent bacteriuria and bacteremia associated with the use of indwelling catheters.

Neomycin is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, bacitracin, other antibiotics and a variety of glucocorticoids. There is no evidence that these topical preparations shorten the time required for healing of wounds.

THERAPEUTIC USES

Neomycin has been used widely for topical application in a variety of infections of the skin and mucous membranes, including those associated with burns, wounds, ulcers, and infected dermatoses. Such treatment does not eradicate bacteria from the lesions.

For hepatic encephalopathy, a daily dose of 4–12 g (in divided doses) by mouth is given, provided that renal function is normal. Because renal insufficiency is a complication of hepatic failure and neomycin is nephrotoxic, it is used rarely for this indication. Lactulose is a much less toxic agent and is preferred.

ABSORPTION AND EXCRETION

Neomycin is poorly absorbed from the GI tract and is excreted by the kidney. Patients with renal insufficiency may accumulate the drug. About 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces.

UNTOWARD EFFECTS

Hypersensitivity reactions, primarily rashes, occur in 6–8% of patients when neomycin is applied topically. Individuals sensitive to this agent may develop cross-reactions when exposed to other aminoglycosides. The most important toxic effects of neomycin are renal damage and deafness. Toxicity has been reported in patients with normal renal function after topical application or irrigation of wounds with 0.5% neomycin solution. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities. The most important adverse effects resulting from the oral administration of neomycin are intestinal malabsorption and superinfection.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

PROTEIN SYNTHESIS INHIBITORS AND MISCELLANEOUS ANTIBACTERIAL AGENTS

TETRACYCLINES

Tetracyclines (Table 46–1) are inhibitors of bacterial protein synthesis.

EFFECTS ON PATHOGENIC MICROORGANISMS These drugs are bacteriostatic antibiotics with activity against a wide range of aerobic and anaerobic gram-positive and gram-negative bacteria. They intrinsically are more active against gram-positive than gram-negative microorganisms but also are effective against microorganisms such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp. that are resistant to cell-wall-active antimicrobial agents. Resistance of a bacterial strain to any one member may result in cross-resistance to other tetracyclines.

Tetracyclines are active against many spirochetes, including *Borrelia burgdorferi* (Lyme disease) and *Treponema pallidum* (syphilis). Tetracyclines are active against *Chlamydia* and *Mycoplasma*.

Effects on Intestinal Flora

Many tetracyclines can markedly alter enteric flora. Sensitive aerobic and anaerobic microorganisms are suppressed markedly during long-term tetracycline regimens and overgrowth of tetracycline-resistant microorganisms occurs, particularly yeasts (Candida spp.), enterococci, Proteus, and Pseudomonas. Tetracyclines occasionally cause pseudomembranous colitis due to Clostridium difficile.

MECHANISM OF ACTION AND RESISTANCE Tetracyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 46–1). They enter gram-negative bacteria by passive diffusion through channels formed by porins in the outer cell membrane and by active transport that pumps tetracyclines across the cytoplasmic membrane.

Resistance is widespread and often is inducible. The three main resistance mechanisms are: (1) decreased accumulation of tetracycline (decreased antibiotic influx or acquisition of an energy-dependent efflux pathway); (2) production of a ribosomal protein that displaces tetracycline from its target, a “protection” that also may occur by mutation; and (3) enzymatic inactivation of tetracyclines. Cross-resistance amongst tetracyclines depends on which mechanism is operative. Tetracycline resistance due to a ribosomal protection mechanism produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Absorption Oral absorption of most tetracyclines is incomplete and the percentage of absorbed drug rises as the dose increases. Tetracycline absorption is impaired by concurrent ingestion of dairy products; aluminum hydroxide gels; calcium, magnesium, iron or zinc salts; and bismuth subsalicylate. After a single oral dose, peak plasma concentrations of oxytetracycline and tetracycline are attained in 2–4 hours. These drugs have half-lives in the range of 6–12 hours and often are given two to four times daily. Demeclocycline also is incompletely absorbed but can be administered in lower daily dosages because its $t_{1/2}$ of 16 hours provides effective plasma concentrations for 24–48 hours.

After oral dosing, doxycycline and minocycline are almost completely absorbed and have half-lives of 16–18 hours; they therefore are administered less frequently and at lower doses than tetracycline, oxytetracycline, or demeclocycline. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally. Food, including dairy products, does not interfere with the absorption of doxycycline or minocycline.

Distribution Tetracyclines distribute widely throughout the body, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow, and in bone, dentine, and enamel of unerupted teeth (*see below*). Meningeal inflammation is not required for passage of tetracyclines into the cerebrospinal fluid (CSF). Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relatively high concentrations are found in breast milk.

Excretion Except for doxycycline, most tetracyclines are primarily eliminated by the kidney, although they also are concentrated in the liver, excreted in bile, and partially reabsorbed *via* enterohepatic recirculation. Minocycline is significantly metabolized by the liver. Comparable amounts of tetracycline (*i.e.*, 20–60%) are excreted in the urine within 24 hours following oral or intra-

Table 46-1

Structural Formulas of the Tetracyclines

Tetracycline

Congener	Substituent(s)	Position(s)
Chlortetracycline	-Cl	7
Oxytetracycline	-OH, -H	5
Demeclocycline	-OH, -H; -Cl	6; 7
Methacycline	-OH, -H; CH ₂	5; 6
Doxycycline	-OH, -H; -CH ₃ , -H	5; 6
Minocycline	-H, -H; -N(CH ₃) ₂	6; 7

venous administration. Approximately 10–35% of a dose of oxytetracycline is excreted in active form in the urine, where it can be detected within 30 minutes and peaks ~5 hours after administration. The rate of renal clearance of demeclocycline is less than half that of tetracycline. Decreased hepatic function or biliary obstruction reduces excretion of these drugs, prolonging half-lives and raising plasma concentrations.

Minocycline is metabolized to a considerable extent and is recovered from urine and feces in lower amounts than other tetracyclines. The drug persists in the body long after its administration is stopped. The $t_{1/2}$ of minocycline is not prolonged in patients with hepatic failure.

Doxycycline at recommended doses does not accumulate significantly in patients with renal failure and thus is one of the safest of the tetracyclines in this setting. The drug is excreted in the feces. Its $t_{1/2}$ may be significantly shortened by concurrent therapy with barbiturates, phenytoin, rifampin, or other inducers of hepatic CYPs.

FIGURE 46-1 Inhibition of bacterial protein synthesis by tetracyclines. Messenger RNA (mRNA) attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added to the chain moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. Tetracyclines inhibit bacterial protein synthesis by binding to the 30S subunit and blocking tRNA binding to the A site.

ROUTES OF ADMINISTRATION AND DOSAGE A variety of tetracyclines are available for oral, parenteral, and topical administration. Tetracycline, oxytetracycline (TERRAMYCIN, others), demeclocycline (DECLOMYCIN), minocycline (MINOCIN, others), and doxycycline (VIBRAMYCIN, others) are available in the U.S.

Oral Administration The oral dose of tetracycline ranges from 1 to 2 g/day in adults. Children older than 8 years of age should receive 25–50 mg/kg/day in 2–4 divided doses. The dose of doxycycline for adults is 100 mg 12 hours apart on the first day and then 100 mg once a day, or twice daily when severe infection is present; for children older than 8 years of age, the dose is 4–5 mg/kg/day in two divided doses the first day, then 2–2.5 mg/kg given once or twice daily. The dose of minocycline for adults is 200 mg initially, followed by 100 mg every 12 hours; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 hours.

GI distress, nausea, and vomiting can be minimized by administration of tetracyclines with food. Cholestyramine and colestipol can bind orally administered tetracyclines and interfere with their absorption. Generally, tetracyclines should be administered 2 hours before or 2 hours after meals and other drugs that interfere with their absorption.

Parenteral Administration Doxycycline, the preferred parenteral tetracycline in the U.S., is indicated in severe illness, in patients unable to ingest medication, or when the oral drug causes nausea and vomiting. Tetracyclines should not be given intramuscularly because of local irritation and poor absorption.

The usual intravenous dose of doxycycline is 200 mg in one or two infusions on the first day and 100 mg once or twice daily subsequently. For children who weigh <45 kg, the dose is 4.4 mg/kg on the first day and then 2.2 mg/kg/day thereafter. The intravenous dose of minocycline for adults is 200 mg, followed by 100 mg every 12 hours. Children older than 8 years of age should receive an initial dose of 4 mg/kg, followed by 2 mg/kg every 12 hours. Each 100 mg of minocycline must be diluted with 500–1000 mL of compatible fluid and slowly infused over 6 hours to minimize toxicity.

Local Application Except for local use in the eye, topical use of the tetracyclines is not recommended. Minocycline sustained-release microspheres for subgingival administration are used in dentistry as an adjunct in patients with adult periodontitis.

THERAPEUTIC USES The tetracyclines have been used extensively to treat infectious diseases and as food additives in animals, leading to widespread resistance. They remain useful for infections caused by rickettsiae, mycoplasmas, and chlamydiae; doxycycline is used for respiratory infections that increasingly are resistant to other drugs.

Rickettsial Infections Tetracyclines may be life-saving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus, scrub typhus, rickettsialpox, and Q fever. Improvement often is evident within 24 hours. Doxycycline is the drug of choice for suspected or proven Rocky Mountain spotted fever in adults and children, including those <9 years of age, in whom the risk of staining of teeth is outweighed by the seriousness of the potentially fatal infection.

Mycoplasma Infections *Mycoplasma pneumoniae* is sensitive to tetracyclines, which shorten the duration of clinical manifestations in atypical pneumonia.

Chlamydia Doxycycline (100 mg twice daily for 21 days) is first-line therapy for *Lymphogranuloma Venereum*. If relapse occurs, treatment is resumed with full doses and continued for longer periods.

Pneumonia, bronchitis, or sinusitis caused by *Chlamydia pneumoniae* responds to tetracycline therapy. The tetracyclines also are of value in psittacosis. Drug therapy for 10–14 days usually is adequate.

Trachoma Doxycycline (100 mg twice daily for 14 days) or tetracycline (250 mg four times daily for 14 days) is effective for Trachoma. This disease is important in early childhood before the complete calcification of permanent teeth, and tetracyclines therefore often are contraindicated.

Sexually Transmitted Diseases Doxycycline is not recommended for gonococcal infections. *C. trachomatis* often is a coexistent pathogen in acute pelvic inflammatory disease. Doxycycline, 100 mg intravenously twice daily, is recommended for at least 48 hours after substantial clinical improvement, followed by oral therapy at the same dosage to complete a 14-day course. Doxycycline usually is combined with a cephalosporin to cover anaerobes and facultative aerobes.

Acute epididymitis in men <35 years old is caused by *C. trachomatis* or *Neisseria gonorrhoeae*. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline, 100 mg orally twice daily for 10 days. Sexual partners also should be treated.

Nonpregnant, penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline (e.g., doxycycline, 100 mg orally twice daily for 2 weeks). Tetracyclines should not be used for neurosyphilis.

Anthrax Doxycycline 100 mg every 12 hours (2.2 mg/kg every 12 hours for children weighing <45 kg) is indicated for prevention or treatment of anthrax. It should be combined with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for bioterrorism exposures.

Bacillary Infections

Brucellosis Tetracyclines in combination with rifampin or streptomycin are effective for infections caused by *Brucella* spp. Effective regimens are doxycycline, 200 mg/day, plus rifampin, 600–900 mg/day for 6 weeks, or the usual dose of doxycycline plus streptomycin 1 g/day, intramuscularly.

Tularemia Although streptomycin is preferable, tetracyclines also are effective for both ulceroglandular and typhoidal types of tularemia.

Cholera Doxycycline (300 mg as a single dose) is effective in reducing stool volume and eradicating *Vibrio cholerae* from the stool within 48 hours. Antimicrobial agents are not substitutes for fluid and electrolyte replacement in this disease, and some strains of *V. cholerae* are resistant to tetracyclines.

Other Bacillary Infections Tetracycline therapy often is ineffective in infections caused by Shigella, Salmonella, or other Enterobacteriaceae because of a high prevalence of drug-resistant strains. Resistance similarly limits usefulness for travelers' diarrhea.

Coccal Infections Community strains of methicillin-resistant *S. aureus* often are susceptible to tetracycline, doxycycline, or minocycline, which can be effective for uncomplicated skin and soft-tissue infections. Approximately 85% of strains of *S. pneumoniae* are susceptible to tetracyclines, and doxycycline remains effective for empirical therapy of community-acquired pneumonia.

Other Infections Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis. *Borrelia* spp., including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to tetracyclines. The tetracyclines have been used to treat susceptible atypical mycobacteria.

Acne Tetracyclines (250 mg orally twice a day) have been used to treat acne.

UNTOWARD EFFECTS

Toxic Effects

Gastrointestinal All tetracyclines can produce GI irritation, typically after oral administration. Tolerability can be improved by administering the drug with food, but *tetracyclines should not be taken with dairy products or antacids*. Tetracycline has been associated with esophagitis and pancreatitis. *Pseudomembranous colitis caused by overgrowth of C. difficile is a potentially life-threatening complication.*

Photosensitivity Demeclocycline, doxycycline, and other tetracyclines to a lesser extent may produce photosensitivity reactions in treated individuals exposed to sunlight.

Hepatic Toxicity Hepatic toxicity typically develops in patients receiving 2 g or more of drug per day parenterally but also may occur when large quantities are administered orally. Pregnant women are particularly susceptible.

Renal Toxicity Tetracyclines may aggravate azotemia in patients with renal disease because of their catabolic effects. Doxycycline has fewer renal side effects than do other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this effect has been exploited to treat the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 29). Fanconi syndrome has occurred in patients taking outdated tetracycline, presumably due to toxic effects on the proximal tubule.

Effects on Teeth Children treated with a tetracycline may develop permanent brown discoloration of the teeth. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk is highest when given before the first dentition but may develop if

the drug between the ages of 2 months and 5 years, Tetracycline treatment of pregnant patients may produce tooth discoloration in their children.

Miscellaneous Effects

Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the drug exposure is short. Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used for pleurodesis of malignant pleural effusions. Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation, and thrombocytopenic purpura. Tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even at the usual doses. Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. Symptoms occur soon after the initial dose and usually disappear within 1–2 days after drug cessation.

Hypersensitivity Reactions

Various skin reactions rarely may follow the use of any of the tetracyclines. More severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even with oral administration. Other hypersensitivity reactions are burning of the eyes, cheilosis, glossitis, pruritus ani or vulvae, and vaginitis, which can persist for months after cessation of therapy. Fever, eosinophilia, and asthma also have been observed. Cross-sensitization among the various tetracyclines is common.

Biological Effects Other Than Allergic or Toxic

*The tetracyclines administered orally or parenterally may lead to the development of superinfections caused by strains of bacteria or fungi resistant to these agents. Pseudomembranous colitis due to overgrowth of toxin-producing *C. difficile* presents with severe diarrhea, fever, and stools containing mucous membrane neutrophils. Discontinuation of the drug, combined with the oral administration of metronidazole or vancomycin, usually is curative.*

GLYCYLCYCLINES

The glycylyclines are tetracycline analogs that retain activity against tetracycline-resistant organisms containing genes mediating drug efflux or ribosomal protection. The drug tigecycline (TIGACYL) is FDA approved for the treatment of skin and soft tissue infections.

CHLORAMPHENICOL

Chloramphenicol has the following structure:

MECHANISM OF ACTION Chloramphenicol inhibits protein synthesis in bacteria, and to a lesser extent, in eukaryotic cells. It binds reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin). The drug prevents the binding of the amino acid-containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate is blocked, inhibiting peptide bond formation (Figure 46–2).

Chloramphenicol also inhibits protein synthesis in mammalian mitochondria via a similar mechanism, perhaps because their ribosomes somewhat resemble bacterial ribosomes; erythrocytic cells are particularly sensitive.

ANTIMICROBIAL ACTIONS AND RESISTANCE

*Chloramphenicol is bacteriostatic against a broad spectrum of bacteria and may be bactericidal against *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*. Many gram-negative bacilli and most anaerobes are inhibited in vitro. Some aerobic gram-positive cocci, including *Streptococcus pyogenes*, *S. agalactiae* (group B streptococci), and *S. pneumoniae*, are sensitive. *S. aureus* tends to be less susceptible. Chloramphenicol is active against *Mycoplasma*, Chlamydia, and Rickettsia.*

FIGURE 46-2 *Inhibition of bacterial protein synthesis by chloramphenicol.* Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site and inhibits the transpeptidation reaction. Chloramphenicol binds to the 50S ribosomal subunit near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other's actions if given concurrently. See Figure 46-1 and its legend for additional information.

The Enterobacteriaceae are variably sensitive to chloramphenicol. P. aeruginosa is resistant to even very high concentrations of chloramphenicol. Strains of V. cholerae have remained largely susceptible to chloramphenicol. Prevalent strains of Shigella and Salmonella are resistant to multiple drugs, including chloramphenicol.

Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug by preventing its binding to bacterial ribosomes. Resistance also can result from decreased permeability or ribosomal mutation.

ABSORPTION, DISTRIBUTION, FATE, AND EXCRETION Chloramphenicol (CHLORO-MYCETIN) is absorbed rapidly from the GI tract. For intravenous or intramuscular use, chloramphenicol succinate is a prodrug that is hydrolyzed by esterases to chloramphenicol *in vivo*. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce bioavailability, since up to 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 hours) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and achieves therapeutic concentrations in CSF. Chloramphenicol is present in bile, milk, and placental fluid. It also is found in the aqueous humor after subconjunctival injection.

Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol are excreted in the urine. Patients with impaired liver function have decreased metabolic clearance, and dose should be decreased. About 50% of chloramphenicol is bound to plasma proteins; this is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dose adjustment usually is not required. However, if the dose of chloramphenicol has been reduced because of cirrhosis, clearance by hemodialysis may be significant. Drug administration after hemodialysis minimizes this effect. Variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of plasma drug levels.

THERAPEUTIC USES Therapy with chloramphenicol must be limited to infections for which its benefits outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and potentially less toxic are available, they should be used instead of chloramphenicol.

Typhoid Fever

Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever. The adult dose of chloramphenicol for typhoid fever is 1 g every 6 hours for 4 weeks.

Bacterial Meningitis

Chloramphenicol is an alternative drug for meningitis caused by H. influenzae, N. meningitidis, and S. pneumoniae in patients who have severe allergy to β -lactams and in developing countries. The total daily dose for children should be 50–75 mg/kg of body weight, divided into equal doses given intravenously every 6 hours for 2 weeks.

Rickettsial Diseases

Tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. In patients allergic to these drugs, in those with reduced renal function, in pregnant women, and in children <8 years of age who require prolonged or repeated courses of therapy, chloramphenicol may be the drug of choice. Rickettsial diseases, such as Rocky Mountain spotted fever, respond well to chloramphenicol. For adults, a dose of 50 mg/kg/day is recommended for all the rickettsial diseases. The daily dose of chloramphenicol for children with these diseases is 75 mg/kg, divided into equal portions and given every 6–8 hours. Therapy should be continued until the patient has improved and is afebrile for 24–48 hours.

Brucellosis

If tetracyclines are contraindicated, 750–1000 mg of chloramphenicol orally every 6 hours is recommended.

UNTOWARD EFFECTS Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. Much of its toxicity can be attributed to these effects.

Hypersensitivity Reactions Rashes may result from chloramphenicol hypersensitivity. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

Hematological Toxicity Chloramphenicol causes a dose-related toxicity presenting as anemia, leukopenia, or thrombocytopenia and an idiosyncratic response manifested by aplastic anemia, often leading to fatal pancytopenia. Pancytopenia occurs more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on multiple occasions. Although the estimated incidence is only 1 in 30,000 courses of therapy, the fatality rate is high with complete bone-marrow aplasia, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for ~70% of cases of blood dyscrasias due to chloramphenicol, while hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The proposed mechanism involves conversion of the nitro group to a toxic intermediate by intestinal bacteria.

Dose-related erythroid suppression probably reflects inhibition of mitochondrial protein synthesis in erythroid precursors, which impairs iron incorporation into heme. Bone marrow suppression occurs regularly with plasma concentrations >25 $\mu\text{g/mL}$ and is observed with large doses of chloramphenicol, prolonged treatment, or both. Dose-related bone marrow suppression may progress to aplasia if treatment is continued, but most cases of aplasia develop without prior dose-related marrow suppression.

The risk of aplastic anemia does not contraindicate the use of chloramphenicol in situations in which it may be life-saving. The drug should never be used in undefined situations or in diseases readily, safely, and effectively treated with other antimicrobial agents.

Toxic and Irritative Effects Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow oral administration of chloramphenicol. Rare toxic effects are blurred vision and digital paresthesias. Tissues with high oxygen consumption (*e.g.*, brain, heart) may be particularly susceptible to chloramphenicol's effects on mitochondrial enzymes.

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome* if exposed to excessive doses of chloramphenicol. This syndrome usually begins several days after treatment is started. Within 24 hours, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose, green stools occur. The children are severely ill by the end of the first day. Over the next 24 hours, they turn an ashen-gray color and become flaccid and hypothermic. A similar syndrome has occurred in adults who were

accidentally overdosed with the drug. Death occurs in ~40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae.

Two mechanisms contribute to chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol; and (2) inadequate renal excretion of unconjugated drug. At the onset, plasma chloramphenicol concentrations usually exceed 100 $\mu\text{g/mL}$ but may be only 75 $\mu\text{g/mL}$. For children under 2 weeks of age, the maximum daily chloramphenicol dose is 25 mg/kg of body weight; thereafter, full-term infants may receive up to 50 mg/kg daily.

DRUG INTERACTIONS Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of CYP substrates, including *coumadin*, *phenytoin*, *chlorpropamide*, HIV protease inhibitors, *rifabutin*, and *tolbutamide*. Severe toxicity and death have occurred due to these drug interactions. Concurrent administration of *phenobarbital* or *rifampin*, which potently induce CYPs, shortens chloramphenicol's $t_{1/2}$ and may result in subtherapeutic drug concentrations.

MACROLIDES (ERYTHROMYCIN, CLARITHROMYCIN, AND AZITHROMYCIN)

Macrolide antibiotics inhibit bacterial protein synthesis (Figure 46–3). Macrolides contain a many-membered lactone ring (14 for erythromycin and clarithromycin and 15 for azithromycin) to which are attached one or more deoxy sugars. Azithromycin has an additional methyl-substituted nitrogen in the lactone ring that improves acid stability and tissue penetration and broadens the activity spectrum.

ANTIBACTERIAL ACTIVITY

Erythromycin usually is bacteriostatic. It is most active in vitro against aerobic gram-positive cocci and bacilli. Cross-resistance is complete. The prevalence of macrolide resistance among group A streptococcal isolates is related to consumption of macrolide antibiotics within the population. Only 5% of penicillin-susceptible strains are macrolide-resistant, whereas 50% or more of penicillin-resistant strains may be macrolide-resistant. Staphylococci are not reliably sensitive to erythromycin. Macrolide-resistant strains of S. aureus are potentially also resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli are sensitive to erythromycin, including Clostridium perfringens, Corynebacterium diphtheriae, and Listeria monocytogenes.

Erythromycin is inactive against most aerobic enteric gram-negative bacilli but has modest activity in vitro against other gram-negative organisms, including H. influenzae and N. meningitidis, and good activity against most strains of N. gonorrhoeae. Useful antibacterial activity also is observed against Pasteurella multocida, Borrelia spp., and Bordetella pertussis. Resistance is

FIGURE 46–3 *Inhibition of bacterial protein synthesis by the macrolide antibiotics erythromycin, clarithromycin, and azithromycin.* Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin apparently inhibits the translocation step wherein the nascent peptide chain temporarily residing at the A site of the transferase reaction fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 46–1 and its legend for additional information.

MECHANISM OF ACTION Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 46–3) at or very near the site that binds chloramphenicol (Figure 46–2). Erythromycin does not inhibit peptide bond formation *per se*, but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate ~100 times more erythromycin than do gram-negative bacteria.

Resistance to macrolides can result from: (1) drug efflux by an active pump mechanism; (2) ribosomal protection by inducible or constitutive production of methylase enzymes that modify the ribosomal target and decrease drug binding; (3) macrolide hydrolysis by esterases produced by Enterobacteriaceae; and (4) chromosomal mutations that alter a 50S ribosomal protein (found in *B. subtilis*, *Campylobacter* spp., mycobacteria, and gram-positive cocci).

ABSORPTION, DISTRIBUTION, AND EXCRETION

Absorption Erythromycin base is incompletely but adequately absorbed from the upper small intestine. Because it is inactivated by gastric acid, the drug is administered as enteric-coated tablets, as capsules containing enteric-coated pellets that dissolve in the duodenum, or as an ester. Food may impair absorption. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability and are less affected by food. Higher erythromycin concentrations can be achieved by intravenous administration.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but hepatic first-pass metabolism reduces bioavailability to ~50%. Peak concentrations occur 2 hours after drug administration. Clarithromycin may be given with or without food, but the extended-release form should be administered with food to improve bioavailability.

Azithromycin administered orally is absorbed rapidly and distributed widely throughout the body, except to the brain and CSF. Azithromycin should not be given with food. Azithromycin also can be given intravenously.

Distribution Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Concentrations in the middle ear may be inadequate for the treatment of otitis media caused by *H. influenzae*. Protein binding is ~70–80% for erythromycin base and even higher for the estolate. Erythromycin crosses the placenta, and drug concentrations in fetal plasma are ~5–20% of those in maternal circulation. Concentrations in breast milk are 50% of those in serum.

Clarithromycin and its active metabolite, 14-hydroxyclearithromycin, achieve high intracellular concentrations throughout the body. Tissue concentrations, including the middle ear, generally exceed serum concentrations. Protein binding ranges from 40–70% and is concentration dependent.

Azithromycin's unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Protein binding is 50% at low plasma concentrations and less at higher concentrations.

Elimination Only 2–5% of orally administered erythromycin is excreted in active form in the urine; this value is from 12–15% after intravenous infusion. The antibiotic is concentrated in the liver and is excreted in the bile. The serum $t_{1/2}$ of erythromycin is ~1.6 hours; although this may be prolonged in patients with anuria, dosage reduction is not routinely recommended in renal insufficiency. The drug is not removed significantly by peritoneal or hemodialysis.

Clarithromycin is metabolized in the liver to several metabolites. Primary metabolic pathways are oxidative *N*-demethylation and hydroxylation at the 14 position to form an active metabolite. The elimination half-lives are 3–7 hours for clarithromycin and 5–9 hours for 14-hydroxyclearithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics, and longer half-lives are observed after larger doses. The amount of clarithromycin excreted unchanged in the urine ranges from 20–40%, depending on the dose and the formulation (tablet vs. oral suspension). An additional 10–15% of a dose is excreted in the urine as 14-hydroxyclearithromycin. Dose adjustment is not needed unless the creatinine clearance is <30 mL/min.

Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The $t_{1/2}$, 40–68 hours, is prolonged because of extensive tissue sequestration and binding.

DOSAGE The usual oral dose of erythromycin (*erythromycin base*; E-MYCIN, others) for adults ranges from 1 to 2 g/day, in divided doses, usually given every 6 hours. Daily doses of erythromycin

as large as 8 g have been well tolerated. Food ideally should not be taken concurrently with erythromycin base or the stearate formulations but is acceptable with *erythromycin estolate* or *erythromycin ethylsuccinate* (E.E.S., others). The oral dose of erythromycin for children is 30–50 mg/kg/day, divided into four portions; this dose may be doubled for severe infections. Intravenous administration is reserved for the therapy of severe infections, such as legionellosis. The usual dose is 0.5–1 g every 6 hours; 1 g of erythromycin gluceptate has been given intravenously every 6 hours for up to 4 weeks with no adverse effects except for local thrombophlebitis. *Erythromycin lactobionate* (ERYTHROCIN LACTOBIONATE-I.V.) is available for intravenous injection.

Clarithromycin (BIAXIN FILMTABS, BIAXIN XL FILMTABS, and BIAXIN granules for suspension) usually is given twice daily at a dose of 250 mg for children older than 12 years and adults with mild-to-moderate infection. Larger doses (e.g., 500 mg twice daily) are indicated for serious infections such as pneumonia or when infection is caused by organisms such as *H. influenzae*. Children younger than 12 years old should receive 7.5 mg/kg twice daily. The 500-mg, extended-release formulation is given as two tablets once daily. Clarithromycin (500 mg) is also packaged with *lansoprazole* (30 mg) and *amoxicillin* (1 g) as a combination regimen (PREVPAC) administered twice daily for 14 days to eradicate *H. pylori*.

Azithromycin (ZITHROMAX tablet, oral suspension, and powder for intravenous injection) should be given 1 hour before or 2 hours after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or skin and skin-structure infections, a loading dose of 500 mg is given on the first day, followed by 250 mg/day for 4 additional days. Treatment or prophylaxis of *M. avium-intracellulare* infection in AIDS patients requires 500 mg daily in combination with other agents for treatment, or 1200 mg once weekly for primary prevention. Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated. Uncomplicated nongonococcal urethritis presumed to be due to *C. trachomatis* is treated with a single 1-g dose of azithromycin, which also is effective for chancroid. Azithromycin (1 g/week for 3 weeks) is an alternative drug for granuloma inguinale or lymphogranuloma venereum.

In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum 500 mg) and 5 mg/kg (maximum 250 mg/day) on days 2–5. The dose for tonsillitis or pharyngitis is 12 mg/kg/day, up to 500 mg total, for 5 days.

THERAPEUTIC USES

Mycoplasma pneumoniae Infections

A macrolide is one drug of choice for mycoplasma infections.

Legionnaires' Disease

Because of excellent in vitro activity, superior tissue concentration, convenience of once-daily dosing, and better tolerability, azithromycin has supplanted erythromycin as the first-line drug for legionellosis. The recommended dose is 500 mg daily, intravenously or orally, for 10–14 days.

Chlamydial Infections

Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. During pregnancy, erythromycin base, 500 mg four times daily for 7 days, is recommended as first-line therapy for chlamydial urogenital infections. Azithromycin is a suitable alternative. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg/day in four divided doses for 10–14 days).

Pneumonia caused by Chlamydia pneumoniae responds to macrolides, fluoroquinolones, and tetracyclines in standard doses. A specific etiological diagnosis in community-acquired pneumonia rarely is made, and length of treatment (typically 7–10 days) is based on clinical response.

Diphtheria

Erythromycin 250 mg four times daily for 7 days is very effective for acute infections or for eradicating the carrier state. Other macrolides likely are also effective but are not FDA-approved for this indication. Antibiotics do not alter the course of an acute infection with diphtheria or decrease the risk of complications. Antitoxin is indicated in the treatment of acute infection.

Pertussis

Erythromycin is the drug of choice for treating persons with B. pertussis disease and for postexposure prophylaxis of household members and close contacts. A 7-day regimen of erythromycin estolate (40 mg/kg/day, maximum 1 g/day) is sufficient. Clarithromycin and azithromycin also are effective. If administered early in the course of whooping cough, erythromycin may shorten the

duration of illness; it has little influence on the disease once the paroxysmal stage is reached. Nasopharyngeal cultures should be obtained if pertussis does not improve with erythromycin therapy, since resistance has been reported.

Streptococcal Infections

The macrolides are valuable alternatives for treatment of patients who have a serious allergy to penicillin. Unfortunately, macrolide-resistant strains are increasingly encountered.

Staphylococcal Infections

Macrolides no longer can be relied upon unless *in vitro* susceptibility has been documented.

Campylobacter Infections

Fluoroquinolones largely have replaced erythromycin for this disease in adults. Erythromycin remains useful for treatment of *Campylobacter* gastroenteritis in children.

Helicobacter pylori Infection

Clarithromycin 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g, each administered twice daily for 10–14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori*.

Tetanus

Erythromycin (500 mg orally every 6 hours for 10 days) may be given to eradicate *C. tetani* in patients with tetanus who are allergic to penicillin. The mainstays of therapy are débridement, physiological support, tetanus antitoxin, and anticonvulsants.

Mycobacterial Infections

The use of these drugs in the treatment and prevention of mycobacterial infections is described in Chapter 47.

PROPHYLACTIC USES

Erythromycin is an effective alternative for the prophylaxis of recurrences of rheumatic fever in individuals who are allergic to penicillin.

UNTOWARD EFFECTS Erythromycin rarely causes serious side effects. Allergic reactions include fever, eosinophilia, and rash, either alone or in combination; these manifestations resolve after therapy is stopped. Cholestatic hepatitis, the most striking side effect, is caused primarily by erythromycin estolate and rarely by the ethylsuccinate or the stearate and may be a hypersensitivity reaction to the estolate ester. The illness starts after 1–3 weeks of treatment and presents with nausea, vomiting, and abdominal cramps. These symptoms soon are followed by jaundice, fever, leukocytosis, eosinophilia, and elevated plasma transaminases. Liver biopsy reveals cholestasis and periportal inflammation, sometimes with necrosis of neighboring parenchymal cells. Findings usually resolve within a few days after drug cessation and rarely are prolonged.

Oral or intravenous administration of erythromycin, especially in large doses, frequently is accompanied by epigastric distress. Erythromycin stimulates GI motility by acting on motilin receptors and is used postoperatively to promote peristalsis and in patients with gastroparesis to speed gastric emptying (see Chapter 37). These dose-related GI symptoms occur more commonly in children and young adults; they may be reduced by prolonging the infusion time to 1 hour or by pretreatment with glycopyrrolate. Intravenous infusion of 1-g doses, even when dissolved in a large volume, often is followed by thrombophlebitis, which can be minimized by slow rates of infusion.

Erythromycin can cause cardiac arrhythmias, including QT prolongation with polymorphic ventricular tachycardia. Most patients have had underlying cardiac disease, or the arrhythmias were seen in combination with other drugs (see Chapter 34).

DRUG INTERACTIONS Erythromycin and clarithromycin inhibit CYP3A4 and cause significant drug interactions. Erythromycin potentiates the effects of carbamazepine, glucocorticoids, cyclosporine, digoxin, ergot alkaloids, theophylline, triazolam, valproate, and coumadin, probably by interfering with their CYP-mediated metabolism (see Chapter 3). Clarithromycin has a similar drug interaction profile. Azithromycin lacks these drug interactions, but caution still is advised when using azithromycin in conjunction with drugs that interact with erythromycin.

VANCOMYCIN

Vancomycin is a complex tricyclic glycopeptide (MW ~1500 Da). It acts by inhibiting cell wall synthesis (Figure 46–4).

ANTIBACTERIAL ACTIVITY Vancomycin is primarily active against gram-positive bacteria. *S. aureus* and *S. epidermidis*, including strains resistant to methicillin, usually are inhibited. *S. pyogenes*, *S. pneumoniae*, and viridans streptococci are highly susceptible to vancomycin. *Bacillus* spp., including *B. anthracis*, are highly sensitive. Essentially all species of gram-negative bacilli and mycobacteria are resistant to vancomycin.

MECHANISMS OF ACTION AND RESISTANCE Vancomycin inhibits cell wall synthesis by binding with high affinity to the D-Ala-D-Ala terminus of precursor units (Figure 46-4). It is bactericidal for dividing microorganisms.

FIGURE 46-4 Inhibition of bacterial cell wall synthesis. Vancomycin inhibits the polymerization or transglycosylase reaction (A) by binding to the D-Ala-D-Ala terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript n). These (NAM-NAG)_n peptidoglycan polymers are located within the cell wall. *Van A*-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal D-lactate for D-Ala, reducing vancomycin-binding affinity by 1000 times. β -Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (B) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the five Glys in this example) of one chain, displacing the terminal D-Ala of an adjacent chain.

Vancomycin-resistant strains of enterococci have emerged as major nosocomial pathogens in the U.S. Vancomycin resistance determinants in *E. faecium* and *E. faecalis* are located on a transposon that is readily transferred among enterococci, and potentially other gram-positive bacteria. These strains typically are resistant to multiple antibiotics, including *streptomycin*, *gentamicin*, and *ampicillin*. Resistance to streptomycin and gentamicin is of special concern, because the combination of an aminoglycoside with a cell-wall-synthesis inhibitor is the only reliably bactericidal regimen for enterococcal endocarditis.

Enterococcal resistance to vancomycin is the result of alteration of the D-Ala-D-Ala target to D-Ala-D-lactate or D-Ala-D-Ser, which bind vancomycin poorly. Several mutations are required for this target alteration and distinct phenotypes have been described. The *Van A* phenotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *E. faecalis*. The *Van B* phenotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin, and consequently, many strains remain susceptible to teicoplanin.

S. aureus and coagulase-negative staphylococci may express reduced or "intermediate" susceptibility to vancomycin or high-level resistance. Intermediate resistance is associated with (and may be preceded by) a heterogeneous phenotype in which a small proportion of cells within the population (~ 1 in 10^6) will grow in the presence of vancomycin concentrations above 4 $\mu\text{g/mL}$. The basis of the intermediate phenotype is not well understood.

High-level vancomycin-resistance in *S. aureus* ($\text{MIC} \geq 32 \mu\text{g/mL}$) has resulted from a conjugative plasmid into which the *Van A* transposon was integrated by an interspecies horizontal gene transfer from *E. faecalis* to a methicillin-resistant strain of *S. aureus*.

Infections caused by intermediate strains have failed to respond to vancomycin. Prior treatment courses and low vancomycin levels may predispose patients to infection with such vancomycin-intermediate strains, which typically are resistant to methicillin and multiple other antibiotics. Their emergence is a major concern because vancomycin has been the only antibiotic to which staphylococci were reliably susceptible.

ABSORPTION, DISTRIBUTION, AND EXCRETION Vancomycin is poorly absorbed after oral administration. For parenteral therapy, the drug should be administered intravenously. The drug has a serum elimination $t_{1/2}$ of ~ 6 hours. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed, bile, and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose is excreted by glomerular filtration.

THERAPEUTIC USES Vancomycin (VANCOCIN, others) is marketed for intravenous use as a sterile powder. It should be diluted and infused over at least 60 minutes to avoid infusion-related adverse reactions. The usual dose of vancomycin for adults is 30 mg/kg/day in 2–3 divided doses. A trough serum concentration of 5–15 $\mu\text{g/mL}$ (10–20 $\mu\text{g/mL}$ for serious infections such as endocarditis or meningitis) is recommended. Doses above 30 mg/kg/day may be required to achieve these trough concentrations, and up to 60 mg/kg/day has been suggested for meningitis. The "peak" concentration is not monitored routinely but should generally remain below 60 $\mu\text{g/mL}$ to avoid ototoxicity.

Pediatric doses are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 hours; for infants 8–30 days old, 15 mg/kg followed by 10 mg/kg every 8 hours; for older infants and children, 10 mg/kg every 6 hours.

Dosage alteration is required for patients with impaired renal function. The drug has been used effectively in functionally anephric and dialysis patients by the administration of 1 g (~ 15 mg/kg) every 5–7 days. Because there is considerable variation in how well vancomycin is dialyzed with different membranes, blood levels should be monitored to guide dose adjustments.

Vancomycin can be administered orally to patients with pseudomembranous colitis, although metronidazole is preferred. The dose for adults is 125–250 mg every 6 hours; the total daily dose for children is 40 mg/kg, given in three to four divided doses.

Vancomycin should be used only to treat serious infections and is particularly useful in the management of infections due to methicillin-resistant staphylococci and in severe staphylococcal infections in patients who are allergic to penicillins and cephalosporins. Vancomycin is less rapidly bactericidal than the antistaphylococcal β -lactams (e.g., nafcillin or cefazolin) and may be less efficacious. Treatment with vancomycin is effective and convenient when there is disseminated staphylococcal infection or localized shunt infection in a patients receiving hemodialysis or peritoneal dialysis, because the drug can be administered once weekly or in the dialysis fluid.

Intraventricular administration of vancomycin (via a shunt or reservoir) has been necessary in a few cases of CNS infections due to susceptible microorganisms that did not respond to intravenous therapy alone.

In penicillin-allergic patients, vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci or, combined with an aminoglycoside, for enterococcal endocarditis. Vancomycin has become an important antibiotic in the management of known or suspected penicillin-resistant pneumococcal infections.

UNTOWARD EFFECTS Among the hypersensitivity reactions produced by vancomycin are rashes and anaphylaxis. Chills and fever may occur. Rapid intravenous infusion may cause erythematous or urticarial reactions, flushing, tachycardia, and hypotension. The extreme flushing that can occur is called “red-neck” or “red-man” syndrome. This results from a direct toxic effect of vancomycin on mast cells to induce histamine release.

Auditory impairment, sometimes permanent, is associated with excessive plasma concentrations of the drug (60–100 $\mu\text{g}/\text{mL}$). Nephrotoxicity is unusual when appropriate doses are used, as judged by renal function and determinations of blood levels of the drug. Caution must be exercised when ototoxic or nephrotoxic drugs (e.g., aminoglycosides) are coadministered or in patients with impaired renal function.

KETOLIDES (TELITHROMYCIN)

Telithromycin (Ketek) is a semisynthetic derivative of erythromycin with modifications that render it less susceptible to methylase- and efflux-mediated resistance, increasing activity against many macrolide-resistant gram-positive strains. The structure of telithromycin is:

TELITHROMYCIN

ANTIBACTERIAL ACTIVITY Telithromycin is active against staphylococci, streptococci, *S. pneumoniae*, *Haemophilus* spp., *Moraxella catarrhalis*, mycoplasma, chlamydia, and *Legionella*. It is slightly more potent than erythromycin.

MECHANISM OF ACTION AND RESISTANCE Ketolides and macrolides have the same ribosomal target site, but structural modifications within ketolides neutralize the common mechanisms that confer macrolide resistance. Introduction of the 3-keto function converts a methylase-inducing macrolide into a noninducing ketolide. This moiety also prevents drug efflux. The carbamate substitution at C11–C12 enhances binding to the ribosomal target site, even when the site is methylated, by introducing an extra interaction of the ketolide with the ribosome. Inducible and constitutive methylase-producing strains of *S. pneumoniae* are therefore telithromycin-susceptible. However, constitutive methylase-producing strains of *S. aureus* and *S. pyogenes* are telithromycin-resistant because the strength of the ketolide interaction with the fully methylated ribosomal binding site is insufficient to overcome resistance.

ABSORPTION, DISTRIBUTION, AND EXCRETION Telithromycin is formulated as a 400-mg tablet for oral dosing. It is well absorbed with ~60% bioavailability. Peak serum concentrations are achieved within 30 minutes to 4 hours. With a $t_{1/2}$ of 9.8 hours, the drug can be given

once daily. It is 60–70% bound by serum protein, principally albumin. It penetrates well into most tissues, exceeding plasma concentrations by approximately two- to tenfold or more. Telithromycin is concentrated in macrophages and leukocytes, where high concentrations are maintained 24 hours after dosing. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No dose adjustment is required for hepatic failure or mild-to-moderate renal failure, but dose reduction is advised when the creatinine clearance is <30 mL/min.

THERAPEUTIC USES Telithromycin is approved for treatment of community-acquired pneumonia of mild-to-moderate severity in patients ≥ 18 years old. Although telithromycin is not indicated for treatment of severe pneumonia or bacteremia, almost 90% of patients who proved to have pneumococcal bacteremia were clinically cured after taking it. In premarketing trials of telithromycin on patients with community-acquired pneumonia caused by multiple-drug-resistant strains of *S. pneumoniae*, over 90% of patients were cured.

UNTOWARD EFFECTS Telithromycin generally is well tolerated. Nausea, vomiting, and diarrhea occur in 3–10% of treatment courses. Slowed accommodation can cause visual symptoms. Reversible hepatic dysfunction with elevated transaminases or hepatitis and pseudomembranous colitis has been reported; in some cases, the hepatotoxicity has been severe and even fatal. Telithromycin is not recommended for routine use in patients with myasthenia gravis due to possible disease exacerbation.

Telithromycin may cause clinically significant QTc prolongation and increased risk of ventricular arrhythmia in predisposed patients (see Chapter 34). It should not be used in patients with long QT syndrome, uncorrected hypokalemia or hypomagnesemia, profound bradycardia, or in patients receiving certain antiarrhythmics (e.g., quinidine, procainamide, amiodarone) or other agents that prolong QTc (e.g., cisapride, pimozide).

Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Coadministration of rifampin, a potent CYP inducer, decreases the serum concentrations of telithromycin by 80%, while CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations. Serum concentrations of CYP3A4 substrates (e.g., pimozide, cisapride, midazolam, statins, cyclosporine, phenytoin) are increased by telithromycin. Telithromycin also increases peak serum concentrations of metoprolol and digoxin.

CLINDAMYCIN

Clindamycin is a congener of *lincomycin*.

CLINDAMYCIN

MECHANISM OF ACTION Clindamycin binds to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (Figures 46–2 and 46–3), and ribosome binding by one of these drugs may inhibit the interaction of the others. Macrolide resistance due to ribosomal methylation also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. Clindamycin is not a substrate for macrolide efflux pumps; thus, strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.

ANTIBACTERIAL ACTIVITY Clindamycin resembles erythromycin in its *in vitro* activity against susceptible strains of pneumococci, *S. pyogenes*, and viridans streptococci. Ninety percent or more of strains of streptococci, including some that are macrolide-resistant, remain susceptible to

clindamycin. Methicillin-susceptible strains of *S. aureus* usually are susceptible to clindamycin, but methicillin-resistant strains of *S. aureus* and coagulase-negative staphylococci frequently are resistant.

Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially B. fragilis, but resistance increasingly is encountered. Between 10–20% of clostridial species other than C. perfringens are resistant. Strains of Actinomyces israelii and Nocardia asteroides are sensitive. Essentially all aerobic gram-negative bacilli are resistant. M. pneumoniae is resistant. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for Pneumocystis jiroveci pneumonia and T. gondii encephalitis, respectively.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Absorption Clindamycin is nearly completely absorbed following oral administration. Food does not affect absorption significantly. The $t_{1/2}$ of the antibiotic is ~3 hours.

Clindamycin palmitate, an oral prodrug, is hydrolyzed rapidly *in vivo*. Its absorption is similar to clindamycin. The phosphate ester of clindamycin, given parenterally, also is rapidly hydrolyzed to the active parent compound.

Distribution Clindamycin is widely distributed in many fluids and tissues, including bone. Significant concentrations are not attained in CSF, but concentrations sufficient to treat cerebral toxoplasmosis are achieved. The drug readily crosses the placenta. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes and alveolar macrophages and in abscesses.

Excretion Only ~10% of clindamycin is excreted unaltered in the urine; small quantities are found in the feces. However, antimicrobial activity persists in feces for at least 5 days after therapy is stopped and growth of clindamycin-sensitive microorganisms may be suppressed for 2 weeks.

Clindamycin is inactivated by metabolism to *N*-de-methylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Accumulation of clindamycin can occur in patients with severe hepatic failure, and dosage adjustments may be required.

THERAPEUTIC USES The oral dose of clindamycin (CLEOCIN) for adults is 150–300 mg every 6 hours; for severe infections, it is 300–600 mg every 6 hours. Children should receive 8–12 mg/kg/day of *clindamycin palmitate hydrochloride* (CLEOCIN PEDIATRIC) in three or four divided doses, or for severe infections, 13–25 mg/kg/day. However, children weighing ≤10 kg should receive half teaspoonful of this preparation (37.5 mg) every 8 hours as a minimal dose.

For serious infections due to aerobic gram-positive cocci and the more sensitive anaerobes, intravenous or intramuscular administration is recommended in dosages of 600–1200 mg/day, divided into three or four equal doses for adults. Clindamycin phosphate (CLEOCIN PHOSPHATE) is available for intramuscular or intravenous use. For more severe infections, particularly those proven or suspected to be caused by B. fragilis, Peptococcus, or Clostridium species other than C. perfringens, parenteral administration of 1.2–2.4 g/day of clindamycin is suggested. Daily doses as high as 4.8 g have been given intravenously to adults. Children should receive 10–40 mg/kg/day in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Although many infections with gram-positive cocci respond to clindamycin, the high incidence of diarrhea and the occurrence of pseudomembranous colitis limit its use to infections where it is clearly superior to other agents. Clindamycin is particularly valuable for anaerobic infections, especially those due to B. fragilis. Clindamycin is not predictably useful for the treatment of bacterial brain abscesses; metronidazole, in combination with penicillin or a third-generation cephalosporin, is preferred.

Clindamycin is the drug of choice for lung abscess and anaerobic lung and pleural space infections. Clindamycin (600–1200 mg given intravenously every 6 hours) in combination with pyrimethamine (a 200-mg loading dose followed by 75 mg orally each day) and leucovorin is effective for treatment of encephalitis caused by T. gondii in patients with AIDS. Clindamycin (600 mg intravenously every 8 hours, or 300–450 mg orally every 6 hours for less severe disease) in combination with primaquine (15 mg of base once daily) is useful for mild-to-moderate cases of P. jiroveci pneumonia in AIDS patients.

Clindamycin also is available as a topical solution, gel, or lotion (CLEOCIN T, others) and as a vaginal cream (CLEOCIN). It is effective topically (or orally) for acne vulgaris and bacterial vaginosis.

UNTOWARD EFFECTS The incidence of diarrhea associated with clindamycin ranges from 2–20%. A number of patients have developed pseudomembranous colitis caused by *C. difficile* toxin, with abdominal pain, fever, and bloody diarrhea. *This syndrome may be lethal.* Drug

discontinuation and treatment with metronidazole or vancomycin usually is curative, but relapses can occur. Agents that inhibit peristalsis (e.g., opioids) may worsen the condition.

Rashes occur in ~10% of patients treated with clindamycin and may be more common in HIV-infected patients. Other uncommon reactions include reversible elevation of serum transaminases, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration. Clindamycin may potentiate the effect of a neuromuscular blocking agent administered concurrently.

QUINUPRISTIN/DALFOPRISTIN

Quinupristin/dalfopristin (SYNERCID) combines quinupristin, a streptogramin B, with dalfopristin, a streptogramin A, in a 30:70 ratio. These compounds are more soluble derivatives of pristinamycin and thus are suitable for intravenous administration.

ANTIBACTERIAL ACTIVITY Quinupristin/dalfopristin is active against gram-positive cocci and organisms responsible for atypical pneumonia (e.g., *M. pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*), but largely inactive against gram-negative organisms. The combination is bactericidal against streptococci and many strains of staphylococci, but bacteriostatic against *E. faecium*.

MECHANISM OF ACTION Quinupristin and dalfopristin are protein synthesis inhibitors that bind to the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and also inhibits polypeptide elongation. Dalfopristin binds at an adjacent site, changing the conformation of the 50S ribosome; this synergistically enhances the binding of quinupristin at its target site and also directly interferes with polypeptide-chain formation. The synergistic binding to the ribosome often results in bactericidal activity.

RESISTANCE Resistance to quinupristin is mediated by genes encoding a ribosomal methylase that prevents binding of drug to its target or encoding lactonases that inactivate type B streptogramins. Resistance to dalfopristin is mediated by genes that encode acetyltransferases, which inactivate type A streptogramins, or by staphylococcal genes that encode ATP-binding efflux proteins that pump type A streptogramins out of the cell. Resistance determinants are located on plasmids that may be transferred by conjugation. Resistance to quinupristin/dalfopristin always is associated with a resistance gene for type A streptogramins. Methylase-encoding genes can render the combination bacteriostatic instead of bactericidal, making it ineffective in infections where bactericidal activity is necessary (e.g., endocarditis).

ABSORPTION, DISTRIBUTION, AND EXCRETION Quinupristin/dalfopristin is administered by intravenous infusion over at least 1 hour. The $t_{1/2}$ is 0.85 hour for quinupristin and 0.7 hour for dalfopristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfopristin. Hepatic metabolism by conjugation is the principal means of clearance, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. Hepatic insufficiency increases the plasma AUC of active component and metabolites by 180% for quinupristin and 50% for dalfopristin.

THERAPEUTIC USES Quinupristin/dalfopristin is approved in the U.S. for treatment of infections caused by vancomycin-resistant strains of *E. faecium* and complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes*. In Europe, it also is approved for treatment of nosocomial pneumonia and infections caused by methicillin-resistant strains of *S. aureus*. Cure rates for a variety of infections caused by vancomycin-resistant *E. faecium* were ~70% with quinupristin/dalfopristin at a dose of 7.5 mg/kg every 8–12 hours. Quinupristin/dalfopristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

UNTOWARD EFFECTS The most common side effects are pain and phlebitis at the infusion site, which are minimized by infusion through a central venous catheter. Arthralgias and myalgias are more common in patients with hepatic insufficiency and are managed by reducing the dosing frequency from every 8 to every 12 hours. Quinupristin/dalfopristin inhibits CYP3A4. Coadministration of other CYP3A4 substrates with quinupristin/dalfopristin may cause significant toxicity. Caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

LINEZOLID

Linezolid (ZYVOX) is a synthetic antimicrobial agent of the oxazolidinone class.

LINEZOLID

ANTIBACTERIAL ACTIVITY Because of its unique mechanism of action, linezolid is active against strains that are resistant to multiple other agents, including penicillin-resistant strains of *S. pneumoniae*; methicillin-resistant, vancomycin-intermediate and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci.

MECHANISM OF ACTION Linezolid inhibits protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. There is no cross-resistance with other drug classes. Resistance in enterococci and staphylococci is due to point mutations of the 23S rRNA. Since bacteria have multiple copies of 23S rRNA genes, resistance generally requires mutations in two or more copies.

ABSORPTION, DISTRIBUTION, AND EXCRETION Linezolid is well absorbed after oral administration and may be taken without regard to food. Dosing for oral and intravenous preparations is the same. The $t_{1/2}$ is ~4–6 hours. Linezolid is 30% protein-bound and distributes widely to well-perfused tissues.

Linezolid is nonenzymatically oxidized to inactive derivatives. Approximately 80% of the drug appears in the urine, 30% as active compound, and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. No dose adjustment is needed in renal insufficiency. Linezolid and its breakdown products are eliminated by dialysis; therefore the drug should be administered after hemodialysis.

THERAPEUTIC USES

Linezolid is FDA-approved for treatment of infections caused by vancomycin-resistant E. faecium; nosocomial pneumonia caused by methicillin-susceptible and-resistant strains of S. aureus; community-acquired pneumonia caused by penicillin-susceptible strains of S. pneumoniae; complicated skin and skin-structure infections caused by streptococci and methicillin-susceptible and -resistant strains of S. aureus; and uncomplicated skin and skin-structure infections. Linezolid (600 mg twice daily) has had clinical and microbiological cure rates in the range of 85–90% in treatment of a variety of infections caused by vancomycin-resistant E. faecium. A 400-mg, twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections.

Cure rates with linezolid (~60%) were similar to those with vancomycin for nosocomial pneumonia caused by methicillin-resistant or -susceptible S. aureus. Linezolid efficacy also was similar to that of either oxacillin or vancomycin for skin and skin-structure infections, the majority of cases due to by S. aureus. Linezolid appears comparable in efficacy to vancomycin for methicillin-resistant strains. Linezolid may be effective for patients with methicillin-resistant S. aureus infections who are failing vancomycin therapy or whose isolates have reduced susceptibility to vancomycin. Linezolid is bacteriostatic for staphylococci and enterococci and probably should not be used to treat suspected endocarditis.

Linezolid should be reserved as an alternative agent for infections caused by multiple-drug-resistant strains. It should not be used when other agents are likely to be effective. Indiscriminate use and overuse will hasten selection of resistant strains and the eventual loss of this valuable new agent.

UNTOWARD EFFECTS The drug generally has minor side effects (*e.g.*, GI complaints, headache, rash). Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or disorders of platelet function and in patients receiving therapy for >2 weeks. Linezolid is a weak, nonspecific inhibitor of MAO. Patients receiving concomitant therapy with adrenergic or serotonergic agents or consuming more than 100 mg of tyramine daily may have palpitations, headache, or hypertensive crisis. Peripheral and optic neuropathy after prolonged use reverse upon drug discontinuation.

SPECTINOMYCIN

Spectinomycin selectively inhibits protein synthesis in gram-negative bacteria by binding to and affecting the 30S ribosomal subunit. Unlike aminoglycosides, spectinomycin does not cause misreading of messenger RNA and is not bactericidal. Bacterial resistance may be mediated by mutations in the 16S ribosomal RNA or by drug modification by adenyltransferase.

Spectinomycin is rapidly absorbed after intramuscular injection. The drug is not significantly bound to plasma protein and is renally excreted within 48 hours.

Spectinomycin's only therapeutic use is in the treatment of gonorrhea caused by strains resistant to first-line drugs, or if there are contraindications to the use of these drugs. For gonococcal infections, spectinomycin is an alternative drug in patients who are intolerant or allergic to β -lactam antibiotics and quinolones. Spectinomycin also is useful in pregnancy for patients who are intolerant to β -lactams in whom quinolones are contraindicated. The recommended dose is a single, deep intramuscular injection of 2 g. A disadvantage of this regimen is that spectinomycin has no effect on incubating or established syphilis and is not active against *Chlamydia* spp. It also is less effective for pharyngeal infections; follow-up cultures to document cure should be obtained.

Spectinomycin produces few significant untoward effects. Local pain, urticaria, chills, fever, dizziness, nausea, and insomnia have been noted.

POLYMYXIN B AND COLISTIN

The polymyxins are a group of closely related antibiotics elaborated by various strains of *Bacillus polymyxa*. Colistin is produced by *Bacillus colistinus*. These drugs, which are cationic detergents, are basic peptides of ~1000 Da.

Colistin (polymyxin E) is available as colistin sulfate for oral use and as colistimethate sodium for parenteral administration (not recommended). The antimicrobial activities of polymyxin B and colistin are restricted to gram-negative bacteria.

Polymyxins are amphipathic agents that interact with phospholipids and disrupt the structure of cell membranes to increase permeability. Polymyxin B sensitivity apparently is related to the phospholipid content of the cell wall-membrane complex, which may prevent access of the drug to the cell membrane.

These drugs are not absorbed when given orally and poorly absorbed from mucous membranes and burn surfaces. They are cleared renally, and dose modification is required with impaired renal function.

Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Parenteral preparations are rarely used, but colistin may be useful as a salvage regimen for infections caused by multiple-drug-resistant organisms.

Infections of the skin, mucous membranes, eye, and ear due to polymyxin B-sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *P. aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative.

Because of their extreme nephrotoxicity, these drugs are rarely if ever used except topically. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption. Hypersensitization is uncommon with topical use. Neurological reactions include muscle weakness and apnea, paresthesias, vertigo, and slurred speech. Polymyxins are nephrotoxic, and coadministration with aminoglycosides should be avoided.

TEICOPLANIN

Teicoplanin is a glycopeptide antibiotic mixture of related compounds that is approved in the U.S. and Europe. It is like vancomycin in mechanism of action, spectrum of activity, and renal elimination.

MECHANISMS OF ACTION AND RESISTANCE

*Teicoplanin inhibits cell-wall synthesis by binding to the D-Ala-D-Ala terminus of cell wall precursor units (Figure 46-4) and is active only against gram-positive bacteria. It is bactericidal against susceptible strains, except for enterococci. It is active against methicillin-susceptible and methicillin-resistant staphylococci, *Listeria monocytogenes*, *Corynebacterium* spp., *Clostridium* spp., and anaerobic gram-positive cocci. Nonviridans and viridans streptococci, *S. pneumoniae*, and enterococci generally are highly sensitive. Some strains of coagulase-positive and coagulase-negative staphylococci, as well as enterococci and other organisms that are intrinsically resistant to vancomycin, are resistant to teicoplanin.*

Resistance can emerge in susceptible staphylococci during therapy. The Van A phenotype of vancomycin resistance also confers resistance to teicoplanin by altering the cell-wall target so that the glycopeptide does not bind. Strains of enterococci with Van B resistance often remain susceptible to teicoplanin.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Teicoplanin can be given safely by intramuscular injection. It is highly bound by plasma proteins (~90%) and has an extremely long serum elimination $t_{1/2}$ (up to 100 hours) in patients with normal renal function. The dose of teicoplanin in adults is 6–30 mg/kg/day, with higher dosages reserved for serious staphylococcal infections. Once-daily dosing is possible for most infections because of the prolonged serum $t_{1/2}$. Teicoplanin doses must be adjusted in patients with renal insufficiency. For functionally anephric patients, administration once weekly is appropriate, but trough serum drug concentrations should be monitored to determine that the therapeutic range (e.g., 15–20 µg/mL) has been maintained.

THERAPEUTIC USES

Teicoplanin has been used to treat a wide variety of infections, including osteomyelitis and endocarditis, caused by methicillin-resistant and methicillin-susceptible staphylococci, streptococci, and enterococci. Teicoplanin generally is comparable to vancomycin in efficacy, except for treatment failures from low doses used for such serious infections as endocarditis. Teicoplanin is not as efficacious as antistaphylococcal penicillins for treating bacteremia and endocarditis caused by methicillin-susceptible *S. aureus* (cure rates of 60–70% vs. 85–90% for the penicillins). The efficacy of teicoplanin against *S. aureus* may be improved by adding an aminoglycoside (e.g., gentamicin) to provide a synergistic effect. Strains of streptococci are uniformly susceptible to teicoplanin. This drug has been very effective in a once-daily regimen for patients with streptococcal osteomyelitis or endocarditis. Teicoplanin is among the most active drugs against enterococci and apparently is effective, although only bacteriostatic, for serious enterococcal infections. It should be combined with gentamicin to achieve a bactericidal effect in the treatment of enterococcal endocarditis.

UNTOWARD EFFECTS

The main side effect reported for teicoplanin is rash, which is dose-related. Hypersensitivity reactions, drug fever, neutropenia, and ototoxicity also have been reported.

DAPTOMYCIN

Daptomycin (CUBICIN) is a cyclic lipopeptide that was resurrected in response to increasing need for bactericidal antibiotics effective against vancomycin-resistant gram-positive bacteria.

ANTIBACTERIAL ACTIVITY

Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria. Approximately 90% of strains of staphylococci and streptococci are highly sensitive, as are *E. faecalis* and *E. faecium*. Daptomycin may be active against vancomycin-resistant strains.

MECHANISMS OF ACTION AND RESISTANCE

Daptomycin binds to bacterial membranes, resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. Due to its unique mechanism of action, there are no known resistance mechanisms. Very rarely (~0.2%), clinical resistance to daptomycin has emerged during therapy. Staphylococci with decreased susceptibility to vancomycin have higher daptomycin MICs than fully susceptible strains.

ABSORPTION, FATE, AND EXCRETION

Daptomycin is only administered intravenously. Daptomycin displays linear pharmacokinetics at doses up to 8 mg/kg. Protein binding is 92%. The serum $t_{1/2}$ normally is 8 hours, permitting once-daily dosing. Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. If the creatinine clearance is <30 mL/min, the dose is administered every 48 hours. For hemodialysis patients, the dose should be given immediately after dialysis.

Daptomycin neither inhibits nor induces CYPs and has no important drug–drug interactions. Caution is recommended when daptomycin is coadministered with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

THERAPEUTIC USES

Daptomycin is indicated for treatment of complicated skin and skin-structure infections caused by methicillin-susceptible and methicillin-resistant strains of *S. aureus*, hemolytic streptococci, and vancomycin-susceptible *E. faecalis*. Its efficacy is comparable to that of vancomycin.

UNTOWARD EFFECTS

Elevations of creatine kinase may occur; this does not require drug discontinuation unless clinical findings suggest an otherwise unexplained myopathy.

BACITRACIN

The bacitracins are a mixed group of polypeptide antibiotics. The major constituent is bacitracin A. Bacitracin inhibits cell wall synthesis. A variety of gram-positive cocci and bacilli, *Neisseria*, *H. influenzae*, and *Treponema pallidum* are sensitive to the drug. A unit of the antibiotic is equivalent to 26 μg of the USP standard.

Bacitracin is available in ophthalmic and dermatologic ointments; the antibiotic also is available as a powder for the preparation of topical solutions. The ointments are applied directly to the involved surface one or more times daily. A number of topical preparations of bacitracin, to which neomycin or polymyxin or both have been added, are available, and some contain the three antibiotics plus hydrocortisone. For open infections such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer respond well to the topical use of bacitracin when caused by susceptible bacteria. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci. Oral bacitracin has been used with some success for the treatment of antibiotic-associated diarrhea caused by *C. difficile*. Serious nephrotoxicity results from the parenteral use of bacitracin. Hypersensitivity reactions rarely result from topical application.

MUPIROICIN

Mupirocin (*BACTROBAN*) is active against many gram-positive and selected gram-negative bacteria. It has good activity against *S. pyogenes* and methicillin-susceptible and methicillin-resistant strains of *S. aureus*. It is bactericidal at concentrations achieved with topical application.

Mupirocin inhibits bacterial protein synthesis by reversible inhibition of Ile tRNA synthase. There is no cross-resistance with other antibiotic classes. Clinically insignificant, low-level resistance results from mutations of the gene encoding Ile tRNA synthase or an extra chromosomal copy of a gene encoding a modified Ile tRNA synthase. High-level resistance is mediated by a plasmid or chromosomal copy of a gene encoding a "bypass" synthetase that binds mupirocin poorly.

Mupirocin is available as a 2% cream or ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatological preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*. Systemic absorption through intact skin or skin lesions is minimal. Any mupirocin absorbed is rapidly metabolized to inactive monic acid.

Mupirocin is effective in eradicating *S. aureus* carriage. The consensus is that patients who may benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft tissue infections.

Mupirocin may cause irritation and sensitization and contact with the eyes should be avoided. Systemic reactions to mupirocin occur rarely, if at all. Application of the ointment to large surface areas should be avoided in patients with renal failure to avoid accumulation of polyethylene glycol from the ointment.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

CHEMOTHERAPY OF TUBERCULOSIS, *MYCOBACTERIUM AVIUM* COMPLEX DISEASE, AND LEPROSY

Mycobacteria cause tuberculosis, *Mycobacterium avium* complex (MAC) disease, and leprosy. Tuberculosis remains the leading worldwide cause of death due to infectious disease. “First-line” agents for the chemotherapy of tuberculosis combine the greatest efficacy with an acceptable degree of toxicity (Table 47–1), and the large majority of patients with tuberculosis are treated successfully with these drugs. Occasionally, it may be necessary to resort to “second-line” drugs.

I. DRUGS FOR TUBERCULOSIS

ISONIAZID

Isoniazid (NYDRAZID, others) remains the primary drug for tuberculosis. All patients with disease caused by sensitive strains should receive the drug if they can tolerate it.

ANTIBACTERIAL ACTIVITY AND MECHANISM OF ACTION

Isoniazid is bacteriostatic for “resting” bacilli but bactericidal for dividing microorganisms. Isoniazid is a prodrug that is converted by mycobacterial catalase-peroxidase into an active metabolite. It inhibits biosynthesis of mycolic acids—long, branched lipids that are attached to a unique polysaccharide in the mycobacterial cell wall. Mycolic acids are unique to mycobacteria. The target of the isoniazid derivative is enoyl-ACP reductase of fatty acid synthase II, which converts unsaturated to saturated fatty acids in mycolic acid biosynthesis.

BACTERIAL RESISTANCE

Isoniazid resistance most commonly results from mutations in catalase-peroxidase that decrease its activity, preventing conversion of the prodrug isoniazid to its active metabolite. Mutations in genes involved in mycolic acid biosynthesis also cause resistance.

Isoniazid monotherapy leads to resistance. This resistance typically develops after a few weeks of therapy but can vary. Approximately 1 in 10⁶ tubercle bacilli will be genetically resistant to isoniazid; since tuberculous cavities may contain as many as 10⁹ microorganisms, it is not surprising that isoniazid selects for resistant bacteria. The incidence of primary resistance to isoniazid in the U.S. is estimated at 8% of isolates but may be much higher in Asian and Hispanic immigrants, large urban areas, and border communities.

ABSORPTION, DISTRIBUTION, AND EXCRETION Isoniazid is readily absorbed after oral or parenteral administration. Isoniazid diffuses readily into all body fluids and cells. The drug achieves significant quantities in pleural and ascitic fluids; concentrations in the cerebrospinal fluid (CSF) with inflamed meninges are similar to those in the plasma. Isoniazid penetrates well into caseous material and persists in therapeutic concentrations.

From 75 to 95% of a dose of isoniazid is excreted in the urine within 24 hours, mostly as metabolites. The main excretory products in humans result from acetylation (acetylisoniazid) and hydrolysis (isonicotinic acid).

Slow and rapid inactivators (acetylators) of isoniazid differ in the polymorphic arylamine *N*-acetyltransferase type 2 (NAT2); in the U.S., the incidence of “slow acetylators” is ~50%. The serum $t_{1/2}$ in fast acetylators is 1 hour *versus* 2–5 hours in slow acetylators, resulting in serum isoniazid levels in fast acetylators that are 30–50% of those in slow acetylators. Because isoniazid is relatively nontoxic, sufficient drug can be administered to fast acetylators to achieve a therapeutic effect. Hepatic insufficiency also increases drug concentrations, and dosage reduction is recommended for slow acetylators in this setting. Slow acetylators rarely may accumulate toxic concentrations if their renal function is impaired.

Table 47-1

Drugs Used in the Treatment of Tuberculosis, *Mycobacterium avium* Complex, and Leprosy

Mycobacterial Species	First-Line Therapy	Alternative Agents
<i>M. tuberculosis</i>	Isoniazid + rifampin*+ pyrazinamide + ethambutol or streptomycin	Moxifloxacin or gatifloxacin; cycloserine; capreomycin; kanamycin; amikacin; ethionamide; clofazimine; aminosalicyclic acid
<i>M. avium</i> complex	Clarithromycin or azithromycin + ethambutol with or without rifabutin	Rifabutin; rifampin; ethionamide; cycloserine; moxifloxacin or gatifloxacin
<i>M. kansasii</i>	Isoniazid + rifampin*+ ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin or gatifloxacin
<i>M. fortuitum</i> complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
<i>M. marinum</i>	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
<i>M. leprae</i>	Dapsone + rifampin ± clofazimine	Minocycline; moxifloxacin or gatifloxacin; clarithromycin; ethionamide

*In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and nonnucleoside reverse transcriptase inhibitors.

THERAPEUTIC USES Isoniazid is the most important drug for the treatment of tuberculosis. Toxic effects are minimized by prophylactic therapy with *pyridoxine* and careful patient surveillance. For treatment of active infections, the drug is combined with another agent, although it is used alone for prophylaxis.

Isoniazid usually is given orally in a single daily dose of 5 mg/kg, with a maximum of 300 mg. Children should receive 10–20 mg/kg/day (300 mg maximum). After 2 months of daily therapy with isoniazid, rifampin, and pyrazinamide, patients with sensitive strains of M. tuberculosis may be treated twice-weekly with isoniazid (15 mg/kg orally) plus rifampin (10 mg/kg, up to 600 mg/dose) for 4 months.

Pyridoxine, vitamin B6, (10–50 mg/day) is coadministered with isoniazid to minimize the risk of peripheral neuropathy and central nervous system (CNS) toxicity in malnourished patients and those predisposed to neuropathy (e.g., slow acetylators, elderly, pregnant women, human immunodeficiency virus [HIV]-infected subjects, diabetics, alcoholics, and uremics).

UNTOWARD EFFECTS Adverse reactions to isoniazid occur in ~5%, including rash (2%), fever (1.2%), jaundice (0.6%), and peripheral neuritis (0.2%). Isoniazid hypersensitivity may result in fever, rashes, and hepatitis. Hematological reactions also may occur (e.g., agranulocytosis, eosinophilia, thrombocytopenia, and anemia). Vasculitis associated with antinuclear antibodies may appear but disappears when the drug is stopped.

Peripheral neuritis occurs in ~2% of patients receiving 5 mg/kg of drug daily if pyridoxine is not given concurrently. Prophylactic administration of pyridoxine considerably decreases the risk of peripheral neuritis and other nervous system disorders.

Isoniazid may precipitate convulsions, usually in patients with known seizure disorders. Optic neuritis also has occurred. Muscle twitching, dizziness, ataxia, paresthesias, stupor, and potentially fatal encephalopathy are other manifestations of neurotoxicity. A number of mental abnormalities may appear, including euphoria, transient memory impairment, loss of self-control, and psychosis.

Isoniazid inhibits phenytoin parahydroxylation, and signs and symptoms of toxicity occur in ~25% of patients given both drugs, particularly in slow acetylators. Concentrations of phenytoin in plasma should be monitored, and its dose adjusted if necessary.

Severe hepatic injury leading to death may occur in individuals receiving isoniazid, typically presenting 4–8 weeks after initiation of therapy. Liver biopsy reveals bridging and multilobular

necrosis. Drug continuation after hepatic dysfunction develops may worsen the damage. Alcoholic hepatitis increases the risk, but chronic carriers of the hepatitis B virus tolerate isoniazid. Age is the most important risk factor for isoniazid-induced hepatotoxicity; it is rare in patients <20 years old, occurs in 0.3% of those 20–34 years old, and increases to 1.2% and 2.3% in individuals 35–49 and >50 years of age, respectively. Up to 12% of patients receiving isoniazid may have elevated serum transaminase levels. Patients receiving isoniazid should be evaluated monthly for symptoms of hepatitis and warned to discontinue the drug if symptoms occur. Some clinicians follow serum transaminases at monthly intervals in high-risk individuals (older age, excessive alcohol intake, history of liver disease); an elevation >five times normal is cause for drug discontinuation. Isoniazid should be administered with great care to those with preexisting hepatic disease.

RIFAMPIN AND OTHER RIFAMYCINS

The rifamycins (rifampin, rifabutin, rifapentine) are related macrocyclic antibiotics produced by *Amycolatopsis mediterranea*; rifampin (RIFADIN; RIMACTANE) is a semisynthetic derivative of rifamycin B.

RIFAMPIN

ANTIBACTERIAL ACTIVITY

Rifampin inhibits the growth of most gram-positive and many gram-negative bacteria. Rifampin in concentrations of 0.005–0.2 $\mu\text{g}/\text{mL}$ inhibits the growth of *M. tuberculosis* in vitro. Among nontuberculous mycobacteria, *Mycobacterium kansasii* is inhibited by 0.25–1 $\mu\text{g}/\text{mL}$. The majority of strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *M. avium* are suppressed but certain strains may be resistant. *Mycobacterium fortuitum* is highly resistant to the drug. Rifampin increases the in vitro activity of streptomycin and isoniazid against *M. tuberculosis*.

MECHANISM OF ACTION AND BACTERIAL RESISTANCE Rifampin forms a stable complex with DNA dependent RNA polymerase, leading to suppression of initiation of chain formation (but not chain elongation) in RNA synthesis. High concentrations of rifampin can inhibit RNA synthesis in mammalian mitochondria, viral DNA-dependent RNA polymerases, and reverse transcriptases. Rifampin is bactericidal for both intracellular and extracellular microorganisms.

Mycobacteria may rapidly develop rifampin resistance as a one-step process, and 1 of every 10^7 – 10^8 tubercle bacilli is resistant to the drug; thus, rifampin should not be used alone. Microbial resistance is due to mutations in DNA-dependent RNA polymerase that reduce drug binding to the polymerase.

ABSORPTION, DISTRIBUTION, AND EXCRETION Following gastrointestinal (GI) absorption, rifampin is eliminated rapidly in the bile, and an enterohepatic circulation ensues. During this time, the drug is progressively deacetylated by hepatic CYPs; after 6 hours, nearly all drug in the bile is in the deacetylated form, which retains antibacterial activity. Intestinal reabsorption is reduced by deacetylation (and by food); thus, metabolism facilitates drug elimination. The rifampin $t_{1/2}$ is progressively shortened (~40%) during the first 14 days of treatment due to induction of hepatic CYPs; $t_{1/2}$ is increased by hepatic dysfunction and may be decreased in slow acetylators concurrently receiving isoniazid. Dosage adjustment is not necessary in patients with renal insufficiency. Rifampin is distributed throughout the body and reaches effective concentrations in the CSF. The drug may impart an orange-red color to bodily fluids.

THERAPEUTIC USES Rifampin for oral administration is available alone and as a fixed-dose combination with isoniazid (150 mg of isoniazid, 300 mg of rifampin; RIFAMATE) or with isoniazid and pyrazinamide (50 mg of isoniazid, 120 mg of rifampin, and 300 mg pyrazinamide;

RIFATER). A parenteral form of rifampin also is available. *Rifampin and isoniazid are the most effective drugs available for the treatment of tuberculosis.*

The dose of rifampin for tuberculosis treatment in adults is 600 mg daily, given either 1 hour before or 2 hours after a meal. Children should receive 10 mg/kg given in the same way. Rifampin should never be used alone for the treatment of tuberculosis because of the rapidity with which resistance may develop.

Rifampin also is indicated for the prophylaxis of meningococcal disease and Haemophilus influenzae meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children should receive 10–15 mg/kg, to a maximum of 600 mg. Combined with a β -lactam antibiotic or vancomycin, rifampin is used in selected cases of staphylococcal endocarditis or osteomyelitis. Rifampin may be used to eradicate nasal staphylococci in patients with chronic furunculosis.

UNTOWARD EFFECTS In usual doses, <4% of patients with tuberculosis have significant adverse reactions to rifampin, most commonly rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents, or who had preexisting liver disease. Hepatitis from rifampin rarely occurs in patients with normal hepatic function; likewise, the combination of isoniazid and rifampin appears generally safe. Chronic liver disease, alcoholism, and old age increase the risk of severe hepatitis when rifampin is given alone or concurrently with isoniazid.

Rifampin should not be administered less than twice weekly and/or in daily doses of 1.2 g or greater because this is associated with frequent side effects. A flu-like syndrome with fever, chills, and myalgias develops in 20% of patients so treated.

As a potent inducer of hepatic CYPs, rifampin decreases the $t_{1/2}$ of many drugs, including HIV protease and nonnucleoside reverse transcriptase inhibitors, *digoxin, quinidine, disopyramide, mexiletine, tocainide, ketoconazole, propranolol, metoprolol, clofibrate, verapamil, methadone, cyclosporine, glucocorticoids, oral anticoagulants, theophylline, barbiturates, oral contraceptives, halothane, fluconazole, and the sulfonyleureas.* The interaction between rifampin and oral anticoagulants can impair anticoagulation. By enhancing the catabolism of steroids, rifampin can decrease effectiveness of oral contraceptives and induce adrenal insufficiency in patients with marginal adrenal reserve (see Chapter 59). The increased metabolism of methadone and other narcotics has led to inadequate pain control or withdrawal symptoms.

GI disturbances produced by rifampin (epigastric distress, nausea, vomiting, abdominal cramps, diarrhea) have occasionally required drug discontinuation. CNS symptoms include fatigue, drowsiness, headache, dizziness, ataxia, confusion, inability to concentrate, generalized numbness, pain in the extremities, and weakness. Hypersensitivity reactions include fever, pruritus, urticaria, various rashes, and eosinophilia. Hemolysis, hemoglobinuria, hematuria, renal insufficiency, and acute renal failure have been observed rarely, likely due to hypersensitivity reactions. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. The drug is best avoided during pregnancy.

Rifabutin (MYCOBUTIN) is a rifampin derivative and has the same mechanism of action. Because rifabutin is a less potent inducer of CYPs, it is used in tuberculosis-infected HIV patients treated concurrently with protease inhibitors. Unique side effects of rifabutin include polymyalgia and anterior uveitis. About 25% of rifampin-resistant *M. tuberculosis* isolates are rifabutin-sensitive, so it may have a role in the treatment of multidrug-resistant tuberculosis.

Rifapentine (PRIFITIN) has a longer $t_{1/2}$ than rifampin and rifabutin, which allows once-weekly dosing. It has an intermediate capacity to induce CYPs, between rifabutin and rifampin. In HIV-infected patients, rifapentine may select for rifamycin resistance; rifabutin is therefore preferred in this situation.

ETHAMBUTOL

The structure of ethambutol is:

ETHAMBUTOL

ANTIBACTERIAL ACTIVITY, MECHANISM OF ACTION, RESISTANCE

Nearly all strains of *M. tuberculosis* and *M. kansasii* and many strains of MAC are sensitive to ethambutol. Sensitivities of other mycobacteria are variable. Ethambutol has no effect on other bacteria. Growth inhibition by ethambutol requires 24 hours and is mediated by inhibition of arabinosyl transferases involved in cell wall biosynthesis. Resistance to ethambutol develops very slowly in vitro, but can result from single amino acid mutations when given alone.

ABSORPTION, DISTRIBUTION, AND EXCRETION

About 80% of an oral dose of ethambutol is absorbed from the GI tract. Concentrations in plasma peak 2–4 hours after the drug is taken and are proportional to the dose. The drug has a $t_{1/2}$ of 3–4 hours. Within 24 hours, 75% of an ingested dose of ethambutol is excreted unchanged in the urine; up to 15% is excreted in the form of aldehyde and dicarboxylic acid derivatives. The drug is renally excreted.

THERAPEUTIC USES Ethambutol (MYAMBUTOL) has been used with notable success in the therapy of tuberculosis when given concurrently with isoniazid and largely has replaced aminosalicylic acid. Ethambutol is available for oral administration in tablets. The usual adult dose is 15 mg/kg given once a day. Some clinicians use 25 mg/kg/day for the first 60 days, followed by 15 mg/kg/day, particularly for those treated previously. Dose adjustment is necessary in patients with impaired renal function. Ethambutol is not recommended for children under 5 years of age because of concern about the ability to test their visual acuity. Children from ages 6–12 years should receive 10–15 mg/kg/day.

UNTOWARD EFFECTS The most important side effect is optic neuritis, resulting in decreased visual acuity and red–green color blindness. The incidence of this reaction is proportional to the dose of ethambutol and is <1% in patients receiving the recommended daily dose of 15 mg/kg. The intensity of the visual difficulty is related to the duration of therapy after visual impairment first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are recommended. Recovery usually occurs when ethambutol is withdrawn.

Fewer than 2% of patients who received daily doses of 15 mg/kg of ethambutol had adverse reactions, including diminished visual acuity, rash, drug fever, pruritus, joint pain, GI upset, malaise, headache, dizziness, confusion, disorientation, and hallucinations. Numbness and tingling of the fingers owing to peripheral neuritis are infrequent. Anaphylaxis and leukopenia are rare. Therapy with ethambutol increases urate concentration in the blood in ~50% of patients, owing to decreased renal excretion of uric acid.

STREPTOMYCIN**ANTIBACTERIAL ACTIVITY**

Streptomycin is bactericidal for the tubercle bacillus in vitro. The vast majority of strains of M. tuberculosis are sensitive. M. kansasii is frequently sensitive, but other mycobacteria are only occasionally susceptible. Streptomycin in vivo does not eradicate the tubercle bacillus, probably because the drug does not readily enter living cells and thus cannot kill intracellular microbes. The broader pharmacology of streptomycin is covered in chapter 45.

BACTERIAL RESISTANCE

Primary resistance to streptomycin is found in only 2–3% of isolates of M. tuberculosis. Selection for resistant tubercle bacilli occurs in vivo; the longer therapy, the greater the incidence of resistance.

THERAPEUTIC USES The use of streptomycin for the treatment of pulmonary tuberculosis has declined sharply. Many clinicians still prefer to give 4 drugs, of which streptomycin may be one, for the most serious forms of tuberculosis, (e.g., disseminated disease or meningitis). Adults should be given 15 mg/kg/day in divided doses given by intramuscular injection every 12 hours, not to exceed 1 g/day. Children should receive 20–40 mg/kg/day in divided doses every 12–24 hours, not to exceed 1 g/day. Therapy usually is discontinued after 2–3 months, or sooner if cultures become negative.

UNTOWARD EFFECTS In tuberculosis patients treated with streptomycin, 8% had adverse reactions; half of which involved the auditory and vestibular functions of the eighth cranial nerve. Other problems included rash and fever.

PYRAZINAMIDE

Pyrazinamide is the synthetic pyrazine analog of nicotinamide and has the following structure:

PYRAZINAMIDE

ANTIBACTERIAL ACTIVITY

Pyrazinamide exhibits bactericidal activity *in vitro* only at a slightly acidic pH; this poses no problem since the drug kills tubercle bacilli residing in acidic phagosomes within the macrophage. The target of pyrazinamide is the mycobacterial fatty acid synthase I gene involved in mycolic acid biosynthesis. Resistance develops rapidly if pyrazinamide is used alone.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Pyrazinamide is well absorbed from the GI tract and widely distributed throughout the body, including the CNS, lungs, and liver. The plasma $t_{1/2}$ is 9–10 hours in patients with normal renal function. The drug is excreted primarily by glomerular filtration. Pyrazinamide is hydrolyzed to pyrazinoic acid and subsequently hydroxylated to 5-hydroxypyrazinoic acid.

THERAPEUTIC USES

Pyrazinamide is an important component of short-term (6-month) multiple-drug therapy of tuberculosis. The daily dose for adults is 15–30 mg/kg in a single oral dose. The maximum dose is 2 g/day, regardless of weight. Children should receive 15–30 mg/kg/day; daily doses also should not exceed 2 g. Pyrazinamide is safe and effective when administered twice or thrice weekly (at increased dosages).

UNTOWARD EFFECTS

Hepatic injury is the most serious side effect of pyrazinamide. Current regimens (15–30 mg/kg/day) are much safer than higher doses used previously. Prior to pyrazinamide administration, all patients should have liver function tests, which should be repeated at frequent intervals. If evidence of significant hepatic damage appears, therapy must be stopped. Pyrazinamide should not be given to individuals with any degree of hepatic dysfunction unless this is absolutely unavoidable.

The drug inhibits urate excretion, rarely precipitating an acute flare of gout. Other adverse effects are arthralgias, nausea and vomiting, dysuria, malaise, and fever.

QUINOLONES

The fluoroquinolones are highly active against *M. tuberculosis* and are important drugs for multidrug-resistant tuberculosis (Table 47–1). Agents such as gatifloxacin (TEQUIN) and moxifloxacin (AVELOX) are most active and least likely to select for quinolone resistance. Mycobacterial resistance to one fluoroquinolone imparts cross-resistance for the entire class.

ETHIONAMIDE

ETHIONAMIDE (TRECATOR-SC) has the following structure:

ETHIONAMIDE

MECHANISM OF ACTION AND ANTIBACTERIAL ACTIVITY, RESISTANCE

Ethionamide is a prodrug that is activated by an NADPH-specific monooxygenase to a sulfoxide, and thence to 2-ethyl-4-aminopyridine. Although these products are not toxic, a transient intermediate presumably is the active antibiotic. Like isoniazid, ethionamide inhibits mycobacterial growth by inhibiting the activity of the enoyl-ACP reductase of fatty acid synthase II. Both drugs thus inhibit mycolic acid biosynthesis with consequent impairment of cell-wall synthesis. Resistance can develop rapidly *in vivo* when ethionamide is used as a single-agent treatment, including low-level cross-resistance to isoniazid.

ABSORPTION, DISTRIBUTION, AND EXCRETION

The $t_{1/2}$ of the drug is 2 hours. Approximately 50% of patients are unable to tolerate a single dose >500 mg because of GI disturbance. Ethionamide is rapidly and widely distributed, with significant concentrations in CSF. Ethionamide is cleared by hepatic metabolism; like aminosalicylic acid, ethionamide inhibits the acetylation of isoniazid in vitro.

THERAPEUTIC USES

Ethionamide is a secondary agent, to be used concurrently with other drugs only when therapy with primary agents is ineffective or contraindicated. The initial dose of ethionamide for adults is 250 mg twice daily given orally; it is increased by 125 mg/day every 5 days until a dose of 15–20 mg/kg/day is achieved. The maximal dose is 1 g daily. The drug is taken with meals in divided doses to minimize gastric irritation. Children should receive 15–20 mg/kg/day in two divided doses, not to exceed 1 g daily.

UNTOWARD EFFECTS

Common reactions to ethionamide are anorexia, nausea and vomiting, gastric irritation, and neurologic symptoms, including depression, drowsiness, and asthenia. Convulsions and peripheral neuropathy are rare. Other neurological manifestations include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine relieves the neurologic symptoms and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia also have been observed. Hepatitis has developed in ~5% of cases and reverses when treatment is stopped; hepatic function should be assessed periodically.

AMINOSALICYLIC ACID**ANTIBACTERIAL ACTIVITY**

Aminosalicylic acid is bacteriostatic. In vitro, most strains of *M. tuberculosis* are sensitive to a concentration of 1 $\mu\text{g/mL}$. Microorganisms other than *M. tuberculosis* are unaffected.

MECHANISM OF ACTION AND BACTERIAL RESISTANCE

Aminosalicylic acid is a structural analog of para-aminobenzoic acid, and has the same mechanism of action as the sulfonamides (see Chapter 43). Nonetheless, the sulfonamides are ineffective against *M. tuberculosis*, and aminosalicylic acid is inactive against sulfonamide-susceptible bacteria. Resistant strains of tubercle bacilli emerge slowly in patients treated with aminosalicylic acid.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Aminosalicylic acid is readily absorbed from the GI tract. The drug is distributed throughout total body water; it reaches high concentrations in pleural fluid and caseous tissue, but CSF levels are low. It has a $t_{1/2}$ of 1 hour, and concentrations in plasma are negligible within 4–5 hours after a single dose. Over 80% of the drug is excreted in the urine; >50% as an acetylated derivative; the largest portion of the remainder is the free acid. The drug should not be used in the setting of renal insufficiency.

THERAPEUTIC USES

Aminosalicylic acid (PASER) is a second-line agent in the management of tuberculosis. It is administered orally in a daily dose of 10–12 g. Because of GI irritation, it is administered after meals and divided into 2–4 equal portions. Children should receive 150–300 mg/kg/day in 3–4 divided doses.

UNTOWARD EFFECTS

GI problems (e.g., anorexia, nausea, epigastric pain, and diarrhea) are predominant and often limit patient adherence. Patients with peptic ulcers tolerate the drug especially poorly. Hypersensitivity reactions to aminosalicylic acid are seen in up to 10% of patients. Fever may develop abruptly or may appear gradually and be low-grade. Generalized malaise, arthralgias, and sore throat may be present. Rashes appear as isolated reactions or accompanied by fever. Hematological abnormalities include leukopenia, agranulocytosis, eosinophilia, lymphocytosis, an atypical mononucleosis syndrome, thrombocytopenia, and hemolytic anemia.

CYCLOSERINE

Cycloserine (SEROMYCIN) is a broad-spectrum antibiotic that is used with other drugs in the treatment of tuberculosis when primary agents have failed. Cycloserine is D-4-amino-3-isoxazolidone.

ANTIBACTERIAL ACTIVITY

Cycloserine inhibits *M. tuberculosis* in concentrations of 5–20 $\mu\text{g/mL}$ in vitro. There is no cross-resistance between cycloserine and other tuberculostatic agents.

MECHANISM OF ACTION

Cycloserine and D-Ala are structural analogs; thus, cycloserine inhibits reactions in which D-Ala is involved in bacterial cell-wall synthesis.

ABSORPTION, DISTRIBUTION, AND EXCRETION

When given orally, 70–90% of cycloserine is rapidly absorbed. Cycloserine is distributed throughout body fluids and tissues. CSF concentrations are comparable to those in plasma. About 50% of a parenteral dose of cycloserine is excreted unchanged in the urine in the first 12 hours; a total of 65% is recoverable in the active form over a period of 72 hours. Very little of the antibiotic is metabolized. The drug may reach toxic concentrations in patients with renal insufficiency; it is removed from the circulation by hemodialysis.

THERAPEUTIC USES

Cycloserine is used only when retreatment is necessary or microorganisms are resistant to other drugs. It must be given together with other effective agents. The usual dose for adults is 250–500 mg twice daily.

UNTOWARD EFFECTS

Side effects typically affect the CNS, appearing within 2 weeks of therapy and disappearing after drug withdrawal. They include: somnolence, headache, tremor, dysarthria, vertigo, confusion, nervousness, irritability, psychotic states, paranoid reactions, catatonic reactions, twitching, ankle clonus, hyperreflexia, visual disturbances, paresis, and seizures. Large doses or concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

OTHER DRUGS

These agents are all secondary drugs used only for treatment of disease caused by resistant *M. tuberculosis* or by nontuberculous mycobacteria. They all are given parenterally and have similar pharmacokinetics and toxicity. *Since these agents are potentially ototoxic and nephrotoxic, no two drugs from this group should be used simultaneously, and they should not be combined with streptomycin.*

Amikacin is an aminoglycoside (see Chapter 45) that is extremely active against several mycobacterial species and has a role in the treatment of disease caused by nontuberculous mycobacteria.

Capreomycin (CAPASTAT) is an antimycobacterial cyclic peptide elaborated by Streptococcus capreolus. Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. Capreomycin is used only in conjunction with other appropriate drugs in treatment of pulmonary tuberculosis when bactericidal agents cannot be tolerated or when causative organisms have become resistant.

Capreomycin is given intramuscularly, which may be painful. The daily dose is 15–30 mg/kg/day or up to 1 g for 60–120 days, followed by 1 g two to three times a week. Adverse reactions associated with capreomycin are hearing loss, tinnitus, transient proteinuria, and azotemia. Severe renal failure is rare. Eosinophilia is common, and leukocytosis, leukopenia, rashes, and fever have also been observed.

CHEMOTHERAPY OF TUBERCULOSIS

Most patients are treated in the ambulatory setting, often after diagnosis and initial therapy in a general hospital. Patients must be seen frequently to follow the course of their disease and treatment. The local health department should be notified and contacts should be investigated for the possibility of disease and for the appropriateness of prophylactic therapy.

Most new cases of tuberculosis in the U.S. are caused by microorganisms that are sensitive to isoniazid, rifampin, ethambutol, and pyrazinamide. *To prevent the development of resistance to these agents, treatment must include at least 2 drugs to which the bacteria are sensitive.* The preferred 6-month treatment program for drug-sensitive tuberculosis in adults and children consists of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin (for sensitive organisms) for 4 additional months. The combination of isoniazid and rifampin for 9 months is equally effective for sensitive tuberculosis. Because of the increasing frequency of drug resistance, the Centers for Disease Control and Prevention (CDC) recommends initial therapy with a 4-drug regimen (isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin) pending sensitivity results. Directly observed therapy is best and ensures treatment completion rates of ~90%.

Drug interactions are a special concern in patients receiving highly active antiretroviral therapy (HAART). The rifamycins accelerate the metabolism of protease inhibitors and nonnucleoside reverse transcriptase inhibitors. Rifabutin has the least effect on serum levels and is indicated in this setting.

HIV-infected patients may benefit from longer (9–12-month) treatment regimens. Treatment should be initiated with at least a 4-drug regimen consisting of isoniazid, rifabutin, pyrazinamide, and ethambutol or streptomycin. An initial 5- or 6-drug regimen may be appropriate in patients likely infected with multidrug-resistant strains. Treatment should be continued for at least 6 months after three negative cultures have been obtained. If isoniazid or rifampin cannot be used, therapy should be continued for at least 18 months (12 months after cultures become negative). Chemoprophylaxis (*see below*) should be undertaken if a patient with HIV infection has a positive tuberculin test (induration ≥ 5 mm), a history of a positive tuberculin skin test that was not treated with chemoprophylaxis, or recent close contact with a potentially infectious patient with tuberculosis. Isoniazid does not reduce the incidence of tuberculosis in anergic patients with HIV, so chemoprophylaxis in this setting has been abandoned.

THERAPY OF SPECIFIC TYPES OF TUBERCULOSIS

Therapy for drug-sensitive pulmonary tuberculosis consists of isoniazid (5 mg/kg, up to 300 mg/day), rifampin (10 mg/kg/day, up to 600 mg daily), pyrazinamide (15–30 mg/kg/day or a maximum of 2 g/day), and a fourth agent, typically either ethambutol (usual adult dose of 15 mg/kg once per day) or streptomycin (1 g daily). The streptomycin dose is reduced to 1 g twice weekly after 2 months. Pyridoxine, 15–50 mg/day, also should be included for most adults to minimize adverse reactions to isoniazid. Isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin are given for 2 months; isoniazid and rifampin are then continued for 4 more months. Doses in children are isoniazid, 10 mg/kg/day (300 mg maximum); rifampin, 10–20 mg/kg/day (600 mg maximum); pyrazinamide, 15–30 mg/kg/day (2 g maximum). Isoniazid, rifampin, and ethambutol are considered safe during pregnancy.

Clinical improvement usually is seen within the first 2 weeks of therapy. Progressive radiological improvement also is evident. Over 90% of patients who receive optimal treatment will have negative cultures within 3–6 months. Cultures that remain positive after 6 months frequently yield resistant microorganisms; the need for an alternative therapeutic program should then be considered.

Chemotherapy failure may be due to (1) irregular or inadequate therapy (resulting in persistent or resistant mycobacteria) caused by poor patient adherence to the protracted therapeutic regimen; (2) the use of a single drug, with interruption necessitated by toxicity or hypersensitivity; (3) an inadequate initial regimen; or (4) primary resistance of the microorganism.

PROBLEMS IN CHEMOTHERAPY

Bacterial Resistance to Drugs

An important problem in the chemotherapy of tuberculosis is bacterial resistance, primarily due to poor patient adherence. To prevent noncompliance and the attendant development of drug-resistant tuberculosis, directly observed therapy is advisable for most patients (i.e., a health care provider observes the patient take the medications 2–5 times weekly).

Where drug resistance is suspected (i.e., in previously treated patients), therapy should be instituted with 5 or 6 drugs, including 2 or 3 that the patient has not previously received. Such a regimen might include isoniazid, rifampin, pyrazinamide, ethambutol, streptomycin, and ethionamide. Some physicians include isoniazid in the therapeutic regimen, even if microorganisms are resistant, on the belief that disease with isoniazid-resistant mycobacteria does not “progress” during such therapy. Others discontinue isoniazid to lessen the possibility of toxicity. Therapy should be continued for at least 24 months.

Nontuberculous (Atypical) Mycobacteria

*These microorganisms (not including *M. avium* complex) frequently are resistant to many of the commonly used agents; drugs therefore should be selected based on sensitivity in vitro (Table 47–1). Surgical removal of infected tissue followed by long-term treatment with effective drugs may be needed.*

**M. kansasii* and *M. tuberculosis* cause similar disease. Therapy of the former with isoniazid, rifampin, and ethambutol has been successful. *Mycobacterium marinum* causes skin lesions. A combination of rifampin and ethambutol is probably effective; minocycline or tetracycline is active in vitro and is used by some physicians. *M. scrofulaceum* is an uncommon cause of cervical lymphadenitis that is treated with surgical excision. Microbes of the *M. fortuitum* complex (including *Mycobacterium chelonae*) may cause chronic lung disease and infections of skin and soft tissues. The microorganisms are highly resistant to most drugs, but amikacin, cefoxitin, and tetracyclines are active in vitro.*

CHEMOPROPHYLAXIS OF TUBERCULOSIS Chemoprophylaxis of tuberculosis involves treating latent infection to prevent progression to active disease. Latent infection may be

diagnosed by a positive reaction to a purified protein derivative (PPD) of tuberculosis injected intradermally (the “tuberculin test”). The CDC recommends prophylaxis with isoniazid for 6–9 months or rifampin for 4 months if isoniazid cannot be used. A 2-month regimen of daily rifampin and pyrazinamide has also been used in HIV-infected individuals.

Prophylactic therapy should be considered in patients exposed to tuberculosis who have evidence of infection, including immunosuppressed patients (*e.g.*, HIV-infected) with >5 mm induration on PPD testing; immunocompetent patients with >10 mm induration on PPD testing and risk factors for TB but no apparent disease; and those with a history of tuberculosis in whom the disease is currently “inactive.” The main risk of chemoprophylaxis is isoniazid-induced hepatitis. Monitored isoniazid prophylaxis minimizes this risk, even in patients over the age of 35.

Household contacts and other close associates of patients with tuberculosis who have negative tuberculin tests should receive isoniazid for at least 6 months after the contact has been broken, regardless of age. This is especially important for children. If the PPD test becomes positive, therapy should be continued for 12 months.

Patients with “inactive” tuberculosis who have not received adequate therapy should be considered for 1 year of isoniazid treatment. HIV-infected intravenous drug abusers with a positive PPD test have ~8% chance per year of developing active tuberculosis. Isoniazid prophylaxis in HIV-infected persons appears to be as effective as in non-immunocompromised persons. The CDC recommends that isoniazid prophylaxis be continued for 12 months. Persons infected with HIV who are exposed to multidrug-resistant tuberculosis should receive prophylaxis with rifampin and pyrazinamide (with close monitoring for hepatic toxicity) or high-dose ethambutol and pyrazinamide, with or without a fluoroquinolone.

Isoniazid prophylaxis is contraindicated for patients who have active hepatic disease or who have had reactions to the drug. In these individuals, rifampin for 4 months can be given. In pregnant women, prophylaxis usually should be delayed until after delivery. For prophylaxis, isoniazid generally is given to adults in a daily dose of 300 mg. Children should receive 10 mg/kg to a maximal daily dose of 300 mg. Pyridoxine should be coadministered in individuals susceptible to isoniazid-induced neuropathy.

II. DRUGS FOR MYCOBACTERIUM AVIUM COMPLEX

Before the advent of HAART and the use of prophylaxis, disseminated MAC infection occurred in 15–40% of patients with HIV infection; MAC infections now are greatly reduced. Patients with MAC infection usually have advanced HIV disease, with CD4 counts <100/mm³ and symptoms of fever, night sweats, weight loss, and anemia at the time of diagnosis. In non-HIV-infected persons, MAC infection usually is limited to the lungs and presents with a chronic productive cough and radiographic evidence of limited, diffuse, and/or cavitary disease. Although standard antimycobacterial drugs have little activity against MAC, newer agents with activity against MAC are used both to prevent and to treat MAC in AIDS patients.

RIFABUTIN

Rifabutin shares a common mechanism of action with rifampin (inhibition of mycobacterial RNA polymerase) but is more active *in vitro*.

ANTIBACTERIAL ACTIVITY AND BACTERIAL RESISTANCE

Rifabutin has better activity against MAC organisms than rifampin and is active in vitro against MAC bacteria isolated from HIV-infected (typically M. avium) and non-HIV-infected individuals (~40% M. intracellulare). Rifabutin also inhibits the growth of many strains of M. tuberculosis. Cross-resistance between rifampin and rifabutin is common in M. tuberculosis, although some strains are resistant to rifampin yet sensitive to rifabutin. Most M. avium strains resistant to rifampin are still sensitive to rifabutin.

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION Rifabutin is given orally, usually at 300 mg/day. Following GI absorption, it is metabolized by hepatic CYPs and eliminated in a biphasic manner with a mean terminal $t_{1/2}$ of ~45 hours, predominantly in urine and bile. Dosage adjustment is not necessary in patients with impaired renal function.

THERAPEUTIC USES Rifabutin is effective for the prevention of MAC infection in HIV-infected individuals and can decrease the frequency of MAC bacteremia. Azithromycin or clarithromycin is more effective and less likely to interact with HAART drugs. Rifabutin also is commonly substituted for rifampin in the treatment of tuberculosis in HIV-infected patients, as it has a less profound CYP-dependent drug interaction. Rifabutin also is used in combination with clarithromycin and ethambutol for the therapy of MAC disease.

UNTOWARD EFFECTS Rifabutin generally is well tolerated in persons with HIV infection; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%). Overall, neutropenia occurred in 25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses >450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms occur. Like rifampin, the drug causes an orange-tan discoloration. Rarely, thrombocytopenia, a flu-like syndrome, hemolysis, myositis, chest pain, and hepatitis have occurred.

Although less potent than rifampin, rifabutin does induce hepatic CYPs and can decrease the $t_{1/2}$ of a number of drugs, including *zidovudine*, *prednisone*, *digitoxin*, *quinidine*, *ketoconazole*, *propranolol*, *phenytoin*, *sulfonylureas*, and *warfarin*.

MACROLIDES

Clarithromycin and azithromycin are used to treat MAC and other nontuberculous mycobacteria. Clarithromycin alters the metabolism of many other drugs that are metabolized by CYPs, leading to many potential drug interactions. The broader pharmacology of these macrolides is presented in Chapter 46.

ANTIBACTERIAL ACTIVITY AND BACTERIAL RESISTANCE

Clarithromycin is approximately fourfold more active than azithromycin against MAC and is active against most nontuberculous mycobacteria. Azithromycin's lower potency may be compensated for by its greater penetration; tissue levels exceed plasma levels by 100-fold.

Use of clarithromycin or azithromycin alone is associated with the development of resistance, and they therefore should not be used as monotherapy of MAC infection.

THERAPEUTIC USES

Clarithromycin (500 mg twice daily) or azithromycin (500 mg daily) is used in combination with ethambutol, with or without rifabutin, for treatment of MAC infection. Treatment should be lifelong in HIV-infected individuals. Azithromycin has minimal effect on drugs metabolized by CYP3A4.

UNTOWARD EFFECTS

The high doses used to treat MAC infections rarely cause tinnitus, dizziness, and reversible hearing loss.

QUINOLONES

The quinolones (e.g., ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin) inhibit MAC bacteria in vitro. M. fortuitum and M. kansasii also are sensitive to these quinolones but M. chelonae usually are resistant. Single-agent therapy of M. fortuitum infection with ciprofloxacin has led to resistance. Ciprofloxacin, 750 mg twice daily or 500 mg three times daily, has been used in a 4-drug regimen (with clarithromycin, rifabutin, and amikacin) as salvage therapy for MAC infections in HIV-infected patients. Multidrug-resistant tuberculosis has been treated with ofloxacin,

300 or 800 mg/day, in combination with second-line agents. Moxifloxacin and gatifloxacin are more active than the older fluoroquinolones and would be expected to be useful agents clinically. For more on the quinolones, see Chapter 43.

AMIKACIN

Amikacin (see Chapter 45) may have a role as a third or fourth agent in a multiple-drug regimen for MAC treatment.

CHEMOTHERAPY OF MYCOBACTERIUM AVIUM COMPLEX

Clarithromycin and azithromycin both have excellent activity against many strains of MAC, with clinical responses (decrease or elimination of bacteremia, resolution of fever and night sweats) demonstrated even with single-drug therapy. To avoid resistance, most clinicians treat disseminated MAC infections with clarithromycin or azithromycin plus ethambutol. In some situations, rifabutin, clofazimine, and/or a quinolone are added. Drug interactions and adverse drug reactions are common with multiple-drug regimens, necessitating drug discontinuation in ~50% of patients. Clinical improvement is expected in the first 1–2 months of treatment, with sterilization of blood cultures within 3 months of starting therapy. Treatment of MAC infection in HIV-infected individuals typically is lifelong. Isoniazid and pyrazinamide have no role in the treatment of MAC infection.

Prophylaxis of MAC infection with clarithromycin or azithromycin should be strongly considered for HIV-infected persons whose CD4 count is <50/mm³.

III. DRUGS FOR LEPROSY

The worldwide incidence of leprosy (Hansen's disease) has plummeted by nearly 90% to ~534,000. The cornerstone of this global elimination strategy is the provision of effective multidrug chemotherapy, namely dapsone, rifampin, and clofazimine (Table 47–1), to all leprosy patients in the world. The success of the strategy is evident; by the end of 2003, over half of the countries considered endemic for leprosy in 1985 had achieved disease elimination (*i.e.*, a prevalence rate of <1 case per 10,000 inhabitants).

SULFONES

The sulfones are derivatives of 4,4'-diaminodiphenylsulfone (dapsone), all of which share certain pharmacological properties. Only dapsone and sulfoxone are considered here.

ANTIBACTERIAL ACTIVITY, MECHANISM OF ACTION, AND RESISTANCE

Because *Mycobacterium leprae* does not grow on artificial media, *in vivo* assays with rat footpads have been used to test potential therapeutic agents. Dapsone is bacteriostatic for *M. leprae* due to competitive inhibition of dihydropteroate synthase, which prevents bacterial utilization of para-aminobenzoic acid.

M. leprae may develop drug resistance during therapy, which is termed secondary resistance; this typically occurs in lepromatous (multibacillary) patients treated with a single drug. The incidence is as high as 19%. Partial-to-complete primary resistance in previously untreated patients has been described in 2.5–40% of patients, depending on geographical location.

THERAPEUTIC USES

Dapsone is given orally with a daily dose of 100 mg. Therapy usually is begun with smaller amounts, and doses are increased to those recommended over 1–2 months. Therapy should be continued for at least 3 years and may be necessary for life.

UNTOWARD EFFECTS

Hemolysis is the most common untoward reaction and develops in almost every individual treated with 200–300 mg of dapsone per day. Doses of 100 mg or less in normal healthy persons and 50 mg or less in healthy individuals with glucose-6-phosphate dehydrogenase deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after dapsone administration. While diminished red-cell survival usually occurs during the use of sulfones—presumably a dose-related effect of their oxidizing activity—hemolytic anemia is unusual unless the patient also has a disorder of either the erythrocytes or the bone marrow. The hemolysis may be so severe that manifestations of hypoxia become striking.

Anorexia, nausea, and vomiting may follow oral administration of sulfones. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy, drug fever, hematuria, pruritus, psychosis, and a variety of rashes have been reported. An

infectious mononucleosis-like syndrome occurs occasionally. The sulfones may induce an exacerbation of lepromatous leprosy by a process analogous to the Jarisch-Herxheimer reaction. This "sulfone syndrome" may develop 5–6 weeks after initiation of treatment. Its manifestations include fever, malaise, exfoliative dermatitis, jaundice with hepatic necrosis, lymphadenopathy, methemoglobinemia, and anemia.

Used properly, the sulfones may be given safely for many years in doses adequate for the successful therapy of leprosy. Treatment should be initiated with a small dose and then increased gradually. Patients must be under consistent laboratory and clinical supervision. The reactions induced by the sulfones, especially those related to the "sulfone syndrome," may require the cessation of treatment as well as the institution of specific measures to reduce the threat to life.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Dapsone is absorbed rapidly and nearly completely from the GI tract. Di-substituted sulfones (e.g., sulfoxone) are absorbed incompletely when administered orally and largely excreted in the feces. Peak concentrations of dapsone in plasma are reached within 2–8 hours after administration; the mean $t_{1/2}$ is ~20–30 hours. About 70% of the drug is bound to plasma protein.

The sulfones are distributed throughout total body water and are present in all tissues. They are retained in skin and muscle and especially in liver and kidney. The sulfones persist in the circulation for a long time because of reabsorption from the bile; periodic interruption of treatment is advisable for this reason. Dapsone is acetylated in the liver by the same enzyme that acetylates isoniazid. Daily administration of 50–100 mg results in serum levels exceeding the usual minimal inhibitory concentrations, even in rapid acetylators, in whom the serum $t_{1/2}$ of dapsone is shorter than usual.

Approximately 70–80% of a dose of dapsone is excreted in the urine as an acid-labile mono-N-glucuronide and mono-N-sulfamate.

RIFAMPIN

Rifampin is rapidly bactericidal for *M. leprae* with a minimal inhibitory concentration of <1 µg/mL. Infectivity of patients is reversed rapidly by therapy that includes rifampin.

CLOFAZIMINE

Clofazimine (LAMPRENE) binds preferentially to GC-rich mycobacterial DNA, increases mycobacterial phospholipase A_2 activity, and inhibits microbial K^+ transport. It is weakly bactericidal against *M. intracellulare*. The drug also exerts an anti-inflammatory effect and prevents the development of erythema nodosum leprosum. Clofazimine is recommended as a component of multiple-drug therapy for leprosy. It also is useful for treatment of chronic skin ulcers produced by *Mycobacterium ulcerans*.

Clofazimine is orally absorbed and accumulates in tissues. Human leprosy from which dapsone-resistant bacilli have been recovered has been treated with clofazimine with good results. However, unlike dapsone-sensitive microorganisms, in which killing occurs immediately after dapsone is administered, dapsone-resistant strains do not exhibit an appreciable effect until 50 days after initiation of therapy with clofazimine. The daily dose of clofazimine is usually 100 mg. Patients treated with clofazimine may develop red discoloration of the skin.

CHEMOTHERAPY OF LEPROSY

Leprosy is a continuum between two extremes. At one end of the spectrum is tuberculoid leprosy, characterized by skin macules with clear centers and well-defined margins. *M. leprae* is rarely found in smears made from quiescent lesions but may appear during activity. Noncaseating foci are present. The patient's cell-mediated immunity is normal, and a skin test for infection by leprosy is invariably positive. The disease is characterized by prolonged remissions with periodic reactivation.

The other extreme is the widely disseminated lepromatous form, characterized by markedly impaired cell-mediated immunity and diffuse infiltration of the skin. *M. leprae* is demonstrable in smears, and granulomas containing bacteria-laden histiocytes are present. As the disease progresses, large nerve trunks are involved and anesthesia, atrophy of skin and muscle, absorption of small bones, ulceration, and spontaneous amputations may occur.

Effective therapy heals ulcers and mucosal lesions in months. Cutaneous nodules respond more slowly, and years may be needed to eradicate bacteria from mucous membranes, skin, and nerves. The degree of residual pigmentation or depigmentation, atrophy, and scarring depends upon the extent of the initial involvement. Severe ocular lesions respond poorly to sulfones, but early treatment may prevent progression. Keratoconjunctivitis and corneal ulceration may be secondary to nerve involvement.

The WHO recommends therapy with multiple drugs for all patients with leprosy to reduce the development of resistance, provide adequate therapy when primary resistance already exists, and reduce the duration of therapy. For patients with lepromatous disease, the following regimen is suggested: dapson, 100 mg/day; plus clofazimine, 50 mg/day (unsupervised); plus rifampin, 600 mg, and clofazimine, 300 mg, once a month under supervision for 1–5 years. Some prefer to treat lepromatous leprosy with daily dapson (100 mg) and daily rifampin (450–600 mg). All drugs are given orally. The minimal duration of therapy is 2 years, and treatment should continue until acid-fast bacilli are not detected in lesions.

Patients with a small population of bacteria (i.e., with tuberculoid disease) should be treated with dapson, 100 mg daily, plus rifampin, 600 mg once monthly for a minimum of 6 months. The regimen is repeated if relapse occurs. Single-dose multidrug therapy with rifampin (600 mg), ofloxacin (400 mg), or minocycline (100 mg) also may be as effective.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

ANTIFUNGAL AGENTS

SYSTEMIC ANTIFUNGAL AGENTS

Systemic fungal infections are a major cause of death in patients whose immune system is compromised due to cancer or its chemotherapy, organ transplantation, or HIV-1 infection. Fungi also commonly cause superficial infections of the skin and other soft tissue structures. Many antifungal agents in clinical use are targeted at distinctive components of the fungal cell membrane; others alter cell wall synthesis or nucleic acid synthesis (see Figure 48–1).

Amphotericin B

Amphotericin B is the antifungal agent with the broadest spectrum of activity and remains the drug of choice for the vast majority of life-threatening systemic fungal infections. Amphotericin B is a heptaene macrolide; its amphoteric behavior results from a carboxyl group on the main ring and a primary amino group on mycosamine that confer aqueous solubility at pH extremes.

AMPHOTERICIN B

DRUG FORMULATIONS

Amphotericin B is complexed with deoxycholate (C-AMB) and marketed as a lyophilized powder (FUNGIZONE) containing 50 mg of amphotericin B that forms a colloid in water. Three lipid formulations of amphotericin B are marketed in the U.S. Amphotericin B colloidal dispersion (ABCD, AMPHOTEC, AMPHOCIL) contains equimolar amounts of amphotericin B and cholesteryl sulfate. AMBISOME is a small, unilamellar vesicle formulation that combines amphotericin B (50 mg) with 350 mg of lipid (phosphatidylcholine, cholesterol, and distearoylphosphatidylglycerol, in molar ratio of 10:5:4) in an ~10% molar ratio. Amphotericin B lipid complex (ABLC, ABELCET) contains dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol in a 7:3 mixture with ~35 mol% of amphotericin B.

The role of lipid formulations of amphotericin B in fungal infections remains to be determined. The risk of adverse effects such as nephrotoxicity is decreased by ~50% with lipid formulations, but they cost 20–50 times more and may be associated with a greater risk of febrile infusion reactions.

ANTIFUNGAL ACTIVITY

*Amphotericin B has useful clinical activity against a broad range of pathogenic fungi and against the protozoa, *Leishmania braziliensis* and *Naegleria fowleri*, but has no antibacterial activity. The antifungal activity of amphotericin B depends principally on binding the sterol ergosterol in the membrane of sensitive fungi. By virtue of interaction with sterols, amphotericin forms pores that increase membrane permeability and allow leakage of small molecules (Figure 48–1).*

ABSORPTION, DISTRIBUTION, AND EXCRETION Gastrointestinal (GI) absorption of amphotericin B is negligible and intravenous delivery is used. Amphotericin B in plasma is >90% bound to proteins. Drug elimination apparently is unchanged in anephric patients and those on hemodialysis. Hepatic or biliary disease has no known effect on drug metabolism in humans. The terminal phase of elimination has a $t_{1/2}$ of ~15 days. Concentrations of amphotericin B in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of plasma trough concentrations. Little amphotericin B penetrates into cerebrospinal fluid (CSF), vitreous humor, or amniotic fluid.

FIGURE 48–1 Mechanism of action of amphotericin, imidazoles, triazoles, and allylamines in fungi. Amphotericin B and other polyenes, such as nystatin, bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles, such as itraconazole and fluconazole, inhibit 14- α -sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of 14- α -methylsterols. The allylamines, such as naftifine and terbinafine, inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins (e.g., caspofungin) inhibit the formation of glucans in the fungal cell wall.

THERAPEUTIC USES

The usual dose of C-AMB is 0.5–0.6 mg/kg, administered in 5% glucose over 4 hours. *Candida esophagitis* in adults responds to 0.15–0.2 mg/kg daily. Rapidly progressive mucormycosis or invasive aspergillosis is treated with doses of 1–1.2 mg/kg daily until progression is arrested.

Intrathecal infusion of amphotericin B (C-AMB) is used in patients with meningitis caused by *Coccidioides*. Treatment is initiated with 0.05–0.1 mg and increased on a three-times-weekly schedule to 0.5 mg, as tolerated. Therapy is then continued on a twice-weekly schedule.

Amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of cryptococcal meningitis, severe or rapidly progressing histoplasmosis, blastomycosis, coccidioidomycosis, penicilliosis marneffeii, and in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B is given once weekly to prevent relapse in patients with AIDS who have been treated successfully for cryptococcosis or histoplasmosis.

ABCD is approved for patients with invasive aspergillosis who are not responding to or are unable to tolerate C-AMB. Ambisome is approved for empiric therapy of neutopenic patients not responding to appropriate antibacterial agents and for salvage therapy of aspergillosis, cryptococcosis, and candidiasis. ABLC is approved for salvage therapy of deep mycoses.

UNTOWARD EFFECTS

The major acute reaction to intravenous amphotericin B is fever and chills, which typically end spontaneously in ~30 minutes and often abate with subsequent infusions. Tachypnea and modest hypotension may occur, but true bronchospasm or anaphylaxis is rare. Patients with preexisting cardiac or lung disease may become hypotensive or hypoxic. Pretreatment with oral acetaminophen or intravenous glucocorticoids decreases reactions, while meperidine may shorten the duration of established reactions.

Transient azotemia occurs in 80% of patients who receive C-AMB for deep mycoses. Toxicity is dose-dependent and increased by concurrent therapy with other nephrotoxic agents (e.g., aminoglycosides, cyclosporine). Permanent impairment is uncommon in adults with normal renal function unless the cumulative dose is >3–4 g. Renal tubular acidosis and wasting of K^+ and Mg^{2+} also may occur during and for several weeks after therapy, often requiring repletion. Administration of 1 L of normal saline intravenously prior to C-AMB administration is recommended for adults who can tolerate the Na^+ load. Azotemia occurs less frequently with lipid preparations of amphotericin, and saline loading is not needed.

Hypochromic, normocytic anemia is usual with C-AMB and reverses slowly following cessation of therapy. It likely reflects decreased production of erythropoietin and often responds to

erythropoietin. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common.

Arachnoiditis, manifested by fever and headache, can occur with intrathecal injection of C-AMB; it may be decreased by intrathecal administration of 10–15 mg of hydrocortisone. Other serious problems that attend the use of intrathecal injections depend on the injection site. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain.

Flucytosine

Flucytosine is an antimetabolite whose spectrum of antifungal activity is considerably more restricted than that of amphotericin B. Flucytosine is a fluorinated pyrimidine:

FLUCYTOSINE

ANTIFUNGAL ACTIVITY

Susceptible fungi deaminate flucytosine to 5-fluorouracil, a potent antimetabolite (Figure 48–2). Fluorouracil is metabolized to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase). 5-FUMP then is either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase that thus inhibits DNA synthesis. The selective action of flucytosine is due to the relatively low level of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

Resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis; it can result from loss of the permease necessary for cytosine transport or decreased activity of UPRTase or cytosine deaminase (Figure 48–2).

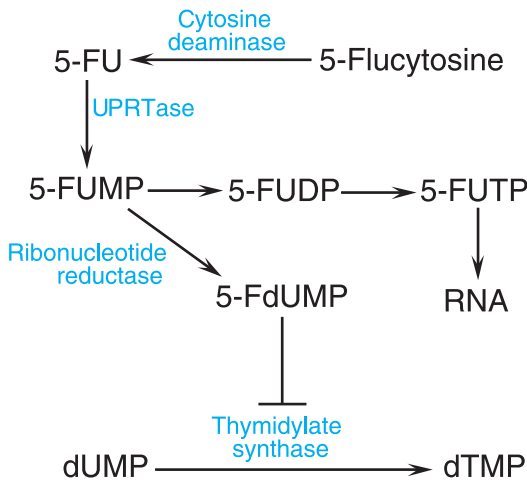

FIGURE 48–2 Action of flucytosine in fungi. 5-Flucytosine is transported by cytosine permease into the fungal cell, where it is deaminated to 5-fluorouracil (5-FU). The 5-FU is then converted to 5-fluorouracil-ribose monophosphate (5-FUMP) and then is either converted to 5-fluorouridine triphosphate (5-FUTP) and incorporated into RNA or converted by ribonucleotide reductase to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), which is a potent inhibitor of thymidylate synthase. 5-FUDP, 5-fluorouridine-5'-diphosphate; dUMP, deoxyuridine-5'-monophosphate; dTMP, deoxyuridine-5'-monophosphate UPRTase, uracil phosphoribosyl transferase.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Flucytosine is absorbed rapidly and well from the GI tract, widely distributed, and minimally bound to plasma proteins. Flucytosine concentration in CSF is 65–90% of that found simultaneously in plasma. Approximately 80% of a dose is excreted unchanged in the urine. The $t_{1/2}$ of the drug normally is 3–6 hours but may reach 200 hours in renal failure. Dose modification is necessary in patients with decreased renal function, and plasma concentrations should be measured periodically to maintain peak concentrations of 50–100 $\mu\text{g/mL}$. Flucytosine is cleared by hemodialysis, and patients should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

THERAPEUTIC USES

Flucytosine (ANCOBON) is clinically useful for *Cryptococcus neoformans*, *Candida* spp., and *chromoblastomycosis*. It is given orally at 100 mg/kg/day, in divided doses at 6-hour intervals and is used predominantly in combination with amphotericin B. An all-oral regimen of flucytosine plus fluconazole has been advocated for therapy of AIDS patients with cryptococcosis, but the combination has substantial GI toxicity without evidence that flucytosine improves the outcome. The combination of flucytosine with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward if amphotericin B–induced azotemia occurs. It is common practice in HIV-negative patients with cryptococcal meningitis to begin with C-AMB or AMBISOME plus flucytosine and change to fluconazole after the patient has improved.

UNTOWARD EFFECTS Flucytosine may cause leukopenia and thrombocytopenia. Rash, nausea, vomiting, diarrhea, and enterocolitis also have been noted. In ~5% of patients, hepatic transaminases are elevated, but this reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia or when plasma drug concentrations are >100 $\mu\text{g/mL}$.

Imidazoles and Triazoles

The azole antifungals include the imidazoles and triazoles. These drugs have the same spectrum of antifungal activity and share a common mechanism by inhibiting fungal CYPs that are essential for ergosterol biosynthesis (Figure 48–1). Of the drugs available in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, and sulconazole are imidazoles; terconazole, itraconazole, fluconazole, and voriconazole are triazoles.

ANTIFUNGAL ACTIVITY Azoles are active against *C. albicans*, *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, *C. neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides* species, *Paracoccidioides brasiliensis*, and dermatophytes. *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *C. krusei* and the agents of mucormycosis are resistant.

Azoles inhibit 14- α -sterol demethylase, a microsomal CYP that is essential for ergosterol biosynthesis (Figure 48–1). This results in the accumulation of 14- α -methylsterols that disrupt the packing of acyl chains of phospholipids and impair the functions of membrane-bound enzymes such as ATPase and those of the electron transport system, resulting in inhibited fungal growth.

Azole resistance has caused clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary mechanism of resistance in C. albicans is accumulation of mutations in the gene encoding 14- α -sterol demethylase; cross-resistance to all azoles results.

Ketoconazole

Ketoconazole has been replaced by itraconazole for the treatment of all mycoses except when cost is the primary determinant. Itraconazole lacks ketoconazole's corticosteroid suppression, while retaining most of its properties and expanding the antifungal spectrum.

Itraconazole

This synthetic triazole is an equimolar racemic mixture of four diastereoisomers.

ITRACONAZOLE

ABSORPTION, DISTRIBUTION, AND EXCRETION Itraconazole (SPORONOX) is available as a capsule and solutions for oral or intravenous administration. The capsule is better absorbed with food, but the oral solution is better absorbed in the fasting state and provides peak plasma concentrations that are >150% of those obtained with the capsule. Both the oral solution and intravenous formulations are solubilized in a 40:1 weight ratio of itraconazole:hydroxypropyl- β -cyclodextrin. Itraconazole and its active metabolite hydroxy-itraconazole are >99% bound to plasma proteins and neither appears in urine or CSF. The $t_{1/2}$ of itraconazole is ~30 hours; steady-state levels are not reached for 4 days (7 days for hydroxy-itraconazole); thus, loading doses are used when treating deep mycoses. Severe liver disease increases itraconazole plasma concentrations. Itraconazole should not be used for onychomycosis during pregnancy or in women contemplating pregnancy (category C).

THERAPEUTIC USES

Oral itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to B. dermatitidis, H. capsulatum, P. brasiliensis, and C. immitis and also is useful for indolent invasive aspergillosis outside the CNS, particularly following initial therapy with amphotericin B. The intravenous formulation is approved for the initial 2 weeks of therapy with blastomycosis, histoplasmosis, and indolent aspergillosis, and for empirical therapy of febrile neutropenic patients not responding to antibiotics and at high risk of fungal infections. The intravenous route is most appropriate for patients unable to tolerate oral drug or unable to absorb itraconazole because of decreased gastric acidity. Approximately half the patients with distal subungual onychomycosis respond to itraconazole. Although not approved, itraconazole is a reasonable choice for pseudallescheriasis, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or Penicillium marneffei infections have a decreased incidence of relapse if given prolonged itraconazole "maintenance" therapy; it is unclear whether patients responding to highly active antiretroviral therapy (HAART) will require less than lifelong therapy. Because of frequent relapses, itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients. Long-term therapy has provided clinical improvement in non-HIV-infected patients with allergic bronchopulmonary aspergillosis.

Itraconazole solution is approved for oropharyngeal and esophageal candidiasis. Because of its GI side effects (see below), itraconazole solution usually is reserved for patients not responding to fluconazole who are not receiving protease inhibitors or other drugs that preclude its use. Itraconazole capsules and oral solution are not bioequivalent and should not be used interchangeably.

UNTOWARD EFFECTS

Itraconazole and other azoles can interact with many drugs by virtue of their effects on CYP3A4 (Table 48-1); these interactions can cause serious toxicity from the companion drug, including fatal cardiac arrhythmias, and may decrease itraconazole concentrations below therapeutic levels.

Itraconazole rarely has led to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. Itraconazole can lead to congestive heart failure in patients with impaired ventricular function. In the absence of interacting drugs, itraconazole capsules are well tolerated at 200 mg daily. GI distress occasionally prevents use of 400 mg/day. In patients receiving 50–400 mg/day, nausea and vomiting, hypertriglyceridemia, hypokalemia, elevated serum aminotransferases, and rash occurred in between 2–10% of patients. Occasionally, rash necessitates drug discontinuation, but most other adverse effects

Table 48-1

Interactions of Itraconazole and other Triazoles with Other Drugs

Other Drug Concentration Increased	Itraconazole Concentration Decreased
Alfentanil	Drugs that decrease gastric acidity
Alprazolam	H ₂ -receptor blockers
Amprenavir	Proton pump blockers
Atorvastatin	Simultaneous antacids (includes didanosine buffer)
Buspirone	Carbamazepine
Busulfan	Isoniazid
Cisapride	Nevirapine
Cyclophosphamide	Phenobarbital
Cyclosporine	Phenytoin
Delavirdine	Rifampin, rifabutin
Diazepam	St. John's wort
Digoxin	Itraconazole Concentration Increased
Dihydropyridine Ca ²⁺ channel blockers	Amprenavir
Docetaxel	Amprenavir
Felodipine	Clarithromycin
Haloperidol	Grapefruit juice
Indinavir	Indinavir
Loratidine	Lopinavir
Lovastatin	Ritonavir
Methylprednisolone	
Midazolam	
Nisoldipine	
Phenytoin	
Pimozide	
Quinidine	
Ritonavir	
Saquinavir	
Sildenafil	
Simvastatin	
Sirolimus	
Sulfonylureas (glyburide, others)	
Tacrolimus	
Triazolam	
Trimetrexate	
Verapamil	
Vinca alkaloids (vincristine, vinblastine)	
Warfarin	

can be handled with dose reduction. Doses of 300 mg twice daily have led to adrenal insufficiency, lower limb edema, hypertension, and rhabdomyolysis; therefore, doses above 400 mg/day are not recommended for long-term use.

Relative to capsules, the oral solution of itraconazole more frequently causes diarrhea, abdominal cramps, anorexia, and nausea. GI side effects are common, but adherence generally is unimpaired. Anaphylaxis and severe rash have rarely occurred.

Intravenous itraconazole has all the adverse effects of capsules but generally is well tolerated. Due to chemical phlebitis, a dedicated catheter port is required, and infusion durations <1 hour are not recommended. The intravenous formulation is contraindicated in patients with a creatinine clearance <30 mL/min.

DOSAGE For deep mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for 3 days. Thereafter, two 100-mg capsules are given twice daily with food. Divided

doses allegedly increase the plasma AUC. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or with pulse therapy (200 mg twice daily for 1 week out of each month). A loading dose of itraconazole is given as a 200-mg intravenous infusion over 1 hour twice daily for 2 days, followed by 200 mg once daily for 12 days. Itraconazole oral solution should be taken fasting in a dose of 100 mg once daily and swished vigorously in the mouth before swallowing to optimize topical effect. Patients with oropharyngeal or esophageal candidiasis are given 100 mg of the solution twice a day for 2–4 weeks.

Fluconazole

Fluconazole is a fluorinated bistriazole.

FLUCONAZOLE

ABSORPTION, DISTRIBUTION, AND EXCRETION Fluconazole is almost completely absorbed from the GI tract irrespective of food or gastric acidity. Only 10% of drug in circulation is protein bound. Renal excretion accounts for >90% of elimination, with a $t_{1/2}$ of ~25 hours. Fluconazole readily diffuses into body fluids, including breast milk, sputum, saliva, and CSF. The dosage interval should be increased from 24–48 hours for a creatinine clearance of 21–40 mL/min and to 72 hours at 10–20 mL/min. In renal failure, a dose of 100–200 mg is given after hemodialysis.

DRUG INTERACTIONS

Fluconazole inhibits CYP3A4 and CYP2C9 and thus significantly increases plasma concentrations of amprenavir, cisapride, cyclosporine, phenytoin, sulfonyleureas, tacrolimus, theophylline, telithromycin, and warfarin. Patients receiving >400 mg daily or azotemic patients may experience additional drug interactions. Rifampin decreases the fluconazole AUC by ~25%.

THERAPEUTIC USES

Candidiasis

Fluconazole, 200 mg on the first day and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Esophageal candidiasis responds to 100–200 mg/day, which also is used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of immunocompetent patients. Fluconazole is not proven to be effective treatment for deep candidiasis in profoundly neutropenic patients.

Cryptococcosis

Fluconazole, 400 mg/day, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient has been stabilized with intravenous amphotericin B. Thereafter, the dose is decreased to 200 mg daily and continued indefinitely. If the patient responds to HAART, maintains a CD4 count >200/mm³ for at least 6 months, and has no meningeal symptoms, it is reasonable to discontinue fluconazole as long as the CD4 count is maintained and CSF culture and cryptococcal antigen are negative. For AIDS patients with cryptococcal meningitis and favorable prognostic signs, initial therapy with 400 mg daily may be considered. Fluconazole 400 mg/day has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or AMBISOME and for patients with pulmonary cryptococcosis.

Other Mycoses

Fluconazole is the drug of choice for coccidioidal meningitis and is comparable to itraconazole for other forms of coccidioidomycosis. Fluconazole is less active than itraconazole against

histoplasmosis, blastomycosis, sporotrichosis, and ringworm and neither prevents nor treats aspergillosis or mucormycosis.

UNTOWARD EFFECTS

Nausea and vomiting may occur at doses >200 mg/day; patients receiving 800 mg daily may require parenteral antiemetics. Regardless of dose, side effects in patients receiving >7 days of drug include nausea, headache, skin rash, vomiting, abdominal pain, and diarrhea (all at 1–4%). Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare deaths due to hepatic failure or Stevens-Johnson syndrome have occurred. Fluconazole is associated with skeletal and cardiac deformities in infants born to women taking high doses during pregnancy and should be avoided during pregnancy (category C).

DOSAGE

Fluconazole (DIFLUCAN, others) is marketed as tablets for oral administration, powder for oral suspension, and intravenous solutions containing 2 mg/mL. Dosage is 50–800 mg once daily for oral or intravenous administration. Children are treated with 3–6 mg/kg once daily.

Voriconazole

Voriconazole (VFEND; UK-109,495) is a triazole that is similar to fluconazole but has increased activity and an expanded spectrum.

VORICONAZOLE

ABSORPTION, DISTRIBUTION, AND EXCRETION

Oral bioavailability is nearly complete, and gastric acid is not necessary for absorption. The volume of distribution is high (4.6 L/kg), with extensive tissue distribution; metabolism is by hepatic CYPs, especially 2C19. Less than 2% of native drug but most of the inactive metabolites are secreted in the urine. The oral dose is not adjusted for azotemia or hemodialysis.

Plasma elimination $t_{1/2}$ is 6 hours. Voriconazole exhibits nonlinear kinetics, and higher doses disproportionately increase drug exposure. Genetic polymorphisms in CYP2C19 can cause up to a fourfold difference in drug exposure; ~20% of Asians are poor metabolizers compared to 2% of Caucasians and African Americans. Drug exposure is increased considerably in the elderly and in patients with mild or moderate hepatic insufficiency. Patients with hepatic cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose.

The intravenous formulation of voriconazole contains sulfobutyl ether β -cyclodextrin (SBECD), which is excreted by the kidney. Accumulation of SBECD occurs with a creatinine clearance <50 mL/min; in that setting, oral voriconazole is preferred.

DRUG INTERACTIONS

In decreasing rank order, voriconazole is metabolized by, and inhibits, CYP2C19, CYP2C9, and CYP3A4, as does its major metabolite, voriconazole N-oxide. Inhibitors or inducers of these enzymes may increase or decrease voriconazole plasma concentrations, respectively, while voriconazole may increase the plasma concentrations of other drugs metabolized by these enzymes.

Coadministration with rifampin, rifabutin, or ritonavir is contraindicated because of accelerated voriconazole metabolism. Efavirenz and perhaps other nonnucleoside reverse transcriptase inhibitors (NNRTIs) significantly increase voriconazole metabolism and slow the metabolism of the NNRTI. When given with phenytoin, the voriconazole dose should be doubled. Drugs that significantly accumulate in patients receiving voriconazole include cyclosporine,

tacrolimus, phenytoin, rifabutin, warfarin, and sirolimus. Because the sirolimus AUC increases 11-fold when voriconazole is given, coadministration is contraindicated. Omeprazole dose should be reduced by half if 40 mg or more per day is given. Until more experience with voriconazole is gained, it is prudent to be observant for drug interactions that occur with other azoles (Table 48–1).

THERAPEUTIC USES

Voriconazole is superior to C-AMB as primary therapy of invasive aspergillosis. Although not approved, voriconazole has been used for the empirical therapy of neutropenic patients whose fever did not respond to antibacterial therapy. Voriconazole is approved for use in esophageal candidiasis and as salvage therapy in patients with *P. boydii* and *Fusarium* infections.

UNTOWARD EFFECTS

Although the drug is generally well tolerated, hepatotoxicity has been reported and liver function should be monitored. Voriconazole can prolong the QTc interval, which can be significant in patients with other risk factors for torsades de pointes. Approximately 30% of patients note transient visual changes (e.g., blurred vision, altered color perception, and photophobia) beginning about half an hour after administration and lasting for another half hour. Activities that require keen vision should be avoided, but no sequelae occur. Uncommonly, confusion or transient visual hallucinations occur. Patients receiving their first intravenous infusion have had anaphylactoid reactions requiring drug discontinuation. Rash occurs in 6% of patients. Voriconazole is teratogenic in animals and should not be used in pregnancy (category D).

DOSAGE

Treatment usually is initiated with 6 mg/kg every 12 hours for two doses, followed by 4 mg/kg every 12 hours, administered at 3 mg/kg/hour. As the patient improves, oral administration is continued at 200 mg every 12 hours. Patients failing to respond may be given 300 mg every 12 hours. Oral drug should be given either 1 hour before or 1 hour after meals.

Echinocandins

Echinocandins inhibit formation of $\beta(1,3)D$ -glucans in the cell wall of *Candida* and caspofungin is approved for clinical use. Susceptible fungi include *Candida* and *Aspergillus* species. Resistance can be conferred in *C. albicans* by mutation in one of the genes that encodes $\beta(1,3)D$ -glucan synthase. Azole-resistant isolates of *C. albicans* remain susceptible to echinocandins.

CASPOFUNGIN

Caspofungin (cancidas, MK-0991) is a water-soluble, lipopeptide synthesized from a fermentation product called pneumocandin Bo. In susceptible yeasts, caspofungin causes lysis.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Caspofungin is not absorbed orally. After intravenous injection, caspofungin is eliminated from the bloodstream with a $t_{1/2}$ of ~10 hours. Catabolism is largely by hydrolysis and N-acetylation, followed by excretion in urine and feces. Mild or moderate hepatic insufficiency increases the AUC by 55% and 76%, respectively. About 97% of serum drug is bound to albumin. Dose adjustment is unnecessary for renal insufficiency or hemodialysis.

THERAPEUTIC USE

Caspofungin is approved for patients with invasive aspergillosis who are failing or intolerant of drugs such as amphotericin B or voriconazole and for esophageal candidiasis. A clinical trial of caspofungin in deeply invasive candidiasis found noninferiority to C-AMB, leading to approval for that indication. Caspofungin also is approved to treat persistently febrile neutropenic patients with suspected fungal infections.

UNTOWARD EFFECTS

Caspofungin is well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have occurred with rapid infusions. Other effects are comparable to those in patients receiving fluconazole.

DOSAGE

Caspofungin is administered intravenously once daily over 1 hour. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose may be increased to 70 mg daily in patients failing to respond. Esophageal candidiasis is treated with 50 mg daily.

Griseofulvin

ANTIFUNGAL ACTIVITY

Griseofulvin is fungistatic in vitro for various species of the dermatophytes.

MECHANISM OF ACTION

Griseofulvin inhibits fungal mitosis, presumably disrupting the mitotic spindle by interacting with polymerized microtubules. Griseofulvin also may bind to a microtubule-associated protein.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Micronized and ultramicronized powders are used to facilitate dissolution (FULVICIN U/F and GRIS-PEG, respectively). Griseofulvin has a $t_{1/2}$ in plasma of ~1 day. The primary metabolite is 6-methylgriseofulvin.

Griseofulvin is deposited in keratin precursor cells and persists in keratin to provide prolonged resistance to fungi. The new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum within 4–8 hours of oral administration. Sweat and transepidermal fluid loss play important roles in drug transfer to the stratum corneum. Only a very small fraction of the drug is present in body fluids and tissues.

THERAPEUTIC USES

*Readily treatable mycotic infections include those of the hair (tinea capitis) caused by *Microsporum canis*, *M. audouinii*, *Trichophyton schoenleinii*, and *T. verrucosum*; “ringworm” of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *T. rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *T. mentagrophytes*) and beard (*Trichophyton* species). Griseofulvin also is effective in “athlete’s foot” or epidermophytosis involving the skin and nails, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum*. Topical therapy is preferred. *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses. Since very high doses of griseofulvin are carcinogenic and teratogenic in animals, it should not be used systemically to treat trivial infections that respond to topical therapy. Griseofulvin is not effective in treatment of subcutaneous or deep mycoses.*

DOSAGE

The recommended daily dose of griseofulvin is 5–15 mg/kg for children and 0.5–1 g for adults. Doses of 1.5–2 g daily may be used for short periods in severe infections. Best results are obtained when the daily dose is divided and given at 6-hour intervals, although the drug often is given twice per day. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6–9 months for fingernails, and at least a year for toenails.

UNTOWARD EFFECTS

Frequent adverse effects include headache (~15% of patients), GI symptoms (e.g., nausea, vomiting, diarrhea, heartburn, flatulence), and rash. More serious reactions include hepatotoxicity, serum sickness reaction, angioedema, and hematologic effects (e.g., leukopenia, neutropenia, punctate basophilia, and monocytosis). Blood studies should be checked weekly during treatment. Estrogen-like effects have been observed in children.

Griseofulvin induces hepatic CYPs and increases metabolism of warfarin, sometimes necessitating dose adjustment; it also may reduce the efficacy of low-estrogen oral contraceptive agents.

Terbinafine

Terbinafine is a synthetic allylamine that is structurally similar to naftifine. It probably acts by inhibiting fungal squalene epoxidase and blocking ergosterol biosynthesis. Terbinafine is well absorbed, but bioavailability is only 40% because of first-pass hepatic metabolism. Proteins bind

>99% of the drug in plasma. The drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ of 12 hours extends to 200–400 hours at steady state, and the drug can be found in plasma for weeks after prolonged therapy. Terbinafine is not recommended in patients with marked renal or hepatic failure. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Rarely, hepatotoxicity, severe neutropenia, or toxic epidermal necrolysis may occur. Systemic terbinafine therapy for onychomycosis should be postponed during pregnancy.

Terbinafine (LAMISIL), given as one 250-mg tablet daily, is at least as effective for nail onychomycosis as 200 mg daily of itraconazole, and slightly more effective than pulse itraconazole therapy. Treatment typically is for 3 months. Although not approved for this use, terbinafine (250 mg daily) also is effective in ringworm elsewhere on the body.

TOPICAL ANTIFUNGAL AGENTS

Topical treatment is useful in many superficial fungal infections—*i.e.*, those confined to the stratum corneum, squamous mucosa, or cornea, including dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Topical administration usually is unsuccessful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. The efficacy of topical agents depends not only on the type of lesion and the mechanism of drug action, but also on the viscosity, hydrophobicity, and acidity of the formulation. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin may be a useful adjunct to therapy.

A plethora of topical agents is available for the treatment of superficial mycoses, the preferred formulations of which usually are creams or solutions. Powders, whether applied by shake containers or aerosols, largely are used for the feet and moist lesions of the groin and other intertriginous areas.

Imidazoles and Triazoles for Topical Use

Indications for topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm. Agents for topical use should be selected based on cost and availability.

CUTANEOUS APPLICATION

The preparations for cutaneous use are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They are applied twice daily for 3–6 weeks.

VAGINAL APPLICATION

Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once daily for 1–7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher doses. These preparations are administered for 3–7 days. Approximately 3–10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no teratogenic effects in humans have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile irritation. Cross-allergenicity among these compounds is presumed to exist.

ORAL USE

Use of the oral troche of clotrimazole is properly viewed as topical therapy. The only indication for the 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to local drug action.

Clotrimazole

CLOTRIMAZOLE

Absorption of clotrimazole is <0.5% after application to intact skin; from the vagina, it is 3–10%. Fungicidal concentrations remain in the vagina for up to 3 days after drug application. The small amount absorbed is metabolized in the liver and excreted in bile.

Cutaneous clotrimazole occasionally may cause stinging, erythema, edema, vesication, desquamation, pruritus, and urticaria. When it is applied to the vagina, ~1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. The sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause GI irritation. In patients using troches, the incidence of this side effect is ~5%.

THERAPEUTIC USES

Clotrimazole is available as a 1% cream, lotion, and solution (LOTTRIMIN, MYCELEX, others), 1% or 2% vaginal cream or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTTRIMIN, MYCELEX-G, others), and 10-mg troches (MYCELEX, others). For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For nonpregnant females, one 200-mg tablet may be used once a day for 3 days. Troches are to be dissolved slowly in the mouth five times a day for 14 days.

Clotrimazole cures dermatophyte infections in 60–100% of cases. Cure rates in cutaneous candidiasis are 80–100%. In vulvovaginal candidiasis, the cure rate is usually >80% with the 7-day regimen. A 3-day regimen of 200 mg once a day is similarly effective as is single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may approach 100% in the immunocompetent host.

Econazole

Econazole is the deschloro derivative of miconazole. Econazole readily penetrates the stratum corneum and achieves effective concentrations down to the mid-dermis. Less than 1% of an applied dose is absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching. Econazole nitrate (SPECTAZOLE, others) is available as a water-miscible cream (1%) to be applied twice a day.

Miconazole

Miconazole is a close chemical congener of econazole with the following structure:

Miconazole readily penetrates the stratum corneum and persists there for >4 days after application. Less than 1% is absorbed into the blood. Systemic absorption from the vagina is <1.3%. Adverse effects from vaginal application include burning, itching, or irritation in ~7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy.

THERAPEUTIC USES

Miconazole nitrate is available as an ointment, cream, solution, spray, or powder (MICATIN, MONISTAT-DERM, others). To avoid maceration, only the lotion should be applied to intertriginous areas. It is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (MONISTAT 7, MONISTAT 3, others), to be applied at bedtime for 7, 3, or 1 day(s), respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate is >90%. In the treatment of vulvovaginal candidiasis, the cure rate after 1 month is ~80–95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *C. glabrata* also respond.

hydrochloride (NAFTIN) is available as a 1% cream or gel. Applied twice daily, it is effective for the topical treatment of tinea cruris and tinea corporis. The drug is well tolerated, although local irritation and contact dermatitis have occurred. Naftifine also may be efficacious off label for cutaneous candidiasis and tinea versicolor.

Terbinafine

Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *M. furfur*, but the cream also can be used in cutaneous candidiasis and tinea versicolor. Oral terbinafine apparently is effective in treatment of ringworm and in some cases of onychomycosis.

Butenafine

Butenafine hydrochloride (MENTAX) is a benzylamine derivative with a mechanism of action and spectrum of antifungal activity similar to those of terbinafine, naftifine, and other allylamines.

Polyene Antifungal Antibiotics

NYSTATIN

Nystatin is a tetraene macrolide that is structurally similar to amphotericin B and has the same mechanism of action. Nystatin is not absorbed from the GI tract, skin, or vagina.

Nystatin (MYCOSTATIN, NILSTAT, others) is used only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Topical preparations include ointments, creams, and powders, each containing 100,000 units per gram. Powders are preferred for moist lesions and are applied two or three times a day. Imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis.

An oral suspension that contains 100,000 units per mL of nystatin is given four times a day. Premature and low-birth-weight neonates should receive 1 mL of this preparation, infants 2 mL, and children or adults 4–6 mL per dose. Older children and adults should be instructed to swish the drug around the mouth and then swallow. Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon. A 200,000-unit troche (mycostatin pastilles) is available for the treatment of oral candidiasis, and a 500,000-unit oral tablet is sold for the treatment of nonesophageal membrane GI candidiasis.

AMPHOTERICIN B

Topical amphotericin B (FUNGIZONE) also is used for cutaneous candidiasis. A lotion, cream, and ointment are marketed that contain 3% amphotericin B and are applied to the lesion 2–4 times daily.

Miscellaneous Antifungal Agents

UNDECYLENIC ACID

Undecylenic acid is 10-undecenoic acid. The drug is fungistatic against a variety of fungi, including those that cause ringworm. Undecylenic acid (DESENE, others) is available in a foam, ointment, cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compound undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate (CALDESENE, CRUEX) is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compound ointment, may be applied to the skin. The preparations usually are not irritating to tissue, and sensitization is uncommon. In tinea pedis, the infection frequently persists despite intensive treatment and the clinical “cure” rate is at best ~50%. Other agents therefore are preferred. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatological conditions.

ANTIVIRAL AGENTS (NONRETROVIRAL)

Viruses are obligate intracellular parasites that contain either double- or single-stranded DNA or RNA enclosed in a protein coat called a *capsid*. Some viruses also possess a lipid envelope that, like the capsid, may contain antigenic glycoproteins. Most viruses contain or encode enzymes essential for viral replication inside a host cell, and they usurp the metabolic machinery of their host cell. Table 49–1 outlines the stages of viral replication and the classes of antiviral agents that act at each stage of replication. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit virus-directed rather than host cell-directed nucleic acid or protein synthesis.

Figure 49–1 provides a schematic diagram of the replicative cycle of a DNA virus (A) and an RNA virus (B). DNA viruses include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes), adenoviruses (conjunctivitis, sore throat), hepadnaviruses (hepatitis B virus [HBV]), and papillomaviruses (warts). Typically, DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into messenger RNA (mRNA) by host cell polymerase and mRNA is translated into virus-specific proteins.

For RNA viruses, replication in the host cell relies either on enzymes in the virion (the whole infective viral particle) to synthesize its mRNA or on the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA (Figure 49–1B). Most RNA viruses complete their replication in the cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. RNA viruses include rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (poliomyelitis, meningitis, colds, hepatitis A), arenaviruses (meningitis, Lassa fever), flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C), orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), and coronaviruses (colds, severe acute respiratory syndrome [SARS]).

Retroviruses are RNA viruses that cause diseases such as acquired immunodeficiency syndrome (AIDS) (see Chapter 50) and T-cell leukemias (human T-cell lymphotropic virus I [HTLV-I]). They contain a reverse transcriptase that makes a DNA copy of the viral RNA template. The DNA copy integrates into the host genome, at which point it is referred to as a *provirus* and is transcribed into both genomic RNA and mRNA for translation into viral proteins. The polymerase of hepadnaviruses possesses reverse transcriptase activity.

Although many compounds show antiviral activity *in vitro*, most affect some host cell function and are associated with unacceptable toxicity. Effective agents typically have a restricted spectrum of antiviral activity and target a specific viral protein, most often an enzyme involved in viral nucleic acid synthesis (polymerase or transcriptase) or a viral processing protein (protease). Single-nucleotide changes leading to critical amino acid substitutions in a target protein often can cause resistance to antiviral drugs. Most agents inhibit active replication, so viral replication may resume following drug removal, and effective host immune responses are essential for recovery from infection. Clinical failures of antiviral therapy may occur with drug-sensitive virus in immunocompromised patients or following emergence of resistant variants. Most drug-resistant viruses are recovered from immunocompromised patients or those with chronic infections (e.g., HBV) with high viral loads and repeated or prolonged courses of antiviral treatment. Antiviral agents do not eliminate nonreplicating or latent virus, although some drugs are used effectively for chronic suppression of disease reactivation. Clinical efficacy requires inhibitory concentrations at the site of infection, usually within infected cells. For example, nucleoside analogs must be taken up and phosphorylated intracellularly for activity; consequently, concentrations of critical enzymes or competing substrates influence antiviral effects in cells of different types and in different metabolic states. *In vitro* sensitivity tests for antiviral agents generally are not standardized, and results depend on the assay system, cell type, viral inoculum, and laboratory. Therefore, clear relationships among drug concentrations active *in vitro*, those achieved in blood or other body fluids, and clinical response are not established for most agents.

Table 49–2 summarizes currently approved antiviral drugs.

ANTIHERPESVIRUS AGENTS

Herpes simplex virus type 1 (HSV-1) typically causes diseases of the mouth, face, skin, esophagus, or brain. Herpes simplex virus type 2 (HSV-2) usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates.

Table 49–1

Stages of Virus Replication and Possible Targets of Action of Antiviral Agents

Stage of Replication	Classes of Selective Inhibitors
<i>Cell entry</i>	
Attachment	Soluble receptor decoys, antireceptor antibodies,
Penetration	fusion protein inhibitors
<i>Uncoating</i>	Ion channel blockers, capsid stabilizers
Release of viral genome	
<i>Transcription of viral genome*</i>	
Transcription of viral messenger RNA	Inhibitors of viral DNA polymerase, RNA poly-
Replication of viral genome	merase, reverse transcriptase, helicase, primase,
<i>Translation of viral proteins</i>	or integrase
Regulatory proteins (early)	Interferons, antisense oligonucleotides, ribozymes
Structural proteins (late)	Inhibitors of regulatory proteins
<i>Posttranslational modifications</i>	
Proteolytic cleavage	Protease inhibitors
Myristoylation, glycosylation	
<i>Assembly of virion components</i>	Interferons, assembly protein inhibitors
<i>Release</i>	Neuraminidase inhibitors, antiviral antibodies,
Budding, cell lysis	cytotoxic lymphocytes

*Depends on specific replication strategy of virus, but virus-specified enzyme required for part of process.

Acyclovir is the prototype of antiviral agents that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis (Figure 49–2). Related agents include *peniclovir* and *ganciclovir*.

Acyclovir and Valacyclovir

CHEMISTRY AND ANTIVIRAL ACTIVITY Acyclovir is an acyclic guanine nucleoside analog that lacks a 3'-hydroxyl on the side chain. *Valacyclovir* is the L-valyl ester prodrug of acyclovir.

Acyclovir's clinical use is limited to herpesviruses. Acyclovir is most active against HSV-1, approximately half as active against HSV-2, a tenth as potent against varicella-zoster virus (VZV) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) and human herpesvirus (HHV-6). Uninfected mammalian cells generally are unaffected by high acyclovir concentrations.

MECHANISMS OF ACTION AND RESISTANCE Acyclovir's selective inhibition of viral DNA synthesis depends on interaction with two distinct viral proteins: HSV thymidine kinase (TK) and DNA polymerase (Figure 49–2). Cellular uptake and initial phosphorylation are facilitated by TK. The affinity of acyclovir for HSV TK is ~200 times greater than for the host enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which is present in 40- to 100-fold higher concentrations in HSV-infected than in uninfected cells and competes for endogenous deoxyguanosine triphosphate (dGTP). Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much smaller extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because it lacks a 3' α -hydroxyl group. By *suicide inactivation*, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

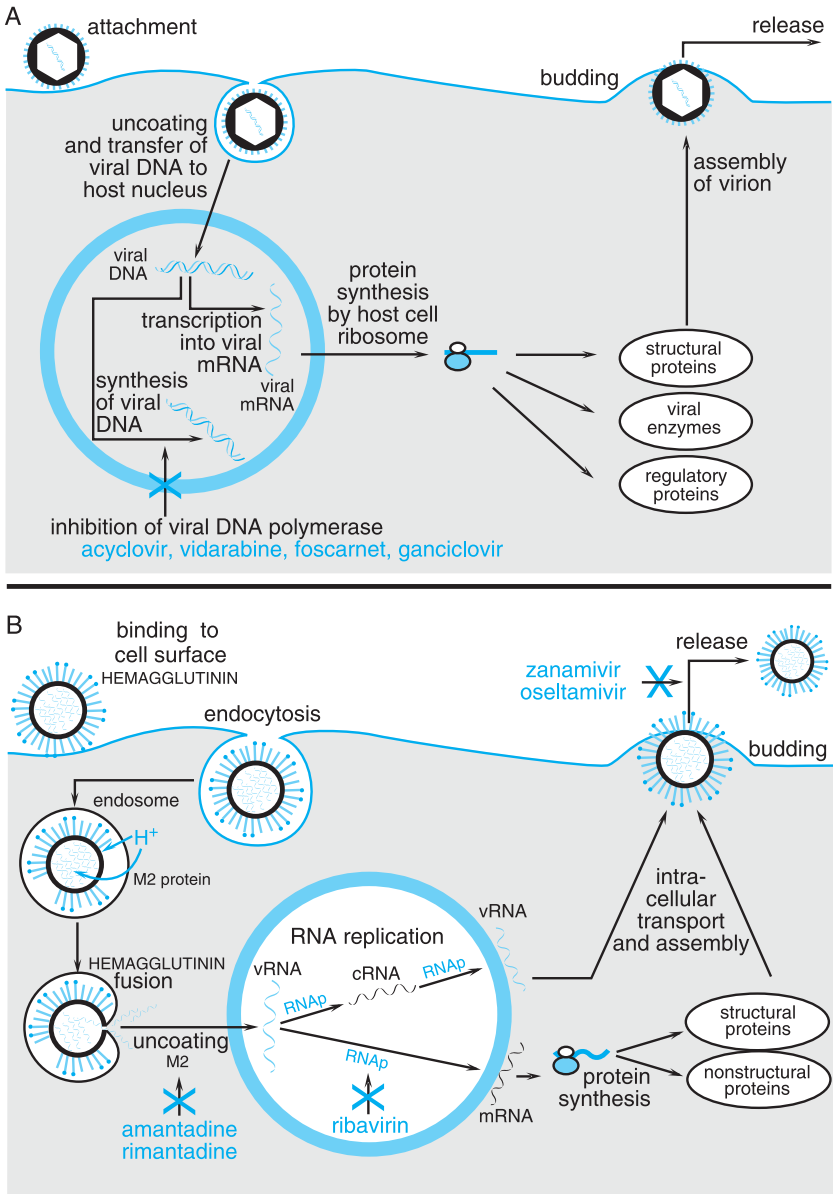

FIGURE 49-1 Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. *Key:* mRNA = messenger RNA; cDNA = complementary DNA; vRNA = viral RNA; DNAP = DNA polymerase; RNAP = RNA polymerase; cRNA = complementary RNA. An X on top of an arrow indicates a block or inhibition. **A.** Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpes virus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as thymidine kinases, DNA polymerases, etc. After DNA replication, the bulk of the herpes virus genes (called *late genes*) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. **B.** Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNAP segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAP complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus. Small capitals indicate virus proteins.

Table 49–2

Nomenclature of Antiviral Agents

Generic Name	Other Names	Trade Names (USA)	Dosage Forms Available
<i>Antiherpesvirus agents</i>			
Acyclovir	ACV, acycloguanosine	ZOVIRAX	IV, O, T, ophth*
Cidofovir	HPMPC, CDV	VISTIDE	IV
Famciclovir	FCV	FAMVIR	O
Foscarnet	PFA, phosphonoformate	FOSCAVIR	IV, O*
Fomivirsen	ISIS 2922	VITRAVENE	Intravitreal
Ganciclovir	GCV, DHPG	CYTOVENE	IV, O, intravitreal
Idoxuridine	IDUR	HERPES, STOXIL, DENDRID	Ophth
Penciclovir	PCV	DENAVIR	T, IV*
Trifluridine	TFT, trifluorothymidine	VIROPTIC	Ophth
Valacyclovir		VALTREX	O
Valganciclovir		VALCYTE	O
<i>Anti-influenza agents</i>			
Amantadine		SYMMETREL	O
Oseltamivir	GS4104	TAMIFLU	O
Rimantadine		FLUMADINE	O
Zanamivir	GG167	RELENZA	Inhaled
<i>Antihepatitis agents</i>			
Adefovir dipivoxil	Bis-pom-PMEA	HEPSERA	O
Interferon-alfa		INTRON A, ROFERON A, INFERGEN, ALFERON N, WELLFERON*	Injected
Lamivudine	3TC	EPIVIR	O
Pegylated interferon alfa		PEGASYS, PEG-INTRON	SC
<i>Other antiviral agents</i>			
Ribavirin		VIRAZOLE, REBETOL, COPEGUS	O, inhaled, IV*
Imiquimod		ALDARA	Topical

*Not currently approved for use in USA.

ABBREVIATIONS: IV, intravenous; O, oral; T, topical; ophth, ophthalmic.

Acyclovir resistance results from three mechanisms: absence or partial production of viral TK, altered TK substrate specificity (*e.g.*, phosphorylation of thymidine but not acyclovir), or altered viral DNA polymerase. Resistant variants are present in native virus populations, and heterogeneous mixtures of viruses occur in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral TK activity; viral DNA polymerase mutants are rare. Resistance typically is defined by inhibitory concentrations of $>2\text{--}3\ \mu\text{g/mL}$, which predict failure of therapy in immunocompromised patients.

Similarly, acyclovir resistance in VZV isolates is caused by mutations in its TK or polymerase.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Oral bioavailability of acyclovir (~10–30%) decreases with increasing dose. Valacyclovir is converted rapidly and virtually completely to acyclovir after oral administration. This conversion reflects first-pass intestinal and hepatic metabolism by enzymatic hydrolysis. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. The oral bioavailability of acyclovir increases to ~70% following valacyclovir administration. Peak acyclovir concentrations occur ~2 hours after dosing. Peak plasma concentrations of valacyclovir are only 4% of acyclovir levels. Less than 1% of an administered dose of valacyclovir is recovered in the urine, and most is eliminated as acyclovir.

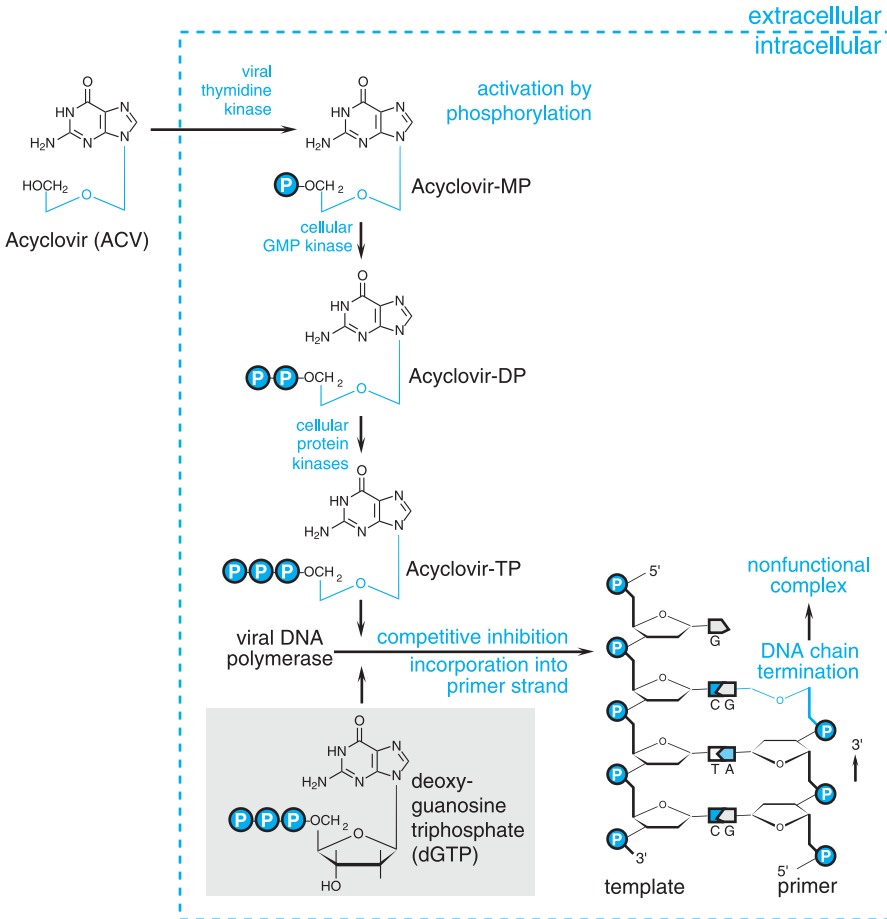

FIGURE 49–2 Conversion of acyclovir to acyclovir triphosphate leading to DNA chain termination. Acyclovir is converted to the monophosphate (MP) derivative by a herpes virus thymidine kinase. Acyclovir-MP is then phosphorylated to acyclovir-DP and acyclovir-TP by cellular enzymes. Uninfected cells convert very little or no drug to the phosphorylated derivatives. Thus, acyclovir is selectively activated in cells infected with herpesviruses that code for appropriate thymidine kinases. Incorporation of acyclovir-MP from acyclovir-TP into the primer strand during viral DNA replication leads to chain termination and formation of an inactive complex with the viral DNA polymerase. (Adapted from Elion, 1982, with permission.)

Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and cerebrospinal fluid (CSF). Compared with plasma, salivary concentrations are low, and vaginal secretion concentrations vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low.

The plasma elimination half-life of acyclovir is ~2.5 hours in adults with normal renal function, 4 hours in neonates, and 20 hours in anuric patients. Renal excretion of unmetabolized acyclovir by glomerular filtration and tubular secretion is the principal route of elimination.

UNTOWARD EFFECTS

Acyclovir generally is well tolerated. Topical acyclovir may cause mucosal irritation and transient burning when applied to genital lesions.

Oral acyclovir infrequently is associated with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may cause headache, nausea, diarrhea, nephrotoxicity, and CNS symptoms. High doses of valacyclovir have been associated

with confusion and hallucinations, nephrotoxicity, and uncommonly, severe thrombocytopenia, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities is recognized in infants born to women exposed to acyclovir during pregnancy.

The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Preexisting renal insufficiency, high doses, and acyclovir plasma levels $>25 \mu\text{g/mL}$ are risk factors for both. Reversible renal dysfunction occurs in $\sim 5\%$ of patients, likely related to crystalluria. Manifestations include nausea and vomiting, flank pain, and azotemia. Rapid infusion, dehydration, and inadequate urine flow increase the risk. Infusions should be given at a constant rate over at least an hour. Nephrotoxicity usually resolves with drug cessation and volume expansion. Neurotoxicity occurs in 1–4% of patients and can cause altered sensorium, tremor, myoclonus, delirium, seizures, or extrapyramidal signs. Phlebitis following extravasation, rash, diaphoresis, nausea, hypotension, and interstitial nephritis also may occur. Hemodialysis may be useful in severe cases.

Severe somnolence and lethargy may occur with combinations of zidovudine and acyclovir. Concomitant cyclosporine enhances nephrotoxicity. Probenecid decreases acyclovir renal clearance and prolongs the plasma $t_{1/2}$ of elimination. Acyclovir may decrease the renal clearance of other drugs eliminated by active renal secretion (e.g., methotrexate).

THERAPEUTIC USES In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones, which typically are milder. These drugs are particularly useful in immunocompromised patients because these individuals experience more frequent and more severe HSV and VZV infections. Since VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating varicella or zoster infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster.

Herpes Simplex Virus Infections

In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7–10 days) and valacyclovir (1000 mg twice daily for 7–10 days) significantly reduce virus shedding, symptoms, and time to healing. Intravenous acyclovir (5 mg/kg every 8 hours) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Patient-initiated acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1–2 days. Recurring genital herpes can be suppressed by chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). The rate of recurrences decreases by $\sim 90\%$ during use, and subclinical shedding is markedly reduced, such that valacyclovir suppression of genital herpes reduces the risk of transmission to a susceptible partner by $\sim 50\%$ over an 8-month period.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m² four times daily for 10 days in children) but has only modest benefit in recurrent orolabial herpes. High-dose valacyclovir (2 g twice over one day) shortens the duration of recurrent orolabial herpes by ~ 1 day. Topical acyclovir is modestly effective in recurrent labial and genital herpes simplex virus infections. Acyclovir prophylaxis (400 mg twice daily for one week) reduces the risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and frequency of cesarean section in women with primary or recurrent genital herpes.

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m² every 8 hours for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5–10 days are also effective. Recurrences are common after drug cessation and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in viscerally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m² every 8–12 hours) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200–400 mg three times daily for

6 months) also reduces the risk of VZV infection. In HSV encephalitis, acyclovir (10 mg/kg every 8 hours for at least 10 days) reduces mortality by >50% and improves neurological outcome. Higher doses (15–20 mg/kg every 8 hours) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 hours for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections. In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following acyclovir may occur.

An ophthalmic formulation of acyclovir (not available in the U.S.) is effective in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; in immunocompromised hosts, resistant HSV isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 6% to 17% of immunocompromised patients receiving acyclovir treatment. Recurrences after acyclovir cessation usually are due to sensitive virus but may be due to acyclovir-resistant virus in AIDS patients. In patients with progressive disease, intravenous foscarnet therapy is effective, but vidarabine is not.

Varicella-Zoster Virus Infections

If begun within 24 hours of rash onset, oral acyclovir is efficacious in varicella of children and adults. In children weighing up to 40 kg, acyclovir (20 mg/kg, up to 800 mg per dose, four times daily for 5 days) reduces fever and new lesion formation by ~1 day. Such use should be considered in those at risk of moderate-to-severe illness (persons >12 years old, secondary household cases, those with chronic cutaneous or pulmonary disorders, or those receiving glucocorticoids or long-term salicylates). In adults treated within 24 hours, oral acyclovir (800 mg five times daily for 7 days) reduces the time to crusting of lesions by ~2 days, the maximum number of lesions by 50%, and duration of fever. Intravenous acyclovir is effective in varicella pneumonia or encephalitis of previously healthy adults. Oral acyclovir (10 mg/kg four times daily) given between 7 and 14 days after exposure may reduce the risk of varicella.

In older adults with localized herpes zoster, oral acyclovir (800 mg five times daily for 7 days) reduces pain and healing times if initiated within 72 hours of rash onset. Treatment of zoster ophthalmicus reduces ocular complications. Prolonged acyclovir and concurrent prednisone for 21 days speed zoster healing and improve quality-of-life compared with either therapy alone. Valacyclovir (1000 mg three times daily for 7 days) provides more rapid relief of zoster-associated pain than acyclovir in adults over 50 with zoster.

In immunocompromised patients with herpes zoster, intravenous acyclovir (500 mg/m² every 8 hours for 7 days) reduces viral shedding, healing time, risks of cutaneous dissemination and visceral complications, and the length of hospitalization. In immunosuppressed children with varicella, intravenous acyclovir decreases healing time and the risk of visceral complications.

Acyclovir-resistant VZV isolates uncommonly have been recovered from HIV-infected children and adults who may manifest chronic hyperkeratotic or verrucous lesions and sometimes meningoradiculitis. Intravenous foscarnet appears to be effective for acyclovir-resistant VZV infections.

Other Viruses

Acyclovir is ineffective in established CMV infections but has been used for CMV prophylaxis in immunocompromised patients. High-dose intravenous acyclovir (500 mg/m² every 8 hours for one month) in CMV-seropositive bone marrow transplant recipients is associated with ~50% lower risk of CMV disease and, when combined with prolonged oral acyclovir (800 mg four times daily through 6 months), improves survival. Following engraftment, valacyclovir (2000 mg four times daily to day 100) appears as effective as intravenous ganciclovir prophylaxis. High-dose oral acyclovir or valacyclovir (2000 mg four times daily) suppression for 3 months may reduce the risk of CMV disease and its sequelae in some solid-organ transplant recipients, but oral valganciclovir is preferred. Compared with acyclovir, high-dose valacyclovir reduces CMV disease in advanced HIV infection but is associated with greater toxicity and possibly shorter survival.

Cidofovir

CHEMISTRY AND ANTIVIRAL ACTIVITY Cidofovir (1-[(S)-3-hydroxy-2-(phosphonomethoxy)-propyl]cytosine dihydrate) is a cytidine nucleotide analog with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses.

Cidofovir is a phosphonate that is phosphorylated by cellular but not virus enzymes. It inhibits acyclovir-resistant TK-deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations, but not those with DNA polymerase mutations, and some foscarnet-resistant

CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet.

MECHANISMS OF ACTION AND RESISTANCE Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate both acts as a competitive inhibitor with respect to dCTP and an alternative substrate for viral DNA polymerase. The diphosphate has a prolonged intracellular $t_{1/2}$ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases. A phosphocholine metabolite has a prolonged intracellular $t_{1/2}$ (~87 hours) and may serve as an intracellular drug reservoir. The prolonged intracellular $t_{1/2}$ of cidofovir diphosphate allows infrequent dosing regimens.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to 30% of retinitis patients by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Cidofovir has very low oral bioavailability. Plasma levels after intravenous dosing decline biphasically with a terminal $t_{1/2}$ of 2.6 hours. The volume of distribution approximates total-body water. CSF penetration is low. Topical cidofovir gel may result in low plasma concentrations (<0.5 $\mu\text{g}/\text{mL}$) in patients with large mucocutaneous lesions.

Cidofovir is cleared by glomerular filtration and tubular secretion and >90% of the dose is recovered unchanged in the urine. Probenecid (2 g 3 hours before and 1 g 2 and 8 hours after each infusion) blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. The $t_{1/2}$ is increased markedly with renal failure. Both peritoneal dialysis and hemodialysis remove >50% of the dose.

UNTOWARD EFFECTS

Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Proximal tubular dysfunction includes proteinuria, azotemia, glycosuria, and metabolic acidosis. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity. On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10–15% show an elevated serum creatinine, and 15–20% develop neutropenia. Anterior uveitis that is responsive to topical glucocorticoids and cycloplegia occur commonly and ocular hypotony occurs infrequently with intravenous cidofovir. Administration with food and pretreatment with antiemetics, antihistamines, and/or acetaminophen may improve tolerance.

Probenecid but not cidofovir alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of drugs similarly affected by probenecid (e.g., β -lactam antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs], acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin). Concurrent nephrotoxic agents are contraindicated, and an interval of 1 week before beginning cidofovir treatment is recommended after prior exposure to aminoglycosides, intravenous pentamidine, amphotericin B, foscarnet, NSAIDs, or contrast dye. Cidofovir and oral ganciclovir in combination are poorly tolerated at full doses.

Topical application of cidofovir is associated with local reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration.

Cidofovir is considered a potential human carcinogen and is classified as pregnancy category C.

THERAPEUTIC USES

Intravenous *cidofovir* is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous *cidofovir* (5 mg/kg once a week for 2 weeks followed by dosing every 2 weeks) increases the time to progression of CMV retinitis in previously untreated patients and in those failing or intolerant of ganciclovir and foscarnet therapy. CMV viremia may persist during *cidofovir* administration. Maintenance doses of 5 mg/kg are more effective but less well tolerated than 3 mg/kg doses. Intravenous *cidofovir* has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients, and progressive multifocal leukoencephalopathy or extensive molluscum contagiosum in HIV patients. Reduced doses (0.25–1 mg/kg every 2–3 weeks) without probenecid may be beneficial in BK virus nephropathy in renal transplant patients.

Topical *cidofovir* gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralesional *cidofovir* induces remissions in adults and children with respiratory papillomatosis.

Docosanol

Docosanol is a long-chain saturated alcohol that is FDA approved as a 10% over-the-counter cream for the treatment of recurrent orolabial herpes. Topical treatment beginning within 12 hours of prodromal symptoms or lesion onset reduces healing time by ~1 day and is well tolerated. Treatment initiation at papular or later stages provides no benefit.

Famciclovir and Penciclovir

CHEMISTRY AND ANTIVIRAL ACTIVITY *Famciclovir* is a diacetyl ester prodrug of 6-deoxy penciclovir. *Penciclovir* (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine) is an acyclic guanine nucleoside analog.

PENCICLOVIR

Penciclovir resembles acyclovir in its spectrum of activity and potency against HSV and VZV. It also inhibits HBV.

MECHANISMS OF ACTION AND RESISTANCE Penciclovir inhibits viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral TK. Penciclovir triphosphate competitively inhibits viral DNA polymerase (Figure 49–2). Although penciclovir triphosphate is approximately one one-hundredth times as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in infected cells at much higher concentrations and for more prolonged periods. The prolonged intracellular half-life of penciclovir triphosphate, 7–20 hours, provides prolonged antiviral effects. Because penciclovir has a 3'-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation.

Resistance during therapy is low. TK-deficient, acyclovir-resistant herpesviruses are cross resistant to penciclovir.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Oral *penciclovir* has low (5%) bioavailability, while *famciclovir* is well absorbed orally and converted rapidly to *penciclovir* by side chain deacetylation and purine ring oxidation. The bioavailability of *penciclovir* is ~70% after oral administration of *famciclovir*. Food slows absorption without reducing overall bioavailability. A small quantity of the 6-deoxy precursor but no *famciclovir* is detectable in plasma. The volume of distribution is ~twice the volume of total-body water. The $t_{1/2}$ of elimination of *penciclovir* is 2 hours, and >90% is excreted unchanged in the urine. Following oral *famciclovir* administration, nonrenal clearance accounts for ~10% of each dose,

primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) mostly are eliminated in the urine. The plasma $t_{1/2}$ is 10 hours when the creatinine clearance is <30 mL/min; hemodialysis effectively removes penciclovir. Lower peak plasma concentrations of penciclovir but equal overall bioavailability occur with compensated hepatic insufficiency.

UNTOWARD EFFECTS

Oral famciclovir is associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (mostly in the elderly) have been reported. Topical penciclovir rarely (~1%) is associated with local reactions. Short-term tolerance of famciclovir is comparable with that of acyclovir.

Penciclovir is mutagenic at high concentrations. Long-term administration (1 year) does not affect spermatogenesis in men. Safety during pregnancy is not established and the drug is pregnancy category B.

THERAPEUTIC USES

Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for HSV and VZV infections in various countries. Oral famciclovir (250 mg three times a day for 7–10 days) is as effective as acyclovir in treating first-episode genital herpes. In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice a day for 5 days) reduces healing time and symptoms by ~1 day. Famciclovir (250 mg twice a day for up to 1 year) effectively suppresses recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice a day) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 hours for 7 days) is comparable with intravenous acyclovir for mucocutaneous HSV infections in immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 hours while awake for 4 days) shortens healing time and symptoms by ~1 day.

In immunocompetent adults with VZV of <3 days duration, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir in reducing healing time and zoster-associated pain, particularly in older individuals. Famciclovir is comparable with valacyclovir in treating zoster and reducing associated pain in older adults. Famciclovir (500 mg three times a day for 7–10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with ophthalmic zoster.

Famciclovir causes dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine. Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

Fomivirsen

Fomivirsen is a phosphorothioate antisense oligonucleotide complementary to the mRNA sequence for the major immediate-early region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir.

Fomivirsen is given by intravitreal injection for patients intolerant of or unresponsive to other therapies for CMV retinitis. Following injection, it is cleared from the vitreous humor with a $t_{1/2}$ of ~55 hours through distribution to the retina and probably local exonuclease digestion. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330 μ g weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay retinitis progression. Ocular side effects include iritis in up to 25% of patients, which can be managed with topical glucocorticoids, vitritis, cataracts, and increased intraocular pressure in 15–20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions.

Foscarnet

CHEMISTRY AND ANTIVIRAL ACTIVITY Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analog that inhibits herpesviruses and HIV.

High concentrations of 0.5–1 mM reversibly inhibit the proliferation of uninfected cells.

FOSCARNET SODIUM

MECHANISMS OF ACTION AND RESISTANCE Foscarnet inhibits viral nucleic acid synthesis by interacting directly with herpesvirus DNA polymerase or HIV reverse transcriptase (Figure 49–1A). It is taken up slowly by cells and does not undergo significant intracellular metabolism. Foscarnet reversibly and noncompetitively blocks the pyrophosphate binding site of the viral polymerase and inhibits pyrophosphate cleavage from deoxynucleotide triphosphates. Foscarnet has ~100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase α . Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase that reduce foscarnet activity.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Vitreous levels approximate those in plasma, and CSF levels average 66% of those in plasma.

Over 80% of foscarnet is excreted unchanged in the urine. Plasma clearance is proportional to creatinine clearance, and dose adjustments are indicated for small decreases in renal function. Plasma elimination is complex, with an initial $t_{1/2}$ of 4–8 hours and a prolonged terminal $t_{1/2}$ of 4 days. Sequestration in bone with gradual release accounts for a ~10–20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

UNTOWARD EFFECTS

Foscarnet's major dose-limiting toxicities are nephrotoxicity and hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but usually are reversible after drug cessation. High doses, rapid infusion, volume depletion, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Acute tubular necrosis, crystalline glomerulopathy, nephrogenic diabetes insipidus, and interstitial nephritis have been described. Saline loading may reduce the risk of nephrotoxicity.

Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common, including increases or decreases in Ca^{2+} and phosphate, hypomagnesemia, and hypokalemia. Concomitant intravenous pentamidine administration increases the risk of hypocalcemia.

CNS side effects include headache, tremor, irritability, and seizures. Other side effects are rash, fever, nausea or vomiting, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation, while oral foscarnet may cause gastrointestinal (GI) disturbance. High foscarnet concentrations in animals are mutagenic and may cause tooth and skeletal abnormalities. Safety in pregnancy or childhood is uncertain.

THERAPEUTIC USES

Intravenous foscarnet is effective for CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections. Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration.

In CMV retinitis in AIDS patients, foscarnet (60 mg/kg every 8 hours or 90 mg/kg every 12 hours for 14–21 days followed by chronic maintenance at 90–120 mg/kg every day in one dose) is associated with clinical stabilization in ~90% of patients. A comparison of foscarnet with ganciclovir in AIDS patients found comparable control of CMV retinitis but improved overall survival in the foscarnet-treated group, possibly related to the drug's intrinsic anti-HIV activity. Patients discontinue foscarnet because of side effects over three times as often as ganciclovir. A combination of foscarnet and ganciclovir is more effective than either drug alone in refractory retinitis; combinations may be useful in treating ganciclovir-resistant CMV infections in solid-organ transplant patients. Foscarnet benefits other CMV syndromes in AIDS or transplant patients but is ineffective as monotherapy in treating CMV pneumonia in bone marrow transplant patients. When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 hours for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir with less neutropenia. Foscarnet may reduce the risk of Kaposi's sarcoma in HIV-infected patients. Intravitreal injections also are used.

In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 hours for 7 days or longer) are associated with cessation of viral shedding and complete healing of lesions in ~75% of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream may be useful in chronic acyclovir-resistant infections in immunocompromised patients.

Ganciclovir and Valganciclovir

CHEMISTRY AND ANTIVIRAL ACTIVITY Ganciclovir (9-[1,3-dihydroxy-2-propoxymethyl] guanine) is an acyclic guanine nucleoside analog that is similar in structure to

acyclovir except for an additional hydroxymethyl group on the side chain. Valganciclovir is the L-valyl ester prodrug of ganciclovir.

This agent has inhibitory activity against all herpesviruses but is especially active against CMV. Inhibitory concentrations for human bone marrow progenitors are similar to those inhibitory for CMV replication, a finding consistent with ganciclovir's myelotoxicity in clinical use.

MECHANISMS OF ACTION AND RESISTANCE Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral TK during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by cellular enzymes. At least tenfold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate competitively inhibits deoxyguanosine triphosphate incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Ganciclovir is incorporated into both viral and cellular DNA. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (Figures 49-1A and 49-2).

Intracellular ganciclovir triphosphate concentrations are tenfold higher than those of acyclovir triphosphate and decline much more slowly with an intracellular elimination $t_{1/2} > 24$ hours. These differences may account for ganciclovir's greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

CMV can become resistant to ganciclovir by reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase encoded by the UL97 gene or mutations in viral DNA polymerase. Resistance has been associated primarily with impaired phosphorylation but sometimes only with DNA polymerase mutations. Highly resistant variants with dual UL97 and polymerase mutations are cross-resistant to cidofovir and variably to foscarnet. Ganciclovir also is much less active against acyclovir-resistant TK-deficient HSV strains.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

The oral bioavailability of ganciclovir is ~6–9% following ingestion with food. Oral valganciclovir is well absorbed and hydrolyzed rapidly to ganciclovir; the bioavailability of ganciclovir is ~60% following valganciclovir. Food increases the bioavailability of valganciclovir by ~25%. High oral valganciclovir doses with food provide ganciclovir exposures comparable with intravenous dosing. Following intravenous dosing, vitreous fluid levels equal or exceed those in plasma. Vitreous levels decline with a $t_{1/2}$ of 24 hours.

The plasma $t_{1/2}$ is ~2–4 hours in patients with normal renal function. Over 90% of ganciclovir is eliminated unchanged by renal excretion. Consequently, the plasma $t_{1/2}$ increases almost linearly as creatinine clearance declines and may reach 28–40 hours with severe renal insufficiency.

UNTOWARD EFFECTS

Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in ~15–40% of patients and thrombocytopenia in 5–20%. Neutropenia may be fatal; it appears most commonly during the second week of treatment and usually reverses within 1 week of drug cessation. Recombinant granulocyte colony-stimulating factor (G-CSF, filgrastim, lenograstim) may be useful in treating ganciclovir-induced neutropenia (see Chapter 53). Oral valganciclovir is associated with nausea, pain, and diarrhea in addition to the toxicities associated with intravenous ganciclovir.

CNS side effects occur in 5–15% of patients and range from headache to behavioral changes to convulsions and coma. About one-third of patients will prematurely stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea and vomiting, and eosinophilia also have occurred.

Teratogenicity, embryotoxicity, and reproductive toxicity have been observed in ganciclovir-treated animals, and it is classified as pregnancy category C.

Zidovudine and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic drugs that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. Zalcitabine increases oral ganciclovir exposure by ~22%. Oral ganciclovir doubles the absorption and peak plasma concentrations of didanosine and increases zidovudine by ~20%.

THERAPEUTIC USES

Ganciclovir is effective for treatment and chronic suppression of CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant recipients. In CMV retinitis, induction treatment (5 mg/kg intravenously every 12 hours for 10–21 days) is associated with improvement or stabilization in ~85% of patients. Reduced viral excretion is usually evident by 1 week, and funduscopy improvement by 2 weeks. Because of the high risk of relapse, AIDS patients with retinitis require suppressive therapy (a total of 30–35 mg/kg/week, in divided doses). Oral ganciclovir (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treatment. Oral valganciclovir is comparable with intravenous dosing for initial control (900 mg twice daily for 21 days initial treatment) and sustained suppression (900 mg daily) of CMV retinitis.

Intravitreal ganciclovir injections have been used, and an intraocular sustained-release ganciclovir implant (VITRASERT) is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 hours for 14–21 days) may benefit other CMV syndromes in AIDS patients or solid-organ transplant recipients. Response rates of >67% have been found in combination with a decrease in immunosuppressive therapy. The duration of therapy depends on the clearance of viremia; early switch from intravenous ganciclovir to oral valganciclovir is feasible. Recurrent CMV disease occurs commonly after initial treatment. In bone marrow transplant recipients with CMV pneumonia, ganciclovir alone is ineffective. However, ganciclovir combined with intravenous immunoglobulin or CMV immunoglobulin reduces the mortality of CMV pneumonia by about one-half. Ganciclovir treatment may benefit infants with congenital CMV disease.

Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients. In bone marrow transplant recipients in whom CMV is isolated from bronchoalveolar lavage or other sites, preemptive ganciclovir treatment (5 mg/kg every 12 hours for 7–14 days followed by 5 mg/kg every day to days 100–120 after transplant) is highly effective in preventing CMV pneumonia and appears to reduce mortality. Ganciclovir initiation at the time of engraftment also reduces CMV disease rates but does not improve survival, probably due to infections owing to ganciclovir-related neutropenia.

Intravenous ganciclovir, oral ganciclovir, and oral valganciclovir reduce the risk of CMV disease in solid-organ transplant recipients. Oral ganciclovir (1000 mg three times daily for 3 months) reduces CMV disease risk in liver transplant recipients. Oral valganciclovir prophylaxis generally is more effective than high-dose oral acyclovir. Oral valganciclovir (900 mg once daily) provides somewhat greater antiviral effects and similar reductions in CMV disease as oral ganciclovir in mismatched solid-organ transplant recipients.

In advanced HIV disease, oral ganciclovir (1000 mg three times daily) may reduce the risk of CMV disease in those not receiving didanosine. The addition of oral high-dose ganciclovir (1500 mg three times daily) to the intraocular ganciclovir implant further delays the time to retinitis progression and reduces the risk of new CMV disease and possibly of Kaposi's sarcoma.

Ganciclovir resistance emerges in a minority of transplant patients, especially mismatched solid-organ recipients, and is associated with poor prognosis. The use of antithymocyte globulin and prolonged ganciclovir exposure are risk factors. Recovery of ganciclovir-resistant CMV isolates has been associated with progressive CMV disease in AIDS and other immunocompromised patients. Over one-quarter of retinitis patients have resistant isolates by 9 months of therapy, and resistant CMV has been recovered from CSF, vitreous fluid, and visceral sites.

A ganciclovir ophthalmic gel formulation appears to be effective in treating HSV keratitis. Oral ganciclovir reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B.

Idoxuridine

Idoxuridine (5-iodo-2'-deoxyuridine) is an iodinated thymidine analog that inhibits the *in vitro* replication of various DNA viruses, including herpesviruses and poxviruses.

Inhibitory concentrations of idoxuridine for HSV-1 are at least tenfold higher than those of acyclovir. Idoxuridine lacks selectivity, as low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA, increasing their susceptibility to breakage and leading to faulty transcription. Resistance to idoxuridine develops readily.

In the U.S., idoxuridine is approved only for topical treatment of HSV keratitis, although it is available elsewhere for topical treatment of herpes labialis, genitalis, and zoster. In ocular HSV infections, topical idoxuridine is more effective in epithelial than in stromal infections. Adverse reactions include pain, pruritus, inflammation, and edema involving the eye or lids; allergic reactions occur rarely.

Trifluridine

Trifluridine (5-trifluoromethyl-2'-deoxyuridine) is a fluorinated pyrimidine nucleoside with *in vitro* inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and some adenoviruses.

Trifluridine inhibits replication of herpesviruses, including acyclovir-resistant strains. Trifluridine also inhibits cellular DNA synthesis at relatively low concentrations.

TRIFLURIDINE INHIBITION OF VIRAL DNA SYNTHESIS Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate competitively inhibits thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Resistance in clinical HSV isolates has been described.

Trifluridine is FDA approved for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions, irritation, and keratopathy are uncommon. Topical trifluridine also is effective in some patients with acyclovir-resistant HSV cutaneous infections.

ANTI-INFLUENZA AGENTS

Amantadine and Rimantadine

CHEMISTRY AND ANTIVIRAL ACTIVITY *Amantadine* (1-adamantanamine hydrochloride) and its α -methyl derivative *rimantadine* (α -methyl-1-adamantanane methylamine hydrochloride) are tricyclic amines.

Both agents specifically inhibit the replication of influenza A viruses. Rimantadine is 4–10 times more active than amantadine.

MECHANISMS OF ACTION AND RESISTANCE Amantadine and rimantadine inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel.

Primary drug resistance is uncommon in field isolates but occurs in some avian and swine influenza viruses, including H5N1 human isolates. Resistance is selected readily by virus passage in the presence of drug and is seen in 30% or more of isolates recovered during treatment. Resistance with >100-fold increases in inhibitory concentrations has been associated with single-nucleotide changes leading to amino acid substitutions in the transmembrane region of M2. Amantadine and rimantadine share cross-susceptibility and resistance.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

The pharmacokinetics of amantadine and rimantadine are listed in Table 49–3. The elderly require only one-half the weight-adjusted dose of amantadine to achieve equivalent drug levels. Both drugs have very large volumes of distribution. Nasal secretion and salivary levels of amantadine approximate those found in the serum. Amantadine is excreted in breast milk. Rimantadine

Table 49–3

Pharmacological Characteristics of Antivirals for Influenza

	Amantadine	Rimantadine	Zanamivir	Oseltamivir
Spectrum (types of influenza)	A	A	A, B	A, B
Route/formulations	Oral (tablet/capsule/syrup)	Oral (tablet/syrup)	Inhaled (powder) Intravenous*	Oral (capsule/syrup)

Dose adjustments	$Cl_{cr} \leq 50$ Age ≥ 65 yrs	$Cl_{cr} \leq 10$ Age ≥ 65 years	None	$Cl_{cr} \leq 30$

*Investigational.

[†]Systemic absorption 4–17% after inhalation.

[‡]For antivirally active oseltamivir carboxylate (GS4071).

concentrations in nasal mucus are 50% higher than those in plasma. Amantadine is excreted largely unmetabolized in the urine. Because amantadine's elimination is highly dependent on renal function, the elimination $t_{1/2}$ increases up to twofold in the elderly and even more with renal impairment. Dose adjustment is advised even with mildly decreased renal function. In contrast, rimantadine is metabolized extensively by hydroxylation, conjugation, and glucuronidation; 60–90% is excreted in urine as metabolites.

UNTOWARD EFFECTS

The most common side effects of amantadine and rimantadine are GI and CNS complaints, including nervousness, light-headedness, difficulty concentrating, insomnia, and anorexia or nausea. CNS side effects occur in ~5–33% of patients treated with amantadine at doses of 200 mg/day but are significantly less frequent with rimantadine. Especially in the elderly, the neurotoxic effects of amantadine may be increased by concomitant use of antihistamines and psychotropic or anticholinergic drugs. Amantadine dose reductions are required in older adults (100 mg/day) because of decreased renal function, but 20–40% of infirm elderly experience side effects even at the lower dose. At 100 mg/day, rimantadine is significantly better tolerated in nursing home residents than is amantadine.

High amantadine plasma concentrations (1.0–5.0 $\mu\text{g/mL}$) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures and coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Amantadine is teratogenic in animals and possibly in humans. The safety of these drugs has not been established in pregnancy (category C).

THERAPEUTIC USES

Amantadine and rimantadine are effective for the prevention and treatment of influenza A virus infections. Seasonal prophylaxis with either drug (a total of 200 mg/day in one or two divided doses in young adults) is ~70–90% protective against influenza A illness. Efficacy has been shown during pandemic influenza, in preventing nosocomial influenza, and in curtailing nosocomial outbreaks. Doses of 100 mg/day are better tolerated yet still protective against influenza. Postexposure prophylaxis with either drug provides protection of exposed family contacts if ill young children are not concurrently treated.

Seasonal prophylaxis is an alternative in high-risk patients if the influenza vaccine cannot be administered or may be ineffective due to impaired immunity. Prophylaxis should be started as soon as influenza is identified in a community and continued for the period of risk (usually 4–8 weeks). Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immunity develops.

In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/day for 5 days) reduces duration of fever and systemic complaints by 1–2 days, speeds functional recovery, and may decrease the duration of virus shedding. In children, rimantadine treatment may be associated with less illness and lower viral titers during the first 2 days of treatment, but treated children have more prolonged virus shedding. The optimal dose and duration of therapy in children are not established.

Resistant variants have been recovered from ~30% of treated outpatient children or adults by the fifth day of therapy. Resistant variants also arise commonly in immunocompromised patients and inpatient children. Illnesses owing to apparent transmission of resistant virus associated with failure of drug prophylaxis have been documented in contacts of drug-treated ill persons in households and in nursing homes. Resistant variants appear to be pathogenic and can cause typically disabling influenza.

Osetamivir

CHEMISTRY AND ANTIVIRAL ACTIVITY Osetamivir carboxylate [(3R, 4R, 5S)-4-acetylamino-5-amino-3-(1-ethylpropoxy)-1-cyclohexene-1-carboxylic acid] is a sialic acid analog that potently inhibits influenza virus neuraminidases.

OSETAMIVIR CARBOXYLATE

Oseltamivir phosphate is an ethyl ester prodrug. Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of *zanamivir*. It inhibits amantadine- and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

MECHANISMS OF ACTION AND RESISTANCE Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions, which is essential for virus release from infected cells. Oseltamivir carboxylate causes a conformational change in neuraminidase's active site and inhibits its activity, leading to viral aggregation at the cell surface and reduced virus spread within the respiratory tract.

Influenza variants selected *in vitro* for resistance to oseltamivir carboxylate contain hemagglutinin and/or neuraminidase mutations. The most commonly recognized resistant variants have reduced infectivity and virulence in animal models. Outpatient oseltamivir therapy has been associated with recovery of resistant variants in ~0.5% of adults and 5.5% of children; a higher frequency (~18%) occurs in hospitalized children.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Oral oseltamivir phosphate is absorbed rapidly (Table 49–3) and cleaved to the active carboxylate by esterases in the GI tract and liver. The bioavailability of the carboxylate is ~80%; food does not decrease bioavailability but reduces GI symptoms. The carboxylate has a volume of distribution similar to extracellular water. Both prodrug and active metabolite are eliminated primarily unchanged by the kidney.

UNTOWARD EFFECTS

Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis, probably owing to local irritation. GI complaints usually are relatively mild, typically resolve in 1–2 days despite continued dosing, and are diminished by administration with food. The frequency of GI complaints is ~10–15% when oseltamivir is used to treat influenza and <5% when used for prophylaxis. An increased frequency of headache in the elderly has been reported.

Oseltamivir phosphate and the carboxylate do not interact with CYPs in vitro. Their protein binding is low. Safety in pregnancy is uncertain (pregnancy category C). Oseltamivir is not approved for children <1 year of age.

THERAPEUTIC USES

Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children aged 1–12 years (weight-adjusted dosing) with acute influenza reduces illness duration by ~1–2 days, speeds functional recovery, and reduces the risk of complications requiring antibiotic use by 40–50%. Treatment halves the risk of subsequent hospitalization in adults. When used for prophylaxis during the influenza season, oseltamivir (75 mg once daily) is effective (~70–90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use (7–10 days) protects against influenza in household contacts.

Zanamivir

CHEMISTRY AND ANTIVIRAL ACTIVITY Zanamivir (4-guanidino-2,4-dideoxy-2,3-dehydro-*N*-acetyl neuraminic acid) is a sialic acid analog that potently and specifically inhibits the neuraminidases of influenza A and B viruses. Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity but affects neuraminidases from other pathogens and mammalian sources only at much higher concentrations. Zanamivir inhibits *in vitro* replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants.

MECHANISMS OF ACTION AND RESISTANCE Zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract.

In vitro resistance to zanamivir results from mutations in the viral hemagglutinin and/or neuraminidase. Hemagglutinin variants generally have mutations in or near the receptor binding site that make them less dependent on neuraminidase for release from cells, although they typically retain some drug susceptibility. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir resistance has not emerged in immunocompetent hosts but has been seen in immunocompromised patients.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

The oral bioavailability of zanamivir is low (<5%) (Table 49–3), and the drug is delivered by oral inhalation. After inhalation, ~15% is deposited in the lower respiratory tract and ~80% in the oropharynx. Overall bioavailability is <20%. The plasma $t_{1/2}$ of zanamivir averages 2.5–5 hours after inhalation but only 1.7 hours following intravenous dosing. Over 90% is eliminated in the urine unmetabolized.

UNTOWARD EFFECTS

Topical zanamivir generally is well tolerated. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations, have occurred in patients with underlying asthma or chronic obstructive airway disease; zanamivir generally is not recommended in these settings.

Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy category C).

THERAPEUTIC USES

Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections. Early zanamivir treatment (10 mg twice daily for 5 days) of febrile influenza in ambulatory adults and children >5 years old shortens the duration of illness by 1–3 days and in adults reduces by 40% the risk of lower respiratory tract complications requiring antibiotic use. Once-daily zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, protects against household transmission.

ANTIHEPATITIS AGENTS

Adefovir

CHEMISTRY AND ANTIVIRAL ACTIVITY Adefovir dipivoxil (9-[2-[bis[(pivaloyloxy)methoxy]phosphiny]methoxy]ethyl]adenine, bis-POM PME) is a diester prodrug of adefovir, an acyclic phosphonate nucleotide analog of adenosine monophosphate.

ADEFOVIR DIPIVOXIL

Clinical use is limited to HBV infections, including lamivudine-resistant HBV strains. Oral adefovir dipivoxil shows dose-dependent inhibition of hepadnavirus replication. *In vitro* combinations of adefovir and lamivudine or other anti-HBV nucleosides show enhanced antihepadnavirus activity.

MECHANISMS OF ACTION AND RESISTANCE Adefovir dipivoxil enters cells and is deesterified to adefovir. Cellular enzymes convert adefovir to the diphosphate, which competitively inhibits viral DNA polymerases and reverse transcriptases and also serves as a chain terminator of viral DNA synthesis. Its selectivity relates to a higher affinity for HBV DNA polymerase compared with cellular polymerases. The intracellular $t_{1/2}$ of the diphosphate is prolonged and once-daily

dosing is feasible. Adefovir resistance has been detected in ~4% of chronically infected HBV patients during 3 years of treatment, reflecting unique point mutations in the HBV polymerase. The consequences of emerging resistance remain to be determined.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine and blood to adefovir. Adefovir bioavailability is ~30–60%. Food does not affect bioavailability. Adefovir has low protein binding (<5%) and has a volume of distribution similar to body water (~0.4 L/kg).

Adefovir is renally excreted. After oral administration of adefovir dipivoxil, ~30–45% of the dose is recovered unchanged in urine within 24 hours; the elimination $t_{1/2}$ is 5–7.5 hours. Dose reductions are indicated for Cl_{Cr} values <50 mL/min. Adefovir is removed by hemodialysis.

UNTOWARD EFFECTS

Adefovir dipivoxil causes dose-related nephrotoxicity, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria, which usually are reversible after discontinuation. The lower dose (10 mg/day) used in chronic HBV infection patients has been associated with few adverse events (e.g., headache, abdominal discomfort, diarrhea, and asthenia) and negligible renal toxicity compared with a threefold higher dose. Adverse events lead to drug discontinuation in ~2% of patients. After 2 years of dosing, the risk of a significant rise in serum creatinine is ~2% but is higher in those with preexisting renal insufficiency. Acute, sometimes severe exacerbations of hepatitis can occur in patients stopping adefovir. Close monitoring is needed, and resumption of antiviral therapy may be required.

No clinically important drug interactions are recognized, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. An increased risk of lactic acidosis and hepatic steatosis may exist when adefovir is combined with antiretroviral agents.

High doses in animals cause renal tubular dysfunction, hepatotoxicity, and toxicity to lymphoid tissues. Adefovir dipivoxil is not associated with reproductive toxicity (pregnancy category C).

THERAPEUTIC USES

Adefovir dipivoxil is approved for treatment of chronic HBV infections. In patients with HBV e-antigen (HBeAg)-positive chronic hepatitis B, adefovir dipivoxil (10 mg/day) results in >100-fold reduced serum HBV DNA levels and, in about one-half of patients, improved hepatic histology and normalizes aminotransferase levels by 48 weeks. Continued therapy is associated with increasing frequencies of aminotransferase normalization and HBeAg seroconversion. In patients with HBeAg-negative chronic HBV, adefovir is associated with similar biochemical and histological benefits. Regression of cirrhosis may occur in some patients.

In patients with lamivudine-resistant HBV infections, adefovir dipivoxil results in sustained reductions in serum HBV DNA levels, but lamivudine alone or added to adefovir is not beneficial. In patients with dual HIV and lamivudine-resistant HBV infections, adefovir dipivoxil (10 mg/day) significantly reduces HBV DNA levels and also has been used successfully in patients with lamivudine-resistant HBV infections both before and following liver transplantation. The optimal duration of treatment in different populations, possible long-term effects on HBV complications, and combined use with other anti-HBV agents are under study.

Interferons

CLASSIFICATION AND ANTIVIRAL ACTIVITY Interferons (IFNs) possess antiviral, immunomodulating, and antiproliferative activities (see Chapter 52). They are synthesized by host cells in response to various inducers and stimulate an antiviral state in cells. There are three major classes of human interferons with antiviral activity: α , β , and γ . Clinically used recombinant α IFNs (Table 49–2) are nonglycosylated proteins of ~19,500 Da.

IFN- α and IFN- β are produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor α). IFN- γ production is restricted to T-lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN- α and IFN- β have antiviral and antiproliferative actions; stimulate the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and up-regulate class I major histocompatibility complex (MHC) antigens. IFN- γ has less antiviral activity but more potent immunoregulatory effects. Most animal viruses are inhibited by IFNs, although DNA viruses are relatively insensitive.

MECHANISMS OF ACTION Following binding to specific cellular receptors, IFNs activate the JAK-STAT pathway and stimulate the transcription of specific genes, leading to synthesis of >20 proteins that contribute to viral resistance at different stages of viral infection (Figure 49–3). For many viruses, the major effect is inhibition of protein synthesis. IFN-induced proteins include 2'-5'-oligoadenylate [2-5(A)] synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The protein kinase selectively phosphorylates and inactivates eukaryotic initiation factor 2 (eIF-2). Certain viruses counter IFN effects by blocking production or activity of selected IFN-inducible proteins. For example, IFN resistance in HCV is attributable to inhibition of the IFN-induced protein kinase. IFNs also may modify the immune response; IFN-induced expression of MHC antigens may enhance lytic effects of cytotoxic T-lymphocytes.

Viruses

A. DNA

B. RNA

1. orthomyxoviruses and retroviruses
2. picornaviruses and most RNA viruses

IFN Effects

1. Transcription inhibition

activates Mx protein
blocks mRNA synthesis

2. Translation inhibition

activates methylase, thereby reducing
mRNA cap methylation

activates 2'5' oligoadenylate synthetase
→ 2'5'A → inhibits mRNA splicing
and activates RNase L → cleaves
viral RNA

activates protein kinase P1 → blocks
eIF-2 α function → inhibits initiation
of mRNA translation

activates phosphodiesterase → blocks
tRNA function

3. Protein processing inhibition

inhibits glycosyltransferase, thereby reducing
protein glycosylation

4. Virus maturation inhibition

inhibits glycosyltransferase, thereby reducing
glycoprotein maturation

causes membrane changes → blocks
budding

FIGURE 49–3 Interferon-mediated antiviral activity occurs via multiple mechanisms. The binding of IFN to specific cell surface receptor molecules signals the cell to produce a series of antiviral proteins. The stages of viral replication that are inhibited by various IFN-induced antiviral proteins are shown. Most of these act to inhibit the translation of viral proteins (mechanism 2), but other steps in viral replication also are affected (mechanisms 1, 3, and 4). The roles of these mechanisms in the other actions of IFNs are under study. *Key:* IFN = interferon; mRNA = messenger RNA; Mx = specific cellular protein; tRNA = transfer RNA; RNase L = latent cellular endoribonuclease; 2'5'A = 2'-5'-oligoadenylates; eIF-2 α = protein synthesis initiation factor.

Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

After intramuscular or subcutaneous injection of IFN- α , absorption is >80%. Plasma levels are dose-related, peaking at 4–8 hours and returning to baseline by 18–36 hours. Levels of 2-5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 hours and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 hours and returns to baseline by 6 days after injection. Intramuscular or subcutaneous injections of IFN- β result in negligible plasma levels, although increases in 2-5(A) synthetase levels may occur. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain.

Because IFNs induce long-lasting cellular effects, their activities are poorly predicted from usual pharmacokinetic measures. After intravenous dosing, clearance of IFN from plasma occurs in a complex manner. With subcutaneous or intramuscular dosing, the plasma elimination $t_{1/2}$ of IFN- α ranges from 3 to 8 hours, largely due to distribution to the tissues, cellular uptake, and catabolism in the kidney and liver. Negligible amounts are excreted in the urine. Clearance of IFN- α_2 is reduced by ~70% in dialysis patients.

Attachment of IFN proteins to large, inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing. Two pegylated IFNs are available: peginterferon alfa-2a and peginterferon alfa-2b. PegIFN alfa-2b has a 12,000-Da PEG that increases the plasma $t_{1/2}$ from 2 to 3 hours to 30–54 hours. PegIFN alfa-2a contains a branched-chain 40,000-Da PEG bonded to IFN- α_2a and has a plasma $t_{1/2}$ of ~80–90 hours. For pegIFN alfa-2a, peak serum concentrations occur up to 120 hours after dosing and remain detectable throughout the weekly dosing interval; steady-state levels occur 5–8 weeks after initiation of weekly dosing. For pegIFN alfa-2a, dose-related maximum plasma concentrations occur at 15–44 hours after dosing and decline by 96–168 hours. These differences in pharmacokinetics may be associated with differences in antiviral effects. Increasing PEG size is associated with longer $t_{1/2}$ and less renal clearance. About 30% of pegIFN alfa-2b is cleared renally; pegIFN alfa-2a is cleared primarily by the liver. Dose reductions in both pegylated IFNs are indicated in end-stage renal disease.

UNTOWARD EFFECTS

Injection of IFN doses of 1–2 million units or greater usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 hours. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with antipyretics. Up to one-half of patients receiving intralesional therapy for genital warts experience an initial influenza-like illness, discomfort at the injection site, and leukopenia.

Dose-limiting toxicities of systemic IFN are myelosuppression; neurotoxicity (e.g., somnolence, confusion, depression); autoimmune disorders including thyroiditis; and rarely, cardiovascular effects with hypotension. Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, and pneumonia may occur. Alopecia and personality change are common in IFN-treated children. The development of neutralizing antibodies to exogenous IFNs may rarely be associated with loss of clinical responsiveness. Safety during pregnancy is not established (category C).

IFN reduces the metabolism of various drugs by hepatic CYPs. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin, as well as the neuro- and cardiotoxicity of other drugs.

Pegylated IFNs are tolerated about as well as standard IFNs; discontinuation rates range from 2% to 11%, although the frequencies of fever, nausea, local inflammation, and neutropenia may be somewhat higher. Severe neutropenia and the need for dose modifications are higher in HIV-coinfected persons.

THERAPEUTIC USES

Recombinant, natural, and pegylated IFNs are approved in the U.S. for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi's sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis.

Hepatitis B Virus

In patients with chronic HBV infection, parenteral administration of IFNs is associated with serological, biochemical, and histological improvement in 25–50% of the patients. Lasting responses

require moderately high IFN doses and prolonged administration (typically 5–10 million units/day in adults and 6 million units/m² in children three times per week for 4–6 months). Plasma HBV DNA and polymerase activity decline promptly in most patients, but complete disappearance is sustained in <33% of patients. Low pretherapy serum HBV DNA levels and high aminotransferase levels predict response. Sustained responses are infrequent in those with vertically acquired infection, anti-HBe positivity, or concurrent immunosuppression owing to HIV. PegIFN alfa-2a is superior to conventional IFN alfa-2a in HBeAg-positive patients, and treatment (180 mg once weekly for 24 weeks) is associated with normalization of aminotransferases in ~60% and sustained viral suppression in ~20% of HBeAg-negative patients. Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes. High-dose IFN can cause myelosuppression and clinical deterioration in those with decompensated liver disease.

Remissions in chronic hepatitis B induced by IFN are sustained in >80% of patients treated and frequently are followed by loss of HBV surface antigen (HbsAg), histological improvement or stabilization, and reduced risk of liver-related complications and mortality. IFN may benefit some patients with glomerulonephritis owing to chronic HBV infection. Antiviral effects and improvements occur in ~50% of chronic hepatitis D virus (HDV) infections, but relapse is common unless HbsAg disappears. IFN does not appear to be beneficial in acute HBV or HDV infections.

Hepatitis C Virus

In chronic HCV infection, IFN alfa-2b monotherapy (3 million units three times a week) is associated with aminotransferase normalization and loss of plasma viral RNA in ~50–70% of patients; relapse rates are high, and sustained virologic remission is observed in <25% of patients. Sustained viral responses are associated with long-term histological improvement and reduced risk of hepatocellular carcinoma and hepatic failure. Viral genotype and pretreatment RNA level influence treatment response, but early viral clearance is the best predictor of sustained response. Nonresponders generally do not benefit from IFN monotherapy retreatment, but they and patients relapsing after monotherapy may respond to combined pegylated IFN and ribavirin treatment (see below). IFN treatment may benefit HCV-associated cryoglobulinemia and glomerulonephritis. IFN administration during acute HCV infection appears to reduce the risk of chronicity.

Pegylated IFNs are superior to conventional thrice-weekly IFN monotherapy in inducing sustained remissions in treatment-naive patients. Monotherapy with pegIFN alfa-2a (180 µg subcutaneously weekly for 48 weeks) or pegIFN alfa-2b (weight-adjusted doses of 1.5 µg/kg/week) is associated with sustained response in 30–39%, including stable cirrhotic patients, and is a treatment option in patients unable to take ribavirin.

The efficacy of conventional and pegylated IFNs is enhanced by the addition of ribavirin. In previously untreated patients, combined therapy with pegIFN alfa-2a (180 µg once weekly for 48 weeks) and ribavirin (1–1.2 g/day in divided doses) gives higher sustained viral response rates than IFN–ribavirin combinations. The dose and duration of therapy depend on the specific genotype of HCV virus. Approximately 15–20% of those failing to respond to combined IFN–ribavirin will have sustained responses to combined pegIFN–ribavirin. Histological improvement may occur in patients who do not achieve sustained viral responses. In patients with compensated cirrhosis, treatment may reverse cirrhotic changes and possibly reduce the risk of hepatocellular carcinoma.

Papillomavirus

In refractory condylomata acuminata (genital warts), intralesional injection of various IFNs is associated with complete clearance in 36–62% of patients, but other treatments are preferred. Relapse occurs in 20–30% of patients. *Verruca vulgaris* may respond to intralesional IFN-α. Intramuscular or subcutaneous administration is associated with regression in wart size but greater toxicity. Systemic IFN may provide benefit in recurrent juvenile laryngeal papillomatosis and laryngeal disease in older patients.

Other Viruses

IFNs have effects in various herpesvirus infections including genital HSV infections, localized herpes-zoster infection, and CMV infections of renal transplant patients. IFN generally is associated with more side effects and inferior results relative to conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections.

In HIV-infected persons, IFNs have antiretroviral effects, but, the combination of zidovudine and IFN gave only transient benefit and excessive hematological toxicity. IFN-α (3 million units three times weekly) is effective for HIV-related thrombocytopenia resistant to zidovudine therapy.

Except for adenovirus, IFN has broad-spectrum antiviral activity against respiratory viruses. However, prophylactic intranasal IFN- α is protective only against rhinovirus colds, and chronic use is limited by nasal side effects. Intranasal IFN is ineffective in established rhinovirus colds.

Lamivudine

CHEMISTRY AND ANTIVIRAL ACTIVITY Lamivudine, the (–)-enantiomer of 2',3'-dideoxy-3'-thiacytidine, is a nucleoside analog that inhibits HIV reverse transcriptase and HBV DNA polymerase. Its use in HIV infections is discussed in Chapter 50. It inhibits HBV replication with negligible cellular cytotoxicity. Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination. The intracellular $t_{1/2}$ of the triphosphate is 18 hours in HBV-infected cells, permitting infrequent dosing.

LAMIVUDINE

MECHANISMS OF ACTION AND RESISTANCE Lamivudine triphosphate potently inhibits the DNA polymerase/reverse transcriptase of HBV. Lamivudine has enhanced antiviral activity against hepadnaviruses when combined with adefovir or penciclovir. Point mutations in the HBV DNA polymerase markedly reduce sensitivity. Lamivudine resistance confers cross-resistance to agents such as *emtricitabine* and is often associated with an additional mutation that confers cross-resistance to famciclovir. Lamivudine-resistant HBV retains susceptibility to adefovir and partially to entecavir. Viruses bearing certain mutations are less replication competent than wild-type HBV, but lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Following oral administration, lamivudine is absorbed rapidly with a bioavailability of ~80% in adults. Lamivudine is distributed widely in a volume comparable with total-body water. The plasma $t_{1/2}$ of elimination averages ~9 hours, and ~70% of the dose is excreted unchanged in the urine. About 5% is metabolized to an inactive trans-sulfoxide metabolite. In HBV-infected children, doses of 3 mg/kg/day provide drug levels comparable with those in adults receiving 100 mg daily. Dose reductions are indicated for creatinine clearance <50 mL/min.

UNTOWARD EFFECTS

At doses used for chronic HBV infection, lamivudine generally is well tolerated. Flares in aminotransferase levels occur in ~15% of patients after cessation.

THERAPEUTIC USES

Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children. In adults, doses of 100 mg/day for 1 year suppress HBV DNA levels, normalize aminotransferase levels in >40% of patients, and reduce hepatic inflammation in >50% of patients. Seroconversion with antibody to HBeAg occurs in <20% of recipients at 1 year. In children aged 2–17 years, lamivudine (3 mg/kg/day to a maximum of 100 mg for 1 year) is associated with normalization of aminotransferase levels in ~50% and seroconversion to anti-Hbe in ~20% of cases. In those without emergence of resistant variants, prolonged therapy is associated with sustained suppression of HBV DNA, histological improvement, and an increased proportion of patients experiencing loss of HBeAg and undetectable HBV DNA. Prolonged therapy halves the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis. The frequency of lamivudine-resistant variants increases progressively with continued administration, and frequencies of 38%, 53%, and 67% are found after 2, 3, and 4 years of treatment, respectively. The risk of resistance is higher after transplantation and in HIV/HBV-coinfected patients.

Combined use of IFN or pegIFN alfa-2a with lamivudine has not consistently improved responses in HBeAg-positive patients. The addition of lamivudine to pegINF alfa-2a for 1 year of therapy does not improve posttreatment response rates in HBeAg-negative patients. In HIV and HBV coinfections, higher lamivudine doses are associated with antiviral effects and uncommonly anti-HBe seroconversion. Administration of lamivudine before and after liver transplantation may suppress recurrent HBV infection.

Ribavirin

CHEMISTRY AND ANTIVIRAL ACTIVITY Ribavirin (1- β -D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide) is a purine nucleoside analog with a modified base and D-ribose sugar.

Ribavirin inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses. Therapeutic concentrations reversibly inhibit macromolecular synthesis and proliferation of uninfected cells, suppress lymphocyte responses, and alter cytokine profiles.

MECHANISMS OF ACTION AND RESISTANCE Ribavirin alters cellular nucleotide pools and inhibits viral mRNA synthesis. Intracellular phosphorylation to the mono-, di-, and triphosphate derivatives is mediated by host cell enzymes. In both uninfected and RSV-infected cells, the predominant derivative is the triphosphate, which has an intracellular $t_{1/2}$ of <2 hours. Ribavirin monophosphate competitively inhibits cellular inosine-5'-phosphate dehydrogenase and interferes with the synthesis of GTP and thus nucleic acid synthesis. Ribavirin triphosphate also competitively inhibits the GTP-dependent 5' capping of viral messenger RNA and specifically influenza virus transcriptase activity. Ribavirin has multiple sites of action, and some of these (e.g., inhibition of GTP synthesis) may potentiate others (e.g., inhibition of GTP-dependent enzymes). Ribavirin also may enhance viral mutagenesis such that some viruses may be inhibited in effective replication, so-called lethal mutagenesis.

Emergence of viral resistance to ribavirin has been reported in Sindbis and HCV.

ABSORPTION, DISTRIBUTION, AND ELIMINATION

Ribavirin is actively taken up by nucleoside transporters in the proximal small bowel with bioavailability of ~50%. Extensive accumulation occurs in plasma, and steady state is reached by 4 weeks. Food substantially increases plasma levels. With aerosol administration, levels in respiratory secretions are very high.

The volume of distribution for ribavirin is large (~10 L/kg) owing to its cellular uptake. Plasma protein binding is negligible. The plasma $t_{1/2}$ increases to 200–300 hours at steady state, partly because erythrocytes concentrate ribavirin triphosphate and then release it with a $t_{1/2}$ of ~40 days. Hepatic metabolism and renal excretion of ribavirin and its metabolites are the principal routes of elimination. Hepatic metabolism involves deribosylation and hydrolysis to a triazole carboxamide. Ribavirin should be used cautiously in patients with creatinine clearances of <50 mL/min.

UNTOWARD EFFECTS

Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of ventilator valves and tubing. Techniques to reduce environmental exposure of health care workers are recommended.

Systemic ribavirin causes dose-related reversible anemia owing to extravascular hemolysis and bone marrow suppression. Elevations in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations therefore result. Bolus intravenous infusion may cause rigors. About 20% of chronic HCV infection patients receiving combination IFN-ribavirin therapy discontinue treatment because of side effects. In addition to IFN toxicities, oral ribavirin increases the risk of fatigue, cough, rash, pruritus, nausea, insomnia, dyspnea, depression, and particularly, anemia. Preclinical studies indicate that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. To prevent possible teratogenic effects, up to 6 months is required for washout following cessation of long-term treatment.

Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy category X).

Ribavirin inhibits the phosphorylation and antiviral activity of pyrimidine nucleoside HIV reverse-transcriptase inhibitors such as zidovudine and stavudine but increases the activity of purine nucleoside reverse-transcriptase inhibitors (e.g., didanosine) *in vitro*. It appears to increase the risk of mitochondrial toxicity from didanosine (see Chapter 50).

THERAPEUTIC USES

Oral ribavirin in combination with parenteral pegIFN alfa-2a or -2b is standard treatment for chronic HCV infection. Ribavirin monotherapy for 6–12 months reversibly decreases aminotransferases to normal in ~30% of patients but does not affect HCV RNA levels. Combination therapy with pegIFN alfa-2a and oral ribavirin (500 mg, or 600 mg if weight is >75 kg, twice daily for 24–48 weeks) increases the likelihood of sustained responses to ~60%. The combination is superior to IFN or pegIFN monotherapy and combinations of pegIFN alfa-2 and ribavirin in both treatment-naïve patients and those not responding to, or relapsing after, IFN monotherapy. Combined ribavirin and pegIFN alfa-2a or -2b is effective in achieving sustained viral responses in a minority of HCV/HIV-coinfected patients. Combined therapy has been used in the management of recurrent HCV infection after liver transplantation.

Ribavirin aerosol is approved in the U.S. for treatment of RSV bronchiolitis and pneumonia in hospitalized children. Aerosolized ribavirin (usual dose of 20 mg/mL as the starting solution in the drug reservoir of the small particle aerosol generator unit for 18 hours' exposure per day for 3–7 days) may reduce some illness measures, but it generally is not recommended. No consistent benefit on duration of hospitalization, ventilatory support, mortality, or long-term pulmonary function has been found. High-dose, reduced-duration therapy (60 mg/mL in the drug reservoir of the small particle aerosol generator unit for 2 hours three times daily) has been used. Aerosol ribavirin combined with intravenous immunoglobulin appears to reduce mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients.

Intravenous and/or aerosol ribavirin has been used occasionally in treating severe influenza virus infection and in the treatment of immunosuppressed patients with adenovirus, vaccinia, parainfluenza, or measles virus infections. Aerosolized ribavirin reduces duration of fever but has no other beneficial effects in influenza infections in hospitalized children. Intravenous ribavirin decreases mortality in Lassa fever and has been used in treating other arenavirus-related hemorrhagic fevers. Intravenous ribavirin is beneficial in hemorrhagic fever with renal syndrome owing to hantavirus infection but ineffective in hantavirus-associated cardiopulmonary syndrome or SARS.

ANTIRETROVIRAL AGENTS AND TREATMENT OF HIV INFECTION

OVERVIEW OF HIV INFECTION

In 2004, an estimated 42 million people were living with HIV infection worldwide, mostly in resource-poor countries. Of those who would benefit, fewer than 5% were receiving combination antiretroviral therapy, even though such treatment reduces the complications of infection and has the capacity to produce near normal life expectancies for some patients with a previously lethal disease.

Pathogenesis of HIV-Related Disease

Human immunodeficiency viruses (HIVs) are lentiviruses, retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Replication is constant following infection; while some infected cells may harbor nonreplicating but infectious virus for years, there generally is no true period of viral latency following infection. Humans and chimpanzees are the only hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is a close relative whose distribution is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar sensitivities to most antiretroviral drugs, although the nonnucleoside reverse transcriptase inhibitors have no activity against HIV-2.

VIRUS STRUCTURE HIV has a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane (Figure 50–1). The viral genome includes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins; *pol* overlaps *gag* and encodes three important enzymatic activities—an RNA-dependent DNA polymerase or reverse transcriptase, HIV protease, and the viral integrase; and *env* encodes the large transmembrane envelop protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virus production or combat host defenses, including *tat*, *rev*, *nef*, and *vpr*.

VIRUS LIFE CYCLE HIV tropism is controlled by the envelope (*env*) protein gp160 (Figure 50–1). The major target for *env* binding is the CD4 receptor present on lymphocytes and macrophages; cell entry also requires binding to a coreceptor, generally the chemokine receptor CCR5 (present on macrophage lineage cells) or CXCR4. Most infected individuals harbor predominantly the CCR5-tropic virus; it is believed that this virus is responsible for sexual transmission of HIV and that the first cells infected in sexual transmission express this coreceptor. A shift from CCR5 to CXCR4 is associated with advancing disease and heralds accelerated loss of CD4 helper T cells and increased risk of immunosuppression. The obligatory role of coreceptors in HIV entry provides a novel target for pharmacotherapy, and the FDA has recently approved a new drug that targets CCR5 to inhibit viral entry.

The gp41 domain of *env* controls the fusion of the virus lipid bilayer with that of the host cell. Thereafter, full-length viral RNA enters the cytoplasm and is replicated by reverse transcriptase to a short-lived RNA-DNA duplex; the original RNA is degraded by RNase H to allow creation of a full-length double-stranded DNA copy of the virus (Figure 50–1). Because the HIV reverse transcriptase is error-prone and lacks a proofreading function, mutation is quite frequent (~3 bases/9300 base-pair replication). Viral DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location.

Following integration, the virus may remain quiescent, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the virus is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid (Figure 50–1). The transmembrane envelope and other structural proteins assemble at the cell surface, concentrated in lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating a new enveloped HIV particle containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into this particle; thus, replication can begin immediately after the virus enters a new cell.

HOW THE VIRUS CAUSES DISEASE Sexual acquisition of HIV infection is thought to be mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2–4 weeks, with 10^9 or more cells becoming infected. This peak is associated with a transient dip in the number of peripheral CD4 (helper) T lymphocytes. As

FIGURE 50-1 Replicative cycle of HIV-1 showing the sites of action of available antiretroviral agents. Available antiretroviral agents are shown in blue. Key: RT, reverse transcriptase; cDNA, complementary DNA; mRNA, messenger RNA; RNase H, ribonuclease H; gp120 + gp41, extracellular and intracellular domains, respectively, of envelope glycoprotein.

a result of new host immune responses and target cell depletion, the number of infectious virions—as reflected by the plasma HIV RNA concentration (also known as *viral load*)—declines to quasi-steady state. This *set point* of viral activity reflects the interplay between host immunity and the pathogenicity of the infecting virus. In the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the CD4 lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 count falls to <200 cell per mm^3 , there is an increasing risk of opportunistic infection. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical disease—usually an opportunistic infection such as *Pneumocystis carinii* pneumonia—of 8–10 years. Occasional patients can harbor HIV for more than two decades without significant decline in CD4 count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses.

An important question is whether HIV disease is a consequence purely of CD4 lymphocyte depletion or also involves other factors. Most natural history data support the former. Regardless, successful therapy is based on inhibition of HIV replication; treatments designed to boost the host immune system without exerting a direct antiviral effect have had no reliable clinical benefit.

Principles of HIV Chemotherapy

Current treatment assumes that all aspects of the disease derive from direct toxic effects of HIV on host cells, mainly CD4 T lymphocytes. The goal of therapy therefore is to suppress viral replication as much as possible for as long as possible.

Deciding when to initiate therapy has been the subject of some debate. The advent of more effective drugs capable of increasing CD4 cell counts to normal or near normal levels led some to advocate a strategy of early use of combination drug therapy regardless of disease stage or symptoms. It now appears that true eradication of HIV is not possible, at least with current drugs, as there is a reservoir of long-lived, quiescent T cells harboring infectious HIV DNA incorporated into the host chromosome. Natural history studies also point to a low risk of short-term disease progression when the CD4 cell count is >350 cells per mm^3 or plasma HIV RNA concentrations were $<50,000$ copies per mL. The toxic risks of long-term combination chemotherapy, the need for nearly perfect adherence to prescribed regimens, the inconvenience of some regimens, and the high cost of life-long treatment point to a risk-benefit ratio that favors treating only patients with low CD4 counts and/or very high viral load (Table 50-1).

Drug resistance is also an extensive and serious problem. Because of the high mutation rate of HIV and the tremendous number of infectious virions, there is a high likelihood that any infected individual will harbor viruses with single-amino-acid mutations conferring some degree of resistance

Table 50–1

U.S. Department of Health and Human Services Guidelines for Initiating Therapy in Treatment-Naive HIV-Infected Patients, 2004

A. Patient Characteristics			
Clinical Category	CD4 Count	Plasma HIV RNA	Recommendation
AIDS-defining illness* or severe symptoms	Any value	Any value	Treat
Asymptomatic	<200 cells/mm ³	Any value	Treat
Asymptomatic	>200 cells/mm ³ , but <350 cells/mm ³	Any value	Offer treatment, following full discussion of pros and cons with each patient
Asymptomatic	>350 cells/mm ³	>100,000 copies/mL	Most physicians recommend deferring therapy, but some will treat
Asymptomatic	>350 cells/mm ³	<100,000 copies/mL	Defer therapy
B. Preferred and Alternative Regimens			
Preferred Regimens			Number of Pills per Day
NNRTI-based	EFV + (3TC or FTC) + (AZT or TDF) (not for use in first trimester of pregnancy or in women with high pregnancy potential)		2–3
PI-based	LPV/r + (3TC or FTC) + AZT		8–9
Alternative Regimens			Number of Pills per Day
NNRTI-based	EFV + (3TC or FTC) + (ABC or ddI or d4T**)		2–4
	NVP + (3TC or FTC) + (AZT or d4T or ddI or ABC or TDF)		3–6
PI-based	ATV + (3TC or FTC) + (AZT or d4T or ABC or ddI) or (TDF + RTV 100 mg/d)		3–6
	FosAPV + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	FosAPV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	IDV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		7–12
	LPV/r + (3TC or FTC) + (d4T or ABC or TDF or ddI)		7–10
	NFV + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		5–8
	SQV/RTV [†] + (3TC or FTC) + (AZT or d4T or ABC or TDF or ddI)		13–16
	ABC + AZT + 3TC, only when a preferred or an alternative NNRTI- or a PI-based regimen cannot or should not be used		2
Regimens That Should Not Be Used		Rationale	
AZT + d4T		Pharmacologic antagonism between AZT and d4T	
ABC + TDF + 3TC once daily as a triple-NRTI regimen		High rate of early virological nonresponse seen in treatment-naive patients	
TDF + ddI + 3TC combination once daily as a triple-NRTI regimen		High rate of early virological nonresponse seen in treatment-naive patients	

(Continued)

Table 50–1

U.S. Department of Health and Human Services Guidelines for Initiating Therapy in Treatment-Naïve HIV-Infected Patients, 2004 (Continued)
B. Preferred and Alternative Regimens

Regimens That Should Not Be Used	Rationale
ATV + IDV	Potential additive hyperbilirubinemia
ddI + DDC	Additive peripheral neuropathy
FTC + 3TC	Similar resistance profile with no potential benefit
3TC + DDC	<i>In vitro</i> antagonism
SQV hard-gel capsule as single protease inhibitor	Poor oral bioavailability and inferior antiretroviral activity when compared with other protease inhibitors
d4T + DDC	Additive peripheral neuropathy

ABBREVIATIONS: EFV, efavirenz; 3TC, lamivudine; AZT, zidovudine; TDF, tenofovir disoproxil fumarate; d4T, stavudine; LPV/r, lopinavir/ritonavir coformulation; FTC, emtricitabine; NVP, nevirapine; ddI, didanosine; ATV, atazanavir; fosAPV, fosamprenavir; RTV, ritonavir; IDV, indinavir; NFV, nelfinavir; SQV, saquinavir.

*AIDS-defining illness per Centers for Disease Control, 1993. Severe symptoms include unexplained fever or diarrhea >2–4 weeks, oral candidiasis, or >10% unexplained weight loss.

**Higher incidence of lipatrophy, hyperlipidemia, and mitochondrial toxicities reported with d4T than with other NRTIs.

†Low-dose (100–400 mg) ritonavir per day.

‡The triple-NRTI regimen had reduced efficacy compared with NNRTI-based regimens in one large controlled clinical trial and should be used only when an NNRTI- or PI-based regimen cannot or should not be used as first-line therapy.

to any known antiretroviral drug. A combination of active agents therefore is needed to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis. Intentional drug holidays (structured treatment interruptions) allow the virus to replicate anew and increase the risk of drug resistance and disease progression; they therefore are not recommended.

The standard of care is to use at least three drugs simultaneously for the entire duration of treatment (Table 50–1). The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA <50 copies/mL) within 24 weeks of starting treatment. Four or more drugs are often used simultaneously in pretreated patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience. Most clinicians prefer to use drugs that attack at least two different molecular sites (and that thus are from different drug classes). In treatment-naïve patients, a three-drug regimen containing a single drug class is less effective than one that includes drugs from two classes. Regimens containing three or four different classes are reserved for treatment-experienced patients who have failed multiple previous regimens. This acknowledges the benefit of reserving at least one drug class for future treatment in case of failure.

Failure of an antiretroviral regimen involves a persistent increase in plasma HIV RNA in a patient who previously responded or failure to reduce plasma HIV RNA significantly in a patient who has taken the prescribed regimen for more than 12 weeks. This indicates resistance to one or more of the drugs and necessitates a change in treatment. The selection of new drugs is based on the patient's treatment history and viral resistance testing. Treatment failure generally requires a completely new drug combination, as adding a single effective agent to a failing regimen is functionally equivalent to monotherapy. The risk of failing a regimen depends on the percent of prescribed doses taken in any given treatment period. This places an important educational burden on the clinician and requires exceptional patient responsibility.

DRUGS USED TO TREAT HIV INFECTION

Nucleoside and Nucleotide Reverse Transcriptase Inhibitors

The HIV-encoded, RNA-dependent DNA polymerase, also called reverse transcriptase, converts viral RNA into proviral DNA that then is incorporated into a host cell chromosome. Inhibitors of this enzyme are either nucleoside/nucleotide analogs or nonnucleoside inhibitors (Figure 50–2 and Table 50–2). Like all available antiretroviral drugs, nucleoside and nonnucleoside reverse transcriptase inhibitors prevent infection of susceptible cells but have no impact on cells that already

FIGURE 50-2 Structures and mechanism of nucleoside and nucleotide reverse transcriptase inhibitors.

harbor HIV. Nucleoside and nucleotide analogs must enter cells and undergo phosphorylation to generate synthetic substrates for the enzyme (Figure 50-3). The fully phosphorylated analogs block replication of the viral genome both by competitively inhibiting incorporation of native nucleotide and by terminating elongation of nascent proviral DNA because they lack a 3'-hydroxyl group.

All but one of the drugs in this class is a nucleoside that must be triphosphorylated at the 5'-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleoside monophosphate analog that requires two phosphates for full activity. These compounds inhibit both HIV-1 and HIV-2 and several have broad-spectrum activity against other retroviruses; some are also active against hepatitis B virus (HBV) or the herpesviruses.

Although many of the drugs in this class induce only a modest decrease in HIV RNA when used as monotherapy, several have favorable safety and tolerability profiles that make them a valuable component of combination regimens.

Table 50–2

Pharmacokinetic Properties of Nucleoside and Nucleotide Reverse Transcriptase Inhibitors*

Parameter	Zidovudine	Lamivudine	Stavudine [†]	Didanosine [‡]	Abacavir	Zalcitabine	Tenofovir	Emtricitabine

[‡]Parameters reported for the didanosine chewable tablet formulation.

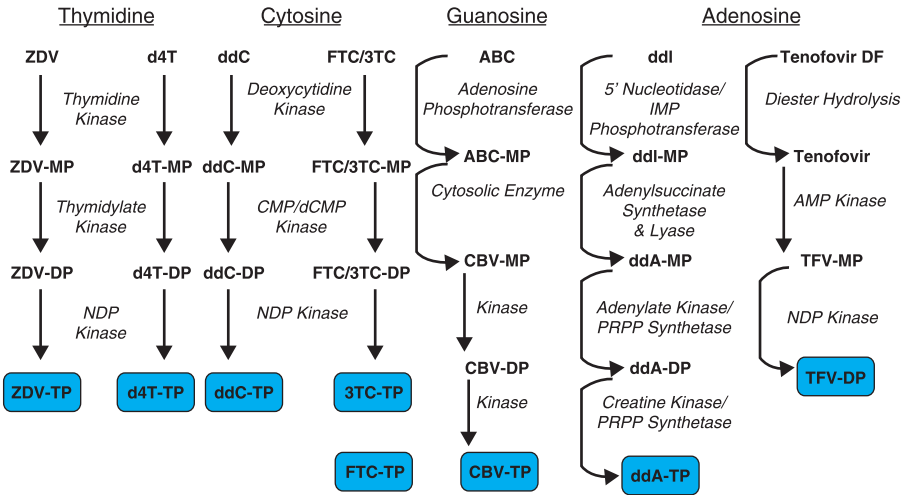

FIGURE 50–3 Intracellular activation of nucleoside analog reverse transcriptase inhibitors. Drugs and phosphorylated anabolites are abbreviated; the enzymes responsible for each conversion are spelled out. The active antiretroviral anabolite for each drug is shown in the blue box. Key: ZDV, zidovudine; d4T, stavudine; ddC, dideoxycytidine; FTC, emtricitabine; 3TC, lamivudine; ABC, abacavir; ddi, didanosine; DF, disoproxil fumarate; MP, monophosphate; DP, diphosphate; TP, triphosphate; AMP, adenosine monophosphate; CMP, cytosine monophosphate; dCMP, deoxycytosine monophosphate; IMP, inosine 5′-monophosphate; PRPP, phosphoribosyl pyrophosphate; NDR, nucleoside diphosphate.

Mechanisms of Action and Resistance Resistance to nucleoside reverse transcriptase inhibitors, especially thymidine analogs, occurs slowly relative to the NNRTIs and protease inhibitors. In most cases, high-level resistance requires a minimum of 3–4 codon substitutions, although 1 two-amino-acid insertion is associated with resistance to all drugs in this class. Cross-resistance is common but often confined to drugs having similar chemical structures; for example, zidovudine is a thymidine analog, and a zidovudine-resistant isolate is much more likely to be cross-resistant to the thymidine analog stavudine than to the cytosine analog lamivudine. These mutations are termed *thymidine-analog mutations (TAMs)*. Substitutions at codon 184 are associated with high-level resistance to lamivudine and emtricitabine; these same amino acid substitutions restore sensitivity to zidovudine and reduce the fitness of HIV, perhaps explaining the sustained virologic benefits of combination therapy with lamivudine and zidovudine.

Absorption, Distribution, and Elimination Most nucleoside and nucleotide reverse transcriptase inhibitors are eliminated from the body primarily by renal excretion. The parent compounds are generally eliminated rapidly from plasma with elimination half-lives of 1–10 hours (Table 50–2). Despite rapid clearance from plasma, the critical pharmacological pathway for these agents is production and elimination of the intracellular nucleoside triphosphate or nucleotide diphosphate, which is the active anabolite. These reservoirs allow for less frequent dosing, and all approved nucleoside and nucleotide reverse transcriptase inhibitors are dosed once or twice daily, with the exception of zalcitabine, which is dosed every 8 hours. These drugs are not substrates for hepatic CYPs and thus generally are not involved in clinically significant drug interactions. Specific exceptions to this are described below under the individual drugs.

Adverse Effects The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although these drugs have low affinity for human DNA polymerases α and β , some are capable of inhibiting human DNA polymerase γ , the mitochondrial enzyme. As a result, important toxicities common to this class of drugs result in part from inhibition of mitochondrial DNA synthesis. These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with stavudine, zidovudine, didanosine, and zalcitabine. Risk factors for this lactic acidosis-hepatic steatosis syndrome include female gender, obesity, and prolonged exposure to the causative drugs. Drugs that are subject to mitochondrial toxicities generally should not be coadministered with other

agents that can cause neuropathy (e.g., *ethambutol*, *isoniazid*, *vincristine*, *cisplatin*, and *pentamidine*) or pancreatitis. Phosphorylated emtricitabine, lamivudine, and tenofovir have low affinity for DNA polymerase γ and are largely devoid of mitochondrial toxicity.

Zidovudine

Zidovudine is a synthetic thymidine analog with potent activity against a broad spectrum of retroviruses including HIV-1, HIV-2, and human T-cell lymphotropic viruses (HTLV) I and II. The drug has no impact in cells already infected with HIV. It is most effective in activated lymphocytes because the phosphorylating enzyme, thymidine kinase, is S-phase specific.

The steps involved in zidovudine phosphorylation are shown in Figure 50–3. Because the conversion of zidovudine 5′-monophosphate to diphosphate is very inefficient, high concentrations of the monophosphate accumulate inside the cell. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of the active species. The 5′-triphosphate terminates the elongation of proviral DNA because it is incorporated into nascent DNA but lacks a 3′-hydroxyl group, while the monophosphate competitively inhibits thymidylate kinase.

Zidovudine may be taken irrespective of food and undergoes rapid first-pass hepatic metabolism to 5-glucuronyl zidovudine. Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia, which generally resolve within the first few weeks of therapy. The mitochondrial toxicities shared by this class are commonly encountered. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used together.

Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission; it also is recommended for postexposure prophylaxis in HIV-exposed healthcare workers, also in combination with other antiretroviral agents. The standard of care for treatment-naïve patients (Table 50–1B) is to combine zidovudine with a potent protease inhibitor and another nucleoside analog or with an NNRTI and another nucleoside analog. The Met-to-Val substitution at reverse transcriptase codon 184 associated with use of lamivudine greatly restores sensitivity to zidovudine, and these drugs are often used in combination.

Didanosine

Didanosine is a purine nucleoside analog active against HIV-1, HIV-2, and HTLV-1. After entering the cell, it is converted by phosphorylation to the active anabolite dideoxyadenosine 5′-triphosphate. Single codon mutations, including TAMs, can contribute to didanosine resistance.

Didanosine is acid labile, and therefore is administered with an antacid buffer. Food decreases bioavailability and all formulations of didanosine must be administered at least 30 minutes before or 2 hours after eating; this complicates dosing of didanosine with other antiretroviral agents that must be administered with food, such as many HIV protease inhibitors. Because of the long intracellular $t_{1/2}$ of the active anabolite, didanosine can be administered once daily.

The most serious toxicities with didanosine are peripheral neuropathy and pancreatitis, both due to mitochondrial toxicity. It should be avoided in patients with a history of pancreatitis or neuropathy and should not be coadministered with other drugs that can cause neuropathy. Diarrhea is reported more frequently with didanosine than with other nucleoside analogs, perhaps related to the antacid in the oral preparations. The buffering agents also can impair the bioavailability of other coadministered drugs.

Stavudine

Stavudine is a synthetic thymidine analog reverse transcriptase inhibitor that is active against HIV-1 and HIV-2. After entering the cell, it is phosphorylated to its active form, stavudine 5′-triphosphate. Unlike zidovudine, the monophosphate does not accumulate within the cell.

Stavudine is well absorbed and its bioavailability is not affected by food. The dose should be adjusted in patients with renal insufficiency. A sustained-release formulation that can be given once daily is FDA-approved.

The most common adverse effect with stavudine is peripheral neuropathy, which occurs in ~12% of patients. Combining stavudine with zidovudine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis, and these drugs should not be used together under most circumstances. Lactic acidosis and hepatic steatosis also have been seen and are more common with stavudine than with zidovudine or abacavir. Of all the nucleoside analogs, stavudine is most strongly linked to the HIV lipodystrophy syndrome, perhaps due to toxic effects on adipocytes.

Zalcitabine

Zalcitabine is a synthetic cytosine analog reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and hepatitis B virus. After entering the cell, it is phosphorylated to its active anabolite, dideoxycytidine-5'-triphosphate. In addition to DNA polymerase γ , zalcitabine also weakly inhibits DNA polymerase β .

The drug is well absorbed orally and food does not affect bioavailability. The drug is largely excreted unchanged in the urine, and the dose must be reduced in patients with impaired renal function. It is recommended that zalcitabine be administered every 8 hours in patients with normal renal function.

Zalcitabine toxicities are similar to those of the other dideoxynucleotide analogs didanosine and stavudine. Severe peripheral neuropathy has been reported in up to 15% of patients. Pancreatitis occurs rarely with zalcitabine therapy, but coadministration of other drugs that cause pancreatitis should be avoided. One distinctive toxicity of zalcitabine is oral ulceration and stomatitis. An erythematous rash also is common but generally self-limited. The necessity of frequent administration, the risk of toxicities, and the inferior antiviral activity compared to more convenient agents limits the use of zalcitabine in the U.S.

Lamivudine

Lamivudine is a cytosine analog active against HIV-1, HIV-2, and HBV. The molecule is manufactured as the pure *cis*-(-) enantiomer (Figure 50–2), which is more potent and substantially less toxic. The active species is the intracellular triphosphate derivative, which has low affinity for human DNA polymerases. High-level resistance to lamivudine occurs with single-amino-acid mutations at codon 184 that can reduce *in vitro* sensitivity to the drug by up to 1000-fold but restore sensitivity to zidovudine. This effect may contribute to the sustained virologic benefits of combination therapy with lamivudine and zidovudine.

The oral bioavailability of lamivudine is >80% and is not affected by food. It is excreted primarily unchanged in the urine, and dose adjustment is recommended for patients with a creatinine clearance of <50 mL/min. Lamivudine is one of the least toxic antiretrovirals and has few significant effects. Neutropenia, headache, and nausea have been reported.

Many trials have confirmed the value of lamivudine in three-drug regimens with other nucleoside analogs, protease inhibitors, and/or NNRTIs. It is a common component of therapy based on its safety, convenience, and efficacy. Since lamivudine and emtricitabine have nearly identical resistance and activity patterns, there is no rationale for their combined use.

Abacavir

Abacavir is a synthetic purine analog that is converted in the cell to carbovir triphosphate, a potent inhibitor of the HIV-1 reverse transcriptase. It is the only approved antiretroviral that is a guanosine analog. Abacavir's oral bioavailability is >80% regardless of food intake. Because of the prolonged $t_{1/2}$ of carbovir triphosphate, the drug can be administered once daily. The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity reaction that occurs in 2–9% of patients. This reaction typically begins within 6 weeks of drug initiation and is characterized by fever, abdominal pain and other GI complaints, a maculopapular rash, malaise, and fatigue. Less common are respiratory complaints, headache, and paresthesias. The presence of fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate drug discontinuation. Patients must be warned about these symptoms, and those who exhibit the hypersensitivity reaction should never be retreated with abacavir. The hypersensitivity syndrome results from an immune reaction that is genetically linked to the HLA-B and the heat shock protein 70 loci, providing one of the most striking pharmacogenetic associations ever described.

Abacavir is widely used in combination with other antiretroviral agents, and is supplied in coformulations with zidovudine or lamivudine for twice-daily administration and with lamivudine for once-daily administration.

Tenofovir

Tenofovir is a derivative of adenosine 5'-monophosphate lacking a complete ribose ring and is the only nucleotide analog currently marketed for the treatment of HIV infection; it is active against HIV-1, HIV-2, and HBV.

Because of poor bioavailability, it is administered as a disoproxil fumarate prodrug. The prodrug is rapidly converted to tenofovir, which then is phosphorylated by cellular kinases to the active

metabolite, tenofovir diphosphate (Figure 50–3). It can be dosed once daily. It primarily is excreted unchanged in the urine, and the dose should be decreased in patients with renal insufficiency.

Tenofovir generally is well tolerated, with few adverse events except for flatulence. Rare episodes of acute renal failure and Fanconi's syndrome have been reported, and the drug should be used with caution in patients with preexisting renal disease. It can increase the AUC of didanosine, and the drugs probably should not be used together.

Tenofovir is FDA-approved as a component of combination HIV therapy for adults and has proven value in three-drug regimens with other agents, including other nucleoside analogs, protease inhibitors, and/or NNRTIs.

Emtricitabine

Emtricitabine is a cytosine analog that is chemically related to lamivudine and shares many of its properties. It is active against HIV-1, HIV-2, and HBV.

High-level host resistance to emtricitabine occurs with the same mutation (M184V) that affects lamivudine sensitivity, although the mutation apparently occurs less frequently. This mutation restores sensitivity to zidovudine.

Emtricitabine has excellent oral absorption and can be taken without regard to food. It has a long elimination $t_{1/2}$ and can be administered once daily. It is excreted primarily unchanged in the urine. It is one of the least toxic antiretroviral drugs and has few significant adverse effects. Prolonged exposure has been associated with hyperpigmentation. It is not subject to any known metabolic drug interactions. Emtricitabine is approved in several combination regimens for HIV-1 therapy and has similar efficacy to lamivudine.

Nonnucleoside Reverse Transcriptase Inhibitors

The chemical structures of the three approved NNRTIs are shown in Figure 50–4, and their pharmacokinetic properties are summarized in Table 50–3.

FIGURE 50–4 Structures and mechanism of nonnucleoside reverse transcriptase inhibitors.

Table 50-3

Pharmacokinetic Properties of Nonnucleoside Reverse Transcriptase Inhibitors*

Parameter	Nevirapine [†]	Efavirenz [‡]	Delavirdine

[†]Reported mean values in adults with normal renal and hepatic function.

[‡]Values at steady state after multiple oral doses.

MECHANISM OF ACTION AND RESISTANCE These drugs are noncompetitive inhibitors that bind to a peripheral site on HIV-1 reverse transcriptase. The binding site is a hydrophobic pocket in the p66 subunit of reverse transcriptase, distant from the active site and not essential for function. Occupation of the site by an NNRTI induces a conformational change that greatly reduces the enzyme's activity. Because the binding site for NNRTIs is strain-specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses. They have no activity against host cell DNA polymerases. NNRTIs do not require intracellular phosphorylation for activity. Resistance can develop rapidly, sometimes within a few days or weeks. Single codon mutations can reduce susceptibility to these drugs by over 100-fold, and cross-resistance to the other NNRTIs is seen with most of these mutations (most often codons 103 or 181 in the hydrophobic binding pocket). Therefore, *any patient who fails treatment with one NNRTI because of a specific resistance mutation should be considered to have failed the entire class.*

Absorption, Distribution, and Elimination These drugs are administered orally and rapidly absorbed. Food generally does not affect their absorption. They are metabolized primarily by hepatic CYPs 3A4 or 2B6. Thus, they are subject to multiple interactions with other drugs that are either substrates or inducers of these enzymes. Efavirenz and nevirapine are moderately potent inducers of CYP3A4, whereas delavirdine is an inhibitor.

Adverse Effects The most frequent adverse effect with these drugs is rash, which typically occurs in 15–25% of patients. The most severe form is life-threatening Stevens-Johnson syndrome. Elevations of hepatic transaminases also are common with all drugs of this class, although the propensity to cause severe hepatitis varies somewhat with the different agents (*see* below).

Nevirapine Nevirapine is FDA-approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents. Resistance can develop rapidly and the drug should never be used as a single agent or as the sole addition to a failing regimen. Nevirapine readily crosses the placenta and therefore has been used to prevent mother-to-child transmission of HIV-1. In addition to elevated hepatic transaminases, severe and fatal hepatitis has been associated with nevirapine use; this may be more common in women, especially during pregnancy. Although nevirapine is inexpensive and generally well tolerated in intrapartum usage, the high prevalence of nevirapine resistance and the recognition of fatal hepatitis have prompted reexamination of this approach to the prevention of vertical transmission. In particular, the drug should not be initiated in women with CD4 cell counts >250 per mm³ or men with CD4 counts >400 per mm³ unless benefits clearly outweigh the risks.

Delavirdine Due to its shorter t_{1/2} and rapid emergence of resistance, delavirdine is the least used of the NNRTIs. Its absorption is best at acid pH and may be decreased by histamine H₂ receptor antagonists or proton pump inhibitors. It is cleared predominantly by CYP3A4 and has an elimination t_{1/2} of 6 hours. It should be avoided with CYP3A4 substrates with a narrow therapeutic index and not combined with potent inducers of CYP3A4 (*e.g.*, carbamazepine, phenobarbital, phenytoin, rifabutin, and rifampin).

Efavirenz Efavirenz (Figure 50–4) is widely used in the developed world because of its convenience, effectiveness, and long-term tolerability. It should only be used in combination with other effective agents and should not be added as the sole new agent to a failing regimen. It is cleared predominantly by CYP2B6 with a prolonged $t_{1/2}$ that permits once-daily dosing. In addition to rash, the predominant adverse effects of efavirenz involve the CNS (*e.g.*, dizziness, impaired concentration, dysphoria, frank psychosis, depression, or hallucinations). Fortunately, these CNS side effects generally lessen or resolve within the first 4 weeks of therapy. Efavirenz is the only antiretroviral drug that is unequivocally teratogenic, causing neural tube defects; thus, women of childbearing potential should use two methods of birth control and avoid pregnancy while taking this drug.

HIV Protease Inhibitors

The HIV protease inhibitors emerged from rational drug design based on the structure of a peptide-enzyme complex. They produce favorable long-term suppression of viremia, elevation of CD4 lymphocyte counts, reduced disease progression, and improved survival when combined with other antiretroviral drugs. These virologic benefits must be balanced against short- and long-term toxicity.

MECHANISM OF ACTION AND RESISTANCE HIV protease inhibitors are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease. This protease is a homodimer consisting of two 99-amino-acid monomers; each monomer contains an Asp residue that is essential for catalysis. The preferred cleavage site for this enzyme is the N-terminal side of Pro residues, especially between Phe and Pro (Figure 50–5). Human aspartyl proteases contain only one polypeptide chain and are not significantly inhibited by HIV protease inhibitors. These drugs bind reversibly to the active site of the protease and prevent proteolytic cleavage of HIV gag and pol proteins into essential structural and enzymatic components of the virus. This prevents the metamorphosis of HIV virus particles into their mature infectious form. Infected patients treated with HIV protease inhibitors as sole agents experience a 100–1000-fold decrease in plasma HIV RNA concentrations within 12 weeks, an effect similar in magnitude to that produced by NNRTIs.

In patients treated with single protease inhibitors, viral replication in the presence of drug selects for drug resistance. The speed with which HIV develops resistance to protease inhibitors is intermediate between that of nucleoside analogs and NNRTIs, typically with a rebound in HIV RNA levels within 3–4 months. Unlike the NNRTIs, high-level resistance to the protease inhibitors generally requires the accumulation of a minimum of four to five codon substitutions, which may take many months. Primary resistance may result from mutations in the protease-active site that confer resistance only to the specific drug by causing a three- to five-fold decrease in sensitivity. These are followed by secondary mutations, often distant from the active site, that compensate for the reduction in proteolytic efficiency, which often are associated with cross-resistance to multiple HIV protease inhibitors.

Absorption, Distribution, and Elimination The HIV protease inhibitors are all absorbed orally. The absorption of several members is decreased by concomitant use of proton pump inhibitors, suggesting that pH is important. An important shared toxicity for these drugs is the potential for metabolic drug interactions based on their hepatic metabolism (Tables 50–4, 50–5). With the exception of nelfinavir, which is predominantly metabolized by CYP2C19, these drugs are metabolized by and inhibit CYP3A4. The magnitude of this effect varies, with ritonavir by far the most potent. The pharmacokinetic properties of the HIV protease inhibitors also are notable for high interindividual variability, which may reflect differential activity of intestinal and hepatic CYPs. Because of its capacity to inhibit CYP3A4, a low dose of ritonavir is commonly combined with other HIV protease inhibitors to improve their pharmacokinetic profiles by increasing oral bioavailability and prolonging the $t_{1/2}$, often permitting once-daily administration. Following hepatic conversion, these drugs are largely excreted *via* bile in the feces.

Adverse Effects Adverse effects seen commonly with HIV protease inhibitors include nausea and vomiting, anorexia, and diarrhea. Of more consequence, this drug class is frequently associated with the development of lipodystrophy, a metabolic syndrome characterized by insulin resistance and dyslipidemia. The long-term impact of the metabolic syndrome on cardiovascular events remains unknown. As a result of their capacity to inhibit CYP3A4 metabolism, protease inhibitors commonly are involved in clinically significant pharmacokinetic drug interactions, and patients and providers must be vigilant for such interactions. These drugs generally should not be coadministered with other CYP3A4 substrates that have a narrow therapeutic index, such as midazolam, triazolam, propafenone, and ergot derivatives.

Specific Drugs

Saquinavir Saquinavir is a peptidomimetic HIV protease inhibitor that inhibits HIV-1 and HIV-2 replication. Of all of the HIV protease inhibitors, saquinavir inhibits CYP3A4 least potently. Typically, saquinavir is administered once or twice daily in combination with zidovudine to improve pharmacokinetics.

Ritonavir Ritonavir is a peptidomimetic HIV protease inhibitor that is active against HIV-1 and HIV-2. Ritonavir is an extremely potent inhibitor of CYP3A4 and is frequently combined with most of the protease inhibitors to enhance their pharmacokinetic profiles and allow a reduction in dose and dosing frequency. Typically, a low dose of ritonavir (100 or 200 mg twice daily) is used, as it is better tolerated and just as effective at inhibiting CYP3A4.

Indinavir Indinavir is a peptidomimetic HIV protease inhibitor that is tenfold more potent against the HIV-1 protease than that of HIV-2. Indinavir is absorbed rapidly after oral administration. Unlike other protease inhibitors, food adversely affects indinavir bioavailability; this can be alleviated by coadministration of zidovudine. Unique adverse effects of indinavir are crystalluria and nephrolithiasis, which stem from its poor solubility; patients should drink at least 2 L of water daily

FIGURE 50-5 Mechanism of action of an HIV protease inhibitor.

Table 50-4

Drug Interactions Between Nucleoside Reverse Transcriptase Inhibitors and HIV Protease Inhibitors*

	Effect of NNRTI on Plasma AUC of PI (% Change)			Effect of PI on Plasma AUC of NNRTI (% Change)

Atazanavir	NR	NR	↓74%	NR	NR	NR

ABBREVIATIONS: NNRTI, nonnucleoside reverse transcriptase inhibitor; PI, HIV protease inhibitor; AUC, area under the plasma concentration–time curve; ↑, increase, ↓, decrease; ↔, no change; NR, not reported.

[†]Reported mean change in the AUC of the standard dose of the affected drug by the standard dose of the affecting drug; studies using modified dosing regimens were dose-normalized.

[‡]Parameters reported for the saquinavir soft-gel capsule formulation.

[§]Lopinavir is only available in a coformulation with ritonavir.

to diminish these complications. Indinavir frequently causes unconjugated hyperbilirubinemia, which is generally asymptomatic and not associated with long-term sequelae. Because indinavir is less soluble at higher pH, antacids or other buffering agents should not be coadministered. Rifampin lowers the indinavir AUC by 90% and is contraindicated, while the dose of rifabutin should be reduced by 50% when coadministered with indinavir.

Nelfinavir Nelfinavir is a nonpeptidic protease inhibitor that is active against HIV-1 and HIV-2. It is absorbed more slowly after oral administration than the other HIV-1 protease inhibitors and is very sensitive to food effects. It undergoes extensive hepatic metabolism, primarily by CYP2C19, to an active metabolite M8. Concomitant use of drugs that induce CYP2C19 may be contraindicated (e.g., rifampin) or may require an increase in the nelfinavir dose (e.g., rifabutin). Although liver disease may prolong the $t_{1/2}$ of the drug, it has been used in HIV-infected patients with significant hepatic dysfunction without evidence of untoward toxicity.

Fosamprenavir Fosamprenavir is a prodrug that is converted to amprenavir, a nonpeptide HIV protease inhibitor; the increased aqueous solubility of the prodrug markedly improves bioavailability. The drug is active against both HIV-1 and HIV-2. Amprenavir is the HIV protease inhibitor that is most likely to produce rash, possibly because it contains a sulfonamide moiety. It generally is combined with ritonavir.

Lopinavir Lopinavir is a peptidomimetic HIV protease inhibitor that is structurally similar to ritonavir and inhibits both HIV-1 and HIV-2. It is only administered in combination with ritonavir, and should be taken with food because oral bioavailability is increased by 50% with a high fat meal.

Atazanavir Atazanavir is a peptide protease inhibitor that is active against both HIV-1 and HIV-2. Absorption is increased by food and it is recommended that the drug be administered with a meal. Absorption may be pH dependent, because proton pump inhibitors substantially reduce drug concentration after oral dosing. Like indinavir, atazanavir frequently causes unconjugated hyperbilirubinemia. The drug may be less likely than other HIV protease inhibitors to cause lipodystrophy.

Tipranavir The FDA recently granted approval for tipranavir, the first member of a new class of nonpeptide inhibitors of the HIV-1 protease, in combination therapy. Although it also binds to the active site of the HIV-1 protease, tipranavir differs in structure from previously available peptidomimetic protease inhibitors and retains activity against HIV-1 isolates that are resistant to other HIV protease inhibitors. Tipranavir, coadministered with ritonavir, is approved for the treatment of HIV-1-infected adults with evidence of viral replication and who have received multiple treatment regimens or have HIV-1 strains resistant to multiple protease inhibitors. As noted in a “black box”

Table 50-5

Drug Interactions Amongst HIV Protease Inhibitors*

Drug Exerting Effect	Drug Affected (Change in Plasma AUC)

[‡]Lopinavir is only available in a coformulation with ritonavir.

[§]This represents the impact of additional ritonavir (100 mg bid) on the AUC of lopinavir in the coformulation of 400 mg lopinavir with 100 mg ritonavir bid.

warning, administration of the tipranavir/ritonavir combination has been associated with hepatitis and hepatic decompensation, including fatalities, and special vigilance is indicated in patients with chronic hepatitis B or C coinfection.

Entry Inhibitors

Enfuvirtide is a 36-amino-acid synthetic peptide whose sequence is derived from a part of the trans-membrane gp41 region of HIV-1. Enfuvirtide is not active against HIV-2 but has a broad range of potencies against HIV-1 isolates.

MECHANISMS OF ACTION AND RESISTANCE The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell. Enfuvirtide inhibits infection of CD4 cells by free virus particles, as well as cell-to-cell transmission of HIV-1 *in vitro*. Because of its unique mechanism of action, enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes.

HIV-1 can develop resistance to enfuvirtide though specific mutations in the enfuvirtide-binding domain of gp41. Single amino acid substitutions can confer up to 450 times resistance *in vitro*, although high-level clinical resistance is generally associated with two or more amino acid changes.

Absorption, Distribution, and Elimination Enfuvirtide must be given parentally. Peak concentration after subcutaneous administration occurs on average 4 hours after dosing, with an apparent volume of distribution of 5.5 L. Pharmacokinetics of the subcutaneous drug are not affected by injection site. A deamidated metabolite at the C-terminal Phe is formed in humans, but no other significant metabolites are detected. The mean elimination $t_{1/2}$ is 4 hours, necessitating twice-daily administration. The drug is highly bound by proteins, mainly albumin.

Adverse Effects The most prominent adverse effects of enfuvirtide are injection site reactions, including pain, erythema, induration, and nodules or cysts. These cause drug discontinuation in ~5% of patients. Use of enfuvirtide has been associated with increased lymphadenopathy and pneumonia. The causal role and underlying mechanism are under investigation.

Therapeutic Use Enfuvirtide is FDA-approved for use only in treatment-experienced adults who have evidence of HIV-1 replication despite ongoing antiretroviral therapy. Treatment response appears to be much more likely in patients with at least two other active drugs in the regimen, based on history and HIV genotype. Given its cost, inconvenience, and cutaneous toxicity, enfuvirtide is reserved for patients who have failed all other feasible antiretroviral regimens.

CURRENT TREATMENT GUIDELINES

Guidelines for initiating therapy in treatment naïve HIV-infected patients are summarized in Table 50–1. These regulations are based on a consensus assessment of the results of published clinical trials regarding when to initiate treatment, when to change treatment regimens, and which regimens perform best in terms of antiviral efficacy, safety, and tolerability. Practitioners need to be aware that guidelines provide general guidance rather than absolute recommendations for the average uncomplicated patient and may need to be modified based on intercurrent disease, concurrent medications, and other circumstances.

Current treatment guidelines center around two important questions: when to start therapy in treatment-naïve individuals and when to change therapy in individuals who are failing their current regimen. The specific drugs recommended may change as new choices become available. However, *it is likely that future treatment guidelines will continue to be driven by the important principles mentioned earlier; (1) combination therapy in order to prevent the emergence of resistant virus; (2) emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication; and (3) the need for life-long treatment under most circumstances.*

SECTION IX

CHEMOTHERAPY OF NEOPLASTIC DISEASES

51

ANTINEOPLASTIC AGENTS

Few categories of medication have a narrower therapeutic index and a greater potential for causing harmful side effects than do the antineoplastic drugs. A thorough understanding of their pharmacology, drug interactions, and clinical pharmacokinetics is essential for safe and effective use. The diversity of agents used to treat neoplastic disease is summarized in Table 51–1. Figure 51–1 shows some of the common targets for chemotherapeutic agents currently used to treat neoplastic disease.

In designing specific regimens for clinical use, many factors must be considered. Drugs are most effective in combination, and may be synergistic because of their biochemical interactions. It is more effective to combine drugs that do not share common mechanisms of resistance and do not overlap in their major toxicities. Cytotoxic drugs should be used as close as possible to their maximum individual doses and should be given as frequently as possible to discourage tumor regrowth and to maximize dose intensity—the dose given per unit time—a key parameter in the success of chemotherapy. Since the tumor cell population in patients with clinically detectable disease exceeds 10^9 cells, and since each cycle of therapy kills <99% of the cells, it is necessary to repeat treatments in multiple cycles to eradicate tumor cells.

THE CELL CYCLE An understanding of cell-cycle kinetics is essential for the proper use of antineoplastic agents (Figure 51–2). Many of the most effective cytotoxic agents damage DNA, and their toxicity is greater during the S, or DNA synthetic, phase of the cell cycle. Others, such as the vinca alkaloids and taxanes, block formation of a functional mitotic spindle in M phase. Human neoplasms that are most susceptible to chemotherapy are those with a high percentage of cells undergoing division. Similarly, normal tissues that proliferate rapidly (*e.g.*, bone marrow, hair follicles, and intestinal epithelium) are most subject to damage by cytotoxic drugs, which often limits their usefulness. Conversely, slowly growing tumors with a small growth fraction (*e.g.*, carcinomas of the colon or non–small cell lung cancer) often are less responsive to cycle-specific drugs. *Understanding of cell-cycle kinetics and the controls of normal and malignant cell growth is crucial to the design of current therapeutic regimens and the search for new drugs.*

ACHIEVING THERAPEUTIC BALANCE AND EFFICACY The treatment of most cancer patients requires a skillful interdigitation of multiple treatment modalities, including surgery and irradiation, with drugs. Each of these forms of treatment carries its own risks and benefits. Not all drug regimens are appropriate for all patients, and factors such as renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems must be considered. Beyond those considerations, however, are less quantifiable factors such as the likely natural history of the tumor being treated, the patient's willingness to undergo difficult and potentially dangerous treatments, the patient's physical and emotional tolerance for side effects, and the likely long-term gains and risks involved.

One of the greatest challenges of therapeutics is to adjust dose to achieve a therapeutic, but non-toxic, outcome. While it is customary to base dose on body surface area for individual patients, dose adjustment based on renal function or on pharmacokinetic monitoring can meet specific targets such as desired drug concentration in plasma or area under the concentration–time curve (AUC), a measure of tissue exposure. For example, thrombocytopenia caused by *carboplatin* is a direct function of AUC, which in turn is determined by renal clearance of the parent drug. Basic pharmacokinetic principles can be thus used to achieve a desired AUC for carboplatin based on creatinine clearance. Similarly, therapeutic success during high-dose therapy for pediatric acute lymphoblastic leukemia (ALL) is related to achieving targeted methotrexate concentrations in plasma. Monitoring of steady-state levels of methotrexate allows dose adjustment and improves outcome.

Molecular tests increasingly are used to identify patients likely to benefit from treatment and those at highest risk of toxicity. Pretreatment testing to select patients for response to treatment is standard practice for hormonal therapy of breast cancer and for treatment with antibodies such as

Table 51-1

Chemotherapeutic Agents Useful in Neoplastic Disease

Class/Type of agent	Nonproprietary names (other names)	Disease*
<i>Alkylating agents</i>		
Nitrogen mustards	Mechlorethamine Cyclophosphamide Ifosfamide	Hodgkin's disease; non-Hodgkin's lymphoma Acute and chronic lymphocytic leukemia; Hodgkin's disease; non-Hodgkin's lymphoma; multiple myeloma; neuroblastoma; breast, ovary, lung cancer; Wilms' tumor; cervix, testis cancer; soft-tissue sarcoma
	Melphalan (L-sarcolysin) Chlorambucil	Multiple myeloma; breast, ovarian cancer Chronic lymphocytic leukemia; primary macroglobulinemia; Hodgkin's disease; non-Hodgkin's lymphoma
Ethyleneimines and methylmelamines	Altretamine Thiotepa	Ovarian cancer Bladder, breast, ovarian cancer
	Methylhydrazine derivative Alkyl sulfonate	Procabazine (<i>N</i> -methylhydrazine, MIH) Busulfan
Nitrosoureas	Carmustine (BCNU)	Hodgkin's disease; non-Hodgkin's lymphoma; primary brain tumor; melanoma
	Streptozocin (streptozotocin)	Malignant pancreatic insulinoma; malignant carcinoid
Triazenes	Dacarbazine (DTIC; dimethyltriazenoimida- zole carboxamide), temozolomide	Malignant melanoma; Hodgkin's disease; soft-tissue sarcomas; glioma; melanoma
Platinum coordination complexes	Cisplatin, carboplatin, oxaliplatin	Testicular, ovarian, bladder, esophageal, lung, colon cancer
<i>Antimetabolites</i>		
Folic acid analogs	Methotrexate (amethopterin)	Acute lymphocytic leukemia; choriocarcinoma; breast, head, neck, and lung cancer; osteogenic sarcoma; bladder cancer
Pyrimidine analogs	Pemetrexed	Mesothelioma, lung cancer
	Fluorouracil (5-fluorouracil, 5-FU), capecitabine Cytarabine (cytosine arabinoside)	Breast, colon, esophageal, stomach, pancreas, head and neck; pre-malignant skin lesion (topical) Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin's lymphoma
Purine analogs and related inhibitors	Gemcitabine	Pancreatic, ovarian, lung cancer
	Mercaptopurine (6-mercaptopurine, 6-MP)	Acute lymphocytic and myelogenous leukemia
	Pentostatin (2'-deoxycoformycin), cladribine, fludarabine	Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin's lymphoma

Natural and semi-synthetic products

Vinca alkaloids	Vinblastine, vinorelbine	Hodgkin's disease; non-Hodgkin's lymphoma: breast, lung, and testis cancer
	Vincristine	Acute lymphocytic leukemia; neuroblastoma; Wilms' tumor; rhabdomyosarcoma; Hodgkin's disease; non-Hodgkin's lymphoma
Taxanes	Paclitaxel, docetaxel	Ovarian, breast, lung, bladder, head and neck cancer
Epipodophyllotoxins	Etoposide	Testis, small-cell lung, and other lung cancer; breast cancer; Hodgkin's disease; non-Hodgkin's lymphomas; acute myelogenous leukemia; Kaposi's sarcoma
Camptothecins	Teniposide	Same as etoposide; acute lymphoblastic leukemia in children
	Topotecan, irinotecan	Ovarian cancer; small-cell lung cancer; colon and lung cancer
Antibiotics	Dactinomycin (actinomycin D)	Choriocarcinoma; Wilms' tumor; rhabdomyosarcoma; testis; Kaposi's sarcoma
	Daunorubicin (daunomycin, rubidomycin) Doxorubicin	Acute myelogenous and acute lymphocytic leukemia Soft-tissue, osteogenic, and other sarcoma; Hodgkin's disease; non-Hodgkin's lymphoma; acute leukemia; breast, genitourinary, thyroid, lung, stomach cancer; neuroblastoma and other childhood sarcomas
Anthracenedione	Mitoxantrone	Acute myelogenous leukemia; breast and prostate cancer
	Bleomycin	Testis, and cervical cancer; Hodgkin's disease; non-Hodgkin's lymphoma
Enzyme	Mitomycin (mitomycin C)	Stomach, anal, and lung cancer
	L-Asparaginase	Acute lymphocytic leukemia
<i>Miscellaneous agents</i>		
Substituted urea	Hydroxyurea	Chronic myelogenous leukemia; polycythemia vera; essential thrombocytosis
Differentiating agents	Tretinoin, arsenic trioxide	Acute promyelocytic leukemia
	Protein tyrosine kinase inhibitors	Imatinib
Proteasome inhibitor	Gefitinib, erlotinib	Non-small-cell lung cancer
	Sunitinib	GI stromal tumors, advanced renal cell carcinoma
	Bortezomib	Multiple myeloma

trastuzumab (*her-2/neu* receptor) and rituximab (*CD20*). However, in the use of traditional cytotoxic therapy, molecular testing has not been routinely employed. Inherited differences in protein sequence or expression levels (polymorphisms) occur commonly in the population, and affect either toxicity or response. In 5-fluorouracil therapy, polymorphisms of drug target genes affect response rates and toxicity. Tandem repeats in the promoter region of the gene encoding thymidylate synthase (*TS*), the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer. Polymorphisms of the dihydropyrimidine dehydrogenase (*DPD*) gene, which degrades 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare homozygous individual. Other polymorphisms appear to affect the clearance and therapeutic activity of cancer drugs, including methotrexate, irinotecan, and 6-mercaptopurine (see below).

Specific activating mutations in the epidermal growth factor receptor (*EGFR*) gene in patients with lung cancer are associated with a high rate of response to the *EGFR* inhibitor gefitinib. Molecular tests to select patients for specific treatments undoubtedly will shorten the required time for drug testing and approval, improve the outcome of cancer therapy, and realize savings in the cost and toxicity of ineffective drugs.

Despite efforts to anticipate the development of complications, anticancer agents have variable pharmacokinetics and toxicity in individual patients. The causes of this variability are not always clear and often may be related to interindividual differences in drug metabolism, drug interactions, or bone marrow reserves. In dealing with toxicity, the physician must provide vigorous supportive care, including, where indicated, platelet transfusions, antibiotics, and hematopoietic growth factors (see Chapter 53). Other delayed toxicities affecting the heart, lungs, or kidneys may lead to permanent organ damage or death. Fortunately, such toxicities can be minimized by adherence to standardized protocols and guidelines for drug use. Clinical practice guidelines for many antineoplastic drugs can be obtained at the National Comprehensive Cancer Network web site (www.nccn.org/professionals/physician_gls/default.asp).

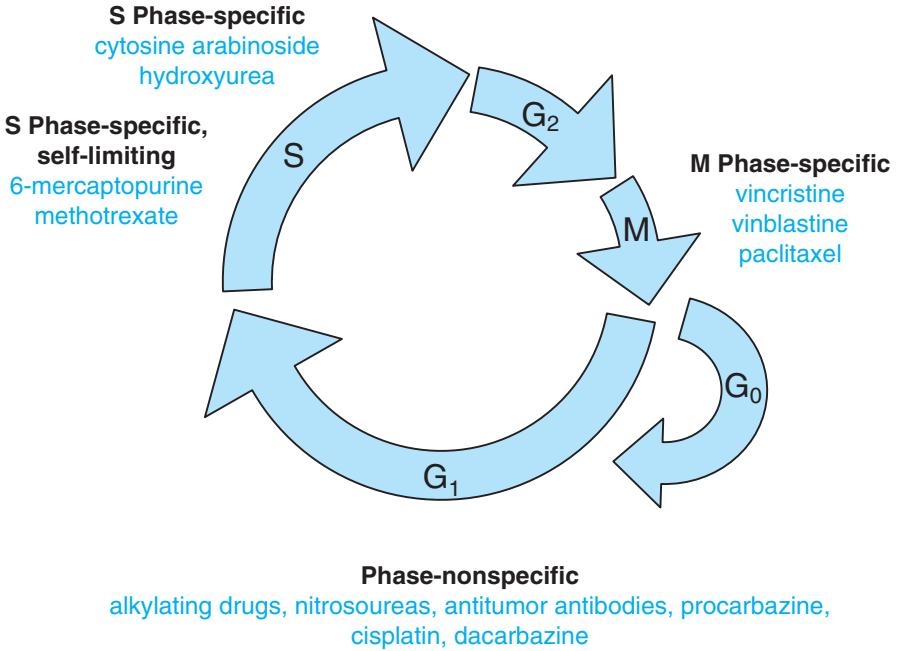

FIGURE 51–2 *The cell cycle and the relationship of antitumor drug action to the cycle.* G_1 is the gap period between mitosis and the beginning of DNA synthesis. Resting cells (cells that are not preparing for cell division) are said to be in a subphase of G_1 , G_0 . S is the period of DNA synthesis, G_2 the premitotic interval, and M the period of mitosis. Examples of cell cycle–dependent anticancer drugs are listed in *blue* below the phase in which they act. Drugs that are cytotoxic for cells at any point in the cycle are called phase–nonspecific drugs.

I. ALKYLATING AGENTS

In 1942, Goodman, Gilman, and colleagues launched the modern era of cancer chemotherapy with clinical studies of several nitrogen mustards in patients with lymphoma. At present five major types of alkylating agents are used in the chemotherapy of neoplastic diseases: (1) the nitrogen mustards, (2) the ethyleneimines, (3) the alkyl sulfonates, (4) the nitrosoureas, and (5) the triazenes. The methylhydrazine and platinum complexes also are included here, even though they do not formally alkylate DNA and use a different means to form covalent adducts with DNA.

Pharmacological Actions

The most important pharmacological actions of the alkylating agents are those that disturb DNA synthesis and cell division (Figure 51–3). The capacity of these drugs to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Whereas certain alkylating agents may have damaging effects on tissues with normally low mitotic indices—for example, liver, kidney, and mature lymphocytes—effects in these tissues usually are delayed. Acute effects are manifest primarily against rapidly proliferating tissues. Lethality of DNA alkylation depends on recognition of the adduct, creation of DNA strand breaks by repair enzymes, and an intact apoptotic response.

In normal nondividing cells, DNA damage activates a checkpoint that blocks cell-cycle progression at the G_1/S interface allowing cells to either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and are resistant to these drugs.

While DNA is the ultimate target of all alkylating agents, there is a crucial distinction between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylat-

FIGURE 51-3 Mechanism of action of alkylating agents.

ing agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that cross-linking of DNA strands is a much greater threat to cellular survival than effects such as single-base alkylation and the resulting depurination and chain scission. On the other hand, the more frequent methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify DNA sequence. These new sequences are transmitted to subsequent generations, and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

Mechanisms of Resistance to Alkylating Agents

Resistance to an alkylating agent develops rapidly when used as a single agent. Specific biochemical changes implicated in the development of resistance include:

1. Decreased permeation of actively transported drugs (mechlorethamine and melphalan);
2. Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates;
3. Increased activity of DNA repair pathways, which may differ for the various alkylating agents. Thus, increased activity of the complex nucleotide excision repair (NER) pathway seems to correlate with resistance to most chloroethyl and platinum adducts. Alkyl guanine transferase (AGT) activity determines response to BCNU and to methylating drugs such as the triazines, procarbazine, and busulfan;
4. Increased rates of metabolism of the activated forms of cyclophosphamide and ifosfamide to their inactive keto and carboxy metabolites by aldehyde dehydrogenase.

TOXICITIES OF ALKYLATING AGENTS

Bone Marrow Toxicity

The alkylating agents differ in their patterns of antitumor activity and in the sites and severity of their side effects. Most cause dose-limiting toxicity to bone marrow and intestinal mucosa. Most alkylating agents, including nitrogen mustard, melphalan, chlorambucil, cyclophosphamide, and

ifosfamide, cause acute myelosuppression, with a nadir of the peripheral blood granulocyte count at 6–10 days and recovery in 14–21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used in preparation for allogeneic bone marrow transplantation. Carmustine and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4–6 weeks after drug administration and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have been used to treat various autoimmune diseases. Immunosuppression is reversible at doses used in most anti-cancer protocols.

Mucosal Toxicity

Alkylating agents are highly toxic to dividing mucosal cells, leading to oral mucosal ulceration and intestinal denudation. The mucosal effects are particularly significant in high-dose chemotherapy protocols associated with bone marrow reconstitution, as they predispose to bacterial sepsis arising from the gastrointestinal (GI) tract. In these protocols, cyclophosphamide, melphalan, and thiotepa have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, a number of additional toxicities become limiting (Table 51–2).

Neurotoxicity

Central nervous system (CNS) toxicity is manifest by nausea and vomiting, particularly after intravenous administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic of these agents, producing altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects have been linked to the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan may cause seizures; in addition, it accelerates the clearance of *phenytoin*, an antiseizure medication (see Chapter 19).

Other Organ Toxicities

While bone marrow and mucosal toxicities occur predictably and acutely, other organ toxicities may occur after prolonged or high-dose use; these effects can appear after months or years, and may be irreversible and even lethal. All alkylating agents can cause pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver, an often-fatal side effect that may be reversed by the investigational drug defibrotide. After multiple cycles of therapy, the nitrosoureas and ifosfamide may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes a severe hemorrhagic cystitis; in high-dose regimens, this side effect can be prevented by coadministration of 2-mercaptoethanesulfonate (mesna or MESNEX), which conjugates acrolein. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity. Proximal, and less commonly distal, tubules may be affected, with impaired Ca²⁺ and Mg²⁺ reabsorption, glycosuria, and

Table 51–2

Dose-Limiting Extramedullary Toxicities of Single Alkylating Agents

Drug	MTD,* mg/m ²	Fold Increase Over Standard Dose	Major Organ Toxicities
Cyclophosphamide	7000	7	Cardiac, hepatic VOD
Ifosfamide	16,000	2.7	Renal, CNS, hepatic VOD
Thiotepa	1000	18	GI, CNS, hepatic VOD
Melphalan	180	5.6	GI, hepatic VOD
Busulfan	640	9	GI, hepatic VOD
Carmustine (BCNU)	1050	5.3	Lung, hepatic VOD
Cisplatin	200	2	PN, renal
Carboplatin	2000	5	Renal, PN, hepatic VOD

*Maximum tolerated dose (MTD; cumulative) in treatment protocols.

ABBREVIATIONS: GI, gastrointestinal; CNS, central nervous system; PN, peripheral neuropathy; VOD, veno-occlusive disease.

renal tubular acidosis. Nephrotoxicity is correlated with the total dose of drug received and increases in frequency in children <5 years of age. The syndrome has been attributed to chloroacetaldehyde and/or acrolein excreted in the urine. The more unstable alkylating agents (e.g., mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use, and produce ulceration if extravasated. Most alkylating agents cause alopecia. Finally, all alkylating agents have toxic effects on the male and female reproductive systems, causing premature ovarian failure in women and irreversible azoospermia in men.

Leukemogenesis

The alkylating agents are highly leukemogenic. Acute nonlymphocytic leukemia, often associated with partial or total deletions of chromosome 5 or 7, peaks in incidence about 4 years after therapy and may affect 5% of patients treated with regimens containing alkylating drugs. It often is preceded by a period of neutropenia or anemia, and bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, which is less common with cyclophosphamide.

CLINICAL PHARMACOLOGY

Nitrogen Mustards

The unique pharmacological characteristics of the individual agents are considered here.

MECHLORETHAMINE Mechlorethamine was the first clinically used nitrogen mustard and is the most reactive drug in this class.

Severe local reactions of exposed tissues necessitate rapid intravenous injection of mechlorethamine for most uses. In either water or body fluids, at rates affected markedly by pH, mechlorethamine rapidly undergoes chemical degradation as it combines with either water or cellular nucleophiles, and the parent compound disappears within minutes from the bloodstream.

Mechlorethamine HCl (MUSTARGEN) was formerly used primarily in the combination chemotherapy regimen MOPP (mechlorethamine, vincristine [ONCOVIN], procarbazine, and prednisone) in patients with Hodgkin's disease. It is given by intravenous bolus administration in doses of 6 mg/m² on days 1 and 8 of the 28-day cycles of each course of treatment. Mechlorethamine is used topically for treatment of cutaneous T-cell lymphoma as a solution that is rapidly mixed and applied to affected areas of skin. Mechlorethamine has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

The major acute toxic manifestations of mechlorethamine are nausea and vomiting, lacrimation, and myelosuppression. Leukopenia and thrombocytopenia limit the amount of drug that can be given in a single course. Like other alkylating agents, mechlorethamine blocks reproductive function and may produce premature ovarian failure in women and oligospermia in men. Since fetal abnormalities can be induced, this drug should not be used in the first trimester of pregnancy and should only be used with caution in later stages of pregnancy. Breast-feeding must be stopped before therapy with mechlorethamine is initiated.

Local reactions to extravasation of mechlorethamine into the subcutaneous tissue result in a severe and persistent induration. If it is obvious that extravasation has occurred, the involved area should be promptly infiltrated with a sterile isotonic solution of sodium thiosulfate (167 mM), which reacts avidly with nitrogen mustard and thereby protects tissue constituents. An ice compress then should be applied intermittently for 6–12 hours.

CYCLOPHOSPHAMIDE The cytotoxic action of this drug is similar to that of other alkylating agents. The drug is not a vesicant, and produces no local irritation. Cyclophosphamide is well absorbed orally and is activated by CYP2B to 4-hydroxycyclophosphamide, which is in a steady state with the acyclic tautomer aldophosphamide. A closely related oxazaphosphorine, ifosfamide, is hydroxylated by CYP3A4. This difference may account for the somewhat slower activation of ifosfamide *in vivo*, and the interpatient variability in toxicity of both molecules. The rate of metabolic activation of cyclophosphamide varies considerably and increases with successive doses in high-dose regimens, but appears to be saturable above infusion rates of 4 g/90 min and concentrations of parent compound >150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, and perhaps by other enzymes, yielding the inactive metabolites carboxyphosphamide and 4-ketocyclophosphamide; ifosfamide is inactivated in an analogous reaction. The active cyclophosphamide metabolites (e.g., 4-hydroxycyclophosphamide and aldophosphamide) are carried in the circulation to tumor cells, where aldophos-

phamide cleaves spontaneously, stoichiometrically generating phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.

Ample fluid intake is recommended for routine clinical use, and vigorous intravenous hydration is required during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage may require cystectomy for control of bleeding.

The syndrome of inappropriate secretion of antidiuretic hormone has been observed in patients receiving cyclophosphamide, usually at doses >50 mg/kg (see Chapter 29). Since these patients usually are vigorously hydrated to prevent bladder toxicity, water intoxication is a possibility.

Pretreatment with cytochrome (CYP) inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorene but does not alter total exposure to active metabolites over time and does not affect toxicity or efficacy. Cyclophosphamide is eliminated by hepatic metabolism and can be used at full doses in patients with renal insufficiency. Maximal concentrations in plasma are achieved 1 hour after oral administration; the $t_{1/2}$ of parent drug in plasma is ~7 hours.

Cyclophosphamide (CYTOXAN, NEOSAR, others) is administered orally or intravenously. Recommended doses vary widely; published protocols for the dosage of cyclophosphamide and other chemotherapeutic agents and for the method and sequence of administration should be consulted. As a single agent, a daily oral dose of 100 mg/m² for 14 days has been recommended as adjuvant therapy for breast cancer, and for patients with lymphomas and chronic lymphocytic leukemia (CLL). A higher dosage of 500 mg/m² intravenously every 2–4 weeks in combination with other drugs often is employed in the treatment of breast cancer and lymphomas. The neutrophil nadir of 500–1000 cells/mm³ generally serves as a guide to dosage adjustments in prolonged therapy. In regimens associated with bone marrow or peripheral stem cell rescue, cyclophosphamide may be given in total doses of 5–7 g/m² over a 3–5-day period. GI ulceration, cystitis (counteracted by mesna and diuresis), and less commonly, pulmonary, renal, hepatic, and cardiac toxicities may occur after therapy with total doses >200 mg/kg.

The clinical spectrum of activity for cyclophosphamide is very broad. It is a component of many effective drug combinations for non-Hodgkin's lymphomas, ovarian cancers, and solid tumors in children. Complete remissions and cures have been reported when cyclophosphamide was given as a single agent for Burkitt's lymphoma. It frequently is used in combination with methotrexate (or doxorubicin) and fluorouracil as adjuvant therapy after surgery for breast cancer.

Because of its potent immunosuppressive properties, cyclophosphamide has been used to prevent organ rejection after transplantation. It has activity in nonneoplastic disorders, including Wegener's granulomatosis, rheumatoid arthritis, and nephrotic syndrome. Caution is advised when the drug is considered for these conditions, both because of its acute toxic effects and because of its potential for inducing sterility, teratogenic effects, and leukemia.

IFOSFAMIDE Ifosfamide (IFEX), an analog of cyclophosphamide, also is activated by ring hydroxylation in the liver. Severe urinary tract and CNS toxicity initially limited the use of ifosfamide, but adequate hydration and coadministration of mesna have reduced its bladder toxicity. Ifosfamide is approved for use in combination for germ cell testicular cancer and is widely used to treat pediatric and adult sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue; in these regimens, in total doses of 12–14 g/m², it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 hours to 7 days after starting the ifosfamide infusion; this toxicity may result from chloroacetaldehyde. Although clinical experience is limited, administration of methylene blue, 50 mg, the day before ifosfamide and 3 times/day during drug infusion, lowers the incidence of neurotoxicity from 30% to near zero. Ifosfamide also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 minutes at a dose of up to 1.2 g/m²/day for 5 days. Intravenous mesna is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and again 4 and 8 hours later, for a total mesna dose of 60% of the ifosfamide dose. Alternatively, mesna may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles usually are repeated every 3–4 weeks.

Ifosfamide has a plasma elimination $t_{1/2}$ of ~15 hours after doses of 3.8–5 g/m² and a somewhat shorter $t_{1/2}$ at lower doses, although its pharmacokinetics are highly variable due to variable rates

of hepatic metabolism. Ifosfamide has virtually the same toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and in the absence of mesna, urothelial damage.

MELPHALAN The pharmacology of melphalan, the Phe derivative of nitrogen mustard, is similar to that of mechlorethamine. The drug is not a vesicant. When given orally, melphalan absorption is incomplete and variable, and 20–50% of the drug is recovered in the stool. The drug has a $t_{1/2}$ in plasma of ~45–90 minutes, and 10–15% of the dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression. Oral *melphalan* (ALKERAN) for multiple myeloma (MM) is used in doses of 6–8 mg daily for a period of 4 days, in combination with other agents. A rest period of up to 4 weeks should then intervene. The usual intravenous dose is 15 mg/m² infused over 15–20 minutes. Doses are repeated at 2-week intervals for 4 doses and then at 4-week intervals based on response and tolerance. Dosage adjustments should be considered based on blood cell counts and in patients with renal impairment. Melphalan in a dose of 180–200 mg/m² also may be used in myeloablative regimens for bone marrow or peripheral blood stem cell reconstitution. The toxicity of melphalan is mostly hematological and similar to that of other alkylating agents. Nausea and vomiting are less frequent. Alopecia does not occur at standard doses, and changes in renal or hepatic function have not been observed.

CHLORAMBUCIL The cytotoxic effects of chlorambucil on bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with the nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses, and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or more. Oral absorption of chlorambucil is adequate and reliable. The drug has a $t_{1/2}$ in plasma of ~1.5 hours; it is almost completely metabolized to phenyl acetic acid mustard and decomposition products. In treating CLL, the standard initial daily dosage of chlorambucil (LEUKERAN) is 0.1–0.2 mg/kg, given once daily and continued for 3–6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy (usually 2 mg daily) often is required to maintain clinical remission. It is a standard agent for patients with CLL and Waldenström's macroglobulinemia, and may be used for follicular lymphoma. In CLL, chlorambucil may be given orally for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Although it is possible to induce marked hypoplasia of the bone marrow with excessive doses of chlorambucil over long periods, its myelosuppressive action usually is moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity may rarely be encountered. A marked increase in the incidence of acute myelocytic leukemia (AML) and other tumors was noted in a large controlled study of its use for the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy.

MISCELLANEOUS ALKYLATING DRUGS

While nitrogen mustards containing chlorethyl groups constitute the most widely used class of alkylating agents, alternative structures with greater chemical stability and defined activity in specific types of cancer continue to have value in clinical practice.

Ethyleneimines and Methylmelamines

ALTRETAMINE Altretamine (HEXALEN), formerly known as hexamethylmelamine, is structurally similar to the alkylating agent triethylenemelamine (*tretamine*), but its precise mechanism of action is unknown. It is used as a palliative treatment for persistent or recurrent ovarian cancer following treatment failure with a cisplatin- or alkylating agent–based combination. The usual dose of altretamine as a single agent in ovarian cancer is 260 mg/m² daily in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles. Following oral administration, altretamine is well absorbed from the GI tract and undergoes rapid demethylation in the liver. Peak plasma levels, which vary widely, are reached between 0.5 and 3 hours. The principal metabolites are pentamethylmelamine and tetramethylmelamine, which are highly bound to plasma proteins (75% and 50%, respectively) and excreted *via* the urine. The elimination $t_{1/2}$ is 4–10 hours.

The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity. CNS symptoms include ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo. Neurological toxicity appears to be reversible

upon drug discontinuation and may be prevented or decreased by concomitant administration of pyridoxine. Peripheral blood counts and a neurologic examination should be performed before each course of therapy. Therapy should be interrupted for at least 14 days, and subsequently restarted at a lower dose of 200 mg/m² daily, if the white cell count is <2000 cells/mm³ or the platelet count is <75,000 cells/mm³ or if neurotoxic or intolerable GI symptoms occur. If neurologic symptoms fail to stabilize on the reduced dose schedule, altretamine should be discontinued. Nausea and vomiting also are common and may be dose-limiting. Renal toxicity also may be dose-limiting. Rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension developed in patients who received tricyclic antidepressants concurrently with altretamine.

THIOTEPA Thiotepa (THIOPLEX) is composed of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Both thiotepa and its desulfurated primary metabolite, triethylenephosphoramidate (TEPA), to which it is rapidly converted by hepatic CYPs, form DNA cross-links. The aziridine rings open after protonation of the ring-nitrogen, forming a reactive molecule. TEPA becomes the predominant form of the drug in plasma within hours of thiotepa administration. The parent compound has a plasma $t_{1/2}$ of 1.2–2 hours, as compared to a longer $t_{1/2}$ of 3–24 hours for TEPA. Thiotepa pharmacokinetics are essentially the same in children as in adults at conventional doses (up to 80 mg/m²), and drug and metabolite half-lives are unchanged in children receiving high-dose therapy of 300 mg/m²/day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite. Multiple secondary metabolites and chemical degradation products account for the remainder of parent.

The toxicities of thiotepa include myelosuppression, and to a lesser extent mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high-dose regimens, thiotepa produces neurotoxic symptoms, including coma and seizures.

Alkyl Sulfonates

BUSULFAN Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and often was used in the chronic phase of chronic myelogenous leukemia (CML) to suppress granulocyte counts. In some patients, a severe and prolonged pancytopenia resulted. In high-dose regimens, pulmonary fibrosis, GI mucosal damage, and VOD of the liver become important. Busulfan is well absorbed after oral administration in doses of 2–6 mg/day, and has a plasma $t_{1/2}$ of 2–3 hours. The drug is conjugated to glutathione by glutathione S-transferase A1A and further degraded by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. Children <18 years of age clear the drug 2–4 times faster than adults, and tolerate higher doses. A dose of 40 mg/m² given every 6 hours for 4 days has been suggested for children weighing <20 kg. An intravenous preparation is available for high-dose regimens. There is significant variability in busulfan clearance among patients. VOD is associated with high AUC and peak drug levels (AUC >1500 $\mu\text{M} \times \text{min}$) and slow clearance, leading to recommendations for dose adjustment based on drug level monitoring. A target of $C_{ss} = 600\text{--}900 \text{ ng/mL}$ in adults or AUC <1000 $\mu\text{M} \times \text{min}$ in children appears to achieve an appropriate balance between toxicity and therapeutic benefit.

In treating CML, the initial oral dose of busulfan (MYLERAN, BUSULFEX) varies with the total leukocyte count and the severity of the disease; daily doses from 2 to 8 mg for adults (~60 $\mu\text{g/kg}$ or 1.8 mg/m² for children) are used initially and are adjusted appropriately to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to $\leq 10,000 \text{ cells/mm}^3$. A decrease in the leukocyte count is not usually seen during the first 10–15 days of treatment and the leukocyte count may actually increase. Because the leukocyte count may fall for more than a month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to $\sim 15,000 \text{ cells/mm}^3$. A normal leukocyte count usually is achieved within 12–20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches $\sim 50,000 \text{ cells/mm}^3$. Daily maintenance doses are 1–3 mg. In high-dose therapy, doses of 1 mg/kg are given every 6 hours for 4 days, with adjustment based on pharmacokinetics.

High doses of busulfan also have been used effectively in combination with high doses of cyclophosphamide to prepare leukemia patients for bone marrow transplantation. In such high-dose regimens, busulfan is given at 0.8 mg/kg every 6 hours for 4 days. Anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures, which may occur

several hours after each dose. Busulfan induces the metabolism of phenytoin. In patients requiring antiseizure medication, drugs such as lorazepam are recommended as an alternative. When phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted.

The toxic effects of busulfan are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasional patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose busulfan causes VOD of the liver in up to 10% of patients, as well as seizures, hemorrhagic cystitis, alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly by inhibition of the clearance of busulfan and/or its toxic metabolites.

Nitrosoureas

The nitrosoureas are important in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They are bifunctional alkylating agents but differ in both pharmacological and toxicological properties from conventional nitrogen mustards. Carmustine (BCNU) and lomustine (CCNU) are highly lipophilic and readily cross the blood–brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression with recovery 4–6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamoylating moieties.

CARMUSTINE (BCNU) Carmustine's major action is its alkylation of DNA at the O⁶-guanine position, forming an adduct repaired by AGT. Methylation of the AGT promoter region inhibits its expression in ~30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, carmustine produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia. It is unstable in aqueous solution and body fluids. After intravenous infusion, it disappears from the plasma with a variable $t_{1/2}$ of 15–90 minutes. Approximately 30–80% of the drug appears in the urine within 24 hours as degradation products. The entry of alkylating metabolites into the cerebrospinal fluid (CSF) is rapid, and their CSF concentrations are 15–30% of concurrent plasma values. When used alone, carmustine (BICNU) usually is administered intravenously at doses of 150–200 mg/m², given by infusion over 1–2 hours and repeated at 6 weeks. Because of its ability to cross the blood–brain barrier, carmustine is used with procarbazine in the treatment of malignant gliomas. An implantable carmustine wafer (GLIADEL) is used as an adjunct to surgery and radiation in newly diagnosed high-grade malignant glioma patients and as an adjunct to surgery for recurrent glioblastoma multiforme.

STREPTOZOCIN This antibiotic has a methylnitrosourea (MNU) moiety attached to C2 of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals. After intravenous infusions of 200–1600 mg/m², peak concentrations of streptozocin in the plasma are 30–40 µg/mL; the $t_{1/2}$ of the drug is ~15 minutes. Only 10–20% of a dose is recovered intact in the urine. Streptozocin (ZANOSAR) is useful in the treatment of human pancreatic islet cell carcinoma and malignant carcinoid tumors. It is administered intravenously, 500 mg/m² once daily for 5 days; this course is repeated every 6 weeks. Alternatively, 1000 mg/m² can be given weekly for 2 weeks, and the weekly dose then can be increased to a maximum of 1500 mg/m², as tolerated. Nausea is a frequent side effect. Mild, reversible renal or hepatic toxicity occurs in ~two-thirds of cases; in <10% of patients, renal toxicity may be cumulative with each dose and may be fatal. Urinary protein excretion is an early sign of tubular damage and impending renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicity—*anemia, leukopenia, or thrombocytopenia*—occurs in 20% of patients.

Triazines

DACARBAZINE (DTIC) Dacarbazine functions as a methylating agent after metabolic activation in the liver. The active form is a monomethyl triazeno metabolite, MTIC, which kills cells in all phases of the cell cycle. Resistance has been ascribed to removal of methyl groups from the O⁶-guanine bases in DNA by AGT. Dacarbazine is administered intravenously. After an initial rapid

phase of disappearance ($t_{1/2}$ ~20 minutes), dacarbazine is removed from plasma with a terminal $t_{1/2}$ of ~5 hours. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion. Elevated urinary concentrations of 5-aminoimidazole-4-carboxamide are derived from the catabolism of dacarbazine, rather than by inhibition of *de novo* purine biosynthesis. Dacarbazine (DTIC-DOME, others) for malignant melanoma is given in doses of 3.5 mg/kg/day, intravenously, for a 10-day period, repeated every 28 days. Alternatively, 250 mg/m² can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. At present, dacarbazine is employed in combination regimens for the treatment of Hodgkin's disease. It is less effective against malignant melanoma and adult sarcomas. The toxicity of DTIC includes nausea and vomiting in >90% of patients; vomiting usually develops 1–3 hours after treatment and may last up to 12 hours. Myelosuppression, with both leukopenia and thrombocytopenia, usually is mild to moderate. A flu-like syndrome consisting of chills, fever, malaise, and myalgias may occur during DTIC treatment. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatologic reactions also have been reported.

TEMOZOLOMIDE Temozolomide (TEMODAR) is a triazene that has significant activity in patients with malignant gliomas, where it is the standard agent in combination with radiation therapy. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. Temozolomide is administered orally and its bioavailability approaches 100%. Maximum plasma drug concentration reaches 5 µg/mL, or ~10 µM, 1 hour after administration of a dose of 200 mg, and declines with an elimination $t_{1/2}$ of 1.2 hours. The primary active metabolite MTIC reaches a maximum plasma concentration of 150 ng/mL 90 minutes after a dose and declines with a $t_{1/2}$ of 2 hours. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide. The pharmacokinetics of temozolomide are linear over the dose range of 100–260 mg/m². The toxicities of temozolomide mirror those of DTIC.

Methylhydrazines

PROCARBAZINE Several methylhydrazine derivatives have anticancer activity, but only procarbazine (*N*-isopropyl- α -(2-methylhydrazino)-*p*-toluamide) is used clinically. The antineoplastic activity of procarbazine results from its conversion by hepatic CYPs to highly reactive alkylating species that methylate DNA. The first step in activation involves oxidation of the hydrazine function, yielding an azo metabolite that exists in equilibrium with its hydrazone tautomer. *N*-Oxidation of azoprocarbazine generates the isomeric benzylazoxy and methylazoxy metabolites, the latter of which liberates an entity resembling diazomethane, a potent methylating reagent. Free-radical intermediates also may be involved. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Exposure to procarbazine leads to inhibition of DNA, RNA, and protein synthesis *in vivo*. Resistance to procarbazine develops rapidly when it is used as a single agent. One mechanism results from the increased ability to repair methylation of guanine *via* AGT.

Procarbazine is efficiently absorbed from the GI tract and rapidly distributes into the CNS. The drug and its metabolites are predominantly eliminated in the urine, with N-isopropyl-terephthalamidic acid being the major metabolite, accounting for ~25% of doses given either orally or intravenously. Multiple metabolites of the drug (e.g., azo, methylazoxy, and benzylazoxy derivatives) have been identified in the plasma after oral procarbazine. A marked decrease in the apparent clearance of the drug upon repeated daily oral administration has been observed. Although CYPs have well-defined roles in the activation of procarbazine, the concurrent use of antiseizure drugs that induce hepatic CYPs did not significantly alter the pharmacokinetics of the parent drug in brain cancer patients.

The recommended dose of procarbazine (MATULANE) for adults is 100 mg/m² daily for 10–14 days in combination regimens. The drug rarely is used alone. Procarbazine is used in combination with mechlorethamine, vincristine, and prednisone (the MOPP regimen) for the treatment of Hodgkin's disease. Alternative regimens with less leukemogenic potential have largely replaced MOPP. Of primary importance, procarbazine lacks cross-resistance with other mustard-type alkylating agents. Procarbazine has been used in combination with lomustine and vincristine (the PCV regimen) for treating patients with newly diagnosed or recurrent primary brain tumors.

The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks following treatment. GI symptoms such as mild nausea and vomiting occur in most patients; neurological and dermatological manifestations have been noted in 5–10% of cases. Behavioral disturbances also have been reported. Because of

augmentation of sedative effects, the concomitant use of CNS depressants should be avoided. Since procarbazine is a weak monoamine oxidase inhibitor, hypertensive reactions may result from its use concurrently with sympathomimetic agents, tricyclic antidepressants, or ingestion of foods with high tyramine content. Procarbazine has disulfiram-like actions and the ingestion of alcohol should be avoided. Procarbazine is highly carcinogenic, mutagenic, and teratogenic, and its use in MOPP therapy is associated with a 5–10% risk of acute leukemia; the greatest risk is for patients who also receive radiation therapy. Procarbazine also is a potent immunosuppressive agent, and it causes infertility, particularly in males.

PLATINUM COORDINATION COMPLEXES

Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of testicular cancer, ovarian cancer, and cancers of the head and neck, bladder, esophagus, lung, and colon. Although cisplatin and other platinum complexes do not form carbonium ion intermediates or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with the alkylating agents. Cisplatin, carboplatin, and oxaliplatin enter cells by diffusion and by an active Cu^{2+} transporter. Inside the cell, the chloride atoms of cisplatin are replaced by water, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins. Aquation is favored at the low concentrations of Cl^- inside the cell and in the urine. High concentrations of Cl^- stabilize the drug, explaining the effectiveness of Cl^- diuresis in preventing nephrotoxicity (see below). Hydrolysis of carboplatin removes the bidentate cyclobutanedicarboxylate group; this activation reaction occurs slowly. The platinum complexes can react with DNA, forming both intrastrand and interstrand cross-links. DNA adducts formed by cisplatin inhibit DNA replication and transcription and lead to breaks and miscoding, and if recognized by p53 and other checkpoint proteins, induction of apoptosis. The cell cycle specificity of cisplatin appears to differ among cell types, although the effects of cross-linking are most pronounced during S phase. Cisplatin is mutagenic, teratogenic, and carcinogenic. The use of cisplatin- or carboplatin-based chemotherapy for women with ovarian cancer is associated with a fourfold increased risk of developing secondary leukemia.

Resistance to Platinum Analogs

The causes of tumor cell resistance to cisplatin and its analogs are incompletely understood. The various analogs differ in their degree of cross-resistance with cisplatin in experimental tumor systems. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin and other tetravalent analogs do not. A number of factors influence cisplatin sensitivity in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulfhydryls such as metallothionein that bind to and inactivate the drug, and rates of repair of DNA adducts. Repair of cisplatin-DNA adducts occurs through the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in ovarian cancer patients, while overexpression of NER components is associated with poor response to cisplatin-based therapy in lung cancer.

Resistance to cisplatin, but not oxaliplatin, is partly mediated by loss of function in mismatch repair (MMR) proteins. By contrast, MMR repair proficiency is not required for oxaliplatin cytotoxicity. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of Cu^{2+} efflux transporters ATP7A and ATP7B correlates with poor survival after cisplatin-based therapy for ovarian cancer.

Cisplatin

After intravenous administration, cisplatin has an initial plasma elimination $t_{1/2}$ of 25–50 minutes; concentrations of total (bound and unbound) drug fall thereafter, with a $t_{1/2}$ of 24 hours or longer. More than 90% of the platinum in the blood is covalently bound to plasma proteins. The unbound fraction, composed predominantly of parent drug, is cleared within minutes. High concentrations of cisplatin are found in the kidney, liver, intestine, and testes, but CNS penetration is poor. Only a small portion of the drug is excreted by the kidney during the first 6 hours; by 24 hours up to 25% is excreted, and by 5 days up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal. Cisplatin (PLATINOL-AQ, others) is given only by the intravenous route. The usual dose is 20 $\text{mg}/\text{m}^2/\text{day}$ for 5 days, 20–30 mg weekly for 3–4 weeks, or 100 mg/m^2 , given once every 4 weeks. To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1–2 L of normal saline prior to treatment. The appropriate amount of cisplatin then is diluted in a solution of dextrose and saline and administered intravenously over a period of 4–6 hours.

Since aluminum inactivates cisplatin, it is important not to use needles or other infusion equipment that contain aluminum when preparing or administering the drug.

Cisplatin, in combination with bleomycin, etoposide, ifosfamide, or vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin induces complete response in most patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

Cisplatin-induced nephrotoxicity largely has been abrogated by pretreatment hydration and diuresis. Amifostine (ETHYOL) is a thiophosphate cytoprotective agent that is approved for the reduction of renal toxicity associated with repeated administration of cisplatin. Amifostine is dephosphorylated by alkaline phosphatase to a pharmacologically active free thiol metabolite. Faster dephosphorylation and preferential uptake by normal tissues results in a higher concentration of the thiol metabolite available to scavenge reactive cisplatin metabolites in normal tissues. Amifostine also is used to reduce xerostomia in patients undergoing irradiation for head and neck cancer, when the radiation port includes a substantial portion of the parotid glands. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. The ototoxicity can be unilateral or bilateral, tends to be more frequent and severe with repeated doses, and may be more pronounced in children. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5-hydroxytryptamine (5-HT₃) antagonists, neurokinin-1 (NK1) receptor antagonists, and glucocorticoids (see Chapter 37). At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy, which may worsen after drug discontinuation and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild-to-moderate myelosuppression, with transient leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to renal electrolyte wasting may produce tetany. Routine measurement of Mg²⁺ concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with glucocorticoids or antihistamines. Cisplatin has been associated with the development of AML, usually 4 years or more after treatment.

Carboplatin

Mechanisms of action and resistance, and the spectrum of clinical activity of carboplatin (CBDCA, JM-8) are similar to those of cisplatin, but the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties. Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most elimination is via renal excretion, with a $t_{1/2}$ in plasma of ~2 hours. A small fraction of platinum become irreversibly bound to plasma proteins and disappears slowly, with a $t_{1/2}$ >5 days. Carboplatin is relatively well tolerated clinically, with less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. Instead, the dose-limiting toxicity is myelosuppression, primarily evident as thrombocytopenia. Carboplatin and cisplatin appear to be equally effective in the treatment of suboptimally debulked ovarian cancer, non-small cell lung cancer, and extensive small cell lung cancer; however, carboplatin may be less effective than cisplatin in germ cell, head and neck, and esophageal cancers. Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. The dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance for patients with a creatinine clearance <60 mL/min.

Carboplatin (PARAPLATIN) is administered as an intravenous infusion over at least 15 minutes and is given once every 28 days. Carboplatin currently is U.S. Food and Drug Administration (FDA)-approved for use in combination with paclitaxel or cyclophosphamide in patients with advanced ovarian cancer and lung cancer.

Oxaliplatin

Oxaliplatin, like cisplatin, has a very brief plasma $t_{1/2}$, probably due to its rapid uptake by tissues and its reactivity. While the ultrafiltrable component has a slow terminal clearance from plasma ($t_{1/2}$ of 273 hours), most of the low-molecular-weight platinum species represent inactive degradation

products. These metabolites undergo renal excretion at a rate dependent on the creatinine clearance. However, no dose adjustment is required for patients with creatinine clearances >20 mL/min, as decreased renal function does not affect the rapid chemical inactivation of the drug and its toxicity at doses of 65–130 mg/m². Oxaliplatin exhibits a wide range of antitumor activity that differs from other platinum agents, and includes gastric and colorectal cancer; its effectiveness in colorectal cancer is perhaps due to its MMR-independent effects. It also suppresses expression of TS, the target enzyme of 5-fluorouracil (5-FU) action, which may promote synergy of these two drugs. In combination with 5-FU, it is approved for treatment of patients with advanced colorectal cancer.

The dose-limiting toxicity of oxaliplatin is peripheral neuropathy. An acute form often is triggered by exposure to cold, and manifests as paresthesias and/or dysesthesias in the upper and lower extremities, mouth, and throat. A second type of peripheral neuropathy is more closely related to cumulative dose and similar to that seen with cisplatin; 75% of patients receiving a cumulative dose of 1560 mg/m² experience some neurotoxicity. Hematologic toxicity is mild to moderate, and nausea is well controlled with 5-HT₃ receptor antagonists. Oxaliplatin is unstable in the presence of chloride or alkaline solutions.

II. ANTIMETABOLITES

FOLIC ACID ANALOGS

Antifolate chemotherapy produced the first cure of a solid tumor, choriocarcinoma. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate, leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N⁵-formyl FH₄), further extended the effectiveness of these drugs to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Most recently, analogs that differ from methotrexate in their transport properties and sites of action have proven useful in treating other cancers.

Folic acid is converted by enzymatic reduction to a series of tetrahydrofolate cofactors that provide carbon groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines) (see Figure 51–4). The biological functions and therapeutic applications of folic acid are further described in Chapter 53. To function as a cofactor in one-carbon transfer reactions, folate must first be reduced by dihydrofolate reductase (DHFR) to tetrahydrofolate (FH₄). Single-carbon fragments are added enzymatically to FH₄ in various configurations and then may be transferred in specific synthetic reactions. In a key metabolic event catalyzed by TS, deoxyuridine monophosphate (dUMP) is converted to thymidine monophosphate (TMP), an essential component of DNA. In this reaction, a one-carbon group is transferred to dUMP from 5,10-methylene FH₄, and the reduced folate cofactor is oxidized to dihydrofolate (FH₂). To function again as a cofactor, FH₂ must be reduced to FH₄ by DHFR. Inhibitors such as methotrexate, with a high affinity for DHFR, prevent the formation of FH₄ and allow a vast accumulation of the toxic inhibitory substrate, FH₂ polyglutamate, behind the blocked reaction, which inhibits TS and other enzymes. Methotrexate also undergoes conversion to a series of polyglutamates (MTX-PGs) in both normal and tumor cells; MTX-PGs constitute an intracellular storage form of folates and folate analogs, and dramatically increase inhibitory potency of the analog for additional sites, including TS and two early enzymes in the purine biosynthetic pathway. The one-carbon transfer reactions crucial for the de novo synthesis of purine nucleotides and thymidylate cease, with the subsequent interruption of the synthesis of DNA and RNA. Toxic effects of methotrexate can be terminated by administering leucovorin, a fully reduced folate coenzyme that replenishes the intracellular pool of tetrahydrofolate cofactors. As with most antimetabolites, methotrexate is only partially selective for tumor cells and is toxic to all rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly.

Pemetrexed and its polyglutamates have a somewhat different spectrum of biochemical actions. Like methotrexate, it inhibits DHFR, but as a polyglutamate, even more potently inhibits glycinamide ribonucleotide formyltransferase (GART) and TS. Unlike methotrexate, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion also differs, with little effect on deoxyadenosine triphosphate (dATP), a profile more characteristic of primary TS inhibition.

Because folic acid and many of its analogs are hydrophilic, they cross the blood–brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells: (1) a folate receptor, which has high affinity for folic acid but much reduced ability to transport methotrexate and other analogs; (2) the reduced folate transporter, the major transit protein for methotrexate, raltitrexed, pemetrexed, and most

FIGURE 51-4 Sites of action of methotrexate and its polyglutamates. AICAR, aminoimidazole carboxamide; TMP, thymidine monophosphate; dUMP, deoxyuridine monophosphate; FH₂Glu_n, dihydrofolate polyglutamate; FH₄Glu_n, tetrahydrofolate polyglutamate; GAR, glycylamido ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.

analogs; and (3) a poorly characterized transporter that is active at low pH. The reduced folate transporter is highly expressed in the hyperdiploid subtype of ALL, which has extreme sensitivity to methotrexate. Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Since these higher polyglutamates are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of entrapment and may account for the prolonged retention of methotrexate in chorionic epithelium (where it is a potent abortifacient), in tumors derived from this tissue, such as choriocarcinoma cells, and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamylated folates and analogs have substantially greater affinity than the monoglutamate form for folate-dependent enzymes required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

New folate antagonists have been identified that are better substrates for the reduced folate carrier and appear to have significant advantages in clinical chemotherapy (see pemetrexed below). In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate (NEUTREXIN) has modest antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of *Pneumocystis jiroveci* pneumonia, where leucovorin provides differential rescue of the host but not the parasite.

The most important new folate analog, MTA or pemetrexed (ALIMTA), is a pyrrole-pyrimidine folate analog. It is avidly transported into cells via the reduced folate carrier, but also may gain

entry by a unique folate transport activity found in mesothelioma cell lines. It is readily converted to polyglutamates that inhibit TS and glycine amide ribonucleotide transformylase, as well as DHFR. It has activity against colon cancer, mesothelioma, and non-small cell lung cancer, and is approved for treatment of mesothelioma.

Different biochemical mechanisms of acquired resistance to methotrexate can affect each known step in methotrexate action, including: (1) impaired transport of methotrexate into cells; (2) production of altered forms of DHFR that have decreased affinity for the inhibitor; (3) increased concentrations of intracellular DHFR through gene amplification or altered gene regulation; (4) decreased ability to synthesize methotrexate polyglutamates; and (5) increased expression of a drug efflux transporter, of the MRP (multidrug resistance protein) class.

DHFR levels in leukemic cells increase within 24 hours after treatment of patients with methotrexate; this likely reflects induction of new enzyme synthesis. The unbound DHFR protein may bind to its own mRNA and inhibit its own translation, while the DHFR-MTX complex is ineffective in blocking the DHFR translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated chromosomal amplicons. Similar gene amplifications of target proteins have been implicated in the resistance to many antitumor agents, including 5-FU and pentostatin (2'-deoxycoformycin). To overcome resistance, high doses of methotrexate may drive entry of drug into transport-defective cells and permit the intracellular accumulation of methotrexate in concentrations that inactivate high levels of DHFR. The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance to this agent seems to arise either from TS amplification, changes in purine biosynthetic pathways, or both.

The primary toxic effects of methotrexate and other folate antagonists used in cancer chemotherapy are exerted against rapidly dividing cells of the bone marrow and GI epithelium. Mucositis, myelosuppression, and thrombocytopenia reach their maximum in 5–10 days after drug administration, and except in instances of altered drug excretion, reverse rapidly thereafter. In addition to its acute toxicities, methotrexate can cause pneumonitis that regresses upon discontinuation of the drug. In some cases, patients can be rechallenged with drug without toxicity. The etiology is unknown. A second toxicity of particular significance in chronic administration to patients with psoriasis or rheumatoid arthritis is hepatic fibrosis and cirrhosis. Increased hepatic portal fibrosis is detected with higher frequency than in control patients after >6 months of continuous oral methotrexate treatment of psoriasis. Its presence mandates drug discontinuation. Acute, reversible elevation of hepatic enzymes is detected in serum after high-dose administration but rarely is associated with permanent changes. Folic acid antagonists are toxic to developing embryos. Methotrexate is highly effective when used with the prostaglandin analog misoprostol in inducing abortion in first-trimester pregnancy.

Methotrexate is readily absorbed from the GI tract at doses of <25 mg/m², but larger doses are absorbed incompletely and are routinely given intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance ($t_{1/2}$ ~2–3 hours). A third phase has a $t_{1/2}$ ~8–10 hours. This terminal phase of disappearance, if unduly prolonged by renal failure, may be responsible for major toxic effects of the drug on the marrow, GI epithelium, and skin. Distribution of methotrexate into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of drug, with resultant prolonged elevation of plasma concentrations and more severe toxicity. Approximately 50% of methotrexate is bound to plasma proteins and may be displaced by a number of drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these are given concomitantly. Up to 90% of a given dose is excreted unchanged in the urine within 48 hours, mostly within the first 8–12 hours. A small amount of methotrexate also is excreted in the stool. Metabolism of methotrexate is usually minimal, but with high doses metabolites are readily detectable; these include 7-hydroxymethotrexate, which is potentially nephrotoxic. Renal excretion of methotrexate occurs through a combination of glomerular filtration and active tubular secretion. Therefore, concurrent use of drugs that reduce renal blood flow (e.g., nonsteroidal anti-inflammatory agents), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin or piperacillin) can delay drug excretion and lead to severe myelosuppression. Particular caution must be exercised in treating patients with renal insufficiency, where the dose should be adjusted in proportion to decreases in renal function and high-dose regimens should be avoided if possible. Methotrexate is retained in the form of polyglutamates for long periods—for example, for weeks in the kidneys and for months in the liver. It is important to emphasize that concentrations of methotrexate in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are

not killed by standard regimens. When high doses of methotrexate are given ($>1.5 \text{ g/m}^2$), cytotoxic concentrations of methotrexate may be attained in the CNS.

Pharmacogenetics may influence the response to antifolates and their toxicity. A mutation in methylenetetrahydrofolate reductase, the enzyme that generates methylenetetrahydrofolate cofactor for TS, reduces its activity and thereby increases methotrexate toxicity. The presence of this polymorphism in leukemic cells confers increased sensitivity to methotrexate, and may also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression, and by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines.

Methotrexate (*amethopterin*; RHEUMATREX, TREXALL, others) has been used in the treatment of severe, disabling psoriasis in doses of 2.5 mg orally for 5 days, followed by a rest period of at least 2 days, or 10–25 mg intravenously weekly. It also is used intermittently at low dosage to induce remission in rheumatoid arthritis.

Methotrexate is a critical drug in the management of ALL in children. Used in high doses, it is of great value in remission induction and consolidation, and in the maintenance of remissions in this highly curable disease. For maintenance therapy, it is administered intermittently at doses of 30 mg/m^2 intramuscularly weekly in 2 divided doses or in 2-day “pulses” of 175–525 mg/m^2 at monthly intervals. Outcome of treatment in children correlates inversely with the rate of drug clearance. During methotrexate infusion, high steady-state levels are associated with a lower leukemia relapse rate. Methotrexate is of limited value in adult leukemia, except for treatment and prevention of leukemic meningitis. The intrathecal administration of methotrexate has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of methotrexate in the CSF and is also effective in patients whose systemic disease has become resistant to methotrexate. The recommended intrathecal dose in all patients >3 years of age is 12 mg. The dose is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the toxicity of methotrexate that escapes into the systemic circulation, although this generally is not necessary. Since methotrexate administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be more effective when given *via* an intraventricular Ommaya reservoir. Methotrexate is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in ~75% of advanced cases treated sequentially with methotrexate and *dactinomycin*, and in $>90\%$ when early diagnosis is made. In the treatment of choriocarcinoma, 1 mg/kg of methotrexate is administered intramuscularly every other day for 4 doses, alternating with leucovorin (0.1 mg/kg every other day). Courses are repeated at 3-week intervals, toxicity permitting, and urinary β -human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt's and other non-Hodgkin's lymphomas, and methotrexate is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose methotrexate with leucovorin rescue (HDM-L) is a component of the standard regimen for adjuvant therapy of osteosarcoma, produces a high complete response rate in CNS lymphomas, and is a part of standard curative therapy for childhood ALL. A 6-72-hour infusion of relatively large doses of methotrexate may be employed every 2–4 weeks (from 1 to 7.5 g/m^2 or more), but only when leucovorin rescue is used. Such regimens produce cytotoxic concentrations of drug in the CSF and protect against leukemic meningitis. A typical regimen includes the infusion of 7.5 g/m^2 methotrexate for 6 hours followed by leucovorin at a dose of 15 mg/m^2 every 6 hours for 7 doses, with the goal of rescuing normal cells to prevent toxicity. Other dosage regimens also are used.

The administration of HDM-L has the potential for renal toxicity, probably related to drug precipitation in the acidic tubular fluid. Thus, vigorous hydration and alkalization of urine are required prior to drug administration. HDM-L should be performed only by experienced clinicians. If methotrexate values measured 48 hours after drug administration are $1 \mu\text{M}$ or higher, higher doses (100 mg/m^2) of leucovorin must be given until the plasma concentration of methotrexate falls below a level of 50 nM. With appropriate hydration and urine alkalization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L approaches 2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing methotrexate levels. Continuous-flow hemodialysis can eliminate methotrexate at a rate approximating 50% of the clearance rate in patients with intact renal function. Alternatively, a methotrexate-cleaving enzyme, carboxypeptidase G2, can be obtained from the National Cancer Institute. Methotrexate concentrations in plasma fall by 99% or greater within 5–15 minutes

following intravenous enzyme administration, with insignificant rebound. Carboxypeptidase G2 also has received limited evaluation as the sole rescue for high-dose methotrexate, without leucovorin, and was effective. Systemically administered carboxypeptidase G2 has little effect on methotrexate levels in the CSF.

The only FDA-approved indication for pemetrexed is for second-line therapy in mesothelioma; it also is used, however, for refractory non-small cell lung cancer. Promising results have been published in first-line use with cisplatin in both tumors.

The primary toxicities of antifolates affect the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dose of methotrexate (and likely pemetrexed) must be reduced in proportion to any reduction in creatinine clearance. Additional toxicities of methotrexate include alopecia, dermatitis, interstitial pneumonitis, nephrotoxicity, defective oogenesis or spermatogenesis, abortion, and teratogenesis. Elevation of hepatic enzymes is a consistent finding with high-dose methotrexate but usually is reversible. On the other hand, low-dose methotrexate may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of methotrexate often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Leucovorin does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of methotrexate, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice-daily on days -1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia and possibly reflecting folate deficiency, is largely eliminated by concurrent administration of low doses of folic acid, 0.35–1 mg/day, beginning 1–2 weeks prior to pemetrexed and continuing while the drug is administered. Intramuscular vitamin B₁₂ (1 mg) is given with the first dose of pemetrexed to correct possible B₁₂ deficiency. There is no evidence that these small doses of folate and B₁₂ compromise the therapeutic effect.

PYRIMIDINE ANALOGS

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function in a variety of ways. Some, such as the fluoropyrimidines and the purine base analogs (6-mercaptopurine and 6-thioguanine) inhibit the synthesis of essential precursors of DNA. Others, particularly the cytidine and adenosine nucleoside analogs, become incorporated into DNA and block its further elongation and its function. Other metabolic effects of these analogs may contribute to their cytotoxicity and even their ability to induce differentiation.

DNA is made up of 2 pyrimidines, thymine and cytosine, and 2 purines, guanine and adenine. RNA differs in that it incorporates uracil instead of thymine. Uracil may serve as a precursor of deoxythymidine monophosphate in the final step of this conversion, TS adds a methyl group to the 5 position of dUMP. Cells can synthesize bases *de novo* and convert them to their active deoxynucleoside triphosphates (dNTPs). The dNTPs then act as substrates for DNA polymerase and become linked in 3'-5' phosphate ester bonds to form DNA strands. Alternatively, cells can salvage either free bases or their deoxynucleoside from the systemic circulation. Uracil, guanine, and their analogs can be taken up by cells and converted intracellularly to deoxynucleotides by the addition of deoxyribose and phosphate groups. Cytosine, thymine, and adenine cannot be activated by mammalian cells, which lack the ability to add the necessary ribose or deoxyribose groups to these particular bases. However, preformed deoxynucleosides containing a deoxyribose linked to cytosine or adenine are readily transported into cells and activated by conversion to deoxynucleotides by intracellular kinases.

The limitations of cell uptake and conversion to active triphosphates determine the form in which specific analogs have been synthesized, varying from base analogs such as fluorouracil (5-fluorouracil, or 5-FU) to nucleosides such as cytosine arabinoside, and even to nucleotides such as fludarabine phosphate. Uracil and guanine analogs (such as 5-FU and 6-thioguanine) are efficiently taken up by cells and converted to dNTPs. Because of the inability to activate cytosine or adenine bases, analogs of cytosine and adenine are synthesized as nucleosides (*cytosine arabinoside* [cytarabine; Ara-C] and *gemcitabine*, for example), which are readily transported into cells and converted by kinases to the active dNTPs. *Fludarabine phosphate*, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogous differ from the physiologic bases by alterations in purine or pyrimidine ring or by altering the sugar

attached to the base, as in the arabinoside Ara-C, or by altering both the base and sugar, as in fluorarabine phosphate.

The best-characterized agents in this class are the halogenated pyrimidines, a group that includes 5-FU, floxuridine (5-fluoro-2'-deoxyuridine, or 5-FUdR), and idoxuridine (5-iodo-deoxyuridine) (see Chapter 49). Iododeoxyuridine behaves as an analog of thymidine, and its primary biological action results from its phosphorylation and ultimate incorporation into DNA in place of thymidylate. In 5-FU, the smaller fluorine allows the molecule to mimic uracil biochemically. However, the fluorine-carbon bond is much tighter than that of C—H and prevents the methylation of the 5 position of 5-FU by TS. Instead, in the presence of the physiological cofactor 5,10-methylene tetrahydrofolate, the fluoropyrimidine locks the enzyme in an inhibited state and prevents the synthesis of thymidylate, a required DNA precursor.

The most clinically important 5-FU analog is capecitabine (N4-pentoxycarbonyl-5'-deoxy-5-fluorocytidine), a drug active against colon and breast cancers. This orally administered agent is converted to 5'-deoxy-5-fluorocytidine by carboxylesterase activity in liver and other normal and malignant tissues, then is converted to 5'-deoxy-fluorodeoxyuridine by the ubiquitous cytidine deaminase. The final step in its activation occurs when thymidine phosphorylase cleaves the 5'-deoxy sugar, leaving intracellular 5-FU. Tumors with elevated thymidine phosphorylase activity are particularly susceptible to this drug.

Cytidine analogs also are potent antitumor agents. The replacement of the ribose of cytidine with arabinose has yielded a useful chemotherapeutic agent, cytarabine (Ara-C). The arabinose analog is recognized enzymatically as a 2'-deoxyriboside; it is phosphorylated to a nucleoside triphosphate that competes with deoxycytidine triphosphate (dCTP) for incorporation into DNA. When incorporated into DNA, it blocks elongation of the DNA strand and transcription. Other cytidine analogs include azacitidine (5-azacytidine) and its deoxyanalog, decitabine, which inhibit DNA methyltransferase. They have antileukemic as well as differentiating actions. The analog 2',2'-difluorodeoxycytidine (gemcitabine) becomes incorporated into DNA and inhibits the elongation of nascent DNA strands. It has useful activity in various human solid tumors, including pancreatic, lung, and ovarian cancer.

Fluorouracil and Floxuridine (Fluorodeoxyuridine)

Fluorouracil (5-FU) requires enzymatic conversion to the nucleotide (ribosylation and phosphorylation) in order to exert its cytotoxic activity; these reactions are illustrated in Figure 51-5. The interaction between FdUMP and TS blocks the synthesis of thymidine triphosphate (TTP), a necessary constituent of DNA. The folate cofactor, 5,10-methylenetetrahydrofolate, and FdUMP form a covalently bound ternary complex with TS. The transfer of the methylene group and two hydrogen atoms from folate to FdUMP is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results. In 5-FU-treated cells, both fluorodeoxyuridine triphosphate (FdUTP) and deoxyuridine triphosphate (dUTP) (the substrate that accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological nucleotide, TTP. Presumably, the incorporation of dUTP and/or FdUTP into DNA activates the excision-repair process. This can lead to DNA strand breakage because DNA repair requires TTP, which is lacking because of TS inhibition. 5-FU incorporation into RNA also causes toxicity because of effects on both the processing and functions of RNA.

FIGURE 51-5 Activation pathways for 5-fluorouracil (5-FU) and 5-floxuridine (FUR). FUDP, floxuridine diphosphate; FUMP, floxuridine monophosphate; FUTP, floxuridine triphosphate; FdR, fluorodeoxyuridine; FdUDP, fluorodeoxyuridine diphosphate; FdUMP, fluorodeoxyuridine monophosphate; FdUTP, fluorodeoxyuridine triphosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.

A number of biochemical mechanisms are associated with resistance to the cytotoxic effects of 5-FU or FdUR. These mechanisms include loss or decreased activity of the enzymes necessary for activation of 5-FU, amplification of TS, and mutation of TS to a form that is not inhibited by FdUMP.

The response to 5-FU correlates significantly with low levels of the degradative enzymes dihydrouracil dehydrogenase and thymidine phosphorylase, and a low level of expression of TS. TS levels are finely controlled by an autoregulatory feedback mechanism wherein unbound TS inhibits the translational efficiency of its own mRNA. When TS is bound to FdUMP, inhibition of translation is relieved, and levels of free TS are restored. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5-FU.

Some malignant cells appear to have insufficient concentrations of 5,10-methylene tetrahydrofolate, and thus cannot form maximal levels of the inhibited TS-FdUMP-folate ternary complex. Addition of exogenous folate in the form of leucovorin increases formation of the complex and has enhanced responses to 5-FU.

In addition to leucovorin, a number of other agents have been combined with 5-FU in attempts to enhance the cytotoxic activity through biochemical modulation. Methotrexate, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances 5-FU activation and increases antitumor activity of 5-FU when given before but not after 5-FU. The combination of cisplatin and 5-FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is not well understood. Oxaliplatin is commonly used with 5-FU and leucovorin for treating metastatic colorectal cancer, but the mechanism responsible for the synergistic clinical effect has not been fully elucidated. Oxaliplatin may inhibit catabolism of 5-FU, perhaps by inhibiting DPD, and may inhibit expression of TS. 5-FU with simultaneous irradiation is curative therapy for anal cancer and enhances local tumor control in head and neck, cervical, rectal, gastroesophageal, and pancreatic cancer; the mechanism for this synergism is unclear.

5-FU is administered parenterally, since oral absorption is unpredictable and incomplete. Metabolic degradation occurs in many tissues, particularly the liver. 5-FU is inactivated by reduction of the pyrimidine ring; this reaction is carried out by DPD, which is found in liver, intestinal mucosa, tumor cells, and other tissues. Although rare, inherited deficiency of DPD leads to greatly increased sensitivity to the drug and profound drug toxicity following conventional doses. DPD deficiency can be detected either by enzymatic or molecular assays using peripheral white blood cells, or by determining the plasma ratio of 5-FU to its metabolite, 5-fluoro-5,6-dihydrouracil.

After intravenous administration of 5-FU, plasma clearance is rapid ($t_{1/2}$, 10–20 minutes). Urinary excretion of a single intravenous dose of 5-FU amounts to only 5–10% in 24 hours. Although the liver contains high concentrations of DPD, dosage does not have to be modified in patients with hepatic dysfunction, presumably because of degradation of the drug at extrahepatic sites or by vast excess of this enzyme in the liver. 5-FU enters the CSF in minimal amounts.

Capecitabine is well absorbed orally. It is rapidly de-esterified and deaminated, yielding high plasma concentrations of 5'-deoxy-fluorodeoxyuridine (5'-dFdU), which disappears with a $t_{1/2}$ of ~1 hour. 5-FU levels are <10% of those of 5'-dFdU. The conversion of 5'-dFdU to 5-FU by thymidine phosphorylase occurs in liver, peripheral tissues, and tumors. Liver dysfunction delays the conversion of the parent compound to 5'-dFdU and 5-FU, but there is no consistent effect on toxicity.

5-Fluorouracil 5-Fluorouracil produces partial responses in 10–20% of patients with metastatic colon carcinomas, upper GI carcinomas, and breast carcinomas. The administration of 5-FU in combination with leucovorin in the adjuvant setting is associated with a survival advantage for patients with colorectal cancers and gastric cancers.

For average-risk patients in good nutritional status with adequate hematopoietic function, the weekly dosage regimen is 500–600 mg/m² with leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses of 500 mg/m² for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5-FU for 5 days must be reduced to 375–425 mg/m² because of mucositis and diarrhea. 5-FU is increasingly used as a biweekly loading dose followed by a 48-hour continuous infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer.

Fluoridine (FdUR)

FdUR (fluorodeoxyuridine; FUDR) is used primarily by continuous infusion into the hepatic artery for treatment of metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate to such infusion is 40–50%, or double that observed with intravenous administration. Intrahepatic arterial infusion for 14–21 days may be used with minimal systemic toxicity. However, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7–14.

Capecitabine (XELODA)

Capecitabine is FDA-approved for the treatment of (1) metastatic breast cancer in patients who have not responded to a regimen of paclitaxel and an anthracycline antibiotic; (2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer for patients in whom fluoropyrimidine monotherapy is preferred. The recommended dose is 2500 mg/m² daily, given orally in two divided doses with food, for 2 weeks followed by a rest period of 1 week. This cycle is then repeated two more times.

COMBINATION THERAPY Higher response rates are seen when 5-FU is used in combination with other agents, such as cyclophosphamide and methotrexate (breast cancer), cisplatin (head and neck cancer), and with oxaliplatin or irinotecan in colon cancer. The combination of 5-FU and oxaliplatin or irinotecan has become the standard first-line treatment for patients with metastatic colorectal cancer. The use of 5-FU in combination regimens has improved survival in the adjuvant treatment for breast cancer, and with oxaliplatin and leucovorin, for colorectal cancer. 5-FU also is a potent radiation sensitizer. Beneficial effects also have been reported when combined with irradiation for cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5-FU is used widely with very favorable results for the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

The clinical manifestations of toxicity caused by 5-FU and flouxuridine are similar and may be difficult to anticipate because of their delayed appearance. The earliest untoward symptoms are anorexia and nausea; these are followed by stomatitis and diarrhea, which are reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5-FU. The nadir of leukopenia usually is between days 9 and 14 after the first injection of drug. Thrombocytopenia and anemia also may occur. Loss of hair, occasionally progressing to total alopecia, nail changes, dermatitis, and increased pigmentation and atrophy of the skin may be encountered. Hand-foot syndrome consisting of erythema, desquamation, pain, and sensitivity to touch of the palms and soles also can occur. Neurological manifestations, including an acute cerebellar syndrome, have been reported, and myelopathy has been observed after the intrathecal administration of 5-FU. Cardiac toxicity, particularly acute chest pain with evidence of ischemia in the electrocardiogram, also may occur. In general, myelosuppression, mucositis, and diarrhea occur less often with infusion than bolus regimens, while hand-foot syndrome occurs more often with infusion than bolus regimens. The low therapeutic indices of these agents emphasize the need for very skillful supervision by physicians familiar with the action of the fluorinated pyrimidines and the possible hazards of chemotherapy. Capecitabine causes much the same spectrum of toxicities as 5-FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

CYTIDINE ANALOGS**Cytarabine (Cytosine Arabinoside; Ara-C)**

Cytarabine (1- β -D-arabinofuranosylcytosine; Ara-C) is the single most effective agent for induction of remission in AML. Ara-C is an analog of 2'-deoxycytidine; the 2'-hydroxyl hinders rotation of the pyrimidine base around the nucleosidic bond and interferes with base stacking. Ara-C penetrates cells by a carrier-mediated process shared by physiological nucleosides. In infants and adults with ALL and the t(4;11) MLL translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter, hENT1, is highly expressed, and its expression correlates with Ara-C sensitivity. At extracellular drug concentrations >10 μ M (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting.

As with most purine and pyrimidine antimetabolites, Ara-C must be "activated" by conversion to the 5'-monophosphate nucleotide (Ara-CMP), a reaction catalyzed by deoxycytidine kinase. Ara-CMP can then react with appropriate deoxynucleotide kinases to form the diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with the physiological substrate deoxycytidine 5'-triphosphate (dCTP) for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue potently inhibits DNA polymerase, in both replication and repair. Fragmentation of DNA is observed in Ara-C-treated cells, and there is cytological and biochemical evidence for apoptosis in both tumor and normal tissues.

The optimal interval between bolus doses of Ara-C is ~8–12 hours, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels for at least one cell cycle. Typical schedules for Ara-C administration employ bolus doses every 12 hours for 5–7 days or a continuous infusion for 7 days. Particular subtypes of AML derive benefit from high-dose Ara-C treatment; these include t(8;21), inv(16), t(9;16), and del(16).

Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting enzyme is deoxycytidine kinase, which produces Ara-CMP. An important degradative enzyme is cytidine deaminase, which deaminates Ara-C to a nontoxic metabolite, arauridine. Cytidine deaminase is found in high activity in many tissues, including some human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite, Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells is associated with a longer duration of complete remission in patients with AML. The ability of cells to transport Ara-C also affects the clinical response.

Because drug concentration in plasma rapidly falls below the level needed to saturate transport and activation processes, high-dose regimens (2–3 g/m² every 12 hours for 6 doses) to achieve 20–50-times higher serum levels give improved results in remission induction and consolidation for AML. Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only ~20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak plasma concentrations disappear rapidly ($t_{1/2}$ of 10 minutes). Less than 10% of the injected dose is excreted unchanged in the urine within 12–24 hours, while most appears as the inactive deaminated product, arabinosyl uracil. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection. After intrathecal administration of the drug at a dose of 50 mg/m², relatively little deamination occurs, even after 7 hours, and peak concentrations decline slowly with a half-life of ~3.4 hours. Concentrations above the threshold for cytotoxicity (0.4 μM) are maintained in the CSF for 24 hours or longer. More recently, a formulation of Ara-C (DEPOCYT) has been developed for sustained release into the CSF. After a standard 50-mg dose, cytarabine concentration is maintained at cytotoxic levels for an average of 12 days, thus avoiding the need for repeated lumbar punctures.

Two standard dosage schedules are recommended for administration of cytarabine (CYTOSAR-U, TARABINE PFS, others): (1) rapid intravenous infusion of 100 mg/m² every 12 hours for 5–7 days; or (2) continuous intravenous infusion of 100 to 200 mg/m² daily for 5–7 days. In general, children tolerate higher doses than do adults. Intrathecal doses of 30 mg/m² every 4 days have been used to treat meningeal leukemia. The intrathecal administration of 50–70 mg of the liposomal formulation of cytarabine (DEPOCYT) every 2 weeks seems to be equally effective as the every-4-day regimen. Conventional cytarabine is indicated for induction and maintenance of remission in acute nonlymphocytic leukemia and is useful in the treatment of other leukemias, such as ALL, AML, and CML in the blast phase. Intrathecal cytarabine is indicated for meningeal leukemia. A depot formulation of cytarabine is indicated for the intrathecal treatment of lymphomatous meningitis and may be useful for carcinomatous meningitis. Cytarabine is a potent myelosuppressive agent capable of producing acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible elevations of hepatic enzymes, noncardiogenic pulmonary edema, and dermatitis. Cerebellar toxicity, manifest as ataxia and slurred speech, and cerebral toxicity, including seizures, dementia, and coma, may follow intrathecal administration or high-dose systemic administration to patients >50 years of age and/or patients with impaired renal function.

Azacitidine (5-Azacitidine)

5-Azacitidine and the closely related investigational drug decitabine (2'-deoxy-5-azacytidine) have antileukemic activity and induce differentiation. 5-Azacitidine is approved for treatment of myelodysplasia; it induces normalization of bone marrow in 15–20% of patients and reduces transfusion requirement in one-third of patients. It becomes incorporated into RNA and DNA and inhibits methylation of DNA, inducing the expression of silenced genes. Thus, it also is used to induce fetal hemoglobin (HbF) synthesis in sickle cell anemia, although it has been largely replaced for this indication by hydroxyurea. It undergoes very rapid deamination by cytidine deaminase, the product hydrolyzing to inactive metabolites. Its major toxicities include myelosuppression, and rather severe nausea and vomiting when given intravenously in large doses (150–200 mg/m²/day for 5 days). In low-dose daily subcutaneous regimens for myelodysplasia, 30 mg/m²/day, it is well tolerated.

Gemcitabine

Gemcitabine (2',2' difluoro deoxycytidine; dFdC), a difluoro analog of deoxycytidine, is used for patients with metastatic pancreatic cancer, non-small cell lung cancer, ovarian, bladder,

esophageal, and head and neck cancer. Gemcitabine enters cells *via* active nucleoside transporters. Intracellularly, deoxycytidine kinase phosphorylates gemcitabine to produce difluorodeoxycytidine monophosphate (dFdCMP), from which point it is converted to difluorodeoxycytidine di- and triphosphate (dFdCDP and dFdCTP). While its anabolism and effects on DNA in general mimic those of cytarabine, there are differences in kinetics of inhibition, additional sites of action, effects of incorporation into DNA, and spectrum of clinical activity. Unlike cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis: dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase; dFdCDP is a potent inhibitor of ribonucleotide reductase, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis; and incorporation of dFdCTP into DNA leads to DNA strand termination that is apparently resistant to repair. The ability of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis.

Gemcitabine is administered by intravenous infusion. The pharmacokinetics of the parent compound is largely determined by deamination, and the predominant urinary elimination product is the inactive metabolite difluorodeoxyuridine (dFdU). Gemcitabine has a short plasma $t_{1/2}$ (~15 minutes), with women and elderly subjects having slower clearance. Clearance is dose-independent but varies widely among individuals. The standard dosing schedule for gemcitabine (GEMZAR) is a 30-minute intravenous infusion of 1–1.2 g/m² on days 1, 8, and 15 of each 28-day cycle. Similar to that of cytarabine, conversion of gemcitabine to dFdCMP by deoxycytidine kinase is saturated at infusion rates of ~10 mg/m²/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 150 minutes. In contrast to infusion duration of 30 minutes, the 150-minute infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells, increases the degree of myelosuppression, but has uncertain effects on antitumor activity.

The activity of dFdCTP on DNA repair mechanisms may allow for increased cytotoxicity of other chemotherapeutic agents, particularly platinum compounds. Preclinical studies of tumor cell lines show that cisplatin-DNA adducts are enhanced in the presence of gemcitabine, presumably through suppression of nuclear excision repair.

The principal toxicity of gemcitabine is myelosuppression. In general, longer-duration infusions lead to greater myelosuppression. Nonhematologic toxicities including a flu-like syndrome, asthenia, and mild elevation in liver transaminases may occur in 40% or more of patients. Although severe nonhematological toxicities are rare, interstitial pneumonitis may occur and is responsive to glucocorticoids. Rarely, patients on gemcitabine treatment for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. Gemcitabine is a very potent radiosensitizer and generally should not be used with radiotherapy.

PURINE ANALOGS

Analogues of naturally occurring purine bases with antileukemic, immunosuppressant, and antiviral properties include mercaptopurine, thioguanine, azathioprine, *acyclovir*, *ganciclovir*, *vidarabine*, and *zidovudine*. Other purine analogs important in cancer therapy include pentostatin (2'-deoxycoformycin), *cladribine*, and fludarabine phosphate.

6-Thiopurine Analogs

6-Mercaptopurine (6-MP) and 6-thioguanine (6-TG) are approved for human leukemias and function as analogs of the natural purines, hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily converted to nucleotides in normal and malignant cells. Nucleotides formed from 6-MP and 6-TG inhibit de novo purine synthesis and become incorporated into nucleic acids. Both 6-TG and 6-MP are excellent substrates for hypoxanthine guanine phosphoribosyl transferase (HGPRT) and are converted in a single step to the ribonucleotides 6-thioguanosine-5'-monophosphate (6-thioGMP) and 6-thioinosine-5'-monophosphate (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase, the enzyme that converts guanosine monophosphate (GMP) to guanosine diphosphate (GDP), T-IMP accumulates intracellularly. T-IMP inhibits the first step in the de novo synthesis of the purine base and thereby inhibits the formation of ribosyl-5-phosphate, as well as conversion of inosine-5'-monophosphate (IMP) to adenine and guanine nucleotides. Of these, the most important point of attack seems to be the reaction of glutamine and 5-phosphoribosyl-1-pyrophosphate (PRPP) to form ribosyl-5-phosphate, the first committed step in the de novo pathway.

The role of incorporation of thiopurines into cellular DNA with regard to therapeutic or toxic effects remains unknown. The incidence of pregnancy-related complications, however, was significantly increased when fathers used mercaptopurine within 3 months of conception. These compounds can cause marked inhibition of the coordinated induction of various enzymes required for DNA synthesis, as well as potentially critical alterations in the synthesis of polyadenylate-containing RNA.

As with other antimetabolites, acquired resistance is a major obstacle. The most common mechanism of 6-MP resistance is deficiency or complete lack of the activating enzyme, HGPRT. Another mechanism of resistance is increased particulate alkaline phosphatase activity. Other potential mechanisms for resistance to 6-MP include: (1) decreased drug transport; (2) alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; (3) altered recognition of DNA breaks and mismatches induced by 6-MP; and (4) increased activity of multidrug resistance protein 5, which exports nucleoside analogs.

Absorption of mercaptopurine is incomplete after oral ingestion and bioavailability is reduced by first-pass metabolism by xanthine oxidase in the liver. Oral bioavailability is only 10–50%, with great interpatient variability and decreased absorption in the presence of food or oral antibiotics. Thus, when used in combination with other drugs, doses should be titrated according to the white blood cell and platelet counts. Bioavailability is increased when mercaptopurine is combined with high-dose methotrexate. After an intravenous dose, the plasma $t_{1/2}$ of the drug is relatively short (~50 minutes in adults), due to rapid metabolic degradation by xanthine oxidase and thiopurine methyltransferase (TPMT). Restricted CNS distribution of mercaptopurine results from an efficient efflux transport system in the blood–brain barrier. In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Expression of the TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity which is associated with increased drug toxicity in individual patients and a lower risk of relapse (see Chapter 4). High concentrations of 6-methylmercaptopurine nucleotides are formed following 6-MP administration. Substantial amounts of the mono-, di-, and triphosphate nucleotides of 6-methylmercaptopurine ribonucleoside (6-MMPR) are found in cells in the blood and bone marrow of patients treated with 6-MP or azathioprine. They are less potent than 6-MP nucleotides as metabolic inhibitors, and their significance in contributing to the activity of 6-MP is not known. The second major pathway for 6-MP metabolism involves its oxidation by xanthine oxidase to 6-thiouric acid, an inactive metabolite. Oral doses of 6-MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor allopurinol.

The initial average daily oral dose of mercaptopurine (6-mercaptopurine, 6-MP; PURINETHOL) is 50–100 mg/m², and is adjusted according to white blood cell and platelet counts. The total dose required to produce bone marrow depression in patients with nonhematological malignancies is ~45 mg/kg, ranging from 18 to 100 mg/kg. Hyperuricemia with hyperuricosuria may occur during treatment; the accumulation of uric acid presumably reflects the destruction of cells with release of purines that are oxidized by xanthine oxidase and an inhibition of the conversion of inosinic acid to nucleic acid precursors. This may be an indication for the use of allopurinol. Special caution must be employed if 6-MP or its imidazolyl derivative, azathioprine, is used with allopurinol because the associated delay in catabolism of the purine analog increases the likelihood of severe toxicity. Patients treated simultaneously with both drugs should receive ~25% of the usual dose of mercaptopurine. The combination of methotrexate and 6-MP is synergistic, based on the effects of methotrexate inhibition of the earliest steps in purine synthesis; methotrexate elevates the intracellular concentration of PRPP, which is required for 6-MP activation.

The principal toxicity of 6-MP is bone marrow depression, although this side effect generally develops more gradually than with folic acid antagonists; accordingly, thrombocytopenia, granulocytopenia, or anemia may not be encountered for several weeks. When depression of normal bone marrow elements occurs, dose reduction usually results in prompt recovery. Anorexia, nausea, or vomiting is seen in ~25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6-MP, and usually resolve upon discontinuation of therapy. The long-term complications associated with 6-MP and its derivative azathioprine are opportunistic infection and an increased incidence of squamous cell malignancies of skin. Teratogenic effects during the first trimester are associated with chronic 6-MP, and AML has been reported after prolonged use of 6-MP for Crohn's disease.

Fludarabine Phosphate

A fluorinated deamination-resistant nucleotide analog of the antiviral agent vidarabine (9- β -D-arabinofuranosyl-adenine), this compound is active in CLL and low-grade lymphomas. After rapid extracellular dephosphorylation to the nucleoside fludarabine, it is rephosphorylated intracellularly by deoxycytidine kinase to the active triphosphate derivative. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and ribonucleotide reductase, and is incorporated into DNA and

RNA. The triphosphate nucleotide is an effective chain terminator when incorporated into DNA, and the incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation. A major effect of this drug may be its activation of apoptosis, which may explain its activity against indolent lymphoproliferative disease, where only a small fraction of cells are in S phase.

Fludarabine phosphate administered intravenously is rapidly converted to fludarabine in the plasma. The terminal $t_{1/2}$ of fludarabine is ~10 hours. The compound is primarily eliminated by renal excretion, and ~23% appears in the urine as fludarabine because of its relative resistance to deamination by adenosine deaminase (ADA).

Fludarabine phosphate (FLUDARA) is available for intravenous use. The recommended dose of fludarabine phosphate is 20–30 mg/m² daily for 5 days. The drug is administered intravenously by infusion during a period of 30 minutes to 2 hours. Dosage may need to be reduced in renal impairment. Treatment may be repeated every 4 weeks, and at these doses gradual improvement usually occurs during a period of 2–3 cycles.

Fludarabine phosphate is used primarily for the treatment of patients with CLL, although experience is accumulating that suggests effectiveness in B-cell lymphomas refractory to standard therapy. In CLL patients previously refractory to a regimen containing a standard alkylating agent, response rates of 32–48% have been reported. Activity also has been seen with indolent non-Hodgkin's lymphoma, promyelocytic leukemia, cutaneous T-cell lymphoma, and Waldenström's macroglobulinemia. In patients with previously untreated low-grade lymphomas, fludarabine phosphate in combination with either cyclophosphamide or with dexamethasone and mitoxantrone has resulted in a high rate of response.

Toxic manifestations include myelosuppression, nausea and vomiting, chills and fever, malaise, anorexia, and weakness. Lymphopenia and thrombocytopenia are dose limiting and possibly cumulative. CD4⁺ T cells are depleted with therapy. Opportunistic infections and tumor lysis syndrome have been reported. Peripheral neuropathy may occur at standard doses. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Rarely, CLL patients may develop an acute hemolytic anemia or pure red cell aplasia during fludarabine treatment. Severe pneumonitis responsive to glucocorticoids has been encountered. Because a significant fraction of drug (~25%) is eliminated in the urine, patients with compromised renal function should be treated with caution, and initial doses should be reduced proportionate to serum creatinine levels.

Cladribine

An ADA-resistant purine analog, cladribine (2-chlorodeoxyadenosine; 2-CdA) has demonstrated potent activity in hairy cell leukemia, CLL, and low-grade lymphomas. After intracellular phosphorylation by deoxycytidine kinase and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and adenosine triphosphate (ATP), as well as apoptosis, and is a potent inhibitor of ribonucleotide reductase. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme, deoxycytidine kinase, or escape of ribonucleotide reductase from inhibition.

Cladribine is moderately well absorbed orally (55%), but is routinely administered intravenously. The drug is excreted by the kidneys, with a terminal $t_{1/2}$ in plasma of ~7 hours. Cladribine crosses the blood-brain barrier and reaches CSF concentrations of ~25% of those seen in plasma. In patients with meningeal involvement, however, CSF concentrations can approach those in plasma.

Cladribine (LEUSTATIN) is administered as a single course of 0.09 mg/kg/day for 7 days by continuous intravenous infusion. Cladribine is considered the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL, and is a secondary agent in other leukemias and low-grade lymphomas, Langerhans cell histiocytosis, cutaneous T-cell lymphomas including mycosis fungoides and the Sézary syndrome, and Waldenström's macroglobulinemia.

The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and are correlated with decreased CD4⁺ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome. Neurological and immunosuppressive adverse effects are less evident than with pentostatin at clinically active doses.

Pentostatin (2'-Deoxycofornycin)

Pentostatin, a transition-state analog of the intermediate in the ADA reaction, is a potent inhibitor of ADA. Its effects mimic the phenotype of genetic ADA deficiency, which is associated with

severe immunodeficiency affecting both T- and B-cell functions. Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting ribonucleotide reductase. Deoxyadenosine also inactivates *S*-adenosyl homocysteine hydrolase. The resulting accumulation of *S*-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. In combination with 2'-deoxyadenosine, it is capable of inducing apoptosis in human monocytoid leukemia cells. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

Pentostatin is administered intravenously, and a single dose of 4 mg/m² has a terminal t_{1/2} of 5.7 hours. The drug is eliminated almost entirely by renal excretion, and proportional reduction of dosage is indicated in patients with renal impairment.

Pentostatin (NIPENT) is available for intravenous use. The recommended dosage is 4 mg/m² administered every other week. After hydration with 500–1000 mL of 5% dextrose in 0.45% saline, the drug is administered by rapid intravenous injection or by infusion during a period of up to 30 minutes, followed by an additional 500 mL of fluids. Extravasation does not produce tissue necrosis. Pentostatin is extremely effective in producing complete remissions in hairy cell leukemia. Complete responses of 58% and partial responses of 28% have been reported, even in patients who were refractory to interferon- α . Activity also is seen against CLL, CML, promyelocytic leukemia, cutaneous T-cell lymphoma, non-Hodgkin's lymphoma, and Langerhans cell histiocytosis. Pentostatin has no significant activity against solid tumors or MM.

Toxic manifestations include myelosuppression, GI symptoms, rashes, and abnormal liver function studies at standard (4 mg/m²) doses. Depletion of normal T cells occurs at these doses, and neutropenic fever and opportunistic infections can occur. Immunosuppression may persist for several years after discontinuation of pentostatin therapy. At higher doses (10 mg/m²), major renal and neurological complications are encountered. The use of pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

III. NATURAL PRODUCTS

ANTIMITOTIC DRUGS

Vinca Alkaloids

Vinblastine and vincristine—alkaloids purified from the periwinkle plant—are used for treatment of leukemias, lymphomas, and testicular cancer. A closely related derivative, *vinorelbine*, has important activity against lung cancer and breast cancer. The vinca alkaloids are cell cycle–specific agents, and in common with other drugs such as *colchicine*, *podophyllotoxin*, and taxanes, block cells in mitosis. The vinca alkaloids bind specifically to β -tubulin and block its ability to polymerize with α -tubulin into microtubules. In the absence of an intact mitotic spindle, duplicated chromosomes cannot align along the division plate and cell division is arrested in metaphase. Cells blocked in mitosis undergo changes characteristic of apoptosis.

In addition to their key role in the formation of mitotic spindles, microtubules are found in high concentration in the brain and are essential to cellular functions such as movement, phagocytosis, and axonal transport. Side effects of the vinca alkaloids, such as their neurotoxicity, may be due to disruption of these functions.

Despite their structural similarity, the vinca alkaloids have unique individual patterns of clinical effectiveness (see below). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance, in which tumor cells become cross-resistant to a wide range of chemically dissimilar agents after exposure to a single (natural product) drug. Such multidrug-resistant tumor cells display cross-resistance to vinca alkaloids, the epipodophyllotoxins, anthracyclines, and taxanes. Chromosomal abnormalities consistent with gene amplification have been observed in resistant cells in culture, and the cells contain markedly increased levels of the P-glycoprotein, a membrane efflux pump that transports drugs from the cells. Calcium channel blockers such as verapamil can reverse resistance of this type. Other membrane transporters such as the multidrug resistance-associated protein (MRP), and the closely related breast cancer resistance protein, may mediate multidrug resistance. Other forms of resistance to vinca alkaloids stem from mutations in β -tubulin or in the relative expression of its isoforms; both changes prevent the effective binding of the inhibitors to their target.

Vincristine is a standard component of regimens for treating pediatric leukemias, lymphomas, and solid tumors. In large-cell non-Hodgkin's lymphomas, vincristine remains an important drug,

particularly when used in the CHOP regimen with cyclophosphamide, doxorubicin, and prednisone. As mentioned above, vincristine is more useful for remission induction in lymphocytic leukemia. Vincristine also is a standard component of regimens used to treat pediatric solid tumors such as Wilms' tumor, neuroblastoma, and rhabdomyosarcoma. Vinblastine is employed in bladder cancer, testicular carcinomas, and Hodgkin's disease. Vinorelbine has activity against non-small cell lung cancer and breast cancer. The limited myelosuppressive action of vincristine makes it a valuable component of a number of combination therapy regimens for leukemia and lymphoma, while the lack of neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes a mild neurotoxicity as well as myelosuppression, has an intermediate toxicity profile.

The nadir of leukopenia following vinblastine or vinorelbine occurs 7–10 days after drug administration. Vincristine in standard doses, 1.4–2 mg/m², causes little reduction of formed elements in the blood. All three agents cause hair loss and local cellulitis if extravasated. A syndrome of hyponatremia due to inappropriate secretion of vasopressin occurs rarely after vincristine administration (see Chapter 29). While all 3 derivatives may cause neurotoxic symptoms, vincristine has predictable cumulative effects. Numbness and tingling of the extremities and loss of deep tendon reflexes are the most common and earliest signs, followed by motor weakness. Sensory changes do not usually warrant an immediate reduction in drug dose, but loss of motor function should lead to a reevaluation of the therapeutic plan, and under most circumstances, drug discontinuation. Rarely, patients may experience vocal cord paralysis or loss of extraocular muscle function. High-dose vincristine causes severe constipation. Inadvertent intrathecal vincristine administration produces devastating and invariably fatal central neurotoxicity, with seizures and irreversible coma.

The liver extensively metabolizes all three agents, and the conjugates and metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found in the urine unchanged. In patients with hepatic dysfunction (bilirubin >3 mg/dL), a 75% reduction in dose of any of the vinca alkaloids is advisable. The pharmacokinetics of each of the three drugs are similar, with central and tissue elimination half-lives of 1 and 20 hours for vincristine, 3 and 23 hours for vinblastine, and 1 and 45 hours for vinorelbine, respectively.

Vinblastine

Vinblastine sulfate (VELBAN, others) is given intravenously; special precautions must be taken against subcutaneous extravasation, since this may cause painful ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose of 0.3 mg/kg of body weight, myelosuppression reaches its maximum in 7–10 days. If a moderate level of leukopenia (~3000 cells/mm³) is not attained, the weekly dose may be increased gradually by increments of 0.05 mg/kg. In regimens designed to cure testicular cancer, vinblastine is used in doses of 0.3 mg/kg every 3 weeks.

The most important clinical use of vinblastine is with bleomycin and cisplatin (see below) in the curative therapy of metastatic testicular tumors, although it has been supplanted by etoposide or ifosfamide in this disease. It is a component of the standard curative ABVD regimen for Hodgkin's disease (adriamycin, bleomycin, vinblastine, and dacarbazine). It also is active in Kaposi's sarcoma, neuroblastoma, and histiocytosis X, and in carcinoma of the breast and choriocarcinoma.

The nadir of the leukopenia that follows the administration of vinblastine usually occurs within 7–10 days, after which recovery ensues within 7 days. Other toxic effects of include neurological manifestations as described above. GI disturbances including nausea, vomiting, anorexia, and diarrhea may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis. Local injection of hyaluronidase and application of moderate heat to the area may be of help by dispersing the drug.

Vincristine

Vincristine sulfate (ONCOVIN, VINCASAR PFS, others) used together with glucocorticoids is the treatment of choice to induce remissions in childhood leukemia; common dosages for these drugs are vincristine, intravenously, 2 mg/m² of body surface area weekly, and prednisone, orally, 40 mg/m² daily. Adult patients with Hodgkin's disease or non-Hodgkin's lymphomas usually receive vincristine as part of a complex protocol. When used in the MOPP regimen (see below), the recommended dose of vincristine is 1.4 mg/m². Vincristine seems to be better tolerated by children than by adults, who may experience severe, neurological toxicity. Drug administration more frequently than every 7 days or at higher doses seems to increase toxic manifestations without improving the response rate. Maintenance therapy with vincristine is not recommended in children with leukemia.

Precautions also should be used to avoid extravasation during intravenous administration of vincristine.

In large-cell lymphoma, a liposomal formulation of vincristine (ONCO-TCS), given in doses of 2 mg/m², has less neurotoxicity and retains activity in patients who relapse after vincristine therapy. It has the expected advantages of slower elimination and greater tissue distribution as compared to the unmodified drug.

The clinical toxicity of vincristine is mostly neurological. The more severe neurological manifestations may be avoided or reversed either by suspending therapy or reducing the dosage upon occurrence of motor dysfunction. Severe constipation may be prevented by a prophylactic program of laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses above 2 mg/m². Alopecia occurs in ~20% of patients given vincristine; however, it is always reversible, frequently without cessation of therapy. Although less common than with vinblastine, leukopenia may occur with vincristine, and thrombocytopenia, anemia, polyuria, dysuria, fever, and GI symptoms have been reported occasionally. The syndrome of inappropriate secretion of antidiuretic hormone occasionally has occurred during vincristine therapy. In view of the rapid action of the vinca alkaloids, it is advisable to prevent hyperuricemia by the administration of allopurinol.

Vinorelbine

Vinorelbine (NAVELBINE, others) is administered in normal saline as an intravenous infusion of 30 mg/m² given over 6–10 minutes. A lower dose (20–25 mg/m²) may be required for patients who have received prior chemotherapy. When used alone, it is initially given every week until progression of disease or dose-limiting toxicity. When used with cisplatin for the treatment of non-small cell lung carcinoma, it is given every 3 weeks. Like the other vinca alkaloids, it is eliminated by hepatic metabolism, and has an elimination $t_{1/2}$ of 24 hours. Its primary toxicity is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. It may cause allergic reactions and mild, reversible elevations in liver enzymes. Doses should be reduced in patients with elevated bilirubin or with >75% liver replacement by metastatic disease.

Taxanes

Paclitaxel (TAXOL), a compound first isolated from the bark of the Western yew tree, and its semi-synthetic congener docetaxel (TAXOTERE) exhibit unique pharmacological actions. They differ from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β -tubulin and promote rather than inhibit microtubule formation. The drugs have a central role in the therapy of ovarian, breast, lung, esophageal, bladder, and head and neck cancers. Their optimal dose, schedule, and use in drug combinations still are evolving.

Paclitaxel has very limited solubility and must be administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil (CREMOPHOR EL), a formulation likely responsible for a high rate of hypersensitivity reactions. Patients receiving this formulation are protected by pretreatment with a histamine H₁ receptor antagonist such as diphenhydramine, an H₂ receptor antagonist such as cimetidine (see Chapter 24), and a glucocorticoid such as dexamethasone (see Chapter 59). Docetaxel, which is somewhat more soluble, is administered in polysorbate 80 and causes a lower incidence of hypersensitivity reactions. Pretreatment with dexamethasone is required to prevent progressive, and often disabling, fluid retention.

Paclitaxel binds specifically to β -tubulin and antagonizes the disassembly of microtubules; bundles of microtubules and aberrant structures derived from microtubules appear in the M phase of the cell cycle, causing mitotic arrest. Cell killing is dependent on both drug concentration and duration of cell exposure. Drugs that block cell cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted; the sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule. Paclitaxel decreases doxorubicin clearance and enhances cardiotoxicity, while docetaxel has no apparent effect on anthracycline pharmacokinetics.

The basis of clinical drug resistance is not known. Resistance to taxanes in some tumor cells is due to increased expression of the P-glycoprotein; other resistant cells have β -tubulin mutations and may display heightened sensitivity to vinca alkaloids. Cell death occurs by apoptosis.

Paclitaxel is administered as a 3-hour infusion of 135–175 mg/m² every 3 weeks, or as a weekly 1-hour infusion of 80–100 mg/m². Longer infusions (96 hours) have yielded significant response rates in breast cancer patients, but this form of treatment has serious practical limitations. The drug undergoes extensive CYP-mediated hepatic metabolism (primarily CYP2C8), and <10% of

a dose is excreted in the urine intact. The primary metabolite is 6-OH paclitaxel, which is inactive, but multiple additional hydroxylation products are found in plasma.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate, possibly related to its dissolution in the vehicle of 50% ethanol and 50% polyethoxylated castor oil, and the nonlinearity of concentrations of the diluent. In studies of 96-hour infusion of 35 mg/m²/day, the presence of hepatic metastases >2 cm in diameter decreased clearance and led to high drug concentrations in plasma and greater myelosuppression. Paclitaxel disappears from the plasma compartment with a $t_{1/2}$ of 10–14 hours and a clearance of 15–18 L/hour/m². The critical plasma concentration for inhibiting bone marrow elements depends on duration of exposure, but likely is in the range of 50–100 nM.

Docetaxel pharmacokinetics are similar to those of paclitaxel. Its elimination $t_{1/2}$ is ~12 hours, and its clearance is 22 L/hour/m². Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites. Unlike paclitaxel, the pharmacokinetics of docetaxel are linear up to doses of 115 mg/m².

Dose reductions in patients with abnormal hepatic function have been suggested and 50–75% doses of taxanes should be used in the presence of hepatic metastases >2 cm or in patients with abnormal serum bilirubin. Drugs that induce (e.g., phenytoin and phenobarbital) or inhibit (e.g., antifungal imidazoles) CYP2C8 or CYP3A4 significantly alter drug clearance and toxicity. Paclitaxel clearance is markedly delayed by cyclosporine and other drugs that inhibit the P-glycoprotein. This inhibition may be due to a block of CYP-mediated metabolism or effects on biliary excretion of parent drug or metabolites.

Docetaxel and paclitaxel have become central components of regimens for treating metastatic ovarian, breast, lung, and head and neck cancers. Docetaxel has significant activity with estramustine for treatment of hormone-refractory prostate cancer. Either drug is administered once weekly or once every 3 weeks, with comparable response rates and somewhat different patterns of toxicity. Docetaxel produces greater leukopenia and peripheral edema, while paclitaxel causes a higher incidence of hypersensitivity, myalgias, and neuropathy (particularly when used in combination with a platinum analog). The optimal schedule of taxane administration, alone or in combination with other drugs, is still under evaluation.

Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8–11 days after a dose and reverses rapidly by days 15–21. Used with filgrastim (granulocyte-colony stimulating factor; G-CSF), doses as high as 250 mg/m² over 24 hours are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving paclitaxel. In high-dose schedules, or with prolonged use, a distal sensory neuropathy can be disabling, particularly in patients with underlying diabetic or alcoholic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-hour infusions and in the weekly schedule.

Hypersensitivity reactions have occurred in patients receiving paclitaxel infusions of short duration (1–6 hours), but largely are averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₂ receptor antagonists. Premedication is not necessary with 96-hour infusions. Many patients experience asymptomatic bradycardia, and occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-hour infusions.

Docetaxel tends to cause more severe, but short-lived, neutropenia than does paclitaxel. It causes less severe peripheral neuropathy and asthenia, and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, 8 mg/day, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause a progressive interstitial pneumonitis, with respiratory failure supervening if the drug is not discontinued.

CAMPTOTHECIN ANALOGS

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I; the lead compound, *camptothecin*, was isolated from the Chinese tree *Camptotheca acuminata*. The camptothecin analogs, irinotecan and *topotecan*, have activity in colorectal, ovarian, and small cell lung cancer. All camptothecins have a fused five-ring backbone beginning with a weakly basic quinoline moiety and terminating with a lactone ring. Although necessary for the biological activity of the camptothecins, the lactone ring is unstable, undergoing reversible, nonenzymatic, pH-dependent hydrolysis. Consequently, the camptothecins exist as an equilibrium mixture of the intact lactone and opened-ring carboxylate forms in biological fluids. Substituents on the A and B quinoline rings can modulate the equilibrium position between the closed and opened lactone ring forms through effects on their relative affinities for binding to plasma proteins. For instance, the carboxylate form of camptothecin binds to serum albumin with 200 times greater

affinity than the intact lactone, and is the predominant form in plasma and whole blood. In contrast, the lactone form of SN-38 (the biologically active metabolite of irinotecan) binds preferentially to serum albumin, shifting the equilibrium in the opposite direction.

The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled to permit replication, recombination, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing, and both have become the target of cancer chemotherapies. Camptothecin analogs inhibit the function of topoisomerase I, while a number of different chemical entities (e.g., anthracyclines, epipodophyllotoxins, acridines) inhibit topoisomerase II. Topoisomerase I binds covalently to double-stranded DNA through a reversible trans-esterification reaction. This reaction yields an intermediate complex and a single-strand DNA break. This "cleavable complex" allows for relaxation of the DNA torsional strain, either by passage of the intact single-strand through the nick, or by free rotation of the DNA about the noncleaved strand. Once the DNA torsional strain has been relieved, the topoisomerase I reseals the cleavage and dissociates from the newly relaxed double helix.

The camptothecins bind to and stabilize the normally transient DNA-topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the religation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death. Camptothecins are therefore S-phase-specific drugs. This has important clinical implications, because S-phase-specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold to optimize therapeutic efficacy. In fact, studies of low-dose, protracted administration of camptothecin analogs has shown less toxicity, and equal or greater antitumor activity than shorter, more intense courses. Since entry into S phase is required to kill tumor cells exposed to camptothecins, drugs that abolish the G₁-S checkpoint enhance camptothecin lethality.

Decreased intracellular drug accumulation has been observed in several cell lines resistant to camptothecin analogs. Topotecan, but not SN-38 or the intact lactone form of irinotecan, is a substrate for P-glycoprotein; however, compared with other substrates, such as etoposide or doxorubicin, it is a relatively poor substrate. Other reports have associated topotecan or irinotecan resistance with the MRP class of transporters. Drug metabolism could have a role in resistance to irinotecan, but the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to the active SN-38. Transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins. Moreover, the degree of topoisomerase I downregulation in peripheral blood mononuclear cells is correlated with plasma AUC or neutrophil nadir in ovarian cancer patients treated with a 21-day continuous intravenous infusion of topotecan. Mutations and post-translational modifications leading to reduced topoisomerase I enzyme catalytic activity or DNA binding affinity have been described in association with camptothecin resistance. Finally, exposure of cells to topoisomerase I-targeted agents leads to increased expression of topoisomerase II, providing a rationale for sequential therapy with topoisomerase I and II inhibitors.

Topotecan

Topotecan is only approved for intravenous administration. An oral dosage form for the drug in development has a bioavailability of 30–40% in cancer patients. Topotecan exhibits linear pharmacokinetics and is rapidly eliminated from systemic circulation (biological $t_{1/2}$, 3.5–4.1 hours) compared with other camptothecins. Only 20–35% of the total drug in plasma is found to be in the active lactone form. Elimination of the lactone appears to result mainly from rapid hydrolysis to the carboxylate followed by renal excretion, with 30–40% of the administered dose excreted in the urine within 24 hours. Doses should be reduced in proportion to reductions in creatinine clearance. Although several oxidative metabolites have been identified, hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is relatively low (7–35%), which may explain its relatively greater CNS penetration.

Topotecan (HYCAMTIN) is indicated for previously treated patients with ovarian and small cell lung cancer. Its significant hematological toxicity has limited its use in combination with other active agents in these diseases (e.g., cisplatin). Promising antitumor activity also has been observed in hematological malignancies, particularly in CML and in myelodysplastic syndromes.

The recommended dosing regimen of topotecan is a 30-minute infusion of 1.5 mg/m²/day for 5 consecutive days every 3 weeks. Since a significant fraction of the topotecan administered is excreted in the urine, severe toxicities have been observed in patients with decreased creatinine

clearance. Therefore, the dose of topotecan should be reduced to 0.75 mg/m²/day in patients with moderate renal dysfunction (creatinine clearance 20–40 mL/min), and topotecan should not be administered to patients with creatinine clearance <20 mL/min. Topotecan clearance and toxicity are not significantly altered in patients with hepatic dysfunction, and therefore no dose reduction is necessary in these patients.

The dose-limiting toxicity of topotecan with all schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at the recommended phase II dose of 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

Irinotecan

The conversion of irinotecan to SN-38 is mediated predominantly by carboxylesterases in the liver. Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only ~4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. The biological $t_{1/2}$ of SN-38 is 11.5 hours, which is much longer than topotecan. Oral administration does not appear to be feasible because the bioavailability of irinotecan is only 8%. Plasma protein binding is at least 43% for irinotecan and 92–96% for SN-38.

In contrast to topotecan, hepatic metabolism represents an important route of elimination for both irinotecan and SN-38. Several oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bispiperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in brain cancer patients who were concurrently taking antiepileptic drugs that induce hepatic CYPs, further attesting to the importance of oxidative hepatic metabolism as a route of elimination for this drug.

Conjugation of SN-38 with glucuronic acid through the hydroxyl group at position C10 liberated by cleavage of the bispiperidine promoity, is the only known metabolite of SN-38. Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and their metabolites, although urinary excretion also contributes significantly (14–37%). Uridine diphosphate-glucuronosyltransferase (UGT), particularly the UGT1A1 isoform, converts SN-38 to its inactive glucuronidated derivative. The extent of SN-38 glucuronidation is inversely correlated with the risk of severe diarrhea after irinotecan therapy. Polymorphisms of UGT1A1 (which glucuronidates bilirubin) are associated with familial hyperbilirubinemia syndromes such as Crigler-Najjar syndrome and Gilbert syndrome (which occurs in up to 15% of the general population and results in a mild hyperbilirubinemia that may be clinically silent), and may have a major impact on the clinical use of irinotecan. Baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38 are positively correlated in patients treated with irinotecan. Severe irinotecan toxicity has been observed in cancer patients with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38.

Approved dosage schedules of irinotecan (CAMPTOSAR) in the U.S. include: 125 mg/m² as a 90-minute infusion administered weekly for 4 out of 6 weeks, 350 mg/m² given every 3 weeks, 100 mg/m² every week, or 150 mg/m² every other week. Irinotecan has significant clinical activity in patients with advanced colorectal cancer. It is the treatment of choice in combination with fluoropyrimidines for advanced colorectal cancer in patients who have not received chemotherapy previously or as a single agent following failure on a 5-FU regimen. Irinotecan may have an increasing role in the treatment of other solid tumors, including small cell and non–small cell lung cancer, cervical cancer, ovarian cancer, gastric cancer, and brain tumors.

The dose-limiting toxicity of irinotecan is delayed diarrhea, with or without neutropenia. In initial studies, up to 35% of patients experienced severe diarrhea. Adoption of an intensive loperamide (see Chapter 38) regimen (4 mg of loperamide starting at the onset of any loose stool beginning more than a few hours after receiving therapy, followed by 2 mg every 2 hours) has effectively reduced this incidence by more than half. However, once severe diarrhea does occur, standard doses of anti-diarrheal agents tend to be ineffective, although the diarrhea episode generally resolves within a week and, unless associated with fever and neutropenia, is rarely fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14–47% of the patients treated with the every-3-week schedule, and is less frequent in patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients,

and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 hours after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Atropine may be prophylactically administered to patients who have experienced a cholinergic reaction, prior to the administration of additional cycles of irinotecan. Other common and generally manageable toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. Finally, there have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy.

ANTIBIOTICS

Dactinomycin (Actinomycin D)

Actinomycin D, first isolated from a species of *Streptomyces*, has beneficial effects in the treatment of solid tumors in children and choriocarcinoma. The actinomycins bind double-helical DNA; the planar phenoxazone ring intercalates between adjacent guanine–cytosine base pairs of DNA and the polypeptide chains extend along the minor groove of the helix, resulting in a dactinomycin-DNA complex with great stability. Binding of dactinomycin blocks transcription of DNA by RNA polymerase. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II. Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin, and is among the most potent antitumor agents known.

Dactinomycin is administered by intravenous injection. The drug is excreted both in bile and in the urine and disappears from plasma with a terminal $t_{1/2}$ of 36 hours. Metabolism of the drug is minimal. Dactinomycin does not cross the blood–brain barrier. The usual daily dose of dactinomycin (actinomycin D; COSMEGEN) is 10–15 $\mu\text{g}/\text{kg}$; this is given intravenously for 5 days. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2–4 weeks. In other regimens, 3 to 6 $\mu\text{g}/\text{kg}/\text{day}$, for a total of 125 $\mu\text{g}/\text{kg}$, and weekly maintenance doses of 7.5 $\mu\text{g}/\text{kg}$ have been used.

The most important clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms' tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs (e.g., vincristine and cyclophosphamide). Antineoplastic activity has been noted in Ewing's tumor, Kaposi's sarcoma, and soft tissue sarcomas. Dactinomycin can be effective in women with advanced cases of choriocarcinoma in combination with methotrexate. Dactinomycin also has been used as an immunosuppressant in renal transplants.

Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to x-ray radiation. Severe injury may occur as a result of local toxic extravasation.

Daunorubicin, Doxorubicin, Epirubicin, Idarubicin, and Mitoxantrone

These anthracycline antibiotics are among the most important antitumor agents. They are derived from the fungus *Streptococcus peucetius* var. *caesius*. *Idarubicin* and *epirubicin* are analogs of the naturally produced anthracyclines, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. *Daunorubicin* and *idarubicin* have been used primarily in the acute leukemias, whereas *doxorubicin* and *epirubicin* display broader activity against human solid tumors. These agents, which all possess potential for generating free radicals, cause an unusual and often irreversible cardiomyopathy that is related to the total dose of the drug. The structurally similar agent mitoxantrone (an anthracenedione) has useful activity against prostate cancer and AML, is used in high-dose chemotherapy, and has significantly less cardiotoxicity than do the anthracyclines.

The anthracycline antibiotics have a tetracyclic ring structure attached to an unusual sugar, daunosamine. Cytotoxic agents of this class all have quinone and hydroquinone moieties on adjacent rings that permit the gain and loss of electrons. A number of important biochemical effects have been described for the anthracyclines and anthracenediones, all of which could contribute to their therapeutic and toxic effects. These compounds can intercalate with DNA, directly affecting transcription and replication. A more important action is the ability of these drugs to form a

tripartite complex with topoisomerase II and DNA. Formation of the tripartite complex with anthracyclines and with etoposide inhibits the religation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while overexpression of transcription-linked DNA repair may contribute to resistance. Anthracyclines can form semiquinone radical intermediates, which in turn can react with oxygen to produce superoxide anion radicals. These can generate both hydrogen peroxide and hydroxyl radicals ($\cdot\text{OH}$), which attack DNA and oxidize DNA bases. The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron. Enzymatic defenses such as superoxide dismutase and catalase are believed to have an important role in protecting cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as α tocopherol or by an iron chelator, dexrazoxane (ZINECARD), which protects against cardiac toxicity. Exposure of cells to anthracyclines leads to apoptosis.

Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Attempts to reverse or prevent the emergence of resistance through the simultaneous use of inhibitors of P-glycoprotein, such as Ca^{2+} channel blockers, steroidal compounds, and others, have yielded inconclusive results, primarily because of the effects of these inhibitors on anthracycline pharmacokinetics and metabolism. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by the breast cancer resistance protein. Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

Daunorubicin, doxorubicin, epirubicin, and idarubicin usually are administered intravenously. Careful infusion over 10–15 minutes is recommended to prevent extravasation, since severe local vesicant action may result. The drugs are cleared by a complex pattern of hepatic metabolism and biliary excretion. The plasma disappearance curve for doxorubicin is multiphasic, with elimination half-lives of 3 hours and ~30 hours. All anthracyclines are converted to an active alcohol intermediate that plays a variable role in their therapeutic activity. Idarubicin has a $t_{1/2}$ of ~15 hours, and its active metabolite, idarubicinol, has a $t_{1/2}$ of ~40 hours. There is rapid uptake of the drugs in the heart, kidneys, lungs, liver, and spleen. They do not cross the blood–brain barrier. Daunorubicin and doxorubicin are eliminated by metabolic conversion to a variety of aglycones and other inactive products. Idarubicin is primarily metabolized to idarubicinol, which accumulates in plasma and likely contributes significantly to its activity. Clearance is delayed in the presence of hepatic dysfunction, and at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

IDARUBICIN AND DAUNORUBICIN

The recommended dosage for idarubicin (IDAMYCIN) is 12 mg/m² daily for 3 days by intravenous injection in combination with cytarabine. Daunorubicin (daunomycin, rubidomycin; CERUBIDINE, others) is available for intravenous use. The recommended dosage is 30–60 mg/m² daily for 3 days. Total doses of >1000 mg/m² are associated with a high risk of cardiotoxicity. A liposomal formulation of daunorubicin citrate (DAUNOXOME) is indicated for the treatment of acquired immunodeficiency syndrome (AIDS)-related Kaposi's sarcoma. It is given in a dose of 40 mg/m² infused over 60 minutes and repeated every 2 weeks. Patients should be advised that the drug may impart a red color to the urine. Daunorubicin is primarily used in the treatment of AML in combination with Ara-C and has largely been replaced by idarubicin.

The toxic manifestations of daunorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, and dermatological manifestations. Cardiac toxicity is a peculiar adverse effect observed with these agents. It is characterized by tachycardia, arrhythmias, dyspnea, hypotension, pericardial effusion, and congestive heart failure that responds poorly to digitalis (see below).

DOXORUBICIN

Doxorubicin (ADRIAMYCIN, others) is available for intravenous use. The recommended dose is 50–75 mg/m², administered as a single rapid intravenous infusion that is repeated after 21 days. A doxorubicin liposomal product (DOXIL) is available for treatment of AIDS-related Kaposi's sarcoma and is given intravenously in a dose of 20 mg/m² over 30 minutes and repeated every 3 weeks. As for daunorubicin, patients should be advised that the drug may impart a red color to the urine. Doxorubicin is effective in malignant lymphomas but also is active in a number of solid tumors, particularly breast cancer. Used in combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the treatment of lymphomas. It is a valuable component of chemotherapy regimens for adjuvant and metastatic carcinoma of the breast and small cell carcinoma of the lung. The drug also is beneficial in a wide range of pediatric and adult sarcomas, including osteogenic, Ewing's, and soft tissue sarcomas.

The toxic manifestations of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with leukopenia usually reaching a nadir during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, GI disturbances, and alopecia are common but reversible. Erythematous streaking near the site of infusion (“ADRIAMYCIN flare”) is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa). Such reactions may occur even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity. Two types of cardiomyopathies may occur:

1. An acute form is characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias. This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 hours after a single dose, and elevation of troponin T is found in a minority of patients in the first few days following drug administration. An exaggerated manifestation of acute myocardial damage, the “pericarditis–myocarditis syndrome,” may be characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.
2. Chronic, cumulative dose-related toxicity (usually at or above total doses of 550 mg/m²) is manifested by congestive heart failure. The mortality rate in patients with congestive failure approaches 50%. Total dosage of doxorubicin as low as 250 mg/m² can cause myocardial changes, including a decrease in the number of myocardial fibrils, mitochondrial changes, and cellular degeneration. Sequential echocardiograms have detected structural abnormalities in 25% of children who received up to 300 mg/m² of doxorubicin, although <10% have clinical manifestations of cardiac disease in long-term follow-up. The frequency of clinically apparent cardiomyopathy is 1–10% at total doses below 450 mg/m², increasing to >20% at total doses higher than 550 mg/m²; this total dosage therefore should be exceeded only under exceptional circumstances or with concomitant use of dexrazoxane, a cardioprotective iron-chelating agent. Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant herceptin increases the risk of cardiotoxicity. Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a three- to tenfold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. A total dose limit of 300 mg/m² is advised for pediatric cases; concomitant administration of dexrazoxane may reduce troponin T elevations that predict later cardiotoxicity.

NEWER ANALOGS OF DOXORUBICIN Valrubicin (VALSTAR) is approved for intravesical therapy of bacille Calmette-Guérin–refractory urinary bladder carcinoma *in situ* in patients for whom immediate cystectomy would be associated with unacceptable morbidity or mortality. Epirubicin (4'-epidoxorubicin, ELLENCE) is approved as a component of adjuvant therapy following resection of early lymph node–positive breast cancer. A related anthracenedione, mitoxantrone, has been approved for use in AML. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. Acute myelosuppression, cardiac toxicity, and mucositis are its major toxicities; the drug causes less nausea and vomiting and alopecia than doxorubicin. It also is used as a component of experimental high-dose chemotherapy regimens, with uncertain efficacy. Mitoxantrone (NOVANTRONE) is supplied for intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m² for 3 days as a component of a regimen that also includes cytosine arabinoside. Mitoxantrone also is used in advanced, hormone-resistant prostate cancer in a dose of 12–14 mg/m² every 21 days. Mitoxantrone is also approved for the treatment of late-stage, secondary progressive multiple sclerosis.

EPIPODOPHYLLOTOXINS

Two of the many semisynthetic derivatives of podophyllotoxins show significant therapeutic activity in several human neoplasms, including pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin's disease, and large cell lymphomas. These derivatives, etoposide (VP-16-213) and teniposide (VM-26), have no effect on microtubular structure or function at usual concentrations even though podophyllotoxin binds to tubulin at a site distinct from that for interaction with the vinca alkaloids. Etoposide and teniposide have similar mechanisms of action and activities against different tumors. Unlike podophyllotoxin, but like the anthracyclines, they form a

ternary complex with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G₂ phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate amplification of the gene that encodes the P-glycoprotein, mutation or decreased expression of topoisomerase II, or mutations of the p53 tumor suppressor gene.

Etoposide

Oral administration of etoposide results in variable absorption that averages ~50%. After intravenous injection, peak plasma concentrations of 30 µg/mL are achieved; there is a biphasic clearance with a terminal $t_{1/2}$ of ~6–8 hours in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in creatinine clearance. In patients with advanced liver disease, low serum albumin and elevated bilirubin (which displaces etoposide from albumin) increase the unbound fraction of drug, increasing the toxicity of any given dose. However, guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1–10% of those in plasma.

The intravenous dose of etoposide (VEPESID, TOPOSAR, ETOPOPHOS) in combination therapy for testicular cancer is 50–100 mg/m² for 5 days, or 100 mg/m² on alternate days for 3 doses. For small cell carcinoma of the lung, the dose in combination therapy is 50–120 mg/m²/day intravenously for 3 days, or 50 mg/day orally for 21 days. Cycles of therapy usually are repeated every 3–4 weeks. When given intravenously, the drug should be administered slowly during a 30–60-minute infusion to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide.

A disturbing complication of etoposide therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11 at 11q23. This locus contains the MLL or mixed-lineage leukemia gene that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and onset of leukemia (1–3 years), as compared to the 4–5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia. Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses above 2000 mg/m², seem to be at higher risk of leukemia.

Etoposide is used primarily for treatment of testicular tumors, in combination with bleomycin and cisplatin, and in combination with cisplatin and ifosfamide for small cell carcinoma of the lung. It also is active against non-Hodgkin's lymphomas, acute nonlymphocytic leukemia, and Kaposi's sarcoma associated with AIDS. Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it is frequently used for high-dose chemotherapy in total doses of 1500–2000 mg/m². The dose-limiting toxicity of etoposide is leukopenia, with a nadir at 10–14 days and recovery by 3 weeks. Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea occur in ~15% of patients treated intravenously and in ~55% of patients who receive the drug orally. Alopecia is common but reversible. Fever, phlebitis, dermatitis, and allergic reactions including anaphylaxis have been observed. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity is increased in patients with decreased serum albumin, an effect related to decreased protein binding of the drug.

Teniposide

Teniposide (VUMON) is administered intravenously. It has a multiphasic pattern of clearance from plasma. After distribution, half-lives of 4 hours and 10–40 hours are observed. Approximately 45% of the drug is excreted in the urine, but in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure. Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood–brain barrier. However, teniposide has produced responses in small cell and non-small cell lung cancer metastases in the brain. Teniposide is available for treatment of refractory ALL in children and appears to be synergistic with cytarabine. It is administered by intravenous infusion in doses that range from 50 mg/m²/day for 5 days to 165 mg/m²/day twice weekly. The spectrum of activity includes acute leukemia in children, particularly monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

Bleomycins

The bleomycins are fermentation products of *Streptococcus verticillus*. The drug currently employed clinically is a mixture of bleomycin A₂ and B₂. The bleomycins differ only in their terminal amino acid, which can be altered by the amino acids added to the fermentation medium. Bleomycins have significant antitumor activity against squamous carcinoma of the cervix, and against lymphomas and testicular tumors. They are minimally myelo- and immunosuppressive but cause unusual cutaneous side effects and pulmonary fibrosis. Because their toxicities do not overlap with those of other drugs, and because of their unique mechanism of action, bleomycins maintain an important role in combination chemotherapy.

The core of the bleomycin molecule is a complex metal-binding structure containing a pyrimidine chromophore linked to propionamide, a β-aminoalanine amide side chain, and the sugars L-gulose and 3-O-carbamoyl-D-mannose. Attached to this core are a tripeptide chain and a terminal bithiazole carboxylic acid; this latter segment binds to DNA. The bleomycins form equimolar complexes with metal ions, including Cu²⁺ and Fe²⁺. Bleomycin's cytotoxic action results from its ability to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA. Bleomycin causes accumulation of cells in the G₂ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, and fragments, as well as translocations. Bleomycin causes scission of DNA by generating reactive oxygen species. In the presence of O₂, Fe²⁺, and a reducing agent, the metal–drug complex becomes activated and functions mechanistically as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to produce activated species of oxygen. Metal-bleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-cytochrome P450 reductase. Bleomycin binds to DNA through its amino-terminal peptide, and the activated complex generates free radicals that cleave the deoxyribose backbone of the DNA chain. Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. This hydrolase activity is low in skin and lung and bleomycin concentrations in these sites are relatively high, perhaps contributing to skin and pulmonary toxicity. Resistance has been attributed to decreased uptake, cleavage by the hydrolase, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

Bleomycin is administered parenterally, either intravenously or intramuscularly, or instilled into the bladder for local treatment of bladder cancer. Bleomycin crosses the blood–brain barrier poorly. The elimination $t_{1/2}$ is ~3 hours. About two-thirds of the drug normally is excreted in the urine. Concentrations in plasma are greatly elevated if usual doses are given to patients with renal impairment, and such patients are at high risk of developing pulmonary toxicity. Doses of bleomycin should be reduced when the creatinine clearance is <60 mL/min.

The recommended dose of bleomycin (BLENOXANE, others) is 10–30 U/m² given weekly by the intravenous or intramuscular route. It also may be administered as a subcutaneous injection or as an intrapleural or intracystic instillation. Total courses exceeding 250 U should be given with great caution because of a marked increase in pulmonary toxicity. However, pulmonary toxicity may occur at lower doses (see below).

Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is used as a component of the standard ABVD regimen for Hodgkin's disease. Bleomycin also is given intrapleurally (60 U) for malignant pleural effusions.

Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. It does, however, cause significant cutaneous toxicity, including hyperpigmentation, hyperkeratosis, erythema, and even ulceration. These changes begin with tenderness and swelling of the distal digits and progress to erythematous, ulcerating lesions over the elbows, knuckles, and other pressure areas. Skin changes often leave a residual hyperpigmentation at these points and may recur when patients are treated with other antineoplastic drugs.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on x-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5–10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and ~1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests do not predict the early onset of this complication. The risk is related to total dose, with a significant increase above total doses of 250 U, in patients over 70 years of age, and in those with underlying pulmonary disease; single doses of 30 U/m² or more also are associated with an increased risk of pulmonary toxicity. High concentrations of inspired oxygen during anesthesia or

respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known therapy for bleomycin pneumonitis except for standard management and pulmonary care.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and an acute and sometimes fatal reaction observed in patients with lymphomas that is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse. This does not appear to be classical anaphylaxis and has occurred in ~1% of patients with lymphomas. Patients should receive a test dose of bleomycin (1 U), followed by a 1-hour period of observation, before the drug is administered on standard dosage schedules. Exacerbations of rheumatoid arthritis also have been reported. Raynaud's phenomenon and coronary artery occlusive events have been reported in patients with testicular tumors treated with bleomycin in combination regimens.

Mitomycin

This antibiotic has limited clinical utility and has been replaced by less toxic and more effective drugs.

ENZYMES

L-ASPARAGINASE *L-Asparaginase* (L-asp) was introduced into cancer chemotherapy in an effort to exploit a distinct qualitative difference between normal and malignant cells. While most normal tissues can synthesize L-asparagine in amounts sufficient for protein synthesis, some lymphoid malignancies derive the required amino acid from plasma. L-Asp, by catalyzing the hydrolysis of circulating asparagine to Asp and ammonia, deprives these malignant cells of the asparagine necessary for protein synthesis, leading to cell death. L-Asp commonly is used in combination with other agents, including methotrexate, doxorubicin, vincristine, and prednisone, for the treatment of ALL and for high-grade lymphomas. The order of drug administration in these combinations may be critical; synergistic cytotoxicity results when methotrexate precedes the enzyme, but the reverse sequence abrogates methotrexate cytotoxicity. The latter outcome is a consequence of the inhibition of protein synthesis by L-asp, an effect that stops the progression of cells through the cell cycle and negates the effect of methotrexate, a drug that exerts its greatest effect during the DNA synthetic phase of the cell cycle. Resistance arises through induction of asparagine synthetase in tumor cells. For unknown reasons, hyperdiploid ALL cells are particularly sensitive to L-asp.

L-Asparaginase (ELSPAR) is given parenterally. Three preparations of L-asp are used clinically that differ in their pharmacokinetics and immunogenicity. After intravenous administration, Escherichia coli–derived L-asp has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma, and a $t_{1/2}$ of 14–24 hours. It is given in doses of 6000–10,000 IU every third day for 3–4 weeks. An Erwinia preparation (see below), used in patients hypersensitive to the enzyme from E. coli, has a shorter $t_{1/2}$ (16 hours) and requires administration of higher doses. Pegaspargase (PEG-L-ASPARAGINASE; ONCASPAR) is a preparation in which the enzyme is conjugated to 5 KDa units of polyethylene glycol and is cleared much less rapidly. Its plasma $t_{1/2}$ is 6 days, and it is administered in doses of 2500 IU/m² intramuscularly every week. Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies).

Intermittent dosage regimens have an increased risk of anaphylaxis. In hypersensitive patients, circulating antibodies lead to immediate inactivation of the enzyme and L-asp levels rapidly become immeasurable after drug administration. Not all patients with neutralizing antibodies experience hypersensitivity, although enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the E. coli preparation and circumvents the rapid antibody-mediated clearance seen with E. coli enzyme in relapsed patients. Only partial depletion of CSF asparagine is achieved by the various asparaginase preparations in clinical use.

L-Asp has minimal effects on bone marrow and GI mucosa. Its most serious toxicities result from its antigenicity and its inhibition of protein synthesis. Hypersensitivity reactions occur in 5–20% of patients and may be fatal. These reactions are heralded by the appearance of circulating neutralizing antibody in some, but not all, hypersensitive patients. In these patients, pegaspargase is a safe alternative, and the Erwinia enzyme may be used with caution. Other toxicities result from inhibition of protein synthesis in normal tissues and include hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, and hypoalbuminemia. The clotting problems may take the form of spontaneous thrombosis, or less frequently, hemorrhagic episodes. Brain magnetic resonance imaging (MRI) studies should be considered in

patients treated with L-asp who present with seizures, headache, or altered mental status. L-Asp-induced thromboses occur with greater frequency in patients with underlying inherited disorders of coagulation, such as factor V Leiden, elevated serum homocysteine, protein C or S deficiency, antithrombin III deficiency, or the G20210A variant of prothrombin. Intracranial hemorrhage in the first week of L-asp treatment is an infrequent but devastating complication. L-Asp also suppresses immune function. Coma has been attributed to ammonia toxicity resulting from L-asparagine hydrolysis. Pancreatitis also has been observed.

IV. MISCELLANEOUS AGENTS

HYDROXYUREA

This drug has unique and diverse biological effects that have led to exploration of its clinical utility as an antileukemic drug, radiation sensitizer, and an inducer of HbF in patients with sickle cell disease. Its use has been encouraged because the drug is orally administered and its toxicity in most patients is modest and limited to myelosuppression. Hydroxyurea (HU) inhibits the enzyme ribonucleoside diphosphate reductase, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides and is a crucial rate-limiting step in the biosynthesis of DNA. HU destroys a tyrosyl free radical that binds iron in the catalytic center of the human ribonucleotide reductase subunit hRRM2. The drug is specific for the S phase of the cell cycle, when concentrations of the target reductase are maximal, and causes cells to arrest at or near the G₁-S interface. Since cells are highly sensitive to irradiation in the G₁-S boundary, combinations of HU and irradiation cause synergistic toxicity. Through depletion of deoxynucleotides, HU also may potentiate the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors, and facilitates the incorporation of drugs such as Ara-C, gemcitabine, or fludarabine into DNA. HU also induces the expression of a number of genes (e.g., TNF- α , IL-6) and accelerates the loss of extrachromosomally amplified genes present in double-minute chromosomes formed in response to methotrexate therapy.

HU reduces vaso-occlusive events in patients with sickle cell disease. It does so via several mechanisms that ultimately increase synthesis of HbF, which promotes solubility of hemoglobin within red cells. It also reduces adhesion of red cells to vascular endothelium, and by suppressing the production and adhesiveness of neutrophils, decreases their contribution to vascular occlusion. HU reduces the frequency of painful events, acute chest syndrome, and secondary strokes in sickle cell patients.

The oral bioavailability of hydroxyurea is excellent (80–100%), and comparable plasma concentrations are seen after oral or intravenous dosing. Peak plasma concentrations are reached 1–1.5 hours after oral doses of 15–80 mg/kg. Hydroxyurea disappears from plasma with a $t_{1/2}$ of 3.5–4.5 hours. The drug readily crosses the blood–brain barrier, and it appears in significant quantities in breast milk. From 40% to 80% of the drug is recovered in the urine within 12 hours after either intravenous or oral administration. It seems prudent to modify doses for patients with abnormal renal function until individual tolerance can be assessed. In cancer treatment, two dosage schedules for hydroxyurea (HYDREA, DROXIA, others), alone or in combination with other drugs, are most commonly used in a variety of clinical situations: (1) intermittent therapy with 80 mg/kg administered orally as a single dose every third day; or (2) continuous therapy with 20–30 mg/kg administered as a single daily dose. In patients with essential thrombocythemia and in sickle cell disease, HU is given in daily dose of 15–30 mg/kg, depending on tolerance and myelosuppression. Dosage should be adjusted according to the number of leukocytes in the peripheral blood. Treatment is typically continued for a period of 6 weeks to determine its effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advised.

The principal use of HU has been as a myelosuppressive agent in myeloproliferative syndromes, particularly in essential thrombocythemia with platelet counts >1.5 million cells/mm³ or history of arterial or venous thrombosis. It dramatically lowers the risk of thrombosis by lowering the platelet count, through its effect on neutrophil and red cell counts, and by reducing L-selectin expression and increasing NO production of neutrophils.

In CML, HU largely has been replaced by imatinib. HU has produced anecdotal, temporary remissions in patients with advanced cancers (e.g., head and neck or genitourinary carcinomas, melanoma). HU has been incorporated into several schedules with concurrent irradiation, as it can synchronize cells into a radiation-sensitive phase of the cell cycle.

HU (DROXIA) is FDA-approved for the treatment of adult patients with sickle cell disease, and appears to be effective in children and in patients with sickle cell- α -thalassemia and sickle cell-hemoglobin C disease.

Hematopoietic depression—involving leukopenia, megaloblastic anemia, and occasionally thrombocytopenia—is the major toxic effect; bone marrow recovery usually is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, and mild dermatological reactions. More rarely, stomatitis, alopecia, and neurological manifestations have occurred. Increased skin and fingernail pigmentation and painful leg ulcers may occur. Hydroxyurea has uncertain effect on the risk of secondary leukemia in patients with myeloproliferative disorders and should be used with caution in nonmalignant diseases. Hydroxyurea is a potent teratogen in animals and should not be used in women who may become pregnant.

DIFFERENTIATING AGENTS

A hallmark of malignant transformation is a block in differentiation. A number of chemical entities, including vitamin D and its analogs, retinoids, benzamides and other inhibitors of histone deacetylase, various cytotoxics and biological agents, and inhibitors of DNA methylation, can induce differentiation in tumor cell lines.

Retinoids

TRETINOIN The biology and pharmacology of retinoids are discussed in detail in Chapter 62. The most important of these for cancer treatment is *tretinoin* (all-trans retinoic acid; ATRA), which induces a high rate of complete remission in acute promyelocytic leukemia (APL) as a single agent, and in combination with anthracyclines, has become part of a curative regimen for this disease. Under physiologic conditions, the RAR- α receptor dimerizes with the retinoid X receptor (RXR) to form a complex that binds ATRA tightly, displacing a repressor of differentiation. In APL cells, there is a t(15;17) translocation that results in a fusion protein (PML-RAR- α) that binds retinoids with much decreased affinity, lacks PML transcription factor function (*i.e.*, inhibition of proliferation and promotion of myeloid differentiation), and blocks the function of transcription factors such as C/EBP, which promote myeloid differentiation. Physiologic concentrations of retinoid are inadequate but pharmacologic concentrations displace the repressor from the fusion protein, activating the differentiation program and promoting degradation of the PML-RAR- α fusion protein. Resistance to ATRA arises by further mutation of the fusion gene that abolishes ATRA binding or by loss of expression of the fusion gene.

The usual dosing regimen of orally administered ATRA is 45 mg/m²/day until remission is achieved. ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. In combination with an anthracycline, ATRA achieves >70% relapse-free, long-term survival. ATRA reaches a plasma concentration of 400 ng/ml and is cleared by CYP-mediated elimination with a $t_{1/2}$ of <1 hour. Treatment with CYP inducers increases drug metabolism and may result in resistance to ATRA. Remission rate and time to remission induction improve with the inclusion of other chemotherapy. When used as a single agent, especially in patients with >5000 leukemic cells per mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature appearing neutrophils of leukemic origin. These cells can clog small vessels in the pulmonary circulation and elsewhere, resulting in the “retinoic acid syndrome” characterized by fever, respiratory distress, pulmonary infiltrates, pleural or pericardial effusions, and mental status changes. Glucocorticoids and chemotherapy decrease the occurrence of the retinoic acid syndrome. Retinoids as a class, including ATRA, cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, and hyperlipidemia.

Arsenic Trioxide (ATO)

ATO is administered as a 2-hour intravenous infusion in doses of 0.15 mg/kg/day for up to 60 days, until remission is documented. Further consolidation therapy resumes after a 3-week break. The primary mechanism of elimination is by enzymatic methylation to metabolites that have uncertain biological effects. Peak concentrations of ATO in plasma reach 5–7 μ M with rapid conversion to metabolites. Little drug appears in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and lightheadedness. Ten percent or fewer of patients will experience a leukocyte maturation syndrome similar to that seen with ATRA. O₂, glucocorticoids, and temporary discontinuation of ATO lead to full reversal of this syndrome. Another important and potentially dangerous side effect is lengthening of the QT interval on the electrocardiogram in 40% of patients. The basis for this conduction defect appears to be enhanced Ca²⁺ flux and an inhibition of K⁺ channels in myocardial tissue by

As_2O_3 , which leads to atrial or ventricular arrhythmias in a small minority of patients. Daily monitoring of the ECG and repletion of serum K^+ in patients with hypokalemia are standard measures in ATO therapy.

PROTEIN TYROSINE KINASE INHIBITORS

Abnormal activation of specific protein tyrosine kinases has been demonstrated in many human neoplasms, making them attractive molecular targets for cancer therapy. There currently are 3 small-molecular-weight protein tyrosine kinase inhibitors that are FDA-approved and many others in clinical trials.

Imatinib

IMATINIB MESYLATE

Imatinib mesylate (GLEEVEC, GLIVEC; 4-[(4-methyl-1-piperazinyl) methyl]-N-[4-methyl-3-[[[4-(3-pyridinyl)-2-pyrimidinyl] amino]-phenyl]benzamidemethanesulfonate) was developed through combined use of high throughput screening and medicinal chemistry. Imatinib inhibits protein tyrosine kinase activities of ABL and its activated derivatives v-ABL, BCR-ABL, and EVT6-ABL, the platelet-derived growth factor receptor (PDGFR), and KIT receptor tyrosine kinases. Imatinib binds in the ATP-binding site of the kinase domain and exhibits a high level of selectivity towards these three kinases. Complete inhibition of proliferation with cell death through apoptosis occurs in cells dependent on activated ABL, KIT, or PDGFR for proliferation. This includes cells expressing BCR-ABL in CML, mutant KIT isoforms associated with gastrointestinal stromal tumors (GISTs), the ETV6-PDGFR fusion associated with a subset of chronic myelomonocytic leukemia (CMML), and the FIP1L1-PDGFR fusion associated with hypereosinophilic syndrome (HES).

Resistance to imatinib can be manifested by a failure to achieve a specific desired response (i.e., primary) or by the loss of a desired response (i.e., secondary). Secondary resistance predominantly results from mutations in the kinase domain that render it less sensitive to imatinib, although some patients have amplification of the kinase target.

Imatinib is nearly completely absorbed after oral administration with peak plasma concentrations achieved within 2–4 hours. Following oral administration in healthy volunteers, the elimination $t_{1/2}$ of imatinib and its major active metabolite, the N-desmethyl derivative, are ~18 and 40 hours, respectively. There is no significant change in the pharmacokinetics of imatinib on repeated dosing or with administration of food. Doses >300 mg/day achieve trough levels of 1 μ M, which corresponds to in vitro levels required to kill BCR-ABL-expressing cells. Improved responses may be observed with doses of 600 or 800 mg/day compared to 400 mg/day, consistent with dose-dependent inhibition of the kinase.

CYP3A4 is the major enzyme responsible for metabolism of imatinib. Other CYPs play a minor role in imatinib's metabolism. Imatinib increased the peak plasma concentration and AUC of simvastatin by 2 and 3.5 times, respectively, and coadministration with rifampin, an inducer of CYP3A4, reduces plasma imatinib AUC by ~70%. Elimination of imatinib occurs predominantly in the feces, mostly as metabolites.

Imatinib has efficacy in diseases in which the ABL, KIT, or PDGFR have dominant roles in driving the proliferation of the tumor because of mutations that result in constitutive activation of the kinase, either by fusion with another protein or point mutations. Thus, imatinib shows remarkable therapeutic benefits in patients with CML (BCR-ABL), GIST (KIT mutation positive), CMML (EVT6-PDGFR), HES (FIP1L1-PDGFR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR). The situation in GIST is particularly instructive, as patients with an exon 11 mutation of KIT have a significantly higher partial response rate (72%) than those with no detectable KIT mutations (9%). Thus, KIT mutational status predicts response. The currently recommended dose of imatinib is 400–600 mg/day.

The most frequently reported drug-related adverse events are nausea, vomiting, edema, and muscle cramps. Most events are mild to moderate, and only 2–5% of patients permanently discontinue therapy, most commonly because of rashes and elevations of transaminases (each in <1% of patients). Edema can manifest at any site, most commonly in the ankles and periorbital tissues. Severe fluid retention (pleural effusion, pericardial effusion, pulmonary edema, and ascites) is reported in 1–2% of patients taking imatinib. The probability of edema increases with higher imatinib doses and in persons >65 years old. Neutropenia and thrombocytopenia are consistent findings in all studies in leukemia patients, with a higher frequency at doses \geq 750 mg. The occurrence of cytopenias also is dependent on the stage of CML, with a frequency of severe neutropenia and thrombocytopenia between two- and threefold higher in blast crisis and accelerated phase compared to chronic phase. In solid tumor patients, severe neutropenia has been reported in <5% of patients. Thrombocytopenia is much less common.

Gefitinib

The EGFR belongs to the ERB family of receptor tyrosine kinases. The EGFR type 1 (ErbB1 or HER1) is overexpressed in many common malignancies, and may be activated by autocrine loops in many others. A truncated version of the EGFR (EGFRvIII) that has lost a portion of the extracellular ligand-binding domain and is constitutively activated is found in a subset of patients with glioblastoma.

Gefitinib (IRESSA; 4-(3-chloro-4-fluoroanilino)-7-methoxy-6-(3-morpholinopropoxy) quinazoline) was discovered by screening a library for compounds that inhibited EGFR tyrosine kinase activity. Gefitinib is a specific inhibitor of the EGFR tyrosine kinase that competitively inhibits ATP binding. Gefitinib is 100 times less potent against highly related tyrosine kinases such as HER2 (ErbB2/neu) and does not inhibit a variety of serine/threonine kinases. The predominant problem with the clinical use of gefitinib has been relatively low response rates. Levels of EGFR expression do not correlate with clinical responses; however, patients whose non-small cell lung tumors have point mutations in the EGFR respond dramatically to gefitinib, similar to imatinib response in GIST with KIT mutations (see above). Thus, primary resistance could result from tumors that are not uniquely dependent on EGFR activity for survival. Although target inhibition by gefitinib has been demonstrated in normal skin, it is possible that poor tumor penetration of the drug could lead to incomplete EGFR inhibition. Alternatively, drug efflux, unappreciated mutations that affect drug sensitivity, or a variety of other factors may mediate lack of responsiveness.

Following oral administration of gefitinib, peak plasma concentrations are achieved within 3–7 hours. Mean absolute bioavailability of the oral formulation is 59%. Exposure to gefitinib is not significantly altered by food; however, coadministration of drugs that cause sustained elevations in gastric pH to ≥ 5 reduce mean gefitinib AUC by 47%. Administration of gefitinib once daily results in two- to eightfold accumulation with steady-state achieved after 7–10 doses. At steady state, circulating plasma concentrations typically are maintained within a two- to threefold range over the 24-hour dosing interval. The mean terminal $t_{1/2}$ is 41 hours.

Metabolism of gefitinib is predominantly via CYP3A4. The major metabolite in plasma is O-desmethyl gefitinib; it is 14 times less potent than gefitinib. Inducers of CYP3A4 activity may increase metabolism and decrease gefitinib plasma concentrations. Coadministration with rifampin (a CYP3A4 inducer) reduced mean gefitinib AUC by 83%. Coadministration with itraconazole (a CYP3A4 inhibitor) resulted in an 80% increase in the mean AUC of gefitinib. Elimination of gefitinib is primarily by metabolism and excretion in feces.

Gefitinib is approved for the treatment of patients with non-small cell lung cancer who have failed standard chemotherapy. Single-agent responses in these heavily pretreated patients are in the 12–18% range. However, there is a subset of patients who respond dramatically to gefitinib and these are predominantly nonsmoking women with bronchoalveolar tumors. This subset of patients has EGFR mutations that render the EGFR hypersensitive to ligand and to gefitinib. Many of the same EGFR mutations are found in tumors from patients that respond to another small molecule EGFR inhibitor, erlotinib (TARCEVA). The recommended dose of gefitinib is one 250-mg tablet daily, taken with or without food.

The most common adverse drug reactions are diarrhea, rash, acne, pruritus, dry skin, nausea, vomiting, and anorexia. A higher rate of most of these adverse events is observed in patients treated with 500 mg/day of gefitinib as compared to treatment with 250 mg/day. Most adverse events are of mild-to-moderate grade. Less than 2% of patients have permanently discontinued therapy. Adverse drug reactions usually occur within the first month of therapy and generally are reversible. Asymptomatic increases in liver transaminases have been observed and periodic liver function testing should be performed. Interstitial lung disease, which may be acute in onset, has been observed uncommonly in patients receiving gefitinib, and some cases have been fatal. The overall frequency of interstitial lung disease is ~0.3% outside of Japan and ~2% in Japan.

Erlotinib

Erlotinib (TARCEVA; [N-(3-ethynylphenyl)-6,7-bis(2-methoxyethoxy)-4-quinazolinamine]) is a human HER1/EGFR tyrosine kinase inhibitor. It is indicated for treatment of patients with locally advanced or metastatic non-small cell lung cancer. Erlotinib is ~60% absorbed after oral administration and its bioavailability is increased to almost 100% by food. Peak plasma levels occur 4 hours after an oral dose. Following absorption, erlotinib is ~93% protein-bound to albumin and α_1 -acid glycoprotein. Its $t_{1/2}$ is ~36 hours. Erlotinib is metabolized primarily by CYP3A4 and to a lesser extent by CYP1A2 and CYP1A1. The most common adverse reactions in patients receiving erlotinib were diarrhea and rash. Serious interstitial lung disease also has been reported. Other adverse effects include elevated liver enzymes and bleeding, especially in patients receiving warfarin. Coadministration of CYP3A4 inhibitors is expected to increase toxicity to erlotinib.

THALIDOMIDE AND LENALIDOMIDE

Thalidomide has been reintroduced to clinical practice as an oral agent for the management of erythema nodosum leprosum (ENL) and in other disease settings, most notably MM. *Lenalidomide* is a thalidomide derivative with improved potency and safety profile compared to thalidomide. Thalidomide is a nonpolar racemic mixture of cell permeable and rapidly interconverting S(–) and R(+) isomers. The precise mechanisms responsible for thalidomide's clinical activity remain to be elucidated. Multiple distinct, but potentially complementary, mechanisms have been proposed to explain the antitumor activity of thalidomide and its derivatives, including stimulation of T cells and NK cells, inhibition of angiogenesis and tumor cell proliferation, and modulation of hematopoietic stem cell differentiation (Figure 51–6).

Thalidomide absorption from the GI tract is slow and highly variable (4 hours to reach peak concentration, with a range of 1–7 hours). It is widely distributed throughout most tissues and organs, with a large apparent volume of distribution. Thalidomide metabolism via hepatic CYPs is limited, and no induction of its own metabolism is noted with prolonged use. Elimination of thalidomide is mainly by spontaneous nonenzymatic hydrolysis, which occurs in all body fluids, with an apparent mean clearance of 10 L/h for the (R)-enantiomer and 21 L/h for the (S)-enantiomer in adults. Thalidomide and over 50 metabolites are rapidly excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces. Both single and multiple dosing of thalidomide in elderly prostate cancer patients shows significantly longer $t_{1/2}$ at higher doses (1200 mg daily) versus lower doses (200 mg daily). Conversely, no effect of increased age on elimination $t_{1/2}$ was identified in the age range of 55–80 years. The impact of renal or hepatic dysfunction on thalidomide clearance remains to be defined.

Lenalidomide is rapidly absorbed following oral administration, with peak plasma levels occurring 0.6–1.5 hours postdose. The AUC values increase proportionately with increasing dose, both over a single-dose range of 5–400 mg and after multiple dosing with 100 mg daily. The $t_{1/2}$ increases with dose, from ~3 hours at the 5-mg dose, to ~9 hours at the 400-mg dose (the higher dose is believed to provide a better estimate of the $t_{1/2}$ due to the prolonged elimination phase). Approximately 70% of the orally administered dose of lenalidomide is excreted by the kidney.

Thalidomide (THALOMID) is used to treat patients with relapsed and refractory MM, as well as early stage disease. The National Comprehensive Cancer Network (NCCN; www.nccn.org) Clinical Practice Guidelines for Multiple Myeloma includes thalidomide as an option for salvage therapy in patients with relapsed or refractory MM, or as initial therapy in combination with dexamethasone for patients with advanced myeloma. Thalidomide is also in clinical trials for use in treating a variety of solid tumors and myelodysplasias.

Lenalidomide (REVLIMID) is approved for treatment of transfusion-dependent anemia due to low- or intermediate-risk myelodysplastic syndromes associated with the 5q cytogenetic deletion, with or without additional cytogenetic abnormalities. It is being examined for use in combination with dexamethasone in newly diagnosed patients with MM, and in combination with agents such as bortezomib in relapsed and refractory MM. It is also being evaluated for use in treating many of the same neoplasias for which thalidomide might be useful, including myelodysplastic syndromes and certain solid tumors.

Thalidomide generally is well tolerated at doses <200 mg daily, the typical doses used to treat MM and ENL. The most common adverse effects reported in cancer patients are sedation and constipation, while the most serious one is treatment-emergent peripheral neuropathy, which occurs in 10–30% of patients with MM or other malignancies in a dose- and time-dependent manner. Thalidomide-related neuropathy is an asymmetric, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. The incidence of peripheral neuropathy increases with higher cumulative doses of thalidomide, especially in elderly patients. Although clinical improvement typically occurs upon drug discontinuation, long-standing residual sensory loss can occur. Particular caution should be applied in cancer patients with preexisting neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids or bortezomib). An increasing incidence of thromboembolic events in

FIGURE 51-6 Schematic overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in light gray boxes. The proposed sites of action for thalidomide (dark blue letters within circles) are hypothesized to be operative for thalidomide derivatives also. **A.** Direct anti-MM effect on tumor cells including G1 growth arrest and/or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the anti-apoptotic effect of Bcl-2 family members, blocking NF- κ B signaling, and inhibition of the production of IL-6. **B.** Inhibition of MM cell adhesion to bone marrow stromal cells due partially to the reduction in IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and IFN- γ , that increase the number and cytotoxic functionality of natural killer (NK) cells.

thalidomide-treated patients has been reported. This appears to be very rare in patients treated with thalidomide as a single agent and generally occurs when thalidomide is combined with glucocorticoids or particularly anthracycline-based chemotherapy. The 2006 NCCN Practice Guidelines for Multiple Myeloma (www.nccn.org) include the possible prophylactic use of anticoagulants in patients receiving thalidomide therapy.

Ongoing studies are characterizing the adverse-effect profile of lenalidomide and addressing its potential for interactions with other drugs. More clinical experience is required to determine whether lenalidomide is completely devoid of some of thalidomide's side effects. Because of the risk of teratogenic effects, thalidomide and lenalidomide are regulated by the FDA to prevent fetal drug exposure (see System for Thalidomide Education and Prescribing Safety (STEPS) Program [www.thalomid.com/steps_program.aspx] and RevAssist [www.revlimid.com/default.aspx]).

ESTRAMUSTINE

Estramustine (EMCYT), a combination of estradiol coupled to normustine (normitrogen mustard) by a carbamate link, has weaker estrogenic and antineoplastic activity than estradiol and other alkylating agents, respectively. While the combination was intended to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not appear to function as an alkylating agent. Rather, estramustine binds to β -tubulin and microtubule-associated proteins, causing microtubule disassembly and antimetabolic actions. Estramustine is used for the treatment

of metastatic or progressive prostate cancer at a usual initial dose of 10–16 mg/kg daily in 3 or 4 divided doses. Following oral administration, at least 75% of a dose of estramustine is absorbed from the GI tract and rapidly dephosphorylated. Estramustine is found in the body mainly as its oxidized 17-keto analog isomer, estromustine; both forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma $t_{1/2}$ of 10–20 hours, respectively, and are excreted with their metabolites, mainly in the feces. In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, and elevated risk of thrombosis, and fluid retention) and is associated with hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions including angioedema.

Bortezomib

Bortezomib (VELCADE); (1R)-3-methyl-1-[[[(2S)-1-oxo-3-phenyl-2-[pyrazinylcarbonyl]amino]propyl]butyl]boronic acid binds to the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. Inhibition of the proteasome disrupts multiple signaling cascades within the cell, often leading to cell death. The most important consequences of proteasome inhibition are believed to result from downregulation of NF- κ B, a key transcription factor that promotes cell survival. In a similar manner, bortezomib disrupts ubiquitin-proteasome regulation of p21, p27, and p53, which are key regulatory proteins in the cell cycle and initiators of apoptosis. The antineoplastic activity of bortezomib in tumors is likely due to a greater dependence on cell proliferating pathways in cancer relative to normal tissues.

After intravenous administration of 1–1.3 mg/m² of bortezomib in patients without renal or hepatic impairment, there is a rapid distribution phase (<10 minutes), followed by a longer elimination phase of 5–15 hours. Plasma protein binding averaged 83%. The mean terminal elimination in preclinical studies was 5.4 hours, with an average clearance of 66 L/h. Peak pharmacodynamic activity (proteasome inhibition) occurred at 1 hour with a mean of 61% inhibition and a $t_{1/2}$ of ~24 hours. Inhibition of the 20S subunit was 10–30% at 96 hours. Proteasome inhibition is highly concentration dependent.

Bortezomib is primarily metabolized to an inactive metabolite by hepatic CYPs. Debronation accounts for >90% of total metabolism, with CYP3A4 being more active than CYP2D6. Ongoing studies in patients with hepatic or renal impairment should define pathways of elimination that will help guide dose reduction in such patients. Bortezomib is a poor inhibitor of hepatic CYPs.

Bortezomib is available for intravenous injection only. Each vial contains 3.5 mg of bortezomib as a sterile lyophilized powder and 35 mg of mannitol. Prior to use, the contents of each vial are reconstituted with 3.5 mL of normal (0.9%) saline. The reconstituted product should be clear and colorless and should be administered to patients within 8 hours. The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus, and this should be given on days 1, 4, 8, and 11 of every 21-day cycle (10-day rest period per cycle). At least 72 hours should elapse between doses. For severe nonhematologic and hematologic toxicities, the drug should be held until resolution and subsequent doses should be reduced by 25%. In clinical trials, some patients have received 2 mg/m² without severe toxicity.

Bortezomib is FDA-approved for patients with MM who have received 2 prior therapies and are progressing on their current therapy. The drug is being studied in combination with other drugs in MM as well as other hematologic neoplasms and solid tumors. Escalating doses of bortezomib have resulted in dose-limiting GI, hematopoietic, lymphatic, and renal toxicities. At the standard dose and schedule, serious toxicities encountered in >5% of patients included thrombocytopenia, fatigue, peripheral neuropathy, neutropenia, anemia, nausea and vomiting, diarrhea, limb pain, dehydration, and weakness. Peripheral neuropathy was encountered more frequently in patients with a prior history of neuropathy or preexisting numbness, pain, or burning, where dose reductions of bortezomib are recommended. Usually, the neuropathy improves or resolves completely after several months off treatment. Hypotension associated with the injection of bortezomib has been rarely encountered, and caution should be taken with patients who are volume-depleted, have a history of syncope, or who are on antihypertensive medications.

Zoledronic Acid

Zoledronic acid (ZOMETA) is a bisphosphonate (see Chapter 61) indicated for the treatment of patients with bony metastases and for patients with MM. A direct antitumor effect on myeloma cells has been proposed; some data suggest that inhibition of bone matrix-degrading proteinases may inhibit tumor cell invasion in breast and prostate cancers.

Mitotane

The principal application of *mitotane* (*o,p'*-DDD) is in the treatment of neoplasms derived from the adrenal cortex. The drug causes a rapid reduction in the levels of corticosteroids and their metabolites in blood and urine, a response that is useful both in guiding dosage and in following the course of hypercorticism resulting from an adrenal tumor or adrenal hyperplasia.

Mitotane (LYSDREN) is administered in initial daily oral doses of 2–6 g, usually given in 3 or 4 divided portions, but the maximal tolerated dose may vary from 2 to 16 g/day. Treatment should be continued for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly, since it interferes with the adrenal suppression produced by mitotane. Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30–50% of such patients. Although the administration of mitotane produces anorexia and nausea in ~80% of patients, somnolence and lethargy in 34%, and dermatitis in 15–20%, these effects do not contraindicate the use of the drug at lower doses. Since this drug damages the adrenal cortex, administration of corticosteroids is indicated, particularly in patients with evidence of adrenal insufficiency, shock, or severe trauma.

BIOLOGICAL RESPONSE MODIFIERS

In contrast to small molecules, biological response modifiers include biological agents that beneficially affect the patient's biological response to a neoplasm. Included are agents that mediate their antitumor effects indirectly (*e.g.*, by enhancing the immunologic response to neoplastic cells) or directly on the tumor cells (*e.g.*, differentiating agents). Recombinant proteins with potent effects on the function and growth of both normal and neoplastic cells that currently are in clinical trials include the interferons (*see* Chapters 49 and 52), interleukins (*see* Chapter 52), hematopoietic growth factors (*see* Chapter 53) such as *erythropoietin*, filgrastim (granulocyte colony-stimulating factor [G-CSF]), and *sargramostim* (granulocyte-macrophage colony-stimulating factor [GM-CSF]), *tumor necrosis factor* (TNF), and monoclonal antibodies such as *trastuzumab*, *cetuximab*, and *rituximab*. Among the agents now approved for clinical use in specific neoplastic diseases are *interferon- α* for use in hairy cell leukemia, *condylomata acuminata*, CML, and Kaposi's sarcoma associated with AIDS; *interleukin-2* (IL-2) for kidney cancer; *trastuzumab* for breast cancer; and *rituximab* for B-cell lymphomas.

Interleukin-2 (IL-2, ALDESLEUKIN, PROLEUKIN)

IL-2 is not directly cytotoxic to cancer cells; rather, it induces and expands a T-cell response that is cytolytic for tumor cells. Clinical trials have studied the antitumor activity of IL-2 both as a single agent and with adoptive cellular therapy using IL-2-stimulated autologous lymphocytes obtained by leukopheresis, termed *lymphokine-activated killer* (LAK) cells; addition of LAK cells to the treatment regimen has not improved overall response rates.

Because the $t_{1/2}$ of IL-2 in humans is short (13 minutes for α and 85 minutes for β), most clinical schedules have explored either continuous infusion or multiple intermittent dosing. The most significant antitumor activity has been demonstrated with the most intense dosing schedules: continuous intravenous infusion for 5 days every other week for 2 cycles, or intravenous bolus dosing every 8 hours daily for 5 days every other week.

The toxicities of IL-2 likely are related to the activation and expansion of cytotoxic lymphocytes in organs and within vessels, resulting in inflammation and vascular leak, and to the secondary release by activated cells of other cytokines, such as TNF- α and interferon. When given at maximally tolerated doses of 600,000 units/kg every 8 hours for up to 5 days, IL-2 causes hypotension, arrhythmias, peripheral edema, prerenal azotemia, elevated liver transaminases, anemia, thrombocytopenia, nausea, vomiting, diarrhea, confusion, and fever.

Reproducible antitumor activity has been reported in advanced MM and renal cell cancer, where response rates (partial and complete) are seen in 20–30% of patients. Complete responses, seen in ~5–10% of patients, appear to be durable, with some patients free of disease beyond 5 years. IL-2 is being studied in the treatment of AML, where it is capable of inducing remission in relapsed patients. Given following bone marrow transplantation, it appears that IL-2 can lengthen the remission duration compared to historical controls.

Monoclonal Antibodies

Cancer cells express a variety of antigens that are attractive targets for monoclonal antibody-based therapy (Table 51–3). Several monoclonal antibodies are FDA-approved for treating lymphoid and

solid tumor malignancies, including rituximab and *alemtuzumab* for lymphoid malignancies, and trastuzumab for breast cancer. Because murine monoclonal antibodies have a short $t_{1/2}$ and induce a human anti-mouse antibody immune response, they usually are chimerized or humanized when used as therapeutic agents. The nomenclature adopted for therapeutic monoclonal antibodies is to terminate the name in *-ximab* for chimeric antibodies and *-umab* for humanized antibodies. A variety of mechanism(s) of cell killing have been described for naked monoclonal antibodies, including antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC) and direct induction of apoptosis, but the clinically relevant mechanisms remain uncertain. Monoclonal antibodies also may be engineered to combine the antibody with a toxin (immunotoxins), such as *gemtuzumab ozogamicin* (MYLOTARG) or *denileukin difitox* (ONTAK), or combined with a radioactive isotope, as in the case of *90Y-ibritumomab tiuxetan* (ZEVALIN) (Table 51–3). More recently, antibodies have been engineered to contain a second specificity, known as bi-specific antibodies.

Naked Monoclonal Antibodies

RITUXIMAB Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen (Tables 51–3 and 51–4), which is found on cells from the pre-B-cell stage through terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms. Monoclonal antibody binding to CD20 generates transmembrane signals in B-cells, but it is not known how ligation of the CD20 receptor produces cell death independent of ADCC or complement-mediated pathways. Rituximab initially was approved for relapsed indolent lymphomas and has shown activity in a wide variety of clinical settings. Recent studies have demonstrated significant activity of rituximab in mantle cell lymphoma, relapsed aggressive B-cell lymphomas, and CLL. The use of maintenance rituximab has gained increased acceptance, based on demonstration of delayed time to progression, but effects on survival have not been demonstrated. Rituximab and chemotherapy are synergistic, suggesting it sensitizes lymphoma cells to the apoptotic effects of chemotherapy by directly acting on tumor cells; rituximab is being clinically combined with agents such as fludarabine and combinations such as CHOP. The addition of rituximab to CHOP chemotherapy significantly improves the event-free survival of diffuse large B-cell lymphoma.

Rituximab demonstrates dose-dependent pharmacokinetics. At a dose of 375 mg/m², the mean serum $t_{1/2}$ was 76 hours after one dose and 206 hours after the last dose, with considerable interindividual variation. The wide range of $t_{1/2}$ likely reflects differences in patient tumor burden and normal B-cell populations. Rituximab toxicities are mostly related to infusion reactions, although there are increasing reports of late-onset neutropenia and rare reports of severe skin toxicity (Table 51–4).

ALEMTUZUMAB Alemtuzumab (CAMPATH) targets the CD52 antigen present on normal neutrophils and lymphocytes as well as most B- and T-cell lymphomas (Tables 51–3 and 51–4). CD52 is expressed at reasonable levels and does not modulate with antibody binding, making it a good target for unconjugated monoclonal antibodies. Alemtuzumab induces tumor cell death through ADCC and CDC (Table 51–4). Clinical activity has been demonstrated in low-grade lymphomas and CLL, including patients with disease refractory to purine analogs.

Alemtuzumab demonstrates dose-dependent pharmacokinetics. Alemtuzumab has a mean $t_{1/2}$ of 12 days and steady-state levels are reached ~week 6 of treatment, although there is significant variability. The most concerning side effects are acute infusion reactions and the depletion of hematopoietic cells and T cells (Table 51–4). Opportunistic infections are a serious and sometimes fatal side effect, particularly in patients who have received purine analogs. The broad expression of CD52 in T cells has led to the testing of alemtuzumab in T-cell lymphomas. Studies have shown a high response rate in mycosis fungoides, and combination chemotherapy trials are being conducted in aggressive T-cell lymphomas.

TRASTUZUMAB Trastuzumab (HERCEPTIN) targets the HER2/neu (ErbB-2) member of the EGF family of protein tyrosine kinase receptors. Activation of HER2/neu enhances metastatic potential and inhibits apoptosis. HER2/neu is overexpressed in up to 30% of breast cancers and is associated with clinical resistance to cytotoxic and hormone therapy. Trastuzumab can initiate Fc γ -receptor-mediated ADCC and directly induce apoptosis.

Trastuzumab is approved for HER2/neu overexpressing metastatic breast cancer in combination with paclitaxel as initial treatment or as monotherapy following chemotherapy relapse. Trastuzumab also is synergistic with other cytotoxic agents, but only in HER2/neu-overexpressing cancers. HER2/neu expression also is found in other solid tumors and responses have been reported in colorectal and non-small cell lung cancer. Other tumors that express HER2/neu at relatively high frequency include pancreas and stomach.

Table 51–3

Monoclonal Antibodies Approved for Hematopoietic and Solid Tumors

Antigen and tumor cell targets	Antigen function	Naked antibodies	Radioisotope-based antibodies	Toxin-based antibodies
Antigen: CD20 Tumor type: B-cell lymphoma and CLL	Proliferation/differentiation	Rituximab (chimeric)	¹³¹ I-tositumomab; ⁹⁰ Y-ibritumomab tiuxetan	None
Antigen: CD52 Tumor type: B-cell CLL and T-cell lymphoma	Unknown	Alemtuzumab (humanized)	None	None
Antigen: CD25 α subunit Tumor type: T-cell mycosis fungoides	Activation antigen	Daclizumab (humanized)	None	Denileukin diftitox (diphtheria toxin)
Antigen: CD33 Tumor type: acute myeloid leukemia	Unknown	Gemtuzumab (humanized)	None	Gemtuzumab ozogamicin
Antigen: HER2/neu (ErbB-2) Tumor type: breast cancer	Tyrosine kinase	Trastuzumab (humanized)	None	None
Antigen: EGFR (ErbB-1) Tumor type: colorectal; NSCLC; pancreatic, breast	Tyrosine kinase	Cetuximab (chimeric)	None	None
Antigen: VEGF Tumor type: colorectal cancer	Angiogenesis	Bevacizumab (humanized)	None	None

ABBREVIATIONS: CLL, chronic lymphocytic leukemia; EGFR, epidermal growth factor receptor; NSCLC, non-small cell lung cancer; VEGF, vascular endothelial growth factor.

Table 51-4

Dose and Toxicity of Monoclonal Antibody-Based Drugs

Drug	Mechanism	Dose and Schedule	Major Toxicity
Rituximab	ADCC; CDC; apoptosis	375 mg/m ² IV infusion weekly for 4 weeks	Infusion-related toxicity with fever, rash, and dyspnea; B-cell depletion; late-onset neutropenia
Alemtuzumab	ADCC; CDC; apoptosis	Escalation 3, 10, 30 mg/m ² IV 3 times per week followed by 30 mg/m ² 3 times per week for 4 to 12 weeks	Infusion-related toxicity, T-cell depletion with increased infection; hematopoietic suppression; pancytopenia
Trastuzumab	ADCC; apoptosis; inhibition of HER2 signaling with G ₁ arrest	Loading dose of 4 mg/kg infusion followed by 2 mg/kg weekly	Cardiomyopathy; infusion-related toxicity
Cetuximab	Inhibition of EGFR signaling; apoptosis; ADCC	Loading dose of 400 mg/kg infusion followed by 250 mg/kg weekly	Infusion-related toxicity; skin rash in 75%
Bevacizumab	Inhibition of angiogenesis/neovascularization	5 mg/kg IV every 14 days until disease progression	Hypertension; pulmonary hemorrhage; gastrointestinal perforation; proteinuria; congestive heart failure
Denileukin diftitox	Targeted diphtheria toxin with inhibition of protein synthesis	9–18 µg/kg per day IV for the first 5 days every 3 weeks	Fever; arthralgia; asthenia; hypotension
Gemtuzumab ozogamicin	Double DNA strand breaks and apoptosis	2 doses of 9 mg/m ² IV separated by 14 days	Infusion-related toxicity; hematopoietic suppression; mucosal hepatic (VOD); and skin toxicity
⁹⁰ Y-ibritumomab tiuxetan	Targeted radiotherapy	0.4 mCi/kg IV	Hematologic toxicity; myelodysplasia
¹³¹ I-tositumomab	Targeted radiotherapy	Patient-specific dosimetry	Hematologic toxicity; myelodysplasia

ABBREVIATIONS: ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; EGFR, epidermal growth factor receptor; VOD, veno-occlusive disease.

Trastuzumab has dose-dependent pharmacokinetics with a mean $t_{1/2}$ of 5.8 days at the 2-mg/kg maintenance dose. Steady-state levels were achieved between the 16th and the 32nd weeks. The infusion effects of trastuzumab are typical of other monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Allergic reactions also may be observed. Cardiac dysfunction is an unexpected and potentially serious side effect that was observed in the pivotal trial of trastuzumab chemotherapy. Left ventricular dysfunction was seen most commonly in those patients who received doxorubicin and cyclophosphamide.

CETUXIMAB Cetuximab (ERBITUX) recognizes the EGF receptor (EGFR; also termed ErbB1 or HER1). Activation of EGFR tyrosine kinase activity is associated with proliferation, survival, and angiogenesis. EGFR expression is found in 60–75% of colorectal cancers, where it has been linked to tumor progression and a poor prognosis. Multiple epithelial cancers, such as breast, lung, kidney, prostate, brain, pancreas, bladder, and head and neck malignancies, also express EGFR and are potential therapeutic targets of cetuximab. Although the mechanism of tumor cell killing by cetuximab is uncertain, it is likely to involve inhibition of EGF binding and signaling. The role of more classical immune mechanisms, such as ADCC, is unclear. Cetuximab is FDA-approved for the treatment of EGFR-positive metastatic colorectal cancer as a single agent in patients who were unable to tolerate irinotecan-based therapy, or in combination with irinotecan for refractory patients. Studies in head and neck cancer in combination with radiation therapy suggest that cetuximab improves local control.

Cetuximab displays nonlinear pharmacokinetics. Following the recommended dose regimen, steady-state levels are achieved by the third weekly infusion. The mean $t_{1/2}$ is 114 hours (range, 75–188 hours). Toxic side effects observed with cetuximab include infusion reactions. The incidence of rash is significantly greater than that observed with other monoclonal antibodies; it may occur in 75% of patients, and may be severe in 16%. Interestingly, there is a correlation between development and intensity of rash and duration of benefit from cetuximab.

BEVACIZUMAB Bevacizumab (AVASTIN) targets the vascular-endothelial growth factor (VEGF) and inhibits its interaction with the VEGFR1 and VEGFR2 receptors. VEGF is an angiogenic growth factor that regulates vascular proliferation and permeability and inhibits apoptosis of new blood vessels. VEGF expression is increased in several tumor types, including breast, ovarian, non-small cell lung, and colorectal cancer, and its expression correlates with neovascularization within tumors. In colorectal cancer, microvessel density is associated with progression of adenomas to carcinomas and with metastatic potential and poor prognosis. Bevacizumab is FDA-approved for metastatic colorectal cancer in combination with 5-FU. There also is evidence of bevacizumab efficacy in clear-cell renal cancer as a single agent and in non-small cell lung cancer and breast cancer in combination with chemotherapy.

The pharmacokinetics of bevacizumab varies by sex, body weight, and tumor burden. Clearance is higher in patients with greater tumor burden, but the relationship with clinical outcome has not been explored. Bevacizumab has an estimated $t_{1/2}$ of 20 days (range, 11–50 days) and a predicted time to reach steady state of 100 days at the therapeutic dose. Infusion-related toxicities are relatively uncommon. However, this agent has a number of unique and potentially serious toxicities, including severe hypertension, proteinuria, congestive heart failure, hemorrhage, and GI perforation.

Monoclonal Antibody-Cytotoxic Conjugates

GEMTUZUMAB OZOGAMICIN Gemtuzumab ozogamicin (MYLOTARG) comprises a monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of *calicheamicin*, a potent enediyne antitumor antibiotic. The CD33 antigen is found on most hematopoietic cells, on >80% of AML, and in most myelodysplasias. Following binding to CD33, gemtuzumab ozogamicin undergoes endocytosis with cleavage of calicheamicin within the lysosome, which ultimately causes double-strand DNA breaks and cell death. Gemtuzumab ozogamicin is FDA-approved for the treatment of CD33-positive AML in first relapse in patients >60 years old who are not candidates for conventional cytotoxic therapy. Studies exploring new roles for gemtuzumab ozogamicin are being conducted, including treatment of refractory and previously untreated AML.

Pharmacokinetics of gemtuzumab ozogamicin at the standard 9 mg/m² dose showed half-lives of total and unconjugated calicheamicin of 41 and 143 hours, respectively. Following a second dose, the $t_{1/2}$ increased to 64 hours and the AUC was twice that of the initial dose. Serious toxicities may occur with gemtuzumab ozogamicin. Like other monoclonal antibodies, infusion-related toxicities occur with the first infusion but are ameliorated by glucocorticoids. The primary toxicities are

bone marrow suppression and hepatic toxicity. Hepatic toxicity can be serious and may lead to fatal VOD. In the phase 2 study, significant hyperbilirubinemia was observed in 23% of patients; this may represent subclinical VOD in some cases.

Radioimmuno-Conjugates

Radioimmuno-conjugates use monoclonal antibody to target radioactive particles to tumor cells (Tables 51–3 and 51–4). ^{131}I (^{131}I) is a commonly used radioisotope; the γ emission of ^{131}I can be used for both imaging and therapy, but releasing free ^{131}I and ^{131}I -tyrosine into the blood presents a potential health hazard to caregivers. The β emitter, ^{90}Y (^{90}Y), is an attractive alternative to ^{131}I , based on its higher energy and longer path length, which may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. However, disadvantages include its inability to image, limited availability, and expense.

Radioimmuno-conjugates have been developed with monoclonal antibodies against CD20 conjugated with ^{131}I (^{131}I -tositumomab or BEXXAR) and ^{90}Y -ibrutinomab tiuxetan (ZEVALIN) that have response rates in relapsed lymphoma of 65–80%. These agents are well tolerated with most toxicity attributable to bone marrow suppression. However, there are reports of secondary leukemias (Table 51–4). Pretargeting has been used to increase the therapeutic index of radioimmuno-conjugates by initially treating with avidin-labeled monoclonal antibody, followed 1–2 days later by ^{90}Y -conjugated biotin. This technique may improve the specificity of radioisotope delivery to tumor cells and increase the therapeutic index.

Immunotoxin

DENILEUKIN DIFTITOX Denileukin diftitox (ONTAK) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria toxin. The human IL-2 receptor (IL-2R) is not expressed on resting T cells, but is constitutively expressed on malignant lymphocytes of both T-cell and B-cell origin. Denileukin diftitox is FDA-approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Denileukin diftitox is being evaluated in patients with CD25-negative tumors and modulators of CD25 expression are being combined in an attempt to increase response rates. *Bexarotene* increases the level of CD25 expression on malignant T cells and provides a rationale for combining these agents.

Systemic exposure to denileukin diftitox is variable but proportional to dose. It has a distribution $t_{1/2}$ of 2–5 minutes with a terminal $t_{1/2}$ of ~70 minutes. Immunologic reactivity to denileukin diftitox can be detected in virtually all patients after treatment but does not preclude clinical benefit with continued treatment. Denileukin diftitox clearance in later cycles of treatment is accelerated by two- to threefold as a result of development of antibodies, but serum levels are greater than required to produce cell death in IL-2R-expressing cell lines (1–10 ng/mL for more than 90 minutes). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities associated with denileukin diftitox are acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity.

Colony-Stimulating Factors

Many agents used for cancer chemotherapy suppress bone marrow production of hematopoietic cells, often limiting the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (*i.e.*, erythropoietin), granulocytes (*i.e.*, granulocyte colony-stimulating factor), and granulocytes and macrophages (*i.e.*, granulocyte-macrophage colony-stimulating factor) have enormously advanced the ability to use combination therapy or high-dose therapy with diminished complications such as febrile neutropenia. Whether this will result in improved survival rates for specific cancers remains to be determined. The individual growth factors and specifics of therapy are described in detail in Chapter 53.

V. HORMONES AND RELATED AGENTS

GLUCOCORTICOIDS

The glucocorticoids are discussed in detail in Chapter 59. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, the greatest value of glucocorticoids as cytotoxic agents is in the treatment of acute leukemia in children and malignant lymphoma in children and

adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in up to 30% of children. Although these responses frequently are characterized by complete disappearance of all detectable leukemic cells from the peripheral blood and bone marrow, the remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. For these reasons, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for Hodgkin's disease and non-Hodgkin's lymphoma, as well as for treatment of MM and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

Dexamethasone is used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4–6 mg every 6 hours have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Because acute changes in dosage can lead to a rapid recrudescence of symptoms, dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Gradual tapering of the dosage may be undertaken if a clinical response to definitive antitumor therapy has been achieved.

Several glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 59). Prednisone, for example, usually is administered orally in doses as high as 60–100 mg, or even higher, for the first few days and gradually reduced to levels of 20–40 mg/day.

PROGESTINS

Progestational agents (see Chapter 57) have been used as second-line hormonal therapy for metastatic hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS.

ESTROGENS AND ANDROGENS

Carcinomas arising from the prostate and mammary gland often retain some of the hormonal responsiveness of their normal counterparts for varying periods of time. By changing the hormonal environment of such tumors, it is possible to alter the course of the neoplastic process.

ANTIANDROGEN THERAPY IN PROSTATE CANCER

Although the antiandrogenic treatment of metastatic prostate carcinoma is palliative, life expectancy is increased and thousands of patients have benefited. When distant metastases already are present, hormonal therapy becomes the primary treatment for prostate cancer. Pharmacological approaches to reduce the concentrations of endogenous androgens or inhibit their action include antiandrogens, or more commonly, the administration of gonadotropin-releasing hormone (GnRH) agonists or antagonists with or without antiandrogens (see below).

Among men with metastatic prostate cancer, >90% have an initial favorable response to primary hormonal therapy with androgen deprivation therapy (ADT). This is manifest as disease regression or stabilization and relief of cancer-related symptoms. The average time to progression is 18–36 months, making ADT one of the longest-lasting beneficial treatments in any advanced solid tumor. There is a survival benefit to ADT. Disease progression after ADT signifies an androgen-independent state, with subsequent median survival of only 12 months. However, many men will respond to secondary hormonal therapy even after failure of ADT. Secondary hormonal treatments include androgen receptor (AR) blockers, adrenal androgen synthesis inhibitors, and estrogenic agents. Responses are more variable than to primary hormonal therapy, but a substantial portion of men benefit from these well-tolerated forms of treatment. When patients become refractory to any form of hormonal therapy, their management usually involves chemotherapeutic agents.

Common side effects of all forms of antiandrogen hormonal therapy include vasomotor flushing, loss of libido, gynecomastia, increased weight, decreased bone mineral density (BMD), and loss of muscle mass. There is variability to these side effects. For example, AR blockers cause more gynecomastia compared with GnRH agonists but less vasomotor flushing and loss of BMD. Importantly, the increased cardiovascular toxicity observed with high doses of estrogen is not observed with other forms of ADT.

Gonadotropin-Releasing Hormone Agonists and Antagonists

The most common form of ADT involves suppression of the pituitary with GnRH agonists. GnRH agonists cause an initial surge in levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), followed by inhibition of gonadotropin release (*see* Chapter 55). One important side effect, a transient flare of disease due to the initial gonadotropin surge, can be avoided by temporary (2–4 weeks) administration of AR blockers or by the use of GnRH antagonists (*see* below).

Complete androgen blockade (CAB) refers to combination therapy with androgen-receptor blockers and GnRH agonists. However, the advantages of long-term CAB over GnRH agonists alone are questionable.

Treatment with GnRH antagonists rapidly reduces serum testosterone levels, without the transient initial increase observed after GnRH agonists. *Abarelix* (PLENAXIS) effectively reduces serum testosterone to castrate levels within a week in most men. Other than avoidance of the initial flare, GnRH antagonist therapy offers no advantage compared with GnRH agonists, and GnRH antagonists for prostate cancer are available only in the 1-month depot formulation.

Androgen Receptor Blockers

Compounds that competitively inhibit natural ligands of the AR are called AR blockers or antiandrogens (*see* Chapter 58). AR blockers as monotherapy are not indicated as routine treatment for patients with advanced prostate cancer, although some evidence points to reduced adverse effects of AR blockers relative to GnRH agonists on BMD and body composition. The AR blockers are often given in combination with GnRH agonists, where they act to block potential deleterious effects resulting from transient increases in gonadotropins and testosterone. The most commonly used drugs are members of the nonsteroidal class of AR blockers, including flutamide (EULEXIN, others), *nilutamide* (NILANDRON), and *bicalutamide* (CASODEX).

ESTROGENS AND ANDROGENS IN THE TREATMENT OF BREAST CANCER

Antagonizing the effects of estrogen in breast cancer frequently is effective, and the use of antiestrogens such as *tamoxifen* is now a standard part of hormonal therapy of breast cancer. Immunohistochemical detection of estrogen receptors (ER) and progesterone receptors (PR) has improved selection of patients for hormone therapies. Most patients with ER- or PR-positive tumors will respond to hormonal therapy; these patients also have a better overall prognosis independent of the type of therapy. In contrast, ER- and PR-negative carcinomas rarely respond to hormonal therapy. Clinically detectable responses to hormone therapy usually take 8–12 weeks to detect. If the disease responds or remains stable on a given treatment, the medication typically is continued indefinitely until the disease progresses or unwanted toxicities develop. The duration of an induced remission averages 6–12 months but sometimes can last for many years.

Antiestrogen Therapy

Antiestrogen approaches for the therapy of hormone-receptor positive breast cancer include the use of selective estrogen-receptor modulators (SERMs), selective estrogen receptor downregulators (SERDs), and aromatase inhibitors (AIs).

SELECTIVE ESTROGEN RECEPTOR MODULATORS SERMs bind to the ER and exert either estrogenic or antiestrogenic effects depending on the specific organ. The recent decline in breast cancer mortality is believed to be in part due to the widespread utilization of tamoxifen. In addition to its estrogen antagonist effects on breast cancer, tamoxifen also exerts undesirable estrogenic agonist effects in nonbreast tissues. Several novel antiestrogen compounds have been developed that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen, which can be divided into tamoxifen analogs (*e.g.*, *toremifene*, *droloxifene*, and *idoxifene*), “fixed ring” compounds (*e.g.*, *raloxifene*, *lasofoxifene*, *arzofoxifene*, *miproxifene*, *levormeloxifene*, and EM652), and the SERDs (*e.g.*, *fulvestrant*), the latter also termed “pure antiestrogens”).

TAMOXIFEN Tamoxifen’s broad use is related to its anticancer activity and good tolerability profile allowing chronic daily dosing. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer. Other organs affected by tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (increase in BMD), and liver function (alterations of blood lipid profile).

The use of tamoxifen in the hormonal therapy of breast cancer is described in detail in Chapter 57. Alternative or additional antiestrogen strategies in premenopausal women include oophorectomy or GnRH analogs (see Chapter 55). Tamoxifen also has shown effectiveness in initial trials for preventing breast cancer in women at increased risk. A similar decrease in the incidence of breast cancer also was observed with raloxifene.

TOREMIFENE Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile. Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER-positive or of unknown receptor status. Toremifene has ~40 times lower estrogen agonist effect than tamoxifen *in vitro*, which may make toremifene more effective in combination with an aromatase inhibitor than tamoxifen.

Selective Estrogen Receptor Downregulators

SERDs, also termed “pure antiestrogens,” include compounds such as fulvestrant, RU 58668, SR 16234, ZD 164384, and ZK 191703. SERDs, unlike SERMs, are devoid of any estrogen agonist activity and function as pure antagonists.

FULVESTRANT Fulvestrant (FASLODEX) is the first FDA-approved agent in the new class of ER downregulators. Fulvestrant is approved for postmenopausal women with ER-positive metastatic breast cancer that has progressed despite antiestrogen therapy. Fulvestrant binds to the ER with an affinity >100 times that of tamoxifen; its long, bulky side-chain at the 7 α position sterically hinders receptor dimerization, leading to increased ER turnover and disruption of nuclear localization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells.

This ER “downregulation,” can completely suppress the expression of estrogen-dependent genes, which likely explains why fulvestrant demonstrates efficacy against tamoxifen-resistant breast cancer. Maximum plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and are maintained over a period of 1 month. The plasma $t_{1/2}$ is approximately 40 days. Steady-state concentrations are reached after 3–6 monthly injections.

Fulvestrant generally is well tolerated with the most common adverse events being nausea, asthenia, pain, vasodilation (hot flushes), and headache. Injection site reactions, seen in ~7% of patients, are reduced by giving the injection slowly. In the study comparing anastrozole and fulvestrant, quality-of-life outcome measures were maintained over time with no significant difference between the drugs.

AROMATASE INHIBITORS

AIs are drugs that inhibit aromatase, the enzyme that carries out the final step in the conversion of androgens to estrogen. These drugs have achieved wide use and considerable success in the treatment of early and advanced breast cancer, as described in Chapter 57.

For a complete Bibliographical listing see Goodman & Gilman’s *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

IMMUNOSUPPRESSANTS, TOLEROGENS, AND IMMUNOSTIMULANTS

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Innate, or natural, immunity is broadly reactive, does not require priming, and is of relatively low affinity. Adaptive, or learned, immunity is antigen-specific, depends upon antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system being more active early in an immune response and adaptive immunity becoming progressively dominant over time. The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the normal immune response to infection and tumors but also mediate transplant rejection and autoimmunity.

Immunoglobulins (antibodies) on the B lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self major histocompatibility complex (MHC) antigens [called human leukocyte antigens (HLA)] on the surface of antigen-presenting cells (APCs), such as dendritic cells, macrophages, and other cell types expressing MHC class I and class II antigens. Once activated by specific antigen recognition *via* their respective clonally restricted cell-surface receptors, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that are effectors and regulators of the immune response.

The impact of the immune system in human disease is enormous. Immunological diseases (*e.g.*, rheumatoid arthritis, type 1 diabetes mellitus, and asthma; solid tumors and hematologic malignancies) are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. Immune system–mediated graft rejection remains a formidable obstacle to widespread use of organ transplantation.

IMMUNOSUPPRESSION

In transplantation, the major classes of immunosuppressive drugs are: (1) *glucocorticoids*, (2) *calcineurin inhibitors*, (3) *antiproliferative/antimetabolic agents*, and (4) *biologics (antibodies)*. These drugs have achieved a high degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. However, such therapies require life-long use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibodies directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mTOR (*mammalian target of rapamycin*) inhibitors (*sirolimus*, *everolimus*) and anti-CD25 (interleukin [IL]-2 receptor) antibodies (*basiliximab*, *daclizumab*) target growth factor pathways, substantially limiting clonal expansion and potentially promoting tolerance.

General Approach to Organ Transplantation Therapy

A multitiered approach, similar to that in cancer chemotherapy, is employed in immunosuppressive drug therapy for organ transplants. Several agents are used simultaneously, each of which is directed at a different molecular target within the allograft response (Table 52–1). Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect. Greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression. Therefore, intensive induction and lower-dose maintenance protocols are employed.

Table 52-1

Sites of Action of Selected Immunosuppressive Agents on T-Cell Activation

Drug	Site of Action
Glucocorticoids	Glucocorticoid response elements in DNA (regulate gene transcription)
Muromonab-CD3	T-cell receptor complex (blocks antigen recognition)
Cyclosporine	Calcineurin (inhibits phosphatase activity)
Tacrolimus	Calcineurin (inhibits phosphatase activity)
Azathioprine	Deoxyribonucleic acid (false nucleotide incorporation)
Mycophenolate Mofetil	Inosine monophosphate dehydrogenase (inhibits activity)
Daclizumab, Basiliximab	IL-2 receptor (block IL-2-mediated T-cell activation)
Sirolimus	Protein kinase involved in cell-cycle progression (mTOR) (inhibits activity)

BIOLOGIC INDUCTION THERAPY

In many transplant centers, induction therapy with biologic agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African American patients, or pediatric patients). Most of the limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have prolonged serum half-lives. The anti-interleukin-2 receptor (IL-2R) mAbs—frequently termed anti-CD25—were the first biologics proven to be effective as induction agents.

Biologic agents for induction therapy in the prophylaxis of rejection currently are used in ~70% of de novo transplant patients. Biologics for induction can be divided into two groups: depleting agents and immune modulators. Depleting agents consist of lymphocyte immune globulin, antithymocyte globulin, and muromonab-CD3 mAb (the latter also produces immune modulation); their efficacy derives from their ability to deplete the recipient's CD3-positive cells at the time of transplantation and antigen presentation. The second group, the anti-IL-2R mAbs, does not deplete T lymphocytes, but rather block IL-2-mediated T-cell activation by binding to the α chain of IL-2R.

For patients with high levels of anti-HLA antibodies, humoral rejection mediated by B cells can be modified by plasmapheresis, usually given every other day for 4–5 treatments followed by intravenous immunoglobulin to suppress antibody production.

MAINTENANCE IMMUNOTHERAPY

Therapy typically involves a calcineurin inhibitor (e.g., cyclosporine or tacrolimus), glucocorticoids, and mycophenolate mofetil (a purine metabolism inhibitor; see below), each directed at a discrete site in T-cell activation. Alternatively, sirolimus can be used to limit exposure to the nephrotoxic calcineurin inhibitors. Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate mofetil, sirolimus, and various monoclonal and polyclonal antibodies are all approved for use in transplantation.

THERAPY FOR ESTABLISHED REJECTION

Although low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, or sirolimus are effective in preventing acute cellular rejection, they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection. Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3 mAb.

Glucocorticoids

Glucocorticoid chemistry, pharmacokinetics, and drug interactions are described in Chapter 59. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders.

MECHANISM OF ACTION

Glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity. The mechanisms of glucocorticoid action (i.e., gene regulation, suppression of proinflammatory cytokines, etc.) are detailed in Chapter 59.

THERAPEUTIC USES Glucocorticoids commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. High dose pulses of intravenous *methylprednisolone sodium succinate* (SOLU-MEDROL, A-METHAPRED) are used to reverse acute transplant rejection and acute exacerbations of selected autoimmune disorders. Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone marrow transplantation. Glucocorticoids are used routinely to treat autoimmune disorders (*see* Chapter 59) and acute exacerbations of multiple sclerosis (*see* below). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonad-CD3 and to a lesser extent thymoglobulin (*see* below).

TOXICITY Unfortunately, chronic use of steroids often results in disabling and life-threatening adverse effects, as described in Chapter 59. The advent of combined glucocorticoid/cyclosporine regimens has allowed reduced doses of steroids, but steroid-induced morbidity remains a major problem in many transplant patients.

Calcineurin Inhibitors

Perhaps the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, *cyclosporine* and *tacrolimus*, which target intracellular signaling pathways induced as a consequence of T-cell-receptor activation. Although they are structurally unrelated and bind to distinct molecular targets, they inhibit normal T-cell signal transduction essentially by the same mechanism (*see* Figure 52-1).

FIGURE 52-1 Mechanisms of action of cyclosporine, tacrolimus, and sirolimus on T cells. Both cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FK506-binding protein [FKBP], respectively), forming a complex that binds the phosphatase calcineurin and inhibits the calcineurin-catalyzed dephosphorylation essential to permit movement of the nuclear factor of activated T cells (NFAT) into the nucleus. In the nucleus, NFAT interacts with transcription factor AP-1 (fos/jun), an interaction required for transcription of interleukin-2 (IL-2) and other growth and differentiation-associated cytokines (lymphokines). Sirolimus (rapamycin) works at a later stage in T-cell activation, downstream of the IL-2 receptor. Sirolimus also binds FKBP, but the FKBP-sirolimus complex binds to and inhibits the mammalian target of rapamycin (mTOR), a kinase involved in cell-cycle progression (proliferation). TCR, T-cell receptor.

CYCLOSPORINE**Chemistry**

Cyclosporine (cyclosporin A), a cyclic undecapeptide, is produced by the fungus Beauveria nivea. Cyclosporine is lipophilic and highly hydrophobic, and is formulated for clinical administration using castor oil or other strategies to ensure solubilization.

Mechanism of Action

Cyclosporine suppresses humoral immunity but is much more effective against T-cell–dependent immune mechanisms that underlie transplant rejection and some forms of autoimmunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of antiapoptotic proteins (Figure 52–1). Cyclosporine also increases expression of transforming growth factor- β , a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTL).

Disposition and Pharmacokinetics Cyclosporine is administered intravenously or orally. The intravenous preparation (SANDIMMUNE Injection) is dissolved in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% NaCl or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule (SANDIMMUNE) is absorbed slowly with 20–50% bioavailability. A modified microemulsion formulation (NEORAL) has more uniform and slightly increased bioavailability compared to SANDIMMUNE and is provided as 25-mg and 100-mg soft gelatin capsules and a 100-mg/mL oral solution. SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Drug monitoring is essential to optimize therapy. Because both radioimmunoassays and high-performance liquid chromatography assays are used, the clinician should ensure that the methods are consistent when monitoring an individual patient. Blood is most conveniently sampled at 2 hours after a dose administration (*i.e.*, C_2 levels) rather than prior to dosing. In complex patients with delayed absorption, such as diabetics with gastroparesis, the C_2 level may underestimate the peak cyclosporine level obtained; in rapid absorbers, the C_2 level may have peaked before the blood sample is drawn. If a patient has clinical signs or symptoms of toxicity or there is unexplained rejection or renal dysfunction, a pharmacokinetic profile (*see* Chapter 1) can be used to estimate exposure to the drug.

Cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood is generally biphasic, with a terminal $t_{1/2}$ of 5–18 hours. After intravenous infusion, clearance is ~5–7 mL/min/kg in adult recipients of renal transplants, but results differ by age and patient populations (*e.g.*, slower in cardiac transplant patients, faster in children). Thus, the intersubject variability is so large that individual monitoring is required.

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5–2 hours. Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 minutes of administration decrease the AUC by ~13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.

Cyclosporine is extensively metabolized in the liver by CYP3A and to a lesser degree by the gastrointestinal (GI) tract and kidneys. Cyclosporine and its metabolites are excreted principally through the bile into the feces. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

Therapeutic Uses Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis. Its use in dermatology is discussed in Chapter 62. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate mofetil, and most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Especially for renal transplant patients, algorithms have been developed to delay cyclosporine introduction until a threshold renal function has been attained. Dosage is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient is able to take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to *methotrexate*. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed. Because of its mechanism of action, cyclosporine also has been used successfully in inflammatory bowel disease (*see* Chapter 38).

Toxicity The principal adverse reactions to cyclosporine therapy are renal dysfunction, tremor, hirsutism, hypertension, hyperlipidemia, and gum hyperplasia. Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients treated and is the major indication for cessation or modification of therapy. Hypertension occurs in ~50% of renal transplant and almost all cardiac transplant patients. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this apparently is more problematic in patients treated with tacrolimus (*see* below). Especially at risk are obese patients, African American or Hispanic recipients, or those with family history of type 2 diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in low-density lipoprotein (LDL) cholesterol.

Drug Interactions Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects microsomal enzymes, especially the CYP3A system, may impact cyclosporine blood concentrations. Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca^{2+} channel blockers (*e.g.*, *verapamil*, *nicardipine*), antifungal agents (*e.g.*, *fluconazole*, *ketoconazole*), antibiotics (*e.g.*, *erythromycin*), glucocorticoids (*e.g.*, methylprednisolone), and HIV-protease inhibitors (*e.g.*, *indinavir*). Grapefruit and grapefruit juice block CYP3A and the multidrug efflux pump and should be avoided by patients taking cyclosporine because these effects can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (*e.g.*, *naftillin*, *rifampin*), anticonvulsants (*e.g.*, *phenobarbital*, *phenytoin*), and others (*e.g.*, *octreotide*, *ticlopidine*). In general, close monitoring of cyclosporine blood levels and the levels of other drugs is required when such combinations are used.

Interactions between cyclosporine and sirolimus (*see* below) have led to the recommendation that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Other drug interactions of concern include additive nephrotoxicity when cyclosporine is coadministered with nonsteroidal anti-inflammatory drugs and other drugs that cause renal dysfunction; elevation of methotrexate levels when the two drugs are coadministered; and reduced clearance of *prednisolone*, *digoxin*, and statins.

TACROLIMUS Tacrolimus (PROGRAF, FK506) is a macrolide antibiotic produced by *Streptomyces tsukubaensis*.

Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FK506-binding protein-12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca^{2+} , calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited. As described for cyclosporine and depicted in Figure 52–1, the inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

Disposition and Pharmacokinetics

Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a sterile solution for injection (5 mg/mL). Immunosuppressive activity resides primarily in the parent drug. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. Whole blood, rather than plasma, is the most appropriate sampling compartment to describe tacrolimus pharmacokinetics. For tacrolimus, the trough level seems to correlate better with clinical events than it does for cyclosporine. Target concentrations in many centers are 200–400 ng/mL in the early preoperative period and 100–200 ng/mL 3 months after transplantation. GI absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75–99%, involving primarily albumin and α_1 -acid glycoprotein. Tacrolimus is extensively metabolized in the liver by CYP3A, with a $t_{1/2}$ of ~12 hours; at least some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces.

Therapeutic Uses

Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner akin to cyclosporine and as rescue therapy in patients with rejection despite “therapeutic” levels of cyclosporine. Dosages are intended to achieve blood trough levels of 5–15-ng/mL. Pediatric patients generally require higher doses than do adults.

Toxicity

Nephrotoxicity, neurotoxicity (tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes are all associated with tacrolimus use. As with cyclosporine, nephrotoxicity is limiting. Tacrolimus has a negative effect on pancreatic β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol.

Drug Interactions

Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely, especially when tacrolimus is used with other potentially nephrotoxic drugs. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 hours is required when switching a patient from cyclosporine to tacrolimus. Since tacrolimus is metabolized mainly by CYP3A, the potential interactions described above for cyclosporine also apply for tacrolimus.

Antiproliferative and Antimetabolic Drugs

SIROLIMUS Sirolimus (*rapamycin*; RAPAMUNE) is a macrocyclic lactone produced by *Streptomyces hygroscopicus*.

Mechanism of Action

Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (Figure 52–1). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. The sirolimus–FKBP-12 complex does not affect calcineurin activity but rather inhibits a protein kinase that is a key enzyme in cell-cycle progression, designated mTOR. Inhibition of mTOR blocks cell-cycle progression at the $G_1 \rightarrow S$ phase transition.

Disposition and Pharmacokinetics After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within ~1 hour after a single dose in healthy subjects and within ~2 hours after multiple oral doses in renal transplant patients. Systemic availability is ~15%, and blood concentrations are proportional to doses between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood, with a blood:plasma ratio of 38 in renal transplant patients. Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes >90% of the immunosuppressive effect. The blood $t_{1/2}$ after multiple doses in stable renal transplant patients is 62 hours. A loading dose of three times the maintenance dose usually provides nearly steady-state concentrations within 1 day.

Therapeutic Uses Sirolimus is indicated for prophylaxis of organ transplant rejection in combination with a calcineurin inhibitor and glucocorticoids. In patients experiencing or at high risk for calcineurin inhibitor–associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate mofetil to avoid permanent renal damage. The initial dosage in patients 13 years or older who weigh <40 kg should be adjusted based on body surface area (1 mg/m²/day) with a loading dose of 3 mg/m². Data regarding doses for pediatric and geriatric patients are lacking. It is recommended that the maintenance dose be reduced by approximately one-third in patients with hepatic impairment. Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

Toxicity The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides. While immunotherapy with sirolimus *per se* is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine alone. Sirolimus also may prolong delayed graft

function in deceased donor kidney transplants, presumably because of its antiproliferative action. Renal function must be monitored closely in such patients. Lymphocele, a surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia, hypo- or hyperkalemia, fever, and GI effects. Delayed wound healing may occur. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections. Prophylaxis for *Pneumocystis jiroveci* pneumonia and cytomegalovirus is recommended.

Drug Interactions Since sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required. As noted above, cyclosporine and sirolimus interact, and their administration should be separated by time. Dose adjustment may be required when sirolimus is coadministered with *diltiazem* or rifampin.

EVEROLIMUS Everolimus (40-*o*-[2-hydroxy] ethyl-rapamycin) is closely related chemically and clinically to sirolimus but has distinct pharmacokinetics. The main difference is a shorter $t_{1/2}$ and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to sirolimus. Aside from the shorter $t_{1/2}$, no studies have compared everolimus with sirolimus in standard immunosuppressive regimens. As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors to enhance toxicity and to reduce rejection. The toxicity of everolimus and the drug interactions seem to be the same as with sirolimus.

AZATHIOPRINE Azathioprine (IMURAN) is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine.

Mechanism of Action

Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Chapter 51). 6-Thio-IMP, a fraudulent nucleotide, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation is thereby inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine.

Disposition and Pharmacokinetics Azathioprine is well absorbed orally and reaches maximum blood levels within 1–2 hours after administration. The $t_{1/2}$ of azathioprine is ~10 minutes, while that of its metabolite 6-mercaptopurine is about an hour. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and *mercaptopurine* are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver and/or erythrocytes. Renal clearance has little impact on biological effectiveness or toxicity, but the dose should be reduced in patients with renal failure.

Therapeutic Uses Azathioprine is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. Although the dose of azathioprine required to prevent organ rejection and minimize toxicity varies, 3–5 mg/kg/day is the usual starting dose. Lower initial doses (1 mg/kg/day) are used for rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

Toxicity The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

Drug Interactions Xanthine oxidase, a key enzyme in the catabolism of azathioprine metabolites, is blocked by allopurinol. If azathioprine and allopurinol are used concurrently, the azathioprine dose must be decreased to 25–33% of the usual dose; it is best not to use these two drugs together. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

MYCOPHENOLATE MOFETIL *Mycophenolate mofetil* (CELLCEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA).

Mechanism of Action

Mycophenolate mofetil is a prodrug that is rapidly hydrolyzed to MPA, a selective, noncompetitive, and reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an important enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation, while other cell types can use salvage pathways; MPA therefore selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

Disposition and Pharmacokinetics Mycophenolate mofetil is rapidly and completely metabolized to MPA after oral or intravenous administration. MPA, in turn, is metabolized to the inactive glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The $t_{1/2}$ of MPA is ~16 hours. Negligible (<1%) amounts of MPA are excreted in the urine. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency. In early renal transplant patients (<40 days post-transplant), plasma concentrations of MPA after a single dose of mycophenolate mofetil are approximately half of those found in healthy volunteers or stable renal transplant patients.

Therapeutic Uses Mycophenolate mofetil is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor, but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. For renal transplants, 1 g is administered orally or intravenously (over 2 hours) twice daily (2 g/day). A higher dose, 1.5 g twice daily (3 g/day), is recommended for African American renal transplant patients and all cardiac transplant patients.

Toxicity The principal toxicities of mycophenolate mofetil are leukopenia, diarrhea, and vomiting. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with mycophenolate mofetil has been associated with devastating viral infections including polyoma nephritis.

Drug Interactions There appear to be no untoward effects produced by combination therapy of mycophenolate mofetil with cyclosporine, trimethoprim-sulfamethoxazole, or oral contraceptives. Unlike cyclosporine, tacrolimus delays elimination of mycophenolate mofetil by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Mycophenolate mofetil has not been tested with azathioprine. Coadministration with antacids containing aluminum or magnesium hydroxide decreases absorption of mycophenolate mofetil; thus, these drugs should not be administered simultaneously. Mycophenolate mofetil should not be administered with *cholestyramine* or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and *ganciclovir* may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

OTHER ANTIPROLIFERATIVE AND CYTOTOXIC AGENTS Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (see Chapter 51) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used as immunosuppressive agents include methotrexate, *cyclophosphamide* (CYTOXAN), *thalidomide*, and *chlorambucil* (LEUKERAN). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, and psoriasis, as well as in cancer therapy (see Chapter 51). Cyclophosphamide and chlorambucil are used in treating childhood nephrotic syndrome and a variety of malignancies (see Chapter 51). Cyclophosphamide also is used widely for treatment of severe systemic lupus erythematosus and other vasculitides such as Wegener's granulomatosis. *Leflunomide* (ARAVA) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis; it increasingly is used in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no studies showing efficacy compared with control patients treated with withdrawal or reduction of immunosuppression alone in BK virus nephropathy. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

FTY720

FTY720 is the first agent in a new class of small molecules, sphingosine 1-phosphate receptor (S1P-R) agonists. It is a prodrug that reduces recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, including inflammatory lesions and organ grafts.

Antibodies

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection. Monoclonal reagents have overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but they are more limited in their target specificity. First-generation murine monoclonal antibodies generally have been replaced by newer chimeric or humanized monoclonal antibodies that lack antigenicity, have prolonged half-lives, and can be mutagenized to alter their affinity to Fc receptors. Both polyclonal and monoclonal products have a place in immunosuppressive therapy (Figure 52–2).

ANTITHYMOCYTE GLOBULIN Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immunized with human thymocytes.

Mechanism of Action

Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell-mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses Antithymocyte globulin is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents. Antilymphocyte-depleting agents (THYMOGLOBULIN, ATGAM) are thought to improve graft survival. A course of antithymocyte-globulin treatment often is given to

FIGURE 52–2 *Generation of monoclonal antibodies.* Mice are immunized with the selected antigen, and spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma that has been selected for its inability to grow in medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only myelomas that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Those of interest based upon a specific screening technique are then selected and cloned by limiting dilution. Monoclonal antibodies can be used directly as supernatants or ascites fluid experimentally but are purified for clinical use. HPRT, hypoxanthine-guanine phosphoribosyl transferase.

renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg/day (given intravenously over 4–6 hours) for 7–14 days. Mean T-cell counts fall by day 2 of therapy. Antithymocyte globulin also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection.

Toxicity Polyclonal antibodies are xenogenic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with glucocorticoids, *acetaminophen*, and/or an antihistamine and administration of the antiserum by slow infusion (over 4–6 hours) into a large-diameter vein minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is rare. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop but do not limit repeated use.

MONOCLONAL ANTIBODIES

Anti-CD3 Monoclonal Antibodies Antibodies directed at the ϵ chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with considerable efficacy in human transplantation. The original mouse IgG_{2a} antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHOCLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes.

Mechanism of Action

Muromonab-CD3 binds to the ϵ chain of CD3, a component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation. Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and extravasation of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen following, margination of T cells onto vascular endothelial walls, and redistribution of T cells to nonlymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines.

Therapeutic Uses Muromonab-CD3 is indicated for treatment of acute organ transplant rejection. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (<1 minute) for 10–14 days. Antibody levels increase over the first 3 days and then plateau. Circulating T cells disappear from the blood within minutes of administration and return within ~1 week after cessation of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody, which can neutralize and prevent its immunosuppressive efficacy. Thus, repeated treatment with the muromonab-CD3 or other mouse monoclonal antibodies generally is contraindicated.

Toxicity The major side effect of anti-CD3 therapy is the “cytokine release syndrome,” which typically begins 30 minutes after infusion of the antibody (but can occur later) and may persist for hours. Antibody binding to the T-cell receptor complex combined with Fc receptor (FcR)–mediated cross-linking is the basis for the initial activating properties of this agent. The syndrome is attributed to increased serum levels of cytokines (including TNF- α , IL-2, IL-6, and interferon- γ), which are released by activated T cells and/or monocytes. The production of TNF- α has been shown to be the major cause of the toxicity. The symptoms usually are worst with the first dose; frequency and severity decrease with subsequent doses. Common clinical manifestations include high fever, chills/rigor, headache, tremor, nausea/vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and CNS disorders, including aseptic meningitis. Potentially fatal pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have occurred.

Glucocorticoid administration before the injection of muromonab-CD3 considerably reduces first-dose reactions and is now standard. Volume status of patients also must be monitored carefully before therapy; steroids and other premedications should be given, and a fully competent resuscitation facility must be immediately available for patients receiving their first several doses.

Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. “Rebound” rejection has been observed when muromonab-CD3 treatment is stopped. Anti-CD3 therapies may be limited by anti-idiotypic or anti-murine antibodies in the recipient.

Anti-IL-2 Receptor (Anti-CD25) Antibodies Daclizumab (ZENAPAX), a humanized murine complementarity-determining region (CDR)/human IgG₁ chimeric monoclonal antibody, and basiliximab (SIMULECT), a murine-human chimeric monoclonal antibody, are produced by recombinant DNA technology. Daclizumab consists of human (90%) constant domains of IgG₁ and variable framework regions of the Eu myeloma antibody and murine (10%) CDR of the anti-Tac antibody.

Mechanism of Action

The exact mechanism of action of the anti-CD25 mAbs is not completely understood but likely results from the binding of the anti-CD25 mAbs to the IL-2 receptor on the surface of activated, but not resting, T cells. Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. Therapy with the anti-IL-2R mAbs is thought to result in a relative decrease of the expression of the α chain, either from depletion of coated lymphocytes or modulation of the α chain secondary to decreased expression or increased shedding.

Therapeutic Uses Daclizumab and basiliximab are used for prophylaxis of acute organ rejection in adult patients. In Phase III trials, daclizumab was administered in five doses (1 mg/kg given intravenously over 15 minutes in 50–100 mL of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. The $t_{1/2}$ of daclizumab was 20 days, resulting in saturation of the IL-2R α on circulating lymphocytes for up to 120 days after transplantation. Daclizumab has been used with maintenance immunosuppression regimens (cyclosporine, azathioprine, and glucocorticoids; cyclosporine and glucocorticoids) and with maintenance triple-therapy regimen—either with cyclosporine or tacrolimus, glucocorticoids, and mycophenolate mofetil (MMF) substituting for azathioprine. Basiliximab, administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation, resulted in a concentration sufficient to saturate IL-2R on circulating lymphocytes for 25–35 days after transplantation. The $t_{1/2}$ of basiliximab was 7 days. Basiliximab has been used with a maintenance regimen consisting of cyclosporine and prednisone.

There is no marker or test to monitor the effectiveness of anti-IL-2R therapy, as saturation of α chain on circulating lymphocytes during anti-IL-2R mAb therapy does not predict rejection. The duration of IL-2R blockade by basiliximab was similar in patients with or without acute rejection episodes.

Toxicity No cytokine-release syndrome has been observed with these antibodies, but anaphylaxis can occur. Although lymphoproliferative disorders and opportunistic infections may occur, the incidence ascribed to anti-CD25 treatment is remarkably low. No significant drug interactions with anti-IL-2-receptor antibodies have been described.

Campath-1H *Campath-1H* (ALEMTUZUMAB) is a humanized mAb that is approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; thus, the drug causes extensive lympholysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization. Although short-term results are promising, further clinical experience is needed.

Anti-TNF Reagents

Infliximab *Infliximab* (REMICADE) is a chimeric anti-TNF- α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF- α and prevents the cytokine from binding to its receptors.

TNF- α is implicated in the pathogenesis of a number of autoimmune diseases, including rheumatoid arthritis and Crohn's disease. Infliximab plus methotrexate improves the signs and symptoms of rheumatoid arthritis more than methotrexate alone. Patients with active Crohn's disease who had not responded to other therapies, including those with fistulae, also improved when treated with infliximab. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate-to-severe Crohn's disease in patients who have failed to respond to conventional therapy and in treatment to reduce the number of draining fistulae in Crohn's disease patients (*see* Chapter 38).

About one of six patients receiving infliximab experience an infusion reaction, characterized by fever, urticaria, hypotension, and dyspnea, within 1–2 hours after antibody administration. Serious infections also have occurred in infliximab-treated patients, most frequently in the upper respiratory and urinary tracts. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported after treatment with infliximab.

Although not a monoclonal antibody, *etanercept* (ENBREL) also targets TNF- α . Etanercept contains the ligand-binding portion of a human TNF- α receptor fused to the Fc portion of human IgG₁, and binds to TNF- α and prevents it from interacting with its receptors. It is approved in the U.S. for treatment of rheumatoid arthritis in patients who have not responded to other treatments. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. As with infliximab, serious infections have occurred. Injection-site reactions (erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab (HUMIRA) is recombinant human IgG₁ monoclonal anti-TNF for intravenous use in rheumatoid arthritis.

LFA-1 Inhibition *Efalizumab* (RAPTIVA) is a humanized IgG₁ mAb targeting the CD11a chain of LFA-1 (lymphocyte function associated antigen). Efalizumab binds to LFA-1 and prevents the LFA-1–ICAM (intercellular adhesion molecule) interaction to block T-cell adhesion, trafficking, and activation. Efalizumab is approved for use in patients with psoriasis. Efalizumab is given as weekly subcutaneous injections. The first dose is 0.7 mg/kg of body weight. Thereafter, each weekly dose is 1 mg/kg (up to a maximum single dose of 200 mg). Pharmacokinetic and pharmacodynamic studies showed that efalizumab produced saturation and 80% modulation of CD11a within 24 hours of therapy. In a subset of 10 patients who received higher dose efalizumab (2 mg/kg) with full-dose cyclosporine, mycophenolate mofetil, and glucocorticoids, 3 patients developed post-transplant lymphoproliferative diseases. While efalizumab appears to be an effective immunosuppressive agent, for transplant rejection, it may be best used in a lower dose and with an immunosuppressive regimen that avoids calcineurin inhibitors.

TOLERANCE

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunologic tolerance, the active state of antigen-specific nonresponsiveness. If attainable, tolerance would represent a true cure for conditions discussed above without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models. In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance induction.

IMMUNOSTIMULATION

General Principles

In contrast to immunosuppressive agents that inhibit the immune response in transplant rejection and autoimmunity, a few immunostimulatory drugs have applicability to infection, immunodeficiency, and cancer.

LEVAMISOLE

Levamisole (*ERGAMISOL*) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication is as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes’ stage C colon cancer. It occasionally has been associated with fatal agranulocytosis.

THALIDOMIDE

Thalidomide (*THALOMID*) is best known for the severe birth defects it caused when administered to pregnant women. For this reason, it is available only under a restricted distribution program and can be prescribed only by specially licensed physicians who understand that thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. Nevertheless, it is indicated for the treatment of patients with erythema nodosum leprosum (see Chapter 47) and also is used in conditions such as multiple myeloma. Its mechanism of action is unclear.

BACILLUS CALMETTE-GUÉRIN (BCG)

Live bacillus Calmette-Guérin (BCG; *TICE BCG*, *THERACYS*) is an attenuated culture of the bacillus of Calmette and Guérin strain of *Mycobacterium bovis*, which induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for treatment and prophylaxis of carcinoma in situ of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection. Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

RECOMBINANT CYTOKINES

Interferons Although interferons (α , β , and γ) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities. The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes. Recombinant *interferon alfa-2b* (IFN- α 2, INTRON A) is obtained by recombinant expression in *E. coli*. It is a member of a family of naturally occurring small proteins with molecular weights of 15–27.6 kDa, produced and secreted by cells in response to viral infections and other inducers. Interferon alfa-2b is indicated in the treatment of a variety of tumors, including hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi's sarcoma. It also is indicated for chronic hepatitis B infection and condylomata acuminata. It is supplied in combination with *ribavirin* (REBETRON) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with interferon alfa-2b or who have relapsed after interferon alfa-2b therapy.

Flu-like symptoms, including fever, chills, and headache, are the most common adverse effects after interferon alfa-2b administration. Adverse effects involving the cardiovascular system (hypotension, arrhythmias, and rarely cardiomyopathy and myocardial infarction) and CNS (depression, confusion) are less frequent.

Interferon gamma-1b (ACTIMMUNE) is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

Interferon beta-1a (AVONEX, REBIF), a 166–amino acid recombinant glycoprotein, and *interferon beta-1b* (BETASERON), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA-approved for the treatment of relapsing and relapsing-remitting multiple sclerosis to reduce the frequency of clinical exacerbations (*see below*). The mechanism of their action in multiple sclerosis is unclear. Flu-like symptoms (fever, chills, myalgia) and injection-site reactions are common adverse effects. The use of these and other interferons in the treatment of viral diseases is discussed in Chapter 49.

Interleukin-2 Human recombinant IL-2 (*aldesleukin*, PROLEUKIN; des-alanyl-1, serine-125 human IL-2) differs from native IL-2 in that it is not glycosylated, has no amino terminal Ala, and has an Ser substituted for the Cys at amino acid 125. The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein equals 18 million International Units. Aldesleukin has the following *in vitro* biologic activities of native IL-2: enhancement of lymphocyte proliferation and growth of IL-2–dependent cell lines; enhancement of lymphocyte-mediated cytotoxicity and killer cell activity; and induction of interferon- γ activity. *In vivo* administration of aldesleukin in animals produces multiple immunologic effects in a dose-dependent manner. Cellular immunity is profoundly activated with lymphocytosis, eosinophilia, thrombocytopenia, and release of multiple cytokines (*e.g.*, TNF- α , IL-1, interferon- γ). Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma. Administration of aldesleukin has been associated with serious cardiovascular toxicity resulting from capillary leak syndrome, which involves loss of vascular tone and leak of plasma proteins and fluid into the extravascular space. Hypotension, reduced organ perfusion, and death may occur. An increased risk of disseminated infection due to impaired neutrophil function also has been associated with aldesleukin treatment.

Immunization

Active immunization involves stimulation with an antigen to develop immunologic defenses against a future exposure, while passive immunization involves administration of preformed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

VACCINES Active immunization, or vaccination, involves administration of an antigen as a whole, killed organism, attenuated (live) organism, or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed (inactivated) organisms are used as the immunogen. In the U.S., vaccination has sharply curtailed or practically eliminated a variety of major infections, including polio, smallpox, diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus.

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or autoimmune diseases. Because T cells optimally are activated by peptides and costimulatory ligands that both are present on antigen-presenting cells, one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen.

Multiple studies have demonstrated the efficacy of DNA vaccines in models of infectious diseases and cancer. The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest.

IMMUNE GLOBULIN Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (*e.g.*, measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (*e.g.*, botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (Table 52–2). Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based upon the indication. The protection provided usually lasts from 1 to 3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunologic diseases such as immune thrombocytopenic purpura and Guillain-Barré syndrome. In contrast, specific immune globulins (hyperimmune) differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies. Specific immune globulin preparations are available for hepatitis B, rabies, tetanus, varicella-zoster, cytomegalovirus, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

Table 52–2

Selected Immune Globulin Preparations

Immune globulin intravenous	BAYGAM GAMMAGARD S/D GAMMAR-P.I.V IVEEGAM SANDOGLOBULIN I.V. others
Cytomegalovirus immune globulin	CYTOGAM
Respiratory syncytial virus immune globulin	RESPIGAM
Hepatitis B immune globulin	BAYHEP B HYPERHEP H-BIG
Rabies immune globulin	BAYRAB IMOGAM RABIS-HT HYPER-AB
Rho(D) immune globulin	BAY-RHO-D WINRH SDF MICRHOGAM RHOGAM others
Tetanus immune globulin	BAYTET HYPERTET

RHO(D) IMMUNE GLOBULIN The commercial forms of Rho(D) immune globulin (Table 52–2) consist of IgG containing a high titer of antibodies against the Rho(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system.

Mechanism of Action

Rho(D) immune globulin binds Rho antigens, thereby preventing sensitization. Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells via the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing red blood cells. This syndrome, called hemolytic disease of the newborn, is life-threatening. The form due to Rh incompatibility is largely preventable by Rho(D) immune globulin.

Therapeutic Use Rho(D) immune globulin is indicated whenever fetal red blood cells are known or suspected to have entered the circulation of an Rh-negative mother unless the fetus is known also to be Rh-negative. The drug is given intramuscularly. The $t_{1/2}$ of circulating immunoglobulin is ~21–29 days.

Toxicity Injection site discomfort and low-grade fever have been reported. Systemic reactions are extremely rare, but myalgia, lethargy, and anaphylactic shock have been reported. As with all plasma-derived products, there is a theoretical risk of transmission of infectious diseases.

INTRAVENOUS IMMUNOGLOBULIN Indications for the use of intravenous immunoglobulin (IVIG) have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections and an array of autoimmune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki’s disease, and autoimmune skin, neuromuscular, and neurologic diseases. The mechanism of action of IVIG in immune modulation is unknown. Although IVIG is effective in many autoimmune diseases, its spectrum of efficacy and appropriate dosing (especially duration of therapy) are unknown. Additional controlled studies of IVIG are needed to identify proper dosing, cost-benefit, and quality-of-life parameters.

A CASE STUDY: IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

CLINICAL FEATURES AND PATHOLOGY Multiple sclerosis (MS) is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic features: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is spared. The disease, which may be episodic or progressive, occurs in early to middle adulthood with prevalence increasing from late adolescence to 35 years and then declining. MS is roughly twice as common in females as in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive, even though several viruses can cause similar demyelinating diseases in laboratory animals and humans. A stronger linkage is genetic: people of Northern European origin have a higher susceptibility to MS, and studies in twins and siblings suggest a genetic component. One genetic determinant of MS may be the class II (or HLA-DR) domain of the MHC on chromosome 6 that encodes the histocompatibility antigens. There is also substantial evidence of an autoimmune component to MS: in MS patients, there are activated T cells and antibodies that are reactive to different myelin antigens including myelin basic protein (MBP). These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts, optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K^+ channels that are normally covered by myelin.

Attacks are classified by type and severity. Thus, physicians refer to acute MS (an acute attack), relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurologic deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients, wherein deterioration with relatively little inflammation is apparent at onset).

PHARMACOTHERAPY FOR MS Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability (Table 52–3).

Table 52-3

Pharmacotherapy of Multiple Sclerosis

Therapeutic Agent	TRADE NAME (dose, regimen)	Indications	Results	Mechanism of Action
IFN β -1a	AVONEX (30 μ g, IM, weekly) REBIF (22 or 44 μ g, SC, 3 times weekly)	Treatment of RRMS	Reduction of relapses by one-third Reduction of new MRI T2 lesions and the volume of enlarging T2 lesions Reduction in the number and volume of Gd-enhancing lesions Slowing of brain atrophy	Acts on blood-brain barrier by interfering with T-cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting the T cell expression of MMP Reduction in T cell activation by interfering with HLA class II and costimulatory molecules B7/CD28 and CD40:CD40L Immune deviation of Th2 over Th1 cytokine profile Same as IFN β -1a
IFN β -1b	BETASERON (0.3 μ g, SC, every other day)	Treatment of RRMS	Same as IFN β -1a	Same as IFN β -1a
Glatiramer acetate	COPAXONE (20 μ g, SC, daily)	Treatment of RRMS	Reduction of relapses by one-third Reduction in the number and volume of Gd-enhancing lesions	Induces T-helper type 2 cells that enter the CNS; mediates bystander suppression at sites of inflammation
Mitoxantrone	NOVANTRONE (12 mg/m ² , as short [5–15 min] IV infusion every 3 months)	Worsening forms of RRMS SPMS	Reduction in relapses by 67% Slowed progression on EDSS, ambulation index, and MRI disease activity	Intercalates DNA (see Chapter 51) Suppresses cellular and humoral immune response

IFN, interferon; IM, intramuscularly; RRMS, relapsing-remitting MS; SC, subcutaneously; SPMS, secondary progressive MS; IV, intravenously. Gd, gadolinium, used in Gd-enhanced MRI to assess number and size of inflammatory brain lesions; EDSS, Expanded Disability Status Scale, a neurologic assessment scale for MS pathology; MMP, matrix metalloprotease.

Non-specific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids are often employed (typically, 1 g/day of methylprednisolone administered intravenously for 3–5 days). There is no evidence that tapered doses of oral prednisone are useful.

For relapsing-remitting attacks, immunomodulatory therapies are approved: beta-1 interferons (interferon beta-1a, interferon beta-1b, and *glatiramer acetate* [COPAXONE]). The interferons suppress the proliferation of T lymphocytes, inhibit their movement into the CNS from the periphery, and shift the cytokine profile from pro- to anti-inflammatory types.

Random polymers that contain amino acids commonly used as MHC anchors and T-cell receptor contact residues have been proposed as possible “universal altered peptide ligands.” Glatiramer acetate (GA) is a random sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) at a molar ratio of A:K:E:Y of 4.5:3.6:1.5:1) with an average length of 40–100 amino acids. Directly labeled GA binds efficiently to different murine H2 I-A molecules, as well as to their human counterparts, the MHC class II DR molecules, but does not bind MHC class II DQ or MHC class I molecules *in vitro*. In clinical trials,

GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by ~30%. *In vivo* administration of GA induces highly cross-reactive CD4⁺ T cells that are immune-deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by MRI. This represents one of the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the T-cell receptor complex.

For relapsing-remitting attacks and for secondary progressive MS, cyclophosphamide and the anthracenedione-derivative *mitoxantrone* (NOVATRONE) are used in patients refractory to other immunomodulators. These agents, used primarily for cancer chemotherapy, have significant toxicities (see Chapter 51). While cyclophosphamide in patients with MS may not be limited by an accumulated dose exposure, mitoxantrone can be tolerated only up to an accumulated dose of 100–140 mg/m². The utility of interferon therapy in patients with secondary progressive MS is unclear. In primary progressive MS, with no discrete attacks and less observed inflammation, suppression of inflammation seems to be less helpful. A minority of patients at this stage will respond to high doses of glucocorticoids. Table 52–3 summarizes immunomodulatory therapies for MS.

Each agent has adverse effects and contraindications that may be limiting: infections (for glucocorticoids); hypersensitivity and pregnancy (for immunomodulators); and prior anthracycline/anthracenedione use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, it is clear that the earlier they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes the more severe form of disability.

SECTION XI

DRUGS ACTING ON THE BLOOD AND THE BLOOD-FORMING ORGANS

53

HEMATOPOIETIC AGENTS

Growth Factors, Minerals, and Vitamins

The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase >20-fold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase 10–20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the nine distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. A number of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematological diseases to use as adjuncts in the treatment of severe infections and in the management of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (*e.g.*, iron, cobalt, and copper) and vitamins (*e.g.*, folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin), and deficiencies generally result in characteristic anemias, or, less frequently, a general failure of hematopoiesis. Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state and knowledge about the correct dose, the use of these agents in various combinations, and the expected response.

I. HEMATOPOIETIC GROWTH FACTORS

GROWTH FACTOR PHYSIOLOGY Steady-state hematopoiesis encompasses the production of more than 400 billion blood cells each day. This production is tightly regulated and can be increased severalfold with increased demand. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells (*see* Figure 53–1).

Stem cell differentiation involves a series of steps that produce so-called burst-forming units (BFU) and colony-forming units (CFU) for each of the major cell lines. Colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating >1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and also stimulate production of additional growth factors, a process called *networking*. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia.

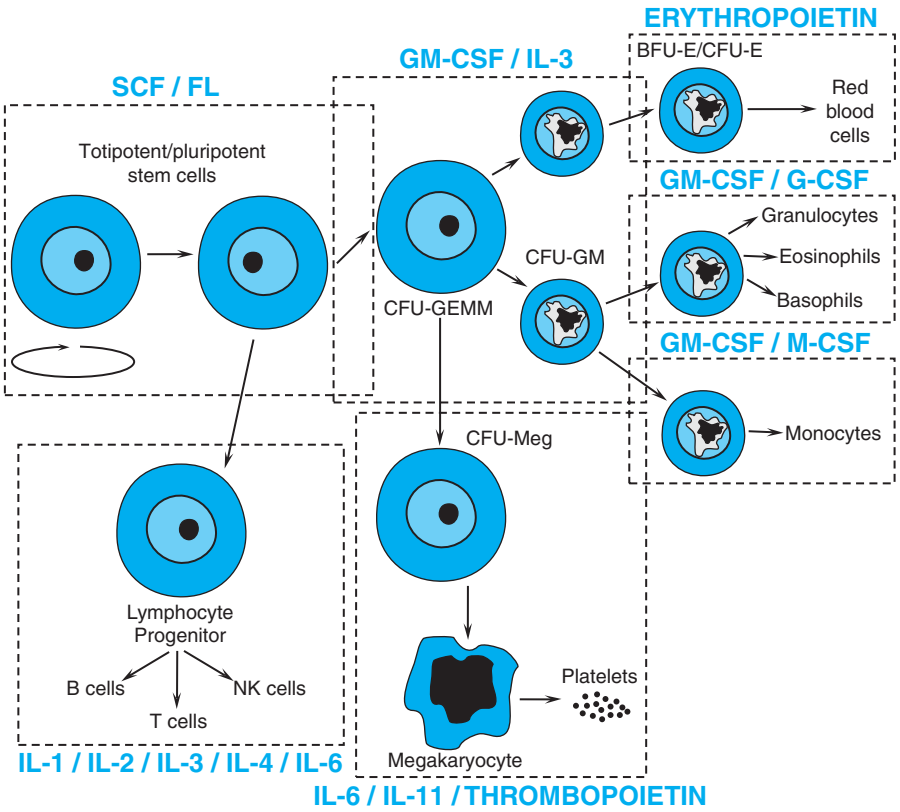

FIGURE 53-1 Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), ligand (FL), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF), together with cell-cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM (granulocyte, erythrocyte, monocyte and megakaryocyte), CFU-GM (granulocyte and macrophage), CFU-Meg (megakaryocyte), BFU-E (erythrocyte), and CFU-E (erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function of the derivative cell line.

ERYTHROPOIETIN

While not the sole growth factor responsible for erythropoiesis, erythropoietin is the most important regulator of the proliferation of committed progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia invariably results. Erythropoiesis is controlled by a highly responsive feedback system in which a sensor in the kidney detects changes in O₂ delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level. Hypoxia-inducible factor (HIF-1) is a heterodimeric (HIF-1 α and HIF-1 β) transcription factor that enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1 α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1 α and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an O₂-sensing defect, characterized by constitutively elevated levels of HIF-1 α and erythropoietin, with a resultant polycythemia. Erythropoietin is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, the first 27 of which are

cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of ~30,000 Da. After secretion, erythropoietin binds to a membrane receptor on committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramatically stimulated. This feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or inflammation, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin.

Recombinant human erythropoietin (*epoetin alfa*) is nearly identical to the endogenous hormone. The carbohydrate modification pattern of the recombinant form differs slightly from that of the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. However, modern assays can detect these differences, which is of significance for detecting athletes who use the recombinant product for “blood doping.”

Available preparations of epoetin alfa include EPOGEN, PROCIT, and EXPREX, supplied in single-use vials of from 2000 to 40000 U/mL for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a $t_{1/2}$ of 4–8 hours. However, the effect on marrow progenitors is sufficiently sustained that it need only be given three times a week to achieve an adequate response. Combination of the weekly dose into a single injection also can achieve virtually identical results. No significant allergic reactions have been associated with the intravenous or subcutaneous administration of epoetin alfa, and—except as noted below—antibodies have not been detected even after prolonged administration.

More recently, novel erythropoiesis-stimulating protein (NESP) or darbepoetin alfa (ARANESP) also has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which four amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to ~24 hours.

THERAPEUTIC USES, MONITORING, AND ADVERSE EFFECTS

Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a poor erythropoietic response. There is a clear dose-response relationship between the epoetin alfa dose and the rise in hematocrit in anephric patients. Epoetin alfa is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also is approved for use in patients with anemia associated with chronic kidney disease and is under review for several other indications.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Virtually all patients eventually will require supplemental iron to increase or maintain transferrin saturation to levels that will adequately support stimulated erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is <100 µg/L or whose serum transferrin saturation is <20% (see below).

During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range (establishing the maintenance dose); the hematocrit then is monitored at regular intervals. If the hematocrit increases by more than 4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte $t_{1/2}$, hematocrit changes lag behind dosage adjustments by 2–6 weeks. The dose of darbepoetin should be decreased if the hemoglobin (Hb) increase exceeds 1 g/dL in any 2-week period because of the association of excessive rate of rise of Hb with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. Serious thromboembolic events have been reported, including migratory thrombophlebitis, microvascular thrombosis, pulmonary embolism, and thrombosis of the retinal artery and temporal and renal veins. Because the higher risk of cardiovascular events from erythropoietic therapies may be associated with higher Hb, the dose should be adjusted to avoid exceeding an Hb level of 12 g/dL. Although epoetin alfa is not associated with direct pressor effects, blood pressure may rise during the early phases of therapy. Erythropoietins should be withheld in patients with preexisting uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred

in chronic renal failure patients treated with epoetin alfa. The incidence of seizures appears to be higher during the first 90 days of therapy with epoetin alfa in patients on dialysis (occurring in ~2.5% of patients) when compared with subsequent 90-day periods. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, arthralgias, and myalgias also have been reported in conjunction with epoetin alfa therapy. Pure red cell aplasia in association with neutralizing antibodies to native erythropoietin has been observed in patients treated with recombinant erythropoietins. Other causes of failure to respond to erythropoietin include underlying infectious, inflammatory, or malignant processes; occult blood loss; underlying hematologic diseases (e.g., thalassemia, refractory anemia, or other myelodysplastic disorders); folic acid or vitamin B₁₂ deficiency; hemolysis; aluminum intoxication; bone marrow fibrosis; and osteitis fibrosa cystica.

Anemia of Chronic Renal Failure

Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of renal failure, the erythropoietin dose and route of administration, and iron availability. Subcutaneous administration is preferred because absorption is slower and the amount of drug required is reduced by 20–40%.

The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2–4-month period to a final Hb of 11–12 g/dL. Treatment to a Hb level >13 g/dL showed a higher incidence of myocardial infarction and death. The drug should not be used to replace emergency transfusion in patients who need immediate correction of a life-threatening anemia.

Patients are started on doses of 80–120 U/kg of epoetin alfa, given subcutaneously, 3 times/week. It can be given on a once-a-week schedule, but somewhat more drug is required for an equivalent effect. If the response is poor, the dose should be progressively increased. The final maintenance dose of epoetin alfa can vary from as little as 10 units/kg to more than 300 units/kg, with an average dose of 75 units/kg, 3 times/week. Children younger than 5 years generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism.

The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20–30% of patients and most often is associated with a rapid rise in hematocrit. Blood pressure usually can be controlled either by increasing antihypertensive therapy or ultrafiltration in dialysis patients or by reducing the epoetin alfa dose to slow the hematocrit response.

Darbepoetin alfa also is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 µg/kg administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in Hb concentration; a rise of less than 1 g/dL every 2 weeks generally is considered safe.

Anemia in AIDS Patients

Epoetin alfa therapy is approved for the treatment of HIV-infected patients, especially those on zidovudine therapy. Excellent responses to doses of 100–300 U/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia.

Cancer-Related Anemias

Epoetin alfa therapy, 150 U/kg 3 times/week or 450–600 U/kg once a week, can reduce the transfusion requirement in cancer patients undergoing chemotherapy when Hb levels fall below 10 g/dL. For anemia associated with hematologic malignancies, recombinant erythropoietin is useful in patients with low-grade myelodysplastic syndrome. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels of more than 500 U/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experienced an improvement in their anemia, sense of well being, and quality of life. This improved sense of well being, particularly in cancer patients, may not be solely due to the rise in the hematocrit.

Case reports have suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells, a possibility that is being evaluated by the U.S. Food and Drug Administration (FDA) and warrants serious attention.

Surgery

Epoetin alfa has been used perioperatively to treat anemia and reduce the need for transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150–300

U/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. This can correct a moderately severe preoperative anemia (i.e., hematocrit 30–36%) and reduce the need for transfusion.

MYELOID GROWTH FACTORS

The myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 53–1). They are active at extremely low concentrations and act *via* membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway.

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)

Recombinant human GM-CSF (*sargramostim*) is a 127–amino acid glycoprotein produced in yeast. Except for the substitution of a Leu in position 23 and variable levels of glycosylation, sargramostim is identical to endogenous human GM-CSF. Sargramostim's primary therapeutic effect is to stimulate myelopoiesis. The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process.

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD), and studies have failed to show a significant effect on transplant mortality, long-term survival, the appearance of GVHD, or disease relapse. However, it may improve survival in transplant patients who exhibit early graft failure. It also has been used to mobilize CD34⁺ progenitor cells for peripheral blood stem cell (PBSC) collection for transplantation after myeloablative chemotherapy. Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy. It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim (LEUKINE) is administered by subcutaneous injection or slow intravenous infusion at doses of 125–500 µg/m²/day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a $t_{1/2}$ of 2–3 hours. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7–10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2–10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, while monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. Higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. Sensitive patients exhibit an acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial O₂ saturation due to granulocyte sequestration in the pulmonary circulation. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmias, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF)

Recombinant human G-CSF (*filgrastim* (NEUPOGEN)) is a 175–amino acid glycoprotein produced in *Escherichia coli*. Unlike natural G-CSF, it is not glycosylated and carries an extra N-terminal Met. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (Figure 53–2). It also enhances the phagocytic and cytotoxic functions of neutrophils.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy. Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. When used as a part of an intensive chemotherapy regimen, it can decrease the frequency of hospitalization for febrile neutropenia and interruptions in the chemotherapy protocol; a positive impact on survival has not been demonstrated. G-CSF also is effective in the treatment of severe congenital neutropenias. In patients with cyclic neutropenia, G-CSF therapy will increase the level of neutrophils and shorten the length of the cycle sufficiently to prevent recurrent bacterial infections. Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or

FIGURE 53-2 Cytokine–cell interactions. Macrophages, T cells, B cells, and marrow stem cells interact via several cytokines (IL-1, IL-2, IL-3, IL-4, IFN [interferon]- γ , GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge.

marrow damage (e.g., moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed. Filgrastim is routinely used in patients undergoing PBSC collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. Moreover, filgrastim-mobilized PBSCs appear more capable of rapid engraftment. PBSC-transplanted patients require fewer days of platelet and red blood cell transfusions and a shorter duration of hospitalization than do patients receiving autologous bone marrow transplants.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 minutes at doses of 1–20 $\mu\text{g}/\text{kg}/\text{day}$. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 $\mu\text{g}/\text{kg}/\text{day}$. The distribution and clearance rate from plasma ($t_{1/2}$ ~3.5 hours) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer chemotherapy increases granulocyte production and shortens the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14–21 days or longer may be necessary to correct the neutropenia. With less intensive chemotherapy, fewer than 7 days of treatment may suffice. In AIDS patients on zidovudine or patients with cyclic neutropenia, chronic G-CSF therapy often is required.

*Adverse reactions to filgrastim include mild-to-moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *E. coli* should not receive the drug. Marked granulocytosis, with counts >100,000/ μL , can occur in patients receiving filgrastim over a prolonged period of time. Mild-to-moderate splenomegaly has been observed in patients on long-term therapy.*

Pegylated recombinant human G-CSF *pegfilgrastim* (NEULASTA) is generated by conjugation of a polyethylene glycol moiety (20 kDa) to the N-terminal Met residue of the G-CSF glycoprotein produced in *E. coli*. The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating $t_{1/2}$ of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing. The recommended dose for pegfilgrastim is 6 mg administered subcutaneously.

THROMBOPOIETIC GROWTH FACTORS

INTERLEUKIN-11 Interleukin-11 is a 23 kDa cytokine that stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 enhances megakaryocyte maturation.

Recombinant human interleukin-11 *oprelvekin* (NEUMEGA) is a bacterially derived, 19 kDa polypeptide that lacks the amino terminal Pro residue and is not glycosylated. The recombinant protein has a 7-hour $t_{1/2}$ after subcutaneous injection. In normal subjects, daily administration of oprelvekin leads to a thrombopoietic response in 5–9 days.

The drug is administered at 25–50 $\mu\text{g}/\text{kg}/\text{day}$ subcutaneously. Oprelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies who display severe thrombocytopenia (platelet count $<20,000/\mu\text{L}$) on a prior cycle of the same chemotherapy and is administered until the platelet count is $>100,000/\mu\text{L}$. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Fluid retention reverses upon drug discontinuation, but volume status should be carefully monitored in elderly patients, those with a history of heart failure, or those with preexisting pleural or pericardial effusions or ascites. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

THROMBOPOIETIN Thrombopoietin is a glycoprotein (45–75 kDa, 332 amino acids) produced by the liver, marrow stromal cells, and many other organs and is the primary regulator of platelet production. Two forms of recombinant thrombopoietin have been developed. One is a truncated version of the native polypeptide, termed recombinant *human megakaryocyte growth and development factor* (rHuMGDF), covalently modified with polyethylene glycol to increase the circulatory $t_{1/2}$. The second is the full-length polypeptide termed *recombinant human thrombopoietin* (rHuTPO).

Results with these agents have been mixed. In cancer patients, recombinant human thrombopoietin therapy has reduced the duration of severe thrombocytopenia and the need for platelet transfusions. On the other hand, in patients treated for 7 days with standard therapy for acute leukemia, the addition of recombinant thrombopoietin failed to accelerate platelet recovery.

II. DRUGS EFFECTIVE IN IRON DEFICIENCY AND OTHER HYPOCHROMIC ANEMIAS

IRON AND IRON SALTS

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. Iron is an essential component of myoglobin; heme enzymes such as the cytochromes, catalase, and peroxidase; and the metalloflavoprotein enzymes, including xanthine oxidase and the mitochondrial enzyme α -glycerophosphate oxidase. Iron deficiency can affect metabolism in muscle independent of the effect of anemia on O_2 delivery, possibly due to a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and impaired heat production.

METABOLISM OF IRON The body store of iron (Table 53–1) is divided between essential iron-containing compounds and excess iron, which is held in storage. Hb (molecular weight, 64,500), contains 4 atoms of iron/molecule, amounting to 1.1 mg of iron/milliliter of red blood cells. Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin has a molecular weight of ~ 450 and is composed of 24 polypeptide subunits that

Table 53–1

<i>Total</i>	$\frac{13}{50}$	$\frac{4}{37}$

form an outer shell that surrounds a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as *hemosiderin* and visible by light microscopy, constitute about one-third of normal stores.

The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes.

Internal exchange of iron is accomplished by the plasma protein transferrin. This 76 kDa β_1 -glycoprotein has 2 binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron–transferrin complex binds to the receptor, and the ternary complex is taken up by receptor-mediated endocytosis. Iron subsequently dissociates in the acidic, intracellular vesicular compartment (the endosomes), and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment. Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply. Apoferritin synthesis is regulated post-transcriptionally by 2 cytoplasmic binding proteins (IRP-1 and IRP-2) and an iron-regulating element on its mRNA (IRE).

The flow of iron through the plasma is 30–40 mg/day in the adult (about 0.46 mg/kg of body weight). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 53–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for ~120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. With abnormalities in erythrocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed *ineffective erythropoiesis*. The rate of iron turnover in plasma may be reduced by one-half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

A remarkable feature of iron metabolism is the degree to which body stores are conserved. Only 10% of the total is lost per year by normal men, *i.e.*, ~1 mg/day. Two-thirds of this iron is excreted from the GI tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal

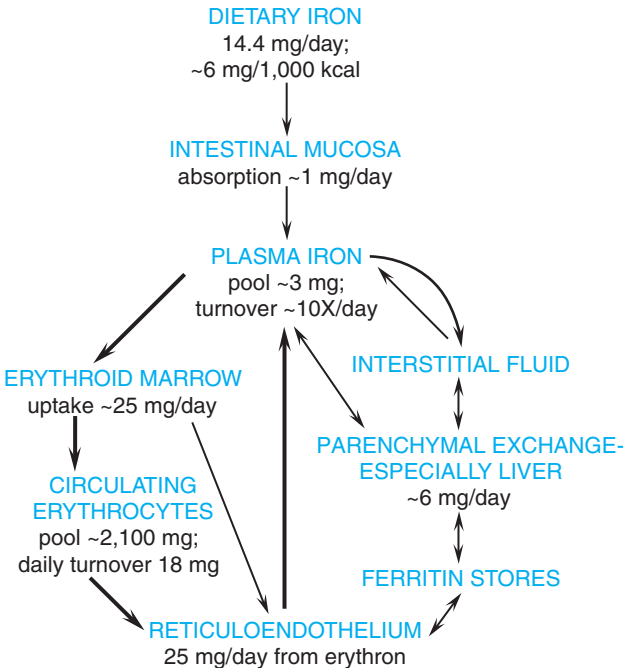

FIGURE 53–3 Pathways of iron metabolism in human beings (excretion omitted).

cells. The other third includes small amounts of iron in desquamated skin and in the urine. Additional losses of iron occur in women due to menstruation; pregnancy and lactation impose even greater requirements (Table 53-2). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding.

IRON REQUIREMENTS AND THE AVAILABILITY OF DIETARY IRON Iron requirements are determined by obligatory physiological losses and the needs imposed by growth. Thus, adult men require only 13 $\mu\text{g}/\text{kg}/\text{day}$ (~ 1 mg of iron), whereas menstruating women require ~ 21 $\mu\text{g}/\text{kg}/\text{day}$ (~ 1.4 mg). In the last two trimesters of pregnancy, requirements increase to ~ 80 $\mu\text{g}/\text{kg}/\text{day}$ (5–6 mg), and infants have similar requirements due to their rapid growth. These requirements (Table 53-3) must be considered in the context of the amount of dietary iron available for absorption.

In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added when food is cooked in iron pots.

Although the iron content of the diet is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it represents 30% of iron absorbed.

The nonheme fraction represents by far the largest amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. Ascorbate forms complexes with and/or reduces ferric to ferrous iron. Meat facilitates the absorption of iron by stimulating production of gastric

Table 53-3

Daily Iron Intake and Absorption

Subject	Iron Requirement, mg/kg	Available Iron in Poor Diet–Good Diet, mg/kg	Safety Factor, available iron/requirement
Infant	67	33–66	0.5–1
Child	22	48–96	2–4
Adolescent (male)	21	30–60	1.5–3
Adolescent (female)	20	30–60	1.5–3
Adult (male)	13	26–52	2–4
Adult (female)	21	18–36	1–2

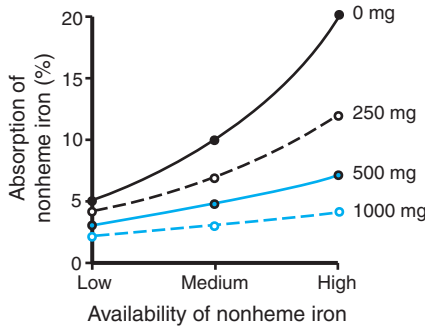

FIGURE 53-4 Effect of iron status on the absorption of nonheme iron in food. The percentages of iron absorbed from diets of low, medium, and high bioavailability in individuals with iron stores of 0, 250, 500, and 1000 mg are portrayed.

acid; other effects also may be involved. Thus, assessment of available dietary iron should include both the amount of iron ingested and an estimate of its availability (Figure 53-4).

IRON DEFICIENCY Iron deficiency is the most common nutritional disorder, and leads to progressive changes in erythropoiesis that are outlined in Figure 53-5. The prevalence of iron-deficiency anemia in the U.S. is 1-4%, depending on the economic status of the population. In developing countries, up to 20-40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption. Most nutritional iron deficiency in the U.S. is mild. More severe iron deficiency is usually the result of blood loss, either from the GI tract, or in women, from the uterus. Impaired absorption of iron from food results most often from partial gastrectomy or malabsorption in the small intestine. Finally, erythropoietin therapy can result in a functional iron deficiency.

	Normal	Iron Depletion	Iron-Deficient Erythropoiesis	Iron-Deficiency Anemia
Iron Stores				
Erythron Iron

FIGURE 53-5 Sequential changes (from left to right) in the development of iron deficiency in the adult. Rectangles enclose abnormal test results that identify the stage of Fe-deficiency. RE marrow Fe, reticuloendothelial hemosiderin; RBC, red blood cells.

Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, effects that may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birth-weight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After age 2–3, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11–18 is insufficient to meet their requirements.

Treatment of Iron Deficiency

GENERAL THERAPEUTIC PRINCIPLES The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient's ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption, and with increasing doses of oral iron, limits iron uptake. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with a moderately severe iron-deficiency anemia, tolerable doses of oral iron will deliver, at most, 40–60 mg of iron/day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Complicating illness also can interfere with the response of an iron-deficiency anemia to iron therapy. By decreasing the number of red cell precursors, intrinsic disease of the marrow can blunt the response. Inflammatory illnesses suppress the rate of red cell production, both by reducing iron absorption and reticuloendothelial release and by direct inhibition of erythropoietin and erythroid precursors. Continued blood loss can mask the response as measured by recovery of the Hb or hematocrit.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the Hb or the hematocrit. An increase in the reticulocyte count is not observed for at least 4–7 days after beginning therapy. An increase in the Hb level takes even longer. A decision as to the effectiveness of treatment should not be made until 3–4 weeks after the start of treatment, when an increase in the Hb concentration (2 g/dL is considered a positive response, assuming that no other change in the patient's clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient's ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3–4 weeks if a favorable response has not occurred.

THERAPY WITH ORAL IRON Orally administered *ferrous sulfate* is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts, and the discrepancy increases at high dosages. Variations in the particular ferrous salt have relatively little effect on bioavailability.

Ferrous sulfate (FEOSOL, others) is the hydrated salt, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, which contains 20% iron. Ferrous fumarate (FEOSTAT, others) contains 33% iron and is moderately soluble in water, stable, and almost tasteless. Ferrous gluconate (FERGON, others), which contains 12% iron, also is used in the therapy of iron-deficiency anemia. Polysaccharide-iron complex (NIFEREX, others), a compound of ferrihydrite and carbohydrate, has comparable absorption. The effective dose of these preparations is based on iron content.

The average dose for the treatment of iron-deficiency anemia is about 200 mg of iron/day (2–3 mg/kg/day), given in three equal doses of 65 mg. Children weighing 15–30 kg can take half the average adult dose, while small children and infants can tolerate relatively large doses of iron (e.g., 5 mg/kg). The dose used is a compromise between the desired therapeutic action and the adverse effects. Prophylaxis and mild nutritional iron deficiency may be managed with modest doses. When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15–30 mg of iron/day are adequate to meet the 3–6 mg daily requirement of the last 2 trimesters.

Table 53-4

Average Response to Oral Iron

Total Dose (mg Fe/day)	Estimated Absorption		Increase in Hemoglobin (g/L of blood/day)
	%	mg	
35	40	14	0.7
105	24	25	1.4
195	18	35	1.9
390	12	45	2.2

When the purpose is to treat iron-deficiency anemia, but the circumstances do not demand haste, a total dose of about 100 mg (35 mg three times daily) may suffice.

The responses expected for different dosage regimens of oral iron are given in Table 53-4. These effects are modified by the severity of the iron-deficiency anemia and by the time of ingestion of iron relative to meals. Bioavailability of iron ingested with food is probably 33–50% of that seen in the fasting subject. Antacids also reduce iron absorption if given concurrently. It is always preferable to administer iron in the fasting state, even if the dose must be reduced because of GI side effects. For patients who require maximal therapy to encourage a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day. Sustained high rates of red cell production require an uninterrupted supply of iron, and oral doses should be spaced equally to maintain a continuous high concentration of iron in plasma.

The duration of treatment is governed by the rate of recovery of Hb and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 0.2 g of Hb/dL of whole blood, the red cell mass usually is reconstituted within 1–2 months. Thus, an individual with an Hb of 5 g/dL may achieve a normal complement of 15 g/dL in about 50 days, whereas an individual with an Hb of 10 g/dL may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3–4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the Hb has returned to normal. With continued bleeding, long-term therapy clearly is indicated.

UNTOWARD EFFECTS OF ORAL PREPARATIONS OF IRON Intolerance to oral preparations of iron primarily is a function of the amount of soluble iron in the upper GI tract and of psychological factors. Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, to demonstrate freedom from symptoms at that level, and then gradually to increase the dosage to that desired. With a dose of 200 mg of iron per day divided into three equal portions, symptoms occur in ~25% of treated individuals versus 13% among those receiving placebo; this increases to ~40% when the dosage of iron is doubled. Nausea and upper abdominal pain are increasingly common at high dosage. Constipation and diarrhea, perhaps related to iron-induced changes in the intestinal bacterial flora, are not more prevalent at higher dosage, nor is heartburn. If a liquid is given, one can place the iron solution on the back of the tongue with a dropper to prevent transient staining of teeth.

Normal individuals apparently control absorption of iron despite high intake, and only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

IRON POISONING

Large amounts of ferrous salts are toxic, but fatalities in adults are rare. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1–2 g of iron may cause death, but 2–10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. All iron preparations should be kept in childproof bottles.

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude,

drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is $<63 \mu\text{m}$ (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of radio-opaque pills remaining in the small bowel. When the plasma concentration of iron exceeds the total iron-binding capacity ($63 \mu\text{m}$; 3.5 mg/L), deferoxamine should be administered (see Chapter 65). Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to ~1%.

THERAPY WITH PARENTERAL IRON When oral iron therapy fails, parenteral iron administration may be an effective alternative. Common indications are iron malabsorption (e.g., sprue, short bowel syndrome), severe intolerance of oral iron, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron also has been given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. *Parenteral iron therapy should be used only when clearly indicated, since acute hypersensitivity, including anaphylactic reactions, can occur.* The belief that the response to parenteral iron, especially iron dextran, is faster than oral iron is open to debate. In otherwise healthy individuals, the rate of Hb response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1–3 weeks. Subsequently, the response is no better than that seen with oral iron.

FDA-approved preparations for parenteral therapy include sodium ferric gluconate complex in sucrose (FERRELECIT), iron sucrose (VENOFER), and iron dextran (INFED, DEXFERRUM). Unlike iron dextran, which requires macrophage processing that may require several weeks, ~80% of sodium ferric gluconate is delivered to transferrin with 24 hours. Sodium ferric gluconate has a much lower risk of serious anaphylactic reactions than iron dextran.

Iron dextran injection (INFED, DEXFERRUM) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight ~180 kDa) that contains 50 mg/mL of elemental iron. It can be administered by either intravenous (preferred) or intramuscular injection. When given by deep intramuscular injection, it is gradually mobilized via the lymphatics and transported to reticuloendothelial cells; the iron then is released from the dextran complex. Intravenous administration gives a more reliable response. Given intravenously in a dose of less than 500 mg, the iron dextran complex is cleared with a plasma $t_{1/2}$ of 6 hours. When 1 g or more is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10–20 mg/h. This slow rate of clearance results in a brownish discoloration of the plasma for several days and an elevation of the serum iron for 1–2 weeks.

Intramuscular injection of iron dextran should only be initiated after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing less than 4.5 kg (10 lb), 1 mL (50 mg of iron) for children weighing less than 9 kg (20 lb), and 2 mL (100 mg of iron) for other patients. Iron dextran should be injected only into the muscle mass of the upper outer quadrant of the buttock using a z-track technique (displacement of the skin laterally before injection).

A test injection of 0.5 mL of undiluted iron dextran or an equivalent amount (25 mg of iron) diluted in saline also should precede intravenous administration of a therapeutic dose of iron dextran. The patient should be observed for signs of immediate anaphylaxis, and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. When widely spaced, total-dose infusion therapy is given, a test dose injection should be given before each infusion because hypersensitivity can appear at any time. The patient should be monitored closely throughout the infusion for signs of cardiovascular instability. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Therefore, iron dextran should be used with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

When hemodialysis patients are started on erythropoietin, oral iron therapy alone generally is insufficient to guarantee an optimal Hb response. It therefore is recommended that sufficient parenteral iron be given to maintain a plasma ferritin level between 100 and 800 $\mu\text{g/L}$ and a transferrin saturation of 20–50%. One approach is to administer an initial intravenous dose of 200–500 mg, followed by weekly or every-other-week injections of 25–100 mg of iron dextran to replace ongoing blood loss. With repeated doses of iron dextran—especially multiple, total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss—accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. While disease-related hemochromatosis has been associated with an increased risk of infections and cardiovascular disease, this has not been shown to be true in hemodialysis patients treated with iron dextran. It seems prudent, however, to withhold the drug if the plasma ferritin exceeds 800 $\mu\text{g/L}$.

Reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease. Phlebitis may occur with prolonged infusions of a concentrated solution or when an intramuscular preparation containing 0.5% phenol is used in error. Of greatest concern is the rare anaphylactic reaction, which may be fatal despite treatment.

COPPER

Copper deficiency is extremely rare, and there is no evidence that copper ever need be added to a normal diet. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc. While an inherited disorder affecting copper transport (Menkes' disease) is associated with reduced activity of several copper-dependent enzymes, this disease is not associated with hematological abnormalities.

The outstanding findings in copper deficiency are leukopenia, particularly granulocytopenia, and anemia; the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of *cupric sulfate* have been given by mouth, or 1–2 mg/day may be added to the solution of nutrients for parenteral administration.

PYRIDOXINE

Patients with sideroblastic anemia characteristically have impaired Hb synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursors, so-called ringed sideroblasts. Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs *isoniazid* and *pyrazinamide*, which act as vitamin B₆ antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine pyridoxine supplementation is recommended (see Chapter 47). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson's disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead. Patients with idiopathic-acquired sideroblastic anemia generally fail to respond to oral pyridoxine; those few individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50–500 mg/day.

III. VITAMIN B₁₂, FOLIC ACID, AND THE TREATMENT OF MEGALOBlastic ANEMIAS

Vitamin B₁₂ and *folic acid* are essential vitamins; the deficiency of either impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Since tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

RELATIONSHIPS BETWEEN VITAMIN B₁₂ AND FOLIC ACID The major roles of vitamin B₁₂ and folic acid in intracellular metabolism are summarized in Figure 53–6. Intracellular vitamin B₁₂ is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Deoxyadenosylcobalamin (deoxyadenosyl B₁₂) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of L-methylmalonyl CoA to succinyl CoA, an important

FIGURE 53-6 Interrelationships and metabolic roles of vitamin B_{12} and folic acid. See text for explanation and Figure 53-9 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II; $\text{CH}_3\text{H}_4\text{PteGlu}_1$, methyltetrahydrofolate.

reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate. In contrast, methylcobalamin (CH_3B_{12}) supports the methionine synthetase reaction, which is essential for normal metabolism of folate. Methyl groups contributed by methyltetrahydrofolate ($\text{CH}_3\text{H}_4\text{PteGlu}_1$) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate–cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product, *S*-adenosylmethionine (SAM), the maintenance of a number of methylation reactions.

Since methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate ($\text{H}_4\text{PteGlu}_1$), the substrate for a number of metabolic steps. Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of Ser to Gly, with the resultant formation of 5,10-methylenetetrahydrofolate ($5,10\text{-CH}_2\text{H}_4\text{PteGlu}$). The latter derivative donates the methylene group to deoxyuridylylate (dUMP) for the synthesis of thymidylate (dTMP)—an extremely important reaction in DNA synthesis. In the process, the $5,10\text{-CH}_2\text{H}_4\text{PteGlu}$ is converted to dihydrofolate (H_2PteGlu). The cycle then is completed by the reduction of the H_2PteGlu to H_4PteGlu by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 51). As shown in Figure 53-6, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines.

Deficiency of either vitamin B_{12} or folate decreases the synthesis of methionine and SAM, thereby interfering with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B_{12} deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 53-6). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B_{12} to accept and transfer methyl groups, and subsequent steps in folate metabolism

that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B₁₂ or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B₁₂ deficiency are less well understood. Damage to the myelin sheath is the most striking lesion in this neuropathy; this observation led to the early suggestion that the deoxyadenosyl B₁₂-dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to SAM are more likely to be responsible.

VITAMIN B₁₂

CHEMISTRY

Vitamin B₁₂ (Figure 53-7) contains three major portions: a planar group or corrin nucleus—a porphyrin-like ring structure with four reduced pyrrole rings (A to D in Figure 53-7) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues; a 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the corrin nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring; and a variable R group—the most important of which are found in cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin. The terms vitamin B₁₂ and cyanocobalamin are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin, since only these derivatives remain active after storage.

Vitamin B ₁₂ Congeners	
Permissive Name	R Group
Cyanocobalamin (Vitamin B ₁₂)	-CN
Hydroxocobalamin	-OH
Methylcobalamin	-CH ₃
5'-Deoxyadenosylcobalamin	-5'-Deoxyadenosyl

FIGURE 53-7 The structures and nomenclature of vitamin B₁₂ congeners.

METABOLIC FUNCTIONS The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative, *SAM*. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate, causing a functional deficiency of other required intracellular forms of folic acid (see Figures 53–6 and 53–7 and discussion above). The hematological abnormalities in vitamin B₁₂-deficient patients result from this process. 5-Deoxyadenosylcobalamin is required for the isomerization of L-methylmalonyl CoA to succinyl CoA (Figure 53–6).

SOURCES IN NATURE Humans depend on exogenous sources of vitamin B₁₂. Vegetables are free of vitamin B₁₂ unless they are contaminated with microorganisms, so that we depend on synthesis in our own alimentary tract or the ingestion of animal products containing vitamin B₁₂. The daily nutritional requirement of 3–5 μg must be obtained from animal by-products in the diet. Despite this, strict vegetarians rarely develop vitamin B₁₂ deficiency, probably because some vitamin B₁₂ is available from legumes and because they often fortify their diets with vitamins and minerals.

ABSORPTION, DISTRIBUTION, ELIMINATION, AND DAILY REQUIREMENTS In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from food and bound to gastric intrinsic factor. When the vitamin B₁₂-intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Adequate intrinsic factor, bile, and sodium bicarbonate (to provide a suitable pH) all are required for ileal transport of vitamin B₁₂. Vitamin B₁₂ deficiency in adults rarely results from a deficient diet *per se*; rather, it usually reflects a defect in one or another aspect of this sequence of absorption (Figure 53–8). Achlorhydria and decreased secretion of intrinsic factor by parietal cells secondary to gastric atrophy or gastric surgery is a common cause of vitamin B₁₂ deficiency in adults. Antibodies to parietal cells or intrinsic factor complex also can play a prominent role. A number of intestinal diseases can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Once absorbed, vitamin B₁₂ binds to transcobalamin II, a plasma β-globulin, for transport to tissues. Two other transcobalamins (I and III) also are present in plasma; their concentrations are related to the rate of turnover of granulocytes. They may represent intracellular storage proteins that

FIGURE 53–8 The absorption and distribution of vitamin B₁₂. Deficiency of vitamin B₁₂ can result from a congenital or acquired defect in any one of the following: (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of transcobalamin II (TcII); or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B₁₂ excreted in bile. The utility of measurements of the concentration of vitamin B₁₂ in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of transcobalamins I and III (TcI and TcIII) in plasma. Finally, the formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as CH₃H₄PteGlu₁.

are released with cell death. Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells, which comprise a storage depot for other tissues. In normal adults, as much as 90% of the body's stores of vitamin B₁₂, from 1 to 10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5–8 μg/day, depending on the size of the body stores. The recommended daily intake of the vitamin in adults is 2.4 μg.

Approximately 3 μg of cobalamins is secreted into bile each day, 50–60% of which is not destined for reabsorption. This enterohepatic cycle is important because interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin. This process may help explain why patients can develop vitamin B₁₂ deficiency within 3–4 years of major gastric surgery, even though a daily requirement of 1–2 μg would not be expected to deplete hepatic stores of more than 2–3 mg during this time.

The supply of vitamin B₁₂ available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (Figure 53–8). The plasma concentration of vitamin B₁₂ normally ranges from 150 to 660 pmol (about 200–900 pg/mL), and deficiency should be suspected whenever the concentration is <150 pmol. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or myeloproliferative disorders. Because the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance.

Defects in intracellular metabolism of vitamin B₁₂ have been reported in children with methylmalonic aciduria and homocystinuria. Potential mechanisms include an inability of cells to transport vitamin B₁₂ or accumulate the vitamin because of a failure to synthesize an intracellular acceptor, a defect in the formation of deoxyadenosylcobalamin, or a congenital lack of methylmalonyl CoA isomerase.

VITAMIN B₁₂ DEFICIENCY Vitamin B₁₂ deficiency is recognized by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (*e.g.*, mucosa and cervical epithelium) also have high requirements for the vitamin.

As a result of an inadequate supply of vitamin B₁₂, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon known as *ineffective hematopoiesis*. Maturation of red cell precursors is highly abnormal (megaloblastic erythropoiesis). Those cells that do leave the marrow also are abnormal, and many cell fragments, poikilocytes, and macrocytes appear in the peripheral blood. The mean red cell volume increases to values greater than 110 fl. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin B₁₂ deficiency usually can be made using measurements of the serum vitamin B₁₂ and/or serum methylmalonic acid. The latter is somewhat more sensitive and has been used to identify metabolic deficiency in patients with normal serum vitamin B₁₂ levels. As part of the clinical management of a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red cell production. The Schilling test can be used to quantitate the absorption of the vitamin and delineate the mechanism of the deficiency. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal disease.

Vitamin B₁₂ deficiency can irreversibly damage the nervous system. Progressive swelling of myelinated neurons, demyelination, and neuronal cell death are seen in the spinal column and cerebral cortex. This causes a wide range of neurological manifestations, including paresthesias, decreased vibration and position senses with resultant unsteadiness, decreased deep tendon reflexes, and in the later stages, confusion, moodiness, loss of memory, and even a loss of central vision. The patient may exhibit delusions, hallucinations, or even overt psychosis. Since the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B₁₂ deficiency

must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic.

VITAMIN B₁₂ THERAPY Vitamin B₁₂ is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Although oral preparations may be used to supplement deficient diets, they are of limited value in the treatment of patients with deficiency of intrinsic factor or ileal disease. Even though small amounts of vitamin B₁₂ may be absorbed by simple diffusion, the oral route of administration cannot be relied upon for effective therapy in the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. Therefore, the treatment of choice for vitamin B₁₂-deficiency is cyanocobalamin administered by intramuscular or subcutaneous injection.

Effective use of vitamin B₁₂ depends on accurate diagnosis and an understanding of the following principles:

1. Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist. Dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine constitute such indications. When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
2. The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder. Full understanding of the etiology of vitamin B₁₂ deficiency involves studies of dietary supply, GI absorption, and transport.
3. Therapy always should be as specific as possible. While a large number of multivitamin preparations are available, the use of "shotgun" vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous. With such therapy, there is the danger that sufficient folic acid will be given to result in a hematological recovery, which can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.
4. Although a therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill, elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.
5. Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6–12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (*e.g.*, pregnancy), reassessment should be performed more frequently.

FOLIC ACID

CHEMISTRY AND METABOLIC FUNCTIONS

Pteroylglutamic acid (PteGlu) (Figure 53–9) contains a pteridine ring linked by a methylene bridge to para-aminobenzoic acid, which is joined by an amide linkage to glutamic acid. While pteroylglutamic acid is the common pharmaceutical form of folic acid, it is neither the principal folate congener in food nor the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 53–9. Each plays a specific role in intracellular metabolism (see "Relationships Between Vitamin B₁₂ and Folic Acid," above, as well as Figure 53–6)

Conversion of homocysteine to methionine. This reaction requires CH₃H₄PteGlu as a methyl donor and utilizes vitamin B₁₂ as a cofactor.

Conversion of serine to glycine. This reaction requires tetrahydrofolate as an acceptor of a methylene group from Ser and utilizes pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of thymidylate.

Synthesis of thymidylate. 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to deoxyuridylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.

Histidine metabolism. H₄PteGlu also acts as an acceptor of a formimino group in the conversion of formiminoglutamic acid to glutamic acid.

FIGURE 53-9 The structures and nomenclature of pteroylglutamic acid (folic acid) and its congeners. X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The subscript that designates the number of residues of glutamate is frequently omitted because this number is variable.

Synthesis of purines. Two steps in the synthesis of purine nucleotides require the participation of derivatives of folic acid. Glycinamide ribonucleotide is formylated by 5,10-CHH₄PteGlu; 5-aminoimidazole-4-carboxamide ribonucleotide is formylated by 10-CHOH₄PteGlu. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

Utilization or generation of formate. This reversible reaction utilizes H₄PteGlu and 10-CHOH₄PteGlu.

DAILY REQUIREMENTS Many food sources are rich in folates, especially green vegetables, liver, yeast, and some fruits, but lengthy cooking can destroy up to 90% of the folate content. Generally, a standard U.S. diet provides 50–500 μg of folate/day, although individuals with high intakes of fresh vegetables and meats may ingest as much as 2 mg/day. In the normal adult, the recommended daily intake is 400 μg, while pregnant or lactating women and patients with high rates of cell turnover (e.g., patients with hemolytic anemia) may require 500–600 μg/day or more. For prevention of neural tube defects, a daily intake of at least 400 μg of folate in food or in supplements, beginning a month before pregnancy and continued for at least the first trimester, is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine (see below).

ABSORPTION, DISTRIBUTION, AND ELIMINATION As with vitamin B₁₂, the diagnosis and management of folic acid deficiency depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 53-10). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a pteroylglutamyl carboxypeptidase associated with mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most or all of the reduced folate that is absorbed. Since most absorption occurs in the proximal small intestine, it is not unusual for folate deficiency to occur with jejunal disease. Both nontropical and tropical sprues are common causes of folate deficiency.

Once absorbed, folate is transported rapidly to tissues as CH₃H₄PteGlu. While certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogs; their role in folate homeostasis is not well understood. An increase in binding capacity is detected in folate deficiency and in certain disease states (e.g., uremia, cancer, and alcoholism).

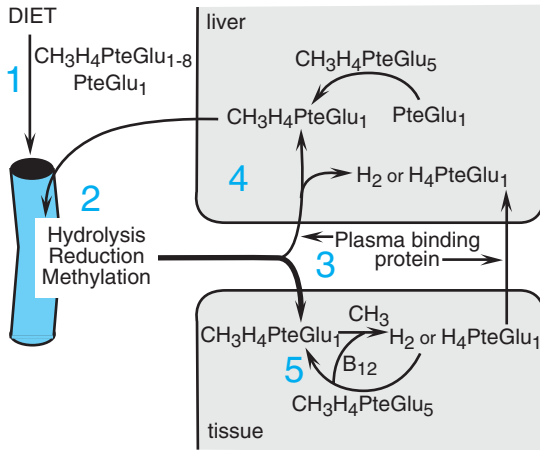

FIGURE 53–10 Absorption and distribution of folate derivatives. Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to $\text{CH}_3\text{H}_4\text{PteGlu}_1$ during GI transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease there may be defects in (3) the concentration of folate binding proteins in plasma and (4) the flow of $\text{CH}_3\text{H}_4\text{PteGlu}_1$ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B_{12} deficiency will (5) “trap” folate as $\text{CH}_3\text{H}_4\text{PteGlu}_1$, thereby, reducing the availability of $\text{H}_4\text{PteGlu}_1$ for its essential roles in purine and pyrimidine synthesis.

A constant supply of $\text{CH}_3\text{H}_4\text{PteGlu}_1$ is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H_2 or H_4PteGlu) and then transports the $\text{CH}_3\text{H}_4\text{PteGlu}_1$ into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide 200 μg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of $\text{CH}_3\text{H}_4\text{PteGlu}$ from hepatic parenchymal cells.

Following uptake into cells, $\text{CH}_3\text{H}_4\text{PteGlu}_1$ acts as a methyl donor for the formation of methylcobalamin and as a source of H_4PteGlu and other folate congeners. Folate is stored within cells as polyglutamates.

FOLATE DEFICIENCY Folate deficiency is a common complication of diseases of the small intestine, which interfere with the absorption of dietary folate and the recirculation of folate through the enterohepatic cycle. In acute or chronic alcoholism, daily intake of dietary folate may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis. However, it also is the most amenable to therapy, inasmuch as the reinstatement of a normal diet is sufficient to overcome the effect of alcohol. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (*e.g.*, methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (*e.g.*, certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia.

Folate deficiency has been implicated in neural tube defects, including spina bifida, encephaloceles, and anencephaly. This is true even in the absence of folate-deficient anemia or alcoholism. An inadequate intake of folate also can result in elevations in plasma homocysteine. Since even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention. Patients who are heterozygous for one or another enzymatic defect and have high normal to moderate elevations of plasma homocysteine may improve with folic acid therapy.

Folate deficiency is recognized by its impact on the hematopoietic system, again reflecting the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B₁₂ deficiency. This finding is to be expected because of the final common pathway of the major intracellular metabolic roles of the 2 vitamins. In contrast, folate deficiency is rarely if ever associated with neurological abnormalities, and the observation of characteristic abnormalities in vibratory and position sense and in motor and sensory pathways is incompatible with isolated folate deficiency.

After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B₁₂ absorption (*e.g.*, gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1–4 weeks, depending on the individual's dietary habits and stores of the vitamin.

GENERAL PRINCIPLES OF THERAPY The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy apply:

1. Prophylactic administration of folic acid should be undertaken for clear indications. Dietary supplementation is necessary when there is a requirement that may not be met by a "normal" diet. The daily ingestion of a multivitamin preparation containing 400–500 μg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breastfeeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg/day has been recommended. Patients on total parenteral nutrition should receive folic acid supplements because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (*e.g.*, hemolytic anemia) generally require larger doses, 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.
2. As with vitamin B₁₂ deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient's history of travel, and the function of the GI tract.
3. Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.
4. *The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind.* The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H₄PteGlu; this circumvents the methylfolate "trap." However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

BLOOD COAGULATION AND ANTICOAGULANT, THROMBOLYTIC, AND ANTIPLATELET DRUGS

OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel and then aggregate to form the primary hemostatic plug. Platelets stimulate local activation of plasma coagulation factors, leading to generation of a fibrin clot that reinforces the platelet aggregate. Later, as wound healing occurs, the platelet aggregate and fibrin clot are degraded. The processes of platelet aggregation and blood coagulation are summarized in Figures 54–1 and 54–2. The pathway of clot removal, fibrinolysis, is shown in Figure 54–3, along with sites of action of fibrinolytic agents.

Coagulation involves a series of zymogen activation reactions (Figure 54–2). At each stage, a precursor protein, or *zymogen*, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The components at each stage include a protease from the preceding stage, a zymogen, a nonenzymatic protein cofactor, Ca^{2+} , and an organizing surface provided by a phospholipid emulsion *in vitro* or by platelets *in vivo*. The final protease generated is thrombin (factor IIa).

INITIATION OF COAGULATION Coagulation is initiated *in vivo* by the extrinsic pathway. Small amounts of factor VIIa in the plasma bind to subendothelial tissue factor following vascular injury. Tissue factor accelerates activation of factor X by VIIa, phospholipids, and Ca^{2+} by ~30,000-fold. VIIa also can activate IX in the presence of tissue factor, providing a convergence between the extrinsic and intrinsic pathways.

Clotting by the intrinsic pathway is initiated *in vitro* when XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of XIIa. Activation of XI to XIa and IX to IXa follows. IXa then activates X in a reaction that is accelerated by VIIIa, phospholipids, and Ca^{2+} . Activation of factor X by IXa appears to occur by a mechanism similar to that for activation of prothrombin and may also be accelerated by platelets *in vivo*. Activation of factor XII is not required for hemostasis, since patients with deficiency of XII, prekallikrein, or high-molecular-weight kininogen do not bleed abnormally, even though their aPTT values (see below) are prolonged. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. The mechanism for activation of factor XI *in vivo* is not known, although thrombin activates factor XI *in vitro*.

Fibrinolysis and Thrombolysis

The fibrinolytic system dissolves intravascular clots as a result of the action of plasmin, an enzyme that digests fibrin. Plasminogen, an inactive precursor, is converted to plasmin by cleavage of a single peptide bond. Plasmin is a relatively nonspecific protease; it digests fibrin clots and other plasma proteins, including several coagulation factors. Therapy with thrombolytic drugs can dissolve both pathological thrombi and fibrin deposits at sites of vascular injury; thus, such drugs also may promote also hemorrhage.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds persists to maintain hemostasis. *Tissue plasminogen activator (t-PA)* is released from endothelial cells in response to various signals, including stasis produced by vascular occlusion. It is rapidly cleared from blood or inhibited by circulating inhibitors, plasminogen activator inhibitor-1 and plasminogen activator inhibitor-2, and thus exerts little effect on circulating plasminogen. t-PA binds to fibrin and converts plasminogen, which also binds to fibrin, to plasmin. Plasminogen and plasmin bind to fibrin at binding sites located near their amino termini that are rich in Lys residues (see below). These sites also are required for plasmin binding to the inhibitor α_2 -antiplasmin. Therefore, fibrin-bound plasmin is protected from inhibition. Any plasmin that escapes this local milieu is rapidly inhibited. Some α_2 -antiplasmin is bound covalently to fibrin and thereby protects fibrin from premature lysis. When plasminogen activators are administered for thrombolytic therapy, massive fibrinolysis is initiated, and the inhibitory controls are overwhelmed. The pathway of fibrinolysis and sites of drug action are summarized by Figure 54–3.

COAGULATION IN VITRO The time in which recalcified plasma will clot after addition of kaolin is termed the *activated partial thromboplastin time (aPTT)*; normal values are from

FIGURE 54-1 Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet membrane proteins that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP (adenosine diphosphate); when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and COX-1 to promote platelet aggregation and secretion. Thromboxane A₂ (TxA₂) is the major product of COX-1 involved in platelet activation. Prostacyclin (PGI₂) synthesized by endothelial cells inhibits platelet activation.

FIGURE 54-2 Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important *in vivo*. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals) and the rounded boxes represent the active proteases. TF, tissue factor; activated coagulation factors are followed by the letter “a.” II, prothrombin; IIa, thrombin.

FIGURE 54-3 Fibrinolysis. Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and cleaves plasminogen to plasmin, resulting in fibrin digestion. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α_2 -antiplasmin (α_2 -AP) inactivates plasmin.

26 to 33 seconds. Alternatively, the time required for recalcified plasma to clot after the addition of “thromboplastin” (a mixture of tissue factor and phospholipids) is termed the *prothrombin time* (PT); a normal value is from 12 to 14 seconds. Because of considerable variation in the performance of the PT, results typically are normalized to an international standard and reported as the “International Normalized Time”, or INR. Typically, the aPTT is used to follow anticoagulation with heparin, while the INR is used to monitor anticoagulation with oral anticoagulants (*see below*).

NATURAL ANTICOAGULANT MECHANISMS Platelet activation and coagulation normally do not occur within an intact blood vessel. Thrombosis is prevented by several regulatory mechanisms that require a normal vascular endothelium. Prostacyclin (prostaglandin I_2 ; PGI_2) is synthesized by endothelial cells and inhibits platelet aggregation and secretion (*see Chapter 25*). Antithrombin is a plasma protein that inhibits coagulation factors of the intrinsic and common pathways (*see below*). Heparan sulfate proteoglycans synthesized by endothelial cells stimulate the activity of antithrombin. Protein C is a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca^{2+} to γ -carboxyglutamate (Gla) residues within its amino-terminal domain. Activated protein C, in combination with its nonenzymatic Gla-containing cofactor (protein S), degrades cofactors Va and VIIIa and thereby greatly diminishes the activation of prothrombin and factor X. Protein C is activated by thrombin only in the presence of thrombomodulin, an integral membrane protein of endothelial cells. Like antithrombin, protein C exerts an anticoagulant effect in the vicinity of intact endothelial cells. Tissue factor pathway inhibitor (TFPI) is found in the lipoprotein fraction of plasma. When bound to factor Xa, TFPI inhibits factor Xa and the factor VIIa–tissue factor complex. By this mechanism, factor Xa may regulate its own production.

PARENTERAL ANTICOAGULANTS

Heparin

BIOCHEMISTRY Heparin is a glycosaminoglycan found in the secretory granules of mast cells. It is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues (Figure 54-4). About 10–15 glycosaminoglycan chains, each containing 200–300 monosaccharide units, are attached to a core protein and yield a proteoglycan of 750–1000 kDa. The glycosaminoglycan is modified to yield a variety of oligosaccharide structures. After the heparin proteoglycan has been transported to the mast cell granule, an endo- β -D-glucuronidase degrades the glycosaminoglycan chains to fragments of ~12,000 Da (~40 monosaccharide units) over a period of hours.

FIGURE 54-4 The antithrombin-binding structure of heparin. Sulfate groups required for binding to antithrombin are indicated in blue.

HEPARAN SULFATE

Heparan sulfate is synthesized from the same repeating disaccharide precursor (D-glucuronic acid linked to N-acetyl-D-glucosamine) as is heparin. However, heparan sulfate undergoes less modification of the polymer than does heparin and therefore contains higher proportions of glucuronic acid and N-acetylglucosamine and fewer sulfate groups. Heparan sulfate on the surface of vascular endothelial cells or in the subendothelial extracellular matrix interacts with circulating antithrombin (see below) to provide a natural antithrombotic mechanism.

SOURCE

Heparin is commonly extracted from porcine intestinal mucosa or bovine lung. Despite the heterogeneity in composition among different commercial preparations of heparin, their biological activities are similar (~150 USP units/mg). The USP unit is the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 hour after the addition of 0.2 mL of 1% CaCl_2 .

Low-molecular-weight heparins (~4500 Da, or 15 monosaccharide units) are isolated from standard heparin by gel filtration chromatography, precipitation with ethanol, or partial depolymerization with nitrous acid and other chemical or enzymatic reagents. Low-molecular-weight heparins differ from standard heparin and from each other in their pharmacokinetic properties and mechanism of action (see below). The biological activity of low-molecular-weight heparin is generally measured with a factor Xa inhibition assay, which is mediated by antithrombin.

MECHANISM OF ACTION Heparin catalyzes the inhibition of several coagulation proteases by antithrombin, a glycosylated, single-chain polypeptide (432 amino acids). Antithrombin is synthesized in the liver and circulates in plasma at an approximate concentration of 2.6 μM . It inhibits activated coagulation factors of the intrinsic and common pathways, including thrombin, Xa, and IXa; however, it has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg-Ser peptide bond in the reactive site of antithrombin and becomes trapped as a stable 1:1 complex.

Heparin increases the rate of the thrombin-antithrombin reaction at least 1000-fold by serving as a catalytic template to which both the inhibitor and the protease bind. Binding of heparin also induces a conformational change in antithrombin that makes the reactive site more accessible to the protease. Once thrombin has become bound to antithrombin, the heparin molecule is released from the complex. The binding site for antithrombin on heparin is a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 54-4). This structure occurs in ~30% of heparin molecules and less abundantly in heparan sulfate. Heparin molecules containing fewer than 18 monosaccharide units (<5400 Da) do not catalyze inhibition of thrombin by antithrombin, since they cannot bind thrombin and antithrombin simultaneously. In contrast, the pentasaccharide shown in Figure 54-4 catalyzes inhibition of factor Xa by antithrombin. In this case, catalysis may occur solely by induction of a conformational change in antithrombin that facilitates reaction with the protease. Low-molecular-weight heparin preparations produce an anticoagulant effect mainly through inhibition of Xa by antithrombin, because the majority of molecules are of insufficient length to catalyze inhibition of thrombin.

Miscellaneous Pharmacological Effects

High doses of heparin can interfere with platelet aggregation and thereby prolong bleeding time. It is unclear to what extent the antiplatelet effect of heparin contributes to the hemorrhagic complications of treatment with the drug. Heparin “clears” lipemic plasma in vivo by causing the

release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect.

CLINICAL USE Heparin is used to initiate treatment of venous thrombosis and pulmonary embolism because of its rapid onset of action. An oral anticoagulant usually is started concurrently, and heparin is continued for at least 4–5 days to allow the oral anticoagulant to achieve its full therapeutic effect. Patients who experience recurrent thromboembolism despite adequate oral anticoagulation (e.g., patients with Trousseau's syndrome) may benefit from long-term heparin administration. Heparin is used in the initial management of patients with unstable angina or acute myocardial infarction, during and after coronary angioplasty or stent placement, and during surgery requiring cardiopulmonary bypass. Heparin also is used to treat selected patients with disseminated intravascular coagulation. Low-dose heparin regimens are effective in preventing venous thromboembolism in certain high-risk patients.

Low-molecular-weight heparin preparations were first approved for prevention of venous thromboembolism. They are also effective in the treatment of venous thrombosis, pulmonary embolism, and unstable angina. Their principal advantage over standard heparin is a more predictable pharmacokinetic profile, which allows weight-adjusted subcutaneous administration without laboratory monitoring. Thus, therapy of many patients with acute venous thromboembolism can be provided in the outpatient setting. Other advantages of low-molecular-weight heparin include a lower incidence of heparin-induced thrombocytopenia and possibly lower risks of bleeding and osteopenia.

In contrast to warfarin, heparin does not cross the placenta and is not associated with fetal malformations; therefore it is the drug of choice for anticoagulation during pregnancy. Heparin does not appear to increase the incidence of fetal mortality or prematurity. If possible, the drug should be discontinued 24 hours before delivery to minimize the risk of postpartum bleeding. Safety and efficacy of low-molecular-weight heparin use during pregnancy have not been adequately evaluated.

ABSORPTION AND PHARMACOKINETICS Heparin is not absorbed through the gastrointestinal (GI) mucosa and must be given by continuous intravenous infusion or subcutaneous injection. Heparin has an immediate onset of action when given intravenously; there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1–2 hours. Low-molecular-weight heparins are absorbed more uniformly.

The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are ~1, 2.5, and 5 hours. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of undegraded heparin appears in the urine. The $t_{1/2}$ of heparin may be shortened in patients with pulmonary embolism and prolonged in patients with hepatic cirrhosis or end-stage renal disease. Low-molecular-weight heparins have longer biological half-lives than do standard preparations of the drug.

ADMINISTRATION AND MONITORING Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a bolus injection of 5000 units, followed by 1200–1600 units/h delivered by an infusion pump. Therapy routinely is monitored by the aPTT; the target is an elevation to 1.8–2.5 times the normal value. The risk of recurrence of thromboembolism is greater in patients who do not achieve a therapeutic level of anticoagulation within the first 24 hours. Initially, the aPTT should be measured and the infusion rate adjusted every 6 hours; dose adjustments may be aided by use of a nomogram. Once a steady dosage schedule has been established, daily monitoring is sufficient.

Subcutaneous administration of heparin can be used for the long-term management of patients in whom warfarin is contraindicated (e.g., during pregnancy). A total daily dose of ~35,000 units administered as divided doses every 8–12 hours usually is sufficient to achieve an aPTT of 1.5 times the control value (measured midway between doses). Monitoring generally is unnecessary once a steady dosage schedule is established.

Low-dose heparin therapy is used prophylactically to prevent deep venous thrombosis and thromboembolism in susceptible patients, to whom it should be administered every 8 hours in a hospital setting; laboratory monitoring is unnecessary in this setting.

LOW-MOLECULAR-WEIGHT HEPARIN PREPARATIONS *Enoxaparin* (LOVENOX), *dalteparin* (FRAGMIN), *tinzaparin* (INNOHEP, others), *ardeparin* (NORMIFLO), *nadroparin* (FRAXIPARINE,

others), and *reviparin* (CLIVARINE) differ considerably in composition, and it cannot be assumed that two preparations with similar anti-factor Xa activity will produce equivalent antithrombotic effects. The more predictable pharmacokinetic properties of low-molecular-weight heparins permit subcutaneous administration in a fixed or weight-adjusted dosage regimen 1–2 times daily. Since they have a minimal effect on tests of clotting *in vitro*, monitoring is not done routinely. Patients with end-stage renal failure may require monitoring with an anti-factor Xa assay because this condition may prolong the $t_{1/2}$ of low-molecular-weight heparin. Specific dosage recommendations for various low-molecular-weight heparins may be obtained from the manufacturers' literature. Nadroparin and reviparin are not available in the U.S.

SYNTHETIC HEPARIN DERIVATIVES *Fondaparinux* (ARIXTRA) is a synthetic pentasaccharide based on the structure of the antithrombin binding region of heparin. It mediates inhibition of factor Xa by antithrombin but does not cause thrombin inhibition due to its short polymer length. Fondaparinux is administered by subcutaneous injection, reaches peak plasma levels in 2 hours, and is excreted in the urine with a $t_{1/2}$ of 17–21 hours. It should not be used in patients with renal failure. Because it does not interact significantly with blood cells or plasma proteins other than antithrombin, fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or low-molecular-weight heparin to trigger the syndrome of heparin-induced thrombocytopenia (*see* below). Fondaparinux is approved for thromboprophylaxis of patients undergoing hip or knee surgery and for the therapy of pulmonary embolism and deep venous thrombosis.

TOXICITIES

Bleeding Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1–5% of patients treated with intravenous heparin for venous thromboembolism, somewhat less in patients treated with low-molecular-weight heparin for this indication. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of drug discontinuation. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the slow intravenous infusion of *protamine sulfate*, a mixture of basic polypeptides that bind tightly to heparin and thereby neutralize its anticoagulant effect. Use the minimal amount of protamine required to neutralize the heparin present in the plasma, ~1 mg of protamine for every 100 units of heparin remaining in the patient, giving it intravenously at a slow rate (up to 50 mg over 10 minutes).

Anaphylactic reactions occur in ~1% of patients with diabetes mellitus who have received protamine-containing insulin (*NPH insulin* or *protamine zinc insulin*) but are not limited to this group. A less common reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, systemic hypotension, and transient neutropenia also may occur after protamine administration.

Heparin-Induced Thrombocytopenia Heparin-induced thrombocytopenia (platelet count <150,000/ μ L or a 50% decrease from pretreatment value) occurs in ~0.5% of medical patients, typically 5–10 days after initiation of therapy with standard heparin. The incidence of thrombocytopenia is lower with low-molecular-weight heparin. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. The incidence of heparin-induced thrombocytopenia and thrombosis is higher in surgical patients. Venous thromboembolism occurs most commonly, but arterial thromboses causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions. These complexes activate platelets by binding to Fc γ IIa receptors, which results in platelet aggregation, release of more platelet factor 4, and thrombin generation. The antibodies also may trigger vascular injury by binding to platelet factor 4 attached to heparan sulfate on the endothelium.

Heparin should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning heparin therapy, regardless of the dose or route of administration. The onset of heparin-induced thrombocytopenia may occur earlier in patients who have received heparin within the previous 3–4 months and have residual circulating antibodies. The diagnosis of heparin-induced thrombocytopenia can be confirmed

by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor 4 complexes. Since thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as *lepirudin*, *argatroban*, or *danaparoid* (see below) should be administered to patients with heparin-induced thrombocytopenia. Low-molecular-weight heparins should be avoided, because these drugs often cross-react with standard heparin in heparin-dependent antibody assays. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the thrombocytopenia has resolved and the patient is adequately anticoagulated with another agent.

Other Parenteral Anticoagulants

LEPIRUDIN Lepirudin (REFLUDAN) is a recombinant derivative (Leu¹-Thr²-63-desulfohirudin) of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. It is a 65-amino-acid protein that binds tightly to both the catalytic site and the extended substrate recognition site of thrombin. Lepirudin is approved in the U.S. for treatment of patients with heparin-induced thrombocytopenia. It is administered intravenously at a dose adjusted to maintain the aPTT at 1.5–2.5 times the median of the laboratory's normal range. The drug is excreted by the kidneys with a $t_{1/2}$ of ~1.3 hours. Lepirudin should be used cautiously in patients with renal failure, since it can accumulate and cause bleeding. Occasionally, patients may develop antihirudin antibodies that paradoxically increase the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

BIVALIRUDIN *Bivalirudin* (ANGIOMAX) is a synthetic, 20-amino-acid polypeptide that directly inhibits thrombin. Bivalirudin contains the sequence Phe¹-Pro²-Arg³-Pro⁴, which occupies the catalytic site of thrombin, followed by a polyGly linker and a hirudin-like sequence that binds to exosite I. Thrombin slowly cleaves the Arg³-Pro⁴ peptide bond and thus regains activity. Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty. The $t_{1/2}$ of bivalirudin in patients with normal renal function is 25 minutes; dosage reductions are recommended for patients with moderate or severe renal impairment.

ARGATROBAN Argatroban, a synthetic compound based on the structure of L-Arg, binds reversibly to the catalytic site of thrombin. Administered intravenously, it has an immediate onset of action and a $t_{1/2}$ of 40–50 minutes. Argatroban is metabolized by hepatic CYPs and is excreted in the bile; therefore dosage reduction is required for patients with hepatic insufficiency. The dosage is adjusted to maintain an aPTT of 1.5–3 times the baseline value. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with or at risk of developing heparin-induced thrombocytopenia.

DANAPAROID Danaparoid (ORGARAN) is a mixture of nonheparin glycosaminoglycans isolated from porcine intestinal mucosa (84% heparan sulfate, 12% dermatan sulfate, 4% chondroitin sulfate) with a mean mass of 5500 Da. Danaparoid is used for prophylaxis of deep venous thrombosis. It also is an effective anticoagulant for patients with heparin-induced thrombocytopenia and has a low rate of cross-reactivity with heparin in platelet-activation assays. Danaparoid mainly promotes inhibition of factor Xa by antithrombin, but it does not prolong the PT or aPTT at the recommended dosage. Danaparoid is administered subcutaneously at a fixed dose for prophylactic use and intravenously at a higher, weight-adjusted dose for full anticoagulation. Its $t_{1/2}$ is ~24 hours. Patients with renal failure may require monitoring with an anti-factor Xa assay because of a prolonged $t_{1/2}$ of the drug. No antidote is available. Danaparoid is no longer available in the U.S.

DROTRECOGIN ALFA *Drotrecogin alfa* (XIGRIS) is a recombinant form of human activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has anti-inflammatory effects. A 96-hour continuous infusion of drotrecogin alfa decreases mortality in adult patients at high risk for death from severe sepsis if given within 48 hours of the onset of organ dysfunction (*e.g.*, shock, hypoxemia, oliguria). The major adverse effect is bleeding.

ORAL ANTICOAGULANTS

Warfarin

CHEMISTRY

Numerous anticoagulants have been synthesized as derivatives of 4-hydroxycoumarin and of the related compound, indan-1,3-dione (Figure 54–5). Only the coumarin derivatives are widely used; the 4-hydroxycoumarin residue, with a nonpolar carbon substituent at the 3 position, is the

FIGURE 54-5 Structural formulas of the oral anticoagulants. 4-Hydroxycoumarin and indan-1,3-dione are the parent molecules from which the oral anticoagulants are derived. The asymmetrical carbon atoms in the coumarins are shown in blue.

minimal structural requirement for activity. This carbon is asymmetrical in warfarin (and in phenprocoumon and acenocoumarol). The enantiomers differ in anticoagulant potency, metabolism, elimination, and interactions with other drugs. Commercial preparations of these anticoagulants are racemic mixtures. No advantage of administering a single enantiomer has been established.

MECHANISM OF ACTION The oral anticoagulants are antagonists of vitamin K (*see* below). Coagulation factors II, VII, IX, and X and the anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9–13 of the amino-terminal glutamate residues are carboxylated to form the Ca^{2+} -binding γ -carboxyglutamate (Gla) residues. This reaction of the decarboxy precursor protein requires CO_2 , O_2 , and reduced vitamin K, and is catalyzed by γ -glutamyl carboxylase in the rough endoplasmic reticulum (Figure 54-6). Carboxylation is directly coupled to the oxidation of vitamin K to its corresponding epoxide.

Therapeutic doses of warfarin decrease by 30–50% the total amount of each vitamin K–dependent coagulation factor made by the liver; in addition, the secreted molecules are undercarboxylated, resulting in diminished biological activity (10–40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Oral anticoagulants have no effect on the activity of fully carboxylated molecules in the circulation. Thus, the time required for the activity of each factor in plasma to reach a new steady state after therapy is initiated or adjusted depends on its individual rate of clearance. The approximate half-lives (in hours) are: factor VII, 6;

FIGURE 54-6 *The vitamin K cycle: γ -glutamyl carboxylation of vitamin K-dependent proteins.* The enzyme γ -glutamyl carboxylase couples the oxidation of the reduced hydroquinone form (KH₂) of vitamin K₁ or K₂ to γ -carboxylation of Glu residues on vitamin K-dependent precursor proteins in the endoplasmic reticulum. A 2,3-epoxide reductase regenerates vitamin KH₂ and is the warfarin-sensitive step. The R on the vitamin K molecule represents a 20-carbon phtyl side chain in vitamin K₁ and a 5- to 65-carbon prenyl side chain in vitamin K₂.

factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long half-lives of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter $t_{1/2}$, in particular factor VII.

DOSAGE The usual adult dose of warfarin (COUMADIN) is 5 mg/day for 2–4 days, followed by 2–10 mg/day as indicated by measurements of the INR. A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly; age correlates with increased sensitivity to oral anticoagulants. Warfarin usually is administered orally but also can be given intravenously without dose modification. Intramuscular injection is not recommended because of the risk of hematoma formation.

ABSORPTION

The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Warfarin usually is detectable in plasma within 1 hour of its oral administration, and concentrations peak in 2–8 hours.

DISTRIBUTION

Warfarin is almost completely (99%) bound to plasma proteins, principally albumin, and the drug distributes rapidly into a volume equivalent to the albumin space (0.14 L/kg). Concentrations in fetal plasma approach the maternal values, but active warfarin is not found in milk (unlike other coumarins and indandiones).

BIOTRANSFORMATION AND ELIMINATION

Warfarin is a racemic mixture of R (weak) and S (potent) anticoagulant enantiomers. S-warfarin is transformed into inactive metabolites by CYP2C9 and R-warfarin is transformed by CYP1A2, CYP2C19 (minor pathway), and CYP3A4 (minor pathway). The inactive metabolites of warfarin are excreted in urine and stool. The $t_{1/2}$ ranges from 25 to 60 hours (mean ~40 hours); the duration of action of warfarin is 2–5 days.

DRUG AND OTHER INTERACTIONS

The list of drugs and other factors that may affect the action of oral anticoagulants is prodigious. Any substance or condition is potentially dangerous if it alters (1) the uptake or metabolism of the oral anticoagulant or vitamin K; (2) the synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis; or (3) the integrity of any epithelial surface. Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs, herbal remedies and food supplements. Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include: reduced absorption of drug caused by binding to cholestyramine in the GI tract; increased volume of distribution and a short $t_{1/2}$ secondary to hypoproteinemia, as in nephrotic syndrome; increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially CYP2C9, by barbiturates, carbamazepine, or rifampin; ingestion of large amounts of vitamin K-rich foods or supplements; and increased levels of coagulation factors during pregnancy. Hence, the PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to CYP2C9 inhibition by amiodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfipyrazone, tolcapon, or zafirlukast, and displacement from protein binding sites caused by loop diuretics or valproate. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause excessive PT prolongation in patients adequately controlled on warfarin. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions increase the prolongation of the PT. Serious interactions that do not alter the PT include inhibition of platelet function by agents such as aspirin and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect; for example, clofibrate increases the rate of turnover of coagulation factors and inhibits platelet function.

SENSITIVITY TO WARFARIN

Approximately 10% of patients require <1.5 mg/day of warfarin to achieve an INR of 2–3. These patients are more likely to possess one or two polymorphic alleles of CYP2C9, the major enzyme responsible for converting the S-enantiomer warfarin to its inactive metabolites. In comparison with the wild-type CYP2C9*1 allele, the variant alleles CYP2C9*2 and CYP2C9*3 have been shown to inactivate S-warfarin much less efficiently in vitro. The variant alleles are present in 10–20% of Caucasians, but in <5% of African Americans or Asians. Polymorphic variations in VKORC1, which encodes a component of the Vitamin K reductase complex (see Figure 54–6), also determine warfarin sensitivity.

TOXICITIES

Bleeding Bleeding is the major toxicity of oral anticoagulant drugs. The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of a potential anatomical source of bleeding. The incidence of major bleeding episodes is generally <5% per year in patients treated with a target INR of 2–3. The risk of intracranial hemorrhage increases dramatically with an INR >4, especially in older patients. In a large outpatient anticoagulation clinic, the most common factors associated with a transient elevation of the INR (>6) were use of a new medication known to potentiate warfarin (e.g., acetaminophen), advanced malignancy, recent diarrheal illness, decreased oral intake, and taking more warfarin than prescribed. Patients must be informed of the signs and symptoms of bleeding, and laboratory monitoring should be done at frequent intervals during intercurrent illnesses or any changes of medication or diet.

If the INR is above the therapeutic range but <5 and the patient is not bleeding or in need of a surgical procedure, warfarin can be discontinued temporarily and restarted at a lower dose once the INR is within the therapeutic range. If the INR is ≥ 5 , vitamin K₁ (phytonadione, MEPHYTON, AQUAMEPHYTON) can be given orally at a dose of 1–2.5 mg (for an INR of 5–9) or 3–5 mg (for an INR >9). These doses of oral vitamin K₁ generally cause the INR to fall substantially within 24–48 hours without rendering the patient resistant to further warfarin therapy. Higher doses may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours, because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdosage (INR >20), adequate concentrations of vitamin K-dependent coagulation factors can be restored by transfusion of fresh frozen plasma (10–20 mL/kg), supplemented

with 10 mg of vitamin K₁, given by slow intravenous infusion. Transfusion of plasma may need to be repeated, since the transfused factors (particularly factor VII) are cleared from the circulation more rapidly than the residual oral anticoagulant. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions, and therefore should be used cautiously. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin can be used if continued anticoagulation is required.

Birth Defects

Administration of warfarin during pregnancy causes birth defects and abortion. Central nervous system (CNS) abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal PT values are in the therapeutic range. Oral anticoagulants should not be used during pregnancy; heparin can be used safely in this circumstance.

Toxicities

A reversible, sometimes painful, bluish discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation (purple toe syndrome) may develop 3–8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Clinical Use

Oral anticoagulants are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of heparin. They also are effective in preventing venous thromboembolism in patients undergoing orthopedic or gynecological surgery and in preventing systemic embolization in patients with acute myocardial infarction, prosthetic heart valves, or chronic atrial fibrillation.

Prior to initiation of therapy, laboratory tests are used in conjunction with the patient's history and physical examination to uncover hemostatic defects that might make the use of oral anticoagulant drugs more dangerous (congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities, *etc.*). Thereafter, the INR calculated from the patient's PT is used to monitor efficacy and compliance. Therapeutic ranges for various clinical indications have been established empirically and reflect dosages that reduce the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications the target INR is 2–3. A higher target INR (*e.g.*, 2.5–3.5) generally is recommended for patients with mechanical prosthetic heart valves.

For treatment of acute venous thromboembolism, heparin usually is continued for at least 4–5 days after oral anticoagulation is begun and until the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of the vitamin K–dependent coagulation factors with long half-lives, especially factor II. Daily INR measurements are indicated at the onset of therapy to guard against excessive anticoagulation in the unusually sensitive patient. The testing interval can be lengthened gradually to weekly and then to monthly for patients on long-term therapy in whom test results have been stable.

Other Oral Anticoagulants

PHENPROCOUMON AND ACENOCOUMAROL These agents are not available in the U.S. but are prescribed in Europe and elsewhere. Phenprocoumon (MARCUMAR) has a longer plasma $t_{1/2}$ (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7–14 days). It is administered in daily maintenance doses of 0.75–6 mg. Acenocoumarol (SINTHROME) has a shorter $t_{1/2}$ (10–24 hours), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1–8 mg daily.

XIMELAGATRAN *Ximelagatran* is a novel drug that is readily absorbed after oral administration and is rapidly metabolized to *melagatran*, a direct thrombin inhibitor. The drug has not yet been approved for use in the U.S.

FIBRINOLYTIC DRUGS

The fibrinolytic pathway is summarized by Figure 54–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of the physiologic components.

PLASMINOGEN

Plasminogen is a single-chain glycoprotein of 791 amino acids; it is converted to an active protease by cleavage at Arg 560. High-affinity binding sites mediate the binding of plasminogen (or plasmin) to carboxyl-terminal Lys residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed thrombin-activatable fibrinolysis inhibitor (TAFI) can remove these Lys residues and thereby attenuate fibrinolysis. The Lys binding sites are in the amino-terminal "kringle" domain of plasminogen, and they also promote formation of complexes of plasmin with α_2 -antiplasmin, the major physiological plasmin inhibitor. A degraded form of plasminogen termed Lys-plasminogen binds to fibrin more rapidly than does intact plasminogen.

 α_2 -ANTIPLASMIN

α_2 -Antiplasmin is a 452 amino acid glycoprotein that forms a stable complex with plasmin, thereby inactivating it. Plasma concentrations of α_2 -antiplasmin (1 μ M) are sufficient to inhibit ~50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a "systemic lytic state," in which hemostasis is impaired. In this state, fibrinogen is destroyed and fibrinogen degradation products impair formation of fibrin and therefore increase bleeding from wounds. α_2 -Antiplasmin inactivates plasmin nearly instantaneously, as long as the Lys binding sites on plasmin are unoccupied by fibrin or other antagonists, such as aminocaproic acid (see below).

STREPTOKINASE *Streptokinase (STREPTASE) is a 47,000 Da protein produced by β -hemolytic streptococci. It forms a stable, noncovalent 1:1 complex with plasminogen, producing a conformational change that exposes the active site on plasminogen that cleaves Arg 560 on free plasminogen to form free plasmin. Streptokinase is rarely used clinically for fibrinolysis since the advent of newer agents.*

TISSUE PLASMINOGEN ACTIVATOR (t-PA) *t-PA is a serine protease that is a poor plasminogen activator in the absence of fibrin. t-PA binds to fibrin via Lys binding sites at its amino terminus and activates bound plasminogen several hundredfold more rapidly than it activates plasminogen in the circulation. The Lys binding sites on t-PA are in a "finger" domain that is homologous to similar sites on fibronectin. Under physiological conditions (t-PA concentrations of 5–10 ng/mL), the specificity of t-PA for fibrin limits systemic formation of plasmin and induction of a systemic lytic state. During therapeutic infusions of t-PA, however, concentrations rise to 300–3000 ng/mL. Clearance of t-PA primarily occurs by hepatic metabolism, with a $t_{1/2}$ of 5–10 minutes. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction. t-PA (*alteplase*, ACTIVASE) is produced by recombinant DNA technology. The currently recommended ("accelerated") regimen for coronary thrombolysis is a 15 mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 minutes (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant mutant variants of t-PA are available (*reteplase*, RETAVASE and *tenecteplase*, TNKASE). They differ from native t-PA by having increased plasma half-lives that allow convenient bolus dosing (2 doses of 15 milliuunits given 30 minutes apart). They also are relatively resistant to inhibition by plasma activator inhibitor-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity.*

HEMORRHAGIC TOXICITY OF THROMBOLYTIC THERAPY *The major toxicity of all thrombolytic agents is hemorrhage, which results from two factors: (1) the lysis of fibrin in "physiological thrombi" at sites of vascular injury; and (2) a systemic lytic state that results from systemic formation of plasmin, which produces fibrinogenolysis and destruction of other coagulation factors (especially factors V and VIII). The actual toxicities of streptokinase and t-PA are difficult to assess. In early clinical trials, many bleeding episodes resulted from the extensive invasive monitoring of therapy that was required by the protocol. Many studies to evaluate thrombolysis involved concurrent systemic heparinization, which also contributes to bleeding complications. Analysis of more recent clinical trials suggests that heparin confers no benefit in patients receiving fibrinolytic therapy plus aspirin.*

The contraindications to fibrinolytic therapy are listed in Table 54–1. Patients with these conditions should not receive such treatment, and invasive procedures (*e.g.*, cardiac catheterization and arterial blood gases) should be avoided. If heparin is used concurrently with either streptokinase or t-PA, serious hemorrhage will occur in 2–4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. The efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical, with ~30% reductions in death and reinfarction in regimens containing aspirin.

Table 54–1

Contraindications to Thrombolytic Therapy

1. Surgery within 10 days, including organ biopsy, puncture of noncompressible vessels, serious trauma, cardiopulmonary resuscitation
2. Serious gastrointestinal bleeding within 3 months
3. History of hypertension (diastolic pressure >110 mm Hg)
4. Active bleeding or hemorrhagic disorder
5. Previous cerebrovascular accident or active intracranial process
6. Aortic dissection
7. Acute pericarditis

Inhibition of Fibrinolysis**AMINOCAPROIC ACID**

Aminocaproic acid (AMICAR) is a Lys analog that competes for Lys binding sites on plasminogen and plasmin, thus blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis. The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophiliacs. Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 hours. For intravenous use, a loading dose of 4–5 g is given over 1 hour, followed by an infusion of 1 g/h until bleeding is controlled. No more than 30 g should be given in a 24-hour period. Rarely, the drug causes myopathy and muscle necrosis.

ANTIPLATELET DRUGS

Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological thromboses that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed. These drugs act by discrete mechanisms, and thus in combination their effects are additive or even synergistic. Their availability has led to a revolution in cardiovascular medicine, whereby angioplasty and vascular stenting of lesions now is feasible with low rates of restenosis and thrombosis when effective platelet inhibition is employed.

ASPIRIN

In platelets, the major cyclooxygenase product is thromboxane A_2 , a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of thromboxane A_2 by acetylating a Ser residue near the active site of platelet cyclooxygenase (COX-1). Since platelets do not synthesize new proteins, the action of aspirin on platelet cyclooxygenase is permanent, lasting for the life of the platelet (7–10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function. Complete inactivation of platelet COX-1 is achieved when 160 mg of aspirin is taken daily. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, used as an antithrombotic drug, is maximally effective at doses of 50–320 mg/day. Higher doses do not improve efficacy and potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding.

Other nonsteroidal anti-inflammatory drugs (NSAIDs) that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens.

DIPYRIDAMOLE

Dipyridamole (PERSANTINE) is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves. A single study suggests that dipyridamole plus aspirin reduces strokes in patients with prior strokes or transient ischemic attack. A formulation containing 200 mg of dipyridamole, in an extended-release form, and 25 mg of aspirin (AGGRENOX) is available.

Dipyridamole interferes with platelet function by increasing the cellular concentration of cyclic AMP. This effect is mediated by inhibition of cyclic nucleotide PDEs and/or by blockade of uptake of adenosine, which acts at adenosine A₂ receptors to stimulate platelet adenylyl cyclase. The only recommended use of dipyridamole is in combination with warfarin for postoperative primary prophylaxis of thromboemboli in patients with prosthetic heart valves.

TICLOPIDINE The agonists of purinergic receptors are extracellular nucleotides. Platelets contain two purinergic receptors, P2Y₁ and P2Y₁₂; both are GPCR for ADP. The ADP-activated platelet P2Y₁ receptor couples to the G_q-PLC-IP₃-Ca²⁺ pathway and induces a shape change and aggregation. Activation of the P2Y₁₂ receptor by ADP couples via G_i to inhibit adenylyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP-dependent inhibition of platelet activation. Apparently, both receptors must be stimulated for platelet activation, and inhibition of either receptor is sufficient to block platelet activation. *Ticlopidine* (TICLID) is a thienopyridine that inhibits the P2Y₁₂ receptor. Ticlopidine is a prodrug that requires conversion to the active thiol metabolite by a hepatic CYP. It is rapidly absorbed and highly bioavailable. It permanently inhibits the P2Y₁₂ receptor by forming a disulfide bridge between the thiol on the drug and a free Cys residue in the extracellular region of the receptor; thus, the effect is prolonged, even though the free drug has a short t_{1/2}. Maximal inhibition of platelet aggregation is not seen until 8–11 days after starting therapy; loading doses of 500 mg sometimes are given to achieve a more rapid onset of action. The usual dose is 250 mg twice/day. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

Adverse Effects

The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count <1500/μL), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombopenia can occur within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate discontinuation of therapy if cell counts decline. Platelet counts also should be monitored. Rare cases of thrombotic thrombocytopenic purpura (TTP)-hemolytic uremic syndrome have been associated with ticlopidine, with a reported incidence of 1 in 1600–4800 patients when the drug is used after cardiac stenting; the mortality associated with these cases is reported to be as high as 18–57%. Remission of TTP has been reported when the drug is stopped.

Therapeutic Uses

Ticlopidine has been shown to prevent cerebrovascular events in secondary prevention of stroke and is at least as good as aspirin in this regard. Ticlopidine also reduces cardiac events in patients with unstable angina; however, its only FDA-approved indication is to reduce the risk of thrombotic stroke in patients who have experienced stroke precursors and in patients who have had a completed thrombotic stroke. Since ticlopidine has a mechanism of action distinct from that of aspirin, combining the drugs should produce additive or even synergistic effects. This appears to be the case, and the combination has been used in patients undergoing angioplasty and stenting for coronary artery disease, with a very low (<1%) frequency of stent thrombosis occurring over a short, 30-day follow-up. As ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP, it is generally reserved for patients who are intolerant or allergic to aspirin or who have failed aspirin therapy.

CLOPIDOGREL The thienopyridine clopidogrel (PLAVIX) is closely related to ticlopidine and appears to have a slightly more favorable toxicity profile with less frequent thrombocytopenia and leukopenia, although TTP has been reported. Clopidogrel is a prodrug with a slow onset of action. The usual dose is 75 mg/day with or without an initial loading dose of 300 mg. The drug is equivalent to aspirin in the secondary prevention of stroke, and in combination with aspirin it appears to be as effective as ticlopidine and aspirin. It is used with aspirin after angioplasty and should be continued for at least 1 year. In one study, the combination of clopidogrel and aspirin clearly was superior to aspirin alone; this finding suggests that the actions of the two drugs are synergistic. FDA-approved indications for clopidogrel are to reduce the rate of stroke, myocardial infarction (MI), and death in patients with recent MI or stroke, established peripheral arterial disease, or acute coronary syndrome.

GLYCOPROTEIN IIb/IIIa INHIBITORS Glycoprotein IIb/IIIa is a platelet-surface integrin designated α_{IIb}β₃. This dimeric glycoprotein is a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation.

The integrin heterodimer/receptor is activated by platelet agonists such as thrombin, collagen, or thromboxane A_2 to develop binding sites for its ligands, which do not bind to resting platelets. Inhibition of binding to this receptor blocks platelet aggregation induced by any agonist. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present, with others under development.

ABCIXIMAB *Abciximab* (REOPRO) is the Fab fragment of a humanized monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells. The antibody is used in conjunction with percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to be quite effective in preventing restenosis, recurrent myocardial infarction, and death. The reduction in total events is ~50% in various large trials. The unbound antibody is cleared from the circulation with a $t_{1/2}$ of ~30 minutes, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured *in vitro* for 18–24 hours after infusion is stopped. It is given as a 0.25-mg/kg bolus followed by 0.125 $\mu\text{g}/\text{kg}/\text{min}$ for 12 hours or longer.

Adverse Effects

The major side effect of abciximab is bleeding, and contraindications are similar to those for fibrinolytic agents. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of anticoagulation with heparin. Thrombocytopenia of <50,000 platelets/ μL is seen in ~2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect, because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions.

Eptifibatide *Eptifibatide* (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. The drug blocks platelet aggregation *in vitro* after intravenous infusion. Eptifibatide is given as a bolus of 180 $\mu\text{g}/\text{kg}$ followed by 2 $\mu\text{g}/\text{kg}/\text{min}$ for up to 96 hours. It is used to treat acute coronary syndrome and for angioplastic coronary interventions. In the latter case, myocardial infarction and death have been reduced by ~20%. Although direct comparisons are lacking, the benefit from eptifibatide seems to be somewhat less than that obtained with abciximab, perhaps because eptifibatide is specific for $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. The duration of action of the drug is relatively short and platelet aggregation is restored within 6–12 hours after cessation of infusion. Eptifibatide generally is administered in conjunction with aspirin and heparin.

Adverse Effects

The major side effect is bleeding. The frequency of major bleeding in trials was ~10%, compared with ~9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5–1% of patients.

Tirofiban *Tirofiban* (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of $\alpha_{IIb}\beta_3$ that appears to have a similar mechanism of action as eptifibatide. Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have been ~20% compared to placebo, results similar to those with eptifibatide. Side effects also are similar to those of eptifibatide. The agent is specific to $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. Meta-analysis of trials using $\alpha_{IIb}\beta_3$ inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited. Tirofiban is administered intravenously at an initial rate of 0.4 $\mu\text{g}/\text{kg}/\text{min}$ for 30 minutes, and then continued at 0.1 $\text{mg}/\text{kg}/\text{min}$ for 12–24 hours after angioplasty or atherectomy. It is used in conjunction with heparin.

THE ROLE OF VITAMIN K

Green plants are a nutritional source of vitamin K, an essential cofactor in the γ -carboxylation of multiple Glu residues of several clotting factors and anticoagulant proteins. The vitamin K–dependent formation of γ -carboxy-glutamate (Gla) residues permits the appropriate interactions of clotting factors, Ca^{2+} , and membrane phospholipids and modulator proteins (Figures 54–1, 54–2, and 54–3). Oral anticoagulant drugs (*e.g.*, coumadin, Figure 54–5) block Gla formation and thereby inhibit clotting; excess vitamin K_1 can reverse these effects.

CHEMISTRY AND OCCURRENCE

Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K₁ and vitamin K₂. Vitamin K₁, or phyloquinone (phytonadione), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K₂ is actually a series of compounds (the menaquinones) in which the phytol side chain of phyloquinone has been replaced by a side chain built up of 2–13 prenyl units. Considerable synthesis of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces. In animals, menaquinone-4 can be synthesized from the vitamin precursor menadione (2-methyl-1,4-naphthoquinone), or vitamin K₃. Depending on the bioassay system used, menadione is at least as active on a molar basis as phyloquinone.

PHYSIOLOGICAL FUNCTIONS AND PHARMACOLOGICAL ACTIONS

Phyloquinone and menaquinones are virtually devoid of pharmacodynamic activity. However, in subjects deficient in vitamin K, the vitamin performs its normal physiological function: to promote the biosynthesis of the γ -carboxy-glutamate (Gla) forms of factors II (prothrombin), VII, IX, and X, anticoagulant proteins C and S, protein Z (a cofactor to the inhibitor of Xa), the bone Gla protein osteocalcin, matrix Gla protein, and growth arrest-specific protein 6 (Gas6). Figure 54-6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. Vitamin K, as KH₂, the reduced hydroquinone, is an essential cofactor for γ -glutamyl carboxylase. Using KH₂, O₂, CO₂, and the glutamate-containing substrate, the enzyme forms a γ -carboxy-glutamyl protein (Gla protein) and concomitantly, the 2,3-epoxide of vitamin K. A coumarin-sensitive 2,3-epoxide reductase regenerates KH₂. The γ -glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and function as a multicomponent complex. Two natural mutations in γ -glutamyl carboxylase lead to bleeding disorders. With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ -carboxylation of Glu also occurs in lung, bone, and other cell types.

HUMAN REQUIREMENTS

In patients made vitamin K-deficient by a starvation diet and antibiotic therapy for 3–4 weeks, the minimum daily requirement is estimated to be 0.03 μ g/kg of body weight and possibly as high as 1 μ g/kg, which is approximately the recommended intake for adults (70 μ g/day).

SYMPTOMS OF DEFICIENCY

The chief manifestation of vitamin K deficiency is an increased bleeding tendency (see discussion of hypoprothrombinemia in section on oral anticoagulants, above). Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The discovery of a vitamin K-dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy ("fetal warfarin syndrome") may be related to a deficiency of the vitamin.

Evidence indicates a role for vitamin K in adult skeletal maintenance and osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and also improves bone mineral density, but the relationship of these two effects is unclear. Bone mineral density in adults is not changed by therapeutic use of oral anticoagulants, but new bone formation may be impaired.

ABSORPTION, FATE, AND EXCRETION

The mechanism of intestinal absorption of compounds with vitamin K activity varies with their solubility. In the presence of bile salts, phyloquinone and the menaquinones are adequately absorbed from the intestine, almost entirely by way of the lymph. Phyloquinone is absorbed by an energy-dependent, saturable process in proximal portions of the small intestine; menaquinones are absorbed by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phyloquinone is incorporated into chylomicrons in close association with triglycerides and lipoproteins. The extremely low phyloquinone levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. Absorbed phyloquinone and menaquinones are concentrated in the liver, but the concentration of phyloquinone declines rapidly. Menaquinones, produced in the lower bowel, are less biologically active than phyloquinone due to their long side chain. Very little vitamin K accumulates in other tissues.

Apparently, there is only modest storage of vitamin K in the body. Under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over a period of several weeks.

THERAPEUTIC USES

Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phylloquinone (AQUAMEPHYTON, KONAKION, MEPHYTON) is available as tablets and in a dispersion with buffered polysorbate and propylene glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON should be given by subcutaneous or intramuscular injection because severe reactions resembling anaphylaxis have followed its intravenous administration.

Inadequate Intake

After infancy, coagulopathy due to dietary deficiency of vitamin K is extremely rare: Vitamin K is present in many foods and also is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. Patients on total parenteral nutrition should receive phylloquinone (1 mg/week, the equivalent of ~150 µg/day).

Hypoprothrombinemia of the Newborn

Healthy newborn infants show decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal intestinal flora. In premature infants and in infants with hemorrhagic disease of the newborn, the concentrations of clotting factors are particularly depressed, possibly reflecting vitamin K deficiency. Measurements of non- γ -carboxylated prothrombin suggest that true vitamin K deficiency occurs in ~3% of live births.

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K. In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin. Commercial infant formulas are supplemented with vitamin K.

In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within ~6 hours. The routine administration of 1 mg phylloquinone intramuscularly at birth is required by law in the U.S. This dose may have to be increased or repeated if the mother has received anticoagulant or anticonvulsant drug therapy or if the infant develops bleeding tendencies. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (10–20 mg/day for 2 weeks).

Inadequate Absorption

Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with either intrahepatic or extrahepatic biliary obstruction or a severe defect in the intestinal absorption of fat from other causes.

Biliary Obstruction or Fistula

Bleeding that accompanies obstructive jaundice or biliary fistula responds promptly to the administration of vitamin K. Oral phylloquinone administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin activity of the blood rapidly returns to normal. If oral administration is not feasible, a parenteral preparation of vitamin K should be used; the usual dose is 10 mg/day.

Malabsorption Syndromes

Among the disorders that result in inadequate absorption of vitamin K from the GI tract are: cystic fibrosis, sprue, inflammatory bowel disease, dysentery, and extensive bowel resection. Since drugs that greatly reduce the bacterial population of the bowel are used frequently in these disorders, the availability of the vitamin may be further reduced. Moreover, dietary restrictions also may limit the availability of the vitamin. For immediate correction of the deficiency, parenteral therapy should be used.

Drug-Induced Hypoprothrombinemia

Anticoagulant drugs such as warfarin act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants is discussed above. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom destroys or inactivates prothrombin.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

SECTION XII

HORMONES AND HORMONE ANTAGONISTS

55

PITUITARY HORMONES AND THEIR HYPOTHALAMIC RELEASING HORMONES

Anterior pituitary hormones are classified into three different groups based on their structural features. *Growth hormone* (GH) and *prolactin* (PRL) belong to the somatotropic family, which in humans also includes *placental lactogen*. The glycoprotein hormones—*thyroid-stimulating hormone* (TSH, also called thyrotropin), *luteinizing hormone* (LH), and *follicle-stimulating hormone* (FSH)—share a common α -subunit but have different β -subunits that determine their distinct biological activities. Placenta-derived *human chorionic gonadotropin* (hCG) also is a member of the glycoprotein hormone family. *Corticotropin* (adrenocorticotropic hormone; ACTH) and *α -melanocyte-stimulating hormone* (α -MSH) are part of a family of peptides derived from *pro-opiomelanocortin* (POMC) by proteolytic processing (see Chapter 21). *Hypothalamic releasing hormones*, peptides released by hypothalamic neurons in the median eminence, positively regulate the secretion of anterior pituitary hormones. These releasing factors include *growth hormone-releasing hormone* (GHRH), *gonadotropin-releasing hormone* (GnRH), *thyroid-releasing hormone* (TRH), and *corticotropin-releasing hormone* (CRH). The hypothalamic peptide *somatostatin* (SST) negatively regulates pituitary secretion of GH and TSH.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from distinct populations of neurons in the supraoptic and paraventricular nuclei that synthesize either *arginine vasopressin* or *oxytocin*. Arginine vasopressin plays an important role in water homeostasis (see Chapter 29); oxytocin plays important roles in labor and parturition and in milk letdown, as discussed below.

GROWTH HORMONE

Growth hormone, the most abundant anterior pituitary hormone, is synthesized and secreted by somatotropes, which account for about 40% of hormone-secreting cells of the anterior pituitary. Due to alternative splicing of the GH gene, the anterior pituitary secretes a heterogeneous mixture of GH peptides; an appreciable fraction of which circulates bound to a protein corresponding to the extracellular domain of the GH receptor. Bound GH has a biological $t_{1/2}$ ten times that of unbound GH, suggesting that the binding protein may provide a reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion. Obesity and estrogen treatment increase circulating levels of GH binding proteins and thus may affect the clinical response to exogenous GH.

Regulation of Growth Hormone Secretion

Daily GH secretion varies throughout life; secretion is high in children, reaches maximal levels at puberty, and then declines in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. The amplitude of secretory pulses is maximal at night; the most consistent period of GH secretion is shortly after the onset of deep sleep.

The regulation of GH secretion (Figure 55-1) incorporates many of the features of the classic negative feedback systems seen in other endocrine axes. GH and its predominant peripheral effector, insulin-like growth factor-1 (IGF-1), act in negative feedback loops to suppress GH secretion. IGF-1 predominantly inhibits GH secretion through direct effects on the anterior pituitary gland. Somatostatin (SST) and ghrelin also contribute to the negative regulation of GH.

Ghrelin is a 28-amino-acid peptide, octanoylated at Ser³, that is synthesized by endocrine cells in the fundus of the stomach and stimulates appetite and food intake through central mechanisms.

SST is synthesized by widely distributed neurons, as well as by neuroendocrine cells in the gastrointestinal (GI) tract and pancreas. SST is synthesized as a prohormone precursor and processed by proteolytic cleavage to generate two predominant forms: SST-14 and SST-28. The somatostatins exert their effects by binding to and activating a family of five related GPCRs that signal through G_i to inhibit cyclic AMP accumulation and to activate K⁺ channels and phosphotyrosine phosphatases.

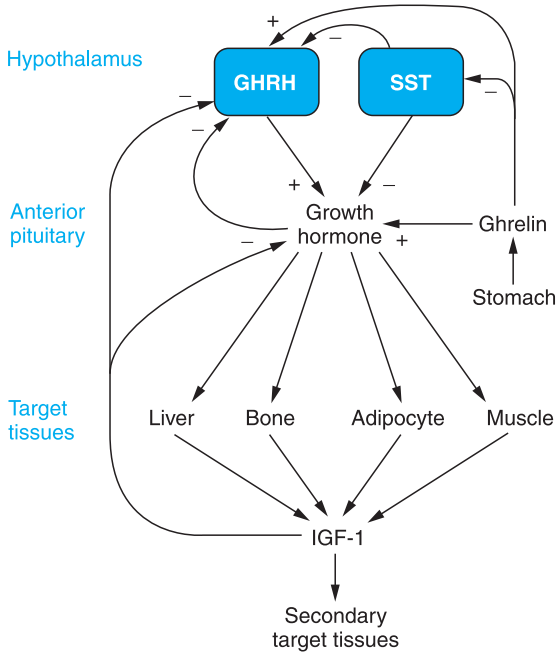

FIGURE 55-1 Secretion and actions of growth hormone. Two hypothalamic factors, growth hormone-releasing hormone (GHRH) and somatostatin (SST), act on the somatotropes in the anterior pituitary to regulate growth hormone secretion. SST also inhibits GHRH release. Growth hormone exerts direct effects on target tissues and indirect effects mediated by stimulating the release of insulin-like growth factor-1 (IGF-1). The gastric peptide ghrelin enhances growth hormone release, directly by actions at the anterior pituitary and indirectly by multiple actions on the hypothalamus. IGF-1 feeds back at the anterior pituitary to inhibit growth hormone secretion and at the hypothalamus to inhibit further GHRH release.

Each of the SST receptor subtypes (abbreviated SSTR or sstr) binds SST with nanomolar affinity; whereas receptor types 1–4 (SSTR1–4) bind the two SSTs with approximately equal affinity, type 5 (SSTR5) has a 10–15-fold greater selectivity for SST-28. SSTR2 and SSTR5 are the most important for regulation of GH secretion. SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated *via* GHRH neurons in the arcuate nucleus. As discussed below, SST analogs play a key role in the therapy of syndromes of GH excess.

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. Dopamine, 5-hydroxytryptamine, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, IGF-1, and GH itself inhibit release, as does the administration of glucose to normal subjects in an oral glucose tolerance test.

These observations form the basis for provocative tests to assess the ability of the pituitary to secrete GH. Provocative stimuli include Arg, glucagon, insulin-induced hypoglycemia, clonidine, and the dopamine precursor levodopa; each can increase circulating GH levels in normal subjects within 45–90 minutes.

Molecular and Cellular Bases of Growth Hormone Action

All effects of GH result from its interactions with the GH receptor, as evidenced by the severe phenotype of rare patients with homozygous mutations of the GH receptor gene (the Laron syndrome of GH-resistant dwarfism). The GH receptor is a widely distributed cell-surface receptor that belongs to the cytokine receptor superfamily. Like other members of the cytokine receptor family, the GH receptor contains an extracellular domain that binds GH, a single membrane-spanning

FIGURE 55–2 Mechanisms of growth hormone and prolactin action and of GH receptor antagonism. **A.** The binding of GH to two molecules of the growth hormone receptor (GHR) induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of mitogen-activated protein kinase (MAPK), which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand-activated homodimer that recruits the JAK-STAT signaling pathway (see text for further details). The GHR also activates the IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. **B.** Pegvisomant, a recombinant pegylated variant of human GH, contains mutations that increase the affinity for the GHR but do not activate downstream signaling by the GHR. It thus interferes with GH signaling in target tissues. JAK2, Janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing.

region, and an intracellular domain that mediates signal transduction. Receptor activation results from the binding of a single GH molecule to two identical receptor molecules, forming a ligand-occupied receptor dimer that presumably brings the intracellular domains of the receptors into close proximity to activate cytosolic components critical for cell signaling.

The ligand-occupied receptor dimer does not have inherent tyrosine kinase activity but, rather, provides docking sites for 2 molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of 2 JAK2 molecules leads to *trans*-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Figure 55–2).

Physiological Effects of Growth Hormone

The most striking physiological effect of GH is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after longitudinal growth ceases and epiphyses have closed. GH stimulates myoblast differentiation (in experimental animals), increases muscle mass (in human subjects with GH deficiency), increases glomerular filtration rate, and stimulates preadipocyte differentiation into adipocytes.

GH acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1 (Figure 55–2). The U.S. Food and Drug Administration (FDA) has approved a new drug application for recombinant human IGF-1 to treat short stature in patients resistant to GH (see below).

Clinical Disorders of Growth Hormone

Both GH deficiency and excess are associated with defined diseases in human beings.

INDICATIONS FOR GROWTH HORMONE TREATMENT GH deficiency in children is a well-accepted cause of short stature; replacement therapy is used to treat children with severe GH deficiency. GH therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner's syndrome, Prader-Willi syndrome (in the absence of morbid obesity or obstructive sleep apnea), chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (*i.e.*, more than 2.25 standard deviations below mean height for age and sex but normal laboratory indices of GH levels).

In adults, GH deficiency is associated with a defined endocrinopathy that includes increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation; decreased muscle mass and exercise capacity; decreased bone density; and impaired psychosocial function. In GH-deficient adults, the consensus is that the most severely affected GH-deficient adults may benefit the most from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome. In this latter setting, GH is administered once daily for 4 weeks.

GH increases mortality in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure and should not be used in these settings. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before initiation of GH therapy.

TREATMENT OF GROWTH HORMONE DEFICIENCY Humans do not respond to GH from nonprimate species. GH for clinical use corresponds in sequence to the human hormone and is produced by recombinant DNA technology.

GH is used for replacement therapy in GH-deficient children, whether the deficiency is congenital or acquired. By convention, *somatropin* refers to the many GH preparations whose sequences match that of native GH (GENOTROPIN, HUMATROPE, NORDITROPIN, NUTROPIN, OMNITROPE, SEROSTIM, TEV-TROPIN, ZORBTIVE), while *somatrem* refers to a derivative of GH with an additional methionine at the amino terminus (PROTROPIN). To mimic the normal pattern of secretion, these preparations typically are administered to GH-deficient children in a dose of 40 $\mu\text{g}/\text{kg}/\text{day}$ subcutaneously in the evening; although the circulating $t_{1/2}$ of GH is only 20 minutes, its biological $t_{1/2}$ is in the range of 9–17 hours, and once-daily administration is sufficient. Higher daily doses (*e.g.*, 50 $\mu\text{g}/\text{kg}$) are employed for patients with Turner's syndrome, who have partial GH resistance. In children with overt GH deficiency, measurements of serum IGF-1 levels are used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. Although the most pronounced increase in growth velocity occurs within the first 2 years of therapy, GH is continued until the epiphyses are fused, and also may be extended into the transition period from childhood to adulthood. The response to GH can be variable. In part, this variability has been attributed to the differential expression of two splice variants of the GH receptor in the human population that differ in their GH responsiveness.

In view of the increased appreciation of the effects of GH on bone density and the manifestations of GH deficiency in adults, some experts continue therapy into adulthood for children with GH deficiency; it is essential to confirm GH deficiency in adulthood so as to identify those patients who will benefit from continuing GH treatment. Clinical response is monitored by serum IGF-1 levels, which should be restored to the mid-normal range adjusted for age and sex. Because estrogen increases the levels of GH binding proteins, women taking oral—but not transdermal—estrogen often require larger GH doses to achieve the target IGF-1 level.

Growth impairment also may be associated with elevated GH levels and GH resistance, most frequently secondary to mutations in the GH receptor (Laron dwarfism). These patients can be treated effectively with subcutaneous administration of recombinant human IGF-1 (INCRELEX, IPLEX). Although this therapy clearly is beneficial in promoting growth, the optimal regimen remains to be established.

In addition to GH, *sermorelin acetate* (GEREF), a synthetic form of human GHRH containing residues 1-29, is FDA-approved for diagnostic purposes. Sermorelin used therapeutically (30 $\mu\text{g}/\text{kg}/\text{day}$ given subcutaneously) was less effective than GH in clinical trials. This agent will not work in patients whose GH deficiency results from defects in the anterior pituitary.

Side Effects of GH Therapy In children, GH therapy is associated with remarkably few side effects. Rarely, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. This generally occurs within the first 8 weeks of therapy, and fundoscopic examination is recommended at the initiation of therapy and periodically thereafter. Leukemia has been reported in some children receiving GH therapy; conditions associated with GH deficiency (e.g., Down's syndrome, cranial irradiation for central nervous system [CNS] tumors) probably explain the apparent association. Despite this, the consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. An increased incidence of type 2 diabetes mellitus has been reported. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

In adults, side effects associated with the initiation of GH therapy include peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias. These symptoms, which occur most frequently in patients who are older or more obese, generally respond to a decrease in dose.

Syndromes of GH Excess

If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. Life expectancy is shortened in these patients due to increased incidences of cardiovascular disease, upper airway obstruction, and GI malignancies (possibly). Because the traditional treatment options, transsphenoidal surgery and radiation, have attendant complications, more attention has been given to pharmacological management of acromegaly.

SOMATOSTATIN ANALOGS The development of analogs of SST (Figure 55–3) revolutionized the medical treatment of acromegaly. Active SST analogs retain the amino acids in positions 7–10 [FWKT] as a core segment constrained in a cyclic structure. The most widely used somatostatin analog is octreotide (SANDOSTATIN), an 8-amino-acid synthetic derivative of somatostatin that has a longer $t_{1/2}$ and binds preferentially to SSTR2 and SSTR5 receptors. Typically, octreotide (100 μg) is administered subcutaneously 3 times daily; bioactivity is virtually 100%, peak effects are seen within 30 minutes, serum $t_{1/2}$ is approximately 90 minutes, and duration of action is ~12 hours. The goal of treatment is to decrease GH levels to <2 ng/mL after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and sex.

In addition to its effect on GH secretion, octreotide can decrease tumor size, although tumor growth generally resumes after octreotide treatment is stopped. Octreotide also has a significant inhibitory effect on thyrotropin secretion, and is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH and are not good candidates for surgery. The use of octreotide in GI disorders is discussed in Chapter 37.

GI side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving octreotide. In most patients, these symptoms diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving octreotide develop gallstones, presumably due to decreased gallbladder contraction and GI transit time. In the absence of symptoms, gallstones are not a contraindication to continued use of octreotide. Compared to somatostatin, octreotide reduces insulin secretion to a lesser extent and only infrequently affects glycemic control.

A long-acting, depot form of octreotide (SANDOSTATIN LAR) can be administered intramuscularly once every 4 weeks; the recommended dose is 20 or 30 mg.

Somatostatin-28 (Prosomatostatin):

Ser-Ala-Asn-Ser-Asn-Pro-Ala-Met-Ala-Pro-Arg-Glu-Arg-Lys-Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys

Somatostatin-14:

Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys

Octreotide: D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr-ol

Lanreotide: D-Nal-Cys-Tyr-D-Trp-Lys-Val-Cys-Thr-NH₂

FIGURE 55–3 Structures of the somatostatins and clinically available analogs. The amino acid sequences of the synthetic somatostatin analogs, octreotide and lanreotide are shown. D-Nal, 3-(2-naphthyl)-D-alanyl.

Lanreotide (SOMATULINE LA) is another long-acting octapeptide analog of somatostatin that causes prolonged suppression of GH secretion when administered in a 30-mg dose intramuscularly. Although its efficacy appears comparable to that of the long-acting formulation of octreotide, its duration of action is shorter; thus, it must be administered either at 10- or 14-day intervals. A 60-mg formulation of lanreotide (SOMATULINE AUTOGEL) reduces the required dosing frequency to once every 4 weeks. Lanreotide has not been approved by the FDA for use in the U.S.

GROWTH HORMONE ANTAGONISTS

Pegvisomant (SOMAVERT) is a GH receptor antagonist that is FDA-approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate JAK-STAT signaling or stimulate IGF-1 secretion (Figure 55–2). It is administered subcutaneously as a 40-mg loading dose under medical supervision, followed by self-administration of 10 mg/day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg/day. Liver function should be monitored in all patients, and pegvisomant should not be used in patients with elevated levels of liver transaminases. Because there are concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up of the pituitary by MRI is mandatory.

PROLACTIN Secretion

Prolactin is related structurally to GH. Whereas serum prolactin levels remain low throughout life in normal males, they are elevated somewhat in normal cycling females. Prolactin levels rise markedly during pregnancy, reach a maximum at term, and decline thereafter unless the mother breast-feeds the infant. Suckling or breast manipulation in nursing mothers stimulates circulating prolactin levels, which can rise 10–100-fold within 30 minutes of stimulation. This response is neurally transmitted from the breast to the hypothalamus and is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The precise mechanism for suckling-induced prolactin secretion is not known but involves both decreased secretion of dopamine by tuberoinfundibular neurons and possibly increased release of factors that stimulate prolactin secretion (*see* below). The suckling response becomes less pronounced after several months of breastfeeding, and prolactin concentrations eventually decline to prepregnancy levels.

Prolactin detected in maternal and fetal blood originates from maternal and fetal pituitaries, respectively. Prolactin also is synthesized by decidual cells near the end of the luteal phase of the menstrual cycle and early in pregnancy; the latter source is responsible for the very high levels of prolactin in amniotic fluid during the first trimester.

Many of the factors that influence prolactin secretion are similar to those that affect GH secretion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Like other anterior pituitary hormones, prolactin is secreted in a pulsatile manner. Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is dopamine, which is released by tuberoinfundibular neurons and interacts with the D₂ receptor on lactotropes to inhibit prolactin secretion. A number of putative prolactin-releasing factors have been described, but their physiological roles are unclear. Under certain pathophysiological conditions, such as severe primary hypothyroidism, persistently elevated levels of TRH can induce hyperprolactinemia and consequent galactorrhea.

Molecular and Cellular Bases of Prolactin Action

The effects of prolactin result from interactions with specific receptors that are widely distributed among a variety of cell types within many tissues. The prolactin receptor is encoded by a single gene, alternative splicing of which gives rise to multiple forms of the receptor, including soluble forms found in the circulation that correspond to the extracellular domain of the receptor. The membrane-bound prolactin receptor is related structurally to receptors for GH and several cytokines and uses similar signaling mechanisms. Like the GH receptor, the prolactin receptor lacks intrinsic tyrosine kinase activity; prolactin induces a conformational change leading to recruitment and activation of JAK kinases (Figure 55–2). The activated JAK2 kinase, in turn, induces phosphorylation, dimerization, and nuclear translocation of the transcription factor STAT5. Unlike human GH and placental lactogen, which bind to the prolactin receptor and are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

Physiological Effects of Prolactin

Prolactin plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelium, which is essential for lactation. Prolactin receptors are present in many other sites; however, the physiological effects of prolactin at these sites remain poorly characterized.

Agents Used to Treat Syndromes of Prolactin Excess

Prolactin has no therapeutic uses. Hyperprolactinemia is a relatively common endocrine abnormality that most often is caused by prolactin-secreting pituitary adenomas. Hyperprolactinemia also can result from: hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals; primary hypothyroidism associated with increased TRH levels; renal failure; treatment with dopamine receptor antagonists. Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, impotence, and infertility.

The therapeutic options for patients with prolactinomas include transsphenoidal surgery, radiation, and treatment with dopamine-receptor agonists that suppress prolactin production *via* activation of D₂ dopamine receptors. Inasmuch as initial surgical cure rates are only 50–70% with microadenomas and 30% with macroadenomas, most patients with prolactinomas ultimately require drug therapy. Thus, dopamine-receptor agonists have become the initial treatment of choice for many patients. These agents generally decrease both prolactin secretion and the size of the adenoma, thereby improving the endocrine abnormalities, as well as the neurological symptoms caused directly by the adenoma (including visual field deficits). It is worth noting, however, that they typically are not curative.

BROMOCRIPTINE

Bromocriptine (*PARLODEL*) is the dopamine-receptor agonist against which newer agents are compared. Bromocriptine is a semisynthetic ergot alkaloid that interacts with D₂ dopamine receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D₁ receptors. Bromocriptine normalizes serum prolactin levels in 70–80% of patients with prolactinomas and decreases tumor size in more than 50% of patients, including those with macroadenomas.

Frequent side effects of bromocriptine include nausea and vomiting, headache, and postural hypotension—particularly on initial use. Less-frequent side effects include nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia. Starting at a low dose (1.25 mg), administered at bedtime, can diminish these side effects. If clinical symptoms persist or serum prolactin levels remain elevated, the dose can be increased gradually, every 3–7 days, to 5 mg twice daily or 2.5 mg three times a day as tolerated. Patients often develop tolerance to the side effects of bromocriptine. Those who do not respond to bromocriptine or who have intractable side effects may respond to a different dopamine agonist. Although a high fraction of the oral dose of bromocriptine is absorbed, only 7% of the dose reaches the systemic circulation because of extensive first-pass hepatic metabolism. Bromocriptine has a relatively short elimination $t_{1/2}$ (2–8 hours). Longer acting forms of bromocriptine have been developed but are not available for use in the U.S. At higher concentrations, bromocriptine is used in the management of acromegaly and at still higher concentrations is used in the management of Parkinson's disease.

Patients with prolactinomas who wish to become pregnant comprise a special subset of hyperprolactinemic patients. Because experience with bromocriptine is more extensive than that with any other D₂ receptor agonist, bromocriptine is recommended as the first-line treatment in this setting. Bromocriptine relieves the inhibitory effect of prolactin on ovulation and permits most patients with prolactinomas to become pregnant without apparent detrimental effects on pregnancy or fetal development.

PERGOLIDE

Pergolide (*PERMAX*), an ergot derivative approved by the FDA for treatment of Parkinson's disease, also is used "off label" to treat hyperprolactinemia. It induces many of the same side effects as does bromocriptine, but it can be given once a day, starting at 0.025 mg at bedtime and increased gradually to a maximum daily dose of 0.5 mg.

CABERGOLINE

Cabergoline (*DOSTINEX*) is an ergot derivative with a longer $t_{1/2}$ (~65 hours), higher affinity, and greater selectivity for the D₂ receptor (~4 times more potent) than bromocriptine. It is FDA-approved for the treatment of hyperprolactinemia and likely will play an increasing role in the

treatment of this syndrome. Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. In some clinical trials, cabergoline has been more effective than bromocriptine in decreasing serum prolactin in patients with hyperprolactinemia, although this may reflect improved adherence to therapy due to decreased side effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. If the serum prolactin remains elevated, the dose can be increased to a maximum of 1.5–2 mg two or three times a week as tolerated; however, the dose should not be increased more often than once every 4 weeks.

QUINAGOLIDE

Quinagolide (*NORPROLAC*) is a nonergot D_2 dopamine agonist with a half-life of 22 hours. Quinagolide is administered once daily at doses of 0.1–0.5 mg/day. It is not approved by the FDA but has been used extensively in Europe.

GONADOTROPIN-RELEASING HORMONE AND GONADOTROPINS

LH and FSH were named initially based on their actions on the ovary. These pituitary hormones, together with the related placental hormone hCG, are collectively referred to as the gonadotropins because of their actions on the gonads. The regulation of gonadotropin secretion is described in detail in Chapters 57 and 58. LH and FSH are synthesized and secreted by gonadotropes; hCG is synthesized by the syncytiotrophoblast of the placenta. Pituitary gonadotropin production is stimulated by GnRH and is further regulated by feedback effects of the gonadal hormones (Figure 55–4; see also Figure 57–2).

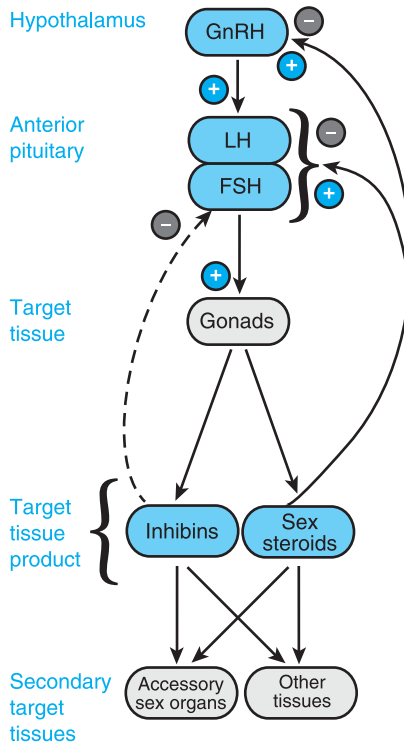

FIGURE 55–4 The hypothalamic-pituitary-gonadal axis. A single hypothalamic releasing factor, GnRH, controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) cause feedback inhibition at the level of the pituitary and the hypothalamus. The preovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

Table 55–1

GnRH and GnRH Analogs

Analog (TRADE NAME)	Dosage Form
<i>Agonists</i>	
GnRH (FACTREL)	IV, SC
Leuprolide (LUPRON, ELIGARD, VIADUR)	IM, SC depot
Buserelin (SUPREFACT)	SC, IN
Nafarelin (SYNAREL)	IN
Deslorelin (SOMAGARD)	SC, IM, depot
Histrelin (SUPPRELIN)	SC
Triptorelin (TRELSTAR DEPOT, LA)	IM
Goserelin (ZOLADEX)	SC implant
<i>Antagonists</i>	
Cetrorelix (CETROTIDE)	SC
Ganirelix (ANTAGON)	SC
Abarelix (PLENAXIS)	SC depot

ABBREVIATIONS: IM, intramuscular; IN, intranasal; IV, intravenous; SC, subcutaneous.

REGULATION OF RELEASE OF GnRH GnRH is a decapeptide with blocked amino and carboxyl termini (Table 55–1) that is derived by proteolytic cleavage of a 92-amino-acid precursor peptide. GnRH release is intermittent and is governed by a hypothalamic neural pulse generator, primarily in the arcuate nucleus, that controls the frequency and amplitude of GnRH release. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes. This downregulation forms the basis for the clinical use of long-acting GnRH analogs to suppress gonadotropin secretion (*see* below).

MOLECULAR AND CELLULAR BASES OF GNRH ACTION GnRH signals through a specific GPCR on gonadotropes that activates $G_{q/11}$ and stimulates the PLC-IP₃-Ca²⁺ pathway (*see* Chapter 1), resulting in increased synthesis and secretion of LH and FSH.

OTHER REGULATORS OF GONADOTROPIN PRODUCTION Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate. The feedback effects of gonadal steroids are sex-, dosage-, and time-dependent. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator that controls GnRH secretion. Higher and more sustained levels of estradiol have positive feedback effects that ultimately result in the gonadotropin surge that precedes ovulation. In men, testosterone inhibits gonadotropin secretion, both directly and after its conversion to estradiol.

Gonadotropin secretion also is regulated by the *inhibins*, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibins are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to selectively inhibit FSH secretion without affecting that of LH.

Molecular and Cellular Bases of Gonadotropin Action

The gonadotropins (LH, FSH, and hCG) are glycosylated heterodimers, each containing a common α -subunit and a distinct β -subunit that confers specificity of action. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproduction technologies (*see* below).

The actions of LH and hCG are mediated by the LH receptor, while those of FSH are mediated by the FSH receptor. These receptors couple to G_s to activate the adenylyl cyclase–cyclic AMP pathway and most, if not all, of the actions of the gonadotropins can be mimicked by cyclic AMP analogs.

Physiological Effects of Gonadotropins

In men, LH acts on testicular Leydig cells to stimulate *de novo* synthesis of testosterone from cholesterol. Testosterone is required for gametogenesis within the seminiferous tubules and for maintenance of libido and male secondary sexual characteristics (*see* Chapter 58). FSH acts on the

Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation, thereby indirectly supporting germ cell maturation.

In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the activity of aromatase in granulosa cells, thereby stimulating the production of estradiol. LH acts on the theca cells to stimulate the *de novo* synthesis of androstenedione, the major precursor of ovarian estradiol in premenopausal women (see Figure 57–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

CLINICAL USES OF GnRH

Synthetic GnRH (*gonadorelin hydrochloride*) and GnRH analogs are used clinically (Table 55–1). The analogs exhibit enhanced potency and a prolonged duration of action compared to GnRH, which has a $t_{1/2}$ of 2–4 minutes. The prolonged actions of the analogs serve to desensitize the GnRH receptor to GnRH, thereby downregulating gonadotropin secretion.

Pure GnRH antagonists also have been developed; these do not cause the initial increase in gonadotropin secretion seen when long-acting GnRH agonists are used.

Therapeutic Uses of GnRH Analogs

SUPPRESSION OF GONADOTROPIN SECRETION Long-acting GnRH agonists markedly inhibit gonadotropin secretion and decrease the production of gonadal steroids by desensitizing GnRH signaling pathways. This pharmacological castration is useful in disorders that respond to reductions in gonadal steroids. A clear indication for this therapy is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a GnRH agonist.

Long-acting GnRH agonists are used for palliative therapy of hormonally responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid effects of transient increases in hormone levels (see Chapter 51). Because it does not transiently increase sex steroid production, an extended-release form of the GnRH antagonist *abarelix* (PLENAXIS) is marketed for use in prostate cancer patients in whom serious adverse consequences might accompany any stimulus to tumor growth (e.g., in patients with spinal cord metastases where increased tumor growth could lead to paralysis).

The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine leiomyomas, and acute intermittent porphyria. *Nafarelin* (SYNAREL) is administered by nasal spray for endometriosis. Depot preparations of *goserelin* (ZOLADEX), *leuprolide* (LUPRON DEPOT, ELEGARD) or *triptorelin* (TRELSTAR LA), which can be administered subcutaneously or intramuscularly monthly or every 3 months, can be used in these settings and may be particularly useful for pharmacological castration in disorders such as paraphilia, for which strict patient compliance is problematic.

The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes, vaginal dryness and atrophy, decreased bone density). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine leiomyomas generally is limited to 6 months unless add-back therapy with estrogens and/or progestins is incorporated into the regimen. In addition to these predicted effects, *abarelix* has been associated with a significant incidence of hypersensitivity reactions, and its therapeutic role remains to be defined. For safety reasons, *abarelix* distribution is limited to physicians who are enrolled in the manufacturer's prescribing program.

MANAGEMENT OF INFERTILITY Two GnRH antagonists, *ganirelix* (ANTAGON) and *cetrorelix* (CETROTIDE) (Table 55–1), have been used to suppress the LH surge and thus prevent premature follicular luteinization in ovarian-stimulation protocols that are part of assisted reproduction techniques.

Therapeutic Uses of Gonadotropins

Gonadotropins are purified from human urine or prepared using recombinant DNA technology. *Chorionic gonadotropin* (PREGNYL, NOVAREL, PROFASI, others), which mimics the action of LH, is obtained from the urine of pregnant women. Urine from postmenopausal women also is the source of *menotropins* (PERGONAL, REPRONEX), which contain roughly equal amounts of FSH and LH, as well as a number of other urinary proteins. Because of their relatively low purity, menotropins are

administered intramuscularly to decrease the incidence of hypersensitivity reactions. *Urofollitropin* (uFSH; BRAVELLE) is a highly purified FSH prepared by immunoconcentration with monoclonal antibodies and pure enough to be administered subcutaneously, as is a purified preparation of FSH and LH derived from urine (MENOPURE).

Recombinant preparations of gonadotropins increasingly are used in clinical practice. The two rFSH preparations that are available (*follitropin* α [GONAL-F] and *follitropin* β [PUREGON, FOLLISTIM]) both exhibit less interbatch variability than do preparations purified from urine and can be administered subcutaneously, since they are considerably purer. The relative advantages of the recombinant preparations (*i.e.*, efficacy, lower frequency of side effects such as ovarian hyperstimulation) have not been definitively established despite much debate in the published literature.

Recombinant forms of hCG (choriogonadotropin alfa; OVIDREL) and LH (LUVERIS, LHADI) also are available.

CRYPTORCHIDISM Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants, becoming less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG can be used to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for 6 doses.

OXYTOCIN

Biosynthesis of Oxytocin

Oxytocin is a cyclic neuropeptide that differs from vasopressin by only 2 amino acids (*see* Chapter 29). It is synthesized as a larger precursor molecule in cell bodies of the paraventricular nucleus, and to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor is rapidly converted by proteolysis to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland. In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits release. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release (e.g., ethanol inhibits release, while pain, dehydration, hemorrhage, and hypovolemia stimulate release).

Physiological Roles of Oxytocin

UTERUS Because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy has been highly debated; however, the finding that the oxytocin antagonist *atosiban* (TRACTOCILE) is effective in suppressing preterm labor (*see* below) supports the physiological importance of oxytocin in this setting. Exogenous oxytocin stimulates the frequency and force of uterine contractions. The responsiveness to oxytocin roughly parallels the increase in spontaneous activity that constitutes the initiation of labor and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Thus, the uterus is more responsive to oxytocin in late pregnancy than in early pregnancy. Progesterone antagonizes the stimulant effect of oxytocin *in vitro*, and a decline in progesterone receptor signaling in late pregnancy may contribute to the normal initiation of human parturition.

BREAST Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Mechanism of Action

In the human myometrium, oxytocin acts *via* specific GPCRs, coupled to G_i and G₁₁, to activate the PLC β -IP₃-Ca²⁺ pathway and enhance activation of voltage-sensitive Ca²⁺ channels. Oxytocin also increases local prostaglandin production, which further stimulates uterine contractions.

Clinical Use of Oxytocin

INDUCTION OF LABOR Oxytocin (PITOCIN, SYNTOCINON) is the drug of choice for labor induction. Indications for induction of labor include situations in which the risk of continued pregnancy to the mother or fetus is considered to be greater than the risks of delivery or of pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, and uteroplacental insufficiency (as in diabetes, preeclampsia, or eclampsia). Before labor is induced, it is essential to verify that the fetal lungs are sufficiently mature and to exclude potential contraindications (*e.g.*, abnormal fetal position, evidence of fetal distress, placental abnormalities, or previous uterine surgery that predisposes to uterine rupture).

Oxytocin is administered by intravenous infusion of a diluted solution (typically 10 mIU/mL), preferably by means of an infusion pump. If uterine hyperstimulation occurs, as evidenced by too-frequent contractions or the development of uterine tetany, the oxytocin should be discontinued immediately. The $t_{1/2}$ of intravenous oxytocin is short (~3 minutes); thus, the hyperstimulatory effects of oxytocin should dissipate over several minutes after the infusion is stopped. Because of its structural similarity to vasopressin, oxytocin at higher doses activates the vasopressin V_2 receptor causing antidiuretic effects. Particularly if hypotonic fluids (*e.g.*, dextrose in water) are infused too liberally, water intoxication may result causing convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

AUGMENTATION OF DYSFUNCTIONAL LABOR To augment hypotonic contractions in dysfunctional labor, it rarely is necessary to exceed an infusion rate of 10 mIU/min, and doses of >20 mIU/min rarely are effective when lower concentrations fail. Potential complications of overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion. Oxytocin usually is effective when there is a prolonged latent phase of cervical dilation and when, in the absence of cephalopelvic disproportion, there is an arrest of dilation or descent.

THIRD STAGE OF LABOR AND PUERPERIUM Postpartum hemorrhage is a significant problem in developed nations and is of even greater importance in underdeveloped countries. After delivery of the fetus or after therapeutic abortion, a firm, contracted uterus greatly reduces the incidence and extent of hemorrhage. Oxytocin (10 IU intramuscularly) often is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, 20 IU of oxytocin is diluted in 1 L of intravenous solution and infused at a rate of 10 mL/min until the uterus is contracted. Then the infusion rate is reduced to 1–2 mL/min until the mother is ready for transfer to the postpartum unit. If this is ineffective, ergot alkaloids such as *ergonovine maleate* (ERGOTRATE) or its methyl analog *methylergonovine maleate* (METHERGINE) or the prostaglandin analog *misoprostol* may be used in normotensive patients. The ergot alkaloids are discussed in more detail in Chapter 11; prostaglandins are discussed in Chapter 25.

Oxytocin-Receptor Antagonists

A peptide analog that competitively inhibits the interaction of oxytocin with its membrane receptor, atosiban (TRACTOCILE), has been introduced in a number of countries for the treatment of preterm labor. Atosiban decreases the frequency of uterine contractions and increases the number of women who remained undelivered. Its efficacy is comparable to β adrenergic agonists but the incidence of side effects is lower. It should be noted, however, that studies to date have failed to demonstrate a significant improvement in infant outcome when preterm labor is delayed.

THYROID AND ANTITHYROID DRUGS

The thyroid gland is the source of two fundamentally different types of hormones, iodothyronines and calcitonin. The iodothyronine hormones—thyroxine (T_4) and triiodothyronine (T_3)—are essential for normal growth and development and play an important role in energy metabolism. Calcitonin is discussed in Chapter 61.

The principal hormones of the thyroid gland are iodine-containing amino acid derivatives of thyronine: T_4 and T_3 (see Figure 56-1). T_4 is a prohormone that is converted to the biologically active form, T_3 . The 3'-monosubstituted compounds are more active than the 3',5'-disubstituted molecules. The affinity of iodothyronines for thyroid hormone receptors (TRs) generally parallels their biological potency.

BIOSYNTHESIS OF THYROID HORMONES The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a complex glycoprotein that forms the bulk of thyroid follicular colloid. The thyroid gland uniquely stores great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass.

The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are summarized in Figure 56-2: (1) uptake of iodide ion (I^-) by the gland; (2) oxidation of iodide and the iodination of tyrosyl groups of thyroglobulin; (3) coupling of iodotyrosine residues by ether linkage to generate the iodothyronines; (4) resorption of the thyroglobulin colloid from the lumen into the cell; (5) proteolysis of thyroglobulin and the release of T_4 and T_3 into the blood; (6) recycling of the iodine within the thyroid cell *via* de-iodination of the mono- and diiodotyrosines and reuse of the I^- ; and (7) conversion of T_4 to T_3 in peripheral tissues and in the thyroid.

- Uptake of Iodide.** Dietary iodine reaches the circulation as iodide. Normally, its concentration in the blood is very low (0.2–0.4 $\mu\text{g/dL}$; about 15–30 nM), but the thyroid actively transports the ion *via* a specific, membrane-bound protein termed the sodium-iodide symporter (NIS). The ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can far exceed 100 when the gland is stimulated. The NIS is inhibited by a number of ions such as thiocyanate and perchlorate (Figure 56-3). Thyrotropin (see below) stimulates the NIS, which is controlled by an autoregulatory mechanism. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression.
- Oxidation and Iodination.** The oxidation of iodide to its active form and the iodination of tyrosine are catalyzed by thyroid peroxidase, a heme-containing enzyme that utilizes hydrogen peroxide (H_2O_2) as the oxidant. The peroxidase is membrane-bound and concentrated at the apical surface of the thyroid cells. The reaction forms mono- and diiodotyrosyl residues in thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle. H_2O_2 is formed near its site of utilization and is stimulated by a rise in cytosolic Ca^{2+} .
- Formation of Thyroxine and Triiodothyronine from Iodotyrosines.** The remaining synthetic step is the coupling of two diiodotyrosyl residues to form T_4 or of one monoiodotyrosyl and one diiodotyrosyl residues to form T_3 . The same peroxidase catalyzes these oxidative reactions. The conformation of thyroglobulin apparently renders it uniquely efficient for the coupling reaction. T_4 predominantly is formed at the amino terminus of thyroglobulin, while T_3 is preferentially localized to the carboxy terminus.

The relative rates of synthetic activity at the various sites depend on the concentration of thyroid-stimulating hormone (TSH) and the availability of iodide, possibly accounting for the varying proportions of T_4 and T_3 depending on iodine supply. Limited iodine is utilized more efficiently in the synthesis of T_3 , the transcriptionally active form, which contains three-fourths as much iodine as T_4 . Eventually, iodine deficiency impairs synthesis of both T_4 and T_3 and hypothyroidism results. In addition to the coupling reaction, intrathyroidal and secreted T_3 is generated by the 5'-deiodination of T_4 .

- Resorption; 5. Proteolysis of Colloid; 6. Secretion of Thyroid Hormones.** Since T_4 and T_3 are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. TSH enhances the degradation of thyroglobulin by increasing the activity of several lysosomal thiol endopeptidases, which selectively cleave

FIGURE 56-1 Thyronine, thyroid hormones, and precursors.

thyroglobulin to hormone-containing intermediates that subsequently are processed by exopeptidases. The liberated hormones then exit the cell.

- Peripheral Conversion of Thyroxine to Triiodothyronine.** The normal daily production of T_4 is 70–90 μg , while that of T_3 is 15–30 μg . Although the thyroid does secrete some T_3 , monodeiodination of T_4 in peripheral tissues accounts for about 80% of circulating T_3 (Figure 56-3). Removal of the 5'-, or outer ring, iodine leads to the formation of T_3 in the “activating” metabolic pathway. The major nonthyroidal site of conversion of T_4 to T_3 is the liver. Thus, when T_4 is given to hypothyroid patients in doses that normalize its plasma concentration, the plasma concentration of T_3 also normalizes. Most peripheral tissues utilize T_3 derived from the circulating hormone. Notable exceptions are the brain and pituitary, where local generation of T_3 is the major source of intracellular hormone. Removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (reverse T_3 ; Figure 56-1). Normally, about 40% of T_4 is converted to T_3 , about 40% is converted to reverse T_3 , and about 20% is metabolized *via* other pathways, such as conjugation in the liver and excretion in the bile. Normal plasma concentrations of T_4 range from 4.5 to 11 $\mu\text{g/dL}$, while those of T_3 are 60–180 ng/dL.

FIGURE 56-3 Pathways of iodothyronine deiodination.

Two distinct 5'-deiodinase enzymes convert T_4 to T_3 ; they are selenoproteins that are encoded by distinct genes and are differentially expressed and regulated. The type I 5'-deiodinase (D1)—which is expressed in the liver, kidney, and thyroid—generates circulating T_3 that is used by most peripheral target tissues. D1 is inhibited by a number of drugs, including the antithyroid drug *propylthiouracil* (see below), *propranolol*, *amiodarone*, and *glucocorticoids*. The decreased plasma T_3 levels observed in a variety of nonthyroidal illnesses result from inhibition of D1 and decreased entrance of T_4 into cells. D1 is upregulated in hyperthyroidism and downregulated in hypothyroidism. Type II 5'-deiodinase (D2) is expressed in the brain, pituitary, and skeletal and cardiac muscle and supplies intracellular T_3 to these tissues. D2 has a much lower K_m for T_4 than does D1 (nM vs. μ M values) and its activity is unaffected by propylthiouracil. D2 is dynamically regulated by its substrate T_4 , such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Thus, D2 appears to autoregulate the intracellular supply of T_3 in the brain and pituitary. Inner ring- or 5-deiodination, a major inactivating pathway for T_4 and T_3 , is catalyzed by the type III deiodinase (D3), another selenoprotein that is found in placenta, skin, uterus, and brain.

TRANSPORT OF THYROID HORMONES IN THE BLOOD Iodine circulates as both organic iodine (95%) and inorganic iodide (5%). Most organic iodine is in T_4 (90–95%), while T_3 contains approximately 5%. Both T_4 and T_3 are transported in the blood in strong but noncovalent association with plasma proteins.

Thyroxine-binding globulin (TBG) is the major carrier of thyroid hormones. An acidic glycoprotein with a molecular weight of ~63,000, TBG binds one molecule of T_4 with very high affinity ($K_a \sim 10^{10} M^{-1}$). T_3 is bound less avidly. T_4 , but not T_3 , also is bound by transthyretin (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than TBG but has a lower affinity ($K_a \sim 10^7 M^{-1}$). Albumin can also bind T_4 when the more avid carriers are saturated, but the physiological significance of this binding generally is unclear.

Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion and prolongs their half-lives in circulation. The free (unbound) hormone is a small percentage (about 0.03% of T_4 and 0.3% of T_3) of the total hormone in plasma. The differential binding affinities for plasma proteins also are reflected in the 10–100-fold differences in circulating hormone concentrations and half-lives of T_4 and T_3 .

Because of the high degree of binding of thyroid hormones to TBG, changes in TBG concentration can have major effects on total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions (e.g., changes in estrogen levels during pregnancy or with administration of oral estrogens) can alter both the amount of TBG and its binding of thyroid hormones (Table 56–1). The increase in TBG induced by estrogen is due to an increase in its sialic acid content that decreases TBG clearance. Since the pituitary responds to and regulates circulating free

Table 56–1

Factors That Alter Binding of Thyroxine to Thyroxine-Binding Globulin

Increase Binding	Decrease Binding
<i>Drugs</i>	
Estrogens	Glucocorticoids
Methadone	Androgens
Clofibrate	L-Asparaginase
5-Fluorouracil	Salicylates
Heroin	Mefenamic Acid
Tamoxifen	Antiseizure medications
Selective estrogen receptor modulators	(phenytoin, carbamazepine)
	Furosemide
<i>Systemic Factors</i>	
Liver disease	Inheritance
Porphyria	Acute and chronic illness
HIV infection

FIGURE 56-4 Pathways of metabolism of thyroxine (T_4) and triiodothyronine (T_3).

ABBREVIATIONS: DIT, diiodotyrosine; MIT, monoiodotyrosine; T_4 S, T_4 sulfate; T_4 G, T_4 glucuronide; T_3 S, T_3 sulfate; T_3 G, T_3 glucuronide; T_4 K, T_4 pyruvic acid; T_3 K, T_3 pyruvic acid; Tetrac, tetraiodothyroacetic acid; Triac, triiodothyroacetic acid.

hormone levels, which are the metabolically active species, minimal changes in free hormone concentrations are seen when the pituitary-thyroid axis is intact; however, laboratory tests that measure only total hormone levels can be misleading in these settings.

DEGRADATION AND EXCRETION T_4 is eliminated from the body with a $t_{1/2}$ of 6–8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3 or 4 days; in hypothyroidism, it may be 9–10 days. These differing half-lives presumably reflect altered rates of hormone metabolism. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The opposite effect is observed when there is reduced TBG or when certain drugs inhibit thyroid hormone binding (Table 56-1). T_3 , which is less avidly bound to protein, has a $t_{1/2}$ of ~1 day.

The liver is the major site of nondeiodinative degradation of thyroid hormones; T_4 and T_3 are conjugated with glucuronic and sulfuric acids through the phenolic hydroxyl group and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in the feces. Steps in breakdown *via* deiodination to inactive metabolites are summarized in Figure 56-4.

REGULATION OF THYROID FUNCTION Thyroid hormone levels are tightly regulated by complex, reciprocal interactions among the hypothalamus, anterior pituitary, and thyroid (Figure 56-5). Thyrotropin-releasing hormone (TRH), which is made and secreted by the TRH neurons in the hypothalamus, stimulates the synthesis and secretion of TSH. TSH, made and secreted by pituitary thyrotropes, stimulates the biosynthesis and release of thyroid hormone. Superimposed on this positive regulatory loop is a negative feedback loop wherein circulating thyroid hormone acts in the hypothalamus and pituitary to decrease TSH stimulation of thyroid hormone release.

Thyrotropin-Releasing Hormone TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-proline amide) that is synthesized in the hypothalamus and released into the hypophyseal-portal circulation. TRH binds to its receptor, a GPCR, stimulates the G_q -PLC-IP₃-Ca²⁺ pathway, and activates PKC, ultimately stimulating the synthesis and release of TSH by the thyrotropes. Although TRH is the dominant regulator of TSH secretion, somatostatin, dopamine, and pharmacological doses of glucocorticoids inhibit TRH-stimulated TSH secretion.

Actions of TSH on the Thyroid TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins (*see* Chapter 55). It is secreted in a pulsatile manner

FIGURE 56-5 Regulation of thyroid hormone secretion. Myriad neural inputs influence hypothalamic secretion of thyrotropin-releasing hormone (TRH). TRH stimulates release of thyrotropin (TSH, thyroid-stimulating hormone) from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones T₃ and T₄. T₃ and T₄ feed back to inhibit the synthesis and release of TRH and TSH. Somatostatin (SST) can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I⁻ are required for thyroxine synthesis, but high levels inhibit thyroxine synthesis and release.

and circadian pattern, its levels in circulation being highest during sleep. Its secretion is precisely controlled by the levels of TRH and by the concentration of free thyroid hormones in the circulation. It is the key direct stimulator of thyroid hormone synthesis and release.

The first measurable effect of TSH on thyroid hormone metabolism is increased secretion, which is detectable within minutes. All phases of hormone synthesis and secretion are eventually stimulated: iodide uptake and organification, endocytosis, and proteolysis of thyroglobulin. There also is increased vascularity of the gland and hypertrophy and hyperplasia of thyroid cells.

The TSH receptor is a GPCR that is structurally similar to the receptors for luteinizing hormone and follicle-stimulating hormone (*see* Chapter 55). These receptors all have large extracellular domains that are involved in hormone binding. TSH binding to its receptor stimulates the G_s-adenylyl cyclase-cyclic AMP pathway. Higher concentrations of TSH activate the G_q-PLC pathway. Both signaling pathways apparently mediate effects of TSH on thyroid function in human beings.

Mutations of the TSH receptor result in clinical thyroid dysfunction. Germline mutations can present as autosomal dominant toxic thyroid hyperplasia (gain-of-function mutations) or as gestational hyperthyroidism due to receptor hypersensitivity to hCG. Somatic mutations that result in constitutive activation of the receptor are associated with hyperfunctioning thyroid adenomas.

RELATION OF IODINE TO THYROID FUNCTION Normal thyroid function requires an adequate intake of iodine; without this, thyroid hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodide gradient that may be 10 times normal. In mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone, in part by preferentially secreting T₃. In more severe deficiency, as is common in some parts of the world, adult hypothyroidism or cretinism may occur.

The daily requirement for iodine in adults is 1–2 μg/kg body weight. In the U.S., recommended daily allowances for iodine range from 40 to 120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 270 μg for lactation. Dairy products and fish have relatively high iodine contents. Because of concerns of iodine insufficiency, iodine supplementation has been widely used for prophylaxis and therapy. The most practical form of this supplementation has been addition of iodide or iodate (now preferred) to table salt. In the U.S., such supplementation is optional and iodized salt provides 100 μg of iodine/g.

ACTIONS OF THYROID HORMONES Most actions of thyroid hormones are mediated by nuclear TRs that are members of the nuclear receptor superfamily. T_3 binds to high-affinity TRs, which then bind to specific DNA sequences (thyroid hormone response elements, TREs) in the promoter/regulatory regions of target genes to modulate gene transcription, and ultimately, protein synthesis. The unliganded TR is bound to the TREs in the basal state, typically repressing gene transcription. Binding by T_3 may activate gene transcription by relieving this repression; the T_3 -TR complex may also have direct activation or repression functions. Like many nuclear receptors, TR typically activates transcription as a heterodimer with the retinoid X receptor. These transcriptional effects are mediated by interactions with a complex group of coactivator and corepressor proteins. Despite its capacity to bind to TRs, T_4 has not been shown to alter gene transcription and probably serves as a prohormone whose actions are manifested following conversion to T_3 .

Two distinct genes encode 2 families of TRs, TR α and TR β , and both genes encode multiple receptor isoforms. Certain isoforms (e.g., TR α_1 and TR β_1) are found in virtually all thyroid hormone-responsive tissues, whereas TR β_2 is expressed only in the anterior pituitary. Resistance to thyroid hormone has been described in patients with mutations in the TR β gene. In addition to nuclear receptor-mediated actions, there are several well-characterized, nongenomic actions of thyroid hormones, including those occurring at the plasma membrane and on the cellular cytoarchitecture.

Growth and Development Thyroid hormone plays a critical role in brain development. The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain that reflect disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of life prevents the development of these abnormalities.

Perhaps the most striking illustration of the pervasive developmental effects of thyroid hormones is provided by children with severe thyroid hormone deficiency from early childhood, a condition termed *cretinism*. This may either be endemic in regions of severe iodine deficiency or sporadic due to failure of the thyroid to develop normally or defects in the synthesis of thyroid hormone. Affected children are dwarfed with short extremities, have mental retardation, and are inactive and listless. Other manifestations include facial puffiness, enlarged tongue, dry and doughy skin, slow heart rate, and decreased body temperature. For full recovery, treatment of patients with cretinism must be initiated before these florid features are apparent. Thus, pregnant women in areas of endemic cretinism due to iodine deficiency are supplemented with iodine and all newborns are screened for thyroid hormone deficiency in many developed nations.

Calorigenic Effects In homeothermic animals, a characteristic response to thyroid hormone is increased O_2 consumption. Most peripheral tissues contribute to this response; heart, skeletal muscle, liver, and kidney are stimulated markedly by thyroid hormone. Indeed, 30–40% of the thyroid hormone-dependent increase in O_2 consumption can be attributed to stimulation of cardiac contractility. The mechanism of the calorigenic effect of thyroid hormone appears to reflect an integrated program by which thyroid hormone regulates the set-point of energy expenditure and maintains the metabolic machinery necessary to sustain it. Even small changes in L-thyroxine replacement dose may significantly alter the set-point for resting energy expenditure in the hypothyroid patient.

Cardiovascular Effects Thyroid hormones directly and indirectly influence cardiac function, and cardiovascular manifestations are prominent clinical consequences of thyroid disease. In hyperthyroidism, there is tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. In hypothyroidism, there is bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

Metabolic Effects

Thyroid hormones stimulate metabolism of cholesterol to bile acids and increase the concentration of receptors for low-density lipoprotein on hepatocytes, perhaps explaining the hypercholesterolemia that is characteristic in hypothyroid states.

Thyroid hormones enhance the lipolytic responses of fat cells to other hormones (e.g., catecholamines) and elevated plasma free fatty acid levels are seen in hyperthyroidism. Hyperthyroidism is an insulin resistant state, as manifested by depleted glycogen stores and enhanced gluconeogenesis; this may precipitate diabetes mellitus or worsen glycemic control in diabetics on treatment. Conversely, insulin requirements are reduced in diabetics who become hypothyroid.

Clinical Aspects of Thyroid Dysfunction

Clinical disorders of the thyroid can result from excessive or deficient production of thyroid hormone or from disorders of thyroid growth.

Assays of thyroid function Advances in thyroid function tests (TFTs), including the development of sensitive assays for TSH and the use of analog assays that provide a reasonable estimate of the free T_4 level, have markedly improved the diagnosis and treatment of thyroid disorders. These assays nonetheless can be misleading, as the TSH level can remain low for weeks to months after a hyperthyroid patient is restored to a euthyroid state and the analog assays of free T_4 can provide misleading results in certain settings such as critical illness.

A considerable advance in the management of thyroid cancer has resulted from the introduction of recombinant human TSH (THYROGEN). A dose of 0.9 mg is administered intramuscularly, followed by an identical dose 24 hours later. The serum thyroglobulin is then measured 48–72 hours after the second TSH injection; this has become the preferred diagnostic test for following patients with differentiated thyroid cancer who have had thyroidectomy and ablation of any remnant tissue with radioactive iodine. This regimen can also be used to stimulate iodine uptake by malignant cells in a total body scan (*see below*).

The percent uptake of a tracer dose of radioactive iodine (the radioactive iodine uptake, or RAIU) can provide important information about the pathogenesis of thyrotoxic states (*see below*).

Thyroid Hyperfunction Thyrotoxicosis is the term applied to any condition caused by elevated levels of circulating free thyroid hormones, while hyperthyroidism is restricted to those conditions in which thyroid hormone production and release are caused by gland hyperfunction.

Graves' disease, a frequent cause of hyperthyroidism, is an autoimmune disorder caused by IgG antibodies that bind to and activate the TSH receptor. Because of the persistent activation of the TSH receptor, the RAIU is increased. Other manifestations of Graves' disease include infiltrative ophthalmopathy and skin involvement (pretibial myxedema). Toxic multinodular goiter or hyperfunctioning adenomas account for 10–40 % of cases of hyperthyroidism and are more common in older patients. Destructive processes involving the thyroid (e.g., thyroiditis) can cause thyrotoxicosis due to leakage of preformed thyroid hormone from the gland. In this case, as with patients taking excessive doses of exogenous thyroid hormone, the RAIU will be suppressed.

Most of the signs and symptoms of thyrotoxicosis stem from excessive heat production, increased motor activity, and increased activity of the sympathetic nervous system. Eventually, the increased energy expenditure is often associated with weight loss. Cardiac manifestations include tachycardia and bounding pulses; older patients or those with underlying heart disease may exhibit angina, arrhythmias (especially atrial fibrillation), and high-output heart failure.

The most severe form of hyperthyroidism is thyroid storm, a rare but life-threatening disease that usually is precipitated by an intercurrent medical problem. Precipitating factors include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and rarely, radioactive iodine ablation. Clinical features are similar to those of thyrotoxicosis, but are more severe. Cardinal features include fever and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. The abnormalities in TFTs are not necessarily worse than those in uncomplicated thyrotoxicosis and thyroid storm is a clinical diagnosis.

Thyroid Hypofunction Hypothyroidism is the most common disorder of thyroid function. It can be divided into patients who have a failure of the thyroid gland to produce sufficient thyroid hormone (primary hypothyroidism) and patients in which pituitary or hypothalamic disease is associated with impaired TSH stimulation (central or secondary hypothyroidism). Worldwide, primary hypothyroidism is caused most often by iodine deficiency. In areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto's thyroiditis) accounts for most cases. Other causes include postpartum thyroiditis, surgical removal, or radioactive iodine ablation of the gland. Hypothyroidism present at birth (cretinism) is the most common preventable cause of mental retardation in the world.

Hypothyroidism, when mild, can be subtle in its presentation. When severe, the signs are overt and the presentation is pathognomonic. The face is puffy and pallid, the skin is cold and dry, and the hair is coarse. The voice is husky, mentation is impaired, and depression may be present. The appetite is poor and constipation is common. The pulse is slow and a pericardial effusion may be present. Patients are lethargic and often complain of cold intolerance and weight gain.

The most severe expression of severe, long-standing hypothyroidism is myxedema coma. This medical emergency occurs most commonly in the elderly, particularly during winter months. Common precipitating factors include pneumonia, cerebrovascular accidents, and congestive heart failure. The clinical course—lethargy proceeding to stupor and then coma—is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers. Cardinal features of myxedema coma are (1) hypothermia, which may be profound; (2) respiratory depression; and (3) unconsciousness. Other clinical features include bradycardia, macroglossia, delayed reflexes, and dry skin. Hyponatremia is common and may be severe. Although the diagnosis is confirmed by measuring TFTs, myxedema coma is a clinical diagnosis.

Disorders of Thyroid Growth Disorders of thyroid growth include diffuse enlargement of the thyroid gland, or goiter, nodular thyroid disease, and thyroid cancer. Goiter may be associated with hypothyroidism and the resultant TSH-induced hypertrophy and hyperplasia of thyroid cells.

Nodular thyroid disease is the most common endocrinopathy; when sensitive techniques such as ultrasound are used, the prevalence of thyroid nodules approaches 50% by age 60. Although these nodules can cause hyperthyroidism due to autonomous function, TFTs often are in the normal range. In this setting, it is important to distinguish benign nodules (solitary or multinodular) from the 5% to 10% that are malignant. Fine needle aspiration for cytopathology is the preferred diagnostic test.

Most thyroid cancers retain many functional aspects of normal thyroid cells. Although the treatment of choice for these tumors—as for all thyroid cancers—is surgical removal, the fact that these differentiated thyroid cancers retain some features of normal thyroid cells has important implications for both diagnosis and therapy (see below).

THERAPEUTIC USES OF THYROID HORMONE The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism or cretinism and for TSH suppression therapy in patients with thyroid cancer and occasionally those with nontoxic goiter.

The synthetic preparations used are the sodium salts of the natural isomers of the thyroid hormones. Levothyroxine sodium ($L-T_4$, SYNTHROID, LEVOXYL, LEVOTHROID, UNITHROID, others) is available in tablets in a variety of doses and as a lyophilized powder for injection. $L-T_4$ has a narrow therapeutic index, and the FDA has mandated demonstration of bioequivalence for brand and generic preparations by the various producers. Liothyronine sodium ($L-T_3$) is available in tablets (CYTOMEL) and in an injectable form (TRIOSTAT). A mixture of $L-T_4$ and $L-T_3$ is marketed as liotrix (THYROLAR). Desiccated thyroid preparations, derived from whole animal thyroids and containing both T_4 and T_3 , have highly variable biologic activity and are much less desirable.

Thyroid Hormone Replacement Therapy

$L-T_4$ is preferred for thyroid hormone replacement because of its consistent potency and prolonged duration of action. Absorption of $L-T_4$ in the small intestine is variable and incomplete (50–80% of the dose absorbed, slightly increased when taken on an empty stomach). Certain drugs may interfere with $L-T_4$ absorption, including cholestyramine, iron and calcium supplements, aluminum hydroxide, and soy products. Enhanced biliary excretion of $L-T_4$ occurs during the co-administration of drugs that induce hepatic CYPs, such as phenytoin, carbamazepine, and rifampin, often necessitating an increase in the dose. $L-T_3$ may be used occasionally when a quicker onset of action is desired, as in patients with myxedema coma, or when a shorter duration of action is desired, as when preparing a patient for ^{131}I therapy for thyroid cancer. It is less desirable for chronic therapy because it is more expensive, must be dosed more frequently, and causes transient elevations of serum T_3 above the normal range.

The average daily adult replacement dose of $L-T_4$ in a 70-kg person is 112 μg given as a single dose, while that for $L-T_3$ is 50–75 μg in divided doses. In healthy younger individuals, therapy can be initiated at the full replacement dose. Because of the prolonged $t_{1/2}$ of T_4 (1 week), steady state levels will not be achieved until 5 weeks after a change in dose; thus, reevaluation of TFTs should not be performed at intervals of less than 6–8 weeks. The goal is to achieve a TSH value in the normal range, since suppression of TSH by overreplacement may be associated with osteoporosis and cardiac dysfunction. In patients with markedly elevated TSH (>50 mIU/mL), it may take more than 8 weeks for the TSH to reach a steady state. In patients with central hypothyroidism, the dose should be adjusted based on the free T_4 and patient well-being. In noncompliant young patients, the total weekly dose of $L-T_4$ can safely be administered as a single dose once weekly. In individuals over age 60, initiation of therapy at lower doses of $L-T_4$ (25–50 $\mu\text{g}/\text{day}$)

minimizes the risk of exacerbating undiagnosed heart disease. For individuals with preexisting cardiac disease, $L-T_4$ is initiated at 12.5 $\mu\text{g}/\text{day}$, with increases of 12.5–25 $\mu\text{g}/\text{day}$ every 6–8 weeks. Because of its long $t_{1/2}$, a lapse of several days of $L-T_4$ therapy is unlikely to have significant consequences; if more prolonged interruption is necessary, $L-T_4$ can be given parenterally at a dose 25–50% less than the daily oral requirement.

Thyroid Hormone Replacement during Pregnancy Due to estrogen-induced increases in TBG and transplacental passage of $L-T_4$ from mother to fetus, a higher dose of $L-T_4$ often is required in hypothyroid patients who become pregnant (typically 25–40% over basal). Because even mild hypothyroidism may be associated with impaired psychomotor development, any woman whose TSH is elevated should be treated during pregnancy. Serum TSH should be determined during the first trimester in all patients with preexisting hypothyroidism and in those at risk for developing the disorder. Some screen all pregnant women in the first trimester. Therapy with $L-T_4$ should be administered to keep the TSH in the normal range and adjusted based on the serum TSH throughout the pregnancy.

Treatment of Myxedema Coma

Myxedema coma is the extreme expression of severe, long-standing hypothyroidism. In addition to supportive care and treatment of the precipitating cause, treatment with thyroid hormone is essential. Based on uncertain oral absorption, thyroid hormone generally is given parenterally (e.g., a loading dose of 200–300 μg of $L-T_4$ intravenously followed by a second dose of 100 μg 24 hours later). A daily maintenance dose is then continued intravenously until the patient has improved sufficiently for oral therapy. Because of its more rapid onset of action, some clinicians add $L-T_3$ (10 μg intravenously every 8 hours) until the patient is stable. Overly aggressive treatment with either $L-T_4$ or $L-T_3$ may be associated with increased mortality.

Treatment of Cretinism

An initial daily dose of $L-T_4$ of 10–15 $\mu\text{g}/\text{kg}$ is recommended to rapidly normalize the serum T_4 concentration, which will increase the serum T_4 concentration to the upper half of the normal range within 1–2 weeks. Individual $L-T_4$ doses are then adjusted at 4–6-week intervals during the first 6 months, at 2-month intervals during the 6–18-month period, and then at 3–6-month intervals to maintain serum free T_4 levels in the upper half of the normal range, or even slightly above the normal range, with a normal TSH. Clinical guides for assessing response include growth, motor development, bone maturation, and developmental progress.

Treatment of Thyroid Nodules

Thyroid hormone is sometimes used to suppress growth in patients with a benign solitary thyroid nodule and a normal TSH, but such therapy generally is not recommended. Suppression therapy is of no value if the nodule is autonomous, as indicated by a subnormal TSH. Once TSH is suppressed, a radioisotope scan should be performed; if significant uptake persists, the gland is non-suppressible and $L-T_4$ therapy should be discontinued. Suppression therapy should not be used in patients with known coronary artery disease, since the risks of precipitating cardiac arrhythmias or angina are considerable.

Thyroid Cancer

$L-T_4$ therapy to suppress TSH stimulation to growth of differentiated thyroid cancers is the cornerstone of therapy following surgical removal and radioactive ablation with ^{131}I (see below). In tumors with more worrisome prognostic features, the goal is to suppress the TSH to undetectable levels. For tumors judged to be of lower risk, the $L-T_4$ dose is typically adjusted so that the TSH is below the normal range but still detectable.

ANTITHYROID DRUGS AND OTHER THYROID INHIBITORS

A large number of compounds interfere either directly or indirectly with the synthesis, release, or action of thyroid hormones (Table 56–2). Inhibitors are classified into four categories: (1) antithyroid drugs, which interfere directly with the synthesis of thyroid hormones; (2) ionic inhibitors, which block the iodide transport mechanism; (3) high concentrations of iodine itself, which decrease release of thyroid hormones and may also decrease hormone synthesis; and (4) radioactive iodine, which damages the gland with ionizing radiation. Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis, including inhibitors of the peripheral deiodination of T_4 to T_3 , β adrenergic receptor antagonists, and Ca^{2+} channel blockers.

Table 56-2

Antithyroid Compounds

Process Affected	Examples of Inhibitors
Active transport of iodide	Complex anions: perchlorate, fluoborate, pertechnetate, thiocyanate
Iodination of thyroglobulin	Thionamides: propylthiouracil, methimazole, carbimazole Thiocyanate; iodide
Coupling reaction	Aniline derivatives; sulfonamides
Hormone release	Thionamides; sulfonamides
Iodotyrosine deiodination	Lithium salts; iodide
Peripheral iodothyronine deiodination	Nitrotyrosines
Hormone excretion/inactivation	Thiouracil derivatives; amiodarone
Hormone action	Oral cholecystographic agents
Binding in gut	Inducers of hepatic drug-metabolizing enzymes: phenobarbital, rifampin, carbamazepine, phenytoin Thyroxine analogs; amiodarone Cholestyramine

Antithyroid Drugs

The antithyroid drugs that have greatest clinical utility are the thioureylenes, which belong to the family of thionamides (Figure 56-6).

MECHANISM OF ACTION Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines. The inhibition of hormone synthesis eventually results in depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. Clinical effects only become apparent when the preformed hormone is reduced and the concentrations of circulating thyroid hormones begin to decline.

In addition to blocking hormone synthesis, propylthiouracil also inhibits the peripheral deiodination of T_4 to T_3 ; this added effect provides a rationale for the choice of propylthiouracil over methimazole in the treatment of severe hyperthyroid states such as thyroid storm.

ABSORPTION, METABOLISM, AND EXCRETION The antithyroid drugs used in the U.S. are propylthiouracil (6-*n*-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; TAPAZOLE). In Europe, carbimazole (NEO-MERCAZOLE), a carboxy derivative that is converted to methimazole, also is used. Some pharmacological properties of propylthiouracil and methimazole are shown in Table 56-3. Because of its shorter $t_{1/2}$, propylthiouracil must be dosed more frequently than methimazole. In severe hyperthyroid states, even a 500-mg dose of propylthiouracil must be dosed every 6-8 hours to yield complete thyroid inhibition, while doses of 20-40 mg of methimazole may be given once-daily. The drugs are concentrated in the thyroid and drugs and metabolites largely are excreted in the urine. Propylthiouracil and methimazole cross the placenta equally and also can be found in milk. Their use in pregnancy is discussed below.

FIGURE 56-6 Antithyroid drugs of the thionamide type.

Table 56-3

Selected Pharmacokinetic Features of Antithyroid Drugs

	Propylthiouracil	Methimazole
Plasma protein binding	~75%	Nil
Plasma $t_{1/2}$	75 minutes	~4–6 hours
Volume of distribution	~20 L	~40 L
Concentrated in thyroid	Yes	Yes
Metabolism of drug during illness		
Severe liver disease	Normal	Decreased
Severe kidney disease	Normal	Normal
Dosing frequency	1–4 times daily	Once or twice daily
Transplacental passage	Low	Low
Levels in breast milk	Low	Low

UNTOWARD REACTIONS The most serious adverse effect of the antithyroid drugs is agranulocytosis, which can occur in up to 0.2% of patients. The development of agranulocytosis apparently is dose related with methimazole but not with propylthiouracil. Agranulocytosis usually occurs during the first few weeks of therapy but may occur later. Surveillance white blood cell counts are of limited value, and patients should be warned to report immediately sore throat or fever that may herald the onset of this reaction. Agranulocytosis is reversible upon discontinuation of the offending drug. Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction; frequent leukocyte counts are then required.

The most common adverse reaction is an urticarial rash that often subsides spontaneously without drug discontinuation and may be relieved by antihistamines or glucocorticoids or by changing antithyroid drugs (cross-sensitivity to propylthiouracil and methimazole is uncommon). Other less common manifestations include arthralgias, paresthesias, headache, nausea, skin pigmentation, and hair loss. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil.

THERAPEUTIC USES

The antithyroid drugs are used as definitive treatment of hyperthyroidism, to control the disorder in anticipation of a spontaneous remission in Graves' disease, while awaiting the effects of radiation, and in preparation for thyroid surgery.

A typical starting dose of propylthiouracil is 100 mg every 8 hours or 150 mg every 12 hours. When doses >300 mg/day are needed in severely hyperthyroid patients, the drug should be administered at least every 8 hours. In thyroid storm, propylthiouracil is preferred due to its inhibition of peripheral conversion of T_4 to T_3 ; doses of 200–400 mg every 4 hours are typically employed. In less severely hyperthyroid patients, methimazole often is effective when given once daily (10–30 mg), which may improve patient adherence. Response to therapy is followed by TFTs, remembering that the TSH may remain suppressed even after the patient has become euthyroid. Once euthyroidism is achieved, usually within 12 weeks, the dose can be reduced but should not be stopped lest the hyperthyroid state recur. Continued overtreatment with antithyroid drugs can induce hypothyroidism, often heralded by increased gland size.

Although remission of Graves' disease does occur, experience in the U.S. suggests that this happens in less than 50% of patients. Thus, many endocrinologists in the U.S. prefer radioactive iodine ablation for definitive therapy (see below).

Pregnant women with thyrotoxicosis comprise a special subset of patients. In this setting, radioactive iodine is clearly contraindicated. Propylthiouracil and methimazole cross the placenta equally and either can be used in pregnancy. The dose of antithyroid drug should be minimized to avoid possible hypothyroidism in the fetus; the goal is to keep the free T_4 in the upper half of the normal range or even slightly elevated. Because Graves' disease often improves during pregnancy, TFTs should be followed at 4–6-week intervals, with dose decreases as indicated. In nursing mothers, propylthiouracil is the drug of choice, since very small amounts of drug are found in breast milk and impaired thyroid function has not been demonstrated in suckling babies whose mothers were taking this drug; methimazole also appears to be safe in this setting.

Ionic Inhibitors

The ionic inhibitors interfere with iodide concentration by the thyroid gland. Effective agents are monovalent hydrated anions of a size similar to that of iodide. The best studied, thiocyanate, is unique among these agents because it is not concentrated by the thyroid gland. Perchlorate (ClO_4^-) blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS. Perchlorate at higher doses (2–3 g daily) has caused fatal aplastic anemia; lower doses (750 mg/day) have been used to treat patients with hyperthyroidism due to the administration of pharmacological doses of iodide (see below). Although concern has been raised about potential effects of perchlorate contamination of the water supply, there is no definitive evidence of deleterious effects on thyroid function.

Iodide

High concentrations of iodide inhibit iodide uptake, organification and coupling, and the release of thyroid hormone. In hyperthyroid patients, the response to iodide therapy can be striking. Over time, however, the beneficial effects disappear, even with ongoing therapy. Thus, iodide is often used for the preoperative treatment of hyperthyroidism in anticipation of thyroid surgery, where it causes a salutary decrease in gland vascularity. Iodide also can be administered prophylactically to protect the thyroid from radioactive iodine following a nuclear accident. In euthyroid individuals, the administration of doses of iodide from 1.5 to 150 mg daily does not significantly impair thyroid hormone synthesis. However, euthyroid patients with a wide variety of underlying thyroid disorders (e.g., treated Graves' disease, Hashimoto's thyroiditis, postpartum thyroiditis) may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs, most often certain expectorants, topical antiseptics, amiodarone, and radiological contrast agents.

Occasional individuals show marked hypersensitivity to intravenous administration of iodide or organic preparations of iodine. Angioedema is the cardinal manifestation, and laryngeal edema may lead to suffocation. Later, a serum sickness-like reaction may develop. These reactions to radiographic contrast agents are not due to the iodine *per se*.

Radioactive Iodine

^{131}I has a $t_{1/2}$ of 8 days and emits both γ rays and β particles. Radioactive ablation with ^{131}I is used for the treatment of hyperthyroidism and for adjuvant therapy of differentiated thyroid cancer. The only absolute contraindication to the use of ^{131}I therapy is pregnancy, as the fetal thyroid after the first trimester can concentrate the isotope and thus will be damaged. There is no evidence for increased total cancer mortality or increased incidence of leukemia in treated patients. One study found an increased incidence of colorectal cancer following ^{131}I therapy, leading to the recommendation that laxatives be given prophylactically to all patients receiving ^{131}I . The short-lived ^{123}I is primarily a γ -emitter that is used for diagnostic purposes in thyroid uptake and scans.

Hyperthyroidism

^{131}I is highly useful in the treatment of hyperthyroidism and is viewed by many as the treatment of choice for this condition. There is little benefit from individualized dosing based on thyroid weight and RAIU, and a total dose of approximately 15 mCi is typically employed. Patients who have been pretreated with propylthiouracil to control their hyperthyroidism may need a higher dose; no such effect is seen with methimazole. The course of a patient who has received an effective dose of ^{131}I is characterized by progressive recovery, beginning within a few weeks after treatment and continuing for a period of 2–4 months thereafter. If therapy has been inadequate, the need for further treatment should be apparent within 6–12 months. Adjuvant therapy with β adrenergic antagonists, antithyroid drugs, or both can be used while awaiting the full effects of therapy. The antithyroid drug should be withheld for a few days before and after the ^{131}I to avoid inhibiting iodine uptake and organification.

Radioactive iodine ablation therapy for hyperthyroidism is relatively inexpensive, does not require hospitalization, and is relatively free of adverse effects. It is associated with a high incidence of permanent hypothyroidism, and all patients must be warned of this and followed thereafter for the onset of hypothyroidism. Because thyroid hormone replacement therapy is generally well accepted by the patient, many specialists prefer to treat with relatively higher ^{131}I doses to rapidly and predictably induce hypothyroidism. Another adverse effect of ^{131}I ablation therapy for Graves' disease is the possible worsening of the Graves' ophthalmopathy, particularly if the patient is allowed to become hypothyroid. Although rare, thyroid storm has occurred after therapy with ^{131}I .

Thyroid Carcinoma

Following surgical removal, the most important intervention in the treatment of differentiated thyroid cancer is $L-T_4$ suppression of serum TSH (see above). Radioactive iodine ablation with ^{131}I also plays an important therapeutic role. While most well-differentiated thyroid carcinomas accumulate iodine inefficiently, stimulation of iodine uptake with TSH often is used efficiently to treat residual cervical disease or metastases. Following near total thyroidectomy—the preferred surgical approach—the patient is allowed to become hypothyroid until the TSH is over 30 mIU/L. Thereafter, the patient is given 30–150 mCi of ^{131}I and a total body scan is obtained at one week. Alternatively, recombinant human TSH can be administered to stimulate the uptake of radioactive iodine. The ^{131}I dose is repeated if a rising serum thyroglobulin level or persistent iodine uptake on a total body scan suggests that there is tumor recurrence. Particularly at higher doses, salivary gland dysfunction may occur after radioactive iodine therapy.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

ESTROGENS AND PROGESTINS

Estrogens and *progestins* are steroid hormones with numerous physiological actions. In women, these include developmental effects, control of ovulation, cyclical preparation of the reproductive tract for fertilization and implantation, and metabolic actions. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. Estrogens and progestins are used in menopausal hormone therapy (MHT) and contraception in women. Estrogen- and progesterone-receptor antagonists also are available. Antiestrogens are employed in treating hormone-responsive breast cancer and infertility. The main use of antiprogestins has been for medical abortion. Selective estrogen receptor modulators (SERMs) with tissue-selective agonist or antagonist activities are increasingly available.

ESTROGENS

CHEMISTRY AND BIOSYNTHESIS

Many steroidal and nonsteroidal compounds possess estrogenic activity (Table 57-1 and Figure 57-1). The most potent endogenous estrogen is 17β -estradiol, followed by estrone and estriol. The phenolic A ring is the principal structural feature responsible for selective, high-affinity binding to the estrogen receptors (ERs). Ethinyl substitutions at C17 increase oral potency by inhibiting first-pass hepatic metabolism.

Nonsteroidal compounds with estrogenic or antiestrogenic activity—including flavones, isoflavones (e.g., genistein), and coumestan derivatives—occur in plants and fungi. Synthetic agents—including pesticides (e.g., *p,p'*-DDT), plasticizers (e.g., bisphenol A), and other industrial chemicals (e.g., polychlorinated biphenyls)—also have hormonal or antihormonal activity. While their affinity is relatively weak, their large number, bioaccumulation, and persistence in the environment raise concerns about their potential toxicity in humans and wildlife.

Steroidal estrogens arise from androstenedione or testosterone (Figure 57-1) by aromatization of the A ring, a reaction catalyzed by aromatase (CYP19), an enzyme found in ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblast, preimplantation blastocysts, bone, various brain regions, and other tissues. Ovaries are the principal source of circulating estrogen in premenopausal women. Gonadotropins, acting via receptors that couple to the G_s -adenylyl cyclase-cyclic AMP pathway, increase the activities of aromatase and the cholesterol side-chain cleavage enzyme. The ovary contains the type I isoform of 17β -hydroxysteroid dehydrogenase, which favors the production of testosterone and estradiol from androstenedione and estrone, respectively. In the liver, the type II isoform oxidizes circulating estradiol to estrone, which then is converted to estriol (Figure 57-1). These estrogens are excreted in the urine along with their glucuronide and sulfate conjugates. In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone (DHEA) secreted by the adrenals. In men, the testes produce estrogens but extragonadal aromatization of circulating androstenedione and DHEA accounts for most circulating estrogens.

Local production of estrogens by the aromatization of androgens may play a causal role in the development or progression of diseases such as breast cancer. Estrogens also may be produced from androgens by CYP19 in the central nervous system (CNS) and other tissues and exert local effects near their production site (e.g., in bone they increase bone mineral density).

Physiological and Pharmacological Actions

DEVELOPMENTAL ACTIONS Estrogens in girls cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement, molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions.

Estrogens also play developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility.

Table 57-1

Structural Formulas of Selected Estrogens

Steroidal Estrogens				Nonsteroidal Compounds with Estrogenic Activity
				Diethylstilbestrol
Derivative	R ₁	R ₂	R ₃	Bisphenol A
Estradiol	—H	—H	—H	Genistein
Estradiol valerate	—H	—H	—C(=O)(CH ₂) ₃ CH ₃	
Ethinyl estradiol	—H	—C≡CH	—H	
Mestranol	—CH ₃	—C≡CH	—H	
Estrone sulfate	—SO ₃ H	—*	=O*	
Equilin [†]	—H	—*	=O*	

*Designates C17 ketone.

[†]Also contains 7, 8 double bond.

NEUROENDOCRINE CONTROL OF THE MENSTRUAL CYCLE A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 57-2). A neuronal oscillator or “clock” in the hypothalamus fires at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (see Chapter 55). GnRH interacts with its receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle (see below), controls the relative secretion of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of follicles in the ovary and ovarian production of estrogen and progesterone, which then exert feedback regulation on the pituitary and hypothalamus.

Because GnRH release is intermittent, LH and FSH secretion is pulsatile. The pulse *frequency* is determined by the *hypothalamic GnRH pulse generator* (Figure 57-2), but the amount of gonadotropin released in each pulse (*i.e.*, the pulse *amplitude*) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, *pulsatile* nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles; constant infusion of GnRH inhibits gonadotropin release and ovarian steroid production (see Chapter 55). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release by direct and indirect effects on GnRH neurons.

FIGURE 57-1 The biosynthetic pathway for the estrogens.

Figure 57-3 summarizes the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. In the early follicular phase, GnRH is secreted in pulses with a frequency of $\sim 1/h$. These pulses cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; FSH in particular causes the graafian follicle to mature and secrete estrogen. Effects of estrogens at this time decrease LH and FSH release, so gonadotropin levels gradually fall. The ovarian peptide inhibin also exerts a negative feedback to selectively decrease serum FSH. At midcycle, serum estradiol rises above a threshold level of 150–200 pg/mL for approximately 36 hours, exerting a brief positive feedback at the pituitary to trigger the preovulatory surge of LH and FSH. The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1–2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to the follicular phase pattern, the entire system then resets, and a new cycle occurs.

Progesterone decreases the frequency of GnRH pulses and also exerts a direct pituitary effect to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released. These steroid feedback effects, coupled with the intrinsic activity of the GnRH neurons, lead to relatively frequent LH pulses of small amplitude in the follicular phase, and less frequent pulses of larger amplitude in the luteal phase.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed via aromatization.

EFFECTS OF CYCLICAL GONADAL STEROIDS ON THE REPRODUCTIVE TRACT

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation and pregnancy. If pregnancy does not occur, the uterine endometrium is shed as the menstrual discharge (Figure 57-3).

FIGURE 57-2 Neuroendocrine control of gonadotropin secretion in females. The hypothalamic pulse generator functions as a neuronal “clock” that fires at regular hourly intervals (A), resulting in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 57-3 for additional details.)

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase, estrogen stimulates proliferation and differentiation. One important effect of estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Progesterone is thus important in preparation for implantation and for the decidual reaction that takes place in the uterus at the implantation site. There is a narrow “window of implantation,” spanning days 19–24 of the cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation.

If implantation occurs, human chorionic gonadotropin, produced initially by the trophoblast and later by the placenta, maintains steroid hormone synthesis by the corpus luteum during the early stages of pregnancy. Thereafter, the placenta itself becomes the major site of estrogen and progesterone synthesis.

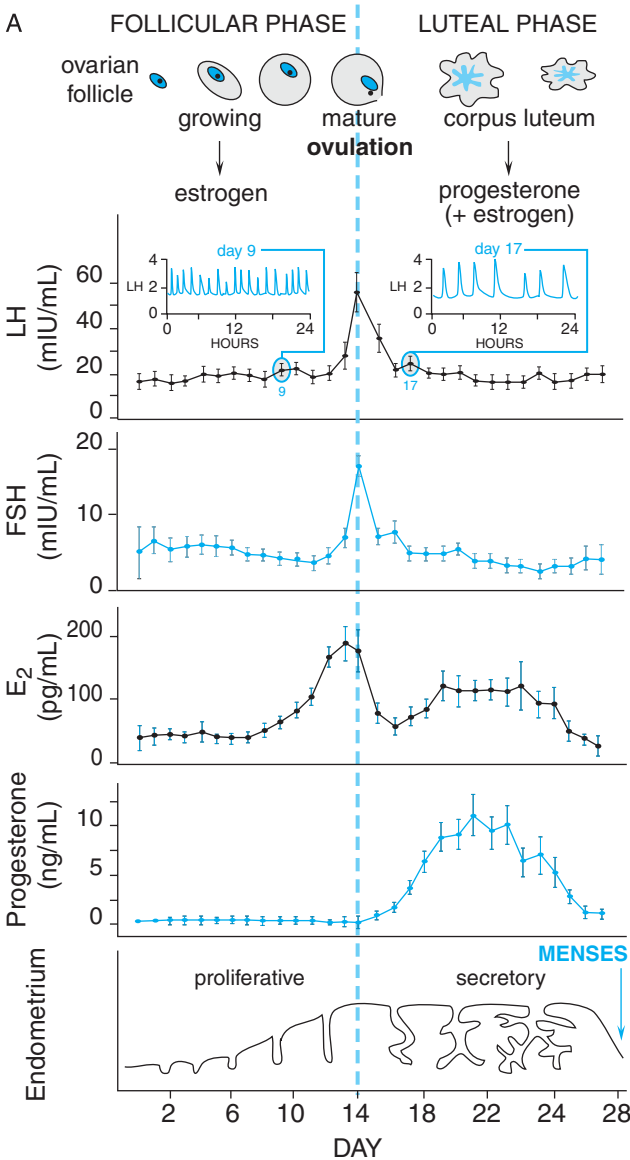

FIGURE 57-3 *Hormonal relationships of the human menstrual cycle.* A. Average daily values of LH, FSH, estradiol (E₂), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (top) and endometrium (bottom) also are illustrated schematically.

Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Redrawn with permission from Thorneycroft et al., 1971).

B. Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) released (*i.e.*, gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at mid-cycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (*i.e.*, the pulse amplitude) during the luteal phase of the cycle.

FIGURE 57-3 (Continued)

METABOLIC EFFECTS Estrogens increase bone mass, largely by decreasing the number and activity of osteoclasts, thereby decreasing bone resorption (see Chapter 61). Estrogens increase high-density lipoprotein (HDL) levels and decrease the levels of low-density lipoprotein (LDL) and Lp(a) (see Chapter 35). Estrogens also increase biliary cholesterol secretion and decrease bile acid secretion, leading to increased saturation of bile with cholesterol that results in gallstone formation in some women receiving estrogens. The decline in bile acid biosynthesis may contribute to the decreased incidence of colon cancer in women receiving combined estrogen-progestin treatment. Estrogens affect many serum proteins, particularly those involved in hormone binding and clotting cascades. In general, estrogens increase plasma levels of corticosteroid-binding globulin (CBG), thyroxine-binding globulin (TBG), and sex hormone-binding globulin (SHBG), which binds both androgens and estrogens.

Estrogens alter a number of pathways that affect the cardiovascular system. Systemic effects include changes in lipoprotein metabolism and in hepatic production of plasma proteins. Estrogens slightly increase coagulation factors II, VII, IX, X, and XII, and decrease the anticoagulation factors protein C, protein S, and antithrombin III (see Chapter 54). Fibrinolytic pathways also are affected; several studies of women treated with estrogen or estrogen with a progestin demonstrate decreased levels of plasminogen-activator inhibitor protein-1 (PAI-1) with a concomitant increase in fibrinolysis. Thus, estrogens increase both coagulation and fibrinolytic pathways. Estrogen actions on the vascular wall include induction of inducible NO synthase and increased production of NO and prostacyclin, all of which promote vasodilation.

Estrogen Receptors; Mechanism of Action

Estrogens exert their effects *via* receptors that are members of the nuclear receptor superfamily. The two ER genes are located on separate chromosomes: *ESR1* encodes ER α , and *ESR2* encodes ER β . Both ERs are estrogen-dependent transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes. Both genes encode multiple isoforms due to differential promoter use and alternative splicing. There are significant differences between the two receptors in their ligand-binding and transactivation domains, and they appear to have different biological functions and respond differently to various estrogenic compounds. However, the high homology in their DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

ER α is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, hypothalamus, endothelial cells, and vascular smooth muscle. *ER β* is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ER α and ER β .

Both ERs are ligand-activated transcription factors that increase or decrease the transcription of target genes. After entering the cell, the hormone binds to an ER in the nucleus. Upon bind-

ing estrogen, a change in ER conformation dissociates heat-shock proteins and causes receptor dimerization, which increases receptor binding to DNA. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes. The ER/DNA complex recruits a cascade of coactivators and other proteins to the promoter region of target genes. Interaction of ERs with antagonists also promotes dimerization and DNA binding but antagonists produce a conformation of ER that facilitates binding of corepressors, which inhibit target gene expression. In addition, both MAP kinase and PI-3-kinase-activated Akt can directly phosphorylate ER α to induce ligand-independent activation of estrogen-target genes. This cross-talk between membrane-bound receptor pathways (i.e., EGF/IGF-1) and the nuclear ER may have implications for diseases such as breast cancer.

Rapid, non-genomic actions of estrogen are mediated by membrane-localized ERs encoded by ESR1.

Absorption, Fate, and Elimination

Various estrogens are available for oral, parenteral, transdermal, or topical administration. For many uses, preparations are available as an estrogen alone or in combination with a progestin. Oral administration may utilize estradiol, conjugated estrogens, esters of estrone and other estrogens, and *ethinyl estradiol*. A micronized preparation of estradiol (ESTRACE, others) can be given orally, but high doses must be used due to first-pass metabolism. Ethinyl estradiol is used orally, as the ethinyl substitution at C17 inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN); *esterified esters*; or mixtures of conjugated estrogens prepared from plant-derived sources (CENESTIN).

Transdermal administration of estradiol (ESTRADERM, VIVELLE, ALORA, CLIMARA, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical cream (ESTRASORB) or as a gel (ESTROGEL). The transdermal route does not lead to the high level of the drug that enters the liver via the portal circulation after oral administration and is thus may decrease estrogen effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels. Estradiol and conjugated estrogen creams also are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring (ESTRING, FEMRING) may be used for slow release of estradiol, and tablets are also available for vaginal use (VAGIFEM). Other preparations are available for intramuscular injection. The esters of estradiol become less polar as the size of the substituents increases; thus, the rate of absorption of oily preparations is progressively slowed, and the duration of action can be prolonged. A single intramuscular injection of compounds such as estradiol valerate (DELESTROGEN) or estradiol cypionate (DEPO-ESTRADIOL) in oil may be absorbed over several weeks.

Estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG; ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Estrogens undergo rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estradiol is converted primarily by 17 β -hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16 α -hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Estrogen conjugates also undergo enterohepatic recirculation.

Ethinyl estradiol is cleared more slowly than is estradiol due to decreased hepatic metabolism, with an elimination $t_{1/2}$ of 13–27 hours. Its primary route of biotransformation is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers.

Untoward Responses

The amount of estrogens (and progestins) in oral contraceptives has been markedly decreased, significantly diminishing the risks associated with their use.

CONCERN ABOUT CARCINOGENIC ACTIONS

Early studies established that estrogens can induce tumors of the breast, uterus, testis, bone, kidney, and other tissues in various animal species. Thereafter, an increased incidence of vaginal and cervical adenocarcinoma was noted in female offspring of mothers who had taken diethylstilbestrol during the first trimester of pregnancy. Estrogen use during pregnancy also can increase the incidence of nonmalignant genital abnormalities in both male and female offspring; pregnant women should not be given estrogens.

The use of unopposed estrogen in postmenopausal women increases the risk of endometrial carcinoma by 5–15-fold, an increase that can be prevented if a progestin is coadministered with the estrogen. Randomized, clinical trials of estrogen-progestin and estrogen-only use in postmenopausal women have established a small but significant increase in the risk of breast cancer, apparently due to the medroxyprogesterone. In women without a uterus who received estrogen alone, the relative risk of breast cancer was insignificantly decreased. Thus, the data suggest that the progestin component in hormone-replacement therapy plays a major role in this increased risk of breast cancer. Importantly, the excess risk of breast cancer associated with menopausal hormone use apparently abates within 5 years after discontinuing therapy.

METABOLIC AND CARDIOVASCULAR EFFECTS

Although they may slightly elevate plasma triglycerides, estrogens generally have favorable overall effects on plasma lipoprotein profiles. However, concurrent administration of progestins may reduce these favorable actions. Currently prescribed doses of estrogens do not increase the risk of hypertension.

Observational studies, clinical trials using surrogate markers of cardiovascular disease, and animal studies suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease. In randomized clinical trials, however, conjugated equine estrogens alone or in combination with medroxyprogesterone acetate (MPA) did not protect against coronary heart disease (CHD). It is unclear whether these results (single dose; relatively older population) apply to other preparations, doses, and patient populations (e.g., women closer to age 50 who typically initiate hormone therapy for relief of vasomotor symptoms). Clearly, oral estrogens significantly increase the risk of thromboembolic disease in healthy women and in women with preexisting cardiovascular disease.

EFFECTS ON COGNITION

Retrospective studies suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer's disease. However, in randomized trials, no protective effect was observed, and the incidence of dementia in the treated group was actually increased.

OTHER POTENTIAL UNTOWARD EFFECTS

Nausea and vomiting occur in some women but often disappear with time and may be minimized by taking estrogens with food or just prior to sleeping. Breast fullness and tenderness and edema may occur, which may be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

Therapeutic Uses

The two major uses of estrogens are as components of combination oral contraceptives (see below) and for MHT. Historically, conjugated estrogens have been the most common agents for postmenopausal use (typically 0.625 mg/day). In contrast, most combination oral contraceptives in current use employ 20–35 µg/day of ethinyl estradiol. The “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. The doses of estrogens employed in both settings have decreased substantially in recent years and untoward effects have a lower incidence and severity than those reported in older studies.

MENOPAUSAL HORMONE THERAPY Established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms

The decline in ovarian function at menopause is associated with vasomotor symptoms, typically hot flashes. Treatment of vasomotor symptoms with estrogen is specific and is the most efficacious pharmacotherapy.

Osteoporosis

Osteoporosis is associated with the loss of bone mass and an increased incidence of fractures. Estrogen therapy clearly is efficacious in decreasing the incidence of fractures, although bone loss resumes when treatment is discontinued. However, because of potential risks associated with estrogen use, first-line use of other drugs should be carefully considered (see Chapter 61). Estrogens are more effective at preventing than restoring bone loss and are most effective if initiated before significant bone loss occurs.

Vaginal Dryness and Urogenital Atrophy

Loss of tissue lining the vagina or bladder in postmenopausal women leads to a variety of symptoms, including dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

Cardiovascular Disease

Prospective studies unexpectedly indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time. While it is not clear if similar results would occur with different drugs/doses or in different patient populations, estrogens (alone or in combination with a progestin) should not be used for the treatment or prevention of cardiovascular disease.

MENOPAUSAL HORMONE REGIMENS Estrogen-replacement therapy, or ERT (i.e., estrogens alone), in postmenopausal women was associated with an increased incidence of endometrial carcinoma; this led to the use of *hormone-replacement therapy*, or HRT, which includes a progestin to limit estrogen-related endometrial hyperplasia. “Hormone-replacement” therapy (now generally referred to as “menopausal hormone” therapy) with both an estrogen and progestin now is recommended for postmenopausal women with a uterus. For women who have undergone a hysterectomy, estrogen alone avoids the possible deleterious effects of progestins. Regardless of the specific agent or regimen, MHT with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

Conjugated estrogens and MPA have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and norethindrone, norgestimate, levonorgestrel, norethisterone, and progesterone also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens that include drug-free days have been used. An example of a cyclic regimen is: (1) administration of an estrogen for 25 days, (2) the addition of MPA for the last 12–14 days of estrogen treatment, and (3) 5–6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding, but may cause intermittent spotting or bleeding. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMPHASE (conjugated estrogens given for 28 days plus MPA given for 14 out of 28 days) are widely used combinations. Other combination products available in the U.S. are FEMHRT (ethinyl estradiol plus norethindrone acetate), ACTIVELLA (estradiol plus norethindrone), and PREFEST (estradiol and norgestimate).

Another pharmacological consideration is the route of administration. Oral administration exposes the liver to higher concentrations of estrogens than transdermal administration and may increase SHBG, other binding globulins, angiotensinogen; and the cholesterol content of bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles but may be preferred in women with hypertriglyceridemia.

Tibolone (LIVIAL) is widely used in Europe for treatment of vasomotor symptoms and prevention of osteoporosis but is not approved in the U.S. The parent compound is metabolized in a tissue-selective manner to metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The drug increases bone mineral density and decreases vasomotor symptoms without stimulating the endometrium, but its effects on fractures, breast cancer, and long-term outcomes remain to be established.

ESTROGEN TREATMENT IN THE FAILURE OF OVARIAN DEVELOPMENT

In several conditions (e.g., Turner’s syndrome), the ovaries do not develop and puberty does not occur. Estrogen therapy at the appropriate time replicates the events of puberty; androgens (see Chapter 58) and/or growth hormone (see Chapter 55) may be used concomitantly to promote normal growth. While estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus shorten ultimate height.

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTIESTROGENS

SERMs: TAMOXIFEN, RALOXIFENE, AND TOREMIFENE Selective ER modulators, or SERMs, exert tissue-selective actions. Their pharmacological goal is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) but antagonist activity in others

(e.g., breast and endometrium). Currently approved SERMs in the U.S. are *tamoxifen* (NOLVADEX, OTHERS), *raloxifene* (EVISTA), and *toremifene* (FARESTON).

ANTIESTROGENS: CLOMIPHENE AND FULVESTRANT These compounds are pure antagonists in all tissues. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women; *fulvestrant* (FASLODEX, ICI 182,780) is used to treat breast cancer in women with disease progression after tamoxifen.

CHEMISTRY

Structures of the trans-isomer of tamoxifen, raloxifene, trans-clomiphene (enclomiphene), and fulvestrant are:

Hepatic metabolism of tamoxifen produces *N*-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active metabolites 4-hydroxytamoxifen and endoxifen, which have 25–50 times higher affinity for both ER α and ER β . Raloxifene is a non-steroidal, polyhydroxylated compound. Clomiphene has two isomers: *zuclomiphene* (*cis*-clomiphene), a weak estrogen agonist, and *enclomiphene* (*trans*-clomiphene), a potent antagonist. Fulvestrant is a 7 α -alkylamide derivative of estradiol.

Pharmacological Effects

All of these agents bind to the ligand-binding pockets of both ER α and ER β and competitively block estradiol binding. However, the conformation of the ligand-bound ERs differs with different ligands. The distinct ER-ligand conformations recruit different coactivators and corepressors onto the promoter of a target gene. While 17 β -estradiol induces a conformation that recruits coactivators to the receptor, tamoxifen induces a conformation that recruits co-repressors to both

ER α and ER β . The agonist activity of tamoxifen in tissues such as the endometrium is mediated by ER α .

Tamoxifen exhibits antiestrogenic, estrogenic, or mixed activity depending on the target gene measured. Tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women, yet it stimulates proliferation of endometrial cells. The drug has an antiresorptive effect on bone and decreases total cholesterol, LDL, and Lp(a) but does not increase HDL and triglycerides. Tamoxifen approximately doubles the relative risk of deep vein thrombosis and pulmonary embolism and endometrial carcinoma. Tamoxifen produces hot flashes and other adverse effects, including cataracts, nausea, and hepatic steatosis. Due to its agonist activity in bone, it does not increase the incidence of fractures.

Raloxifene is an estrogen agonist in bone and reduces the number of vertebral fractures by up to 50% in a dose-dependent manner. The drug also acts as an estrogen agonist in reducing total cholesterol and LDL but does not increase HDL or normalize plasminogen-activator inhibitor 1 in postmenopausal women. Raloxifene does not cause proliferation of the endometrium. Raloxifene has an antiproliferative effect on ER-positive breast tumors and on proliferation of ER-positive breast cancer cell lines and significantly reduces the risk of ER-positive but not ER-negative breast cancer. Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a threefold increase in deep vein thrombosis and pulmonary embolism.

In women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production, clomiphene is used to induce ovulation in conditions such as polycystic ovarian syndrome and dysfunctional bleeding with anovulatory cycles.

Fulvestrant binds to ER α and ER β with an affinity comparable to estradiol but represses transactivation. Fulvestrant also stimulates the proteolytic degradation of ER α , which may explain its efficacy in tamoxifen-resistant breast cancer.

Absorption, Fate, and Excretion

Tamoxifen given orally reaches peak plasma levels after 4–7 hours; it has two elimination phases (half-lives of 7–14 hours and 4–11 days; thus, 3–4 weeks of treatment are required to reach steady-state plasma levels). Tamoxifen is metabolized by hepatic CYPs, some of which it also induces. In humans, the potent antiestrogens 4-hydroxytamoxifen and endoxifen are produced in the liver. The major route of elimination involves N-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite.

Raloxifene has an oral bioavailability of about 2%. The drug has a $t_{1/2}$ of about 28 hours and is eliminated primarily in the feces after hepatic glucuronidation.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces. The long plasma $t_{1/2}$ (5–7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations peak in 7 days and then are maintained for a month. The drug is eliminated primarily via the feces.

Therapeutic Uses

BREAST CANCER Tamoxifen is highly efficacious in the palliation of advanced breast cancer in women with ER-positive tumors and for hormonal treatment of both early and advanced breast cancer in women of all ages. Response rates are ~50% in women with ER-positive tumors and 70% for ER-positive, PR-positive tumors. Tamoxifen increases disease-free and overall survival; a 5-year treatment period is more efficacious than shorter treatments. Tamoxifen reduces by 50% the risk of developing contralateral breast cancer in women at high risk and is approved for primary prevention in this setting. Prophylactic treatment should be limited to 5 years. The most frequent side effect is hot flashes. Tamoxifen increases the risk of endometrial cancer and thromboembolic disease by two- to threefold.

Toremifene has therapeutic actions similar to tamoxifen. Fulvestrant may be efficacious in women who become resistant to tamoxifen, perhaps by downregulating ER α . Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

OSTEOPOROSIS Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. Raloxifene increased lumbar bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30–50%, but did not significantly reduce nonvertebral fractures. Raloxifene does not appear to increase the risk of endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

INFERTILITY Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing FSH levels, clomiphene enhances follicular recruitment. The drug is relatively inexpensive, orally active, and requires less extensive monitoring than do other fertility protocols. Untoward effects include ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. Prolonged use (*e.g.*, 12 or more cycles) may increase the risk of ovarian cancer. Clomiphene should not be administered to pregnant women due to reports of teratogenicity in animals, although there is no evidence of this in humans.

Estrogen-Synthesis Inhibitors

Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their synthesis from adrenal androgens (*see* Chapter 55). The recognition that locally produced estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block estrogen production. Both steroidal (*e.g.*, *formestane* and *exemestane* [AROMASIN]) and nonsteroidal agents (*e.g.*, *anastrozole* [ARIMIDEX], *letrozole* [FEMARA], and *vorozole*) are available. Steroidal (type 1) agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, while the nonsteroidal (type 2) agents interact reversibly with the heme groups of CYPs. Exemestane, letrozole, and anastrozole are approved in the U.S. for the treatment of breast cancer. The structures of exemestane and anastrozole are shown in the 11th edition of the parent text:

These agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in some adjuvant settings; unlike tamoxifen, they do not increase the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating and local levels of estrogens, they produce hot flashes. The marked decreases in estrogen levels are likely to be associated with significant bone loss, but long-term studies are needed.

PROGESTINS

The progestins (Figure 57–4) are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired; a depot form of MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives were developed for use as progestins in oral contraceptives; their predominant activity is progestational, but they also exhibit androgenic activity. The gonanes are “19-nor” compounds that have diminished androgenic activity.

CHEMISTRY

Unlike the ER, which requires a phenolic A ring for high-affinity binding, the PR favors a Δ^4 -3-one A-ring structure in an inverted 1 β , 2 α -conformation. Some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors.

One class of agents is similar to progesterone and its metabolite 17 α -hydroxyprogesterone (Figure 57–4). Compounds such as hydroxyprogesterone caproate have progestational activity but must be used parenterally due to first-pass hepatic metabolism. Further substitutions at the 6-position of the B ring yield orally active compounds with selective progestational activity, such as MPA and megestrol acetate.

A second class of agents includes 19-nor testosterone derivatives. Lacking the C19 methyl group, these testosterone derivatives display primarily progestational rather than androgenic activity. An ethinyl substituent at C17 decreases hepatic metabolism and yields orally active 19-nortestosterone analogs such as norethindrone, norethynodrel, and ethynodiol diacetate. The activity of the latter two compounds is due primarily to their rapid conversion to norethindrone. These compounds have varying degrees of androgenic activity, and to a lesser extent, estrogenic and antiestrogenic activities.

Replacement of the 13-methyl group of norethindrone with a 13-ethyl substituent yields the gonane norgestrel, which is a more potent progestin than the parent compound but has less androgenic activity. Other gonanes—including norgestimate, desogestrel, and gestodene (not available in the U.S.)—reportedly have little if any androgenic activity at therapeutic doses.

*Newer steroidal progestins include the gonane dienogest; 19-nor-progestin derivatives (*e.g.*, nomegestrol, nestorone, and trimegestone), which have increased selectivity for the PR and less androgenic activity than estranes; and the spironolactone derivative drospirenone, which is used in a combination oral contraceptive. Like spironolactone, drospirenone is also a mineralocorticoid receptor antagonist.*

Agents Similar to Progesterone (Pregnanes)*Agents Similar to 19-Nortestosterone (Estranes)**Agents Similar to Norgestrel (Gonanes)*

FIGURE 57-4 Structural features of various progestins.

BIOSYNTHESIS AND SECRETION

Progesterone is secreted by the corpus luteum during the second half of the menstrual cycle under the stimulus of LH (Figure 57-3). After fertilization, the trophoblast secretes hCG into the maternal circulation, which also acts through the LH receptor to sustain the corpus luteum. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration with the fetal adrenal glands, and thereafter the corpus luteum is not essential. Estrogen and progesterone then continue to be secreted in large amounts by the placenta throughout gestation.

Physiological and Pharmacological Actions

NEUROENDOCRINE ACTIONS Progesterone produced in the luteal phase of the cycle decreases the frequency of GnRH pulses, which is one mechanism of action of progestin-containing contraceptives.

REPRODUCTIVE TRACT Progesterone decreases estrogen-driven endometrial proliferation and induces a secretory endometrium (Figure 57-3); the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. Progesterone also influences the endocervical glands, changing the abundant watery secretion of the estrogen-stimulated

structures to a scant, viscid material. These and other effects of progestins decrease penetration of the cervix by sperm.

Finally, progesterone is essential to maintain pregnancy, at least partly by suppressing uterine contractility.

MAMMARY GLAND Mammary gland development requires both estrogen and progesterone. During pregnancy, and to a minor degree during the luteal phase of the cycle, progesterone acts with estrogen to induce proliferation of the acini of the mammary gland.

CNS EFFECTS Progesterone increases basal body temperature by about 0.6°C at midcycle when ovulation occurs. Progesterone also increases the ventilatory response of the respiratory centers to CO₂ and leads to reduced arterial and alveolar PCO₂ in the luteal phase of the menstrual cycle and during pregnancy.

METABOLIC EFFECTS Progesterone increases basal insulin and postprandial insulin levels but does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone and analogs (e.g., MPA) increase LDL and cause either no effect or modest reduction in serum HDL levels. Because of their androgenic activity, the 19-norprogestins may have more pronounced effects on plasma lipids. In one study, MPA decreased the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but did not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly affect beneficial estrogen effects on either HDL or LDL. Progesterone also may diminish the effects of aldosterone in the renal tubule.

Mechanism of Action

A single gene encodes two isoforms of the PR, PR_A and PR_B, by differential use of two distinct estrogen-dependent promoters; the ratios of the individual isoforms vary in reproductive tissues. Since the ligand-binding domains of the PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR resides in the nucleus as an inactive monomer. Upon progesterone binding, the receptors form homo- and heterodimers that bind with high selectivity to progesterone response elements located on target genes. Transcriptional activation by PR occurs primarily by recruitment of co-activators that recognize the activated PR conformation. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but antagonist-bound PR preferentially interacts with corepressors.

The biological activities of PR_A and PR_B are distinct and vary for different target genes. In most cells, PR_B mediates the stimulatory activities of progesterone; PR_A inhibits this action of PR_B and is also a transcriptional inhibitor of other steroid receptors.

Certain effects of progesterone, such as increased Ca²⁺ mobilization in sperm, occur within minutes and reflect nongenomic mechanisms involving membrane-bound PRs that are not derived from the gene encoding PR_A/PR_B.

Absorption, Fate, and Excretion

Progesterone undergoes rapid first-pass metabolism, but high-doses (e.g., 100–200 mg) of micronized progesterone (PROMETRIUM) are orally effective. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), and as a slow-release intrauterine device (PROGESTASERT) for contraception.

Esters [e.g., hydroxyprogesterone caproate (HYALUTIN) and MPA (DEPO-PROVERA)] are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE) may be used orally due to decreased hepatic metabolism. The 19-nor-steroids have good oral activity because the ethinyl substituent at C17 slows hepatic metabolism. Implants and depot preparations for prolonged release of synthetic progestins are widely available.

Progesterone in circulation is bound by albumin and CBG but not by SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of these synthetic compounds to plasma proteins exceeds 90%.

The elimination t_{1/2} of progesterone is ~5 minutes; the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. The synthetic progestins have much longer half-lives (~7 hours for norethindrone, 16 hours for norgestrel, 12 hours for gestodene, and 24 hours for MPA). Metabolism of synthetic progestins is primarily hepatic, and elimination is generally in the urine as conjugates and various polar metabolites.

Therapeutic Uses

The two most frequent uses of progestins are for contraception, either alone or with an estrogen, and in combination with estrogen for hormone therapy of postmenopausal women. Progestins also are used for secondary amenorrhea, abnormal uterine bleeding in patients without underlying fibroids or cancer, luteal-phase support to treat infertility, and premature labor.

Progestins are used diagnostically to test for estrogen secretion and for responsiveness of the endometrium: after progesterone administration to amenorrheic women for 5–7 days, withdrawal bleeding will occur if the endometrium has been stimulated by endogenous estrogens.

Progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens; in this setting, there appears to be less irregular uterine bleeding with sequential rather than continuous administration. Progestins are also used palliatively for metastatic endometrial carcinoma. Megestrol acetate is used as a second-line treatment for breast cancer and also is used off-label for AIDS-related wasting.

ANTIPROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS

The antiprogestin, RU 38486 (often referred to as RU-486) or *mifepristone*, is available for the termination of pregnancy. Antiprogestins have several other potential applications, including uses as contraceptives, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer.

Mifepristone

Mifepristone effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone is considered a PR modulator (PRM) due to its context-dependent antagonist/agonist activity. Another antiprogestin is onapristone, which contains a methyl substituent in the 13 α rather than 13 β orientation. The structures of mifepristone and onapristone are shown in the 11th edition of the parent text.

PHARMACOLOGICAL ACTIONS In the presence of progestins, mifepristone is a competitive antagonist of both PRs and, in certain contexts, may also be an agonist. In contrast, onapristone appears to be a pure progesterone antagonist. Mifepristone also exerts antiglucocorticoid and antiandrogenic actions. Onapristone has less antiglucocorticoid activity than does mifepristone.

Absorption, Fate, and Excretion

Mifepristone has good oral bioavailability. Plasma levels peak within several hours, and the drug is cleared with a plasma $t_{1/2}$ of 20–40 hours, in part because it is bound by α_1 -acid glycoprotein. Metabolites are primarily mono- and di-demethylated products (which may have pharmacological activity) formed via CYP3A4, and to a lesser extent, hydroxylated compounds. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces.

THERAPEUTIC USES

Mifepristone (MIFEPREX) is used to terminate early pregnancy. A prostaglandin (e.g., intramuscular sulprostone, intravaginal gemeprost, or oral misoprostol) is given 48 hours after the mifepristone to ensure expulsion of the detached blastocyst. The success rate with such regimens is >90% among women with pregnancies of <7 weeks' duration. The most severe untoward effect is vaginal bleeding, which typically lasts from 1 to 2 weeks but is rarely severe enough to require blood transfusions (0.1% of patients). High percentages of women also experience abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. A "black box" warning added to product labeling details the risk of serious, and sometimes fatal, infections and bleeding following mifepristone use for medical abortion. Women should be informed of these risks and cautioned to seek immediate medical attention if symptoms of these conditions occur. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its antiglucocorticoid activity. The drug should be used very cautiously in women who are anemic or receiving anticoagulants. Women over 35 years old with cardiovascular risk factors should not be given sulprostone because of possible heart failure.

HORMONAL CONTRACEPTIVES

Oral contraceptives are widely used worldwide and have had a revolutionary impact by providing a convenient, affordable, and reliable means of contraception. Myriad agents with substantially different components, doses, and side effects provide real therapeutic options. In addition to contraceptive actions, these agents have substantial health benefits.

Types of Hormonal Contraceptives

COMBINATION ORAL CONTRACEPTIVES The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. Their theoretical efficacy is considered to be 99.9%. Ethinyl estradiol and mestranol are the two estrogens used (with ethinyl estradiol being much more frequently used). The progestins are 19-nor compounds in the estrane or gonane series that have varying degrees of androgenic, estrogenic, and antiestrogenic activities that may be responsible for some side effects. Compounds such as desogestrel and norgestimate have less androgenic activity than other 19-nor compounds. Combination oral contraceptives are generally provided in 21-day packs with an additional 7 pills containing no active hormone. For monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “drug-free” period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, for different days in the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. Predictable menstrual bleeding generally occurs during the 7-day “off” period each month. The FDA recently approved a levonorgestrel–ethinyl estradiol combination (LYBREL) that is taken continuously for the full 90 days, eliminating any menstrual periods. Additional options include a once-monthly medroxyprogesterone–estradiol cypionate injectable (LUNELLE), an ethinyl estradiol–*norelgestromin* (the active metabolite of norgestimate) patch (ORTHO EVRA) applied weekly, and an ethinyl estradiol–*etonogestrel* (the active metabolite of desogestrel) flexible vaginal ring (NUVARING) used for 3 weeks (followed by a removal for 1 week that leads to menstrual bleeding).

The estrogen content ranges from 20 to 50 µg; most contain 30–35 µg. Preparations containing ≤35 µg of an estrogen are termed “low-dose” pills. The progestin dose is more variable because of different potencies of the compounds. Monophasic pills available in the U.S. contain 0.4–1 mg of norethindrone, 0.1–0.15 mg of levonorgestrel, 0.3–0.5 mg of norgestrel, 1 mg of ethynodiol diacetate, 0.25 mg of norgestimate, and 0.15 mg of desogestrel, with slightly different dose ranges in biphasic and triphasic preparations.

PROGESTIN-ONLY CONTRACEPTIVES Progestin-only contraceptives are only slightly less efficacious than combination oral contraceptives, with theoretical efficacy of 99%. Specific preparations include the “minipill”; low doses of progestins (*e.g.*, 350 µg of norethindrone [NOR-QD, MICRONOR] or 75 µg of norgestrel [OVRETTE]) taken daily without interruption; subdermal implants of 216 mg of norgestrel (NORPLANT II, JADELLE) for slow release and resultant long-term contraceptive action (*e.g.*, up to 5 years); and crystalline suspensions of MPA (DEPO-PROVERA) for intramuscular injection of 150 mg of drug, which provides effective contraception for 3 months.

An intrauterine device (PROGESTASERT) that releases low amounts of progesterone locally is available for insertion on a yearly basis. Its effectiveness is considered to be 97–98%; contraceptive action probably is due to local effects on the endometrium. Another intrauterine device (MIRENA) releases levonorgestrel for up to 5 years. It again is thought to act primarily by local effects.

POSTCOITAL OR EMERGENCY CONTRACEPTIVES The FDA has approved two preparations for postcoital contraception. PLAN-B is two doses of the “minipill” (0.75 mg levonorgestrel per pill) separated by 12 hours; PLAN-B will soon be available without a prescription for women 18 years old and older. PREVEN is two 2-pill doses of a high-dose oral contraceptive (0.25 mg of levonorgestrel and 0.05 mg of ethinyl estradiol per pill) separated by 12 hours. The FDA also has declared other products with the same or very similar composition safe and effective for use as emergency contraceptive pills.

The first dose of such preparations should be taken within 72 hours after intercourse, and this should be followed 12 hours later by a second dose. These treatments reduce the risk of pregnancy following unprotected intercourse by approximately 60–80%. With either preparation, effectiveness appears to increase the sooner after intercourse the pills are taken.

Mechanism of Action

COMBINATION ORAL CONTRACEPTIVES Combination oral contraceptives act by preventing ovulation. Plasma LH and FSH levels are suppressed, the midcycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. While either component alone can exert these effects, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Oral contraceptives exert hypothalamic and pituitary effects. Progesterone diminishes the frequency of GnRH pulses, and oral contraceptives also decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, which likely contributes to the lack of follicular development in oral contraceptive users. The progestin may also inhibit the estrogen-induced LH surge at midcycle. Other effects may contribute to a minor extent to the efficacy of oral contraceptives, including impaired oocyte transport in the fallopian tubes. Progestin also leads to a thick, viscous mucus that reduces sperm penetration and induces an endometrium that is not receptive to implantation.

PROGESTIN-ONLY CONTRACEPTIVES Progestin-only pills and levonorgestrel implants are highly efficacious for contraception. The pills block ovulation in only 60–80% of cycles; effectiveness is thought to be due largely to local effects in the cervix and uterus; such effects also account for the efficacy of intrauterine devices that release progestins. Depot injections of MPA yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Untoward Effects

COMBINATION ORAL CONTRACEPTIVES The consensus is that low-dose oral contraceptives pose minimal health risks in women who have no predisposing risk factors and also provide many beneficial health effects.

Cardiovascular Effects

There is no significant increase in the risk of myocardial infarction or stroke in nonsmokers without other risk factors such as hypertension or diabetes. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because these events are rare in women without other predisposing factors. Nevertheless, the risk is significantly increased in women who smoke or have other factors that predispose to thrombosis. The incidence of hypertension is much lower with low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use apparently does not persist after drug cessation. Studies of low-dose oral contraceptives have not found significant changes in total serum cholesterol or lipoprotein profiles.

Cancer

There is not a widespread association between oral contraceptives and cancer. Combined oral contraceptives may increase the risk of cervical cancer by about twofold, but only in long-term users with human papilloma virus infection. There are reported increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users (perhaps a doubling in the risk of liver cancer after 4–8 years of use) but these are rare cancers and the absolute increases are small.

The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increased relative risk of 1.1–1.2 that is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptives, breast cancer incidence is comparable in past users and never users. In addition, breast cancers diagnosed in women who have used oral contraceptives are more likely to be localized to the breast and thus easier to treat. Thus, overall there is no significant difference in the cumulative risk of breast cancer between those who have ever used oral contraceptives and those who have never used them.

Combination oral contraceptives actually cause a 50% decrease in the incidence of endometrial cancer that lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21 days. These agents also decrease the incidence of ovarian cancer and may decrease the risk of colorectal cancer.

Metabolic and Endocrine Effects

Current low-dose combination contraceptives do not impair and may even improve insulin sensitivity and lipid profiles. In women who smoke, the ethinyl estradiol in oral contraceptives appears to cause a dose-dependent increase in several serum factors that may shift the hemostatic profile toward a hypercoagulable condition.

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including CBG, TBG, and SHBG. While physiological feedback mechanisms generally adjust hormone synthesis to maintain normal “free” hormone levels, these changes can

affect endocrine function tests that measure total plasma hormone levels and may necessitate dose adjustment in patients receiving thyroid-hormone replacement.

Miscellaneous Effects

Nausea, edema, and mild headache occur in some individuals; migraine headaches may be precipitated by oral contraceptives in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day “off” period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-nor progestins.

PROGESTIN-ONLY CONTRACEPTIVES Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequent untoward effect and the major reason women discontinue use of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases; amenorrhea becomes common after a year or more of use.

Progestin-only minipill preparations do not increase thromboembolic events or blood pressure or cause nausea and breast tenderness. Acne may result from the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Aside from bleeding irregularities, headache is the most commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported. Of more concern, many studies have found decreases in HDL levels and increases in LDL levels and decreased bone density. The labeling information for depot MPA for contraceptive injection contains a “black box” warning about increased risk of osteoporosis. There are no increases in breast, endometrial, cervical, or ovarian cancer in women receiving MPA.

Norethindrone implants may be associated with infection, local irritation, pain at the insertion site, and rarely, expulsion of the inserts. Headache, weight gain, mood changes, and acne occur in some patients.

EMERGENCY CONTRACEPTIVE PILLS

Nausea and vomiting are the main untoward effects and may be severe. Emergency contraceptive pills are contraindicated in cases of confirmed pregnancy.

Contraindications

Modern oral contraceptives can contribute to the incidence and severity of certain diseases if other risk factors are present. *The following conditions are considered absolute contraindications for combination oral contraceptives: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract, or other hormone-dependent/responsive neoplasias; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. The risk of serious cardiovascular side effects is particularly marked in women over 35 years of age who smoke heavily (e.g., >15 cigarettes/day); even low-dose oral contraceptives are contraindicated in such patients.*

Other relative contraindications should be considered on an individual basis, including migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians discontinue oral contraceptives for several weeks to minimize the possibility of thromboembolism. These agents should be used with care in women with prior gestational diabetes or uterine fibroids; low-dose pills are preferred in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot MPA and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

Choice of Contraceptive Preparations

Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30–35 µg of estrogen, but preparations with 20 µg may be adequate for lighter women or those over 40 with perimenopausal symptoms, while a preparation containing 50 µg of estrogen may be required for heavier women. Breakthrough bleeding may occur if the estrogen-to-progestin ratio is too low to produce a stable endometrium, and this may be prevented by switching to a pill with a higher ratio.

In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives are an option. The progestin-only minipill may have enhanced effectiveness in nursing mothers and women over 40 in whom fertility may be decreased.

Concomitant administration of medications that may increase metabolism of estrogens (e.g., rifampin, barbiturates, and phenytoin) or reduce their enterohepatic recycling (e.g., tetracyclines and ampicillin) may decrease the effectiveness of oral contraceptives.

The choice of preparation also may be influenced by the specific 19-nor progestin component, since this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne, and unfavorable lipoprotein profiles. These side effects are greatly reduced in low-dose contraceptives, but any patients exhibiting such side effects may benefit by switching to pills that contain a progestin with less androgenic activity. Of the progestins commonly found in oral contraceptives, norgestrel has the most androgenic activity and desogestrel, norgestimate, and drospirenone have the least androgenic activity.

The FDA has approved a triphasic, low-dose combination oral contraceptive (ORTHO TRI-CYCLEN) containing ethinyl estradiol and norgestimate for the treatment of moderate acne vulgaris. Similar preparations (DEMULEN 1/35, DESOGEN, others) also are effective. The mechanism appears to be a decrease in free plasma testosterone due to an increase in plasma SHBG.

Noncontraceptive Health Benefits

Combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. They significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, a protective effect that persists for up to 15 years after oral contraceptives are discontinued. Depot MPA injections also reduce substantially the incidence of uterine cancer. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation, including more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated.

Combination oral contraceptives prevent thousands of deaths, episodes of various diseases, and cases of hospitalization each year in the U.S. alone. Fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering these additional health benefits.

ANDROGENS

TESTOSTERONE AND OTHER ANDROGENS

SYNTHESIS, SECRETION, AND TRANSPORT OF TESTOSTERONE Leydig cells in the testes synthesize testosterone by the pathways shown in Figure 58–1. In women, testosterone primarily serves as a precursor to estrogens but also is the predominant circulating androgen. Testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains almost all other differences between men and women. In the first trimester *in utero*, placental human chorionic gonadotropin (hCG) induces testosterone secretion by the fetal testes (Figure 58–2); this testosterone is essential for virilization of the male internal genitalia. By the beginning of the second trimester, the circulating testosterone level (~250 ng/dL) is close to that of midpuberty. Testosterone production then falls by the end of the second trimester, but by birth the value is again about 250 ng/dL, possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, rises and peaks again at about 250 ng/dL at 2–3 months, and falls to <50 ng/dL by 6 months, where it remains until puberty. During puberty, the serum testosterone concentration in males increases to a much greater degree than in females, so that by early adulthood the serum testosterone concentration is 500–700 ng/dL in men, compared to 30–50 ng/dL in women. This greater testosterone concentration induces the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to some effects of aging.

LH, secreted by the pituitary gonadotropes (*see* Chapter 55), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. LH secretion is stimulated by hypothalamic gonadotropin-releasing hormone (GnRH), while testosterone directly inhibits LH secretion in a negative feedback loop (*see* Chapter 55). GnRH and LH are released in pulses that occur approximately every 2 hours and are greater in magnitude in the morning. Pulsatile administration of GnRH to men who are hypogonadal due to hypothalamic disease restores normal LH pulses and testosterone secretion, but continuous administration does not. Testosterone secretion is likewise pulsatile and diurnal, with the highest plasma concentrations occurring at about 8 AM and the lowest at about 8 PM. The morning peaks diminish as men age.

Sex hormone-binding globulin (SHBG) binds about 40% of circulating testosterone with high affinity, such that testosterone bound to SHBG is unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving approximately 2% unbound or free. In some testosterone assays, the latter two components are considered as “bioavailable” testosterone.

METABOLISM OF TESTOSTERONE TO ACTIVE AND INACTIVE COMPOUNDS

Testosterone has many different effects in tissues, both directly and after its metabolism to two other active steroids, dihydrotestosterone and estradiol (Figure 58–3). The enzyme 5 α -reductase catalyzes the conversion of testosterone to dihydrotestosterone. Although testosterone and dihydrotestosterone both act *via* the androgen receptor (AR), dihydrotestosterone binds with higher affinity and activates gene expression more efficiently. Two forms of 5 α -reductase have been identified: type I, found predominantly in nongenital skin, liver, and bone, and type II, found predominantly in urogenital tissue in men and genital skin in men and women. The enzyme complex aromatase (CYP19), which is present in many tissues, converts testosterone to estradiol. This conversion results in approximately 85% of circulating estradiol in men; the remainder is secreted directly by the testes.

Testosterone is metabolized in the liver to androsterone and etiocholanolone (Figure 58–3), which are biologically inactive. Dihydrotestosterone is metabolized to androsterone, androstenedione, and androstanediol.

Physiological and Pharmacological Effects of Androgens

The biological effects of testosterone can be considered by the receptor it activates and by the tissues in which its effects occur at various stages of life. Testosterone can act as an androgen either directly, by binding to the AR, or indirectly by conversion to dihydrotestosterone. Testosterone also can be converted to estradiol, which activates the estrogen receptor (Figure 58–4).

FIGURE 58-1 Pathway of synthesis of testosterone in the Leydig cells of the testes. Leydig cells express steroid 17 α -hydroxylase (CYP17), which carries out sequential 17-hydroxylation and C17-20 lyase reactions in the biosynthetic pathway to produce androgens. Bold arrows indicate favored pathways.

EFFECTS THAT OCCUR VIA THE ANDROGEN RECEPTOR Testosterone and dihydrotestosterone act as androgens *via* the AR. The AR is a member of the nuclear receptor superfamily that contains amino-terminal, DNA-binding, and ligand-binding domains. After testosterone and dihydrotestosterone bind to the ligand-binding domain, they cause a conformational change that allows the ligand-AR complex to translocate to the nucleus, bind *via* the DNA-binding domain to androgen response elements on certain responsive genes, and regulate their transcription. One

FIGURE 58-2 Schematic representation of the serum testosterone concentration in males from early gestation to old age.

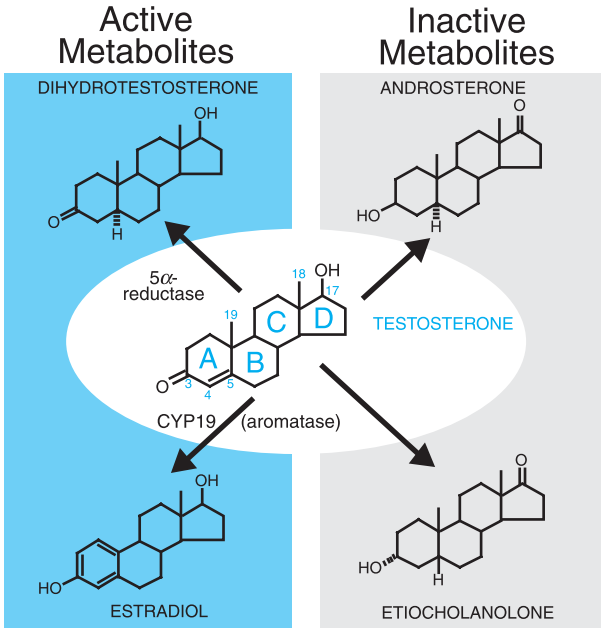

FIGURE 58-3 Metabolism of testosterone to its major active and inactive metabolites.

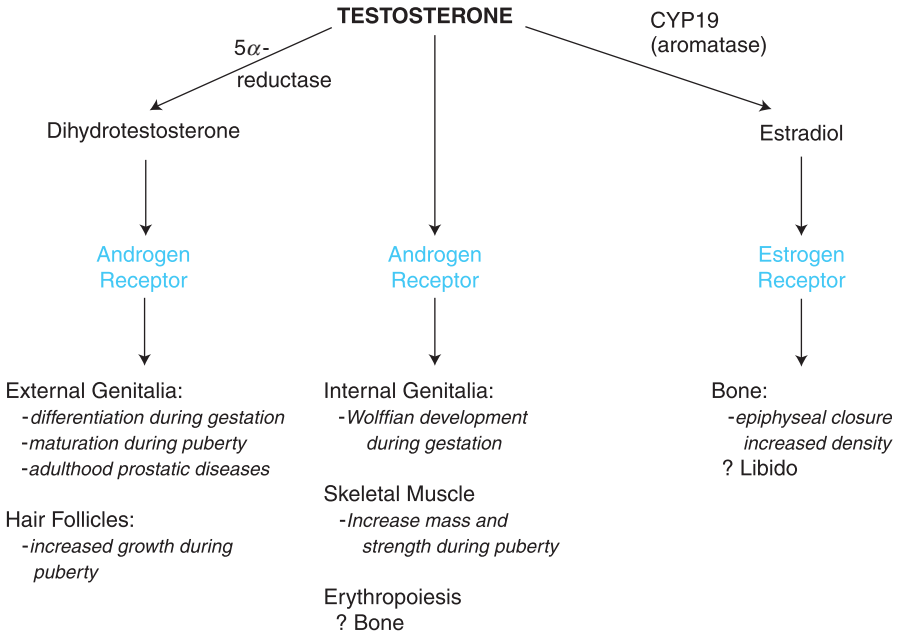

FIGURE 58-4 Direct effects of testosterone and indirect effects mediated by dihydrotestosterone or estradiol.

mechanism by which androgens have different actions in diverse tissues is the higher affinity with which dihydrotestosterone binds to and activates the AR compared to testosterone. Another mechanism involves tissue-specific coactivators and corepressors.

Mutations in the AR cause resistance to the actions of testosterone and dihydrotestosterone. Male sexual differentiation and pubertal development therefore are incomplete. Other AR mutations occur in patients who have spinal and bulbar muscular atrophy, known as Kennedy's disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the AR; they exhibit very mild androgen resistance—manifest principally by gynecomastia—but progressively severe motor neuron atrophy, the basis of which is poorly understood.

Metastatic prostate cancer often regresses initially in response to androgen-deprivation treatment but then becomes unresponsive to continued deprivation. The AR not only continues to be expressed in androgen-independent prostate cancer, but its signaling remains active in the absence of testosterone. This ligand-independent signaling may result from mutations in the AR gene or from changes in AR coregulatory proteins.

EFFECTS THAT OCCUR VIA THE ESTROGEN RECEPTOR Certain effects of testosterone are mediated after its conversion to estradiol by CYP19 (Figures 58–3 and 58–4). In the rare males deficient in CYP19 or the estrogen receptor, the epiphyses do not fuse, long-bone growth continues indefinitely, and the bones are osteoporotic. Estradiol administration corrects the bone abnormalities in patients with CYP19 deficiency, but not if there is an estrogen-receptor defect. Because men have larger bones than women, and bone cells express the AR, testosterone also may have a direct effect on bone *via* the AR. Administration of estradiol to a man with CYP19 deficiency increased his libido, suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol.

EFFECTS OF ANDROGENS AT DIFFERENT STAGES OF LIFE

In Utero

The fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, and the high local concentration of testosterone around the testes induces the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. Farther away, in the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia—the penis and scrotum—and the prostate. The increase in testosterone at the end of gestation (Figure 58–2) may result in further phallic growth.

Puberty

Puberty in boys begins at a mean age of 12 years when pulsatile GnRH stimulates the secretion of FSH and LH from the gonadotropes. The first sign of puberty is a gonadotropin-induced increase in testes size. The increase in testosterone production by Leydig cells, along with the effects of FSH on the Sertoli cells, stimulates the development of the seminiferous tubules, eventually producing mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously; most changes occur gradually over the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair (driven also by adrenal androgens), and then other body hair and facial hair. Muscle mass and strength increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bones also become thicker. The increase in the mass of muscle and bone results in a pronounced increase in body weight. Erythropoiesis increases, resulting in higher hematocrit in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops.

Adulthood

The serum testosterone concentration and the characteristics of the adult male are largely maintained during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness. Two conditions that can develop are of much greater medical significance: benign prostatic hyperplasia and prostate cancer. Prostatic hyperplasia occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate, and is mediated by the conversion of testosterone to

dihydrotestosterone by 5α -reductase II within prostatic cells. Although there is no proven causal role, prostate cancer is dependent on testosterone, at least to some degree and at some time in its course. This dependency is the basis for treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action.

Senescence

As men age, the serum testosterone concentration gradually declines, and the SHBG concentration gradually increases; by age 80, the total testosterone concentration is approximately 80% and the free testosterone is approximately 40% of that present at age 20. This decline in serum testosterone may contribute to several other changes that occur with increasing age in men, including decreased energy, libido, muscle mass and strength, and bone mineral density. A causal role is suggested by the occurrence of similar changes in men who develop hypogonadism at a younger age.

Consequences of Androgen Deficiency

During Fetal Development Testosterone deficiency in a male fetus during the first trimester causes incomplete sexual differentiation. Complete deficiency of testosterone secretion results in entirely female external genitalia; less severe testosterone deficiency impairs virilization of the external genitalia proportionate to the degree of deficiency. Testosterone deficiency at this stage of development also leads to failure of the wolffian ducts to differentiate into the vas deferens and seminal vesicles, but the Müllerian ducts do not form the female internal genitalia as long as the testes secrete Müllerian-inhibiting substance. Similar changes occur if the action of testosterone is diminished because of an abnormality of the AR or of 5α -reductase. Abnormalities of the AR can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization *in utero* and result only in impaired spermatogenesis in adulthood. Abnormal 5α -reductase results in incomplete virilization of the external genitalia *in utero* but normal development of the male internal genitalia, which requires only testosterone.

Testosterone deficiency during the third trimester impairs phallus growth, a condition called micropallus, and causes cryptorchidism—the failure of the testes to descend into the scrotum. These conditions occur commonly in boys whose LH secretion is impaired (*see* Chapter 55).

Before Completion of Puberty Postnatal defects in testosterone synthesis acquired before the anticipated age of puberty result in failure to initiate or complete puberty. All of the pubertal changes described above, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. If growth hormone secretion remains intact when testosterone secretion is subnormal, the epiphyses do not close, and the long bones continue to lengthen. The result is longer arms and legs relative to the trunk. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue (gynecomastia).

After Completion of Puberty Regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the deficiency is severe, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably is detectable within 2 years by dual-energy x-ray absorptiometry, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

In Women Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Some experts have proposed that the loss of androgens, especially the severe loss of both ovarian and adrenal androgens that occurs in panhypopituitarism, is associated with decreased libido, energy, muscle mass and strength, and bone mineral density. Testosterone preparations that yield physiological serum testosterone concentrations in women currently are being developed and tested in clinical trials.

Therapeutic Androgen Preparations

Androgen therapy is complicated by the fact that orally ingested testosterone undergoes rapid hepatic metabolism, and hypogonadal men generally cannot ingest testosterone in sufficient amounts

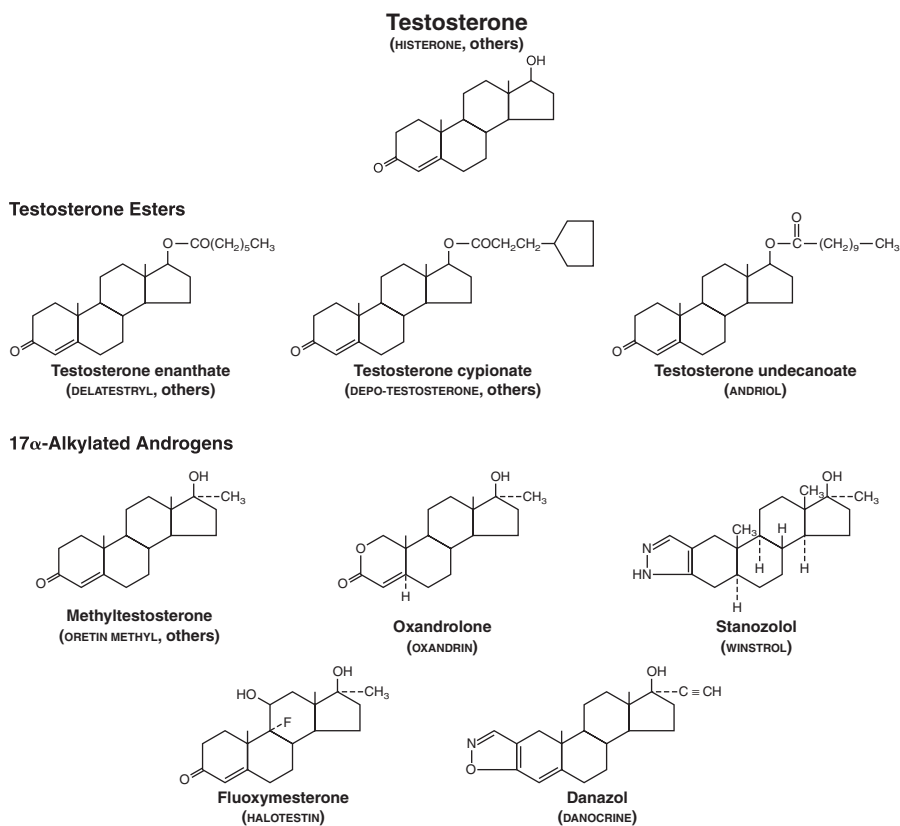

FIGURE 58–5 Structures of some androgens available for therapeutic use.

and with sufficient frequency to maintain a normal serum concentration. Therefore, most pharmaceutical preparations of androgens are designed to bypass the liver.

TESTOSTERONE ESTERS Esterifying a fatty acid to the 17 α hydroxyl group of testosterone makes it even more lipophilic than testosterone. When esters such as *testosterone enanthate* (*heptanoate*) (Figure 58–5) or *cypionate* (*cyclopentylpropionate*) are dissolved in oil and administered intramuscularly every 2 weeks to hypogonadal men, the ester hydrolyzes *in vivo* and results in serum testosterone concentrations that range from higher-than-normal in the first few days after the injection to low-normal just before the next injection (Figure 58–6). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone (Figure 58–5), when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing first-pass hepatic metabolism. *Testosterone undecanoate* in oil also can be injected and produces stable serum testosterone concentrations for a month. The undecanoate ester of testosterone is not currently marketed in the U.S.

ALKYLATED ANDROGENS Adding an alkyl group to the 17 α position of testosterone (Figure 58–5) retards its hepatic metabolism. Consequently, 17 α -alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone itself and cause hepatotoxicity, whereas native testosterone does not.

TRANSDERMAL DELIVERY SYSTEMS Attempts to avoid hepatic first-pass inactivation of testosterone have used chemicals called excipients to facilitate the cutaneous absorption of native

FIGURE 58–6 Pharmacokinetic profiles of three testosterone preparations during their chronic administration to hypogonadal men. Doses of each were given at time 0. Dashed lines indicate range of normal levels.

testosterone in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, one of which (ANDRODERM) is still available. Newer preparations include gels (ANDROGEL, TESTIM) and a buccal tablet (STRIANT). These preparations produce mean serum testosterone concentrations within the normal range in hypogonadal men (Figure 58–6).

Attempts to Design Selective Androgens

ALKYLATED ANDROGENS Decades ago, investigators attempted to synthesize analogs of testosterone that possessed greater anabolic effects than androgenic effects compared to native testosterone. These compounds, most are 17α -alkylated androgens, were called anabolic steroids. None has been convincingly demonstrated to have such a differential effect in human beings. Nonetheless, they have enjoyed considerable popularity among athletes who seek to enhance their performance, as described below.

Therapeutic Uses of Androgens

MALE HYPOGONADISM The best-established indication for androgen administration is to treat male hypogonadism (testosterone deficiency in men). Any of the transdermal testosterone preparations or testosterone esters described above can be used with good efficacy.

Monitoring for Efficacy

The goal of testosterone therapy in hypogonadal men is to mimic as closely as possible the normal serum concentration; therefore, serum testosterone concentration must be monitored. With transdermal patches, the serum testosterone concentration fluctuates during the 24-hour period, with a peak value 6–9 hours after application and a nadir (about 50% of the peak) just before the next patch is applied (Figure 58–6). With testosterone gels, the mean serum testosterone concentration is relatively constant from one application to the next. Occasional random fluctuations can occur, so measurements should be repeated for any dose. When the enanthate or cypionate esters of testosterone are administered once every 2 weeks (typically in a dose of 200 mg), the serum testosterone concentration measured midway between doses should be normal; if not, the dose should be adjusted accordingly.

Normalization of the serum testosterone concentration induces virilization in prepubertal boys and restores virilization in men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years.

Monitoring for Adverse Effects

As long as the dose is not excessive, testosterone has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have). Modified testosterone compounds, such as the 17α -alkylated androgens, may have undesirable effects even when dosages are targeted at physiologic replacement. Raising the serum testosterone concentration from prepubertal or midpubertal levels to that of an adult male at any age can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Replacement of physiological levels of testosterone may occasionally have undesirable effects in the presence of concomitant illnesses. For example, in patients with chronic pulmonary disease, stimulation of erythropoiesis may raise the hematocrit above normal and cause polycythemia. Similarly, the mild degree of sodium and water retention seen with testosterone replacement may exacerbate preexisting congestive heart failure. If the testosterone dose is excessive, erythrocytosis, and uncommonly, salt and water retention and peripheral edema can occur, even in men who have no predisposition to these conditions. Men over 40 whose serum testosterone concentrations have been in the normal adult male range for many years are subject to testosterone-dependent diseases such as benign prostatic hyperplasia and prostate cancer.

The principal side effects of the 17α -alkylated androgens are hepatic, including cholestasis, and uncommonly, peliosis hepatis (blood-filled hepatic cysts). Hepatocellular cancer has rarely been reported. When administered at high doses, these androgens are more likely than others to affect serum lipid concentrations, specifically to decrease high-density lipoprotein cholesterol and increase low-density lipoprotein cholesterol.

All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production,

resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis.

When administered in high doses, androgens that can be converted to estrogens, such as testosterone, cause gynecomastia. Androgens with A ring modifications that prevent aromatization, such as dihydrotestosterone, do not cause gynecomastia, even in high doses.

Monitoring at the Anticipated Time of Puberty Administration of testosterone to testosterone-deficient boys at the anticipated time of puberty must be guided by the fact that testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Thus, boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

MALE SENESCENCE Increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass. It is uncertain at this time if such treatment will worsen benign prostatic hyperplasia or increase the incidence of clinically significant prostate cancer.

ENHANCEMENT OF ATHLETIC PERFORMANCE

Athletes seeking to enhance their performance have taken virtually all androgens produced for human or veterinary purposes. Belated support for this use came from randomized, controlled trials, which showed that normal young men who received testosterone experienced an increase in muscle strength compared to those who received placebo. When this abuse began more than three decades ago, the favored compounds were 17 α -alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called "anabolic steroids"). Because these compounds are readily detected, preparations that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have been used because they have been considered "nutritional supplements."

Certain side effects of anabolic steroid abuse occur specifically in women and children. Both experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

MALE CONTRACEPTION

Scientists long have sought to use androgens—either alone or in combination with other drugs—as a male contraceptive. Because the high concentration of testosterone within the testes, approximately one hundred times that in the peripheral circulation, is necessary for spermatogenesis, suppression of endogenous testosterone production greatly diminishes spermatogenesis. Initial use of testosterone alone required supraphysiologic doses, while addition of GnRH agonists required daily injections. An alternative approach is to combine a progestin with a physiological dose of testosterone to attempt to suppress LH secretion and spermatogenesis but provide a normal serum testosterone concentration; clinical trials are ongoing.

CATABOLIC AND WASTING STATES

Because of its anabolic effects, testosterone has been used to ameliorate catabolic and muscle-wasting states, generally without benefit. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength.

ANGIOEDEMA

Angioedema is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it. The 17 α -alkylated androgens, such as stanozolol and danazol, stimulate hepatic synthesis of the esterase inhibitor and thereby decrease the frequency of acute attacks. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal

closure prevent chronic prophylactic use of androgens, although they are used occasionally to treat acute episodes.

ANTIANDROGENS

Because some effects of androgens are undesirable, agents have been developed to inhibit androgen synthesis or action.

INHIBITORS OF TESTOSTERONE SECRETION Analogs of GnRH effectively inhibit testosterone production by inhibiting LH secretion. They are used to suppress precocious puberty, in assisted reproductive technologies, and to treat prostate cancer (*see* Chapter 55).

Some antifungal drugs such as ketoconazole (*see* Chapter 48) inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess.

Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the AR or inhibit 5α -reductase.

ANDROGEN RECEPTOR ANTAGONISTS

Flutamide, Bicalutamide, and Nilutamide These relatively potent AR antagonists have limited efficacy when used alone because the increased LH secretion elevates serum testosterone concentrations. They primarily are used in conjunction with a GnRH analog in the treatment of metastatic prostate cancer, where they block the action of adrenal androgens that are not inhibited by GnRH analogs. AR antagonists used in this fashion include *flutamide* (EULEXIN), *bicalutamide* (CASODEX), or *nilutamide* (NILANDRON). Bicalutamide is replacing flutamide for this purpose because it has less hepatotoxicity and is taken once daily. Nilutamide apparently has worse side effects than flutamide and bicalutamide. Flutamide also has been used effectively to treat hirsutism in women, but the association with hepatotoxicity argues against its routine use for this cosmetic purpose.

Flutamide

Bicalutamide

Nilutamide

Spirolactone

Spirolactone (ALDAKTONE) (*see* Chapter 28) is an aldosterone antagonist that also is a weak AR antagonist and a weak inhibitor of testosterone synthesis, apparently inhibiting CYP17. When used to treat fluid retention or hypertension in men, gynecmastia is a common side effect.

5 α -REDUCTASE INHIBITORS *Finasteride* (PROSCAR) is an inhibitor of 5 α -reductase, especially the type II isozyme; *dutasteride* (AVODART) is a dual inhibitor of types I and II; both drugs block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These agents are approved for benign prostatic hyperplasia in the U.S. and many other countries. When administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases. Impotence is a well-documented, albeit infrequent, side effect of this use. Finasteride (PROPECIA) also is approved for use in the treatment of male pattern baldness and appears to be as effective as flutamide or the combination of estrogen and *cyproterone* in the treatment of hirsutism.

ADRENOCORTICOTROPIC HORMONE; ADRENOCORTICAL STEROIDS AND THEIR SYNTHETIC ANALOGS; INHIBITORS OF THE SYNTHESIS AND ACTIONS OF ADRENOCORTICAL HORMONES

Corticosteroids and their biologically active synthetic derivatives are classified according to their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. In addition, glucocorticoids potently suppress inflammation, and their usefulness in a variety of inflammatory and autoimmune diseases making them among the most frequently prescribed classes of drugs. Because they exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects, some of which are life-threatening. Therefore, the decision to institute therapy with corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

ADRENOCORTICOTROPIC HORMONE (ACTH; CORTICOTROPIN)

Adrenocorticotrophic hormone (ACTH) a peptide of 39 amino acids, is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC), and is liberated along with α , β , and γ melanocyte-stimulating hormone (MSH) and other physiologically important peptides from the precursor through proteolytic cleavage at dibasic residues by prohormone convertases (*see* Chapter 21). The actions of ACTH and MSH are mediated by their specific interactions with five melanocortin receptor (MCR) subtypes comprising a distinct subfamily of G protein-coupled receptors (GPCRs). The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. MC1Rs also are found on cells of the immune system and are thought to mediate the anti-inflammatory effects of α -MSH in experimental models of inflammation. ACTH, which is identical to α -MSH in its first 13 amino acids, exerts its effects on the adrenal cortex through the MC2R. ACTH has a much higher affinity for the MC2R than for the MC1R; however, under pathological conditions in which ACTH levels are markedly elevated, such as primary adrenal insufficiency, ACTH can signal through the MC1R and cause hyperpigmentation. The α -MSH-responsive MC3R and MC4R receptors in the hypothalamus play key roles in the regulation of appetite and body weight, and they therefore are the subject of considerable investigation as possible targets for drugs that affect appetite. The role of MC5R is less well-defined.

ACTIONS ON THE ADRENAL CORTEX Acting *via* MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA), which can be converted peripherally into more potent androgens. The adrenal cortex is comprised of three zones that produce different steroid products under different regulatory influences. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, the middle zona fasciculata secretes the glucocorticoid cortisol, and the inner zona reticularis secretes DHEA and its sulfated derivative (Figure 59–1).

Cells of the outer zone have receptors for angiotensin II (AngII) and express aldosterone synthase (CYP11B2), an enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by AngII (*see* Chapter 30) and extracellular K^+ and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. In the setting of persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed *ACTH escape*).

Cells of the zona fasciculata have fewer receptors for AngII and express two enzymes, steroid 17 α -hydroxylase (CYP17) and 11 β -hydroxylase (CYP11B1), which catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out a second C17-20 lyase reaction that converts C21 corticosteroids to C19 androgen precursors.

In the absence of the anterior pituitary and ACTH stimulation, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired. Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hyperplasia and hypertrophy of the inner cortical zones, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked

FIGURE 59-1 The adrenal cortex contains three anatomically and functionally distinct compartments. The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiologic regulators of steroid production: AngII and K⁺ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of dehydroepiandrosterone (DHEA) production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.

in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis.

MECHANISM OF ACTION ACTH stimulates the production of adrenocortical steroids by increasing *de novo* biosynthesis. ACTH, binding to MC2R, activates the G_s-adenyl cyclase-cyclic AMP-PKA pathway. Cyclic AMP is an obligatory second messenger for most, if not all, effects of ACTH on steroidogenesis. Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects increased delivery of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. Pathways of adrenal steroid biosynthesis and structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 59-2. The rate-limiting step in steroid hormone production is the conversion of cholesterol to pregnenolone, a reaction catalyzed by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily (*see* Chapter 3). The rate-limiting components in this reaction regulate the mobilization of substrate cholesterol and its delivery to CYP11A1 in the inner mitochondrial matrix.

REGULATION OF ACTH SECRETION

Hypothalamic-Pituitary-Adrenal Axis The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by pituitary corticotropes. These corticotropes, in turn, are regulated by corticotropin-releasing hormone (CRH), a peptide hormone released by CRH neurons of the endocrine hypothalamus. These three organs collectively are referred to as the hypothalamic-pituitary-adrenal (HPA) axis, an integrated system that maintains appropriate levels of glucocorticoids (*see* Figure 59-3). There are 3 characteristic modes of regulation of the HPA axis: diurnal rhythm in basal steroidogenesis, negative feedback regulation by glucocorticoids, and marked increases in steroidogenesis in response to stress. The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at approximately 8 AM. As discussed below, negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

FIGURE 59–2 Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways that are unique to the zona glomerulosa are shown in blue, whereas those that occur in the inner zona fasciculata and zona reticularis are shown in gray. The zona reticularis does not express 3 β -HSD, and thus preferentially synthesizes DHEA. CYP11A1, cholesterol side-chain cleavage enzyme; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; CYP17, steroid 17 α -hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B2, aldosterone synthase; CYP11B1, steroid 11 β -hydroxylase.

DIAGNOSTIC APPLICATIONS OF ACTH

Because all known therapeutic effects of ACTH can be achieved with corticosteroids, synthetic steroid hormones generally are used therapeutically instead of ACTH. A synthetic derivative of ACTH comprised of the first 24 amino acids of the natural hormone, cosyntropin (CORTROSYN, SYN-ACTHEN), is used principally in the diagnostic assessment of the HPA axis. In the standard cosyntropin test, cosyntropin is used at the considerably supraphysiological dose of 250 μ g to maximally stimulate adrenocortical steroidogenesis. Cosyntropin is readily absorbed from

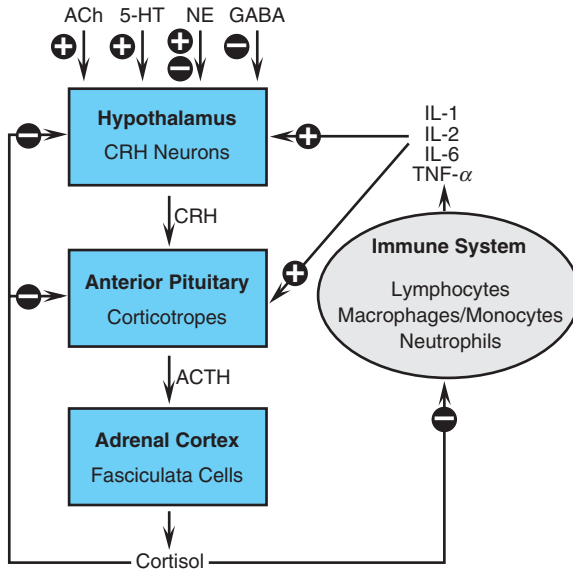

FIGURE 59–3 Overview of the hypothalamic-pituitary-adrenal (HPA) axis and the immune inflammatory network. Also shown are inputs from higher neuronal centers that regulate CRH secretion. + indicates a positive regulator, – indicates a negative regulator, +/- indicates a mixed effect. IL-1, interleukin-1; IL-2, interleukin-2; IL-6, interleukin-6; TNF- α , tumor necrosis factor- α ; CRH, corticotropin-releasing hormone; ACh, acetylcholine; 5-HT, 5-hydroxytryptamine (serotonin); NE, norepinephrine; GABA, γ -aminobutyric acid.

parenteral sites and rapidly disappears from the circulation after intravenous administration; the plasma $t_{1/2}$ is ~15 minutes, primarily due to rapid enzymatic hydrolysis.

CRH Stimulation Test

Synthetic forms of ovine CRH (corticotropin-releasing hormone) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the U.S. and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing in conjunction with petrosal sinus sampling can differentiate between a pituitary source (i.e., Cushing's disease) and an ectopic source of ACTH.

ADRENOCORTICAL STEROIDS

The adrenal cortex synthesizes two classes of steroids: the *corticosteroids*, which have 21 carbon atoms, and the *androgens*, which have 19 (Figure 59–2). The actions of corticosteroids are classified as glucocorticoid (carbohydrate metabolism–regulating) and mineralocorticoid (electrolyte balance–regulating), reflecting their preferential activities. In humans, *cortisol* (*hydrocortisone*) is the main glucocorticoid and aldosterone is the main mineralocorticoid. Typically cortisol is secreted at a rate of 10 mg/day whereas aldosterone is secreted at a rate of 0.125 mg/day. The concentrations of cortisol in peripheral plasma are considerably higher in the morning (16 $\mu\text{g}/\text{dL}$ at 8 AM) than in the late afternoon (4 $\mu\text{g}/\text{dL}$ at 4 PM) reflecting diurnal regulation, whereas the plasma concentrations of aldosterone are lower and more constant (0.01 $\mu\text{g}/\text{dL}$) throughout the day. The daily production of cortisol can rise at least tenfold in the setting of severe stress.

Although adrenal DHEA is an important precursor of testosterone and estradiol synthesis in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Nevertheless, some studies suggest that addition of DHEA to the standard replacement regimen in women with adrenal insufficiency improves subjective well-being and sexuality. The finding that the levels of DHEA and its sulfated derivative DHEA-S fall progressively after the third decade of life has prompted speculation that DHEA may at least partly reverse the adverse consequences of aging. This has led to the wide use of DHEA as a nutritional supplement despite the absence of definitive data.

Physiological Functions and Pharmacological Effects

PHYSIOLOGICAL ACTIONS The effects of corticosteroids are numerous and widespread, and include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist such stressful circumstances as noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feedings, ingestion of relatively large amounts of sodium chloride, and maintenance of an appropriate environmental temperature; stresses such as infection and trauma can be life-threatening when adrenal function is impaired.

The actions of corticosteroids are interrelated to those of other hormones. In the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates their lipolytic action. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed *permissive* and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids traditionally are divided into mineralocorticoids and glucocorticoids according to their relative potencies in Na^+ retention and effects on carbohydrate metabolism (*i.e.*, hepatic deposition of glycogen and gluconeogenesis). In general, potencies of steroids to sustain life in adrenalectomized animals closely parallel their mineralocorticoid activity, while potencies as anti-inflammatory agents closely parallel their effects on glucose metabolism. The effects on Na^+ retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors.

Estimates of potencies of representative steroids in these actions are listed in Table 59–1. Some steroids that are classified predominantly as glucocorticoids (*e.g.*, cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency (*see* below), the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na^+ retention, but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

GENERAL MECHANISMS FOR CORTICOSTEROID EFFECTS Corticosteroids interact with specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive

Table 59–1

Relative Potencies and Equivalent Doses of Representative Corticosteroids

Compound	Anti-inflammatory Potency	Na^+ -Retaining Potency	Duration of Action*	Equivalent Dose, [†] mg
Cortisol	1	1	S	20
Cortisone	0.8	0.8	S	25
Fludrocortisone	10	125	I	‡
Prednisone	4	0.8	I	5
Prednisolone	4	0.8	I	5
6 α -Methylprednisolone	5	0.5	I	4
Triamcinolone	5	0	I	4
Betamethasone	25	0	L	0.75
Dexamethasone	25	0	L	0.75

*S, short (*i.e.*, $t_{1/2} \approx 8$ –12 h; I, intermediate (*i.e.*, $t_{1/2} \approx 12$ –36 h); L, long (*i.e.*, $t_{1/2} \approx 36$ –72 h).

[†]These dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration.

[‡]This agent is not used for glucocorticoid effects.

genes, thereby changing the levels and array of proteins synthesized by the various target tissues. As a consequence of the time required to effect these changes, most effects of corticosteroids are not immediate but become apparent after several hours. This fact is of clinical significance, because a delay generally is seen before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act to increase expression of target genes, there are well-documented examples in which glucocorticoids decrease transcription. In addition to these genomic effects, some immediate actions of corticosteroids may be mediated by membrane-bound receptors.

Regulation of Gene Expression by Glucocorticoids

The GR resides predominantly in the cytoplasm in an inactive form until it binds glucocorticoids. The inactive GR is complexed with other proteins, including heat-shock proteins and an immunophilin. After ligand binding, the GR dissociates from its associated proteins and translocates to the nucleus. There, it interacts with specific DNA sequences called glucocorticoid responsive elements (GREs) within the regulatory regions of affected genes. These GREs thus provide specificity to the regulation of gene transcription by glucocorticoids.

Regulation of Gene Expression by Mineralocorticoids

Like the GR, the MR also is a ligand-activated transcription factor and binds to a very similar, if not identical, hormone responsive element. The selective actions of GR and MR are thought to result from interactions with other transcription factors that also are recruited to the promoter regions of target genes as well as from the restricted pattern of expression of the MR. Unlike the GR, which has a more ubiquitous distribution, the MR is expressed principally in the kidney (distal cortical tubule and cortical collecting duct), colon, salivary glands, sweat glands, and hippocampus.

Receptor-Independent Mechanism for Corticosteroid Specificity

Biochemical studies of the GR and MR led to the surprising finding that aldosterone (a classic mineralocorticoid) and cortisol (predominantly a glucocorticoid) bind the MR with equal affinity. This raised the question of how the apparent specificity of the MR for aldosterone was maintained in the face of much higher circulating levels of cortisol. We now know that the type 2 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β HSD2) plays a key role in corticosteroid specificity, particularly in the kidney, colon, and salivary glands. This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 59–4) and thus forms an enzymatic barrier that prevents cortisol from reaching the MR. Because its predominant form in physiological settings is the hemiacetal derivative (Figure 59–4), aldosterone is resistant to this inactivation and maintains mineralocorticoid activity.

FIGURE 59–4 Structure and nomenclature of corticosteroid products and selected synthetic derivatives. The structure of hydrocortisone is represented in two dimensions. The steroid ring system is not completely planar and the orientation of the groups attached to the steroid rings is an important determinant of the biological activity. The methyl groups at C18 and C19 and the hydroxyl group at C11 project upward (forward in the two-dimensional representation and shown by a solid line connecting the atoms) and are designated β . The hydroxyl at C17 projects below the plane (behind in the two-dimensional representation, and represented by the dashed line connecting the atoms) and is designated α .

CARBOHYDRATE AND PROTEIN METABOLISM Corticosteroids profoundly affect carbohydrate and protein metabolism. Teleologically, these effects of glucocorticoids on intermediary metabolism can be viewed as protecting glucose-dependent tissues (*e.g.*, the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of diabetes in patients who are otherwise predisposed.

LIPID METABOLISM Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in settings of endogenous or pharmacologically induced hypercorticism, such as Cushing's syndrome. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration. With respect to fat distribution, there is increased fat in the back of the neck ("buffalo hump"), face ("moon facies"), and supraclavicular area, coupled with a loss of fat in the extremities.

ELECTROLYTE AND WATER BALANCE Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Thus, electrolyte balance is relatively normal in patients with adrenal insufficiency due to pituitary disease, despite the loss of glucocorticoid production by the inner cortical zones. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na^+ from the tubular fluid; they also increase the urinary excretion of K^+ and H^+ .

These actions on electrolyte transport, in the kidney and in other tissues (*e.g.*, colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na^+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na^+ concentration, hypokalemia, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na^+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism can cause hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of vasopressin, which stimulates water reabsorption in the kidney.

In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca^{2+} metabolism. Steroids interfere with Ca^{2+} uptake in the gut and increase Ca^{2+} excretion by the kidney. These effects collectively lead to decreased total body Ca^{2+} stores.

CARDIOVASCULAR SYSTEM The most striking cardiovascular effects of corticosteroids result from mineralocorticoid-induced changes in renal Na^+ excretion, as is evident in primary aldosteronism. The resultant hypertension can lead to a diverse group of adverse effects on the cardiovascular system (*see* Chapter 32). Consistent with the known actions of mineralocorticoids in the kidney, restriction of dietary Na^+ can lower the blood pressure considerably in mineralocorticoid excess.

Studies also have shown direct effects of aldosterone on the heart and vascular lining; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis is proposed to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension, because treatment with spironolactone, a MR antagonist, blocks the fibrosis without altering blood pressure. Similar effects of mineralocorticoids on cardiac fibrosis in human beings may explain, at least in part, the beneficial effects of spironolactone in patients with congestive heart failure (*see* Chapter 33).

The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced response to vasoconstrictors such as norepinephrine and AngII, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing's syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

SKELETAL MUSCLE Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of

adrenocortical insufficiency. In patients with Addison's disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, termed *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess.

CENTRAL NERVOUS SYSTEM Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability. Patients with adrenal insufficiency exhibit a diverse array of psychiatric manifestations, including apathy, depression, and irritability; some patients are frankly psychotic. Appropriate replacement therapy corrects these abnormalities. Conversely, most patients receiving glucocorticoids respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as euphoria, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic.

FORMED ELEMENTS OF BLOOD Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the occurrence of polycythemia in Cushing's syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish erythrocyte destruction.

Corticosteroids also affect circulating white blood cells. Addison's disease is associated with an increased mass of lymphoid tissue and lymphocytosis. In contrast, Cushing's syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone decreases these circulating cells within 4–6 hours; this effect persists for 24 hours and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and increased demargination from vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the ability of glucocorticoids to activate programmed cell death.

ANTI-INFLAMMATORY AND IMMUNOSUPPRESSIVE ACTIONS In addition to their effects on lymphocyte number, corticosteroids profoundly alter immune response. These effects are important facets of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Glucocorticoids can prevent or suppress inflammation in response to multiple inciting events, including radiant, mechanical, chemical, infectious, and immunological stimuli. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (*see* Chapter 62), to those that are mediated by cellular immune mechanisms, such as transplant rejection (*see* Chapter 52). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. There is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of proinflammatory enzymes, such as COX-2 and NOS.

Absorption, Transport, Metabolism, and Excretion

ABSORPTION Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to rapidly achieve high concentrations of drug in body fluids. More

prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action.

Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, the absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

TRANSPORT, METABOLISM, AND EXCRETION After absorption, >90% of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound can enter cells to mediate corticosteroid effects. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin. CBG is an α -globulin secreted by the liver that has high affinity (association constant of $\sim 7.6 \times 10^7 \text{ M}^{-1}$) for steroids but relatively low total binding capacity, whereas albumin has low affinity (association constant of $1 \times 10^3 \text{ M}^{-1}$) but relatively large binding capacity. CBG has relatively high affinity for cortisol and most of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form.

A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

All of the biologically active adrenocortical steroids and their synthetic congeners have a double bond in the 4,5 position and a ketone group at C3 (Figure 59–4). The metabolism of steroid hormones generally involves sequential additions of oxygen or hydrogen atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring–reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver, and to a lesser extent in the kidney. The resultant sulfate esters and glucuronides are water-soluble and are the predominant forms excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans. The role of 11 β HSD2 in the conversion of cortisol to its inactive 11-keto derivative, cortisone, is discussed above. The type 1 isozyme (11 β HSD1), expressed predominantly in the liver but also in adipocytes, skin, bone and the eye, metabolizes cortisone to cortisol.

Structure–Activity Relationships

The structures of hydrocortisone (cortisol) and some of its major derivatives are shown in Figure 59–4. Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity; for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used (Table 59–1). In addition, these modifications have led to derivatives with greater potencies and longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. None of the available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis. Note that synthetic steroids with an 11-keto substituent, such as cortisone and prednisone, must be metabolized to their corresponding 11 β -hydroxy derivatives before they are biologically active.

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life-threatening and mandate a careful assessment of the risks and benefits in each patient.

WITHDRAWAL OF THERAPY The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. There are several other complications associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. Treatment with supraphysiological doses of glucocorticoids for 2–4 weeks may cause some degree of HPA impairment. The therapeutic approach to acute adrenal

insufficiency is detailed below. There is significant variation among patients with respect to the degree and duration of adrenal suppression after glucocorticoid therapy, making it difficult to establish the relative risk in any given patient. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be one year or longer.

CONTINUED USE OF SUPRAPHYSIOLOGICAL GLUCOCORTICOID DOSES

Since the pharmacological and physiological actions of corticosteroids are mediated by the same receptors, supraphysiological doses of the various glucocorticoid derivatives generally cause side effects that are exaggerated manifestations of their physiological effects. Besides the consequences that result from HPA suppression, other complications of prolonged therapy include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Therapeutic Uses

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Based on extensive clinical experience, a number of therapeutic principles can be proposed. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to one week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond one week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

These principles have several implications for clinical practice. When glucocorticoids are to be given over long periods, the dose must be determined by trial and error and must be the smallest one that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate the tapering process once the initial benefit of glucocorticoid therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent, accurate observations of the patient. It is always essential to weigh carefully the relative dangers of therapy and of the disease being treated.

REPLACEMENT THERAPY Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison's disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in underdeveloped countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy. Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency This life-threatening disease is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus, but sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiovascular function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload such as pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infusion at a rate of 50–100 mg every 8 hours. At this dose, which approximates the maximum daily rate of cortisol secretion in response to stress, hydrocortisone overwhelms the 11β HSD2 barrier in mineralocorticoid-responsive tissues and has sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6–8 hours. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency (see below).

For the treatment of suspected but unconfirmed acute adrenal insufficiency, 4 mg of *dexamethasone sodium phosphate* can be substituted for hydrocortisone, since dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency. Often, plasma ACTH also is measured to provide information about the underlying etiology if the diagnosis of adrenocortical insufficiency is established.

Chronic Adrenal Insufficiency Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis, but with lesser severity. These patients require daily treatment with corticosteroids. Traditional replacement regimens have used hydrocortisone in doses of 20–30 mg/day. *Cortisone acetate*, which is inactive until converted to cortisol by 11β HSD1, also has been used in doses ranging from 25 to 37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally are given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Based on revised estimates of daily cortisol production and clinical studies showing that subtle degrees of glucocorticoid excess can decrease bone density in patients on traditional replacement regimens, many authorities advocate a lower daily hydrocortisone dose of 15–20 mg/day divided into either two doses (e.g., 10–15 mg on awakening and 5 mg in late afternoon) or three doses (e.g., 10 mg on awakening, 5 mg at lunch, and 5 mg in late afternoon). Others prefer to use intermediate-acting (e.g., prednisone) or long-acting (e.g., dexamethasone) glucocorticoids, since no regimen employing shorter-acting steroids can reproduce the peak serum glucocorticoid levels that normally occur before awakening in the morning. The superiority of any one of these regimens has not been rigorously demonstrated. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; *fludrocortisone* generally is used in doses of 0.05–0.2 mg/day. For patients with secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate, as the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone, because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing cortisol metabolism.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency, the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing's syndrome; in children, linear growth may be decreased. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed, but should be less than 100 pg/mL (20 pmol/L).

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., *phenytoin*, barbiturates, or *rifampin*). Dosage adjustments also are needed to compensate for the stress of intercurrent illness, and proper patient education is essential for the execution of these adjustments. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. Patients should be instructed to contact their physician if nausea and vomiting preclude the retention of oral medications. The patient and family members should also be trained to administer parenteral

dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Based largely on empirical data, glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo either elective or emergency surgery. In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 80–100 mg parenterally every 8 hours. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels. Although some data suggest that increases in dose to this degree are not essential for survival even in major surgery, this approach remains the standard clinical practice.

Congenital Adrenal Hyperplasia (CAH) This term denotes a group of genetic disorders in which the activity of one of the several enzymes required for the biosynthesis of cortisol is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. CAH includes a spectrum of disorders whose precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient. In approximately 90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (Figure 59–3).

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH, thereby abrogating the effects that result from overproduction of other steroids such as the adrenal androgens. The typical oral dose of hydrocortisone is approximately 0.6 mg/kg daily in 2 or 3 divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05–0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

THERAPEUTIC USES IN NONENDOCRINE DISEASES Outlined below are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed are not inclusive; rather, they illustrate the principles governing glucocorticoid use in selected diseases for which these drugs are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. For convenience, approximate doses of a representative glucocorticoid (generally prednisone) are provided. This choice is not an endorsement of one particular glucocorticoid preparation over other congeners and is made for illustrative purposes only.

Rheumatic Disorders

Glucocorticoids are used widely in the treatment of a variety of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener's granulomatosis, Churg-Strauss syndrome, and giant cell arteritis.

Glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, glucocorticoids are used as temporizing agents for progressive disease and provide relief until other, slower-acting anti-rheumatic drugs, such as methotrexate or newer agents targeted at tumor necrosis factor take effect. A typical starting dose is 5–10 mg/day of prednisone. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20–40 mg/day of prednisone or equivalent), with rapid taper thereafter. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5–20 mg of triamcinolone acetate or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flares. Intra-articular injections should be performed with intervals of at least 3 months to minimize painless joint destruction, a potential side effect of this treatment.

Renal Diseases

Patients with nephrotic syndrome secondary to minimal change disease generally respond to steroid therapy, and glucocorticoids clearly are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1–2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6–8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2–3 weeks in 85% of patients, and more than 95% of patients will have remission within 3 months. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids.

Allergic Disease

The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, urticaria, drug reactions, bee stings, and angioedema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone 125 mg intravenously every 6 hours, or equivalent) are appropriate. In allergic rhinitis, intranasal steroids are now viewed by many experts as the drug of choice.

Bronchial Asthma

The use of glucocorticoids in bronchial asthma is discussed in Chapter 27.

Preterm Infants

Glucocorticoids such as betamethasone (12 mg intramuscularly every 24 hours for two doses) or dexamethasone (6 mg intramuscularly every 12 hours for four doses) are used frequently in the setting of premature labor to decrease the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in babies delivered prematurely.

Ocular Diseases

Ocular pharmacology, including consideration of the use of glucocorticoids, is discussed in Chapter 63.

GI Diseases

Glucocorticoid therapy is indicated in selected patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn's disease; see Chapter 38).

Malignancies

Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects (see Chapter 51).

Organ Transplantation

In organ transplantation, most patients are kept on a regimen that includes glucocorticoids in conjunction with other immunosuppressive agents (see Chapter 52).

Spinal Cord Injury

Multicenter trials have shown significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 hours of injury with large doses of methylprednisolone (30 mg/kg initially followed by an infusion of 5.4 mg/kg/h for 23 hours).

Diagnostic Applications of Adrenocortical Steroids

In addition to their therapeutic uses, glucocorticoids also are used for diagnostic purposes. The overnight dexamethasone suppression test is used to determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis.

INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS

Four pharmacologic agents are useful inhibitors of adrenocortical secretion. *Mitotane* (o,p'-DDD), an adrenocorticolytic agent, is discussed in Chapter 51. The other inhibitors of steroid hormone biosynthesis are *aminoglutethimide*, *ketoconazole*, and *trilostane*. Aminoglutethimide and ketoconazole are

discussed below. Trilostane is a competitive inhibitor of the conversion of pregnenolone to progesterone, a reaction catalyzed by 3β -hydroxysteroid dehydrogenase. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient's HPA axis must be carefully monitored.

AMINOGLUTETHIMIDE Aminoglutethimide (α -ethyl-*p*-aminophenyl-glutarimide; CYTADREN) primarily inhibits CYP11A1, which catalyzes the initial step in the biosynthesis of all physiological steroids. As a result, the production of all classes of steroid hormones is impaired. Aminoglutethimide also inhibits CYP11B1 and CYP19 (aromatase), which converts androgens to estrogens. Aminoglutethimide has been used primarily to decrease hypersecretion of cortisol in patients with Cushing's syndrome secondary to autonomous adrenal tumors or ectopic production of ACTH. Dose-dependent GI and neurological side effects are relatively common, as is a transient, maculopapular rash. The usual dose is 250 mg every 6 hours, with gradual increases of 250 mg/day at 1–2-week intervals until the desired biochemical effect is achieved, side effects prohibit further increases, or a daily dose of 2 g is reached. Because aminoglutethimide can cause frank adrenal insufficiency, glucocorticoid replacement therapy is necessary, and mineralocorticoid supplements also may be indicated. Aminoglutethimide accelerates the metabolism of dexamethasone, and this steroid therefore should not be used for glucocorticoid replacement in this setting.

KETOCONAZOLE Ketoconazole (NIZORAL) is used primarily as an antifungal agent (*see* Chapter 48). In doses higher than those employed in antifungal therapy, it inhibits adrenal and gonadal steroidogenesis, primarily by inhibiting the activity of CYP17 (17α -hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the most effective inhibitor of steroid hormone biosynthesis in patients with Cushing's disease, though this use of the drug is not FDA-approved. In most cases, a dosage regimen of 600–800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day given in 2–3 doses. Side effects include hepatic dysfunction, which ranges from asymptomatic elevations of transaminase levels to severe hepatic injury. The potential of ketoconazole to interact with a number of CYP enzymes can lead to drug interactions of serious consequence (*see* Chapter 3).

ANTI-GLUCOCORTICIDS

The progesterone receptor antagonist *mifepristone* [RU-486; (11β -4-dimethylaminophenyl)-17 β -hydroxy-7 α -(propyl-1-ynyl)estra-4,9-dien-3-one] is used as an antiprogesterone to terminate early pregnancy (*see* Chapter 57). At higher doses, mifepristone also inhibits the GR and thus has been studied as a potential therapeutic agent in patients with hypercorticism. Currently, it can be recommended only for patients with inoperable causes of cortisol excess that have not responded to other agents.

INSULIN, ORAL HYPOGLYCEMIC AGENTS, AND THE PHARMACOLOGY OF THE ENDOCRINE PANCREAS

Developed nations are witnessing a striking increase in the prevalence of diabetes mellitus (DM), predominantly related to lifestyle changes and the resulting surge in obesity. The metabolic consequences of prolonged hyperglycemia and dyslipidemia, including accelerated atherosclerosis, chronic kidney disease, and blindness, pose an enormous burden on patients with DM and on society. Improvements in our understanding of the pathogenesis of diabetes and its complications and in the prevention and therapy of diabetes are critical to meeting this challenge.

INSULIN

CHEMISTRY

Insulin is a peptide hormone (MW = 5734); it contains an A peptide of 21 amino acids and a B subunit of 30 amino acids, linked by one intrasubunit and two intersubunit disulfide bonds (Figure 60–1). The two chains of insulin form a highly ordered structure with α -helical regions in each of the chains. In solution, insulin can exist as a monomer, dimer, or hexamer. Two molecules of Zn^{2+} are coordinated in the hexamer, and this form of insulin presumably is stored in the β cell granules. Insulin hexamers also comprise most of the highly concentrated preparations used for therapy. As the concentration falls to physiological levels (nM), the hormone dissociates into monomers, which likely are the biologically active form.

Insulin is a member of the insulin-like growth factor (IGF) family. IGF-1 and IGF-2 have structures that are homologous to that of proinsulin, but their short equivalents of the proinsulin C peptide are not removed in the mature proteins. In contrast to insulin, the IGFs are produced in many tissues and likely play a more important function in the regulation of growth than in the regulation of metabolism.

Synthesis, Secretion, Distribution, and Degradation of Insulin

INSULIN PRODUCTION The islet of Langerhans contains four major cell types, each of which synthesizes and secretes a distinct polypeptide hormone: insulin in the β (B) cell, *glucagon* in the α (A) cell, *somatostatin* in the δ (D) cell, and pancreatic polypeptide in the PP or F cell. The β cells make up 60–80% of the islet and form its central core with the α , δ and F cells in a discontinuous mantle around this core. The geographical organization of islet cells facilitates coordinated control of groups of cells. Blood in the islet flows from the β cells to α and δ cells. Thus, the β cell is the primary glucose sensor for the islet, and the other cell types presumably are exposed to particularly high concentrations of insulin.

The β cells synthesize insulin from a single-chain precursor of 110 amino acids termed preproinsulin. The 24-amino-acid N-terminal signal peptide of preproinsulin is rapidly cleaved in the endoplasmic reticulum to form proinsulin (Figure 60–1). Subsequent processing of proinsulin in the secretory granule removes the connector C peptide, giving rise to mature insulin.

The prohormone convertases, PC2 and PC3, convert proinsulin to insulin by proteolytic cleavage of four basic amino acids and removal of the C peptide (Figure 60–1). These Ca^{2+} -dependent endopeptidases are found in the islet cell granules and in other neuroendocrine cells. The conversion of proinsulin to insulin is nearly complete at the time of secretion. Thus, equimolar amounts of inactive C peptide and insulin are released into the circulation, and C peptide serves as a useful index of insulin secretion in assessing β cell mass and in identifying patients with factitious insulin injection or insulin-producing tumors. Since the $t_{1/2}$ of proinsulin in the circulation is much longer than that of insulin, up to 20% of immunoreactive insulin in plasma may reflect proinsulin and intermediates.

Regulation of Insulin Secretion

Insulin secretion is tightly regulated to maintain stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of various nutrients, gastrointestinal (GI) hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids, fatty acids, and ketone bodies stimulate insulin secretion. In general, any condition that activates the sympathetic nervous system (e.g., hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α_2 adrenergic receptors. Predictably, α_2 adrenergic receptor antagonists increase basal concentrations of insulin in plasma, while β_2 adrenergic receptor antagonists decrease them.

FIGURE 60-1 Human proinsulin and its conversion to insulin. The amino acid sequence of human proinsulin is shown. By proteolytic cleavage, four basic amino acids (residues 31, 32, 64, and 65) and the connecting peptide are removed, converting proinsulin to insulin. The sites of action of the endopeptidases PC2 and PC3 are shown.

Glucose, the principal stimulus to insulin secretion, is permissive for the action of many other secretagogues. Glucose provokes insulin secretion more effectively when taken orally than when administered intravenously because the oral route induces the release of GI hormones and stimulates vagal activity. Several GI hormones promote insulin secretion, the most potent of which are glucose-dependent insulinotropic peptide (GIP, also known as gastrointestinal inhibitory peptide) and glucagon-like peptide-1 (GLP-1).

Glucose-induced insulin secretion is biphasic: The first phase reaches a peak after 1–2 minutes and is short-lived; the second phase has a delayed onset but longer duration.

The resting β cell is hyperpolarized, and its glucose-induced depolarization leads to insulin secretion. Glucose enters the β cell by facilitated transport mediated by GLUT2, a specific subtype of glucose transporter. The sugar then is phosphorylated by glucokinase to yield glucose-6-phosphate (G-6-P). Its relatively high K_m (10–20 mM) allows glucokinase to play an important regulatory role at physiological glucose concentrations. Glucokinase's role as a glucose sensor was validated by its association with type 2 maturity-onset diabetes of the young (MODY), a rare monogenic form of diabetes. These glucokinase mutations, which compromise its ability to phosphorylate glucose, raise the threshold for glucose-stimulated insulin release and eventually result in DM.

The increase in oxidizable substrates (e.g., glucose and G-6-P) enhances ATP production, thereby inhibiting an ATP-sensitive K^+ channel. This decrease in K^+ conductance causes E_m to rise, opening a voltage-sensitive Ca^{2+} channel; Ca^{2+} then acts as the insulin secretagogue. The ATP-sensitive K^+ channel in β cells is an octamer composed of four Kir 6.2 and four SUR1 subunits. Both subunits contain nucleotide-binding domains; Kir 6.2 appears to mediate the inhibitory response to ATP; SUR1 binds ADP, the channel activator diazoxide, and the channel inhibitors (and promoters of insulin secretion) sulfonylureas and meglitinide.

DISTRIBUTION AND DEGRADATION OF INSULIN Insulin circulates in blood as a monomer, and its volume of distribution approximates the volume of extracellular fluid. Under fasting conditions, the pancreas secretes about 40 μg (1 unit) of insulin/h into the portal vein to achieve a concentration of insulin in portal blood of 2–4 ng/mL (50–100 $\mu\text{units/mL}$) and in the peripheral circulation of 0.5 ng/mL (12 $\mu\text{units/mL}$) or ~ 0.1 nM. After ingestion of a meal, there is a rapid rise in the concentration of insulin in portal blood, followed by a parallel but smaller rise in the peripheral circulation.

The plasma $t_{1/2}$ of insulin normally is ~ 5 –6 minutes but may be increased in diabetics who develop anti-insulin antibodies. The $t_{1/2}$ of proinsulin is longer than that of insulin, and proinsulin

accounts for ~10% of the immunoreactive insulin in plasma. Since proinsulin is only 2% as potent as insulin, the biologically effective concentration of insulin is lower than estimated by immunoassay. C peptide is secreted in equimolar amounts with insulin, but its molar concentration in plasma is higher because of its considerably longer $t_{1/2}$ (~30 minutes).

Degradation of insulin occurs primarily in liver, kidney, and muscle. About 50% of the insulin that reaches the liver *via* the portal vein is destroyed and never reaches the general circulation. Insulin is filtered by the renal glomeruli and is reabsorbed by the tubules, which also degrade it. Severe impairment of renal function affects insulin clearance to a greater extent than does hepatic disease. Hepatic degradation of insulin operates near its maximal capacity and cannot compensate for diminished renal breakdown.

CELLULAR ACTIONS OF INSULIN Key insulin target tissues for regulation of glucose homeostasis are liver, muscle, and fat, but insulin also exerts potent regulatory effects on other cell types. Insulin stimulates intracellular use and storage of glucose, amino acids, and fatty acids and inhibits catabolic processes such as the breakdown of glycogen, fat, and protein. It does this by stimulating the transport of substrates and ions into cells, promoting the translocation of proteins between cellular compartments, activating and inactivating specific enzymes, and changing the amounts of proteins by altering the rates of transcription and mRNA translation (Figure 60–2).

FIGURE 60–2 Pathways of insulin signaling. The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P) of the receptor's β subunits and a small number of specific substrates (light blue shapes): the insulin receptor substrate (IRS) proteins, Gab-1 and Shc; within the membrane, a caveolar pool of insulin receptor phosphorylates caveolin (Cav), APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades *via* SH2 and SH3 domains to mediate the effects of insulin, with specific effects of insulin resulting from each pathway. In target tissues such as skeletal muscle and adipocytes, a key event is the translocation of the GLUT4 glucose transporter from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and noncaveolar pathways. In the noncaveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP₃) and possibly an atypical form of PKC is involved. In the caveolar pathway, the caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein, TC10. The pathways are inactivated by specific phosphoprotein phosphatases (*e.g.*, PTB1B) and possibly by actions of Ser/Thr protein kinases. In addition to the actions shown, insulin also stimulates the plasma membrane Na⁺,K⁺-ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K⁺ in the cell.

ABBREVIATIONS: APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CrkII, chicken tumor virus regulator of kinase II; GLUT4, glucose transporter 4; Gab-1, Grb-2 associated binder; MAP kinase, mitogen-activated protein kinase; PDK, phosphoinositide-dependent kinase; PI3 kinase, phosphatidylinositol-3-kinase; PIP₃, phosphatidylinositol trisphosphate; PKB, protein kinase B (also called Akt); aPKC, atypical isoform of protein kinase C; Y, tyrosine residue; Y-P, phosphorylated tyrosine residue.

Some effects of insulin occur within seconds or minutes, including the activation of glucose and ion transport systems, the covalent modification of enzymes (*i.e.*, phosphorylation or dephosphorylation), and some effects on gene transcription (*i.e.*, inhibition of the phosphoenolpyruvate carboxykinase gene). Effects on protein synthesis and gene transcription require hours, while those on cell proliferation and differentiation may take days.

REGULATION OF GLUCOSE TRANSPORT Stimulation of glucose transport into muscle and adipose tissue is a key response to insulin. Glucose enters cells by facilitated diffusion through one of a family of five glucose transporters, GLUTs 1–5, that mediate Na⁺-independent facilitated diffusion of glucose into cells. Insulin stimulates glucose transport by promoting translocation of intracellular vesicles that contain the GLUT4 and GLUT1 glucose transporters to the plasma membrane (Figure 60–2). The transporters return to the intracellular pool on removal of insulin.

REGULATION OF GLUCOSE METABOLISM The facilitated diffusion of glucose into cells down a concentration gradient is ensured by glucose phosphorylation. The conversion of glucose to glucose-6-phosphate (G-6-P) is accomplished by one of a family of hexokinases. Hexokinase IV, or *glucokinase*, is coexpressed with GLUT2 in liver and pancreatic β cells and is regulated by insulin. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue, and also is regulated transcriptionally by insulin.

G-6-P is a branch-point substrate that can enter several pathways. Following isomerization to G-1-P, G-6-P can be stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (leading to ATP production); and G-6-P can also enter the pentose phosphate pathway (providing NADPH). Effects of insulin on cellular metabolic enzymes are myriad and generally are mediated by modulating activities of protein kinases and phosphoprotein phosphatases. Figure 60–2 depicts the signaling events following the binding of insulin to its membrane receptor.

REGULATION OF GENE TRANSCRIPTION A major action of insulin is the regulation of transcription of more than 100 specific genes. Insulin inhibits the transcription of phosphoenolpyruvate carboxykinase, contributing to insulin's inhibition of gluconeogenesis; this effect of insulin may explain why the liver overproduces glucose in the insulin-resistant state that is characteristic of type 2 DM.

THE INSULIN RECEPTOR Insulin initiates its actions by binding to its cell-surface receptor. Insulin receptors are present in virtually all cells, including not only the classic targets for insulin action (*i.e.*, liver, muscle, and fat) but also nonclassic targets such as circulating blood cells, neurons, and gonadal cells.

The insulin receptor is a transmembrane glycoprotein composed of two 135 kDa α subunits and two 95 kDa β subunits; the subunits are linked by disulfide bonds to form a β - α - α - β heterotetramer (Figure 60–2). Both subunits are derived from a single-chain precursor molecule that contains the entire sequence of the α and β subunits separated by a processing site consisting of four basic amino acid residues. The α subunits are entirely extracellular and contain the insulin-binding domain, whereas the β subunits are transmembrane proteins that possess tyrosine protein kinase activity. After insulin is bound, receptors aggregate and are internalized rapidly. Since bivalent (but not monovalent) anti-insulin receptor antibodies cross-link adjacent receptors and mimic the actions of insulin, it has been suggested that receptor dimerization is essential for signal transduction. After internalization, the receptor may be degraded or recycled back to the cell surface.

TYROSINE PHOSPHORYLATION AND THE INSULIN ACTION CASCADE

Receptors for insulin and IGF-1 belong to the family of receptor tyrosine kinases, and tyrosine kinase activity is essential for insulin signaling (Figure 60–2). The activated receptors undergo autophosphorylation, which activates their tyrosine kinase activity toward other substrates, principally the four insulin receptor substrates IRS-1, 2, 3, and 4 and Shc Tyrosine phosphorylated IRS proteins recruit signaling cascades via the interaction of SH2 domains with phosphotyrosines, recruiting such proteins as SHP2, Grb2, and SOS and resulting in the activation of MAP kinases and PI3K, which transduce many of insulin's cellular effects. The IGF-1 receptor resembles the insulin receptor and uses similar signaling pathways; furthermore, the two receptors bind each other's ligand, albeit with lower affinity. In addition, IGF-1 and insulin-receptor heterodimers can combine to form hybrid heterotetramers.

Diabetes Mellitus and the Physiological Effects of Insulin

DM consists of a group of disorders characterized by hyperglycemia; altered metabolism of lipids, carbohydrates, and proteins; and an increased risk of complications from vascular disease. Most patients can be classified clinically as having either type 1 or type 2 DM. The American Diabetes Association (ADA) criteria for the diagnosis of DM include symptoms (*e.g.*, polyuria, polydipsia, and unexplained weight loss) and a random plasma glucose concentration of greater than 200 mg/dL (11.1 mM), a fasting plasma glucose concentration of greater than 126 mg/dL (7 mM), or a plasma glucose concentration of greater than 200 mg/dL (11 mM) 2 hours after the ingestion of an oral glucose load.

The incidence of diabetes varies widely throughout the world. In the U.S., 5–10% of all diabetic patients have type 1 DM, with an incidence of 18/100,000 inhabitants/year. The vast majority of diabetic patients (~90% in the U.S.) have type 2 DM. Incidence rates of type 2 DM increase with age, with a mean rate of about 440/100,000/year by the sixth decade in males in the U.S.

Both environmental and genetic components affect the risk of developing DM. These factors are more clearly defined for type 2 DM. Obesity is a major risk factor, and 80–90% of type 2 DM subjects in the U.S. are obese. Studies also support a strong genetic basis for type 2 DM. In a small subset of patients, the genetic basis for type 2 DM is clearly established. Mutations in glucokinase cause the autosomal dominant disorder MODY2; these patients have an increased glycaemic threshold for insulin release that results in persistent mild hyperglycemia. Other single-gene mutations cause the other types of MODY, including those affecting pancreatic transcription factors.

For type 1 DM, the concordance rate for identical twins is only 25–50% and environmental influences must have an important role. Type 1 DM involves an autoimmune attack on the pancreatic β cells. Antibodies to islet cell antigens are detected in up to 80% of patients with type 1 DM shortly after diagnosis or even prior to the onset of clinical disease. Type 1 DM is associated with specific human leukocyte antigen (HLA) alleles, especially at the B and DR loci, and the HLA complex is known to play critical roles in the immune response. However, the trigger for the immune response remains unknown. In about 10% of new cases of type 1 DM, there is no evidence of autoimmune insulinitis. The ADA and the World Health Organization (WHO) therefore subdivide this disease into autoimmune (1A) and idiopathic (1B) subtypes.

Whatever the causes, the final result in type 1 DM is an extensive and selective loss of pancreatic β cells and a state of absolute insulin deficiency. In type 2 DM, β -cell mass is generally reduced by ~50%. At diagnosis, virtually all persons with type 2 DM have a profound defect in first-phase insulin secretion in response to an intravenous glucose challenge, although some of these β -cell abnormalities may be secondary to desensitization by chronic hyperglycemia.

Virtually all forms of DM result from a decrease in the circulating concentration of insulin (insulin deficiency) and a decrease in the response of peripheral tissues to insulin (insulin resistance). These abnormalities lead to alterations in the metabolism of carbohydrates, lipids, ketones, and amino acids; the central feature of the syndrome is hyperglycemia.

Insulin lowers the concentration of glucose in blood by inhibiting hepatic glucose production and by stimulating the uptake and metabolism of glucose by muscle and adipose tissue (Table 60–1). These two important effects occur at different concentrations of insulin. Glucose production is inhibited half maximally by an insulin concentration of about 20 μ units/mL, whereas glucose utilization is stimulated half maximally at about 50 μ units/mL.

Table 60–1

Hypoglycemic Actions of Insulin

Liver	Muscle	Adipose Tissue
Inhibits hepatic glucose production (decreases gluconeogenesis and glycogenolysis)	Stimulates glucose uptake	Stimulates glucose uptake (amount is small compared to muscle)
Stimulates hepatic glucose uptake	Inhibits flow of gluconeogenic precursors to the liver (<i>e.g.</i> , alanine, lactate, and pyruvate)	Inhibits flow of gluconeogenic precursor to liver (glycerol) and reduces energy substrate for hepatic gluconeogenesis (nonesterified fatty acids)

In both types of diabetes, glucagon (elevated in untreated patients) opposes the hepatic effects of insulin by stimulating glycogenolysis and gluconeogenesis but has relatively little effect on peripheral glucose utilization. Thus, in the diabetic patient (depressed insulin signaling and hyperglucagonemia) there is increased hepatic glucose production, decreased peripheral glucose uptake, and decreased conversion of glucose to glycogen in the liver.

Alterations in insulin and glucagon secretion also profoundly affect lipid, ketone, and protein metabolism. At concentrations below those needed to stimulate glucose uptake, insulin inhibits hormone-sensitive lipase in adipocytes and inhibits the hydrolysis of triglyceride stores. This counteracts the lipolytic action of catecholamines, cortisol, and growth hormone and reduces the concentrations of glycerol (a substrate for gluconeogenesis) and free fatty acids (a substrate for production of ketone bodies and a necessary fuel for gluconeogenesis). These actions of insulin are deficient in DM, leading to increased gluconeogenesis and ketogenesis.

The liver produces ketone bodies by oxidizing free fatty acids to acetyl CoA, which then is converted to acetoacetate and β -hydroxybutyrate. The initial step in fatty acid oxidation is transport of the fatty acids into the mitochondria. The essential enzyme in this process, acylcarnitine transferase, is inhibited by intramitochondrial malonyl CoA, one of the products of fatty acid synthesis. Normally, insulin inhibits lipolysis, stimulates fatty acid synthesis (thereby increasing the concentration of malonyl CoA), and decreases the hepatic concentration of carnitine; these factors all decrease the production of ketone bodies. Conversely, glucagon stimulates ketone body production by increasing fatty acid oxidation and decreasing concentrations of malonyl CoA. In patients with type 1 DM, insulin deficiency and glucagon in excess provide a hormonal milieu that favors ketogenesis and may lead to ketoacidosis.

Insulin also enhances the transcription of lipoprotein lipase in the capillary endothelium. Thus, hypertriglyceridemia and hypercholesterolemia often occur in untreated or undertreated diabetics. In addition, insulin deficiency may be associated with increased production of VLDL.

The key role of insulin in protein metabolism usually is evident only in diabetic patients with persistently poor glycemic control. Insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues. The increased conversion of amino acids to glucose also results in increased production and excretion of urea and ammonia. In addition, there are increased circulating concentrations of branched-chain amino acids as a result of increased proteolysis, decreased protein synthesis, and increased release of branched-chain amino acids from the liver.

A nearly pathognomonic feature of diabetes mellitus is thickening of the capillary basement membrane. The progressive narrowing of the vessel lumina causes inadequate perfusion of certain organs, contributing to the major complications of diabetes, including premature atherosclerosis, intercapillary glomerulosclerosis, retinopathy, neuropathy, and ulceration and gangrene of the extremities.

It was hypothesized that the factor responsible for the development of most complications of DM is the prolonged exposure of tissues to elevated concentrations of glucose. The results from the Diabetes Control and Complications Trial (DCCT) definitively demonstrated that most diabetic complications arise from prolonged exposure of tissue to elevated glucose concentrations. The DCCT demonstrated unequivocally that improving day-to-day glycemic control in type 1 DM patients can dramatically decrease diabetic complications. A follow-up study showed that intensive therapy reduced cardiovascular adverse events and that the reduction in the risk of progressive retinopathy and nephropathy persists for at least 4 years, even if tight glycemic control is not maintained. Rigorous control of blood glucose provides similar benefits to patients with type 2 diabetes.

The toxic effects of hyperglycemia may relate to the formation and accumulation of products such as glycosylated proteins and lipids. Advanced glycosylation end-products (AGEs) signal through receptors for AGEs (RAGEs) to alter oxidative stress, inflammatory injury, and a variety of other responses that may contribute to the sequelae of diabetes. In the face of elevated blood glucose, hemoglobin (Hb) becomes glycosylated on its amino terminal valine, forming Hb A_{1c}, the concentration of which reflects the severity and duration of the hyperglycemic state and may be assessed clinically.

A serious complication of intensive therapy is an increased incidence of severe hypoglycemia. Therefore, ADA guidelines for treatment include a contraindication for implementing tight metabolic control in infants younger than 2 years old and an extreme caution in children of 2–7 years of age in whom hypoglycemia may impair brain development. Older patients with significant atherosclerosis also may be vulnerable to permanent injury from hypoglycemia. Current therapies for type 1 and type 2 DM therefore aim for tight metabolic control, always keeping in mind the risks of severe hypoglycemia in individual patients.

Insulin Therapy

Insulin is the mainstay for treatment of virtually all type 1 DM and many type 2 DM patients. When necessary, insulin may be administered intravenously or intramuscularly; however, long-term treatment relies predominantly on subcutaneous injections of the hormone. Subcutaneous administration of insulin differs from physiological secretion of insulin in at least two major ways: The kinetics do not reproduce the normal rapid rise and decline of insulin secretion in response to ingestion of nutrients, and the insulin diffuses into the peripheral circulation instead of being released into the portal circulation; the direct effect of secreted insulin on hepatic metabolic processes thus is eliminated. Nonetheless, when such treatment is performed carefully, considerable success is achieved.

Insulin preparations are classified according to their duration of action into rapid, short, intermediate, and long acting and by their species of origin—human or porcine. Human insulin (HUMULIN, NOVOLIN) is widely available, as is porcine insulin, which differs from human insulin by one amino acid (alanine instead of threonine in position B30). Human insulin, produced using recombinant DNA technology, is more water soluble than porcine insulin owing to the presence of an extra hydroxyl group. The vast majority of preparations now are supplied at neutral pH, which improves stability and permits storage for several days at room temperature.

UNITAGE

Insulin doses are expressed in units. One unit of insulin equals the amount required to reduce the concentration of blood glucose in a fasting rabbit to 45 mg/dL. The current international standard is a mixture of bovine and porcine insulins and contains 24 units/mg. Homogeneous preparations of human insulin contain between 25 and 30 units/mg. Almost all commercial preparations of insulin are supplied at a concentration of 100 units/mL, which is about 3.6 mg insulin per milliliter (0.6 mM). Insulin also is available in a more concentrated solution (500 units/mL) for patients who are resistant to the hormone.

CLASSIFICATION OF INSULINS

Short- and Rapid-Acting Insulins

Traditionally, the short-acting insulins were solutions of regular, crystalline zinc insulin (insulin injection) dissolved in a buffer at neutral pH. These preparations have a rapid onset of action but short duration (Table 60–2). More recently, modified recombinant insulins have been introduced with even more rapid onset and shorter duration of action; they therefore are termed “rapid-acting” insulins.

Table 60–2

Properties of Currently Available Insulin Preparations

Type	Appearance	Added Protein	Zinc Content, mg/100 units	Buffer*	Action, Hours [†]		
					Onset	Peak	Duration
Rapid/Short							
Regular soluble (crystalline)	Clear	None	0.01–0.04	None	0.5–0.7	1.5–4	5–8
Lispro	Clear	None	0.02	Phosphate	0.25	0.5–1.5	2–5
Aspart	Clear	None	0.0196	Phosphate	0.25	0.6–0.8	3–5
Glulisine	Clear	None	None	None	—	0.5–1.5	1–2.5
Intermediate							
NPH (isophane)	Cloudy	Protamine	0.016–0.04	Phosphate	1–2	6–12	18–24
Lente	Cloudy	None	0.2–0.25	Acetate	1–2	6–12	18–24
Slow							
Ultralente	Cloudy	None	0.2–0.25	Acetate	4–6	16–18	20–36
Protamine zinc	Cloudy	Protamine	0.2–0.25	Phosphate	4–6	14–20	24–36
Glargine	Clear	None	0.03	None	2–5	5–24	18–24
Detemir	Clear	None	0.065	Phosphate	1–2	4–14	6–24

*Most insulin preparations are supplied at pH 7.2–7.4. Glargine and Detemir are supplied at a pH of 4.0.

[†]These are approximate figures. There is considerable variation from patient to patient and from time to time in a given patient.

Short-acting (i.e., regular) insulin usually is injected subcutaneously 30–45 minutes before meal, and also may be given intravenously or intramuscularly. After intravenous injection, the blood glucose concentration diminishes swiftly, usually reaching a nadir in 20–30 minutes. In the absence of a sustained infusion of insulin, the hormone is cleared rapidly, and counter-regulatory hormones (e.g., glucagon, epinephrine, cortisol, and growth hormone) restore plasma glucose to baseline in 2–3 hours. In the absence of a normal counter-regulatory response (e.g., in diabetic patients with autonomic neuropathy), plasma glucose will remain suppressed for many hours following an insulin bolus of 0.15 units/kg because the cellular actions of insulin are prolonged far beyond its clearance from plasma.

Regular insulin typically is given subcutaneously, often in combination with an intermediate- or long-acting preparation. Special buffered formulations of regular insulin are available for use in subcutaneous infusion pumps that are less likely to crystallize in the tubing during the slow infusion associated with this type of therapy.

Native insulin in regular insulin forms hexamers that slow absorption and reduce postprandial peaks of subcutaneously injected insulin. These pharmacokinetics stimulated the development of rapid-acting insulin analogs that retain a monomeric or dimeric configuration. Several such compounds are now available for clinical use. These analogs are absorbed three times more rapidly from subcutaneous sites than is human insulin. Consequently, there is a more rapid increase in plasma insulin concentrations and an earlier hypoglycemic response. Injection of the analogs 15 minutes before a meal affords glycemic control similar to that from an injection of human insulin given 30 minutes before the meal.

Owing to their fast onset, the rapid-acting insulin analogs all may be injected immediately before or after a meal. Factors such as gastroparesis or anorexia may cause many diabetic patients to eat fewer calories than anticipated. Due to their pharmacokinetics, the rapid-acting analogs may be administered postprandially based on the amount of food actually consumed, possibly providing smoother glycemic control and decreasing the risk of hypoglycemia.

Insulin lispro (HUMALOG) differs from human insulin only at positions B28 and B29, which are reversed to match the sequence in IGF-1, which does not self-associate. Relative to regular insulin, the prevalence of hypoglycemia is reduced by 20–30% with insulin lispro, and glucose control, as assessed by Hb A_{1c}, is modestly but significantly improved (0.3–0.5%).

Insulin aspart (NOVOLOG) is formed by the replacement of proline at B28 with aspartic acid. Comparison of single subcutaneous doses of insulin aspart and insulin lispro in patients with type 1 DM revealed similar plasma insulin profiles. In clinical trials, insulin aspart and insulin lispro have had similar effects, with lower rates of nocturnal hypoglycemia as compared with regular insulin.

A third rapid-acting insulin analog, insulin glulisine (APIDRA), is available for use in the U.S. In this compound, glutamic acid replaces lysine at B29, and lysine replaces asparagine at B23, again reducing self-association and permitting rapid dissociation into active monomers with kinetics similar to insulin aspart and lispro. Insulin glulisine also is FDA-approved for continuous subcutaneous insulin infusion (CSII) pump use.

The FDA recently approved inhaled insulin for use in patients with type 1 or type 2 DM. This powdered formulation of recombinant human insulin (EXUBERA) is inhaled through the mouth before eating using a special inhalation device. Although the efficacy of inhaled insulin is more clearly documented for patients with type 2 DM, approval also was given for use in subjects with type 1 DM. Some concerns have been expressed about the use of the inhaled formulation in patients with chronic obstructive pulmonary disease and asthma, and additional studies are ongoing in these settings. The inhaled insulin preparation was associated with high titers of anti-insulin antibodies, but this has not been shown to affect the pharmacokinetics of the drug or to impair its glucose-lowering activity.

Intermediate-Acting Insulins

These insulins are formulated to dissolve more gradually when administered subcutaneously; thus, their durations of action are longer. The two preparations used most frequently are neutral protamine Hagedorn (NPH) insulin (isophane insulin suspension) and lente insulin (insulin zinc suspension). NPH insulin is a suspension of insulin in a complex with zinc and protamine in a phosphate buffer. Lente insulin is a mixture of crystallized (ultralente) and amorphous (semilente) insulins in an acetate buffer, which minimizes the solubility of insulin. The pharmacokinetic properties of human intermediate-acting insulins are slightly different from those of porcine preparations. Human insulin has a more rapid onset and shorter duration of action than does porcine insulin. This difference may create a problem with optimal timing for evening therapy; human insulin preparations taken before dinner may not have a sufficient duration of action to prevent hyperglycemia by morning. There is no evidence that lente or NPH insulin has different pharmacodynamic effects when used in combination with regular (soluble) insulin in a twice-daily regimen. Intermediate-acting insulins usually are given either once a day before breakfast or twice a day.

In patients with type 2 DM, intermediate-acting insulin given at bedtime may help normalize fasting blood glucose. When lente insulin is mixed with regular insulin, some of the regular insulin may form a complex with the protamine or Zn^{2+} after several hours, which may slow absorption of the short-acting insulin. NPH insulin does not retard the action of regular insulin when the two are mixed vigorously by the patient or when they are supplied as a mixture.

Long-Acting Insulins

Ultralente insulin (extended insulin zinc suspension) is a long-acting insulin that has a slower onset and a prolonged peak of action. This insulin has been advocated to provide a low basal concentration of insulin throughout the day. Doses given once or twice daily are adjusted according to the fasting blood glucose concentration. The long $t_{1/2}$ of ultralente insulin makes it difficult to determine the optimal dosage because several days of treatment are required before a steady-state concentration of circulating insulin is achieved. Protamine zinc insulin is no longer available in the U.S. Preparations of insulin that are available for clinical use in the U.S. are shown in Table 60–3.

The pharmacokinetic limitations of ultralente insulin have prompted efforts to develop insulin analogs that do not have significant peaks in their action. Insulin glargine (LANTUS) is a long-acting analog of human insulin that has two arginine residues added to the C terminus of the B chain, and glycine replaces an asparagine molecule in position A21 on the A chain. Glargine is a clear solution with a pH of 4.0 that stabilizes the insulin hexamer and results in a prolonged and predictable absorption from subcutaneous tissues. Owing to its acidic pH, insulin glargine cannot be mixed with currently available short-acting or rapid-acting insulin preparations that are formulated at neutral pH. In clinical studies, insulin glargine results in less hypoglycemia, has a sustained “peakless” absorption profile, and provides a better once-daily 24-hour insulin coverage than ultralente or NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and no difference in the frequency of hypoglycemic episodes. Glargine does not accumulate after several injections.

Insulin glargine can be used in combination with various oral antihyperglycemic agents (see below) to effectively lower plasma glucose levels. Combination of insulin glargine with sulfonylureas and/or metformin can reduce both fasting (basal) and postprandial glucose levels. The use of a long-acting basal insulin alone will not control postprandial glucose elevations in insulin-deficient type 1 or type 2 DM. Glargine has been shown in clinical studies to normalize fasting glucose levels following once-daily administration in patients with type 2 DM. Rarely, the glargine dose may need to be divided in very lean, insulin-sensitive type 1 DM patients to achieve good fasting glucose levels. Unlike traditional insulin preparations, the site of administration does not influence the time–action profile of glargine. Similarly, exercise does not influence glargine’s unique absorption kinetics, even when the insulin is injected into a working limb.

Table 60–3

Insulin Preparations Available in the United States

Type	Human	Porcine
Rapid/Short		
Insulin injection (regular)	R, C	P, S
Lispro	R	—
Aspart	R	—
Glulisine	R	—
Intermediate		
Isophane insulin suspension (NPH)	R	P
Insulin zinc suspension (lente)	R	P
Slow		
Extended insulin zinc suspension (ultralente)	R	—
Insulin glargine	R	—
Insulin detemir	R	—
Mixtures		
70% NPH/30% Regular	R	—
50% NPH/50% Regular	R	—
75% Lispro Protamine/25% Lispro	R	—
70% Aspart Protamine/30% Aspart	R	—

ABBREVIATIONS: S, standard insulins; P, purified insulins; C, concentrated insulin; R, recombinant or semisynthetic human insulins.

Another approach to prolong the action of soluble insulin analogs is to add a saturated fatty acid to the ϵ amino group of LysB29, yielding a myristoylated insulin called insulin detemir. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. When administered twice a day, insulin detemir has a smoother time-action profile and a reduced prevalence of hypoglycemia as compared with NPH insulin. Insulin detemir (LEVEMIR) is FDA-approved for use in adult patients with type 1 or type 2 DM who require long-acting insulin. It should not be mixed with any other insulin preparations.

INDICATIONS AND GOALS FOR THERAPY Subcutaneous administration of insulin is the primary treatment for all patients with type 1 DM, for patients with type 2 DM that is not controlled adequately by diet and/or oral hypoglycemic agents, and for patients with postpancreatic diabetes or gestational diabetes. In addition, insulin is critical for the management of diabetic ketoacidosis, and it has an important role in the treatment of hyperglycemic, nonketotic coma and in the perioperative management of both type 1 and type 2 DM. In all cases, the goal is to normalize not only blood glucose but also all aspects of metabolism; the latter is difficult to achieve. Optimal treatment requires a coordinated approach to diet, exercise, and insulin administration.

In many patients, near-normoglycemia can be attained with multiple daily doses of insulin or with infusion pump therapy. The goal is a fasting blood glucose concentration of between 90 and 120 mg/dL (5–6.7 mM) and a 2-hour postprandial value below 150 mg/dL (8.3 mM). Goal Hb A_{1c} values should be below 7% (below 6.5% for some experts). In patients with defective counter-regulatory responses, it may be necessary to accept higher fasting [e.g., 140 mg/dL (7.8 mM)] and 2-hour postprandial [e.g., 200–250 mg/dL (11.1–13.9 mM)] blood glucose concentrations.

DAILY REQUIREMENTS

Insulin production by a normal, thin, healthy person is between 18 and 40 units/day (~0.2–0.5 units/kg/day). About half this amount is secreted in the basal state and about half in response to meals. Thus, basal secretion is about 0.5–1 units/h; after an oral glucose load, insulin secretion may increase to 6 units/h. In obese and insulin-resistant individuals, insulin secretion may be increased fourfold or more.

In type 1 DM patients, the average dose of insulin is usually 0.6–0.7 units/kg/day, with a range of 0.2–1 units/kg/day. Obese patients generally require more (about 2 units/kg/day) because of resistance of peripheral tissues to insulin. As in nondiabetics, the daily requirement for insulin can be divided into basal and postprandial needs. The basal dose (usually 40–60% of the total daily dose) suppresses lipolysis, proteolysis, and hepatic glucose production. The dose necessary for disposition of nutrients after meals usually is given before meals. Insulin often has been administered as a single daily dose of intermediate-acting insulin, alone or in combination with regular insulin. This rarely achieves true euglycemia; since hyperglycemia is the major determinant of long-term diabetic complications, more complex regimens that include combinations of intermediate- or long-acting insulins with regular insulin are used to reach this goal.

Several commonly used dosage regimens that include mixtures of insulin given in two or three daily injections are depicted in Figure 60–3. The most frequently used is the so-called split-mixed regimen involving prebreakfast and presupper injections of a mixture of regular and intermediate-acting insulins (Figure 60–3A). When the presupper NPH or lente insulin is not sufficient to control hyperglycemia throughout the night, the evening dose may be divided into a presupper dose of regular insulin followed by NPH or lente insulin at bedtime (Figure 60–3B). Both normal and diabetic individuals have an increased requirement for insulin in the early morning; this dawn phenomenon makes the kinetics and timing of the evening insulin dose extremely important.

A regimen that is gaining widespread use involves multiple daily injections consisting of basal administration of long-acting insulin (e.g., insulin glargine or detemir) either before breakfast or at bedtime and prandial injections of a short- or rapid-acting insulin (Figure 60–3C). This method, called basal/bolus, is very similar to the pattern of insulin administration achieved with a subcutaneous infusion pump (Figure 60–3E). Following the successful demonstration that intensive glycemic control can reduce the risk of complications in patients with type 2 DM, there has been increased interest in using insulin earlier in the treatment of these patients. Data indicate that 50% of relative β -cell insulin secretory capacity is lost for every 6 years of type 2 DM. This progressive insulin deficiency as type 2 DM progresses makes it increasingly difficult to achieve glycemic control with oral antihyperglycemic agents. An option in this setting is to introduce basal-acting insulin in combination with oral hypoglycemic agents. The exact combination of therapies should be guided by the β -cell secretory reserve in each patient. Thus, in an individual with some exogenous insulin secretory capacity (i.e., a measurable circulating C peptide), combining an oral insulin secretagogue (see below) with basal insulin may provide smooth and efficient glycemic

FIGURE 60-3 Common multidose insulin regimens. **A.** Typical split-mixed regimen consisting of twice-daily injections of a mixture of regular (regular/lispro/aspart/gulis) and intermediate-acting (NPH or lente) insulin. **B.** A variation in which the evening dose of intermediate-acting insulin is delayed until bedtime to increase the amount of insulin available the next morning. **C.** A regimen that incorporates ultralente or glargine insulin. **D.** A variation that includes premeal short-acting insulin with intermediate-acting insulin at breakfast and bedtime. **E.** Patterns of insulin administration with a regimen of continuous subcutaneous insulin infusion.

control. The addition of a second oral agent, such as an insulin sensitizer (see below), either alone or in combination with an oral insulin secretagogue, also may provide good therapeutic results. This combination allows the oral agents to provide postprandial glycemic control while the basal insulin provides the foundation for normalizing fasting or “basal” glucose levels. In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by the use of home glucose monitors and measurements of Hb A_{1c}.

FACTORS THAT AFFECT INSULIN ABSORPTION The degree of control of plasma glucose may be modified by changes in insulin absorption, factors that alter insulin action, diet, exercise, and other factors. Factors that determine the rate of absorption of insulin after subcutaneous

administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, and the volume and concentration of the injected insulin.

Insulin usually is injected subcutaneously in the abdomen, buttock, anterior thigh, or dorsal arm. Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipoatrophy. The abdomen is the preferred site of injection in the morning because insulin is absorbed more rapidly from that site than from the arm. If the patient refuses to inject into the abdomen, it is preferable to select a consistent injection site for each component of insulin treatment (*e.g.*, prebreakfast dose into the thigh, evening dose into the arm).

Increased subcutaneous blood flow (brought about by hot baths or exercise) increases the rate of insulin absorption. In the upright posture, subcutaneous blood flow diminishes considerably in the legs and to a lesser extent in the abdominal wall. An altered volume or concentration of injected insulin affects the rate of absorption and the duration of action. When regular insulin is mixed with lente or ultralente insulin, some of the regular insulin becomes modified, causing a partial loss of the short-acting component. Injections of mixtures of insulin preparations thus should be made without delay. There is less delay in absorption of regular insulin when it is mixed with NPH insulin. Stable, mixed combinations of NPH and regular insulin in proportions of 50:50, 60:40, 70:30, and 80:20, respectively, are available commercially; only the 70:30 and 50:50 combinations are available in the U.S. Combinations of lispro protamine-Lispro (75/25, HUMALOG MIX), aspart protamine-aspart (70/30, NOVOLOG MIX), and glisine are also available in the U.S. (Table 60–3).

Subcutaneous insulin administration may result in anti-insulin IgG antibody formation. In most patients, circulating anti-insulin antibodies do not alter the pharmacokinetics of the injected hormone. Rarely, the pharmacokinetics of the insulin preparations can be altered, potentially leading to increased postprandial hyperglycemia (owing to decreased action of regular insulin) but nighttime hypoglycemia (owing to the prolonged action of intermediate insulin). Because of concerns that IgG anti-insulin antibodies could cross the placenta and cause fetal hyperglycemia by neutralizing fetal insulin or cause fetal or neonatal hypoglycemia due to unpredictable release of insulin from antigen-antibody complexes, it is recommended that only human insulin be used during pregnancy.

CONTINUOUS SUBCUTANEOUS INSULIN INFUSION A number of pumps are available for continuous subcutaneous insulin infusion (CSII) therapy. CSII, or “pump,” therapy is not suitable for all patients because it demands considerable attention, especially during the initial phases of treatment. For patients interested in intensive insulin therapy, a pump may be an attractive alternative to several daily injections. Most pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon and bolus injections that are programmed according to the size and nature of a meal.

Pump therapy presents some unique problems. Since all the insulin used is short-acting or rapid-acting and there is a minimal amount of insulin in the subcutaneous pool at any given time, insulin deficiency and ketoacidosis may develop rapidly if therapy is interrupted accidentally. Although pumps have warning devices that detect changes in line pressure, mechanical problems may occur. There also is a possibility of subcutaneous abscesses and cellulitis. Patient selection is extremely important for success with pump therapy. Offsetting these potential problems, pump therapy can produce a more physiological profile of insulin replacement that apparently decreases the risk of hypoglycemia.

ADVERSE REACTIONS

Hypoglycemia Hypoglycemia is the most common adverse reaction to insulin and may result from an inappropriately large dose, from a mismatch between the time of peak delivery of insulin and food intake, or from additional factors that increase insulin sensitivity (*e.g.*, adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (*e.g.*, exercise). More vigorous efforts to achieve euglycemia are accompanied by more frequent episodes of hypoglycemia. In the DCCT, the incidence of severe hypoglycemic reactions was tripled in the intensive therapy group. Hypoglycemia is the major risk that always must be weighed against benefits of intensive therapy.

There is a hierarchy of physiological responses to hypoglycemia. Endogenous insulin secretion is reduced at a plasma glucose of about 70 mg/dL (3.9 mM); thereafter, counter-regulatory

hormones—epinephrine, glucagon, growth hormone, cortisol, and norepinephrine—are released. Autonomic symptoms of hypoglycemia are first discerned at a plasma glucose level of 60–80 mg/dL (3.3–4.4 mM) and include sweating, hunger, paresthesias, palpitations, tremor, and anxiety. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (*i.e.*, the *neuroglycopenic symptoms*) usually occur at lower plasma glucose levels than do autonomic symptoms.

Glucagon and epinephrine are the predominant counter-regulatory hormones in acute hypoglycemia in normal subjects and in newly diagnosed type 1 DM patient. In patients with type 1 DM of longer duration, the glucagon response to hypoglycemia becomes deficient, but epinephrine maintains effective glucose counter-regulation. If this epinephrine response becomes deficient, as in diabetics of long duration who have autonomic neuropathy, the incidence of severe hypoglycemia increases. The absence of both glucagon and epinephrine can lead to prolonged hypoglycemia, particularly during the night, and can cause convulsions and coma.

In addition to autonomic neuropathy, several related syndromes of defective counter-regulation in intensively treated type 1 DM patients contribute to their increased incidence of severe hypoglycemia. These include hypoglycemic unawareness, altered thresholds for release of counter-regulatory hormones, and deficient secretion of counter-regulatory hormones.

With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients with suggestive symptoms. Nocturnal hypoglycemia is suggested by a history of morning headaches, night sweats, or symptoms of hypothermia; if confirmed, the predinner or bedtime insulin dose should be decreased.

All diabetic patients who receive insulin should be aware of the symptoms of hypoglycemia, carry some form of easily ingested glucose, and carry an identification card or bracelet containing pertinent medical information. When possible, patients who suspect that they are experiencing hypoglycemia should document the glucose concentration with a measurement. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose. When hypoglycemia is severe, it should be treated with intravenous glucose or injection of glucagon (see below).

Insulin Allergy and Resistance

The most frequent allergic manifestations are IgE-mediated local cutaneous reactions, although patients rarely may develop life-threatening systemic responses or insulin resistance owing to IgG antibodies. Attempts should be made to identify the underlying cause of the hypersensitivity response by measuring insulin-specific IgG and IgE antibodies. Skin testing also is useful, although false-positive results are not uncommon. If patients have allergic reactions to porcine insulin, human insulin should be used. If allergy persists, desensitization may be successful in about 50% of cases. Antihistamines may provide relief in patients with cutaneous reactions, whereas glucocorticoids have been used in patients with resistance to insulin or more severe systemic reactions.

Lipoatrophy and Lipohypertrophy

Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) is probably an immune response to insulin, whereas lipohypertrophy (enlargement of subcutaneous fat depots) is ascribed to the lipogenic action of high local concentrations of insulin. Both problems are rare with more purified preparations. However, hypertrophy may occur with human insulin if patients inject themselves repeatedly in the same site. The recommended treatment is to avoid the hypertrophic areas by using other injection sites and to inject insulin into the periphery of the atrophic sites in an attempt to restore the subcutaneous adipose tissue.

Insulin Edema

Edema, abdominal bloating, and blurred vision develop in many diabetic patients with severe hyperglycemia or ketoacidosis that is brought under control with insulin. The edema usually disappears spontaneously within several days to a week and is attributed primarily to renal retention of Na⁺.

INSULIN TREATMENT OF KETOACIDOSIS AND OTHER SPECIAL SITUATIONS

Intravenous administration of insulin is used in patients with diabetic ketoacidosis. In this setting, infusion of a relatively low dose of insulin (0.1 units/kg/h) will produce plasma concentrations of insulin of ~100 μ units/mL, level sufficient to inhibit lipolysis and gluconeogenesis completely and to stimulate near-maximal glucose uptake. In most patients with diabetic ketoacidosis, blood

glucose concentrations will fall by about 10% per hour; the acidosis corrects more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Patients with nonketotic hyperglycemic coma typically are more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. The key to effective therapy is careful and frequent monitoring of the patient's clinical status, glucose, and electrolytes. A frequent error in the management of such patients is the failure to administer subcutaneous insulin at least 30 minutes before intravenous therapy is discontinued.

Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. Two widely used protocols for intravenous insulin administration are the variable-rate regimen and the glucose–insulin–potassium (GIK) infusion method. Both protocols provide stable plasma glucose, fluid, and electrolyte levels during the operative and postoperative period. Other physicians give patients half their normal daily dose of insulin subcutaneously before the procedure and then maintain glucose concentration by administering 5% dextrose in water. Protocols that rely on intermediate-acting insulin subcutaneously on the morning of an operation with 5% dextrose infusions during surgery to maintain glucose concentrations provide less minute-to-minute control than is possible with intravenous regimens and also may increase the likelihood of hypoglycemia.

DRUG INTERACTIONS AND GLUCOSE METABOLISM

Many drugs can cause hypoglycemia or hyperglycemia or alter the response of diabetic patients to their existing therapeutic regimens. Aside from insulin and oral hypoglycemic drugs, drug-induced hypoglycemia is most often caused by ethanol, β adrenergic receptor antagonists, and salicylates. The primary action of ethanol is to inhibit gluconeogenesis. In diabetics, β adrenergic receptor antagonists pose a risk of hypoglycemia because of their capacity to inhibit catecholamine effects on gluconeogenesis and glycogenolysis. These agents also may mask the autonomic symptoms associated with hypoglycemia (e.g., tremor and palpitations). Salicylates enhance β -cell sensitivity to glucose and potentiate insulin secretion and also have a weak insulin-like action in the periphery. A number of drugs have no direct hypoglycemic action but may potentiate the actions of sulfonylureas (see below).

An equally large number of drugs may cause hyperglycemia in normal individuals or impair metabolic control in diabetic patients. Many of these agents have direct effects on peripheral tissues that counter the actions of insulin; examples include epinephrine, glucocorticoids, atypical antipsychotic drugs such as clozapine and olanzapine, and drugs used in HIV-1 infection (especially the protease inhibitors). Other drugs cause hyperglycemia by inhibiting insulin secretion directly (e.g., phenytoin, clonidine, and Ca^{2+} -channel blockers) or indirectly via depletion of K^+ (diuretics). It is important to be aware of such interactions and to modify treatment regimens for diabetic patients accordingly.

ORAL HYPOGLYCEMIC AGENTS

Sulfonylureas

CHEMISTRY

The sulfonylureas are divided into two generations whose structural relationships are shown in Table 60–4. All are substituted arylsulfonylureas that differ by substitutions at the para position on the benzene ring (R_1) and at one nitrogen residue of the urea moiety (R_2). The first generation of sulfonylureas includes tolbutamide, acetohexamide, tolazamide, and chlorpropamide. Second generation sulfonylureas include glyburide (glibenclamide), glipizide, gliclazide, and glimepiride.

MECHANISM OF ACTION Sulfonylureas stimulate insulin release from pancreatic β cells. The acute administration of sulfonylureas to type 2 DM patients increases insulin release from the pancreas. In the initial months of sulfonylurea treatment, fasting plasma insulin levels and insulin responses to oral glucose challenge are increased. With chronic administration, circulating insulin levels decline to those that existed before treatment; despite this, reduced plasma glucose levels are maintained, possibly because reduced plasma glucose increases insulin sensitivity of its target tissues and improves the impaired insulin secretion caused by chronic hyperglycemia.

Sulfonylureas bind to the SUR1 subunits and block the ATP-sensitive K^+ channel. The drugs thus resemble physiological secretagogues (e.g., glucose, leucine).

Table 60-4

Structural Formulas of the Sulfonylureas

General Formula:		
First-Generation Agents	R ₁	R ₂
Tolbutamide (ORINASE, others)	H ₃ C—	—C ₄ H ₉
Chlorpropamide (DIABINESE, others)	Cl—	—C ₃ H ₇
Tolazamide (TOLINASE, others)	H ₃ C—	
Acetohexamide (DYMELOR, others)	H ₃ CCO—	
Second-Generation Agents	R ₁	R ₂
Glyburide (Glibenclamide, MICRONASE, DIABETA, others)		
Glipizide (GLUCOTROL, others)		
Glizclazide (DIAMICRON, others; unavailable in the U.S.)	H ₃ C—	
Glimepiride (AMARYL)		

ABSORPTION, FATE, AND EXCRETION The sulfonylureas have similar spectra of activities; thus, their pharmacokinetics are their most distinctive characteristics. All are effectively absorbed from the gastrointestinal tract, although food and hyperglycemia can reduce the absorption. In view of the time required for absorption, sulfonylureas with short half-lives may be more effective when given 30 minutes before eating. Sulfonylureas in plasma are largely (90–99%) bound to protein, especially albumin. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg.

The first-generation sulfonylureas vary considerably in their half-lives and extents of metabolism. The $t_{1/2}$ of acetohexamide is short, but it is reduced to an active compound whose $t_{1/2}$ is similar to those of tolbutamide and tolazamide (4–7 hours). These drugs may require divided daily doses. Chlorpropamide has a long $t_{1/2}$ (24–48 hours). The second-generation agents are approximately

100 times more potent than are those in the first generation. Although their half-lives are short (3–5 hours), their hypoglycemic effects persist for 12–24 hours, and they often can be administered once daily. All sulfonylureas are metabolized by the liver, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

ADVERSE REACTIONS Adverse effects of the sulfonylureas occur in about 4% of patients taking first-generation drugs and perhaps slightly less often with the second-generation agents. Not unexpectedly, sulfonylureas may cause hypoglycemic reactions, including coma, particularly in elderly patients with impaired hepatic or renal function who are taking longer-acting sulfonylureas. Sulfonylureas can be ranked in order of decreasing risk of causing hypoglycemia. With first-generation agents, longer-acting sulfonylureas result in a greater risk of hypoglycemia (*i.e.*, chlorpropamide > tolbutamide). Second-generation sulfonylureas have very differing risks of hypoglycemia despite similar half-lives. Thus, glyburide (glibenclamide) reportedly results in hypoglycemia in up to 20–30% of users, whereas glimepiride results in hypoglycemia in only 2–4% of users. A long-acting version of glipizide also results in a lower hypoglycemia frequency than glyburide, apparently because glucose-dependent inhibition of insulin secretion during hypoglycemia occurs with glimepiride but not with glyburide.

Severe hypoglycemia in the elderly can present as an acute neurological emergency that may mimic a cerebrovascular accident. Thus, it is important to check the plasma glucose level of any elderly patient presenting with acute neurological symptoms. Because of the long $t_{1/2}$ of some sulfonylureas, it may be necessary to treat elderly hypoglycemic patients for 24–48 hours with an intravenous glucose infusion.

Many other drugs may potentiate the effects of the sulfonylureas, particularly the first-generation agents, by inhibiting their metabolism or excretion. Some drugs also displace the sulfonylureas from binding proteins, thereby transiently increasing the free concentration. These include other sulfonamides, *clofibrate*, and salicylates. Other drugs, especially ethanol, may enhance the action of sulfonylureas by causing hypoglycemia.

Other side effects of sulfonylureas include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and rashes. About 10–15% of patients who receive these drugs, particularly chlorpropamide, develop an alcohol-induced flush similar to that caused by *disulfiram* (*see* Chapter 23). Sulfonylureas, especially chlorpropamide, may induce hyponatremia by potentiating the effects of vasopressin on the renal collecting duct (*see* Chapter 29), and this effect on water retention has been used to therapeutic advantage in patients with mild forms of central diabetes insipidus.

THERAPEUTIC USES Sulfonylureas are used to control hyperglycemia in type 2 DM patients who cannot achieve appropriate control with diet alone. In all patients, continued dietary restrictions are essential to maximize the efficacy of the sulfonylureas. Contraindications to the use of these drugs include type 1 DM, pregnancy, lactation, and for the first-generation agents, significant hepatic or renal insufficiency.

Between 50% and 80% of properly selected patients will respond initially to oral hypoglycemic agents. Concentrations of glucose often are lowered sufficiently to relieve symptoms of hyperglycemia but may not reach normal levels. About 5–10% of patients per year who respond initially to sulfonylureas become secondary failures, as defined by unacceptable levels of hyperglycemia. This may occur as a result of a change in drug metabolism, progression of β -cell failure, change in dietary compliance, or misdiagnosis of a patient with slow-onset type 1 DM. Additional oral agent(s) can produce a satisfactory response, but most of these patients eventually will require insulin. Treatment with the sulfonylureas must be guided by the patient's response, which must be monitored frequently.

The usual initial daily dose and maximum effective dose are as follows (initial/maximum): tolbutamide 500 mg/3000 mg; tolazamide 100 mg/1000 mg; chlorpropamide 250 mg/750 mg; glyburide 2.5–5 mg/20 mg; glipizide 5 mg/40 mg (divided when the daily dose >15 mg); gliclazide 40–80 mg/320 mg; glimepiride 0.5 mg/8 mg.

Combinations of insulin and sulfonylureas have been used in some patients with type 1 and type 2 DM. In type 1 DM patients, there is no evidence that glucose control is improved by combination therapy, while some type 2 DM patients have shown significant improvements in metabolic control. A prerequisite for a beneficial effect of combination therapy is residual β -cell activity; a short duration of diabetes also may predict a good response.

Repaglinide

Repaglinide (PRANDIN) is an oral insulin secretagogue of the meglitinide class.

Like sulfonylureas, repaglinide stimulates insulin release by closing ATP-dependent K^+ channels in pancreatic β cells. The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 hour with a $t_{1/2}$ of ~ 1 hour. These features permit multiple preprandial use as compared with the classical once- or twice-daily dosing of sulfonylureas. Repaglinide is metabolized primarily by the liver to inactive derivatives and should be used cautiously in patients with hepatic insufficiency. Caution is also indicated in patients with renal insufficiency. The major adverse effect of repaglinide is hypoglycemia.

Nateglinide

Nateglinide (STARLIX) is derivative of D-phenylalanine that stimulates insulin secretion by blocking ATP-sensitive K^+ channels in pancreatic β cells. Nateglinide promotes a more rapid but less sustained secretion of insulin than do other available oral antidiabetic agents. The drug's major therapeutic effect is reducing postprandial glycemic elevations in type 2 DM patients. Nateglinide is FDA-approved for use in type 2 DM and is most effective if administered in a dose of 120 mg, 1–10 minutes before a meal. Nateglinide is metabolized primarily by the liver and should be used cautiously in patients with hepatic insufficiency. Dosage adjustment is unnecessary in renal failure. Nateglinide may produce fewer episodes of hypoglycemia than most other oral insulin secretagogues, including repaglinide.

Metformin

Metformin is antihyperglycemic, not hypoglycemic. It does not stimulate insulin release from the pancreas and generally does not cause hypoglycemia, even in large doses. Metformin reduces glucose levels primarily by decreasing hepatic glucose production and by increasing insulin action in muscle and fat. These actions are mediated at least partly by activation of AMP-activated protein kinase (AMP kinase). The mechanism by which metformin reduces hepatic glucose production is controversial, but most data support an effect on reducing gluconeogenesis.

ABSORPTION, EXCRETION, AND DOSING

Metformin is absorbed mainly from the small intestine. The drug is stable, does not bind to plasma proteins, and is excreted unchanged in the urine. It has a $t_{1/2}$ of ~ 2 hours. The maximum recommended daily dose of metformin is 2.5 g divided into three doses with meals.

PRECAUTIONS AND ADVERSE EFFECTS Patients with renal impairment should not receive metformin. Other contraindications include hepatic disease, a history of lactic acidosis, cardiac failure requiring drug therapy, or chronic hypoxic lung disease. These conditions all predispose to the potentially fatal complication of lactic acidosis. Metformin should be discontinued temporarily prior to the administration of intravenous *contrast media* and prior to any surgical procedure. The drug should not be readministered any sooner than 48 hours after such procedures and should be withheld until renal function is determined to be normal.

Acute side effects of metformin occur in up to 20% of patients and include diarrhea, abdominal discomfort, nausea, metallic taste, and anorexia. These usually can be minimized by increasing

the dosage of the drug slowly and taking it with meals. Intestinal absorption of vitamin B₁₂ and folate may be decreased during chronic metformin therapy.

Consideration should be given to stopping treatment with metformin if the plasma lactate level exceeds 3 mM or in the setting of decreased renal or hepatic function. It also is prudent to stop metformin if a patient is undergoing a prolonged fast or is treated with a very low calorie diet. Myocardial infarction or septicemia mandates immediate drug discontinuation.

Metformin lowers Hb A_{1c} values by about 2%, an effect comparable with that of the sulfonylureas. Metformin does not promote weight gain and can reduce plasma triglycerides by 15–20%. Metformin is the only drug that has been demonstrated to reduce macrovascular events in type 2 DM. Metformin can be administered in combination with sulfonylureas, thiazolidinediones, and/or insulin. Fixed-dose combinations containing metformin and glyburide (GLUCOVANCE, others), glipizide (METAGLIP), rosiglitazone (AVANDAMET), and pioglitazone (ACTOPLUSMET) are available.

Thiazolidinediones

The thiazolidinediones, rosiglitazone and pioglitazone, can lower Hb A_{1c} levels by 1–1.5% in patients with type 2 DM. These drugs can be combined with insulin or other classes of oral glucose-lowering agents.

ROSIGLITAZONE

PIOGLITAZONE

MECHANISM OF ACTION Thiazolidinediones are agonists for the peroxisome proliferator-activated receptor γ (PPAR γ). PPAR γ activates insulin-responsive genes that regulate carbohydrate and lipid metabolism. Thiazolidinediones principally act by increasing insulin sensitivity in peripheral tissues—and thus are effective only when insulin is present—but also may lower hepatic glucose production. Thiazolidinediones increase glucose transport into muscle and adipose tissue by enhancing the synthesis and translocation of specific forms of the glucose transporters. The thiazolidinediones also activate genes that regulate fatty acid metabolism in peripheral tissue. Some peripheral actions may be secondary to the stimulation of adiponectin release by adipocytes. Adiponectin increases insulin sensitivity, reportedly by elevating AMP kinase, which stimulates glucose transport into muscle and increases fatty acid oxidation.

ABSORPTION, EXCRETION, AND DOSING Rosiglitazone (AVANDIA) and pioglitazone (ACTOS) are taken once a day. Both agents are absorbed within about 2 hours; maximum clinical effect requires 6–12 weeks. The thiazolidinediones are metabolized by the liver and should not be used if there is active hepatic disease or significant elevations of hepatic transaminases.

Rosiglitazone is metabolized by hepatic CYP2C8, whereas pioglitazone is metabolized by CYP3A4 and CYP2C8. Other drugs that induce or inhibit these enzymes can cause drug interactions. Clinically significant interactions between the available thiazolidinediones and other drugs have not been described.

PRECAUTIONS AND ADVERSE EFFECTS Pioglitazone and rosiglitazone rarely have been associated with hepatotoxicity, and liver function should be monitored in patients receiving these drugs. Hepatotoxicity can occur several months after drug initiation. Any patient who has suffered any hepatotoxicity (even abnormal liver function tests) while on a thiazolidinedione should not receive any drugs in this class. Thiazolidinediones also reportedly cause anemia, weight gain, edema, and plasma volume expansion. Edema is more likely when these drugs are combined with

insulin; they should not be used in patients with New York Heart Association class 3 or 4 heart failure. Fluid retention and even overt heart failure can occur, usually within 6 months of initiating thiazolidinedione therapy. In most cases, the subjects had no past history of heart failure, but all had underlying abnormal cardiac function. Obese hypertensive individuals and those with cardiac diastolic dysfunction are at greatest risk for fluid retention with thiazolidinediones. Thiazolidinediones also can induce peripheral edema independent of heart failure. Exacerbations of fluid retention and/or heart failure should be treated, and the thiazolidinedione should be discontinued. A recent meta-analysis of results from clinical trials also raised the possibility that rosiglitazone is associated with an increased risk of adverse cardiovascular events, including myocardial infarction.

α -Glucosidase Inhibitors

α -Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α -glucosidase in the intestinal brush border. Consequent to this delayed carbohydrate absorption, the postprandial rise in plasma glucose is blunted in both normal and diabetic subjects.

α -Glucosidase inhibitors may be used as monotherapy in elderly patients or in patients with predominantly postprandial hyperglycemia. α -Glucosidase inhibitors typically are used in combination with other oral antidiabetic agents and/or insulin. The drugs should be administered at the start of a meal.

Acarbose (PRECOSE), an oligosaccharide, and *miglitol* (GLYSET), a desoxyxojirimycin derivative, also competitively inhibit glucoamylase and sucrase but have weak effects on pancreatic α -amylase. They reduce postprandial plasma glucose levels in type 1 and type 2 DM subjects. α -Glucosidase inhibitors can significantly improve Hb A_{1c} levels in severely hyperglycemic type 2 DM patients. However, in patients with mild-to-moderate hyperglycemia, the glucose-lowering potential of α -glucosidase inhibitors is about 30–50% of that of other oral antidiabetic agents.

α -Glucosidase inhibitors do not result in hypoglycemia but do cause dose-related malabsorption, flatulence, diarrhea, and abdominal bloating. Titrating the drug dose over weeks to months reduces GI side effects. Smaller doses are given with snacks. Acarbose is most effective when given with a starchy, high-fiber diet with restricted amounts of glucose and sucrose. If hypoglycemia occurs when α -glucosidase inhibitors are used with insulin or an insulin secretagogue, glucose rather than sucrose, starch, or maltose should be administered.

Reduction in the Incidence of Type 2 DM

Type 2 DM is a worldwide health problem and the number of individuals who have impaired glucose tolerance (often termed *prediabetes*) may equal or even exceed the number of people with diabetes. In the U.S., nearly 20 million individuals are diagnosed with diabetes; perhaps twice that number have *impaired glucose tolerance* (IGT), defined as a fasting plasma glucose concentration of 100–126 mg/dL (5.6–7 mM) or 2-hour value in the oral glucose tolerance test of 140–199 mg/dL (7.8–11 mM). The rate of progression of IGT to overt diabetes ranges from 9 to 15%. Particularly troubling is the rapid increase in the incidence of type 2 DM in children, which has increased by tenfold over the last generation. Several clinical trials have investigated the effects of lifestyle modification and/or drugs on reducing the incidence of type 2 DM; lifestyle modification (*e.g.*, exercise and weight loss), metformin, troglitazone (a thiazolidinedione that is no longer available), acarbose, and *Orlistat* (a GI lipase inhibitor used for weight loss) all have shown some protection in various high-risk populations.

Glucagon-like Peptide 1

Oral, as compared with intravenous, delivery of glucose produces a greater release of insulin. Two hormones—*glucose-dependent insulinotropic polypeptide* (GIP) and *glucagon-like peptide-1* (GLP-1)—are released from the upper and lower bowel and augment glucose-dependent insulin secretion. These hormones are termed *incretins*. GLP-1 significantly augments glucose-dependent insulin secretion and consequently has become an attractive target for therapeutic development in type 2 DM. GLP-1 also reduces glucagon secretion, slows gastric emptying, and decreases appetite. Thus, the compound reduces postprandial glucose excursions (*i.e.*, increase in insulin, reduction of glucagon, slowing of gastric emptying) and also induces weight loss. Offsetting these advantages, circulating GLP-1 is rapidly (1–2 minutes) inactivated by the dipeptidyl peptidase IV enzyme (DPP-IV). Thus, GLP-1 must be infused continuously to have therapeutic benefits.

Two synthetic GLP-1 analogs have entered clinical trials. Exendin-4, derived from the salivary gland of the Gila monster, has 53% homology with human GLP-1. Exendin-4 is resistant to DPP-IV

and has full agonist activity at GLP-1 receptors. Exenidin-4 (exenatide, *BYETTA*) is effective in lowering Hb A_{1c} (~1–1.3%) and also promotes weight loss in type 2 DM. The compound is administered subcutaneously twice-daily; studies are planned to test longer-acting formulations. The FDA has approved exenatide for twice-daily injection in combination therapy with other agents in subjects with type 2 DM. Side effects include a self-limiting nausea in 15–30% of patients; hypoglycemia can occur when GLP-1 agonists are used in conjunction with oral insulin secretagogues. A second long-acting analog of GLP-1, NN2211, contains a hexadeconyl fatty acid covalently linked to GLP-1. NN2211 resists the action of DPP-IV but also must be injected. Studies suggest that NN2211 is effective in lowering Hb A_{1c} but may not induce as much weight loss as exenidin-4. Nausea and hypoglycemia also occur with NN2211 when used with oral hypoglycemic agents.

An alternative approach to GLP-1 therapy is to inactivate the DPP-IV protease, thereby increasing endogenous GLP-1 levels. A number of orally effective DPP-IV inhibitors are in clinical trials, and sitagliptin (*JANLVIA*) is now available for therapy of type 2 DM in the U.S. One study in type 2 DM reported similar reductions in Hb A_{1c} as compared with the GLP-1 receptor analogs. These agents are well tolerated and appear to result in less nausea than the GLP-1 analogs. However, since DPP-IV can metabolize a wide range of peptides, there is some concern about their long-term safety. Furthermore, the potency of the DPP-IV inhibitors may be limited by endogenous production of GLP-1. In contrast, pharmacological amounts of injectable GLP-1 analogs can be given with possibly increased therapeutic effect.

Amylin

Amylin is a 37-amino-acid peptide that is produced in pancreatic β cells and cosecreted with insulin. It is structurally related to calcitonin, calcitonin gene-related peptide, and adrenomedullin, and interacts with GPCRs to inhibit glucagon secretion, delay gastric emptying, and suppress appetite. Pramlintide is a modified amylin peptide in which Pro residues are substituted at positions 25, 28, and 29, thereby decreasing the tendency to self-aggregate into amyloid-like plaques. Pramlintide (*SYMLIN*) is FDA-approved for the treatment of patients with type 1 and type 2 DM who are inadequately controlled with insulin therapy.

Several clinical trials have shown beneficial effects of pramlintide on HbA_{1c} levels without concomitant weight gain. For patients with type 1 DM, the starting dose is 15 μ g subcutaneously before major meals, and the dose can be titrated to a maximum of 60 μ g/injection. For patients with type 2 DM, the starting dose is 60 μ g before major meals, with a maximum dose of 120 μ g/injection. Adverse effects include nausea and vomiting, anorexia, and headache. In conjunction with insulin, pramlintide can cause hypoglycemia within 3 hours of the pramlintide injection, particularly in patients with type 1 DM. To minimize the likelihood of this serious adverse effect, the patient should be instructed about the signs and symptoms of hypoglycemia and the prandial dose of short-acting or rapid-acting insulin should be decreased by 50% when pramlintide therapy is initiated, with upward titration thereafter as needed.

GLUCAGON

CHEMISTRY

Glucagon is a single-chain polypeptide of 29 amino acids. It has significant homology with several other polypeptide hormones, including secretin, vasoactive intestinal peptide (VIP), and GIP. Glucagon is synthesized from proglucagon, a 180-amino-acid precursor. An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and glucagon-like peptide-2. Processing of the protein occurs in a tissue-specific fashion; this results in different secretory peptides in pancreatic α cells and intestinal α -like cells (L cells).

In the pancreatic α cell, the granule consists of a central core of glucagon surrounded by a halo of glicentin. Intestinal L cells contain only glicentin and presumably lack the enzyme required to process this precursor to glucagon. Enteroglucagon binds to hepatic glucagon receptors and stimulates adenylyl cyclase with 10–20% of the potency of glucagon. GLP-1 is an extremely potent potentiator of insulin secretion (see above), although it apparently lacks significant hepatic actions.

REGULATION OF SECRETION

Glucagon secretion is regulated by dietary glucose, insulin, amino acids, and fatty acids. The effect of glucose is lost in untreated or undertreated type 1 DM patients and in isolated pancreatic α cells, indicating that at least part of the effect is secondary to stimulation of insulin secretion. Somatostatin also inhibits glucagon secretion, as do free fatty acids and ketones.

Most amino acids stimulate the release of both glucagon and insulin. This coordinated response to amino acids may prevent insulin-induced hypoglycemia in individuals who ingest

a meal of pure protein. Secretion of glucagon also is regulated by the autonomic innervation of the islets. Stimulation of sympathetic nerves or administration of sympathomimetic amines increases glucagon secretion.

GLUCAGON IN DIABETES MELLITUS

Plasma glucagon concentrations are elevated in poorly controlled diabetic patients. Because it enhances gluconeogenesis and glycogenolysis, glucagon exacerbates the hyperglycemia of diabetes. However, this abnormality of glucagon secretion appears to be secondary to the diabetic state and is corrected with improved control of the disease. Although somatostatin-mediated inhibition of glucagon secretion does not restore glucose metabolism to normal, it significantly slows the rate of development of hyperglycemia and ketonemia in insulin-deficient subjects with type 1 DM. In normal individuals, glucagon secretion increases in response to hypoglycemia, but this important defense mechanism against insulin-induced hypoglycemia is lost in type 1 DM.

DEGRADATION

Glucagon is degraded in liver, kidney, plasma, and other sites. Its $t_{1/2}$ in plasma is approximately 3–6 minutes. Proteolytic removal of the amino-terminal histidine residue leads to loss of biological activity.

CELLULAR AND PHYSIOLOGICAL ACTIONS

Glucagon interacts with a GPCR that signals through the G_s -cyclic AMP-PKA pathway to activate phosphorylase and inactivate glycogen synthase, enhancing glycogenolysis and inhibiting glycogen synthesis. In the liver, cyclic AMP also stimulates phosphorylation of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFK2/FBP2), which determines the cellular concentration of fructose-2,6-bisphosphate, a regulator of gluconeogenesis and glycogenolysis. When [glucagon] is high relative to insulin (i.e., when glucose is scarce), PFK2/FBP2 is phosphorylated and acts as a phosphatase, reducing hepatic [fructose-2,6-bisphosphate], which reduces the rate of phosphofructokinase-1 (PFK-1, which is rate limiting in glycolysis), and thence the rate of glycolysis. Under these conditions, glucagon inhibits glycolysis, stimulates gluconeogenesis, and stimulates fatty acid oxidation and ketone body production. Conversely, when insulin predominates (the “fed” state, when glucose is abundant), PFK2/FBP2 is dephosphorylated, favoring its PFK2 activity and raising the level of fructose-2,6-bisphosphate, which stimulates PFK-1 and hepatic glycolysis.

Glucagon also affects tissues other than liver, especially at higher concentrations. It increases lipolysis in adipocytes and the force of cardiac contraction. Glucagon has relaxant effects on the GI tract.

THERAPEUTIC USE

Glucagon extracted from bovine and porcine pancreas has a sequence identical to that of the human hormone. For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. The first two routes are preferred. The hyperglycemic action of glucagon is transient and may be inadequate if glycogen hepatic stores are depleted. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects.

Glucagon also is used to facilitate radiographic examination of the upper and lower GI tract in various procedures. The hormone also has been used as a cardiac inotropic agent for the treatment of shock, particularly when prior administration of a β adrenergic receptor antagonist has rendered β adrenergic receptor agonists ineffective.

SOMATOSTATIN (SST)

In the gut, SST influences the functions of adjacent cells—a paracrine effect—and also acts in an autocrine manner to inhibit its own pancreatic release. The δ cell is the last islet cell to receive blood flow; thus, SST likely regulates insulin and glucagon secretion by β and α cells only via the systemic circulation.

SST is released in response to many of the nutrients and hormones that stimulate insulin secretion, including glucose, arginine, leucine, glucagon, VIP, and cholecystokinin. SST in pharmacological doses inhibits virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder. SST also inhibits nutrient absorption from the intestine, decreases intestinal motility, and reduces splanchnic blood flow.

The major therapeutic use of SST is to block hormone release in endocrine-secreting tumors. Available SST analogs and their clinical uses are described in Chapter 55. Since the analog octreotide also can decrease blood flow to the GI tract, it has been used to treat bleeding esophageal varices, peptic ulcers, and postprandial orthostatic hypotension.

DIAZOXIDE

Diazoxide is an antihypertensive benzothiadiazine with potent hyperglycemic actions when given orally. Diazoxide interacts with the ATP-sensitive K^+ channel on the β -cell membrane and either prevents its closing or prolongs the open time to inhibit insulin secretion; this effect is opposite to that of the sulfonylureas. Diazoxide (PROGLYCEM) is used to treat patients with various forms of hypoglycemia. The usual oral dose is 3–8 mg/kg/day in adults and 8–15 mg/kg/day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide has a $t_{1/2}$ of ~48 hours. Thus, the patient should be maintained at any dosage for several days before evaluating the therapeutic result.

Adverse effects, including Na^+ retention, edema, hyperuricemia, hypertrichosis (especially in children), thrombocytopenia, and leucopenia, sometimes limit its use, but the drug may be quite useful in patients with inoperable insulinomas and in children with hyperinsulinism due to nesidioblastosis.

AGENTS AFFECTING MINERAL ION HOMEOSTASIS AND BONE TURNOVER

PHYSIOLOGY OF MINERAL HOMEOSTASIS AND BONE METABOLISM

Calcium

Adult men and women possess about 1300 g and 1000 g of calcium respectively, more than 99% of which is in bone and teeth. Although the absolute amount of calcium in the extracellular fluid is small, this fraction is stringently regulated. Normal serum calcium ranges from 8.5 to 10.4 mg/dL (4.25–5.2 mEq/L, 2.1–2.6 mM) and includes three components: *ionized* (~50%), *protein-bound* (~40%, predominantly to albumin; a decrease in albumin of 1.0 g/dL from the normal value of 4.0 g/dL typically decreases total serum calcium by ~0.8 mg/dL), and *complexed to anions* such as phosphate and citrate (~10%) (Figure 61–1).

It is the ionized Ca^{2+} (~1.2 mM) that exerts biological effects (*see* Figure 33–2) and this fraction is tightly regulated. Hormones regulate plasma Ca^{2+} by controlling Ca^{2+} entry from the intestine and Ca^{2+} excretion by the kidney. When needed, these same hormones regulate Ca^{2+} withdrawal from the large skeletal reservoir.

CALCIUM STORES Skeletal calcium largely is in a crystalline form that resembles the mineral hydroxyapatite with other ions in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation (*see* below).

CALCIUM ABSORPTION AND EXCRETION In the U.S., ~75% of dietary calcium is obtained from milk and dairy products. The recommended adequate daily intake value for calcium is 1300 mg in adolescents, 1000 mg in adults, and 1250–1500 mg in postmenopausal women; typical intake is only ~50% of these values.

Figure 61–2 illustrates the components of calcium turnover. Calcium enters the body only through the intestine (~300 mg/day), both by facilitated diffusion throughout the small intestine and by active transport in the proximal duodenum. The former accounts for the majority of total calcium uptake, whereas active transport is the process that is regulated by vitamin D. The efficiency of intestinal calcium absorption is inversely related to total calcium intake. Certain drugs such as *glucocorticoids* or *phenytoin* depress intestinal calcium transport. Opposed to uptake is an obligatory calcium loss of 150 mg/d due to mucosal and biliary secretions and sloughing of intestinal cells; diseases associated with chronic diarrhea or malabsorption promote fecal calcium loss.

Calcium excretion in the kidney also is highly regulated. About 9 g of Ca^{2+} is filtered in the glomeruli, of which >98% is reabsorbed in the tubules. The efficiency of tubular reabsorption is tightly regulated by parathyroid hormone (PTH) but also is influenced by filtered Na^+ , the presence of non–reabsorbed anions, and diuretics.

Phosphate

Phosphate is present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone. More than 80% of total body phosphate is found in bone and ~15% in soft tissues. Phosphorus (P) in the body exists in both organic and inorganic forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus exists as inorganic phosphate (P_i) in the form of NaH_2PO_4 and Na_2HPO_4 . The aggregate level of P_i modifies tissue concentrations of Ca^{2+} and plays a major role in renal acid excretion. Within bone, phosphate is complexed with calcium as hydroxyapatite and calcium phosphate.

ABSORPTION, DISTRIBUTION, AND EXCRETION Phosphate is a component of many foods; thus, dietary insufficiency rarely causes phosphate depletion. Intestinal uptake of phosphate primarily is passive, although an active component is stimulated by several factors, including vitamin D. In adults, about two-thirds of ingested phosphate is absorbed, almost all of which is excreted into the urine. In children, phosphate balance is positive and the plasma concentration of phosphate is higher than in adults.

Phosphate excretion by the kidney also is highly regulated. More than 90% of plasma phosphate is filtered at the glomeruli, >80% of which is reabsorbed in the tubules. Renal phosphate reabsorption is regulated by a variety of factors, including PTH and dietary phosphate. Vitamin D has minimal effects on renal phosphate excretion.

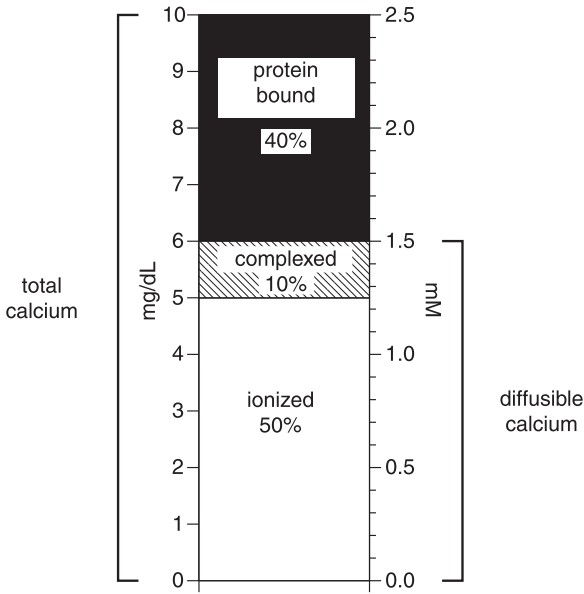

FIGURE 61-1 Pools of calcium in serum. Concentrations are expressed as mg/dL on the left-hand axis and as mM on the right. The total serum calcium concentration is 10 mg/dL or 2.5 mM, divided into three pools: protein-bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusible forms of calcium.

FIGURE 61-2 Schematic representation of the whole body daily turnover of calcium.

PHYSIOLOGY OF CALCIUM AND PHOSPHATE REGULATION

A number of hormones interact to regulate the Ca^{2+} and phosphate concentrations. The most important are PTH and 1,25-dihydroxyvitamin D ($1,25\text{-(OH)}_2\text{D}$; calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 61–3).

Parathyroid Hormone

PTH is a polypeptide hormone that regulates plasma Ca^{2+} by affecting bone formation/resorption, renal Ca^{2+} excretion/reabsorption, and calcitriol synthesis (thereby indirectly regulating GI calcium absorption).

CHEMISTRY

Human PTH consists of a single polypeptide chain of 84 amino acids (molecular weight ~9500). Biological activity is associated with the N-terminal portion and residues 1-27 are required for optimal binding and activation of the PTH receptor. PTH (1-84) has a $t_{1/2}$ in plasma of 2–5 minutes and is predominantly (~90%) cleared by the liver and kidney.

PHYSIOLOGICAL FUNCTIONS The primary function of PTH is to maintain a constant concentration of Ca^{2+} in the extracellular fluid. The principal processes regulated are renal Ca^{2+} reabsorption and mobilization of bone Ca^{2+} (Figure 61–3). The actions of PTH on tissues are mediated by at least two GPCRs that couple to G_s and G_q in cell-specific manners.

FIGURE 61–3 Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. PTH has stimulatory effects on bone and kidney, including the stimulation of 1α -hydroxylase activity in kidney mitochondria leading to the increased production of the biologically active hormone 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxyvitamin D (see Figure 61–5). Solid lines indicate a positive effect; dashed lines refer to negative feedback.

Regulation of Secretion Plasma Ca^{2+} is the major regulator of PTH secretion; hypocalcemia stimulates and hypercalcemia inhibits PTH secretion. Sustained hypocalcemia also induces parathyroid hypertrophy and hyperplasia. Changes in Ca^{2+} modulate PTH secretion by parathyroid cells via the calcium-sensing receptor (CaSR), a GPCR that couples with G_q -PLC and G_i . Occupancy of the CaSR by Ca^{2+} inhibits PTH secretion; thus, the extracellular concentration of Ca^{2+} is controlled by an endocrine negative-feedback system, the afferent limb of which senses the ambient activity of Ca^{2+} and the efferent limb of which releases PTH that then acts to increase Ca^{2+} . The active vitamin D metabolite calcitriol directly suppresses PTH gene expression.

Effects on Bone PTH increases bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid. The apparent cellular target for PTH is the osteoblast. PTH also recruits osteoclast precursors to form new bone remodeling units (*see below*).

Effects on Kidney In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of 25-OHD to calcitriol (Figure 61–3, *see below*). As a result, filtered Ca^{2+} is avidly retained and its plasma concentration increases, whereas phosphate is excreted and its plasma concentration falls. Newly synthesized calcitriol interacts with specific high-affinity vitamin D receptors (VDRs) in the intestine to increase the efficiency of calcium absorption, thereby also increasing the plasma Ca^{2+} concentration.

PTH increases tubular reabsorption of Ca^{2+} , primarily in the distal nephron, with concomitant decreases in urinary Ca^{2+} excretion. Many of these effects are mediated by G_q -induced increases in intracellular cyclic AMP, and subsequent stimulation of the epithelial Ca^{2+} channel TRPV5. As the plasma Ca^{2+} concentration increases, the filtered load of Ca^{2+} also increases; the tubular capacity to reabsorb Ca^{2+} is exceeded and hypercalciuria results. Conversely, reduction of serum PTH depresses tubular reabsorption of Ca^{2+} and thereby increases urinary Ca^{2+} excretion. When the plasma Ca^{2+} concentration falls below 7 mg/dL, the filtered load of Ca^{2+} declines to the point that Ca^{2+} is almost completely reabsorbed despite reduced tubular capacity.

PTH increases renal excretion of P_i by decreasing its reabsorption, an effect mediated by retrieval of the $\text{Na-}P_i$ cotransporter from the luminal membrane rather than a decrease in the number of cotransporters. Fibroblast growth factor 23 also plays important roles in regulating phosphate reabsorption.

*The final step in the activation of vitamin D to calcitriol occurs in the kidney proximal tubular cells. The key enzyme in this process, 1 α -hydroxylase, is a mitochondrial CYP that is regulated by PTH, P_i and Ca^{2+} (*see below*).*

INTEGRATED REGULATION OF EXTRACELLULAR Ca^{2+} CONCENTRATION BY PTH Even modest reductions of serum Ca^{2+} stimulate PTH secretion. Acutely, the regulation of tubular Ca^{2+} reabsorption by PTH suffices to maintain plasma Ca^{2+} homeostasis. With more prolonged hypocalcemia, renal 1 α -hydroxylase is stimulated; this enhances the synthesis and release of calcitriol, which directly stimulates intestinal calcium absorption (Figure 61–3). Finally, PTH and the resulting increase in calcitriol also stimulate Ca^{2+} release from bone.

When plasma Ca^{2+} rises, PTH secretion is suppressed and tubular Ca^{2+} reabsorption decreases. The reduced PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate reduce calcitriol production and thereby decrease intestinal Ca^{2+} absorption. Finally, bone remodeling is suppressed. These physiological events provide an integrated response to positive or negative excursions of plasma Ca^{2+} concentration.

Vitamin D

Vitamin D traditionally was viewed as a permissive factor in calcium metabolism, facilitating efficient absorption of dietary calcium and allowing full expression of PTH action. Vitamin D is a hormone, rather than a vitamin, and plays an active role in calcium homeostasis.

CHEMISTRY AND OCCURRENCE

Ultraviolet irradiation of several animal and plant sterols converts them to compounds possessing vitamin D activity. In animals, the principal precursor sterol is 7-dehydrocholesterol, which is synthesized in the skin; exposure to ultraviolet light in sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3 ; Figure 61–4). Ergosterol, which is present only in plants, is the precursor to vitamin D_2 (ergocalciferol) and its derivatives. Derivatives of vitamin D_2 and vitamin D_3 are both biologically active—although some data suggest that the D_3 hormones may be more potent in certain settings—and are widely available in a variety of commercial vitamin preparations.

FIGURE 61-4 Photobiology and metabolic pathways of vitamin D production and metabolism. Numbering for select positions discussed in the text is shown.

HUMAN REQUIREMENTS AND UNITS The recommended daily dose of vitamin D is 400 IU, or 10 μg . Vitamin D intake in many individuals (*e.g.*, premature infants, the elderly, and African Americans) may be inadequate; contributory factors include decreased intake of dairy products, decreased sun exposure and increased use of sunscreen, and increased prevalence and duration of exclusive breast-feeding.

ABSORPTION, FATE, AND EXCRETION Both vitamins D₂ and D₃ are absorbed from the small intestine and transported as chylomicrons in the lymphatics. Bile salts are essential for adequate absorption. The primary route of vitamin D excretion also is the bile. Severe shortening or inflammation of the small bowel or hepatic or biliary dysfunction may cause overt vitamin D deficiency.

In the blood, vitamin D circulates bound to vitamin D-binding protein. Its plasma $t_{1/2}$ is ~24 hours, but it is stored in fat for prolonged periods.

METABOLIC ACTIVATION Whether endogenously synthesized or acquired from diet, vitamin D requires modification to become biologically active. The primary active metabolite of vitamin D is calcitriol, which is formed by two successive hydroxylations (Figure 61–4).

The initial 25-hydroxylation occurs in the liver to form 25-OH-cholecalciferol or 25-OH-ergocalciferol (collectively termed 25-OHD). 25-OHD has a circulating $t_{1/2}$ of 19 days, and normal levels are 30–80 ng/mL. Because of its prolonged $t_{1/2}$ and precursor role in the production of calcitriol, measurement of serum 25-OHD is the preferred test to evaluate sufficiency of body stores of vitamin D.

After production in the liver, 25-OHD enters the circulation, largely bound by vitamin D-binding protein. Final activation occurs predominantly in the kidney, where 1α -hydroxylase in the proximal tubule converts 25-OHD to calcitriol. This process is highly regulated (Figure 61–5). Calcitriol and 25-OHD also can be hydroxylated by another renal enzyme, 24-hydroxylase, to make compounds that have considerably lower biological activity and presumably are destined for excretion.

PHYSIOLOGICAL FUNCTIONS AND MECHANISM OF ACTION Calcitriol augments absorption and retention of Ca^{2+} and phosphate. The action of calcitriol is mediated by interaction with the VDR, a member of the nuclear receptor family. After binding to calcitriol, the VDR translocates to the nucleus and regulates the transcription of its target genes, likely as a heterodimer with the retinoid X receptor. Calcitriol also exerts nongenomic effects whose physiological relevance is unclear.

In the absence of calcitriol, calcium absorption throughout the small intestine is inefficient and involves passive diffusion via the paracellular pathway. Calcitriol in the proximal duodenum

FIGURE 61–5 Regulation of 1α -hydroxylase activity. Changes in the plasma levels of PTH, Ca^{2+} , and phosphate modulate the hydroxylation of 25-OH vitamin D to the active form, 1,25-dihydroxyvitamin D.

ABBREVIATIONS: 25-OHD, 25-hydroxycholecalciferol; 1,25-(OH)₂D, calcitriol; PTH, parathyroid hormone.

stimulates the TRPV6 Ca^{2+} channels and also induces the synthesis of calbindin D_{9K} , calbindin D_{28K} and the serosal membrane Ca^{2+} -ATPase. The net effect of these actions is to stimulate active calcium uptake.

Calcitriol's effects on bone are predominantly mediated by its actions to stimulate intestinal calcium uptake, although large doses can directly stimulate bone resorption. Similarly, there are direct effects of calcitriol to stimulate Ca^{2+} reabsorption in the distal tubule. The physiological impact of these effects is unknown.

The VDR is distributed widely throughout the body, and calcitriol actions extend well beyond calcium homeostasis. For example, calcitriol and synthetic analogs have been evaluated as antiproliferative agents for therapy of skin diseases (e.g., psoriasis) and cancer.

Calcitonin

Calcitonin is produced by the C cells of the thyroid gland; its actions generally oppose those of PTH. Calcitonin is a single-chain polypeptide hormone of 32 amino acids with an intrachain disulfide bridge. Salmon calcitonin, which differs from the human sequence at approximately half of the residues, is used therapeutically because it is more potent and is cleared more slowly from the circulation.

REGULATION OF SECRETION Calcitonin secretion increases with hypercalcemia and decreases when plasma Ca^{2+} is low; the hormone in circulation has a $t_{1/2}$ of 10 minutes. Circulating concentrations are normally low (<15 pg/mL in males and 10 pg/mL in females) but can be markedly elevated with C cell hyperplasia or medullary thyroid cancer.

MECHANISM OF ACTION Calcitonin actions are mediated by the calcitonin receptor, a GPCR that couples through multiple G proteins to diverse signal transduction pathways. The hypocalcemic and hypophosphatemic effects of calcitonin result primarily from direct inhibition of osteoclast bone resorption.

BONE PHYSIOLOGY

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular component.

A process called modeling drives the growth and development of endochondral bone. Once new bone is laid down, it is subject to a continuous process of breakdown and renewal, called remodeling, by which bone mass is adjusted throughout adult life. This remodeling is carried out by multiple independent bone remodeling units throughout the skeleton (Figure 61–6). In response to physical

FIGURE 61–6 The bone remodeling cycle. Osteoclast precursors fuse and are activated to resorb a lacuna in a previously quiescent surface. These cells are replaced by osteoblasts that deposit new bone to restore the integrity of the tissue.

or biochemical signals, mononuclear precursors are recruited to the bone surface, where they fuse to form the characteristic multinucleated osteoclasts that excavate a cavity into the bone called the resorption lacuna.

Osteoclast production is regulated by osteoblast-derived cytokines. One particularly important factor is RANK ligand (previously called osteoclast differentiation factor), which induces osteoclast formation by activating its RANK receptor. Osteoblasts also produce osteoprotegerin, a decoy ligand that inhibits osteoclast differentiation by blocking the RANK receptor. Estrogen induces osteoprotegerin, which may be one mechanism by which estrogens inhibit osteoclast function and bone resorption in postmenopausal women.

The resorption phase is followed by ingress of preosteoblasts into the base of the resorption cavity. These cells become osteoblasts and elaborate new bone matrix constituents that help form the osteoid. Once the osteoid reaches a thickness of ~15–20 μm , mineralization begins. A complete remodeling cycle normally requires about 3–6 months.

The remodeling process is imperfect and small bone deficits persist on completion of each cycle. Lifelong accumulation of these remodeling deficits underlies the age-related bone loss that begins shortly after growth ceases. Alterations in remodeling activity represent the final pathway through which diverse stimuli—such as dietary insufficiency, hormones, and drugs—affect bone balance.

DISORDERS OF MINERAL HOMEOSTASIS AND BONE

Abnormal Calcium Metabolism

HYPERCALCEMIA The degree and rapidity of onset of hypercalcemia largely dictate the extent of symptoms. Chronic elevation of serum Ca^{2+} to 12–14 mg/dL (3–3.5 mM) generally causes few manifestations, whereas an acute rise to the same level may cause marked neuromuscular manifestations by increasing the threshold for nerve and muscle excitation. Symptoms include fatigue, weakness, anorexia, depression, diffuse abdominal pain, and constipation.

The most common cause of hypercalcemia in outpatients is primary hyperparathyroidism, due either to a single adenoma or diffuse hyperplasia. Primary hyperparathyroidism is often associated with significant hypophosphatemia due to PTH effects on renal phosphate reabsorption. The diagnosis is generally apparent from the elevated serum Ca^{2+} associated with an inappropriately high PTH level. In contrast, secondary hyperparathyroidism is a disorder in which PTH levels are elevated in response to persistent threats to normal calcium homeostasis such as hyperphosphatemia from chronic renal disease.

Hypercalcemia in hospitalized patients is caused most often by a malignancy, either with or without bone metastases. The degree of hypercalcemia here often exceeds considerably that seen with primary hyperparathyroidism (often >13 mg/dL) and lethargy, weakness, and volume depletion may be profound. PTH-related peptide, which is produced by squamous cell and other tumors, can interact with the PTH receptor to cause humoral hypercalcemia. An assay for PTH-related peptide is often diagnostic in these patients, while the PTH level is suppressed due to feedback by the elevated serum Ca^{2+} .

Pharmacologic overdoses of vitamin D may cause hypercalcemia if sufficient 25-OHD is present to stimulate intestinal calcium absorption. Measurement of the serum 25-OHD level is diagnostic. More often, granulomatous disorders such as sarcoidosis are associated with increased production of $1,25(\text{OH})_2\text{D}$ due to expression of 1α -hydroxylase.

HYPOCALCEMIA Mild hypocalcemia (*i.e.*, serum Ca^{2+} in the range of 8–8.5 mg/dL) is usually asymptomatic. Again, the rapidity of onset affects the clinical manifestations. The signs and symptoms of hypocalcemia include tetany, paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic seizures. Nail and tooth changes and calcification of the basal ganglia are encountered with chronic hypocalcemia due to hypoparathyroidism.

Combined deprivation of Ca^{2+} and vitamin D, as observed in malabsorption states, readily promotes hypocalcemia. Serum phosphate also will be low. Hypoparathyroidism is most often a consequence of thyroid or neck surgery, but also may be due to genetic or autoimmune disorders. Pseudohypoparathyroidism, a rare group of genetic disorders associated with decreased PTH action, results from mutations in the gene encoding the α subunit of G_s , which mediates PTH action in the renal tubules. These patients can also exhibit impaired action of multiple other hormones that couple to G_s , but the impaired response to PTH is most severe.

Disturbed Phosphate Metabolism

Dietary inadequacy rarely causes phosphate depletion. Sustained use of aluminum-containing antacids can severely limit phosphate absorption and cause clinically significant phosphate depletion. If severe, hypophosphatemia can cause malaise, muscle weakness, and a bone disorder termed *osteomalacia* that is characterized by undermineralized bone osteoid.

Hyperphosphatemia occurs commonly in chronic renal failure. The increased phosphate level directly stimulates PTH secretion and also has secondary effects due to the reduction in serum Ca^{2+} . Because renal function is impaired, the increased PTH is unable to increase phosphate excretion sufficiently to avoid ongoing phosphate retention. The chronic secondary hyperparathyroidism may result in a bone disease called renal osteodystrophy.

Disorders of Vitamin D

HYPERVITAMINOSIS D The acute or chronic administration of excessive amounts of vitamin D can cause hypervitaminosis D and hypercalcemia. The amount of vitamin D necessary to induce this condition varies widely. As an approximation, prolonged daily ingestion of 50,000 U or more can cause poisoning. The signs and symptoms are those associated with hypercalcemia.

VITAMIN D DEFICIENCY Vitamin D deficiency is associated with inadequate absorption of calcium and phosphate. The resulting decrease in Ca^{2+} stimulates PTH secretion, which acts to restore plasma Ca^{2+} at the expense of bone. Plasma phosphate concentration will remain low due to the phosphaturic effect of PTH. In children, the failure to mineralize newly formed bone results in rickets, a growth disorder in which the long bones may be bowed due to inadequate calcification.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Severe osteomalacia may be associated with extreme bone pain and tenderness and proximal muscle weakness. A low serum level of 25-OHD is diagnostic.

Conditions associated with abnormalities in calcitriol synthesis or response can cause rickets in children and osteomalacia in adults. Specific disorders include X-linked hypophosphatemic rickets due to mutations in the PHEX endoprotease, Vitamin D-dependent rickets due to mutations in 1α -hydroxylase, and hereditary $1,25\text{-(OH)}_2\text{D}$ resistance due to mutations in the VDR.

SPECIFIC DISORDERS OF BONE

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also occur. Fracture risk increases exponentially with age, related both to decreased bone density and to factors such as decreased muscle strength and increased risk of falls.

Osteoporosis can be categorized as primary (idiopathic) or secondary to a systemic illness or medication such as glucocorticoids or phenytoin. A major factor in the former category is the decline in estrogen levels, and the resulting sharp decrease in bone mass that accompanies menopause in women.

PAGET'S DISEASE

Paget's disease affects up to 3% of the population over age 60. It is characterized by single or multiple foci of disordered bone remodeling. The primary pathologic abnormality is increased bone resorption followed by exuberant formation of disorganized bone of poor quality. The altered bone structure can lead to bowing and stress fractures and also is associated with secondary problems such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but potentially lethal complication.

Renal Osteodystrophy

Bone disease is a frequent consequence of chronic renal failure and dialysis. Pathologically, the lesions are typical of hyperparathyroidism, adynamic bone disease, deficiency of vitamin D (osteomalacia), or a combination of the above. The underlying defect reflects increased phosphate and decreased calcium, leading to secondary events that strive to preserve circulating levels of Ca^{2+} at the expense of bone.

PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

HYPERCALCEMIA Hypercalcemia can be life-threatening. Because hypercalcemia compromises renal concentrating mechanisms, such patients frequently are severely volume depleted. Thus, fluid resuscitation with large volumes of isotonic saline is essential. Loop diuretics that augment renal Ca^{2+} excretion may help to counteract the effect of plasma volume expansion with saline but should not be used until volume is replete.

Calcitonin (CALCIMAR, MIACALCIN) can rapidly reduce Ca^{2+} , but the response is generally transient and the magnitude of response is less than with other agents. The recommended starting dose is 4 U/kg administered subcutaneously every 12 hours; if there is no response within 1 or 2 days, the dose may be increased to 8 U/kg every 12 hours, or then to a maximum of 8 U/kg every 6 hours.

Intravenous bisphosphonates (*pamidronate*, *zoledronate*) have proven very helpful in the management of hypercalcemia (*see below* for further discussion of bisphosphonates). Typically, a 60–90-mg dose of pamidronate (AREDIA) is given by intravenous infusion over 4 hours. Alternatively, zoledronate (ZOMETA) can be given in a dose of 4 mg over 15 minutes. Resolution of the hypercalcemia generally occurs within several days and persists for several weeks.

Once the hypercalcemic crisis has resolved, or in patients with milder calcium elevations, long-term therapy can be initiated. Parathyroidectomy remains the definitive therapy for primary hyperparathyroidism. As described below, a Ca^{2+} mimetic that stimulates the CaSR is a promising therapy for hyperparathyroidism. If the hypercalcemia results from malignancy, therapy ideally is directed at the underlying cancer. When this is not possible, intermittent dosing of parenteral bisphosphonates has been used to keep serum Ca^{2+} within an acceptable range.

HYPOCALCEMIA AND OTHER THERAPEUTIC USES OF CALCIUM

Hypoparathyroidism is treated primarily with vitamin D and calcium supplementation. In severe hypocalcemia, symptoms are best treated intravenously. Calcium chloride, calcium gluceptate, and calcium gluconate all can be administered intravenously; the latter two are preferred because they are less irritating. The gluceptate salt also can be administered intramuscularly when the intravenous route is unavailable.

For milder hypocalcemic symptoms, oral calcium suffices, frequently in combination with vitamin D or one of its active metabolites. A number of calcium salts are available. Calcium carbonate is prescribed most frequently, whereas calcium citrate may be absorbed most efficiently. Cost and palatability often outweigh modest differences in efficacy.

THERAPEUTIC USES OF VITAMIN D

SPECIFIC FORMS OF VITAMIN D Calcitriol (1,25-dihydroxycholecalciferol; CALCIEX, ROCALTROL) is available for oral and parenteral use. A number of derivatives are also used therapeutically (Figure 61–7). Doxercalciferol (1α -hydroxyvitamin D_2 , HECTORAL), a prodrug that must be activated by hepatic 25-hydroxylation, is approved for treating secondary hyperparathyroidism. Dihydrotachysterol (DHT, ROXANE) is a reduced form of vitamin D_3 that is converted in the liver to its active form, 25-hydroxydihydrotachysterol. It is active at high doses in mobilizing bone Ca^{2+} and therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. 1α -hydroxycholecalciferol (1-OHD₃, alphacalcidol; ONE-ALPHA) is a synthetic vitamin D_3 analog that is already hydroxylated in the 1α position and is rapidly converted by 25-hydroxylase to 1,25-(OH)₂ D_3 . Because it does not require renal activation, it has been used to treat renal osteodystrophy. Ergocalciferol (CALCIFEROL, DRISDOL) is vitamin D_2 ; it is available for oral, intramuscular, or intravenous administration. It is indicated for the prevention and treatment of vitamin D deficiency and for the treatment of hypoparathyroidism and the genetic disorders of vitamin D synthesis or action described above.

Calcitriol Analogs Several vitamin D analogs suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity (Figure 61–7). They therefore have advantages in treating secondary hyperparathyroidism. Calcipotriol (calcipotriene) is a synthetic derivative of calcitriol with a modified side chain that is used topically for psoriasis (*see Chapter 62*). Paricalcitol (1,25-dihydrox-19-norvitamin D_2 , ZEMPLAR) is a synthetic D_2 derivative that is FDA-approved for intravenous treatment of secondary hyperparathyroidism in patients with chronic renal failure. 22-oxacalcitriol (1,25-dihydroxy-22-oxavitamin D_3 , OCT, maxacalcitol, OXAROL) has a low affinity for vitamin D-binding protein and thus has a shorter $t_{1/2}$. It is used in patients with secondary hyperparathyroidism due to renal failure.

FIGURE 61-7 Vitamin D analogs.

Indications for Therapy with Vitamin D

NUTRITIONAL RICKETS

Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. Its incidence in the U.S. apparently is increasing. Breast-fed infants should receive 400 U of vitamin D daily as a supplement. Since the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may also require supplemental vitamin D. Treatment of fully developed rickets requires a larger dose of vitamin D. Although 1000 U/day probably is sufficient, daily doses of 3000–4000 U/day are frequently used to promote more rapid healing. Vitamin D may be given prophylactically in conditions that impair its absorption (e.g., diarrhea, steatorrhea, and biliary obstruction), sometimes by the parenteral route.

OSTEOMALACIA AND RENAL OSTEODYSTROPHY

Osteomalacia, distinguished by undermineralization of the bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia, but also may develop the complex bone disease called renal osteodystrophy. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization due to decreased renal synthesis of calcitriol. Either a high turnover state reminiscent of primary hyperparathyroidism or a state of adynamic bone may result. The former is treated with dietary phosphate restriction and phosphate binders such as sevelamer (RENAGEL) and lanthanum carbonate (FOSRENOL). Renal osteodystrophy associated with adynamic bone disease may be due to overly aggressive suppression of PTH with calcitriol or other vitamin D analogs. Vitamin D therapy should be discontinued if the 25-OHD and serum calcium levels are elevated.

HYPOPARATHYROIDISM

Vitamin D and its analogs are the mainstay of the therapy of hypoparathyroidism. Dihydro-tachysterol has a faster onset, shorter duration of action than 25-OHD, and traditionally has been the preferred agent. Calcitriol also is effective and often is used acutely while awaiting effects of slower-acting forms of vitamin D.

CALCITONIN

Measurement of serum calcitonin is used diagnostically to detect medullary thyroid cancer, especially in the setting of multiple endocrine neoplasia, type 2. Therapeutically, it is used in the acute management of hypercalcemia. It also is approved for Paget's disease, generally by subcutaneous injection because of limited bioavailability of the intranasal form, and for the therapy of osteoporosis. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week. Side effects include allergic reactions, nausea, hand swelling, urticaria, and rarely intestinal cramping.

BISPHOSPHONATES

Bisphosphonates are pyrophosphate analogs (Figure 61–8); they contain 2 phosphonate groups attached to a germinal (central) carbon that replaces the oxygen in pyrophosphate. They have a strong affinity for bone, especially areas undergoing remodeling. They are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget's disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia.

FIGURE 61–8 Structures of pyrophosphate and bisphosphonates. The substituents (R_1 and R_2) on the central carbon of the bisphosphonate parent structure are shown in blue.

Based on their side chains, the bisphosphonates are grouped into first-, second-, and third-generation drugs. First-generation drugs (e.g., medronate, clodronate, and etidronate) contain minimally modified side-chains or a chlorophenyl group (e.g., tiludronate) and are the least potent agents. Second-generation aminobisphosphonates (e.g., pamidronate, alendronate, and ibandronate) contain an *N*-atom in the side chain and are 10–100 times more potent than the first-generation drugs. Third-generation drugs (e.g., risedronate and zoledronate) contain an *N*-atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation drugs.

Bisphosphonates concentrate at sites of active remodeling and are incorporated into the bone matrix. When the bone is remodeled, they are released in the acid environment of the resorption lacunae and induce apoptosis in the osteoclasts.

Available Bisphosphonates

Several bisphosphonates are available in the U.S. (Figure 61–8). Etidronate (DIDRONEL) is used for the treatment of Paget's disease but largely has been supplanted by pamidronate and zoledronate for hypercalcemia. Pamidronate (AREDIA) is approved in the U.S. for parenteral treatment of hypercalcemia (60–90 mg infused over 4 hours), and also is used for Paget's disease.

Several bisphosphonates are approved for the treatment of Paget's disease, including tiludronate (SKELID), alendronate (FOSAMAX), and risedronate (ACTONEL), typically at higher doses than those employed in osteoporosis. Zoledronate (ZOMETA) also appears to be quite effective as a single infusion of 4 mg.

ABSORPTION, FATE, AND EXCRETION

All oral bisphosphonates have very limited bioavailability. They should be administered with a full glass of water following an overnight fast and at least 30 minutes before breakfast. They are excreted primarily by the kidneys and are not recommended for patients with a creatinine clearance of less than 30 mL/min.

ADVERSE EFFECTS

Although oral bisphosphonates are generally well tolerated, some patients will experience symptoms of esophagitis. Symptoms often abate with fastidious adherence to recommendations for taking these drugs. If symptoms persist, a proton pump inhibitor at bedtime may be helpful. The oral drugs may be better tolerated when taken once weekly or monthly, with no reduction in efficacy. Patients with active upper GI disease should not be given oral bisphosphonates. Mild fever and aches may accompany the first infusion of pamidronate. These symptoms are short-lived and generally do not recur. Zoledronate has been associated with deterioration of renal function. Thus, zoledronate should be given over at least 15 minutes at a maximum dose of 4 mg, and renal function should be assessed periodically.

Therapeutic Uses

HYPERCALCEMIA Pamidronate is used parenterally in the management of malignancy-associated hypercalcemia. Zoledronate is also FDA-approved for this indication and appears to be more effective than pamidronate, at least as safe, and can be infused over 15 minutes rather than 4 hours.

POSTMENOPAUSAL OSTEOPOROSIS The use of bisphosphonates in the prevention and therapy of osteoporosis is described below.

CANCER Second- and third-generation bisphosphonates also may act as anticancer drugs by inhibiting the activation of cancer-associated proteins, such as Ras, through suppression of geranylgeranylation and farnesylation.

PARATHYROID HORMONE

Continuous administration of PTH or high circulating PTH levels achieved in primary hyperthyroidism causes bone demineralization and osteopenia. Paradoxically, intermittent PTH administration promotes bone growth. The FDA has approved human recombinant PTH (1-34) for treating severe osteoporosis, and full-length PTH is also undergoing clinical trials.

ABSORPTION, FATE, AND EXCRETION

Pharmacokinetics and systemic actions of PTH (1-34) (teriparatide, FORTEO) are identical to those for endogenous PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 µg into the thigh or abdomen. With this regimen, serum PTH levels peak at 30 minutes after the

injection and decline to undetectable levels within 3 hours. Teriparatide is eliminated by non-specific enzymatic mechanisms in the liver and kidney.

CLINICAL EFFECTS

In postmenopausal women with osteoporosis, teriparatide increases bone mineral density and reduces the risk of vertebral and nonvertebral fractures. The precise role of this agent relative to other agents used for osteoporosis, alone or in combination, remains to be determined. Candidates for teriparatide therapy at this time are women with a history of an osteoporotic fracture who have multiple risk factors for fracture and who are intolerant or have failed other therapies. The drug is also approved to increase bone mass in men with idiopathic or hypogonadal osteoporosis who are at high risk for fracture.

ADVERSE EFFECTS

In rats, teriparatide increased the incidence of bone tumors, including osteogenic sarcoma. The clinical relevance of this is unclear, especially since higher PTH levels in patients with primary hyperparathyroidism are not associated with an increased tumor risk. Nevertheless, teriparatide use should be limited to 24 months, and the drug should not be used in patients at increased risk for osteosarcoma (e.g., those with Paget's disease, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton).

CALCIUM SENSOR MIMETICS: CINACALCET

Calcimimetics mimic the action of calcium via the CaSR to inhibit PTH secretion by the parathyroid glands. Because of this enhanced sensitivity, they decrease PTH secretion for any given level of Ca^{2+} . The calcimimetic cinacalcet (SENSIPAR) is FDA-approved for the treatment of secondary hyperparathyroidism due to chronic renal disease and for patients with hypercalcemia associated with parathyroid carcinoma (Figure 61–9). In clinical trials, cinacalcet also effectively reduced PTH levels in patients with primary hyperparathyroidism and normalized serum calcium without altering bone mineral density for up to 2 years.

Cinacalcet given orally achieves peak serum levels at 2–6 hours, with maximum biological action (suppression of PTH) at 2–4 hours after administration. After absorption, the drug is eliminated, primarily by the kidney, with a $t_{1/2}$ of 30–40 hours. The drug is also metabolized by multiple hepatic CYPs.

The recommended starting dose of cinacalcet for secondary hyperparathyroidism is 30 mg once daily, with a maximum of 180 mg/day. For the treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum dose of 90 mg four times daily. The dose is titrated upward every 2–4 weeks to maintain the serum PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize the serum calcium (parathyroid carcinoma). Cinacalcet likely will interact with other drugs that are metabolized by hepatic CYPs.

The principal adverse effect of cinacalcet is hypocalcemia. The drug should not be used if the initial serum calcium is <8.4 mg/dL; serum calcium and phosphate concentrations should be measured within one week and PTH should be measured within 4 weeks of therapy initiation. Adynamic bone disease may develop in patients with secondary hyperparathyroidism, so the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

INTEGRATED APPROACH TO OSTEOPOROSIS PREVENTION AND TREATMENT

Osteoporosis is a growing problem in developed nations, causing fractures in 30–50% of older women and 15–30% of older men. Drugs used to manage osteoporosis act by decreasing the rate of bone resorption, thereby slowing the rate of bone loss (antiresorptive therapy), or by promoting bone formation (anabolic therapy). Since bone remodeling is a coupled process, antiresorptive

FIGURE 61–9 Structure of cinacalcet. Cinacalcet exists as optical isomers. The more active *R*-enantiomer is shown.

drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in bone mineral density. Pharmacotherapy of osteoporosis is aimed at restoring bone strength and preventing fractures. The linchpin of this approach has long been antiresorptive drugs such as the bisphosphonates, estrogen, or more recently, the selective estrogen receptor modulator (SERM) raloxifene. These drugs inhibit osteoclast-mediated bone loss, thereby reducing bone turnover. The increases in bone density that they produce are variable and depend on the site and the specific drug (Figure 61–10).

Therapeutic options for osteoporosis were expanded in 2002 when the FDA approved teriparatide for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with osteoporosis. Pharmacotherapy likely will evolve as newer treatment strategies are developed and combinations of antiresorptive and anabolic agents are introduced.

ANTIRESORPTIVE AGENTS

Bisphosphonates Bisphosphonates have emerged as the most effective drugs for treatment and prevention of osteoporosis. Second- and third-generation oral agents (*e.g.*, alendronate, risedronate, ibandronate) have sufficient potency to suppress bone resorption at doses that generally do not inhibit mineralization. They generally are well tolerated (especially when given weekly or monthly). For patients in whom the oral drugs cause severe esophageal distress despite countermeasures, ibandronate (BONIVA, 3 mg every 3 months) can be given intravenously for skeletal protection. A formulation of alendronate in combination with vitamin D (FOSAMAX PLUS D) is approved for treatment of osteoporosis.

Calcium The utility of supplemental calcium to protect bone has been the subject of considerable debate. While the impact of supplementation in adolescents, young adults, or early postmenopausal women is argued, some studies do suggest that supplemental calcium in the elderly, typically in combination with vitamin D, suppresses bone turnover, improves bone mineral density, and decreases the incidence of fractures. Typical dosing has been in the range of 1000 mg/day in adolescents and young adults and 1500 mg/day in the elderly. Calcium supplements are most often taken with meals to improve absorption.

Vitamin D and Its Analogs The role for oral supplementation with vitamin D also has been controversial; at least one prospective trial found that neither vitamin D nor calcium had a major impact on prevention of osteoporotic fractures in women. Nonetheless, supplemental vitamin D may be of value in patients whose intake appears inadequate based on dietary assessment.

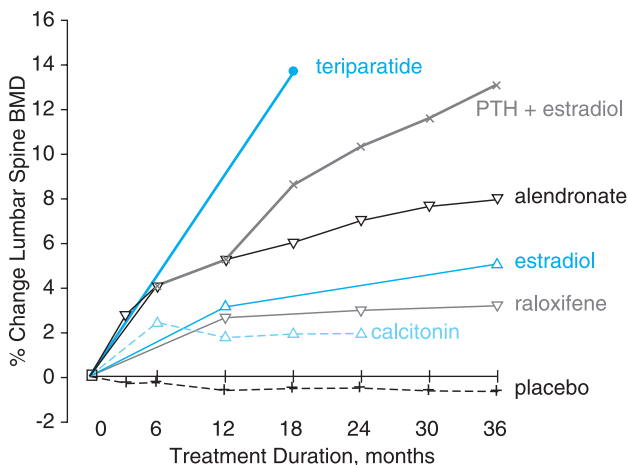

FIGURE 61–10 Relative efficacy of different therapeutic interventions on bone mineral density of the lumbar spine. Teriparatide (40 μ g), PTH (25 μ g) + estradiol, alendronate (10 mg), estradiol (0.625 mg/day), raloxifene (120 mg), calcitonin (200 IU). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

Estrogen Postmenopausal status or estrogen deficiency at any age significantly increases the risk for osteoporosis. Likewise, overwhelming evidence supports the positive impact of postmenopausal estrogen replacement on bone conservation and protection against osteoporotic fractures. The apparently increased risk of adverse cardiovascular events in prospective studies has led to the recommendation that hormone replacement therapy should not be first-line therapy for prevention or treatment of osteoporosis.

Selective Estrogen Receptor Modulators Raloxifene (EVISTA) acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an estrogen antagonist on the breast. In postmenopausal women, raloxifene modestly increases bone mineral density and has been shown to reduce the risk of vertebral compression fractures; in this setting, it is approved for both the prevention and treatment of osteoporosis. The major adverse effect is worsened vasomotor symptoms; the drug also increases the incidence of deep venous thrombosis.

Calcitonin Calcitonin modestly increases bone mass in patients with osteoporosis, particularly those with high bone turnover and is approved for the treatment of established osteoporosis in postmenopausal women.

Combination Therapies

Simultaneous use of PTH and bisphosphonates may inhibit the increase in bone mineral density typically caused by the anabolic agent. A rational strategy is to use anabolic agents (*e.g.*, teriparatide) to increase bone formation, followed by antiresorptive therapy with agents such as bisphosphonates to maintain bone density. The efficacy of such combination therapy in preventing fractures remains to be established in clinical trials.

Paget's Disease

Indications for pharmacotherapy in Paget's disease include severe pain, nerve compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and high fracture risk (i.e., involvement of weight-bearing bones). Bisphosphonates and calcitonin decrease the high rate of bone turnover, often with a salutary decrease in symptoms and alkaline phosphatase level. Either oral or intravenous administration can be used; in patients in whom oral administration is ineffective or poorly tolerated, pamidronate or zoledronate infusions every few months are often effective, with repeat dosing guided by symptoms and alkaline phosphatase levels. Calcitonin generally is viewed as second-line therapy.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

DERMATOLOGICAL PHARMACOLOGY

THE STRUCTURE AND FUNCTION OF SKIN

A unique aspect of dermatological pharmacology is the direct accessibility of the skin as a target organ for diagnosis and treatment (Figure 62–1). The skin acts as a two-way barrier to prevent absorption or loss of water and electrolytes. The barrier resides in the outermost layer of the epidermis, the stratum corneum, as evidenced by approximately equal rates of penetration of chemicals through isolated stratum corneum or whole skin. Having lost their nuclei and cytoplasmic organelles, the corneocytes of the stratum corneum are nonviable. The cells are flattened, and the fibrous keratins are aligned into disulfide cross-linked macrofibers in association with filaggrin, the major protein component of the keratohyalin granule. Each cell develops a cornified envelope resulting from cross-linking of involucrin and keratohyalin, forming an insoluble exoskeleton that acts as a rigid scaffold for the internal keratin filaments. The intercellular spaces are filled with hydrophobic lamellar lipids derived from membrane-coating granules. The combination of hydrophilic cornified cells in hydrophobic intercellular material provides a barrier to both hydrophilic and hydrophobic substances. In dermatological diseases, the thickened epidermis may further diminish the penetration of pharmacological agents into the dermis.

DRUG DELIVERY IN DERMATOLOGICAL DISEASES

Topical Preparations

Appropriate use of topical agents requires an appreciation of the factors that influence percutaneous absorption (*see* Chapter 1). Molecules can penetrate the skin by three routes: through intact stratum corneum, through sweat ducts, or through the sebaceous follicle. The surface of the stratum corneum presents more than 99% of the total skin surface available for percutaneous drug absorption. Passage through this outermost layer is the rate-limiting step for percutaneous absorption. The major steps involved in percutaneous absorption include the establishment of a concentration gradient, which provides the driving force for drug movement across the skin; release of drug from the vehicle (partition coefficient); and drug diffusion across the layers of the skin (diffusion coefficient). Preferable characteristics of topical drugs include low molecular mass (600 Da), adequate solubility in oil and water, and a high partition coefficient. Except for very small particles, water-soluble ions and polar molecules do not penetrate intact stratum corneum.

Metabolism

The viable epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment, including CYPs, epoxide hydrolase, transferases such as *N*-acetyl-transferases, and diverse enzymes including glucuronyl transferases and sulfatases. Transporter proteins that influence influx (OATP) or efflux (MDR and LRD) of certain xenobiotics are present in human keratinocytes. While substrate turnover is considerably less than that for hepatic CYPs, these enzymes influence concentrations of xenobiotics in the skin.

General Guidelines for Topical Therapy

ALTERED BARRIER FUNCTION In many dermatological diseases, such as psoriasis, the stratum corneum is abnormal, and barrier function is compromised. In these settings, percutaneous absorption may be increased to the point that standard drug doses can result in systemic toxicity (*e.g.*, hypothalamic–pituitary–adrenal axis suppression can result from systemic absorption of potent topical glucocorticoids).

HYDRATION Drug absorption is increased with *hydration*. Methods of hydration include occlusion with an impermeable film, application of lipophilic occlusive vehicles such as ointments, and soaking dry skin before occlusion.

FIGURE 62-1 Skin as a pharmacological target. The skin is a multicellular organ containing numerous indigenous cells and structures as well as circulating cells that are potential targets for pharmacological intervention (black arrows). UVB, ultraviolet radiation (290–320 nm); PUVA, psoralen activated by UVA radiation (320–400 nm).

VEHICLE Most topical medications are incorporated into bases or vehicles that are applied directly to the skin. The chosen vehicle can influence drug absorption and provide therapeutic efficacy; for example, an ointment is more occlusive and has superior emollient properties than a cream or a lotion base.

Newer vehicles include liposomes and microgel formulations. Liposomes are concentric spherical shells of phospholipids in an aqueous medium that may enhance percutaneous absorption. Variations in size, charge, and lipid content can influence liposome function substantially. Liposomes penetrate compromised epidermal barriers more efficiently. Microgels are polymers that may enhance solubilization of certain drugs, thereby enhancing penetration and diminishing irritancy.

Transfersomes are a drug-delivery technology based on highly deformable, ultraflexible lipid vesicles that penetrate the skin when applied nonocclusively. Finally, pressure waves generated by intense laser radiation can permeabilize the stratum corneum and may provide a novel system for transdermal drug delivery.

Age

Children have a greater ratio of surface area to mass than adults, so a given amount of topical drug results in a greater systemic dose. Based on transepidermal water loss and percutaneous absorption studies, term infants seem to possess a stratum corneum with barrier properties comparable with adults.

Application Frequency

For certain drugs, once-daily application of a larger dose may be as effective as more frequent applications of smaller doses. The stratum corneum may act as a drug reservoir that allows gradual penetration into the viable skin layers over a prolonged period. Intermittent pulse therapy—treatment for several days or weeks alternating with treatment-free periods—may prevent development of tachyphylaxis associated with drugs such as topical glucocorticoids.

Intralesional Administration

Intralesional drug administration is used mainly for inflammatory lesions but also can be used for treatment of warts and selected neoplasms. Medications injected intralesionally have the advantages of direct contact with the underlying pathologic process, no first-pass metabolism, and the formation of a slowly absorbed depot of drug. In considering the use of intralesional medications, it is important to be cognizant of the possibility of systemic absorption of the medication.

GLUCOCORTICOIDS

Glucocorticoids are prescribed frequently for their immunosuppressive and anti-inflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes.

Mechanisms of glucocorticoid action are numerous, as discussed in Chapter 59. These include apoptosis of lymphocytes, inhibitory effects on the arachidonic acid cascade, depression of production of many cytokines, and myriad effects on inflammatory cells.

Topical glucocorticoids (*see* Chapter 59, Table 59–4) can be grouped based on potency and many of the more potent drugs have a fluorinated hydrocortisone backbone.

THERAPEUTIC USES Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Twice-daily application is sufficient, and more frequent application does not improve response. In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

Intralesional preparations of glucocorticoids include insoluble preparations of *triamcinolone acetonide* (KENALOG-10, others) and *triamcinolone hexacetonide* (KENOLOG-40 and ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

TOXICITY AND MONITORING Chronic use of potent topical glucocorticoids (*e.g.*, diflurasone diacetate 0.05%, betamethasone dipropionate 0.05%) can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used in this site.

Systemic Glucocorticoids

THERAPEUTIC USES Systemic glucocorticoid therapy is used for severe dermatological illnesses. In general, it is best to reserve this method for allergic contact dermatitis to plants (*e.g.*, poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (*see* Chapter 59).

Daily morning dosing with *prednisone* generally is preferred, although divided doses are used occasionally to enhance efficacy. Fewer side effects are seen with alternate-day dosing, and if required for chronic therapy, prednisone is tapered to every other day as soon as it is practical. Pulse therapy using large intravenous doses of *methylprednisolone sodium succinate* (SOLU-MEDROL) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis. The dose usually is 0.5–1 g given over 2–3 hours. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

TOXICITY AND MONITORING Most side effects are dose-dependent. Long-term use is associated with a number of complications, including psychiatric problems, cataracts, myopathy, osteoporosis, avascular bone necrosis, glucose intolerance or overt diabetes mellitus, and hypertension. In addition, psoriatic patients treated with parenteral or topical glucocorticoids may have a pustular flare, particularly if the steroid is tapered rapidly.

RETINOIDS

Retinoids include natural compounds and synthetic derivatives of retinol that exhibit vitamin A activity. First-generation retinoids include *retinol*, *tretinoin* (all-*trans*-retinoic acid), *isotretinoin* (13-*cis*-retinoic acid), and *alitretinoin* (9-*cis*-retinoic acid). Second-generation retinoids, also known as *aromatic retinoids*, were created by alteration of the cyclic end group and include *acitretin*. Third-generation retinoids contain further modifications and are called *arotinoids*. Members of this generation include *tazarotene* and *bexarotene*. *Adapalene*, a derivative of naphthoic acid with retinoid-like properties, does not fit precisely into any of the three generations.

Retinoic acid (RA) exerts its effects on gene expression by activating two families of receptors—*retinoic acid receptors* (RARs) and the *retinoid X receptors* (RXRs)—that are members of the nuclear receptor superfamily. Retinoids (ligands) bind transcription factors (nuclear receptors), and the ligand–receptor complex then binds to the promoter regions of target genes to regulate their expression. The gene products formed contribute to the desirable pharmacological effects of these drugs and their unwanted side effects. Additional complexity arises because each receptor has three isoforms (α , β , and γ) that form homo- and heterodimers. Retinoid-responsive tissues express one or more RAR and RXR subtypes in various combinations that determine activity locally. Human skin contains mainly RAR α and RAR β .

First- and second-generation retinoids can bind to several retinoid receptors because of the flexibility imparted by their alternating single and double bonds. This relative lack of receptor specificity may lead to greater side effects. The structures of third-generation retinoids are much less flexible than those of earlier-generation retinoids and therefore are more selective.

Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, and hair loss. Less frequently, musculoskeletal pain, pseudotumor cerebri, and mood alterations occur. Oral retinoids are potent teratogens and cause severe fetal malformations. Because of this, *systemic retinoids should be used with great caution in females of childbearing potential.*

Retinoids are used in the treatment of diverse diseases and are effective in the treatment of inflammatory skin disorders, skin malignancies, hyperproliferative disorders, photoaging, and many other disorders. Topical retinoids can normalize disordered keratinization in sebaceous follicles and reduce inflammation, and they may enhance the penetration of other topical medications.

Tretinoin

Tretinoin (RETIN-A, others) is used to reduce the hyperkeratinization that leads to microcomedone formation, the initial lesion in acne. Follicular corneocytes become less cohesive as a result of shedding of desmosomes, decreasing tonofilaments, and increasing keratinocyte autolysis and intracellular deposition of glycogen.

In addition to treating acne, tretinoin improves photodamaged human skin. Ultraviolet radiation activates growth factor and cytokine receptors on epidermal keratinocytes and dermal cells. These receptors stimulate MAP kinases, which, in turn, induce c-Jun expression. This transcription factor heterodimerizes with c-Fos to form activated AP-1 complexes that induce the transcription of metalloproteinases that degrade dermal collagens and other proteins. Epidermal effects of tretinoin include increased epidermal and granular layer thickness, decreased melanocytic activity, and increased secretion of a glycosaminoglycan-like substance into the intercellular space. In the dermis, blood vessel vasodilation and angiogenesis and increased papillary dermal collagen synthesis have been documented. Clinically, this translates to modest attenuation of fine and coarse wrinkling, smoother texture, increased pinkness, and diminished hyperpigmentation.

Tretinoin is approved for the treatment of acne vulgaris and as an adjunctive agent for treating photoaging. Topical preparations contain from 0.01% to 0.1% tretinoin in cream, gel, and solution formulations. Initiation of therapy with lower-strength preparations and progression to higher strengths may be useful because individual sensitivity is unpredictable. Tretinoin formulations with a cream base are indicated for dry skin, whereas gel-based formulations are indicated for oily skin. The medication is applied once daily before bedtime to minimize photodegradation. Maximum clinical response in acne may require several months, and maintenance therapy is necessary. A formulation of tretinoin with active drug incorporated into microsponges (RETIN-A MICRO) decreases irritation by slowing the release of the medication and enhances efficacy by targeting delivery to the sebaceous follicle.

A 0.5% emollient cream formulation of tretinoin (RENOVA) is approved for treatment of photoaged skin. Nightly application produces maximum response within 1 year, and application 1–3 times weekly is said to maintain improvement. Treatment must be combined with a rigorous program of photoprotection, including sunscreens, sun avoidance, and photoprotective clothing.

Adapalene

Adapalene (DIFFERIN), a derivative of naphthoic acid, is a synthetic retinoid-like compound that is available in solution, cream, and gel formulations for topical use. In addition to displaying typical retinoid effects, it also has anti-inflammatory properties. Adapalene has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight and tends to be less irritating.

Tazarotene

Tazarotene (TAZORAC) is a third-generation retinoid approved for the treatment of psoriasis and acne vulgaris. This retinoid binds to all three RARs.

Tazarotene gel, applied once daily to dry skin, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. This is the first topical retinoid approved by the FDA for the treatment of psoriasis. Side effects of burning, itching, and skin irritation are relatively common, and patients should avoid sun exposure.

Alitretinoin

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is approved only for treatment of the skin manifestations of Kaposi's sarcoma. Approximately 50% of patients in an open-label trial responded positively to topical application of this drug.

TOXICITY AND MONITORING Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging. These effects often decrease spontaneously with time and are lessened by concomitant use of emollients. Photosensitivity can occur as a result of epidermal thinning, with a resulting greater potential for phototoxic reactions such as sunburn. Although there is little systemic absorption of tretinoin and no alteration in plasma vitamin A levels with its use as a topical agent, most physicians do not prescribe tretinoin during pregnancy and it is category X for pregnant women.

Isotretinoin

Oral isotretinoin (AC CUTANE) is approved for the treatment of severe nodulocystic acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. It normalizes keratinization in the sebaceous follicle, reduces sebocyte number with decreased sebum synthesis, and reduces *Propionibacterium acnes*, the organism that produces inflammation in acne.

THERAPEUTIC USES Isotretinoin is administered orally. The recommended dose is 0.5–2 mg/kg/day for 15–20 weeks. Lower doses are effective but are associated with shorter remissions. The cumulative dose also is important, so smaller doses for longer periods can be used to achieve a total dose in the range of 120 mg/kg. Approximately 40% of patients will relapse, usually within 3 years of therapy, and may require retreatment. Preteens and patients with acne conglobata or androgen excess are at increased risk of relapse. However, mild relapses may respond to conventional management with topical and systemic antiacne agents.

Isotretinoin is prescribed for severe, recalcitrant nodular acne, moderate acne unresponsive to oral antibiotics, and acne that produces scarring. It also is used commonly for other related disorders, such as gram-negative folliculitis, acne rosacea, and hidradenitis suppurativa.

TOXICITY AND MONITORING Dose-dependent adverse effects on the skin and mucous membranes are observed most commonly, including cheilitis, mucous membrane dryness, epistaxis, dry eyes, blepharoconjunctivitis, erythematous eruptions, and xerosis. Alteration of epidermal surfaces may facilitate *Staphylococcus aureus* colonization and, rarely, subsequent infection. Hair loss, exuberant granulation tissue formation, photosensitivity, and decreased night vision are rarer occurrences.

Systemic side effects generally are less significant with short-term therapy. Transitory elevations in serum transaminases occur rarely. Hyperlipidemia is frequent, with 25% of patients developing increased triglyceride levels and, less frequently, increased cholesterol and low-density lipoproteins, and decreased high-density lipoproteins. Myalgias and arthralgias are common complaints. Headaches occur and rarely are a symptom of pseudotumor cerebri. Use of isotretinoin concomitantly with *tetracycline* antibiotics may increase the risk of pseudotumor cerebri.

Some physicians have proposed a causal relationship with mood changes and depression in a limited number of patients. These uncontrolled clinical observations have not been examined in a rigorous, prospective manner. In addition, there is a paucity of data on the effect of retinoids on adult brain function. Long-term therapy may produce skeletal side effects, including diffuse idiopathic skeletal hyperostoses, extraskelatal ossification (particularly at tendinous insertions), and premature epiphyseal closure in children.

Teratogenicity is a major problem; it occurs if the drug is given within the first 3 weeks of gestation and is not dose-related. Teratogenic effects include CNS, cardiac, thymus, and craniofacial abnormalities. Spontaneous abortion occurs in one-third of patients. *Pregnancy is an absolute contraindication to the use of isotretinoin*. Two forms of birth control (one of which must be surgical or hormonal) must be practiced during therapy and for 1 month both before beginning therapy and after completion of therapy; pregnancy tests should be repeated monthly. Patients should not donate blood for transfusion during treatment and for 1 month after treatment.

Other laboratory evaluations should include a complete blood count, liver function tests, and fasting lipid determination before initiating therapy. Testing should be repeated after 1 month of therapy and thereafter only as abnormalities indicate.

Acitretin

Acitretin (SORIATANE) is the major metabolite of *etretinate*, an aromatic retinoid that formerly was approved for psoriasis but withdrawn from the market because of its undesirable pharmacokinetics. Acitretin has an elimination $t_{1/2}$ of 2–3 days.

Acitretin is readily esterified *in vivo* to produce *etretinate*, especially in the presence of *ethanol*. The optimal dosing range for acitretin in adults is 25–50 mg/day, providing efficacy with an acceptable level of side effects. Improvement of plaque psoriasis requires up to 3–6 months for optimal results. As monotherapy, acitretin has an overall rate of complete remission of <50%; response rates are higher when the drug is combined with other modalities. At doses of 10–25 mg/day, both pustular and erythrodermic psoriasis usually respond more rapidly than common plaque psoriasis. Excellent control of these conditions usually can be achieved with acitretin. Common side effects include dry skin and mucous membranes, xerophthalmia, and hair thinning. Less frequently, arthralgias and decreased night vision have been noted. Serious side effects (*e.g.*, hepatotoxicity or pseudotumor cerebri) are rare. *Acitretin is a potent teratogen and should not be used by females who intend to become pregnant during therapy or at any time for at least 3 years following discontinuation of therapy.* The same precautions regarding blood donation described earlier for isotretinoin should be followed. Laboratory monitoring should include a baseline pregnancy test in all female patients and a complete blood count, lipid profile, and hepatic profile in all patients. Serial follow-up of laboratory tests should be conducted every 1–2 weeks until stable and thereafter as clinically indicated.

Bexarotene

Bexarotene (TARGRETIN) is a retinoid that selectively binds RXRs. Bexarotene has been used in patients with cutaneous T-cell lymphoma with a suggested dose of 300 mg/m²/day. Inhibitors of CYP3A4 (*e.g.*, *imidazole antifungals* and *macrolide antibiotics*) will increase and inducers of the CYP3A4 system will decrease plasma levels of bexarotene. Side effects include lipid abnormalities, hypothyroidism secondary to a reversible RXR-mediated suppression of *TSH* gene expression, pancreatitis, leukopenia, and GI symptoms. Blood lipids and thyroid function should be measured before initiating therapy and periodically thereafter.

CANCER CHEMOPREVENTION WITH RETINOIDS Systemic and topical retinoids have been used successfully to treat premalignant skin conditions and may have a role in chemoprevention of skin malignancies. High-dose isotretinoin (2 mg/kg/day) has suppressed skin cancers in patients with increased risk of skin malignancy from congenital disorders such as xeroderma pigmentosa and nevoid basal cell carcinoma syndrome. To achieve an anticancer effect, toxic doses of retinoids generally are required. Acitretin at a dose of 25 mg/day or more appears to reduce the risk of skin cancer by ~25% among patients with psoriasis who are at high risk for squamous cell carcinoma. Isotretinoin also is effective for oral leukoplakia. Topical tazarotene has shown efficacy in some basal cell carcinomas. Cutaneous T-cell lymphoma has been shown to respond to several types of topical and systemic retinoids, including bexarotene. The benefits of long-term retinoid use in malignant lymphomas such as cutaneous T-cell lymphoma are balanced by appreciation of retinoid toxicity and the chronicity of the disease.

PHOTOCHEMOTHERAPY

Electromagnetic radiation is defined by its wavelength and frequency; for convenience, it can be classified into different regions based on its photon energy. For therapeutic purposes, dermatologists are most concerned with the ultraviolet (UV) B (290–320 nm), A-I (320–340 nm), and A-II (340–400 nm) and visible (400–800 nm) spectrum. UVB is the most erythrogenic and melanogenic. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. The longer wavelengths of UVA are a thousand times less erythrogenic than UVB; however, they penetrate more deeply into the skin and contribute substantially to photoaging and photosensitivity diseases. They also enhance UVB-induced erythema and increase the risk of skin carcinogenesis. Visible radiation may augment the severity of some photosensitive eruptions.

Electromagnetic radiation has proven to be highly efficacious in the treatment of numerous dermatologic diseases. Phototherapy and photochemotherapy are treatment methods in which ultraviolet or visible radiation is used to induce a therapeutic response either alone or in the presence of a photosensitizing drug. Phototherapy using UVB or high-dose UVA-I is efficacious in selected dermatological diseases. To be effective, the incident radiation must be absorbed by a target or chromophore in the skin—which in phototherapy is endogenous and in photochemotherapy

must be administered exogenously. Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications before initiation of therapy. Such drugs include phenothiazines, thiazides, sulfonamides, nonsteroidal anti-inflammatory agents, sulfonyleureas, tetracyclines, and benzodiazepines.

PUVA: Psoralens and UVA

Orally administered 8-methoxypsoralen followed by UVA (PUVA) is FDA-approved for the treatment of vitiligo, psoriasis, and cutaneous T-cell lymphoma.

CHEMISTRY

Psoralens belong to the furocoumarin class of compounds. They occur naturally in many plants, including limes, lemons, figs, and parsnips. Two psoralens, 8-methoxypsoralen (methoxsalen) and 4, 5, 8-trimethylpsoralen (trioxsalen, TRISORALEN) are available in the U.S. Methoxsalen is used primarily because of its superior GI absorption.

PHARMACOKINETICS The psoralens are absorbed rapidly after oral administration. Photosensitivity typically is maximal 1–2 hours after ingestion of methoxsalen. There is significant but saturable first-pass elimination in the liver, which may account for variations in plasma levels among individuals after a standard dose. Methoxsalen has a serum $t_{1/2}$ of approximately 1 hour, but the skin remains sensitive to light for 8–12 hours. Despite widespread drug distribution throughout the body, it is photoactivated only in the skin where the UVA penetrates.

MECHANISM OF ACTION The action spectrum for oral PUVA is between 320 and 400 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent formation of mono- and bifunctional adducts in DNA. Type II reactions are oxygen-dependent and involve sensitized transfer of energy to molecular O_2 . The therapeutic effects of PUVA in psoriasis may result from a decrease in DNA-dependent proliferation after adduct formation. Perhaps more important, PUVA can alter cytokine profiles and cause immunocyte apoptosis, thereby interrupting immunopathologic processes.

THERAPEUTIC USES Methoxsalen is supplied in soft gelatin capsules (OXSORALEN-ULTRA) and hard gelatin capsules (8-MOP). The dose is 0.4 mg/kg for the soft capsule and 0.6 mg/kg for the hard capsule taken 1.5–2 hours before UVA exposure. A lotion containing 1% methoxsalen (OXSORALEN) also is available for topical application. It can be diluted for use in bath water to minimize systemic absorption. The risk of phototoxicity is increased with topical PUVA therapy. In studies of PUVA for the treatment of psoriasis, initial clearance rates approaching 90% were achieved. Relapse occurs within 6 months of cessation of treatment in many patients, which has prompted efforts to design maintenance protocols.

PUVA also is used to repigment the leukoderma of vitiligo. Success rates are highest in young individuals with recent onset of disease involving nonacral areas. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed in the treatment of cutaneous T-cell lymphoma, atopic dermatitis, alopecia areata, lichen planus, urticaria pigmentosa, and as a preventive modality in some forms of photosensitivity.

TOXICITY AND MONITORING The major acute side effects of PUVA include nausea, blistering, and painful erythema. PUVA-induced redness and blistering generally peak within 48–72 hours.

Chronic PUVA therapy accelerates photoaging and the development of actinic keratoses, non-melanoma skin cancer, and melanoma. Squamous cell carcinomas occur at 10 times the expected frequency. In patients receiving 250 or more treatments, there is an increased risk of melanoma. Careful monitoring of patients for cutaneous carcinoma therefore is essential.

PHOTOPHERESIS Extracorporeal photopheresis (ECP) has proven effective in the treatment of cutaneous T-cell lymphoma. After oral administration of methoxsalen, leukocytes are separated from whole blood and then exposed to UVA radiation. The irradiated cells then are returned to the patient. Multiple mechanisms probably contribute to the effectiveness of this procedure. ECP simultaneously and efficiently induces apoptosis of disease-causing T cells and conversion of monocytes to functional dendritic cells. By processing and presenting the unique antigenic determinants of pathogenic T-cell clones, the dendritic cells can either initiate a clinically relevant anti-cutaneous T-cell lymphoma cytotoxic response or suppress the activity of autoreactive T-cell clones.

PHOTODYNAMIC THERAPY (PDT) This modality combines the use of photosensitizing drugs and visible light for the treatment of various dermatological disorders, particularly nonmelanoma skin cancer and precancerous actinic keratoses. The concept is predicated on the insight that tumor tissue selectively absorbs greater amounts of porphyrins than surrounding nontumor tissue. The agents most widely employed in photodynamic therapy (PDT) are *porphyrins*, their precursors, or derivatives. The photosensitized chemical reaction is oxygen-dependent. Light delivered to the skin is absorbed by porphyrin molecules. These molecules transfer their energy to oxygen, forming reactive oxygen species that result in injury or destruction of lipid-rich membranes and subsequent tissue damage.

Early studies with PDT employed complex mixtures of poorly defined porphyrins known as hemato-porphyrin derivative (PHOTOFRIN I) or a partially purified mixture known as porfimer sodium (PHOTOFRIN II) that was administered parenterally with subsequent irradiation using polychromatic light sources. The major problem with this approach was the prolonged period (4–6 weeks) of photosensitivity caused by skin retention of the porphyrin formulations. This led to a search for compounds that could be administered topically and that were eliminated more readily from the skin. The porphyrin precursor δ -aminolevulinic acid (ALA) is converted to various porphyrins, particularly protoporphyrin (PROTO), in tissues including the skin (see below). Protoporphyrin subsequently is eliminated rapidly from the body, thereby minimizing the period of skin photosensitivity to a few hours. Topically applied ALA HCl (20% w/v) and, more recently, the methyl ester of ALA have been used successfully for the PDT of various types of nonmelanoma skin cancers and premalignant lesions.

Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Nonhypertrophic actinic keratoses and superficial basal cell carcinomas and Bowen's disease seem to respond best to PDT. Topical ALA products for PDT approved by the FDA include LEVULAN KERASTICK, BLU-U blue light, and METVIX.

ANTIHISTAMINES

Histamine is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch nerves. In addition to histamine, multiple chemical itch mediators can act as pruritogens on C-fibers, including *neuropeptides*, *prostaglandins*, *serotonin*, *acetylcholine*, and *bradykinin*.

Human skin mast cells express H_1 , H_2 , and H_4 receptors but not H_3 receptors. H_1 and H_2 receptors are involved in wheal formation and erythema, whereas only H_1 receptor agonists cause pruritus. Complete blockade of H_1 receptors does not totally relieve itching, and combinations of H_1 and H_2 blockers may be superior to H_1 blockers alone.

Oral *antihistamines*, particularly H_1 -receptor antagonists, have some anticholinergic activity and are sedating (see Chapter 24), making them useful for the control of pruritus. First-generation sedating H_1 receptor antagonists include *hydroxyzine hydrochloride* (ATARAX), which is given in a dose of 0.5 mg/kg every 6 hours; *diphenhydramine* (BENADRYL; others); *promethazine* (PHENERGAN); and *cyproheptadine* (PERIACTIN). *Doxepin* (ADAPIN, SINEQUAN), which has tricyclic antidepressant and sedative antihistamine effects (see Chapter 17), is a good alternative for severe pruritus. A topical formulation of doxepin also is available as a 5% cream (ZONALON), which can be used in conjunction with low-to-moderate potency topical glucocorticoids. The systemic effect from topical doxepin is comparable with that of low-dose oral therapy.

Second-generation H_1 -receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood–brain barrier. They include *cetirizine* (ZYRTEC), *loratadine* (CLARITIN), *desloratadine* (CLARINEX), and *fexofenadine hydrochloride* (ALLEGRA). While second-generation nonsedating H_1 -receptor blockers are as effective as the first-generation H_1 blockers, they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be coadministered with medications that inhibit these enzymes (e.g., imidazole antifungals and macrolide antibiotics).

H_2 -receptor blockers include *cimetidine* (TAGAMET), *ranitidine* (ZANTAC), *famotidine* (PEPCID), and *nizatidine* (AXID). Besides their use in combination with H_1 -receptor blockers for pruritus, the H_2 -receptor blockers have immunomodulating effects, and this property has been exploited in children to treat warts.

ANTIMICROBIAL AGENTS

Antibiotics

These drugs are used commonly to treat superficial cutaneous infections (pyoderma) and noninfectious diseases. Topical agents are very effective for the treatment of superficial bacterial infections

and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and for deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VIII, Chemotherapy of Microbial Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne vulgaris is the most common dermatologic disorder treated with either topical or systemic antibiotics. The anaerobe *P. acnes* is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O₂ tension is low. *P. acnes* generates free fatty acids that are irritants and may lead to microcomedo formation and result in the inflammatory lesions of acne. Suppression of cutaneous *P. acnes* with antibiotic therapy is correlated with clinical improvement.

Resistant strains of *P. acnes* are emerging that may respond to judicious use of retinoids in combination with antibiotics. Commonly used topical antimicrobials in acne include erythromycin, clindamycin (CLEOCIN-T), and benzoyl peroxide and antibiotic-benzoyl peroxide combinations (BENZAMYCIN, BENZACLIN, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON), sulfacetamide/sulfur combinations (SULFACET-R), metronidazole (METROCREAM, METROGEL, NORITATE), and azelaic acid (AZELEX). Systemic therapy is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. Effective agents include tetracycline (SUMYCIN, others), minocycline (MINOCIN, others), erythromycin (ERYC, others), clindamycin (CLEOCIN), and trimethoprim-sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved. Tetracycline is the most commonly employed antibiotic because it is inexpensive, safe, and effective. The initial daily dose is usually 1 g in divided doses. Although tetracycline is an antimicrobial agent, its efficacy in acne may be more dependent on its anti-inflammatory activity.

Minocycline has better GI absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum-sickness-like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

In healthy individuals taking oral antibiotics for acne, laboratory monitoring is not necessary. Orally administered antibiotics also may be indicated in other noninfectious conditions, including acne rosacea, perioral dermatitis, hidradenitis suppurativa, autoimmune blistering diseases, sarcoidosis, and pyoderma gangrenosum.

Cutaneous Infections

Gram-positive organisms, including S. aureus and Streptococcus pyogenes, are the most common cause of pyoderma. Skin infections with gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

Topical therapy frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by S. aureus and S. pyogenes. Pseudomonic acid (MUPIROCIN, BACTROBAN), produced by Pseudomonas fluorescens, is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is highly active against staphylococci and all streptococci except those of group D. It is less active against gram-negative organisms, but it has in vitro activity against Haemophilus influenzae, Neisseria gonorrhoeae, Pasteurella multocida, Moraxella catarrhalis, and Bordetella pertussis. Its antibacterial activity is enhanced by the acid pH of the skin surface. Mupirocin is available as a 2% ointment or cream (BACTODERM, BACTROBAN, BACTROBAN NASAL, EISMYCIN) and is applied three times daily.

Topical therapy often is employed for prophylaxis of superficial infections caused by wounds and injuries. Neomycin is active against staphylococci and most gram-negative bacilli. It may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Bacitracin and polymyxin B are combined in a number of over-the-counter preparations.

*Deeper bacterial infections of the skin include folliculitis, erysipelas, cellulitis, and necrotizing fasciitis. Since streptococcal and staphylococcal species also are the most common causes of deep cutaneous infections, penicillins (especially β -lactamase-resistant β -lactams), and cephalosporins are the systemic antibiotics used most frequently in their treatment (see Chapter 44). A growing concern is the increased incidence of skin and soft tissue infections with hospital- and community-acquired methicillin-resistant *S. aureus* (MRSA) and drug-resistant pneumococci. Infection with community-acquired MRSA often is susceptible to trimethoprim-sulfamethoxazole.*

Antifungal Agents

Fungal infections are among the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. *Griseofulvin*, topical and oral *imidazoles*, *triazoles*, and *allylamines* are the most effective agents available. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 48. Recommendations for cutaneous antifungal therapy are summarized in Table 62–1.

The azoles miconazole (MICATIN, others) and econazole (SPECTRAZOLE, others) and the allylamines naftifine (NAFTIN) and terbinafine (LAMISIL, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor.

Systemic therapy is necessary for the treatment of tinea capitis. Oral griseofulvin (FULVICIN V/F, P/G, others) has been the traditional medication for treatment of tinea capitis. Oral terbinafine is a safe and effective alternative to griseofulvin in treating tinea capitis in children.

TINEA PEDIS Topical therapy with the azoles and allylamines is effective for tinea pedis. Macerated toe web disease may require the addition of antibacterial therapy. *Econazole nitrate*, which has a limited antibacterial spectrum, can be useful in this situation. Systemic therapy with griseofulvin, terbinafine, or *itraconazole* (SPORANOX, others) is used for more extensive tinea pedis. It should be recognized that long-term topical therapy may be necessary in some patients after courses of systemic antifungal therapy.

ONYCHOMYCOSIS Fungal infection of the nails is caused most frequently by dermatophytes and *Candida*. Mixed infections are common. The nail must be cultured or clipped for histological examination before initiating therapy because up to a third of dystrophic nails that appear clinically to be onychomycosis are actually due to psoriasis or other conditions.

Despite the availability of topical treatments, systemic therapy is necessary for effective management of onychomycosis. Treatment of toenails with griseofulvin for 12–18 months produces a cure rate of 50% and a relapse rate of 50% after 1 year. Terbinafine and itraconazole quickly produce high drug levels in the nail, which persist after therapy is discontinued. Additional advantages include a broader spectrum of coverage with itraconazole and few drug interactions with terbinafine. Treatment of toenail onychomycosis requires 3 months with terbinafine (250 mg/day) or itraconazole (pulsed dosing 1 week per month for 3 months). Cure rates of 75% or greater have been achieved with both drugs.

Antiviral Agents

Viral infections of the skin are very common and include verrucae (human papillomavirus [HPV]), herpes simplex (HSV), condyloma acuminatum (HPV), molluscum contagiosum (poxvirus), and chicken pox (varicella-zoster virus [VZV]). *Acyclovir* (ZOVIRAX), *famciclovir* (FAMVIR), and *valacyclovir* (VALTREX) frequently are used systemically to treat herpes simplex and varicella infections

Table 62–1

Recommended Cutaneous Antifungal Therapy

Condition	Topical Therapy	Oral Therapy
Tinea corporis, localized	Azoles, allylamines	—
Tinea corporis, widespread	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Tinea pedis	Azoles, allylamines	Griseofulvin, terbinafine, itraconazole, fluconazole
Onychomycosis	—	Griseofulvin, terbinafine, itraconazole, fluconazole
Candidiasis, localized	Azoles	—
Candidiasis, widespread and mucocutaneous	—	Ketaconazole, itraconazole, fluconazole
Tinea versicolor, localized	Azoles, allylamines	—
Tinea versicolor, widespread	—	Ketaconazole, itraconazole, fluconazole

(see Chapter 49). *Cidofovir* (VISTIDE) may be useful in treating acyclovir-resistant HSV or VZV and other cutaneous viral infections. Topically, acyclovir, *docosanol* (ABREVA), and *penciclovir* (DENAVIR) are available for treating mucocutaneous HSV. *Podophyllin* (25% solution) and *podofilox* (CONDYLOX; 0.5% solution) are used to treat condylomata. The immune response modifier *imiquimod* (ALDARA) is discussed below. Interferons α -2b (INTRONA), α -n1 (not commercially available in the U.S.), and α -n3 (ALFERON N) may be useful for treating refractory or recurrent warts.

Agents Used to Treat Infestations

Infestations with ectoparasites such as body lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

Perhaps the best known antiectoparasitic medication is 1% γ -benzene hexachloride lotion, also known as *lindane*.

Lindane has been used as a commercial insecticide as well as a topical medication. It is highly effective in the treatment of ectoparasites. Neurotoxicity, although a concern with the use of lindane, is a rare side effect when the medication is used correctly. However, the FDA has defined lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing <110 lb. The lotion is applied in a thin layer from the neck down, left in place for 8–12 hours or overnight, and removed by thorough washing at the end of the 8–12-hour period. The treatment may be repeated in 1 week. To avoid problems with neurotoxicity, the lotion should be applied only in a thin coat to dry skin, should not be applied immediately after bathing, and should be kept away from the eyes, mouth, and open cuts or sores. A 1% lindane shampoo also is available for head and body lice.

A second topical agent that is very useful in the treatment of ectoparasites is *permethrin*, a synthetic derivative of the insecticide pyrethrum, which was obtained originally from *Chrysanthemum cinerariifolium*. Neurotoxicity associated with this compound is rare. A 5% cream (ACTICIN, ELIMITE, others) is available for the treatment of scabies. This is used as an 8–12-hour or overnight application. A 1% permethrin cream rinse (NIX) also is available for the treatment of head lice.

Ivermectin (STROMEKTOL), an anthelmintic drug (see Chapter 41) used traditionally to treat onchocerciasis, also is effective in the off-label treatment of scabies.

Because ivermectin does not cross the blood–brain barrier, there is no major CNS toxicity. Ivermectin, available as a 6-mg tablet, is given at a dose of 250–400 $\mu\text{g}/\text{kg}$, which is repeated in a week. Cure rates of 70% after one dose and 95% after two doses given 2 weeks apart have been achieved. For treatment of scabies outbreaks in large groups, this drug has obvious advantages as compared with topical therapy.

ANTIMALARIAL AGENTS

The major antimalarials used commonly in dermatology include *chloroquine* (ARALEN), *hydroxychloroquine* (PLAQUENIL), and to a lesser extent, *quinacrine* (no longer available in the U.S.); all three drugs are useful because of their anti-inflammatory effects, especially in connective tissue disorders and photosensitivity diseases (see Chapter 39).

The mechanism of action of the immunological and anti-inflammatory effects of antimalarials include inhibition of phospholipase A₂, inhibition of platelet aggregation, a range of lysosomal effects (e.g., an increase in pH, membrane stabilization, and inhibition of release and activity of lysosomal enzymes), inhibition of phagocytosis, an increase in intracellular pH in cytoplasmic vacuoles leading to decreased stimulation of autoimmune CD4⁺ T cells, decreased cytokine release from lymphocytes and stimulated monocytes, inhibition of immune complex formation, and antioxidant activity. In patients with porphyria cutanea tarda, chloroquine and hydroxychloroquine bind to porphyrins and/or iron to facilitate their hepatic clearance. The ability to bind to melanin and other pigments may contribute to the retinal toxicity seen occasionally when antimalarial agents are used.

THERAPEUTIC USES FDA-approved dermatological uses of hydroxychloroquine include treatment of discoid and systemic lupus erythematosus. Unapproved but first-line uses include treatment of dermatomyositis, porphyria cutanea tarda, polymorphous light eruption, sarcoidosis, eosinophilic fasciitis, lymphocytic infiltrate of Jessner, lymphocytoma cutis, solar urticaria, granuloma annulare, and some forms of panniculitis.

Usual doses of antimalarials are hydroxychloroquine, 200 mg twice a day; chloroquine, 250–500 mg/day; and quinacrine, 100–200 mg/day. Usually, hydroxychloroquine is started first, and if no improvement is noted in 3 months, quinacrine is added. Alternatively, chloroquine is used as a single agent. Dosing should be adjusted for low-weight individuals so that chloroquine dosing is 2.5 mg/kg/day and hydroxychloroquine is 6.5 mg/kg/day. Antimalarial agents are the treatment of choice for widespread forms of cutaneous lupus that do not respond to topical glucocorticoids and sunscreens. Clinical improvement may be delayed for several months.

Porphyria cutanea tarda, characterized by fluid-filled vesicles and bullae on sun-exposed areas, can be either genetic or associated with alcohol abuse or hepatitis C. Although the associated iron overload is treated with phlebotomy, the dermatologic manifestations sometimes are treated with antimalarial agents. These patients require reduced doses because of the potential for hepatotoxicity, as manifested by elevated transaminase levels, and the rapid excretion of large amounts of uroporphyrins in the urine that can occur with usual doses. Low-dose twice-weekly administration is effective and avoids these side effects.

TOXICITY AND MONITORING The toxic effects of antimalarial agents are described in Chapter 39. The incidence of retinopathy from chloroquine and hydroxychloroquine is low, as long as the doses are as described above and the medication is used for less than 10 years in patients with normal renal function.

Quinacrine does not cause retinopathy. Eye examinations every 6 months or even yearly after a baseline examination probably are sufficient, provided dosing guidelines are followed. Although caution is required, there is evidence that antimalarial agents probably are safe in pregnancy and in children. Rare hematological side effects include agranulocytosis, aplastic anemia, and hemolysis in patients with glucose-6-phosphatase deficiency. Liver function tests and complete blood counts should be performed monthly at the start of therapy and at least every 4–6 months throughout treatment.

CYTOTOXIC AND IMMUNOSUPPRESSANT DRUGS

Cytotoxic and immunosuppressive drugs are used in dermatology for immunologically mediated diseases such as psoriasis, the autoimmune blistering diseases, and leukocytoclastic vasculitis. These agents are discussed in detail in Chapters 51 and 52.

Antimetabolites

METHOTREXATE The antimetabolite methotrexate suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)-positive T cells and endothelial cell E-selectin, which may account for its efficacy in psoriasis. It is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

Methotrexate (RHEUMATREX, others) is equally effective as orally administered *cyclosporine* for the treatment of moderate-to-severe chronic plaque psoriasis. Methotrexate is used often in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologics. A usual starting dose for methotrexate therapy is 5–7.5 mg/week (maximum of 15 mg/week). This dose may be increased gradually to 20–30 mg/week if needed. Widely used regimens include three oral doses given at 12-hour intervals once weekly or weekly intramuscular injections. Doses must be decreased for patients with impaired renal clearance. *Methotrexate should never be coadministered with trimethoprim-sulfamethoxazole, probenecid, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression.* Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal anti-inflammatory agents.

Methotrexate exerts significant antiproliferative effects on the bone marrow; therefore, complete blood counts should be monitored. *Folinic acid (leucovorin)* can be used to rescue patients with hematologic crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary but may not be adequate to identify early hepatic fibrosis in patients receiving chronic methotrexate therapy. Liver biopsy is recommended when the cumulative dose reaches 1–1.5 g. A baseline liver biopsy also is recommended for patients with increased

potential risk for hepatic fibrosis, such as a history of alcohol abuse or infection with hepatitis B or C. Patients with significantly abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Pregnancy and lactation are absolute contraindications to methotrexate use.

Azathioprine (IMURAN) is discussed in detail in Chapters 38 and 52. In dermatologic practice, the drug is used as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet's disease. The usual starting dose is 1–2 mg/kg/day. Since it often takes 6–8 weeks to achieve therapeutic effect, azathioprine often is started early in the course of disease management. Careful laboratory monitoring is important. Thiopurine 5-methyltransferase is critical for the metabolism of azathioprine to nontoxic metabolites. Homozygous deficiency of this enzyme may raise plasma levels of the drug and cause myelosuppression, and some experts advocate measuring this enzyme before initiating azathioprine therapy (*see* Chapter 38).

Fluorouracil (5-FU) interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid to thymidylic acid. Topical formulations (CARAC, EFUDEX, FLUOROPLEX) are used in multiple actinic keratoses, actinic cheilitis, Bowen's disease, and superficial basal cell carcinomas not amenable to other treatments.

Fluorouracil is applied twice daily for 2–4 weeks. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5-FU has been used for keratoacanthomas, warts, and porokeratoses.

ALKYLATING AGENTS *Cyclophosphamide* (CYTOXAN, NEOSAR) is an effective cytotoxic and immunosuppressive agent.

Both oral and intravenous preparations of cyclophosphamide are used in dermatology. Cyclophosphamide is FDA-approved for treatment of advanced cutaneous T-cell lymphoma. Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener's granulomatosis, polyarteritis nodosa, Churg-Strauss angiitis, Behçet's disease, scleromyxedema, and cytophagic histiocytic panniculitis. The usual oral dose is 2–3 mg/kg/day in divided doses, and there is often a 4–6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer.

Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and thus is used only in the most severe, recalcitrant dermatological diseases. The secondary malignancies have included bladder, myeloproliferative, and lymphoproliferative malignancies and have been seen with the use of cyclophosphamide alone or in combination with other antineoplastic drugs.

Mechlorethamine hydrochloride (MUSTARGEN) and *carmustine* (*bischloronitrosourea*, BCNU, BICNU) are used typically to treat cutaneous T-cell lymphoma. Both can be applied as a solution or in ointment form. It is important to monitor complete blood counts and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias.

CALCINEURIN INHIBITORS Cyclosporine (SANDIMMUNE, NEORAL, SANGCYA) is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. Its mechanism of action is discussed in Chapter 52. The presence of calcineurin in Langerhans' cells, mast cells, and keratinocytes may explain the therapeutic efficacy of cyclosporine and the other calcineurin inhibitors (*e.g.*, *tacrolimus* and *pimecrolimus*; *see* below). Cyclosporine is FDA-approved for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dose is 3–5 mg/kg/day given in divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regular monitoring of blood pressure. Alternation with other therapeutic modalities may diminish cyclosporine toxicity. *Laboratory monitoring during therapy is essential.* Cyclosporine is not

mutagenic. However, as with other immunosuppressive agents, patients with psoriasis treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.

Tacrolimus (FK506, PROGRAF), a metabolite of *Streptomyces tsukubaensis*, is a potent macrolide immunosuppressant traditionally used to prevent kidney, liver, and heart allograft rejection (see Chapter 52). Like cyclosporine, tacrolimus works mainly by inhibiting early activation of T lymphocytes, thereby inhibiting the release of IL-2, suppressing humoral and cell-mediated immune responses, and suppressing mediator release from mast cells and basophils. In contrast to cyclosporine, this effect is mediated by binding to intracellular FK506-binding protein 12, generating a complex that inhibits the phosphatase activity of calcineurin.

Tacrolimus is available in oral and topical forms for the treatment of skin disease. Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet's disease. When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia. Topical formulations of tacrolimus penetrate into the epidermis.

In commercially available topical formulations (0.03% and 0.1%), tacrolimus ointment (PROTOPTIC) is effective in and approved for the treatment of atopic dermatitis in adults (0.03% and 0.1%) and children (0.03%). Other uses in dermatology include intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. It is applied to the affected area twice a day and generally is well tolerated.

A major benefit of topical tacrolimus compared with topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus, which tend to improve with continued treatment. Systemic absorption generally is very low and decreases with resolution of the dermatitis. However, topical tacrolimus should be used with extreme caution in patients with Netherton's syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application. It is recommended that patients using tacrolimus use sunscreen and avoid excessive UV exposure.

Pimecrolimus 1% cream (ELIDEL), a macrolide derived from azomycin, is FDA-approved for the treatment of atopic dermatitis in patients >2 years of age. Its mechanism of action and side effect profile are similar to those of tacrolimus. Burning, while occurring in some patients, appears to be less common with pimecrolimus than with tacrolimus. In addition, pimecrolimus has less systemic absorption. Similar precautions with regard to UV exposure should be taken during treatment with pimecrolimus.

MISCELLANEOUS IMMUNOSUPPRESSANT AND ANTI-INFLAMMATORY AGENTS

Mycophenolate mofetil (CELLCEPT) is an immunosuppressant approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (see Chapter 52). Mycophenolic acid depletes guanosine nucleotides essential for DNA and RNA synthesis, and functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation. The drug also may enhance apoptosis.

Mycophenolate mofetil is used increasingly to treat inflammatory and autoimmune diseases in dermatology in doses ranging from 1 to 2 g/day orally. Mycophenolate mofetil is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders, including pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, and pemphigus foliaceus. It also has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum.

Imiquimod (ALDARA) is a synthetic imidazoquinoline amine believed to exert immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon- α (IFN- α), tumor necrosis factor- α (TNF- α), and IL-1, IL-6, IL-8, IL-10, and IL-12.

Approved for the treatment of genital warts imiquimod is applied to genital or perianal lesions three times a week usually for a 16-week period that may be repeated as necessary. Imiquimod is also approved for the treatment of actinic keratoses. In this capacity, imiquimod is applied three times a week for 16 weeks to the face, scalp, and arms. Phase 2 trials evaluating imiquimod for the

treatment of nodular and superficial basal cell carcinomas suggest that imiquimod may prove useful when applied daily over 6–12 weeks, and the drug is FDA-approved for this indication. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget's disease, and Bowen's disease. Irritant reactions occur in virtually all patients, and some develop edema, vesicles, erosions, or ulcers. It appears that the degree of inflammation parallels therapeutic efficacy. No systemic effects have been reported.

Systemic *vinblastine* (VELBAN, others) is approved for use in Kaposi's sarcoma and advanced cutaneous T-cell lymphoma. Intralesional vinblastine also is used to treat Kaposi's sarcoma. Intralesional *bleomycin* (BLENOXANE, others) is used for recalcitrant warts and has cytotoxic and proinflammatory effects. Intralesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Raynaud's phenomenon, local skin necrosis, and flagellate hyperpigmentation. Intralesional bleomycin has been used for palliative treatment of squamous cell carcinoma. Systemic bleomycin has been used for Kaposi's sarcoma (*see* Chapter 51 for a more complete discussion of these agents). Liposomal anthracyclines [specifically *doxorubicin* (DOXL, CAELYX)] may provide first-line monotherapy for advanced Kaposi's sarcoma.

Dapsone (4,4'-diaminodiphenylsulfone) is used in dermatology for its anti-inflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin. Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects; all these actions are likely to be important in autoimmune skin diseases.

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis.

An initial dose of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, always with appropriate laboratory testing. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients before initiating dapsone therapy because dapsone hydroxylamine, the toxic metabolite of dapsone formed by hydroxylation, depletes glutathione within G6PD-deficient cells. The nitroso derivative then causes peroxidation reactions, leading to rapid hemolysis. A maximum dose of 150–300 mg/day should be given in divided doses to minimize the risks of methemoglobinemia. The H₂ blocker cimetidine, at a dose of 400 mg 3 times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

Thalidomide (THALOMID) is an anti-inflammatory, immunomodulating, antiangiogenic agent (*see* Figure 51–6) that also can increase keratinocyte migration and proliferation.

Thalidomide is FDA-approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphthous stomatitis, Behçet's disease, Kaposi's sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. It also may cause an irreversible neuropathy. *Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.*

BIOLOGICAL AGENTS

Biological agents (*see* Chapters 38 and 52) are highly specialized systemic therapies that target specific mediators of the immunologic/inflammatory reactions that are, at least in part, responsible for the clinical manifestations of a disease. The rapidly advancing knowledge of cutaneous immunology has brought with it equally impressive innovations in the therapy of malignant disorders such as cutaneous T-cell lymphoma and of immunologic diseases such as psoriasis and psoriatic arthritis. Investigational studies are evaluating a variety of biological agents for the treatment of malignancy and autoimmune diseases. This section will focus on agents that have been well studied or applied widely to the treatment of dermatological disease.

One thought to be primarily a disorder of keratinocyte hyperproliferation, psoriasis now is known to be an autoimmune process mediated by T lymphocytes that can react with epidermal keratinocytes (Figure 62–2). The mechanism of biological therapies in psoriasis can be illustrated

FIGURE 62–2 Immunopathogenesis of psoriasis. Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as yet undefined antigen(s) presented by antigen-presenting cells. The T cells release proinflammatory cytokines such as TNF- α and IFN- γ that induce keratinocyte and endothelial cell proliferation.

by a conceptual model that outlines four strategies in the treatment of psoriasis: (1) reduction of pathogenic T cells; (2) inhibition of T-cell activation; (3) immune deviation (from a T_H1 to a T_H2 immune response); and (4) blockade of the activity of inflammatory cytokines.

Although there are limited long-term data regarding the efficacy and safety of biological agents solely for the treatment of psoriasis, similar, if not identical, therapies have been used extensively in the treatment of rheumatoid arthritis and Crohn's disease. The major advantage of biological agents in the treatment of psoriasis appears to be that they specifically target the activity of T lymphocytes and cytokines that mediate inflammation with fewer side effects than traditional systemic immunosuppressive/cytotoxic agents.

Alefacept (AMEVIVE) was the first immunobiological agent approved for the treatment of moderate-to-severe psoriasis in patients who are candidates for systemic therapy. Alefacept consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function-associated antigen 3 (LFA-3) protein and a human IgG1 Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T cells, thus blocking a necessary costimulation step in T-cell activation (Figure 62–3). Importantly, since CD2 is expressed preferentially on memory-effector T cells, naive T cells largely are unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T cells through simultaneous binding of its IgG1 portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T cells, thus inducing granzyme-mediated apoptosis of memory-effector T cells.

Alefacept is administered by intramuscular injection at a dose of 15 mg/week for 12 weeks. An additional 12-week course can be initiated if required, and a continuous 24-week regimen is under investigation. Significant reductions in psoriatic lesions have been shown for significant numbers of patients. Alefacept may induce longer remissions than do other biological agents. Adverse effects include a reduction in CD4⁺ lymphocyte counts, requiring a baseline T-lymphocyte count before initiating alefacept and weekly monitoring of T cells during therapy.

Efalizumab (RAPTIVA) is a humanized monoclonal antibody against the CD11a molecule of LFA-1. By binding to CD11a on T cells, efalizumab prevents binding of LFA-1 to intercellular adhesion molecule 1 (ICAM-1) on the surface of antigen-presenting cells, vascular endothelial cells, and cells in the dermis and epidermis (see Figure 62–3), thereby interfering with T-cell activation and migration and cytotoxic T-cell function. Efalizumab is FDA-approved for the treatment of moderate-severe psoriasis in patients who are candidates for systemic therapy.

The drug is administered by subcutaneous injection once a week at a dose of 1 mg/kg, usually for 12 or 24 weeks. Significant reductions in psoriatic lesions have been shown for significant numbers of patients. After discontinuation of therapy, patients may experience rebound of disease. It is recommended that periodic evaluation of platelet levels be performed during therapy. Side effects

FIGURE 62-3 Mechanisms of action of selected biological agents in psoriasis. Newer biological agents can interfere with one or more steps in the pathogenesis of psoriasis, resulting in clinical improvement. See text for details.

generally are mild, and there is no evidence to date of increased risk of malignancy, infection, or end-organ toxicity.

Etanercept (ENBREL) is FDA-approved for the treatment of psoriasis, psoriatic arthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, and ankylosing spondylitis. Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor fused to the Fc portion of IgG1. As a dimeric molecule, it can bind two molecules of TNF- α . Etanercept binds soluble and membrane-bound TNF- α , thereby inhibiting the action of TNF- α .

Etanercept is administered by subcutaneous injection at doses of either 25 or 50 mg twice a week. As with alefacept and efalizumab, significant reductions in psoriatic lesions have been shown for significant numbers of patients. Except for injection-site reactions, the drug is well tolerated. Monthly complete blood counts with a differential should be monitored for the first 3 months of treatment. Potential side effects include aplastic anemia, increased risk of infection, and exacerbation of congestive heart failure and demyelinating disorders. The risk of malignancy is unknown but may be increased with the use of etanercept.

Infliximab (REMICADE) is a mouse-human chimeric monoclonal antibody that binds to soluble and membrane-bound TNF- α and inhibits binding with its receptors. Infliximab is a complement-fixing antibody that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF- α . It also induces proinflammatory cytokines, such as IL-1 and IL-6, and enhances leukocyte migration. Infliximab is FDA-approved for the treatment of Crohn's disease and rheumatoid arthritis, but it is also in phase 3 trials for the treatment of psoriasis.

Infliximab is administered by intravenous infusion over 2 hours at doses of 3 or 5 mg/kg, usually at weeks 0, 2, and 6. As with the other biological agents discussed above, significant reductions in psoriatic lesions have been shown for significant numbers of patients. Complications of therapy include infusion reactions, reactivation of latent tuberculosis infection, exacerbation of congestive heart failure, and multiple sclerosis-like syndromes. Purified protein derivative (PPD) testing is required before initiating therapy. Neutralizing antibodies to infliximab may develop, and concomitant administration of methotrexate or glucocorticoids may suppress antibody formation.

Denileukin diftitox or DAB₃₈₉-IL-2, (ONTAK) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB₃₈₉-IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with >20% of T cells expressing the surface marker CD25. The IL-2 portion of the fusion protein binds the CD25 marker on the T cell and promotes destruction of the T cell by the cytotoxic action of diphtheria toxin.

When 9 or 18 µg/kg/day of DAB₃₈₉-IL-2 is given as an intravenous infusion for 5 consecutive days every 3 weeks for up to 6 months, the overall response rate was 36% with 18 µg/kg/day and 23% with 9 µg/kg/day. Adverse effects included pain, fevers, chills, nausea, vomiting, and diarrhea. Immediate hypersensitivity manifested by hypotension, back pain, dyspnea, and chest pain occurred in 60% of patients within 24 hours of drug administration; other serious side effects are edema, hypoalbuminemia, and/or hypotension, occurring in 20–30% of patients, and elevated blood levels of hepatic transaminases.

INTRAVENOUS IMMUNOGLOBULIN IN DERMATOLOGY

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 52). At the present time it is unclear if IVIG therapy is beneficial for treatment of dermatoses. Reports of successful use of IVIG in the treatment of autoimmune and inflammatory dermatoses are anecdotal. IVIG has been used to treat toxic epidermal necrolysis, dermatomyositis, chronic recalcitrant urticaria/angioedema, atopic dermatitis, systemic lupus erythematosus, and autoimmune blistering disorders.

SUNSCREENS

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens that include chemical agents to absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. Many of the sunscreens available are mixtures of organic chemical absorbers and particulate physical substances. Ideal sunscreens provide a broad spectrum of protection and are formulations that are photostable and remain intact for sustained periods on the skin. They also should be nonirritating, invisible, and nonstaining to clothing. No single sunscreen ingredient possesses all these desirable properties, but many are quite effective nonetheless.

UVA Sunscreen Agents

Currently available UVA filters in the U.S. include (1) avobenzene, also known as Parsol 1789; (2) oxybenzone (2-hydroxy-4-methoxy-benzophenone); (3) titanium dioxide; and (4) zinc oxide. Additional UVA sunscreens, including ecamsule (MEXORYL SX and XL), bisethylhexyloxyphenol methoxyphenyl triazine (TINOSORB S), and methylene bisbenzotriazolyl tetramethylbutylphenol (TINOSORB M), are available in Europe and elsewhere but not in the U.S.

UVB Sunscreen Agents

There are numerous UVB filters, including (1) PABA esters (e.g., padimate O); (2) cinnamates (octinoxate); (3) octocrylene (2-ethylhexyl-2-cyano-3,3 diphenylacrylate); and (4) salicylates (octisalate).

The major measurement of sunscreen photoprotection is the sun protection factor (SPF), which defines a ratio of the minimal dose of incident sunlight that will produce erythema or redness (sunburn) on skin with the sunscreen in place (protected) and the dose that evokes the same reaction on skin without the sunscreen (unprotected). The SPF provides valuable information regarding UVB protection but is useless in documenting UVA efficacy because no standard systems have been developed to measure UVA protection. Such protocols are needed because more than 85% of solar ultraviolet radiation reaching earth's surface is UVA, which penetrates more deeply into human skin than does UVB and appears to play an important role in photoaging and photocarcinogenesis.

There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses and squamous cell carcinomas of the skin.

THE TREATMENT OF PRURITUS

The term *pruritus* is derived from the Latin *prurire*, which means "to itch." Pruritus is a symptom unique to skin that occurs in a multitude of dermatologic disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including

malignant neoplasms, chronic renal failure, and hepatobiliary disease. The treatment of pruritus varies greatly depending on the underlying disorder.

General measures employing copious application of emollients usually are sufficient for xerosis. Inflammatory disorders such as atopic dermatitis, contact dermatitis, and lichen simplex chronicus may respond better to potent topical glucocorticoids and oral doses of sedating antihistamines. Antihistamines are useful in histamine-induced pruritus and in other pruritic disorders in which the sedating effects of these drugs facilitate sleep and reduce scratching at night, when most pruritic disorders are more symptomatic.

Cholestasis-associated pruritus may respond to *cholestyramine* (QUESTRAN, others; see Chapter 35), *ursodeoxycholic acid* (ACTIGALL, others; see Chapter 37), *ondansetron* (ZOFRAN; see Chapter 37), or *rifampin* (see Chapter 47). Recently, *nalmefene* (REVEX) (20 mg twice per day) has been shown to be effective in cholestatic pruritus.

The pruritus of uremia is treated most effectively with UVB radiation. Prurigo, a ubiquitous disorder associated with itchy nodules of the skin, is notoriously difficult to treat. In addition to topical and intralesional steroids, prurigo may respond to the opioid antagonist *naltrexone* (see Chapter 21) at a dose of 50 mg/day or to the proton pump inhibitor *omeprazole* (see Chapter 36).

Gold will ameliorate the itching palm (see Chapter 26) but the relief is generally only temporary.

DRUGS FOR HYPERKERATOTIC DISORDERS

Keratolytic agents—including *lactic acid*, *glycolic acid*, *salicylic acid*, *urea*, and *sulfur*—are employed to treat various forms of hyperkeratosis ranging from calluses and verrucae to severe xerosis. Lactic and glycolic acid are α -hydroxy acids that are thought to disrupt ionic bonds and thus diminish corneocyte cohesion.

Salicylic acid is a β -hydroxy acid that is thought to function through solubilization of intercellular cement, again reducing corneocyte adhesion. It appears to eliminate the stratum corneum layer by layer from the outermost level downward. This contrasts with the α -hydroxy acids, which preferentially diminish cellular cohesion between the corneocytes at the lowest levels of the stratum corneum.

Urea is an antimicrobial agent that denatures and dissolves proteins and increases skin absorption and retention of water. Sulfur is antiseptic, antiparasitic, antiseborrheic, and keratolytic, accounting for its myriad uses in dermatology.

Keratolytics are available in numerous formulations for treating skin diseases. Prolonged use of salicylic acid preparations over large areas, especially in children and patients with renal and hepatic impairment, can result in salicylism (see Chapter 26). Irritation is a common side effect with higher concentrations. Lactic acid (LAC-HYDRIN, others) is an emollient that contains 12% lactic acid that is an effective moisturizer indicated for the treatment of xerosis and ichthyosis vulgaris.

Glycolic acid is marketed in multiple cosmetic preparations (4–10%) and is used for the treatment of xerosis, ichthyosis, and photoaging.

Destructive Agents

Podophyllin (*podophyllum resin*) is a mixture of chemicals from the plant *Podophyllum peltatum* (*mandrake* or *May apple*). The major constituent of the resin is *podophyllotoxin* (*podofilox*). It binds to microtubules and causes mitotic arrest in metaphase. *Podophyllum resin* (10–40%) is applied and left in place for 2–6 hours weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. *Podofilox* (CONDYLOX, others) is available as a 0.5% solution for application twice daily for 3 consecutive days. Weekly cycles may be repeated.

DRUGS FOR ANDROGENETIC ALOPECIA

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than age 40. Up to 50% of men and women are affected. Androgenetic alopecia is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone binds to the androgen receptor, and the hormone–receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic areata is aimed at reducing hair loss and maintaining existing hair. The capacity to stimulate substantial regrowth of human hair remains a formidable pharmacological challenge.

Minoxidil (ROGAINE) was first developed as an antihypertensive agent (see Chapter 32) and was noted to be associated with hypertrichosis in some patients. A topical formulation of *minoxidil*

then was developed to exploit this side effect. Topical minoxidil is available as a 2% solution (ROGAINE) and a 5% solution (ROGAINE EXTRA STRENGTH FOR MEN). Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs. Treatment must be continued, or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

Finasteride (PROPECIA) inhibits the type II isozyme of 5α -reductase, the enzyme that converts testosterone to dihydrotestosterone (see Chapter 58). The type II 5α -reductase is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period, increasing hair counts in the vertex and the frontal scalp. Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. Each of these occurs in <2% of patients. Like minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

TREATMENT OF HYPERPIGMENTATION

Hyperpigmentation is treated with products containing hydroquinone that produce reversible depigmentation of the skin by inhibiting the enzymatic oxidation of tyrosine to 3,4-dihydroxyphenylalanine and also inhibiting other melanocyte metabolic processes. It is indicated for the gradual bleaching of hyperpigmented skin in conditions such as melasma, freckles, and solar lentigines. Concomitant application of SPF 15–30 sunscreens and meticulous photoprotection are essential to minimize sun-induced exacerbation of hyperpigmentation. Numerous preparations are available (SOLAQUIN FORTE, others).

MISCELLANEOUS AGENTS

Capsaicin is a naturally occurring substance derived from hot chili peppers of the genus *Cap-sicum*. Capsaicin interacts with the vanilloid receptor (VR1) on sensory afferents. VR1 is a gated cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to capsaicin stimulates and desensitizes this channel. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available as a 0.025% cream (ZOSTRIX, others) and a 0.075% cream (ZOSTRIX HP, others) to be applied 3–4 times daily. Capsaicin is FDA-approved for the treatment of postherpetic neuralgia and painful diabetic neuropathy, although its efficacy in relieving pain is debatable.

Masoprocol, a dicatechol compound with an aliphatic spacer, is derived from the plant *Larrea divaricata*; it is a potent 5-lipoxygenase inhibitor with antitumor activity. It is effective for the topical therapy of actinic keratoses. Masoprocol is available as a cream (ACTINEX) and is applied twice daily for approximately 1 month. Common side effects include redness, scaling, and pruritus.

For a complete Bibliographical listing see Goodman & Gilman's *The Pharmacological Basis of Therapeutics*, 11th ed., or Goodman & Gilman Online at www.accessmedicine.com.

OCULAR PHARMACOLOGY

OVERVIEW OF OCULAR ANATOMY, PHYSIOLOGY, AND BIOCHEMISTRY

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood–retinal, blood–aqueous, and blood–vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. No organ in the body is more accessible or visible for observation; however, the eye also presents some unique opportunities as well as challenges for drug delivery.

PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS

Drug Delivery Strategies

Properties of varying ocular routes of administration are outlined in Table 63–1. Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. Prolonging the time in the cul-de-sac facilitates drug absorption. Ophthalmic gels (*e.g.*, *pilocarpine* gel) release drugs by diffusion following erosion of soluble polymers. The polymers used include cellulosic ethers, polyvinyl alcohol, carbopol, polyacrylamide, polymethylvinyl ether–maleic anhydride, poloxamer 407, and puronic acid. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the *ganciclovir* intravitreal implant, provide a zero-order rate of delivery over several months to treat cytomegalovirus retinitis in patients with AIDS.

Pharmacokinetics

Classical pharmacokinetic models of systemically administered drugs (*see* Chapter 1) do not fully apply to many ophthalmic drugs. Most ophthalmic medications are formulated to be applied topically or may be injected by subconjunctival, sub-Tenon's, and retrobulbar routes (Figure 63–1 and Table 63–1). Although similar principles of absorption, distribution, metabolism, and excretion determine drug disposition in the eye, these alternative routes of drug administration introduce other variables in compartmental analysis.

ABSORPTION

After topical instillation of a drug, the rate and extent of absorption are determined by the time the drug remains in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug's residence time may be prolonged by changing its formulation. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with plugs or cautery. (Figure 63–2.) Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids so-called first-pass metabolism by the liver, and consequently significant systemic side effects may be caused by topical medications, especially when used chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 63–3.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The time period between drug instillation and its appearance in the aqueous humor is defined as the lag time. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug's diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process due to the cornea's trilamellar "fat-water-fat" composition. The epithelium and endothelium represent barriers for hydrophilic substances, while the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption.

Table 63-1

Some Characteristics of Ocular Routes of Drug Administration*

Route	Absorption Pattern	Special Utility	Limitations and Precautions
Topical	Prompt, depending on formulation	Convenient, economical, relatively safe	Compliance, corneal and conjunctival toxicity, nasal mucosal toxicity, systemic side effects from nasolacrimal absorption
Subconjunctival, sub-Tenon's, and retrobulbar injections	Prompt or sustained, depending on formulation	Anterior segment infections, posterior uveitis, cystoid macular edema	Local toxicity, tissue injury, globe perforation, optic nerve trauma, central retinal artery and/or vein occlusion, direct retinal drug toxicity with inadvertent globe perforation, ocular muscle trauma, prolonged drug effect
Intraocular (intracameral) injections	Prompt	Anterior segment surgery, infections	Corneal toxicity, intraocular toxicity, relatively short duration of action
Intravitreal injection or device	Absorption circumvented, immediate local effect, potential sustained effect	Endophthalmitis, retinitis	Retinal toxicity

*See text for more complete discussion of individual routes.

Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal ulcers and other corneal epithelial defects, may increase drug penetration when anatomic barriers are compromised or removed. Experimentally, drugs may be screened for their potential clinical utility by assessing their corneal permeability coefficients. These pharmacokinetic data combined with the drug's octanol/water partition coefficient (for lipophilic drugs) or distribution coefficient (for ionizable drugs) yield a parabolic

FIGURE 63-1 Anatomy of the globe in relationship to the orbit and eyelids. Various routes of administration of anesthesia are demonstrated by the needle pathways numbered in blue.

FIGURE 63-2 Anatomy of the lacrimal system.

relationship that is a useful parameter for predicting ocular absorption. Of course, other factors also affect corneal absorption in vivo, such as epithelial integrity, blink rate, dilution by tear flow, nasolacrimal drainage, drug binding to proteins and tissue, and transconjunctival absorption.

DISTRIBUTION

Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption.

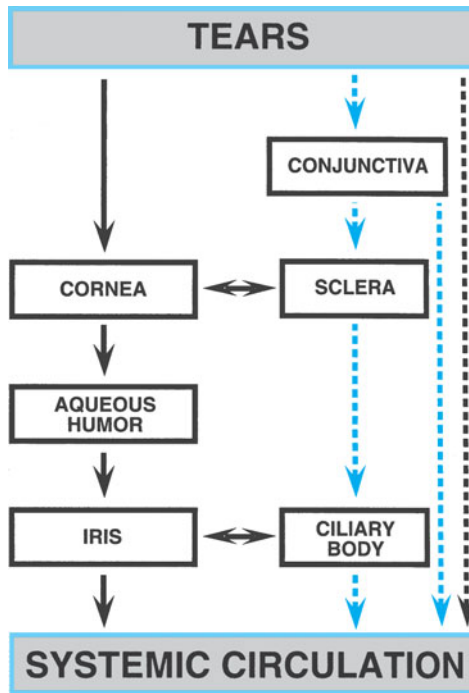

FIGURE 63-3 Possible absorption pathways of an ophthalmic drug following topical application to the eye. Solid black arrows represent the corneal route; dashed blue arrows represent the conjunctival/scleral route; the black dashed line represents the nasolacrimal absorption pathway.

Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (Figure 63–4). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α adrenergic receptor agonists is slower in onset in humans with darkly pigmented irides compared to those with lightly pigmented irides; drug–melanin binding is also a potential reservoir for sustained drug release. Another clinically important consideration for drug–melanin binding involves the retinal pigment epithelium: accumulation of chloroquine (see Chapter 39) causes a toxic retinal lesion that is associated with decreased visual acuity.

METABOLISM

Local enzymatic biotransformation of ocular drugs may be significant since a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, glutathione-conjugating enzymes, catechol-O-methyl-transferase, monoamine oxidase, and 11 β -hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest because of the development of prodrugs for enhanced corneal permeability; in the treatment of glaucoma, for example, dipivefrin hydrochloride is a prodrug for epinephrine, and latanoprost is a prodrug for PGF_{2 α} .

TOXICOLOGY

All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 63–3), so undesirable systemic side effects may occur, as well as potential local toxic effects due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain preservatives such as benzalkonium chloride, chlorobutanol, and chelating agents for their antimicrobial effectiveness. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy.

THERAPEUTIC AND DIAGNOSTIC APPLICATIONS OF DRUGS IN OPHTHALMOLOGY

Chemotherapy of Microbial Diseases in the Eye

ANTIBACTERIAL AGENTS A number of antibiotics have been formulated for topical ocular use (Table 63–2). Appropriate selection of antibiotic and route of administration is dependent on the patient's symptoms, the clinical examination, and the culture/sensitivity results. Specially formulated antibiotics also may be extemporaneously prepared by pharmacists for serious eye infections such as corneal infiltrates or ulcers and endophthalmitis.

Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly in clinical practice. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (*i.e.*, preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics are administered. *Dacryoadenitis*, an infection of the lacrimal gland, is most common in children and young adults. It may be bacterial (typically *Staphylococcus aureus*, *Streptococcus* species) or viral (most commonly seen in mumps, infectious mononucleosis, influenza, and herpes zoster). In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *S. aureus*, *Streptococcus* species, *Diphtheroids*, *Candida* species, and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the eyelids include *hordeolum* and *blepharitis*. A hordeolum, or sty, is an infection of the meibomian, Zeis, or Moll glands at the eyelid margins. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic ointment. Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, and is usually associated with a *Staphylococcus* species. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used, usually in ointment form, particularly when the disease is accompanied by conjunctivitis and keratitis. Systemic *tetracycline*, *doxycycline*, *minocycline*, and *erythromycin* often are effective in reducing severe eyelid inflammation, but must be used for weeks to months.

Conjunctivitis is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. Common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. Less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva

Table 63-2

Topical Antibacterial Agents Commercially Available for Ophthalmic Use*

Generic Name (TRADE NAME)	Formulation [†]	Toxicity [†]	Indications for Use
Bacitracin zinc (AK-TRACIN)	500 units/g ointment	H	Conjunctivitis, blepharitis
Chloramphenicol (AK-CHLOR, CHLOROMYCETIN, CHLOROPTIC)	0.5% solution, 1% ointment	H, BD	Conjunctivitis, keratitis
Ciprofloxacin hydrochloride (CILOXAN)	0.3% solution, 0.3% ointment	H, D-RCD	Conjunctivitis, keratitis
Erythromycin (ILOTYCIN)	0.5% ointment	H	Blepharitis, conjunctivitis
Gatifloxacin (ZYMAR)	0.3% solution	H	Conjunctivitis
Gentamicin sulfate (GARAMYCIN, GENOPTIC, GENT-AK, GENTACIDIN)	0.3% solution, 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis
Levofloxacin (QUIXIN)	0.5% solution	H	Conjunctivitis
Levofloxacin (IQUIX)	1.5% solution	H	Conjunctivitis, keratitis
Moxifloxacin (VIGAMOX)	0.5% solution	H	Conjunctivitis
Ofloxacin (OCUFLOX)	0.3% solution	H	Conjunctivitis, keratitis
Sulfacetamide sodium (BLEPH-10, CETAMIDE, SULF-10, ISOPTO CETAMIDE, SULAMYD SODIUM, others)	10, 15, 30% solution, 10% ointment	H, BD	Conjunctivitis, keratitis
Polymyxin B combinations [‡]	Various solutions Various ointments		Conjunctivitis, blepharitis, keratitis
Tobramycin sulfate (TOBEX, AKTOB)	0.3% solution, 0.3% ointment	H	Conjunctivitis, blepharitis, keratitis

*For specific information on dosing, formulation, and trade names, refer to the *Physician's Desk Reference for Ophthalmology*, which is published annually.

[†]ABBREVIATIONS: H, hypersensitivity; BD, blood dyscrasia; D-RCD, drug-related corneal deposits.

[‡]Polymyxin B is formulated for delivery in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 43 through 46 for further discussion of these antibacterial agents.

or eyelid. More commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus, and vaccinia-variola virus) and bacterial sources (e.g., *Neisseria* species, *Streptococcus pneumoniae*, *Haemophilus* species, *S. aureus*, *Moraxella lacunata*, and *Chlamydial* species). Rare causes of conjunctivitis include *Rickettsia*, fungi, and parasites (in both cyst and trophozoite form). Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation, can occur at any level of the cornea (e.g., epithelium, subepithelium, stroma, and endothelium). It can be due to noninfectious or infectious causes. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections, with tissue loss (corneal ulcers), generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, more peripheral infections usually are not cultured and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for smears, cultures, and sensitivities are performed and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis is usually caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (e.g., after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in the immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt

vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. Immediate vitrectomy (*i.e.*, surgical removal of the vitreous) is beneficial for patients who have light perception-only vision. Vitrectomy for other causes of endophthalmitis (*e.g.*, glaucoma bleb-related, posttraumatic, or endogenous) may be beneficial. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

ANTIVIRAL AGENTS The antiviral drugs used in ophthalmology are summarized in Table 63-3 (*see* Chapter 49 for more details about these agents). The primary indications for antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and is treated by symptomatic relief of irritation.

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and cytomegalovirus. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. *When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea*; hence, patients must be followed very closely. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis, which is presumed to predominantly involve a cell-mediated immune reaction, topical glucocorticoids accelerate recovery. For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral *acyclovir* in reducing the risk of recurrence.

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic *acyclovir*, *valacyclovir*, and *famciclovir* are effective in reducing the severity and complications of herpes zoster ophthalmicus. Currently, there are no ophthalmic preparations of *acyclovir* approved by the FDA, although an ophthalmic ointment is available for investigational use.

Viral retinitis may be caused by herpes simplex virus, cytomegalovirus (CMV), adenovirus, and varicella zoster virus. With the highly active antiretroviral therapy (*see* Chapter 50), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal administration of *ganciclovir* has been found to be an effective

Table 63-3

Antiviral Agents for Ophthalmic Use*

Generic Name (TRADE NAME)	Route of Administration	Ocular Toxicity [†]	Indication for Use
Trifluridine (VIOPTIC)	Topical (1% solution)	PK, H	Herpes simplex keratitis and conjunctivitis
Vidarabine (VIRA-A)	Topical (3% ointment)	PK, H	Herpes simplex keratitis and conjunctivitis
Acyclovir (ZOVIRAX)	Oral, intravenous (200-mg capsules, 400- and 800-mg tablets)		Herpes zoster ophthalmicus Herpes simplex iridocyclitis
Valacyclovir (VALTREX)	Oral (500-mg, 1000-mg tablets)		Herpes simplex keratitis Herpes zoster ophthalmicus
Famciclovir (FAMVIR)	Oral (125-mg, 250-mg, 500-mg tablets)		Herpes simplex keratitis Herpes zoster ophthalmicus
Foscarnet (FOSCAVIR)	Intravenous, Intravitreal		Cytomegalovirus retinitis
Ganciclovir (CYTOVENE) (VITRASERT)	Intravenous, oral, Intravitreal implant		Cytomegalovirus retinitis
Formivirsen (VITRAVENE)	Intravitreal injection		Cytomegalovirus retinitis
Cidofovir (VISTIDE)	Intravenous		Cytomegalovirus retinitis

*For additional details, *see* Chapter 49.[†]ABBREVIATIONS: PK, punctate keratopathy; H, hypersensitivity.

alternative to the systemic route. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous, intravitreal injection, and intravitreal implantation of antiviral medications.

ANTIFUNGAL AGENTS The only currently available topical ophthalmic antifungal preparation is a polyene, *natamycin* (NATACYN). Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration (Table 63–4; see Chapter 48 for details). As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities to guide drug selection.

ANTIPROTOZOAL AGENTS Parasitic infections involving the eye usually manifest themselves as a form of *uveitis*, an inflammatory process of either the anterior or posterior segments, and less commonly as conjunctivitis, keratitis, and retinitis. In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact-lens wearers who develop keratitis, clinicians should be highly suspicious of the presence of *Acanthamoeba*. Additional risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination topical antibiotic, such as *polymyxin B sulfate*, *bacitracin zinc*, and *neomycin sulfate* (NEOSPORIN), and sometimes an imidazole (e.g., *clotrimazole*, *miconazole*, or *ketoconazole*). In the UK, the aromatic diamidines (i.e., *propamidine isethionate* in both topical aqueous and ointment forms, BROLENE) have been used successfully to treat this relatively resistant infectious keratitis. The cationic antiseptic agent *polyhexamethylene biguanide* (PHMB) also is typically used in drop form for *acanthamoeba* keratitis, although it is not an FDA-approved antiprotozoal agent. Topical *chlorhexidine* is an alternative to PHMB. Oral itraconazole or ketoconazole often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis may require many months of treatment.

Toxoplasmosis may present as a posterior (e.g., focal retinochoroiditis, papillitis, vitritis, or retinitis) or occasionally as an anterior uveitis. Treatment is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) *pyrimethamine*, *sulfadiazine*, and *folic acid* (*leucovorin*); (2) *pyrimethamine*, *sulfadiazine*, *clindamycin*, and *folic acid*; (3) *sulfadiazine* and

Table 63–4

Antifungal Agents for Ophthalmic Use*

Drug Class/Agent	Method of Administration	Indications for Use
<i>Polyenes</i>		
Amphotericin B	0.1–0.5% (typically 0.15%) topical solution	Yeast and fungal keratitis and endophthalmitis
	0.8–1 mg subconjunctival	Yeast and fungal endophthalmitis
	5 μ g intravitreal injection	Yeast and fungal endophthalmitis
	Intravenous	Yeast and fungal endophthalmitis
Natamycin	5% topical suspension	Yeast and fungal blepharitis, conjunctivitis, keratitis
<i>Imidazoles</i>		
Fluconazole	Oral, intravenous	Yeast keratitis and endophthalmitis
Itraconazole	Oral	Yeast and fungal keratitis and endophthalmitis
Ketoconazole	Oral	Yeast keratitis and endophthalmitis
Miconazole	1% topical solution	Yeast and fungal keratitis
	5–10 mg subconjunctival	Yeast and fungal endophthalmitis
	10 μ g intravitreal injection	Yeast and fungal endophthalmitis

*Only natamycin (NATACYN) is commercially available for ophthalmic use. The other antifungal drugs must be formulated for the given method of administration. For further dosing information, refer to the *Physicians' Desk Reference for Ophthalmology*. For additional discussion of these antifungal agents, see Chapter 48.

clindamycin; (4) clindamycin; and (5) *trimethoprim-sulfamethoxazole* with or without clindamycin.

Other protozoal infections (*e.g.*, giardiasis, leishmaniasis, and malaria) and helminths are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated.

Use of Autonomic Agents in the Eye

Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology as well as the responses (*i.e.*, mydriasis and cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 63–5 (also see Chapters 6 through 10).

Glaucoma Characterized by progressive optic nerve cupping and visual field loss, glaucoma is responsible for the bilateral blindness of 90,000 Americans (half of whom are African American or Hispanic), and about 2.2 million have the disease (1.9% of the population over age 40). Risk factors associated with glaucomatous nerve damage include increased intraocular pressure (IOP), positive family history of glaucoma, African American heritage, and possibly myopia and hypertension. Elevated IOP is a risk factor for glaucoma. Several clinical trials have determined that reducing IOP can delay glaucomatous nerve damage. Although markedly elevated IOPs (*e.g.*, greater than 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients apparently can tolerate IOPs in the mid-to-high twenties. These patients are referred to as *ocular hypertensives*. A recent prospective trial found that prophylactic medical reduction of IOP reduced the risk of progression to glaucoma from 10% to 5%. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range, and this form of the disease sometimes is called *normal- or low-tension glaucoma*. A reduction of IOP by 30% reduces disease progression from ~35% to ~10%, even for normal-tension glaucoma patients. Despite overwhelming evidence that IOP reduction is a helpful treatment, the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood.

*Current pharmacotherapies are targeted to decrease the production of aqueous humor at the ciliary body and to increase outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique for glaucoma therapy. General principles of patient management based on the patient's health, age, and ocular status include: (1) asthma and chronic obstructive pulmonary disease with a bronchospastic component are relative contraindications to the use of topical β adrenergic receptor antagonists because of the risk of significant side effects from systemic absorption via the nasolacrimal system; (2) some cardiac dysrhythmias (*i.e.*, bradycardia and heart block) also are relative contraindications to β adrenergic antagonists for similar reasons; (3) history of nephrolithiasis can be a contraindication for carbonic anhydrase inhibitors (CAIs); (4) young patients usually are intolerant of miotic therapy secondary to visual blurring from induced myopia; (5) direct miotic agents are preferred over cholinesterase inhibitors in "phakic" patients (*i.e.*, those patients who have their own crystalline lens), since the latter drugs can promote cataract formation; and (6) in patients who have an increased risk of retinal detachment, miotics should be used with caution since retinal tears could occur due to altered forces at the vitreous base produced by drug-induced ciliary body contraction.*

The goal of glaucoma therapy is to prevent progressive glaucomatous optic-nerve damage with minimum risk and side effects. A stepped medical approach may begin with a topical prostaglandin analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP lowering effect, prostaglandin analogs have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The $\text{PGF}_{2\alpha}$ analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN), bimatoprost (LUMIGAN), and unoprostone (RESCULA). $\text{PGF}_{2\alpha}$ analogs appear to lower IOP by facilitating aqueous outflow through the accessory uveoscleral outflow pathway. The mechanism by which this occurs is unclear.

The β receptor antagonists are the next most common topical medical treatment. There are two classes of topical β blockers. The nonselective ones bind to both β_1 and β_2 receptors and include timolol, levobunolol, metipranolol, and carteolol. There is one β_1 -selective antagonist, betaxolol, available for ophthalmic use. It is less likely to cause breathing difficulty than nonselective β blockers, but it is less efficacious than the nonselective β blockers since the β receptors of the ciliary body epithelium and ocular blood vessels are 75–90% β_2 subtype. The molecular basis of β blockade leading to decreased aqueous production and reduced IOP is uncertain.

Table 63-5

Autonomic Drugs for Ophthalmic Use*

Drug Class (TRADE NAME)	Formulation	Indications for Use	Ocular Side Effects
<i>Cholinergic agonists</i>			
Acetylcholine (MIOCHOL-E)	1% solution	Intraocular use for miosis in surgery	Corneal edema
Carbachol (MIOSTAT, ISOPTO CARBACHOL, others)	0.01–3% solution	Intraocular use for miosis in surgery, glaucoma	Corneal edema, miosis, induced myopia, decreased vision, brow ache, retinal detachment
Pilocarpine (AKARPINE, ISOPTO CARPINE, PILOCAR, PILAGAN, PILOPINE-HS, PILOPTIC, PILOSTAT, others)	0.25–10% solution, 4% gel	Glaucoma	Same as for carbachol
<i>Anticholinesterase agents</i>			
Physostigmine (ESERINE)	0.25% ointment	Glaucoma, accommodative esotropia, louse and mite infestation of lashes	Retinal detachment, miosis, cataract, pupillary block glaucoma, iris cysts, brow ache, punctal stenosis of the nasolacrimal system
Echothiophate (PHOSPHOLINE IODIDE)	0.125% solution	Glaucoma, accommodative esotropia	Same as for physostigmine
<i>Muscarinic antagonists</i>			
Atropine (ATROPISOL, ATROPINE-CARE, ISOPTO ATROPINE)	0.5–2% solution, 1% ointment	Cycloplegic retinoscopy, dilated funduscopic exam, cycloplegia [†]	Photosensitivity, blurred vision
Scopolamine (ISOPTO HYOSCINE)	0.25% solution	Same as for atropine	Same as for atropine
Homatropine (ISOPTO HOMATROPINE)	2 & 5% solution	Same as for atropine	Same as for atropine
Cyclopentolate (AK-PENTOLATE, CYCLOGYL, PENTOLAIR)	0.5, 1, & 2% solution	Same as for atropine	Same as for atropine
Tropicamide (MYDRIACYL, TROPICACYL, OPTICYL)	0.5 & 1% solution	Same as for atropine	Same as for atropine
<i>Sympathomimetic agents</i>			
Dipivefrin (PROPINE, AKPRO)	0.1% solution	Glaucoma	Photosensitivity, conjunctival hyperemia, hypersensitivity
Epinephrine (EPINAL, EPIFRIN, GLAUCON)	0.1, 0.5, 1, & 2% solution	Glaucoma	Same as for dipivefrin
Phenylephrine (AK-DILATE, MYDFRIN, NEO-SYNEPHRINE, others)	0.12, 2.5, & 10% solution	Mydriasis	Same as for dipivefrin
Apraclonidine (IOPIDINE)	0.5 & 1% solution	Glaucoma, pre- & postlaser prophylaxis of intraocular pressure spike	Same as for dipivefrin

Sympathomimetic agents (Continued)

Brimonidine (ALPHAGAN)	0.15 and 0.2% solution	Glaucoma	Same as for dipivefrin
Cocaine	1–4% solution	Topical anesthesia, evaluate anisocoria	
Hydroxyamphetamine (PAREDRIE)	1% solution	Evaluate anisocoria	
Naphazoline (AK-CON, ALBALON, CLEAR EYES, NAPHCON, VASOCLEAR, VASOCON REGULAR, others)	0.012–0.1% solution	Decongestant	Same as for dipivefrin
Tetrahydrozoline (COLLYRIUM FRESH, MURINE PLUS, VISINE MOISTURIZING, others)	0.05% solution	Decongestant	Same as for dipivefrin

 α & β Adrenergic antagonists

Dapiprazole (α) (REV-EYES)	0.5% solution	Reverse mydriasis	Conjunctival hyperemia
Betaxolol (β_1 -selective) (BETOPTIC, BETOPTIC-S)	0.25 and 0.5% suspension	Glaucoma	
Carteolol (β) (OCUPRESS)	1% solution	Glaucoma	
Levobunolol (β) (BETAGAN, AKBETA)	0.25 & 0.5% solution	Glaucoma	
Metipranolol (β) (OPTIPRANOLOL)	0.3% solution	Glaucoma	
Timolol (β) (TIMOPTIC, TIMOPTIC XE, BETIMOL)	0.25 & 0.5% solution & gel	Glaucoma	

*Refer to *Physicians' Desk Reference for Ophthalmology* for specific indications and dosing information.

†Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within two diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution.

Times to development of maximal mydriasis and to recovery, respectively, are: for *atropine*, 30–40 minutes and 7–10 days; for *scopolamine*, 20–130 minutes and 3–7 days; for *homatropine*, 40–60 minutes and 1–3 days; for *cyclopentolate*, 30–60 minutes and 1 day; for *tropicamide*, 20–40 minutes and 6 hours.

Times to development of maximal cycloplegia and to recovery, respectively, are: for *atropine*, 60–180 minutes and 6–12 days; for *scopolamine*, 30–60 minutes and 3–7 days; for *homatropine*, 30–60 minutes and 1–3 days; for *cyclopentolate*, 25–75 minutes and 6 hours to 1 day; for *tropicamide*, 30 minutes and 6 hours.

When there are medical contraindications to the use of prostaglandin analogs or β -receptor antagonists, other agents, such as an α_2 adrenergic receptor agonist or topical carbonic anhydrase inhibitor may be first-line therapy. The α_2 adrenergic agonists improve the pharmacologic profile of the nonselective sympathomimetic agent epinephrine and its prodrug derivative, dipivefrin (PROPINE). Epinephrine stimulates both α and β adrenergic receptors. The drug appears to decrease IOP by enhancing both conventional (via a β_2 receptor mechanism) and uveoscleral outflow (perhaps via prostaglandin production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea. It is much better tolerated but still is prone to cause epinephrine-like side effects. The α_2 adrenergic agonist apraclonidine (IOPIDINE) is highly ionized at physiologic pH and therefore does not cross the blood-brain barrier to cause sedation. Brimonidine (ALPHAGAN, others) is also a selective α_2 adrenergic agonist, but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α_2 receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP (Figure 63–3). By activating postsynaptic α_2 receptors, these drugs stimulate the G_i pathway, reducing cyclic AMP production and thereby reducing aqueous humor production.

The development of a topical carbonic anhydrase inhibitor was prompted by the poor side-effect profile of oral CAIs. Dorzolamide (TRUSOPT) and brinzolamide (AZOPT) both work by inhibiting carbonic anhydrase (isoenzyme II), which is found in the ciliary body epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP.

Any of these four drug classes can be used as additive second- or third-line therapy. The β receptor antagonist timolol has been combined with the carbonic anhydrase inhibitor dorzolamide in a single medication (COSOPT) that may improve compliance.

Topical miotic agents are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors. Echothiophate (PHOSPHOLINE IODIDE) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution, and by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed.

If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with CAIs is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 28), followed by methazolamide. The least well-tolerated are acetazolamide tablets.

Toxicity of Agents in Treatment of Glaucoma

Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. Epinephrine-related compounds, effective in IOP reduction, can cause a vasoconstriction-vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related prodrug formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and is therefore more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children under the age of 2.

Systemic absorption of epinephrine-related drugs and β adrenergic antagonists can induce all the side effects found with direct systemic administration. The systemic use of CAIs may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.

Uveitis Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known) is essential in addition to the use of topical therapy. Cyclopentolate, or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine, and homatropine, frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm causes much of the pain associated with anterior uveitis. If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution containing scopolamine 0.3% in combination with 10% phenylephrine is available for this purpose. Topical glucocorticoids usually are adequate to decrease inflammation, but sometimes must be supplemented by systemic glucocorticoids.

Strabismus *Strabismus*, or ocular misalignment, has numerous causes and may occur at any age. Besides causing *diplopia* (double vision), strabismus in children may lead to *amblyopia* (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and drugs. An eye with *hyperopia*, or farsightedness, must accommodate to focus distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest *esotropia* (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about the age of 7, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. Unfortunately this is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye. Echthiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echthiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

Surgery and Diagnostic Purposes For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and α_2 adrenergic agonists frequently are used singly or in combination for this purpose (Table 63–5). Intraoperatively, there are circumstances when miosis is preferred, and two cholinergic agonists are available for intraocular use, *acetylcholine* and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or eyelid droop (ptosis); the *edrophonium test* is helpful in diagnosing these patients (see Chapter 8).

Use of Immunomodulatory Drugs for Ophthalmic Therapy

GLUCOCORTICOIDS Glucocorticoids have an important role in managing ocular inflammatory diseases; their chemistry and pharmacology are described in Chapter 59. Currently the glucocorticoids formulated for topical administration to the eye are *dexamethasone* (DECADRON, others), *prednisolone* (PRED FORTE, others), *fluorometholone* (FML, others), *loteprednol* (ALREX, LOTEMAX), *medrysone* (HMS), and *rimexolone* (VEXOL). Because of their anti-inflammatory effects, topical glucocorticoids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical glucocorticoids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Glucocorticoids are commonly given systemically and by sub-Tenon's capsule injection to manage posterior uveitis. Intravitreal injection of glucocorticoids is used to treat a variety of retinal conditions including age-related macular degeneration, diabetic retinopathy, and cystoid macular edema. Parenteral glucocorticoids followed by tapering oral doses are the preferred treatment for optic neuritis.

Toxicity of Glucocorticoids Glucocorticoid drops, pills, and creams are associated with ocular problems, as are intravitreal and intravenous steroids. Ocular complications include the development of posterior subcapsular cataracts, secondary infections (see Chapter 59), and secondary open-angle glaucoma. There is a significant increase in risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, moderate-to-marked glucocorticoid-induced IOP elevations may occur in up to 90% of patients. Typically, glucocorticoid-induced IOP elevation is reversible once drug administration ceases. However, intraocular or sub-Tenon's steroid-related pressure elevation may persist for months and may require treatment with glaucoma medication or even filtering surgery. Newer topical glucocorticoids, so called “soft steroids” (e.g., loteprednol), reduce but do not eliminate the risk of elevated IOP.

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS (NSAIDs) There are five topical NSAIDs approved for ocular use: *diclofenac* (VOLTAREN), *flurbiprofen* (OCUFEN), *ketorolac* (ACULAR), *bromfenac* (XIBROM), and *nepafenac* (NEVANAC). Diclofenac and flurbiprofen are discussed in Chapter 26. Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac, bromfenac, and

nepafenac are used for postoperative inflammation; nepafenac may be used to relieve pain following cataract surgery. Ketorolac and diclofenac are effective in treating cystoid macular edema occurring after cataract surgery. In patients treated with prostaglandin analogs (e.g., latanoprost or bimatoprost), ketorolac and diclofenac may decrease postoperative inflammation. They also are useful in decreasing pain after corneal refractive surgery. Topical NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

ANTI-HISTAMINES AND MAST-CELL STABILIZERS *Pheniramine* (see Chapter 24) and *antazoline*, both H_1 receptor antagonists, are formulated in combination with *naphazoline*, a vasoconstrictor, for relief of allergic conjunctivitis. Topical antihistamines include *emedastine difumarate* (EMADINE) and *levocabastine hydrochloride* (LIVOSTIN). *Cromolyn sodium* (CROLOM), which prevents the release of histamine and other autacoids from mast cells (see Chapter 27), has found limited use in treating conjunctivitis that is thought to be allergen-mediated, such as vernal conjunctivitis. *Lodoxamide tromethamine* (ALOMIDE) and *pemirolast* (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. *Nedocromil* (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. *Olopatadine hydrochloride* (PATANOL), *ketotifen fumarate* (ZADITOR), and *azelastine* (OPTIVAR) are H_1 antagonists with mast cell–stabilizing properties. *Epinastine* (ELESTAT) antagonizes H_1 and H_2 receptors and exhibits mast cell–stabilizing activity.

IMMUNOSUPPRESSIVE AND ANTIMITOTIC AGENTS The principal application of immunosuppressive and antimetabolic agents to ophthalmology relates to the use of 5-fluorouracil and mitomycin C in corneal and glaucoma surgeries. Interferon α -2b also has occasionally been used. Certain systemic diseases with serious vision-threatening ocular manifestations—such as Behçet’s disease, Wegener’s granulomatosis, rheumatoid arthritis, and Reiter’s syndrome—require systemic immunosuppression (see Chapter 52). In glaucoma surgery, both fluorouracil and mitomycin (MUTAMYCIN), which also are antineoplastic agents (see Chapter 51), improve the success of filtration surgery by limiting the postoperative wound-healing process. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Meticulous care is used to avoid intraocular penetration, since mitomycin is extremely toxic to intraocular structures. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or subconjunctivally during the postoperative course. Although both agents work by limiting the healing process, sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In cornea surgery, mitomycin has been used topically after excision of pterygium, a fibrovascular membrane that can grow onto the cornea. Mitomycin can be used to reduce the risk of scarring after certain procedures to remove corneal opacities and also prophylactically to prevent corneal scarring after excimer laser surface ablation (photorefractive and phototherapeutic keratectomy). Mitomycin also is used to treat certain conjunctival and corneal tumors. Interferon α -2b has been used in the treatment of conjunctival papilloma and certain conjunctival tumors. Although the use of mitomycin for both corneal surgery and glaucoma filtration surgeries augments the success of these surgical procedures, caution is advocated in light of potentially serious delayed ocular complications.

IMMUNOMODULATORY AGENT Topical *cyclosporine* (RESTASIS) is approved for the treatment of chronic dry eye associated with inflammation. Cyclosporine is an immunomodulatory agent that inhibits T-cell activation. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort.

Drugs and Biological Agents Used in Ophthalmic Surgery

ADJUNCTS IN ANTERIOR SEGMENT SURGERY *Viscoelastic* substances assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose, share the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability, and are broadly characterized as dispersive or cohesive. They are used almost exclusively in anterior segment surgery. Complications associated with viscoelastic substances are related to transient elevation of IOP after the procedure.

OPHTHALMIC GLUE Cyanoacrylate tissue adhesive (ISODENT, DERMABOND, HISTOACRYL), while not FDA approved for the eye, is widely used in the management of corneal ulcerations and

perforations. It is applied in liquid form and polymerized into a solid plug. Fibrinogen glue (TISSEEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

CORNEAL BAND KERATOPATHY *Edetate disodium* (disodium EDTA; ENDRATE) is a chelating agent that can be used to treat band keratopathy (*i.e.*, a calcium deposit at the level of Bowman's membrane on the cornea). After the overlying corneal epithelium is removed, it is applied topically to chelate the calcium deposits from the cornea.

ANTERIOR SEGMENT GASES Sulfur hexafluoride (SF_6) and perfluoropropane gases have long been used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in nonexpansile concentrations to treat Descemet's detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema. The gas is injected into the anterior chamber to push Descemet's membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

VITREOUS SUBSTITUTES The primary use of vitreous substitutes is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. Several compounds are available, including gases, perfluorocarbon liquids, and silicone oil (Table 63–6). With the exception of air, the gases expand because of interaction with systemic oxygen, carbon dioxide, and nitrogen, and this property makes them desirable to temporarily tamponade areas of the retina. However, use of these expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a time period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons, with specific gravities between 1.76 and 1.94, are denser than vitreous and are helpful in flattening the retina when vitreous is present. If a lens becomes dislocated into the vitreous, a perfluorocarbon liquid injection posteriorly will float the lens anteriorly, facilitating surgical retrieval. This liquid can be an important tool for flattening and unrolling severely detached and contorted retinas such as those found in giant retinal tears and proliferative vitreoretinopathy but are potentially toxic if it remains in chronic contact with the retina.

Silicone oil has had extensive use for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

SURGICAL HEMOSTASIS AND THROMBOLYTIC AGENTS Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. In some intraocular surgeries, thrombin has a valuable role in hemostasis. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur, but this reaction can be minimized by thorough irrigation after hemostasis is achieved. This coagulation factor also may be applied topically *via* soaked sponges to exposed conjunctiva and sclera, where hemostasis may be a challenge due to the rich vascular supply. Topical *aminocaproic acid* (CAPROGEL) has been advocated to prevent rebleeding after traumatic *hyphema* (blood in the anterior chamber), but recent clinical trials report mixed success. Depending on the intraocular location of a clot, there may be significant problems relating to IOP, retinal degeneration, and persistent poor vision. *Tissue plasminogen activator* (t-PA) (*see* Chapter 54) has been used during intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage. t-PA also has been administered subconjunctivally and intracamerally (*i.e.*, controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

BOTULINUM TOXIN TYPE A IN THE TREATMENT OF STRABISMUS, BLEPHAROSPASM, AND RELATED DISORDERS *Botulinum toxin type A* (BOTOX) is used to treat strabismus, blepharospasm, Meige's syndrome, spasmodic torticollis hemifacial spasm, facial wrinkles, and certain migraine headaches (*see also* Chapter 9). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. The variability in duration of paralysis may be related to the rate of developing antibodies to the toxin, upregulation of nicotinic cholinergic postsynaptic receptors, and aberrant regeneration of motor nerve fibers at the neuromuscular junction. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis).

Table 63-6

Vitreous Substitutes

Vitreous Substitute	Chemical Structure	Characteristics (Duration of Viscosity)
<i>Nonexpansile gases</i>		
Air, Ar, CO ₂ , He, Kr, N ₂ , O ₂ , Xe		Duration of 5-7 days Duration of 1 day
<i>Expansile gases</i>		
Sulfur hexafluoride		Duration of 10-14 days
Octafluorocyclobutane		
Perfluoromethane		Duration of 10-14 days
Perfluoroethane	F ₃ C—CF ₃	Duration of 30-35 days
Perfluoropropane	F ₃ C—CF ₂ —CF ₃	Duration of 55-65 days
Perfluoro- <i>n</i> -butane	F ₃ C—(CF ₂)—CF ₃	
Perfluoropentane	F ₃ C—(CF ₂)—CF ₃	
<i>Silicone oils</i>		
Nonfluorinated silicone oils	(CH ₃) ₃ SiO[(CH ₃) ₂ SiO] _n Si(CH ₃) ₃	Viscosity range from 1000 to 30,000 cs*
Fluorosilicone	(CH ₃) ₃ SiO[(C ₃ H ₄ F ₃)(CH ₃)SiO] _n Si(CH ₃) ₃	Viscosity range from 1000 to 10,000 cs*
“High-tech” silicone oils	(CH ₃) ₃ SiO[(C ₆ H ₅)(CH ₃)SiO] _n Si(CH ₃) ₃	May terminate as trimethylsiloxo (shown) or polyphenylmethylsiloxane, viscosity not reported

*cs, centistoke (unit of viscosity).

BLIND AND PAINFUL EYE Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed.

SYSTEMIC AGENTS WITH OCULAR SIDE EFFECTS Just as certain systemic diseases have ocular manifestations, certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening.

Retina Numerous drugs have toxic side effects on the retina. The antiarthritis and antimalarial medicines *hydroxychloroquine* (PLAQUENIL) and chloroquine can cause a central retinal toxicity. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but will prevent further toxicity. *Sildenafil* (VIAGRA) inhibits PDE5 in the corpus cavernosum for the purpose of helping to achieve and maintain penile erection. The drug also mildly inhibits PDE6, which controls the levels of cyclic GMP in the retina. Visually, this can result in seeing a bluish haze or experiencing light sensitivity. Although no retinal damage has been reported, no long-term studies have been reported. Two newer PDE5 inhibitors, *ildenafil* (LEVITRA) and *tadalafil* (CIALIS), are associated with similar visual disturbances.

Optic Nerve Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. There can be accompanying optic nerve pallor. These medicines include *ethambutol*, *chloramphenicol*, and *rifampin*. Systemic or ocular glucocorticoids can cause elevated IOP and glaucoma. If the glucocorticoids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Anterior Segment Glucocorticoids also have been implicated in cataract formation. If vision is reduced, cataract surgery may be necessary. *Rifabutin*, if used in conjunction with *clarithromycin* or *fluconazole* for treatment of *Mycobacterium avium complex* (MAC) opportunistic infections in AIDS, is associated with an iridocyclitis and even hypopyon. This will resolve with glucocorticoids or by stopping the medication.

Ocular Surface *Isotretinoin* (ACCUTANE) has a drying effect on mucous membranes and is associated with dry eye.

CORNEAL SIDE EFFECTS OF SYSTEMIC MEDICATIONS The cornea, conjunctiva, and even eyelids can be affected by systemic medications. One common drug deposit found in the cornea is from the cardiac medication *amiodarone*. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*. It appears as fine tan or brown pigment in the epithelium that seldom affects vision and rarely causes discontinuation. The deposits disappear slowly if the medication is stopped. Other medications can cause a similar pattern, including *indomethacin*, *atovaquone*, chloroquine, and hydroxychloroquine.

The phenothiazines, including *chlorpromazine* and *thioridazine*, can cause brown pigmentary deposits in the cornea, conjunctiva, and eyelids. The deposits generally are found in Descemet's membrane and the posterior cornea and typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen, perhaps because the medication deposits in the skin are slowly released and accumulate in the eye. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone.

Agents Used to Assist in Ocular Diagnosis

A number of agents are used in an ocular examination (*e.g.*, mydriatic agents and topical anesthetics, and dyes to evaluate corneal surface integrity) to facilitate intraocular surgery (*e.g.*, mydriatic and miotic agents, topical and local anesthetics) and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (*e.g.*, intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed below.

ANTERIOR SEGMENT AND EXTERNAL DIAGNOSTIC USES Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are common external ocular disorders. The dyes *fluorescein*, *rose bengal*, and *lissamine green* are used in evaluating these problems. Available both as a 2% alkaline solution and as an impregnated paper strip, fluorescein reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to help determine the patency of the nasolacrimal system. In addition, this dye is used as part of the procedure of *applanation tonometry* (IOP measurement) and to assist in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with *proparacaine* or *benoxinate* is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. *Fluorexon* (FLUORESOF), a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place). Rose bengal and lissamine green, which also are available as a 1% solution and as saturated paper strips, stain devitalized tissue on the cornea and conjunctiva.

POSTERIOR SEGMENT DIAGNOSTIC AND THERAPEUTIC USES The integrity of the blood–retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either *fluorescein sodium* or *indocyanine green*. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

Verteporfin (VISUDYNE) is a photosensitizing agent approved for photodynamic therapy of the exudative form of age-related macular degeneration with predominantly classic choroidal neovascular membranes. Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is administered intravenously, and once it reaches the choroidal circulation, the drug is light-activated by a nonthermal red laser source. Depending on the size of the neovascular membrane and concerns of occult membranes and recurrence, multiple photodynamic treatments may be necessary. Activation of the drug in the presence of oxygen generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The $t_{1/2}$ of the drug is 5–6 hours. It is eliminated predominantly in the feces. Potential side effects include headache, injection site reactions, and visual disturbances. The drug causes temporary photosensitization, and patients must avoid exposure of skin or eyes to direct sunlight or bright indoor lights for 5 days after treatment.

Use of Anesthetics in Ophthalmic Procedures

Topical anesthetic agents used clinically in ophthalmology include *cocaine*, proparacaine, and *tetracaine* drops and *lidocaine* gel (see Chapter 14). Proparacaine and tetracaine are used topically to perform tonometry, to remove foreign bodies on the conjunctiva and cornea, to perform superficial corneal surgery, and to manipulate the nasolacrimal canalicular system. They also are used topically to anesthetize the ocular surface for refractive surgery using either the excimer laser or placement of intrastromal corneal rings. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. Lidocaine and *bupivacaine* are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. This form of anesthesia eliminates the risks of the anesthetic injection and allows for more rapid visual recovery after surgery. General anesthetics and sedation are important adjuncts for patient care for surgery and examination of the eye, especially in children and uncooperative adults. Most inhalational agents and central nervous system depressants are associated with a reduction in IOP. An exception is *ketamine*, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

Other Agents for Ophthalmic Therapy

VITAMINS AND TRACE ELEMENTS

Table 63–7 summarizes the vitamin deficiencies related to eye function and disease, especially vitamin A. Vitamin A plays an essential role in retinal function; the active vitamin is retinal (vitamin A aldehyde). Vitamin A deficiency interferes with vision in dim light, a condition known as night blindness (*nyctalopia*). Photoreception is accomplished by two types of specialized retinal cells, termed rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The initial step is the absorption of light by a chromophore attached to the receptor protein. 11-cis-retinal is the chromophore of both rods and cones. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. In the synthesis of rhodopsin, 11-cis-retinal is converted to 11-cis-retinal, which then combines with the ϵ -amino group of a specific Lys residue in opsin to form rhodopsin. Most rhodopsin is located in the membranes of the discs situated in the outer segments of the rods. The polypeptide chain of rhodopsin spans the membrane seven times, a characteristic shared by all GPCRs. The visual cycle is initiated by the absorption of a photon of light, followed by the photodecomposition, or bleaching, of rhodopsin, leading ultimately to the isomerization of 11-cis-retinal to the all-trans form and dissociation of the opsin moiety. Activated rhodopsin interacts rapidly with a G protein termed transducin or G_t . Transducin stimulates a cyclic GMP-specific phosphodiesterase (PDE6). The resultant decline in cyclic GMP concentration

Table 63–7

Ophthalmic Effects of Selected Vitamin Deficiencies and Zinc Deficiency

Deficiency	Effects in Anterior Segment	Effects in Posterior Segment
<i>Vitamin</i>		
A (retinol)	Conjunctiva (Bitot's spots, xerosis) Cornea (keratomalacia, punctate keratopathy)	Retina (nyctalopia, impaired rhodopsin synthesis); retinal pigment epithelium (hypopigmentation)
B ₁ (thiamine)		Optic nerve (temporal atrophy with corresponding visual field defects)
B ₆ (pyridoxine) B ₁₂ (cyanocobalamin)	Cornea (neovascularization)	Retina (gyrate atrophy) Optic nerve (temporal atrophy with corresponding visual field defects)
C (ascorbic acid) E (tocopherol)	Lens (?cataract formation)	Retina and retinal pigment epithelium (?macular degeneration)
Folic acid K	Conjunctiva (hemorrhage) Anterior chamber (hyphema)	Vein occlusion Retina (hemorrhage)
<i>Zinc</i>		
		Retina and retinal pigment epithelium (?macular degeneration)

causes a decreased conductance of cyclic GMP-gated Na⁺ channels in the plasma membrane and an increased transmembrane potential; this primary receptor potential leads to the generation of action potentials that travel to the brain via the optic nerve. All-trans-retinal can isomerize to 11-cis-retinal, or alternatively, all-trans-retinal can cycle through all-trans-retinol and 11-cis-retinol to 11-cis-retinal, which combines with opsin to regenerate rhodopsin.

Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays and anatomical deterioration of the rods' outer segments occurs. In rats maintained on a vitamin A-deficient diet, irreversible ultrastructural changes leading to blindness then supervene, a process that takes ~10 months. Following short-term deprivation of vitamin A, dark adaptation can be restored to normal by the addition of retinol to the diet, but this restoration takes several weeks. The reason for this delay is unknown.

The functional and structural integrity of epithelial cells throughout the body requires an adequate supply of vitamin A, which plays a major role in the induction and control of epithelial differentiation in mucus-secreting or keratinizing tissues. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness, one of the most common causes of blindness worldwide.

Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by night blindness, xerosis (dryness), and keratomalacia (corneal thinning), which may lead to perforation; xerophthalmia may be reversed with vitamin A therapy. However, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have some role in corneal epithelial wound healing. There is no evidence to support using topical vitamin A for keratoconjunctivitis sicca in the absence of a nutritional deficiency.

The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

One recent clinical trial found a reduction in the risk of progression of some types of age-related macular degeneration in subjects who received high doses of vitamins C (500 mg), E (400 IU), β -carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg), and other studies are ongoing.

WETTING AGENTS AND TEAR SUBSTITUTES

The management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. Tear substitutes generally are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film. Common viscosity agents include cellulose polymers (e.g., carboxymethylcellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose, and methylcellulose), polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel-like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. In other countries, (but not the U.S.), hyaluronic acid sometimes is used as a viscous agent.

The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions.

Such aqueous and ointment formulations are only fair substitutes for the precorneal tear film, a poorly understood lipid, aqueous, and mucin trilaminar barrier (see above). Many local eye conditions and systemic diseases may affect the precorneal tear film. Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes. There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren's syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes or surgical occlusion of the lacrimal drainage system may be indicated.

OSMOTIC AGENTS AND DRUGS AFFECTING CARBONIC ANHYDRASE

The main osmotic drugs for ocular use include glycerin, mannitol (see Chapter 28), and hypertonic saline. Ophthalmologists occasionally use glycerin and mannitol for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Identifying the cause of corneal edema will guide therapy, and topical osmotic agents, such as hypertonic saline, may temporize the need for surgical intervention in the form of a corneal transplant. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain upon contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred to topical glycerin, which simply clears the cornea temporarily. Reducing IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

PRINCIPLES OF TOXICOLOGY AND TREATMENT OF POISONING

The clinician must evaluate the possibility that a patient's signs and symptoms may be caused by toxic chemicals present in the environment or administered as therapeutic agents. Many adverse effects of drugs mimic symptoms of disease. Appreciation of the principles of toxicology is necessary for the recognition and management of such clinical problems.

DOSE-RESPONSE RELATIONSHIPS; RISK ASSESSMENT

There is a graded dose-response relationship in an *individual* and a quantal dose-response relationship in the *population* (see Chapters 1 and 5). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose is increased. In a quantal dose-response relationship, the percentage of the population affected increases as the dose is raised; the relationship is quantal in that the effect is specified to be either present or absent in a given individual (see Figure 5-4). This quantal dose-response phenomenon is used to determine the *median lethal dose* (LD_{50}) of drugs and other chemicals.

There are marked differences in the LD_{50} values of various chemicals. Some result in death at extremely low doses (LD_{50} for botulinum toxin = 10 pg/kg); others may be relatively harmless in doses of several grams or more (e.g., penicillin). Even a single chemical may be safe at low doses and quite toxic at higher doses, or safe acutely but harmful over time. Thus, it is not possible to categorize all chemicals as either safe or toxic. The real concern is the *risk* associated with use of the chemical. Depending on the use and disposition of a chemical, a very toxic compound ultimately may be less harmful than a relatively nontoxic one.

There is much concern about the risk from exposure to chemicals that produce cancer in laboratory animals. Whether these chemicals are human carcinogens is generally unknown. Regulatory agencies take one of three approaches to potential chemical carcinogens. For food additives, the U.S. Food and Drug Administration (FDA) is very cautious because large numbers of people are likely to be exposed to the chemicals, and they are not likely to have beneficial effects to individuals. For drugs, the FDA weighs the relative risks and benefits of the drugs for patients. Thus, it is unlikely that the FDA will approve the use of a drug that produces tumors in laboratory animals for a mild ailment, but it may approve its use for a serious disease. In fact, most cancer chemotherapeutic drugs also are chemical carcinogens.

In the regulation of environmental carcinogens, agencies such as the Environmental Protection Agency (EPA) attempt to limit lifetime exposure such that the incidence of cancer due to the chemical is no more than one in a million people. To determine the daily allowable exposure for humans, mathematical models are used to extrapolate doses of chemicals that produce a particular incidence of tumors in laboratory animals (often in the range of 10–20%) to those that should produce cancer in no more than one person in a million in a lifetime. The models used are conservative and are thought to provide adequate protection from undue risks from exposure to potential carcinogens. As discussed in Chapter 3, variations in drug metabolism often result in substantial differences between the biological responses of humans and rodents (the common laboratory test animals).

ACUTE VERSUS CHRONIC EXPOSURE Effects of acute exposure to a chemical often differ from those of chronic exposure. Evaluation of *cumulative* toxic effects is receiving increased attention because of chronic exposure to low concentrations of various natural and synthetic chemical substances in the environment.

CHEMICAL FORMS OF DRUGS THAT PRODUCE TOXICITY

Both therapeutic and toxic effects of drugs can be due to the administered agent or metabolites of the drug produced by enzymes, light, or reactive oxygen species. In considering the toxicity of drugs and chemicals, it is important to understand their metabolism, activation, or decomposition. For instance, most organophosphate insecticides are biotransformed by CYPs (cytochromes P450)

FIGURE 64-1 Pathways of acetaminophen metabolism.

to produce the active toxin: parathion is biotransformed to paraoxon, a stable metabolite that binds to and inactivates cholinesterase (see Chapter 8). Some drug metabolites are not chemically stable and are referred to as reactive intermediates; consider the metabolite of acetaminophen (Figure 64-1), which binds to nucleophiles such as glutathione; when cellular glutathione is depleted, the metabolite binds to cellular macromolecules, the mechanism by which acetaminophen kills liver cells (see Chapters 3 and 26). Both parathion and acetaminophen are more toxic under conditions in which CYPs are increased, such as following ethanol or phenobarbital exposure, because CYPs produce the toxic metabolites.

Some chemicals can be activated in the skin by ultraviolet (UV) and/or visible radiation. In photoallergy, radiation absorbed by a drug, such as a sulfonamide, results in its conversion to a more potent allergen than the parent compound. Phototoxic reactions to drugs, in contrast to photoallergic ones, do not have an immunological component. Drugs that are either absorbed locally into the skin or have reached the skin through the systemic circulation may be the object of photochemical reactions within the skin; this can lead directly either to chemically induced photosensitivity reactions or to enhancement of the usual effects of sunlight. Tetracyclines, sulfonamides, chlorpromazine, and nalidixic acid are examples of phototoxic chemicals; generally, they are innocuous to skin if not exposed to light.

SPECTRUM OF UNDESIRABLE EFFECTS

In therapeutics, a drug typically produces numerous effects, but usually only one is sought as the primary goal of treatment; most of the other effects are referred to as *undesirable effects* of that drug for that therapeutic indication. *Side effects* of drugs usually are nondeleterious; they include effects such as dry mouth occurring with tricyclic antidepressant therapy. Some side effects may be

adverse or *toxic*. Mechanistic categorization of *toxic* effects is a necessary prelude to their avoidance or, if they occur, to effect their rational and successful management.

TYPES OF TOXIC REACTIONS Toxic effects of drugs may be classified as pharmacological, pathological, or genotoxic (alterations of DNA), and their incidence and seriousness are related, at least over some range, to the concentration of the toxic chemical in the body. An example of a pharmacological toxicity is excessive depression of the central nervous system (CNS) by barbiturates; of a pathological effect, hepatic injury produced by acetaminophen; of a genotoxic effect, a neoplasm produced by a *nitrogen mustard*. If the concentration of chemical in the tissues does not exceed a critical level, the effects usually will be reversible. The pharmacological effects usually disappear when the concentration of drug or chemical in the tissues is decreased by biotransformation or excretion from the body. Pathological and genotoxic effects may be repaired. If these effects are severe, death may ensue within a short time; if more subtle damage to DNA is not repaired, cancer may appear in a few months or years in laboratory animals or in a decade or more in humans.

Local versus Systemic Toxicity

Local toxicity occurs at the site of first contact between the biological system and the toxicant. Systemic toxicity requires absorption and distribution of the toxicant; most substances, with the exception of highly reactive chemical species, produce systemic toxic effects. The two categories are not mutually exclusive. Tetraethyl lead, for example, injures skin at the site of contact and deleteriously affects the CNS after it is absorbed into the circulation (see Chapter 65).

Most systemic toxicants predominantly affect one or a few organs. The target organ of toxicity is not necessarily the site of accumulation of the chemical. For example, lead is concentrated in bone, but its primary toxic action is on soft tissues; DDT (chlorophenothane) is concentrated in adipose tissue but produces no known toxic effects there.

The CNS is involved in systemic toxicity most frequently because many compounds with prominent effects elsewhere also affect the brain. Next in order of frequency of involvement in systemic toxicity are the heart and circulatory system; the blood and hematopoietic system; visceral organs such as liver, kidney, and lung; and the skin. Muscle and bone are least often affected. With substances that have a predominantly local effect, the frequency of tissue reaction depends largely on the portal of entry (skin, GI tract, or respiratory tract).

Reversible and Irreversible Toxic Effects

The effects of drugs on humans, whenever possible, must be reversible; otherwise, the drugs would be prohibitively toxic. If a chemical produces injury to a tissue, the capacity of the tissue to regenerate or recover largely will determine the reversibility of the effect. Injuries to a tissue such as liver, which has a high capacity to regenerate, usually are reversible; injury to the CNS is largely irreversible because the highly differentiated neurons of the brain have a more limited capacity to divide and regenerate.

Delayed Toxicity

Most toxic effects of drugs occur at a predictable (usually short) time after administration. However, such is not always the case. For example, aplastic anemia caused by chloramphenicol may appear weeks after the drug has been discontinued. Carcinogenic effects of chemicals usually have a long latency period: 20–30 years may pass before tumors are observed. Because such delayed effects cannot be assessed during any reasonable period of initial evaluation of a chemical, there is an urgent need for reliably predictive short-term tests for such toxicity, as well as for systematic surveillance of the long-term effects of marketed drugs and other chemicals (see Chapter 5).

CHEMICAL CARCINOGENS Chemical carcinogens are classified as *genotoxic* or *nongenotoxic*. Genotoxic carcinogens interact with DNA; nongenotoxic carcinogens do not. Chemical carcinogenesis is a multistep process. Most genotoxic carcinogens are themselves unreactive (*procarcinogens* or *proximate carcinogens*) but are converted to *primary* or *ultimate carcinogens* in the body. The drug-metabolizing enzymes often convert the proximate carcinogens to reactive electrophilic intermediates (see Chapter 3). These reactive intermediates can interact with nucleophilic centers in DNA to produce a mutation. Such interaction of the ultimate carcinogen with DNA in a cell is thought to be the initial step in chemical carcinogenesis. The DNA may revert to normal if DNA repair mechanisms operate successfully; if not, the transformed cell may grow into a tumor that becomes apparent clinically.

Nongenotoxic carcinogens, or *promoters*, do not produce tumors alone but do potentiate the effects of genotoxic carcinogens. The time from initiation to the development of a tumor probably depends on the presence of such promoters; for many human tumors, the latent period is 15–45 years.

Two main types of laboratory tests are used to screen for potential carcinogenicity. One is performed to determine whether the chemical is mutagenic, since many carcinogens are also mutagens. Such studies often use assays such as the Ames test. This reverse mutation test uses a strain of *Salmonella typhimurium* that has a mutant gene for the enzyme phosphoribosyl adenosine triphosphate (ATP) synthetase. This enzyme is required for histidine synthesis, and the bacterial strain is unable to grow in a histidine-deficient medium unless a reverse mutation is induced. Because many chemicals are not mutagenic or carcinogenic unless activated by enzymes on the endoplasmic reticulum, rat hepatic microsomes usually are added to the medium containing the mutant bacteria and the drug. The Ames test is rapid and sensitive; its usefulness for the prediction of genotoxic carcinogens is widely accepted; it does not, however, detect nongenotoxic carcinogens (promoters). The second type consists of feeding laboratory rodents the chemical at high dosages for their entire life span, after which autopsies and histopathological examinations are performed on each animal. This latter study can detect both promoters and genotoxic carcinogens.

ALLERGIC REACTIONS Chemical allergy is an adverse reaction that results from previous sensitization to a particular chemical or to one that is structurally similar. Such reactions are mediated by the immune system. The terms *hypersensitivity* and *drug allergy* often are used to describe the allergic state.

For a low-molecular-weight chemical to cause an allergic reaction, it or its metabolic product usually acts as a *hapten*, combining with an endogenous protein to form an antigenic complex. Such antigens induce the synthesis of antibodies, usually after a latent period of at least 1–2 weeks. Subsequent exposure of the organism to the chemical results in an antigen–antibody interaction that provokes the typical manifestations of allergy. Dose–response relationships usually are not apparent for the provocation of allergic reactions.

Allergic responses have been divided into four general categories based on the mechanism of immunological involvement. Type I, or anaphylactic, reactions are mediated by immunoglobulin (IgE) antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils (see Chapter 27). If the Fab portion of the antibody molecule then binds antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the GI tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed immediate hypersensitivity reactions.

Type II, or cytolytic, reactions are mediated by both IgG and IgM antibodies and usually are attributed to their ability to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include penicillin-induced hemolytic anemia, methyl dopa-induced autoimmune hemolytic anemia, quinidine-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. These autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

Type III, or Arthus, reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen–antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called serum sickness occurs. This phenomenon contrasts with the type II reaction, in which the inflammatory response is induced by antibodies directed against tissue antigens. The signs and symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. These reactions usually last for 6–12 days and then subside after the offending agent is eliminated. Several drugs (e.g., sulfonamides, penicillins, certain anticonvulsants, and iodides) can induce serum sickness. Stevens-Johnson syndrome, such as that caused by sulfonamides, is a more severe form of immune vasculitis; manifestations include erythema multiforme, arthritis, nephritis, CNS abnormalities, and myocarditis.

Type IV, or delayed-hypersensitivity, reactions are mediated by sensitized T-lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

IDIOSYNCRATIC REACTIONS

Idiosyncrasy is an abnormal reactivity to a chemical that is peculiar to a given individual. The idiosyncratic response may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of chemicals. Certain idiosyncratic reactions can result from genetic polymorphisms that cause individual differences in drug pharmacokinetics; for example, an increased

incidence of peripheral neuropathy is seen in patients with inherited deficiencies in acetylation when isoniazid is used to treat tuberculosis. The polymorphisms also can be due to pharmacodynamic factors such as drug-receptor interactions (e.g., ~10% of black males develop a serious hemolytic anemia when they receive primaquine as an antimalarial therapy; such individuals have a deficiency of erythrocyte glucose-6-phosphate dehydrogenase [see Chapter 39]). Genetically determined resistance to the anticoagulant action of warfarin is due to an alteration in the vitamin K epoxide reductase, whereas inherent sensitivity to warfarin is due to polymorphisms in CYP2C9 (see Chapter 54).

INTERACTIONS BETWEEN CHEMICALS

Concurrent exposures may alter the pharmacokinetics of drugs by changing rates of absorption, the degree of protein binding, or the rates of biotransformation or excretion of one or both interacting compounds. The pharmacodynamics of chemicals can be altered by competition at the receptor; for example, atropine is used to treat organophosphate insecticide toxicity because it blocks muscarinic cholinergic receptors and prevents their stimulation by the excess acetylcholine accruing from inhibition of acetylcholinesterase by the insecticide. Nonreceptor pharmacodynamic drug interactions also can occur when two drugs have different mechanisms of action: Aspirin and heparin given together can cause unexpected bleeding. The response to combined toxicants thus may be equal to, greater than, or less than the sum of the effects of the individual agents.

Numerous terms describe pharmacological and toxicological interactions. An additive effect describes the combined effect of two chemicals that equals the sum of the effect of each agent given alone; the additive effect is the most common. A synergistic effect is one in which the combined effect of two chemicals exceeds the sum of the effects of each agent given alone. For example, both carbon tetrachloride and ethanol are hepatotoxins, but together they produce much more injury to the liver than expected from the sum of their individual effects. Potentiation is the increased effect of a toxic agent acting simultaneously with a nontoxic one. Isopropanol alone, for example, is not hepatotoxic; however, it greatly increases the hepatotoxicity of carbon tetrachloride. Antagonism is the interference of one chemical with the action of another. An antagonistic agent is often desirable as an antidote. Functional or physiological antagonism occurs when two chemicals produce opposite effects on the same physiological function. For example, this principle is applied to the use of intravenous infusion of dopamine to maintain perfusion of vital organs during certain severe intoxications characterized by marked hypotension. Chemical antagonism or inactivation is a reaction between two chemicals to neutralize their effects. For example, dimercaprol chelates various metals to decrease their toxicity (see Chapter 65). Dispositional antagonism is the alteration of the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence there is reduced. Antagonism at the receptor for the chemical entails the blockade of the effect of an agonist with an appropriate antagonist that competes for the same site. For example, the antagonist naloxone is used to treat respiratory depression produced by opioids (see Chapter 21).

INCIDENCE OF ACUTE POISONING

The true incidence of poisoning in the U.S. is not known, but in 2003, nearly 2.4 million cases were voluntarily reported to the American Association of Poison Control Centers. The number of actual poisonings almost certainly exceeds by far the number reported. Deaths in the U.S. owing to poisoning number more than 1100 per year. The incidence of poisoning in children younger than 5 years of age has decreased dramatically over the past four decades (e.g., there were no reported childhood deaths from aspirin in 2003, compared with ~140 deaths/year in the early 1960s). This favorable trend probably is due to safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

The substances involved most frequently in human poison exposures are shown in Table 64-1. Analgesic drugs lead the list, followed by two nondrug entries, cleaning agents and cosmetics. However, the top five categories of substances that produce deaths are drugs (Table 64-2). The categories most commonly associated with fatalities are analgesics (e.g., acetaminophen and salicylates), sedative-hypnotics/antipsychotics, antidepressants, stimulants and street drugs (including opiates and cocaine), and cardiovascular drugs (including digoxin and Ca²⁺ channel blockers). The most common categories of nonpharmaceutical poisons were alcohols (particularly methanol) and fumes (principally carbon monoxide). Most of the people who die from poisoning are adults, and the deaths often result from intentional rather than accidental exposure. Children younger than 6 years of age account for 52% of the poisoning incidents reported but only 3% of the deaths. Children between 1 and 2 years of age have the highest incidence of accidental poisoning. Fortunately, most of the substances available to these young children are not highly toxic. Iron and pesticides are the leading cause of pediatric accidental poisoning fatalities.

Table 64-1

Substances Most Frequently Involved in Human Poison Exposures in the U.S.

Substance	Number	%*
Analgesics	256,843	10.8
Cleaning substances	225,578	9.5
Cosmetics and personal care products	219,877	9.2
Foreign bodies	110,000	5.0
Sedative-hypnotics/antipsychotics	111,001	4.7
Topicals	105,815	4.4
Cough and cold preparations	100,612	4.2
Antidepressants	99,800	4.2
Bites/envenomations	98,585	4.1
Pesticides	96,112	4.0
Plants	84,578	3.6
Food products, food poisoning	75,813	3.2
Alcohols	69,215	2.9
Antihistamines	69,107	2.9
Antimicrobials	63,372	2.7
Cardiovascular drugs	61,056	2.6
Hydrocarbons	59,132	2.5
Chemicals	54,623	2.3

NOTE: Despite a high frequency of involvement, these substances are not necessarily the most toxic, but rather may only be the most readily accessible.

*Percentages are based on total number of known ingested substances in the U.S. rather than the total number of human exposure cases.

From Watson *et al.*, 2004.

Table 64-2

Categories with Largest Numbers of Deaths*

Category	Number	% of All Exposures
Analgesics	659	0.257
Sedative-hypnotics/antipsychotics	364	0.328
Antidepressants	318	0.316
Stimulants and street drugs	242	0.528
Cardiovascular drugs	181	0.295
Alcohols	139	0.200
Chemicals	50	0.091
Anticonvulsants	65	0.181
Gases and fumes	44	0.106
Antihistamines	71	0.103
Muscle relaxants	52	0.260
Hormones and hormone antagonists	33	0.062
Cleaning substances	33	0.013
Automotive products	30	0.213
Cough and cold preparations	22	0.022
Pesticides	18	0.019

*This list is for deaths in the U.S. From Watson *et al.*, 2004.

The incidence of serious and fatal adverse drug reactions (ADRs) in U.S. hospitals is high. An estimated 2 million hospitalized patients have serious ADRs each year, and about 100,000 suffer fatal ADRs. If this estimate is correct, then more people die annually from medication errors than from highway accidents, breast cancer, or AIDS.

MAJOR SOURCES OF INFORMATION ON POISONING

The web site of the American Association of Poison Control Centers (<http://www.aapcc.org/>) lists 78 members, including 11 regional centers. Valuable information can be obtained from these centers by telephone (800-222-1222). The National Library of Medicine maintains a very informative Web site on toxicology and environmental health (<http://sis.nlm.nih.gov/Tox/ToxMain.html>), including a link to ToxNet (<http://toxnet.nlm.nih.gov/>), a cluster of databases on toxicology, hazardous chemicals, and related areas. Pharmacology textbooks are a good source of information on the treatment of poisoning by drugs.

PREVENTION AND TREATMENT OF POISONING

For clinical purposes, toxic agents can be divided into two classes: those for which a specific treatment or antidote exists and those for which there is no specific treatment. For the vast majority of drugs and other chemicals, there is no specific treatment; symptomatic medical care that supports vital functions is the only strategy.

Supportive therapy is the mainstay of the treatment of drug poisoning. The adage, “Treat the patient, not the poison,” remains the most basic and important principle of clinical toxicology. Maintenance of respiration and circulation takes precedence. Serial measurement and charting of vital signs and important reflexes help to judge the progress of intoxication, response to therapy, and need for additional treatment. This monitoring usually requires hospitalization. The classification in Table 64–3 helps to define the severity of CNS intoxication. Treatment with large doses of stimulants and sedatives often causes more harm than the poison. Chemical antidotes should be used judiciously; heroic measures seldom are necessary.

Treatment of acute poisoning must be prompt. The first goal is to maintain the vital functions if their impairment is imminent. The second goal is to keep the concentration of poison in the crucial tissues as low as possible by preventing absorption and enhancing elimination. The third goal is to combat the pharmacological and toxicological effects at the effector sites.

Prevention of Further Absorption of Poison

EMESIS The routine induction of emesis in emergency rooms is declining. Although emesis still may be indicated for immediate intervention after poisoning by oral ingestion of chemicals, it is

Table 64–3

Signs and Symptoms of CNS Intoxication

Degree of Severity	Characteristics
<i>Depressants</i>	
0	Asleep, but can be aroused and can answer questions
I	Semicomatose, withdraws from painful stimuli, reflexes intact
II	Comatose, does not withdraw from painful stimuli, no respiratory or circulatory depression, most reflexes intact
III	Comatose, most or all reflexes absent, but without depression of respiration or of circulation
IV	Comatose, reflexes absent, respiratory depression with cyanosis or circulatory failure and shock, or both
<i>Stimulants</i>	
I	Restlessness, irritability, insomnia, tremor, hyperreflexia, sweating, mydriasis, flushing
II	Confusion, hyperactivity, hypertension, tachypnea, tachycardia, extrasystoles, sweating, mydriasis, flushing, mild hyperpyrexia
III	Delirium, mania, self-injury, marked hypertension, tachycardia, arrhythmias, hyperpyrexia
IV	As in III, plus convulsions, coma, and circulatory collapse

contraindicated in certain situations: (1) if the patient has ingested a corrosive poison, such as a strong acid or alkali (e.g., drain cleaners), emesis increases the likelihood of gastric perforation and further necrosis of the esophagus; (2) if the patient is comatose or in a state of stupor or delirium, emesis may cause aspiration of the gastric contents; (3) if the patient has ingested a CNS stimulant, further stimulation associated with vomiting may precipitate convulsions; and (4) if the patient has ingested a petroleum distillate (e.g., kerosene, gasoline, or petroleum-based liquid furniture polish), regurgitated hydrocarbons can be aspirated readily and cause chemical pneumonitis. In contrast, emesis *should* be considered if the ingested solution contains potentially dangerous compounds, such as pesticides.

The ability of various hydrocarbons to produce pneumonitis is generally inversely proportional to their viscosity: If the viscosity is high, as with oils and greases, the risk is limited; if the viscosity is low, as with mineral seal oil found in liquid furniture polishes, the risk of aspiration is high.

Vomiting can be induced mechanically by stroking the posterior pharynx. However, this technique is not as effective as the administration of ipecac or apomorphine.

IPECAC The most common household emetic is syrup of ipecac (not ipecac fluid extract, which is 14 times more potent and may cause fatalities). Syrup of ipecac is available OTC in 15 and 30 mL containers. The drug can be given orally, but it takes 15–30 minutes to produce emesis (comparable to the time required for adequate gastric lavage). The oral dose is 15 mL in children from 6 months to 12 years of age and 30 mL in older children and adults. Because emesis may not occur when the stomach is empty, administration of ipecac should be followed by a drink of water.

The current consensus is *that syrup of ipecac should not be administered routinely in the management of poisoned patients*. In studies with various marker substances, the beneficial effects of ipecac-induced emesis were highly variable and diminished rapidly with time. In addition, initial use of ipecac in fact may be counterproductive by reducing the efficacy of other, later, and presumably more effective treatments such as use of activated charcoal, oral antidotes, and whole bowel irrigation (WBI). Ipecac may be indicated when it can be administered to conscious, alert patients within 60 minutes of poisoning.

Ipecac acts as an emetic because of its local irritant effect on the enteric tract and its effect on the chemoreceptor trigger zone (CTZ) in the area postrema of the medulla. Ipecac is not benign; it can produce toxic effects on the heart (due to emetine); this usually is not a problem with the dose used for emesis. If emesis does not occur, ipecac should be removed by gastric lavage. Chronic abuse of ipecac for weight reduction can result in cardiomyopathy, ventricular fibrillation, and death.

Apomorphine

Apomorphine stimulates the CTZ and causes emesis. The drug is unstable in solution and must be prepared just prior to use. Apomorphine is not effective orally and must be given parenterally, usually subcutaneously, 6 mg for adults and 0.06 mg/kg for children. Vomiting ensues in 3–5 minutes. Subcutaneous administration can be an advantage with an uncooperative patient. Because apomorphine is a respiratory depressant, it should not be used if the patient has been poisoned by a CNS depressant or if the patient's respiration is slow and labored. At present, apomorphine is used rarely as an emetic.

GASTRIC LAVAGE Gastric lavage is accomplished by inserting a tube into the stomach and washing the stomach with water, normal saline, or one-half normal saline to remove the unabsorbed poison. The procedure should be performed as soon as possible, but only if vital functions are adequate or supportive procedures have been implemented. The contraindications to this procedure generally are the same as for emesis, and there is the additional potential complication of mechanical injury to the throat, esophagus, and stomach. The current consensus amongst clinical toxicologists is that *gastric lavage should not be used routinely in the management of the poisoned patient but should be reserved for patients who have ingested a potentially life-threatening amount of poison and when the procedure can be undertaken within 60 minutes of ingestion*.

CHEMICAL ADSORPTION Activated charcoal avidly adsorbs many drugs and chemicals on the surfaces of the charcoal particles, thereby preventing absorption and toxicity. Charcoal does not absorb all chemicals (e.g., alcohols, hydrocarbons, metals, and corrosives). The effectiveness of charcoal also depends on the time since the ingestion and on the dose of charcoal; one should attempt to achieve a charcoal–drug ratio of at least 10:1. Activated charcoal also can interrupt the enterohepatic circulation of drugs and enhance the net rate of diffusion of the chemical from the

body into the GI tract. For example, serial doses of activated charcoal have been shown to enhance the elimination of *theophylline* and phenobarbital.

During the last two decades, there has been an increase in the use of activated charcoal and a corresponding decrease in the use of ipecac-induced emesis and gastric lavage in the treatment of poisoning. Studies in patients with drug overdoses and in normal subjects fail to show a benefit of treatment with ipecac or lavage plus activated charcoal as compared with charcoal alone. Based on these findings, American and European clinical toxicologists issued a position paper in 1999 on the use of multidose-activated charcoal in treatment of acute poisoning. They concluded that while experimental and clinical trials demonstrate that elimination of some drugs can be enhanced by treatment with activated charcoal, rarely has charcoal been demonstrated to reduce morbidity or mortality in a controlled study. The position paper recommends consideration of activated charcoal treatment only if a patient has ingested a life-threatening amount of *carbamazepine*, *dapsone*, phenobarbital, *quinine*, or *theophylline*.

Activated charcoal usually is prepared as a mixture of at least 50 g (about 10 heaping table-spoons) in a glass of water. The mixture is then administered either orally or via a gastric tube. Because most poisons do not appear to desorb from the charcoal if charcoal is present in excess, the adsorbed poison need not be removed from the GI tract. Charcoal also may adsorb and decrease the effectiveness of specific antidotes.

Activated charcoal must be distinguished from the so-called universal antidote, which consists of two parts burned toast (not activated charcoal), one part tannic acid (strong tea), and one part magnesium oxide. In practice, the universal antidote is ineffective.

CHEMICAL INACTIVATION

Antidotes can change the chemical nature of a poison by rendering it less toxic or preventing its absorption. Formaldehyde poisoning can be treated with ammonia to promote formation of hexamethylenetetramine; sodium formaldehyde sulfoxylate can convert mercuric ion to the less soluble metallic mercury; and sodium bicarbonate converts ferrous iron to ferrous carbonate, which is poorly absorbed. Chemical inactivation techniques seldom are used today, however, because valuable time may be lost, whereas emetics, activated charcoal, and gastric lavage are rapid and effective. The treatment of choice for ingestion of either acids or alkalis is dilution with water or milk. Similarly, burns produced by acid or alkali on the skin should be treated with copious amounts of water.

PURGATION

The rationale for using an osmotic cathartic is to minimize absorption by hastening the passage of the toxicant through the GI tract. Few, if any, controlled clinical data are available on the effectiveness of cathartics in the treatment of poisoning. Cathartics generally are considered harmless unless the poison has injured the GI tract. Cathartics are indicated after the ingestion of enteric-coated tablets, when the time after ingestion is >1 hour, and for poisoning by volatile hydrocarbons. Sorbitol is the most effective, but sodium sulfate and magnesium sulfate also are used; all act promptly and usually have minimal toxicity. However, $MgSO_4$ should be used cautiously in patients with renal failure or in those likely to develop renal dysfunction, and Na^+ -containing cathartics should be avoided in patients with congestive heart failure.

Whole-bowel irrigation (WBI) promotes defecation and eliminates the entire contents of the intestines. This technique uses a high-molecular-weight polyethylene glycol and isomolar electrolyte solution (PEG-E S) that does not alter serum electrolytes. It is available commercially as GOLYTELY and COLYTE. The current consensus amongst clinical toxicologists is that WBI should not be used routinely in the management of the poisoned patient. WBI may be considered in cases of acute poisoning by sustained-release or enteric-coated drugs and possibly toxic ingestions of iron, lead, zinc, or packets of illicit drugs.

INHALATION AND DERMAL EXPOSURE TO POISONS

When a poison has been inhaled, the first priority is to remove the patient from the source of exposure. Similarly, if the skin has had contact with a poison, it should be washed thoroughly with water. Contaminated clothing should be removed. Initial treatment of all types of chemical injuries to the eye must be rapid; thorough irrigation of the eye with water for 15 minutes should be performed immediately.

Enhanced Elimination of the Poison

BIOTRANSFORMATION

Many chemicals are biotransformed into toxic forms. Thus, inhibition of biotransformation should decrease the toxicity. For example, ethanol is used to inhibit the conversion of methanol to its

highly toxic metabolite, formic acid, by alcohol dehydrogenase (see Chapter 22). Acetaminophen is converted by the CYP system to an electrophilic metabolite that is detoxified by glutathione, a cellular nucleophile (Figure 64–1). Acetaminophen does not cause hepatotoxicity until glutathione is depleted, whereupon the reactive metabolite binds to essential macromolecular constituents of the hepatocyte, resulting in cell death. The liver can be protected by maintenance of the concentration of glutathione, which can be accomplished by the administration of N-acetylcysteine (see Chapter 26).

Some drugs are detoxified by conjugation with glucuronic acid or sulfate before elimination from the body, and the availability of the endogenous cosubstrates for conjugation may limit the rate of elimination; such is the case in the detoxication of acetaminophen. Repletion of these compounds will provide an additional mechanism to treat poisoning. For instance, detoxication of cyanide by conversion to thiocyanate can be accelerated by the administration of thiosulfate.

BILIARY EXCRETION

The liver excretes many drugs and other foreign chemicals into bile, but little is known about efficient ways to enhance biliary excretion of xenobiotics for the treatment of acute poisoning. Inducers of microsomal enzyme activity enhance biliary excretion of some xenobiotics, but the effect is slow in onset.

URINARY EXCRETION

Drugs and poisons are excreted into the urine by glomerular filtration and active tubular secretion (see Chapter 28); they can be reabsorbed into the blood if they are in a lipid-soluble form that will penetrate the tubule or if there is an active mechanism for their transport.

There are no methods known to accelerate the active transport of poisons into urine, and enhancement of glomerular filtration is not a practical means to facilitate elimination of toxicants. However, passive reabsorption from the tubular lumen can be altered. Diuretics inhibit reabsorption by decreasing the concentration gradient of the drug from the lumen to the tubular cell and by increasing flow through the tubule. Furosemide is used most often, but osmotic diuretics also are employed (see Chapter 28). Forced diuresis should be used with caution, especially in patients with renal, cardiac, or pulmonary complications.

Nonionized compounds are reabsorbed far more rapidly than ionized polar molecules; therefore, a shift from the nonionized to the ionized species of the toxicant by alteration of the pH of the tubular fluid may hasten elimination (see Chapter 1). Acidic compounds such as phenobarbital and salicylates are cleared much more rapidly in alkaline than in acidic urine. Clinical toxicologists have issued a position paper on the use of urine alkalization in treatment of acute poisoning. Urine alkalization increases the urine elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, phenobarbital, and salicylate. However, urine alkalization is recommended as first-line treatment only for patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urine alkalization and high urine flow (approximately 600 mL/h) should also be considered in patients with severe 2,4-dichlorophenoxyacetic acid and mecoprop poisoning. Urine alkalization is not recommended as first-line treatment in cases of phenobarbital poisoning because multiple-dose activated charcoal has been shown to be superior. Urine alkalization is contraindicated in the case of compromised renal function or failure. Hypokalemia is the most common complication but can be corrected by giving potassium supplements. Intravenous sodium bicarbonate is used to alkalize the urine.

Renal excretion of basic drugs such as amphetamine theoretically can be enhanced by acidification of the urine. Acidification can be accomplished by the administration of ammonium chloride or ascorbic acid. Urinary excretion of an acidic compound is particularly sensitive to changes in urinary pH if its pK_a is within the range of 3.0–7.5; for bases, the corresponding pH range is 7.5–10.5.

DIALYSIS

Hemodialysis or hemoperfusion usually has limited use in the treatment of intoxication with chemicals. However, under certain circumstances, such procedures can be lifesaving. The utility of dialysis depends on the amount of poison in the blood relative to the total-body burden. Thus, if a poison has a large volume of distribution, as is the case for the tricyclic antidepressants, the plasma will contain too little of the compound for effective removal by dialysis. Extensive binding of the compound to plasma proteins impairs dialysis greatly. The elimination of a toxicant by dialysis also depends on dissociation of the compound from binding sites in tissues; for some chemicals, this rate may be slow and limiting.

Although peritoneal dialysis requires a minimum of personnel and can be started as soon as the patient is admitted to the hospital, it is too inefficient to be of value for the treatment of acute

intoxications. Hemodialysis (extracorporeal dialysis) is much more effective than peritoneal dialysis and may be essential in a few life-threatening intoxications, such as with methanol, ethylene glycol, and salicylates.

Passage of blood through a column of charcoal or adsorbent resin (hemoperfusion) is a technique for the extracorporeal removal of a poison. Because of the high adsorptive capacity and affinity of the material in the column, some chemicals that are bound to plasma proteins can be removed. The principal side effect of hemoperfusion is depletion of platelets.

ANTAGONISM OR CHEMICAL INACTIVATION OF AN ABSORBED POISON

If a patient is poisoned with a compound that acts as an agonist at a receptor for which a specific blocking agent is available, administration of the receptor antagonist may be highly effective. Functional antagonism also can be valuable for support of the patient's vital functions. For example, anticonvulsant drugs are used to treat chemically induced convulsions. However, drugs that stimulate antagonistic physiological mechanisms are not always of clinical value and may even decrease survival because it often is difficult to titrate the effect of one drug against another when the two act on opposing systems. An example of such a complication is the use of CNS stimulants to attempt to reverse respiratory depression. Convulsions are a typical complication of such therapy; mechanical support of respiration is preferred. In addition, the duration of action of the poison and the antidote may differ, sometimes leading to poisoning with the antidote.

Specific chemical antagonists of a toxicant, such as opioid antagonists (see Chapter 21) and atropine as an antagonist of pesticide-induced acetylcholine excess (see Chapter 7), are rare. A recently approved antagonist is fomepizole, an inhibitor of alcohol dehydrogenase, approved for treatment for poisoning by ethylene glycol and methanol. Chelating agents with high selectivity for certain metal ions are used more commonly (see Chapter 65). Antibodies offer the potential for the production of specific antidotes; a notable example is the use of purified digoxin-specific Fab fragments of antibodies in the treatment of potentially fatal cases of poisoning with digoxin (see Chapter 33). The development of human monoclonal antibodies directed against specific toxins has significant potential.

HEAVY METALS AND HEAVY-METAL ANTAGONISTS

Heavy metals exert their toxic effects by combining with one or more reactive groups (ligands) essential for normal physiological functions. Heavy-metal antagonists (*chelating agents*) are designed specifically to compete with these groups for the metals and thereby prevent or reverse toxic effects and enhance the excretion of metals.

HEAVY-METAL ANTAGONISTS

A *chelate* is a complex formed between a metal and a compound that contains two or more potential ligands. The product of such a reaction is a heterocyclic ring. Five- and six-membered chelate rings are the most stable, and polydentate (multiligand) chelators typically form more stable chelates than chelators with only one ligand atom.

The stability of chelates varies with the metal and the ligand atoms. For example, lead and mercury have greater affinities for sulfur and nitrogen than for oxygen ligands; calcium, however, has a greater affinity for oxygen than for sulfur and nitrogen. These differences in affinity serve as the basis for selectivity of action of a chelating agent in the body.

The effectiveness of a chelating agent for the treatment of poisoning by a heavy metal depends on numerous factors: the relative affinity of the chelator for the heavy metal as compared with essential body metals, the distribution of the chelator in the body as compared with the distribution of the metal, and the capacity of the chelator to remove the metal from the body once chelated. Consider the properties of an ideal chelating agent: high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, capacity to form nontoxic complexes with toxic metals, ability to retain chelating activity at the pH of body fluids, and ready excretion of the chelate. A low affinity for Ca^{2+} also is desirable because Ca^{2+} in plasma is readily available for chelation, and a drug might produce hypocalcemia despite high affinity for heavy metals. A therapeutic chelating agent must bind the metal more avidly than endogenous ligands bind the metal. The large number of endogenous ligands is a formidable barrier to the effectiveness of a chelating agent. Observations *in vitro* on chelator–metal interactions provide only a rough guide to the treatment of heavy-metal poisoning. Empirical observations *in vivo* are necessary to determine the clinical utility of a chelator.

Edetate Calcium Disodium

Ethylenediaminetetraacetic acid (EDTA) is a polycarboxylic acid chelator; its sodium salt (*edetate disodium*, Na_2EDTA), and a number of closely related compounds chelate many divalent and trivalent metals. The cation used to make a water-soluble salt of EDTA has an important role in the toxicity of the chelator. Na_2EDTA causes hypocalcemic tetany. However, *edetate calcium disodium* (CaNa_2EDTA) can be used for treatment of poisoning by metals that have higher affinity for the chelating agent than does Ca^{2+} .

MECHANISM OF ACTION

The pharmacological effects of CaNa_2EDTA result from formation of chelates with divalent and trivalent metals in the body. Accessible metal ions (both exogenous and endogenous) with an affinity for CaNa_2EDTA that is higher than that of Ca^{2+} will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells; its volume of distribution approximates extracellular fluid space. Experimental studies in mice have shown that administration of CaNa_2EDTA mobilizes several endogenous metallic cations, including those of zinc, manganese, and iron. The main therapeutic use of CaNa_2EDTA is in the treatment of metal intoxications, especially lead intoxication (see below).

CaNa_2EDTA is available as edetate calcium disodium (CALCIUM DISODIUM VERSENATE). Intramuscular administration of CaNa_2EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa_2EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with CaNa_2EDTA . However, in patients with lead encephalopathy and increased intracranial pressure, excess fluids must be avoided. In such cases, conservative replacement of fluid is advised, and intramuscular administration of CaNa_2EDTA is recommended.

Indications: Lead Poisoning

The successful use of CaNa_2EDTA in the treatment of lead poisoning is due, in part, to the capacity of lead to displace calcium from the chelate. Enhanced mobilization and excretion of lead indicate that the metal is accessible to EDTA. Bone provides the primary source of lead that is chelated by CaNa_2EDTA . After such chelation, lead is redistributed from soft tissues to the skeleton.

Mercury poisoning, by contrast, does not respond to the drug despite the fact that mercury displaces calcium from CaNa_2EDTA in vitro. Mercury is unavailable to the chelate, perhaps because it is too tightly bound by $-\text{SH}$ groups or sequestered in body compartments that are not penetrated by CaNa_2EDTA .

Although the lay press has reported that chelation therapy with CaNa_2EDTA could minimize development of atherosclerotic plaques (which can accumulate calcium deposits), such use of CaNa_2EDTA is without therapeutic rationale and not efficacious.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Less than 5% of CaNa_2EDTA is absorbed from the GI tract. After intravenous administration, CaNa_2EDTA disappears from the circulation with a $t_{1/2}$ of 20–60 minutes. In blood, all of the drug is found in plasma. About 50% is excreted in urine in 1 hour and >95% in 24 hours. For this reason, adequate renal function is necessary for successful therapy. Renal clearance of the compound in dogs equals that of inulin, and glomerular filtration accounts entirely for urinary excretion. Altering either the pH or the rate of flow of urine has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids, but very little gains access to the spinal fluid (5% of the plasma concentration).

TOXICITY

Rapid intravenous administration of Na_2EDTA causes hypocalcemic tetany. However, a slow infusion (<15 mg/min) administered to a normal individual elicits no symptoms of hypocalcemia because of the ready availability of extracirculatory stores of Ca^{2+} . In contrast, CaNa_2EDTA can be administered intravenously in relatively large quantities with no untoward effects because the change in the concentration of Ca^{2+} in the plasma and total body is negligible.

Renal Toxicity

The principal toxic effect of CaNa_2EDTA is on the kidney. Repeated large doses of the drug cause hydropic vacuolization of the proximal tubule, loss of the brush border, and eventually, degeneration of proximal tubular cells. Changes in distal tubules and glomeruli are less conspicuous. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly on cessation of treatment. Renal toxicity may be related to the large amounts of chelated metals that transit the renal tubule in a relatively short period during drug therapy. Some dissociation of chelates may occur because of competition for the metal by physiological ligands or because of pH changes in the cell or the lumen of the tubule. However, a more likely mechanism of toxicity may be interaction between the chelator and endogenous metals in proximal tubular cells.

Other Side Effects

Other less serious side effects have been reported with use of CaNa_2EDTA , including malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever. This, in turn, may be followed by severe myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. Other possible undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B_6 deficiency; transitory hypotension; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

Pentetic Acid (DTPA)

Diethylenetriaminepentaacetic acid (DTPA) is a polycarboxylic acid chelator with a somewhat greater affinity for most heavy metals than EDTA and with a spectrum of clinical effectiveness similar to that of EDTA. Because of its relatively greater affinity for metals, DTPA has been tried in cases of heavy-metal poisoning that do not respond to EDTA, particularly poisoning by radioactive metals. Unfortunately, success has been limited probably because DTPA also has limited access to intracellular sites of metal storage. Because DTPA rapidly binds Ca^{2+} , CaNa_2DTPA is employed. The use of DTPA is investigational.

Dimercaprol

Dimercaprol (2,3-dimercaptopropanol) was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, *British antilewisite* (BAL).

Arsenicals and other heavy metals form a very stable and relatively nontoxic chelate ring with the dimercaprol. It is an oily fluid with a pungent, disagreeable odor typical of mercaptans. Because of its instability in aqueous solutions, peanut oil is the solvent employed in pharmaceutical preparations. Dimercaprol and related thiols are readily oxidized.

MECHANISM OF ACTION The pharmacological actions of dimercaprol result from formation of chelation complexes between its -SH groups and metals. The molecular properties of the dimercaprol-metal chelate have considerable practical significance. With metals such as mercury, gold, and arsenic, the strategy is to attain a stable complex to promote elimination of the metal. Dissociation of the complex and oxidation of dimercaprol can occur *in vivo*. Furthermore, the sulfur-metal bond may be labile in the acidic tubular urine, which may increase delivery of metal to renal tissue and increase toxicity. The dosage regimen therefore is designed to maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL-metal) complex and its rapid excretion. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated fractional dosage until the heavy metal can be excreted.

Dimercaprol is much more effective when given as soon as possible after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol antagonizes the biological actions of metals that form mercaptides with essential cellular -SH groups, principally arsenic, gold, and mercury. It also is used in combination with CaNa_2EDTA to treat lead poisoning, especially when evidence of lead encephalopathy exists. Intoxication by selenites, which also oxidize sulfhydryl enzymes, is not influenced by dimercaprol.

ABSORPTION, DISTRIBUTION, AND EXCRETION Dimercaprol cannot be administered orally; it is given by deep intramuscular injection as a 100 mg/mL solution in peanut oil; thus it should not be used in patients who are allergic to peanuts or peanut products. Peak concentrations in blood are attained in 30–60 minutes. The $t_{1/2}$ is short, and metabolic degradation and excretion are essentially complete within 4 hours.

TOXICITY The administration of dimercaprol produces a number of side effects that usually are more alarming than serious. Reactions to dimercaprol occur in ~50% of subjects receiving 5 mg/kg intramuscularly. The effects of repeated administration of this dose are not cumulative if an interval of at least 4 hours elapses between injections. One of the most consistent responses to dimercaprol is a rise in blood pressure, accompanied by tachycardia. The rise in pressure may be as great as 50 mm Hg in response to the second of 2 doses (5 mg/kg) given 2 hours apart. The pressure rises immediately, but returns to normal within 2 hours.

Other signs and symptoms of dimercaprol toxicity, many of which tend to parallel the change in blood pressure in time and intensity, are, in approximate order of frequency: nausea and vomiting; headache; a burning sensation in the lips, mouth, and throat; and a feeling of constriction, sometimes pain, in the throat, chest, or hands; conjunctivitis, blepharospasm, lacrimation, rhinorrhea, and salivation; tingling of the hands; a burning sensation in the penis; sweating of the forehead, hands, and other areas; abdominal pain; and the occasional appearance of painful sterile abscesses at the injection site. Symptoms often are accompanied by a feeling of anxiety and unrest. Because the dimercaprol-metal complex breaks down easily in an acidic medium, production of alkaline urine protects the kidney during therapy. Children react as do adults, although ~30% also may experience a fever that disappears on withdrawal of the drug. A transient reduction in the percentage of polymorphonuclear leukocytes may be observed. Dimercaprol also may cause hemolytic anemia in patients deficient in glucose-6-phosphate dehydrogenase. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this is a result of arsenic poisoning.

Succimer

Succimer (2,3-dimercaptosuccinic acid, CHEMET) is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify both the distribution and chelating spectrum of the drug. After its absorption in humans, succimer is biotransformed to a mixed disulfide with cysteine.

Succimer produces a lead diuresis with a subsequent lowering of blood lead levels and attenuation of the untoward biochemical effects of lead, manifested by normalization of δ -aminolevulinic acid (δ -ALA) dehydrase activity. The succimer-lead chelate also is eliminated in bile and enters enterohepatic circulation.

A desirable feature of succimer is that it does not significantly mobilize essential metals such as zinc, copper, or iron. Animal studies suggest that succimer is effective as a chelator of arsenic, cadmium, mercury, and other metals. Succimer has been approved in the U.S. for treatment of children with blood lead levels $>45 \mu\text{g/dL}$.

Toxicity with succimer is less than that with dimercaprol, perhaps because its relatively lower lipid solubility minimizes its uptake into cells. Nonetheless, transient elevations in hepatic transaminases are observed following treatment with succimer. The most commonly reported adverse effects of succimer treatment are nausea, vomiting, diarrhea, and loss of appetite. Rashes also have been reported that may necessitate discontinuation of therapy.

Penicillamine

The D-isomer of penicillamine, D- β , β -dimethylcysteine, is used clinically, although the L-isomer also forms chelation complexes. Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine.

ABSORPTION, DISTRIBUTION, AND EXCRETION

Penicillamine is well absorbed (40–70%) from the GI tract and therefore has a decided advantage over many other chelating agents. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained 1–3 hours after administration. Unlike cysteine, its nonmethylated parent compound, penicillamine, is somewhat resistant to attack by cysteine desulfhydrase or L-amino acid oxidase and is relatively stable in vivo. Hepatic biotransformation is responsible for most of the degradation of penicillamine, and very little is excreted unchanged. Metabolites are found in both urine and feces.

THERAPEUTIC USES

Penicillamine (CUPRIMINE, DEPEN) is available for oral administration. For chelation therapy, the usual adult dose is 11.5 g/day in 4 divided doses (see sections under individual metals). The drug should be given on an empty stomach to avoid interference by metals in food.

In addition to its use as a chelating agent for the treatment of copper, mercury, and lead poisoning, penicillamine is used in Wilson's disease (hepatolenticular degeneration owing to an excess of copper), cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson's disease, 1–2 g/day usually is administered in 4 doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate. N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury presumably because it is even more resistant to metabolism.

The rationale for the use of penicillamine in cystinuria is that penicillamine reacts with the poorly soluble cysteine in a thiol–disulfide exchange reaction and forms a relatively water-soluble cysteine–penicillamine mixed disulfide. In cystinuria, the urinary excretion of cystine is used to adjust dosage, although 2 g/day in 4 divided doses usually is employed.

The mechanism of action of penicillamine in rheumatoid arthritis remains uncertain, although suppression of the disease may result from marked reduction in concentrations of immunoglobulin (IgM) rheumatoid factor. A single daily dose of 125–250 mg usually is used to initiate therapy, with dosage increases at intervals of 1–3 months as necessary to a typical range of 500–750 mg/day. Because of toxicity, the drug is used rarely today in this setting.

Other experimental uses of penicillamine include the treatment of primary biliary cirrhosis and scleroderma. The mechanism of action of penicillamine in these diseases also may involve effects on immunoglobulins and immune complexes.

TOXICITY

With long-term use, penicillamine induces several cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, and other less serious reactions, such as dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. The hematological system also may be affected severely; reactions include leukopenia, aplastic anemia, and agranulocytosis. These may occur at any time during therapy, and they may be fatal. Patients obviously must be monitored carefully. Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to the nephrotic syndrome with membranous glomerulopathy. More rarely, fatalities have been reported from Goodpasture's syndrome. Toxicity to the pulmonary system is uncommon, but severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine. Less serious side effects include nausea, vomiting,

diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy, a previous history of penicillamine-induced agranulocytosis or aplastic anemia, or the presence of renal insufficiency.

Trientine

Penicillamine is the drug of choice for treatment for Wilson's disease. However, the drug produces undesirable effects (*see above*) and some patients become intolerant. For these individuals, *trientine* (triethylenetetramine dihydrochloride) is an acceptable alternative. Trientine is an effective cupruritic agent (although possibly less potent than penicillamine) that is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in 2–4 divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 hours of each other.

Deferoxamine

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. Deferoxamine has the desirable properties of a remarkably high affinity for ferric iron ($K_a = 10^{31} M^{-1}$) coupled with a very low affinity for calcium ($K_a = 10^2 M^{-1}$). Studies *in vitro* have shown that it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

Deferoxamine (*deferoxamine mesylate*, DESFERAL MESYLATE) is poorly absorbed after oral administration, and parenteral administration is required in most cases. For severe iron toxicity (serum iron levels $>500 \mu\text{g/dL}$), the intravenous route is preferred. The drug is administered at 10–15 mg/kg/h by constant infusion. Faster rates of infusion (45 mg/kg/h) have been used in a few cases; rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum iron 350–500 $\mu\text{g/dL}$) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with the intramuscular route.

For chronic iron intoxication (*e.g.*, thalassemia), an intramuscular dose of 0.5–1.0 g/day is recommended, although continuous subcutaneous administration (1–2 g/day) is almost as effective as intravenous administration. When blood is being transfused to patients with thalassemia, 2 g deferoxamine (per unit of blood) should be given by slow intravenous infusion (rate not to exceed 15 mg/kg/h) during the transfusion but not by the same intravenous line. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine also has been used for the chelation of aluminum in dialysis patients. Deferoxamine is metabolized principally by plasma enzymes, but the pathways have not been defined. The drug also is excreted readily in the urine.

Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A "pulmonary syndrome" has been associated with high-dose (10–25 mg/kg/h) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent manifestations. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

An orally effective iron chelator now under clinical investigation, *deferiprone* (1,2-dimethyl-3-hydroxypyridin-4-one), may be of value in patients with thalassemia major who are unable or unwilling to receive deferoxamine. Combination therapy with deferoxamine also is under investigation.

HEAVY METAL TOXICITY

Lead Poisoning

Through natural occurrence and its industrial use, lead is ubiquitous in the environment. The removal of tetraethyl lead from gasoline has resulted in a decline in blood levels from 13 $\mu\text{g/dL}$ in the 1980s to $<5 \mu\text{g/dL}$ in the general U.S. population. However, many children living in central portions of large cities still have blood lead concentrations $>10 \mu\text{g/dL}$. The primary sources of environmental exposure to lead are leaded paint and drinking water; most of the overt toxicity from lead results from environmental and industrial exposures.

ACUTE LEAD POISONING

Acute lead poisoning is relatively infrequent and follows ingestion of acid-soluble lead compounds or inhalation of lead vapors. Local actions in the mouth produce marked astringency, thirst, and a metallic taste. Nausea, abdominal pain, and vomiting ensue. The vomitus may be milky from the presence of lead chloride. Although the abdominal pain is severe, it is unlike that of chronic poisoning. Stools may be black from lead sulfide, and there may be diarrhea or constipation. If large amounts of lead are absorbed rapidly, a shock syndrome may develop as the result of massive GI loss of fluid. Acute CNS symptoms include paresthesias, pain, and muscle weakness. An acute hemolytic crisis sometimes causes severe anemia and hemoglobinuria. The kidneys are damaged, and oliguria and urinary changes are evident. Death may occur in 1–2 days. If the patient survives the acute episode, characteristic signs and symptoms of chronic lead poisoning are likely to appear.

CHRONIC LEAD POISONING

Signs and symptoms of plumbism (lead poisoning) include GI, neuromuscular, CNS, hematological, renal, and other disturbances, occurring separately or in combination. The neuromuscular and CNS syndromes usually result from intense exposure, whereas the GI syndrome more commonly reflects a very slowly and insidiously developing intoxication. The CNS syndrome, or lead encephalopathy, is more common among children; the GI syndrome is more prevalent in adults. The CNS syndrome is the most serious manifestation of lead poisoning; early signs include clumsiness, vertigo, ataxia, falling, headache, insomnia, restlessness, and irritability. As the encephalopathy develops, the patient may first become excited and confused; delirium with repetitive tonic-clonic convulsions or lethargy and coma follow. Vomiting, a common sign, usually is projectile. Visual disturbances also are present. The mortality rate among patients who develop cerebral involvement is ~25%. When chelation therapy is begun after the symptoms of acute encephalopathy appear, ~40% of survivors have neurological sequelae (e.g., mental retardation, electroencephalographic abnormalities or frank seizures, cerebral palsy, optic atrophy, or dystonia musculorum deformans).

Exposure to lead occasionally produces clear-cut progressive mental deterioration in children, with normal development during the first 12–18 months of life or longer, followed by a steady loss of motor skills and speech; they may have severe hyperkinetic and aggressive behavior disorders and a poorly controllable convulsive disorder. The lack of sensory perception severely impairs learning. Elevated blood lead levels in infancy and early childhood later may be manifested as decreased attention span, reading disabilities, and failure to graduate from high school. Most studies report a 2–4-point IQ deficit for each $\mu\text{g}/\text{dL}$ increase in blood lead within the range of 5–35 $\mu\text{g}/\text{dL}$. Blood lead concentrations ≥ 10 $\mu\text{g}/\text{dL}$ indicate excessive absorption of lead in children and constitute grounds for environmental assessment, cleanup, and/or intervention. Chelation therapy should be considered when blood lead concentrations exceed 25 $\mu\text{g}/\text{dL}$. The CDC recommends universal screening of children beginning at 6 months of age.

In the absence of a positive history of abnormal exposure to lead, the diagnosis of lead poisoning is missed easily because the signs and symptoms of lead poisoning are shared by other diseases. For example, the signs of encephalopathy may resemble those of various degenerative conditions. Physical examination does not easily distinguish lead colic from other abdominal disorders. Clinical suspicion should be confirmed by determinations of the concentration of lead in blood and protoporphyrin in erythrocytes. A common hematological manifestation of chronic lead intoxication is a hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to that resulting from iron deficiency. The anemia is thought to result from two factors: a decreased life span of the erythrocytes and an inhibition of heme synthesis. Lead at low concentrations decreases heme synthesis at several enzymatic steps (Figure 65–1). This leads to buildup of the diagnostically important substrates δ -ALA, coproporphyrin (both measured in urine), and zinc protoporphyrin (measured in the red cell as erythrocyte protoporphyrin). For children, the erythrocyte protoporphyrin level is insufficiently sensitive to identify children with elevated blood lead levels < 25 $\mu\text{g}/\text{dL}$, and the screening test of choice is blood lead measurement.

The concentration of lead in blood is an indication of recent absorption of the metal. Clinical manifestations associated with increasing concentrations of lead in blood are shown in Figure 65–2. Children with concentrations of lead in blood > 10 $\mu\text{g}/\text{dL}$ are at risk of developmental disabilities. Adults with concentrations < 30 $\mu\text{g}/\text{dL}$ exhibit no known functional injury or symptoms; however, they will have a definite decrease in δ -ALA dehydratase activity, a slight increase in urinary excretion of δ -ALA, and an increase in erythrocyte protoporphyrin. Patients with a blood lead concentration of 30–75 $\mu\text{g}/\text{dL}$ have all the preceding laboratory abnormalities and, usually, nonspecific, mild symptoms of lead poisoning. Clear symptoms of lead poisoning are associated

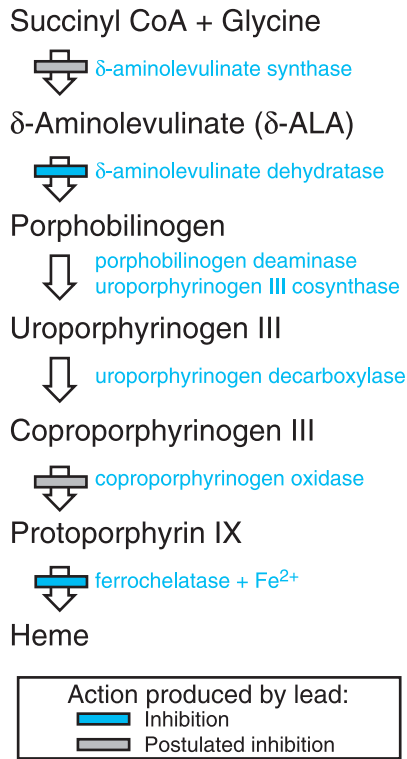

FIGURE 65-1 Lead interferes with the biosynthesis of heme at several enzymatic steps. Steps that definitely are inhibited by lead are indicated by blue blocks. Steps at which lead is thought to act but where evidence for this is inconclusive are indicated by gray blocks.

with concentrations of $>75 \mu\text{g/dL}$ of whole blood, and lead encephalopathy usually is apparent when lead concentrations exceed $100 \mu\text{g/dL}$.

The urinary concentration of lead in normal adults generally is $<80 \mu\text{g/L}$ ($0.4 \mu\text{M}$). Most patients with lead poisoning show concentrations of lead in urine of $150\text{--}300 \mu\text{g/L}$ ($0.7\text{--}1.4 \mu\text{M}$). However, in persons with chronic lead nephropathy or other forms of renal insufficiency, urinary excretion of lead may be within the normal range, even though blood lead concentrations are significantly elevated.

Because the onset of lead poisoning usually is insidious, it often is desirable to estimate the body burden of lead in individuals who are exposed to an environment that is contaminated with the metal. In the past, the edetate calcium disodium (CaNa_2EDTA) provocation test was used to determine whether there is an increased body burden of lead in those for whom exposure occurred much earlier. The provocation test is performed by intravenous administration of a single dose of CaNa_2EDTA (50 mg/kg) followed by collection of urine for 8 hours. The test is positive for children when the lead excretion ratio (μg of lead excreted in the urine per mg of CaNa_2EDTA administered) is >0.6 ; it also may be useful for therapeutic chelation in children with blood levels of $25\text{--}45 \mu\text{g/dL}$. This test is not used in symptomatic patients or in those whose concentration of lead in blood is $>45 \mu\text{g/dL}$ because these patients require the proper therapeutic regimen with chelating agents (see below).

ORGANIC LEAD POISONING

Tetraethyl lead and tetramethyl lead are lipid-soluble compounds that are absorbed readily from the skin, GI tract, and lungs. The toxicity of tetraethyl lead is believed to be due to its metabolic conversion to triethyl lead and inorganic lead. The major symptoms of intoxication with tetraethyl lead are referable to the CNS: insomnia, nightmares, anorexia, nausea and vomiting, diarrhea, headache, muscular weakness, and emotional instability. Subjective CNS symptoms such as

FIGURE 65–2 Manifestations of lead toxicity associated with varying concentrations of lead in blood of children and adults. δ -ALA = δ -aminolevulinic acid.

irritability, restlessness, and anxiety are next evident, usually accompanied by hypothermia, bradycardia, and hypotension. With continued exposure, or in the case of intense short-term exposure, CNS manifestations progress to delusions, ataxia, exaggerated muscular movements, and finally, a maniacal state.

The diagnosis of poisoning by tetraethyl lead is established by relating these signs and symptoms to a history of exposure. The urinary excretion of lead may increase markedly, but the concentration of lead in blood remains nearly normal. Anemia and basophilic stippling of erythrocytes are uncommon in organic lead poisoning. There is little effect on the metabolism of porphyrins, and erythrocyte protoporphyrin concentrations are inconsistently elevated. In the case of severe exposure, death may occur within a few hours or may be delayed for several weeks. If the patient survives the acute phase of organic lead poisoning, recovery usually is complete; however, instances of residual CNS damage have been reported.

TREATMENT OF LEAD POISONING

Initial treatment of the acute phase of lead intoxication involves supportive measures. Prevention of further exposure is important. Seizures are treated with diazepam or phenytoin (see Chapter 19), fluid and electrolyte balances must be maintained, and cerebral edema is treated with mannitol and dexamethasone or controlled hyperventilation. The concentration of lead in blood should be determined or at least a blood sample obtained for analysis prior to initiation of chelation therapy. Chelation therapy is indicated in symptomatic patients or in patients with a blood lead concentration in excess of $50\text{--}60\ \mu\text{g/dL}$ (about $2.5\ \mu\text{M}$). Four chelators are employed: edetate calcium disodium (CaNa_2EDTA), dimercaprol, D-penicillamine, and succimer (2,3-dimercaptosuccinic acid [DMSA], CHEMET). CaNa_2EDTA and dimercaprol usually are used in combination for lead encephalopathy.

CaNa_2EDTA is initiated at a dose of $30\text{--}50\ \text{mg/kg/day}$ in 2 divided doses either by deep intramuscular injection or slow intravenous infusion for up to 5 consecutive days. The first dose of CaNa_2EDTA should be delayed until 4 hours after the first dose of dimercaprol. An additional course of CaNa_2EDTA may be given after an interruption of 2 days. Each course of therapy with CaNa_2EDTA should not exceed a total dose of $500\ \text{mg/kg}$. Urine output must be monitored because the chelator-lead complex is believed to be nephrotoxic. Treatment with CaNa_2EDTA can alleviate symptoms quickly. Colic may disappear within 2 hours; paresthesia and tremor cease

after 4–5 days; coproporphyrinuria, stippled erythrocytes, and gingival lead lines tend to decrease in 4–9 days. Urinary elimination of lead usually is greatest during the initial infusion.

Dimercaprol is given intramuscularly at a dose of 4 mg/kg every 4 hours for 48 hours, then every 6 hours for 48 hours, and finally, every 6–12 hours for an additional 7 days. The combination of dimercaprol and CaNa_2EDTA is more effective than is either chelator alone. In contrast to CaNa_2EDTA and dimercaprol, penicillamine is effective orally and may be included in the regimen at a dosage of 250 mg given 4 times daily for 5 days. During chronic therapy with penicillamine, the dose should not exceed 40 mg/kg/day. Succimer is the first orally active lead chelator available for children, with a safety and efficacy profile that surpasses that of D-penicillamine. Succimer usually is given every 8 hours (10 mg/kg) for 5 days and then every 12 hours for an additional 2 weeks.

General Principles of Therapy

In any chelation regimen, the blood lead concentration should be reassessed 2 weeks after the regimen has been completed; an additional course of therapy may be indicated if blood lead concentrations rebound.

Treatment of organic lead poisoning is symptomatic. Chelation therapy will promote excretion of the inorganic lead produced from the metabolism of organic lead, but the increase is not dramatic.

Mercury

Mercury was an important constituent of many drugs for centuries, but other modes of therapy now have replaced the mercurials and drug-induced mercury poisoning has become rare. However, mercury has a number of important industrial uses, and poisoning from occupational exposure and environmental pollution continues to be an area of concern.

With regard to the toxicity of mercury, 3 major chemical forms of the metal must be distinguished: mercury vapor (elemental mercury), salts of mercury, and organic mercurials. Elemental mercury is the most volatile of the metal's inorganic forms. Human exposure to mercury vapor is mainly occupational. Extraction of gold with mercury and then heating the amalgam to drive off the mercury is a technique that still is used today in some developing countries. Chronic exposure to mercury in ambient air after inadvertent mercury spills in poorly ventilated rooms can produce toxic effects. Mercury vapor also can be released from silver–amalgam dental restorations (the main source of mercury exposure to the general population), but the amount of mercury released does not appear to be of significance for human health except for allergic contact eczema seen in a few individuals.

Salts of mercury exist in 2 states of oxidation—as monovalent mercurous salts or as divalent mercuric salts. Mercurous chloride (Hg_2Cl_2), or calomel, was used in some skin creams as an anti-septic and as a diuretic and cathartic. Mercuric salts are the more irritating and acutely toxic form of the metal. Mercuric nitrate was commonly used in the felt-hat industry; the neurological and behavioral changes depicted by the Mad Hatter in Lewis Carroll's *Alice's Adventures in Wonderland* illustrate the toxic effects of mercuric salts. Mercuric salts still are employed widely in industry, and industrial discharge into rivers has introduced mercury into the environment. The main uses of inorganic mercury today are in chloralkali production, the manufacture of electronics, plastics, fungicides, and germicides, and the formulation of amalgams in dentistry.

The organomercurials in use today contain mercury with one covalent bond to a carbon atom. The alkylmercury salts are by far the most dangerous of these compounds; methylmercury is the most common. Alkylmercury salts have been used widely as fungicides. Major incidents of human poisoning from the inadvertent consumption of mercury-treated seed grain have occurred in Iraq, Pakistan, Ghana, and Guatemala. The most catastrophic incident occurred in Iraq in 1972, when treated grain was ground into flour and made into bread, hospitalizing 6530 and killing 500. Minamata disease results from methylmercury poisoning; residents of Minamata, Japan, were poisoned after eating fish contaminated by mercury from a chemical plant that emptied its effluent directly into Minamata Bay. Eventually, 121 persons were poisoned and 46 died. Because of concerns about methylmercury accumulation in fish, the U.S. Food and Drug Administration (FDA) recommends that pregnant or nursing women, women of childbearing age, and young children avoid eating large fish (e.g., shark, swordfish, king mackerel, and tilefish) and limit their intake of albacore tuna to 6 oz/week.

The possible health risks of thimerosal ($\text{CH}_3\text{CH}_2\text{—Hg—S—C}_6\text{H}_4\text{—COOH}$), an antibacterial preservative used in vaccines, have been debated. The FDA has determined that there is a significant safety margin incorporated into all the acceptable mercury exposure limits, and there are no data or evidence of any harm caused by the level of exposure that some children may have encountered in following the existing immunization schedule. Nevertheless, the availability of vaccines with alternate preservatives led to the removal of all vaccines containing thimerosal.

CHEMISTRY AND MECHANISM OF ACTION

Mercury readily forms covalent bonds with sulfur, and it is this property that accounts for most of the biological properties of the metal. When the sulfur is in the form of sulfhydryl groups, divalent mercury replaces the hydrogen atom to form mercaptides, $X-Hg-SR$ and $Hg(SR)_2$, where X is an electronegative radical and R is protein. Organic mercurials form mercaptides of the type $R-Hg-SR'$. Even in low concentrations, mercurials are capable of inactivating $-SH$ groups of enzymes, thus interfering with cellular metabolism and function. The affinity of mercury for thiols provides the basis for treatment of mercury poisoning with such agents as dimercaprol and penicillamine. Mercury also combines with phosphoryl, carboxyl, amide, and amine groups.

TOXICITY

Elemental Mercury

Elemental mercury is not particularly toxic when ingested because of very low absorption from the GI tract; this is due to the formation of droplets and because the metal in this form cannot react with biologically important molecules. However, inhaled mercury vapor is completely absorbed by the lung and then is oxidized to the divalent mercuric cation by catalase in erythrocytes. Short-term exposure to the vapor of elemental mercury may produce symptoms within several hours, including weakness, chills, metallic taste, nausea, vomiting, diarrhea, dyspnea, cough, and a feeling of tightness in the chest. Pulmonary toxicity may progress to an interstitial pneumonitis with severe compromise of respiratory function. Recovery, although usually complete, may be complicated by residual interstitial fibrosis. Chronic exposure to mercury vapor produces a more insidious form of toxicity that is dominated by neurological effects. The concentrations of mercury vapor in the air and mercury in urine that are associated with the various effects are shown in Figure 65-3.

Inorganic Salts of Mercury

Inorganic ionic mercury (e.g., mercuric chloride) can produce severe acute toxicity. Precipitation of mucous membrane proteins by mercuric salts results in an ashen-gray appearance of the mucosa of the mouth, pharynx, and intestine and also causes intense pain, which may be

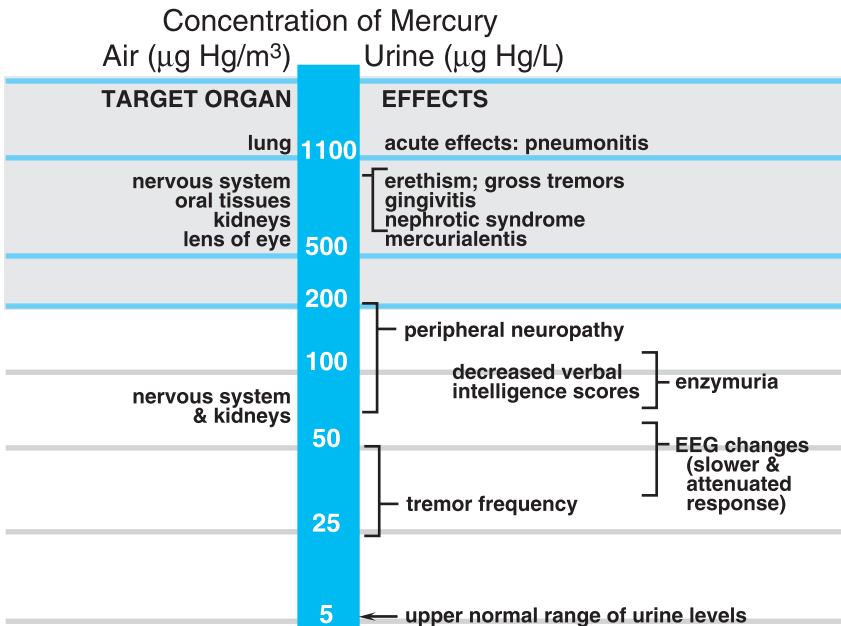

FIGURE 65-3 The concentration of mercury vapor in the air and related concentrations of mercury in urine associated with a variety of toxic effects.

accompanied by vomiting. The vomiting is perceived to be protective because it removes unabsorbed mercury from the stomach; if the patient is awake and alert, vomiting should not be inhibited. The local corrosive effect of ionic inorganic mercury on the GI mucosa results in severe hematochezia with evidence of mucosal sloughing in the stool. Hypovolemic shock and death can occur in the absence of proper treatment, which can overcome the local effects of inorganic mercury.

Systemic toxicity may begin within a few hours of exposure to mercury and last for days. A strong metallic taste is followed by stomatitis with gingival irritation, foul breath, and loosening of the teeth. The most serious and frequent systemic effect of inorganic mercury is renal toxicity. Acute tubular necrosis occurs after short-term exposure, leading to oliguria or anuria. Renal injury also follows long-term exposure to inorganic mercury, where glomerular injury predominates.

Organic Mercurials

Most human toxicological data about organic mercury concern methylmercury. More than 90% of methylmercury is absorbed from the human GI tract. The organic mercurials distribute more uniformly to the various tissues than do the inorganic salts; they also cross the blood-brain barrier and the placenta and thus produce more neurological and teratogenic effects. A significant portion of the body burden of organic mercurials is in the red blood cells; for methylmercury, the red cell-plasma ratio is ~20:1. Symptoms of exposure to methylmercury are mainly neurological; Table 65-1 lists frequency of symptoms and corresponding blood levels of methylmercury. Effects of methylmercury on the fetus can occur even when the mother is asymptomatic; mental retardation and neuromuscular deficits have been observed.

DIAGNOSIS OF MERCURY POISONING

A history of exposure to mercury, either industrial or environmental, is obviously valuable in making the diagnosis of mercury poisoning. Otherwise, clinical suspicions can be confirmed by laboratory analysis. The upper limit of a nontoxic concentration of mercury in blood generally is considered to be 3-4 $\mu\text{g}/\text{dL}$ (0.15-0.20 μM). A concentration of mercury in blood >4 $\mu\text{g}/\text{dL}$ (0.20 μM) is unexpected in normal, healthy adults and suggests the need for environmental evaluation and medical examination to assess the possibility of adverse health effects. Because methylmercury is concentrated in erythrocytes and inorganic mercury is not, the distribution of total mercury between red blood cells and plasma may indicate whether the patient has been poisoned with inorganic or organic mercury. Measurement of total mercury in red blood cells gives a better estimate of the body burden of methylmercury than it does for inorganic mercury. Concentrations of mercury in plasma provide a better index of the body burden of inorganic mercury, but the relationship between body burden and the concentration of inorganic mercury in plasma is not well documented. This may relate to the importance of timing of measurement of the blood sample relative to the last exposure to mercury. The relationship between the concentration of inorganic mercury in blood and toxicity also depends on the form of exposure. For example, exposure to vapor results in concentrations in brain approximately 10 times higher than those that follow an equivalent dose of inorganic mercuric salts.

The concentration of mercury in the urine also has been used as a measure of the body burden of the metal. The normal upper limit for excretion of mercury in urine is 5 $\mu\text{g}/\text{L}$. There is a linear relationship between plasma concentration and urinary excretion of mercury after exposure to vapor; in contrast, the excretion of mercury in urine is a poor indicator of the amount of methylmercury in the blood because methylmercury is eliminated mainly in feces.

Table 65-1

Frequency of Symptoms of Methylmercury Poisoning in Relation to Concentration of Mercury in Blood

Mercury in Blood, $\mu\text{g}/\text{mL}$ (μM)	Cases with Symptoms (%)					
	Paresthesias	Ataxia	Visual Defects	Dysarthria	Hearing Defects	Death
0.1-0.5 (0.5-2.5)	5	0	0	5	0	0
0.5-1 (2.5-5)	42	11	21	5	5	0
1-2 (5-10)	60	47	53	24	5	0
2-3 (10-15)	79	60	56	25	13	0
3-4 (15-20)	82	100	58	75	36	17
4-5 (20-25)	100	100	83	85	66	28

Hair is rich in -SH groups, and the concentration of mercury in hair is about 300 times that in blood. Human hair grows about 20 cm/year, and a history of exposure may be obtained by analysis of different segments of hair.

CHELATION THERAPY FOR MERCURY POISONING

Inorganic or Elemental Mercury

Chelation therapy with dimercaprol (for high-level exposures or symptomatic patients) or penicillamine (for low-level exposures or asymptomatic patients) is used routinely to treat poisoning with either inorganic or elemental mercury. Recommended treatment includes dimercaprol 5 mg/kg intramuscularly initially, followed by 2.5 mg/kg intramuscularly every 12–24 hours for 10 days. Penicillamine (250 mg orally every 6 hours) may be used alone or following treatment with dimercaprol. The duration of chelation therapy will vary, and progress can be monitored by following concentrations of mercury in urine and blood. The orally effective chelator succimer appears to be an effective chelator for mercury, although not FDA-approved for this purpose.

The dimercaprol–mercury chelate is excreted into both bile and urine, whereas the penicillamine–mercury chelate is excreted only into urine. Thus, penicillamine should be used with extreme caution when renal function is impaired. In fact, hemodialysis may be necessary in the poisoned patient whose renal function declines. Chelators still may be used because the dimercaprol–mercury complex is removed by dialysis.

Organic Mercury

The short-chain organic mercurials, especially methylmercury, are the most difficult forms of mercury to mobilize from the body, presumably because of their poor reactivity with chelating agents. Dimercaprol is contraindicated in methylmercury poisoning because it increases brain concentrations of methylmercury in experimental animals. Although penicillamine facilitates the removal of methylmercury from the body, it is not clinically efficacious, and large doses (2 g/day) are needed. During the initial 1–3 days of administration of penicillamine, the concentration of mercury in the blood increases before it decreases, probably reflecting the mobilization of metal from tissues to blood at a rate more rapid than that for excretion of mercury into urine and feces.

Methylmercury compounds undergo extensive enterohepatic recirculation; therefore, introduction of a nonabsorbable mercury-binding substance into the intestinal tract should facilitate their removal from the body. A polythiol resin has been used for this purpose in humans and appears to be effective. The resin has certain advantages over penicillamine. It does not cause redistribution of mercury in the body with a subsequent increase in the concentration of mercury in blood, and it has fewer adverse effects than do sulfhydryl agents that are absorbed. Clinical experience with various treatments for methylmercury poisoning in Iraq indicates that penicillamine, N-acetylpenicillamine, and an oral nonabsorbable thiol resin all can reduce blood concentrations of mercury; however, clinical improvement was not clearly related to reduction of the body burden of methylmercury.

Conventional hemodialysis is of little value in the treatment of methylmercury poisoning because methylmercury concentrates in erythrocytes, and little is contained in the plasma. However, it has been shown that L-cysteine can be infused into the arterial blood entering the dialyzer to convert methylmercury into a diffusible form. Both free cysteine and the methylmercury–cysteine complex form in the blood and then diffuse across the membrane into the dialysate. This method has been shown to be effective in humans. Studies in animals indicate that succimer may be more effective than cysteine in this regard.

Arsenic

Arsenic is found in soil, water, and air as a common environmental toxicant. The average daily human intake of arsenic is about 10 µg, largely ingested with food and water. The major source of occupational exposure to arsenic-containing compounds is from the manufacture of arsenical herbicides and pesticides. Arsenic is used as arsine and as arsenic trioxide in the manufacture of most computer chips using silicon-based technology. Gallium arsenide is used in the production of compound (types III–V) semiconductors that are used for making light-emitting diodes (LEDs), as well as laser and solar devices. Chromated copper arsenate (CCA) was used as a common treatment for outdoor lumber until 2004; this should not pose a health risk unless treated wood is burned in fireplaces or woodstoves. Federal restrictions on the allowable content of arsenic in food and in the occupational environment not only have improved safety procedures and decreased the number of intoxications but also have decreased the amount of arsenic in use; only the annual production of arsenic-containing herbicides is increasing. The incidence of accidental, homicidal, and suicidal arsenic poisoning has diminished greatly in recent decades.

CHEMISTRY AND MECHANISM OF ACTION

The toxicity of a given arsenical is related to the rate of its clearance from the body and therefore to its degree of accumulation in tissues. In general, toxicity increases in the sequence of organic arsenicals $<As^{5+} <As^{3+} <arsine (AsH_3)$. The organic arsenicals contain arsenic covalently linked to a carbon atom, where arsenic exists in the trivalent or pentavalent state. Arspenamine contains trivalent arsenic; sodium arsenilate contains arsenic in the pentavalent form. The organic arsenicals usually are excreted more rapidly than are the inorganic forms.

Arsenate (pentavalent) uncouples mitochondrial oxidative phosphorylation by a mechanism whereby arsenate substitutes for inorganic phosphate in the formation of ATP, with subsequent formation of an unstable arsenate ester that is hydrolyzed rapidly. This process is termed arsenolysis.

Trivalent arsenicals, including inorganic arsenite, are regarded primarily as -SH reagents. As such, trivalent arsenicals inhibit many enzymes by reacting with biological ligands containing available -SH groups. The pyruvate dehydrogenase system is especially sensitive to trivalent arsenicals because of their interaction with two -SH groups of lipoic acid to form a stable 6-membered ring.

ACUTE ARSENIC POISONING

GI discomfort usually is experienced within an hour after intake of an arsenical, although it may be delayed as much as 12 hours after oral ingestion if food is in the stomach. Burning lips, constriction of the throat, and difficulty in swallowing may be the first symptoms, followed by excruciating gastric pain, projectile vomiting, and severe diarrhea. Oliguria with proteinuria and hematuria usually is present; eventually, anuria may occur. The patient often complains of marked skeletal muscle cramps and severe thirst. As the loss of fluid proceeds, symptoms of shock appear. Hypoxic convulsions may occur terminally; coma and death ensue. In severe poisoning, death can occur within an hour, but the usual interval is 24 hours. With prompt application of corrective therapy, patients may survive the acute phase of the toxicity only to develop neuropathies and other disorders. The motor system appears to be spared only in the mildest cases; severe crippling is common.

CHRONIC ARSENIC POISONING

The most common early signs of chronic arsenic poisoning are muscle weakness and aching, skin pigmentation (especially of the neck, eyelids, nipples, and axillae), hyperkeratosis, and edema. GI involvement is less prominent in long-term exposures. Other signs and symptoms that should arouse suspicion of arsenic poisoning include garlic odor of the breath and perspiration, excessive salivation and sweating, stomatitis, generalized itching, sore throat, coryza, lacrimation, numbness, burning or tingling of the extremities, dermatitis, vitiligo, and alopecia. Poisoning may begin insidiously with symptoms of weakness, languor, anorexia, occasional nausea and vomiting, and diarrhea or constipation. Subsequent symptoms may simulate acute coryza. Dermatitis and keratosis of the palms and soles are common features. Mee's lines are found characteristically in the fingernails (white transverse lines of deposited arsenic that usually appear 6 weeks after exposure). Desquamation and scaling of the skin may initiate an exfoliative process involving many epithelial structures of the body. The liver may enlarge, and obstruction of the bile ducts may result in jaundice. Eventually, cirrhosis may occur from the hepatotoxic action. Renal dysfunction also may be encountered. As intoxication advances, encephalopathy may develop. Peripheral neuritis results in motor and sensory paralysis of the extremities; in contrast to lead palsy, the legs usually are more severely affected than the arms. The bone marrow is seriously damaged by arsenic, and all hematological elements may be affected with severe exposure.

CHELATION THERAPY FOR ARSENIC POISONING

Chelation therapy often is begun with dimercaprol (3–4 mg/kg intramuscularly every 4–12 hours) until abdominal symptoms subside and charcoal (if given initially) is passed in the feces. Oral treatment with penicillamine then may be substituted for dimercaprol and continued for 4 days. Penicillamine is given in 4 divided doses to a maximum of 2 g/day. If symptoms recur after cessation of chelation therapy, a second course of penicillamine may be instituted. Succimer (2,3-dimercaptosuccinic acid), a derivative of dimercaprol, is efficacious in the treatment of arsenic poisoning but is FDA-approved only for lead chelation in children.

After long-term exposure to arsenic, treatment with dimercaprol and penicillamine also may be used, but oral penicillamine alone usually is sufficient. The duration of therapy is determined by the clinical condition of the patient, and the decision is aided by periodic determinations of urinary arsenic concentrations. Adverse effects of the chelating agents may limit the usefulness of therapy. Dialysis may become necessary with severe arsenic-induced nephropathy; successful removal of arsenic by dialysis has been reported.

ARSINE

Arsine gas, generated by electrolytic or metallic reduction of arsenic in nonferrous metal products, is a rare cause of industrial intoxication. Rapid and often fatal hemolysis is a unique characteristic of arsine poisoning and probably results from arsine combining with hemoglobin and then reacting with oxygen to cause hemolysis. The classic arsine triad of hemolysis, abdominal pain, and hematuria is noteworthy. If the patient survives the severe hemolysis, death may result from renal failure. Because the hemoglobin–arsine complex cannot be dialyzed, exchange transfusion is recommended in severe cases; forced alkaline diuresis also may be employed (see Chapter 64). Dimercaprol has no effect on the hemolysis, and beneficial effects on renal function have not been established; it therefore is not recommended.

Cadmium

Cadmium ranks close to lead and mercury as a metal of current toxicological concern. Cadmium is used in electroplating and galvanization, and in plastics, paint pigments (cadmium yellow), and nickel–cadmium batteries. Because <5% of the metal is recycled, environmental pollution is an important consideration. Coal and other fossil fuels contain cadmium, and their combustion releases the element into the environment. Extraction and processing of zinc and lead also lead to environmental contamination with cadmium. Workers in smelters and other metal-processing plants may be exposed to high concentrations of cadmium in the air; however, for most of the population, food is the major source of cadmium.

Cadmium occurs only in one valency state (2⁺) and does not form stable alkyl compounds or other organometallic compounds of known toxicological significance. Cadmium initially is distributed to the liver and then redistributes slowly to the kidney as cadmium–metallothionein (Cd–MT), with ~50% of the total-body burden in the liver and kidney after distribution. Cadmium and several other metals induce the expression of metallothionein, a cysteine-rich protein with high affinity for metals such as cadmium and zinc. Metallothionein protects cells against cadmium toxicity by preventing the interaction of cadmium with other proteins.

ACUTE CADMIUM POISONING

Acute poisoning usually results from inhalation of cadmium dusts and fumes (usually cadmium oxide) or from the ingestion of cadmium salts. The early toxic effects are due to local irritation. In the case of oral intake, these include nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody. In the short term, inhaled cadmium is more toxic. Signs and symptoms, which appear within a few hours, include irritation of the respiratory tract with severe, early pneumonitis, chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema or residual emphysema with peribronchial and perivascular fibrosis.

CHRONIC CADMIUM POISONING

The toxic effects of long-term exposure to cadmium differ somewhat with the route of exposure. The kidney is affected following either pulmonary or GI exposure; marked effects are observed in the lungs only after exposure by inhalation. Excretion of β_2 -microglobulin in urine is a sensitive but not specific index of cadmium-induced nephrotoxicity. Measurement of urine β_2 -microglobulin is part of the Occupational Safety and Health Administration (OSHA) standard for monitoring cadmium poisoning. Retinol-binding protein may be a better marker, but its measurement generally is not available. Cadmium is classified as a human carcinogen based mainly on epidemiological studies from workers exposed occupationally to cadmium. These investigations primarily have identified tumors of the lungs and, to a lesser extent, prostate, kidney, and stomach.

TREATMENT OF CADMIUM POISONING BY CHELATION THERAPY

Effective therapy for cadmium poisoning is difficult to achieve. Although there is no proven benefit, some clinicians recommend chelation therapy with CaNa₂EDTA. The dose of CaNa₂EDTA is 75 mg/kg/day in 3–6 divided doses for 5 days. After a minimum of 2 days without treatment, a second 5-day course is given. The total dose of CaNa₂EDTA per 5-day course should not exceed 500 mg/kg. Animal studies suggest that chelation therapy should be instituted as soon as possible after cadmium exposure because a rapid decrease in effectiveness of chelation therapy occurs in parallel with distribution to sites inaccessible to the chelators. The use of dimercaprol and substituted dithiocarbamates appears promising for individuals chronically exposed to cadmium.

Iron

Although iron is not an environmental poison, accidental intoxication with ferrous salts used to treat iron deficiency is a frequently encountered source of poisoning in young children. Iron is discussed further in Chapter 53.

Radioactive Heavy Metals

The widespread production and use of radioactive heavy metals for nuclear generation of electricity, nuclear weapons, laboratory research, manufacturing, and medical diagnosis have generated unique problems in dealing with accidental poisoning by such metals. Because the toxicity of radioactive metals is almost entirely a consequence of ionizing radiation, the therapeutic objective following exposure is chelation of the metals and their removal from the body as rapidly and completely as possible. Treatment of the acute radiation syndrome is largely symptomatic. Attempts have been made to investigate the effectiveness of organic reducing agents, such as mercaptamine (cysteamine), administered to prevent the formation of free radicals; success has been limited.

Major products of a nuclear accident or the use of nuclear weapons include ^{239}Pu , ^{137}Cs , ^{144}Ce , and ^{90}Sr . Isotopes of Sr and Ra are extremely difficult to remove from the body with chelation therapy; these include the affinity of these particular metals for individual chelators and the observation that radiation from Sr and Ra in bone destroys nearby capillaries, thereby decreasing blood flow and isolating the radioisotopes. Many chelating agents have been used experimentally, including CaNa_3DTPA (pentetic acid), which has been shown to be effective against ^{239}Pu . One gram of CaNa_3DTPA , administered by slow intravenous drip on alternate days three times per week has enhanced excretion 50-100-fold in animals and in human subjects exposed in accidents. As is seen commonly with heavy-metal poisoning, effectiveness of treatment diminishes very rapidly with an increasing delay between exposure and the initiation of therapy.

Appendix A

PRINCIPLES OF PRESCRIPTION ORDER WRITING AND PATIENT COMPLIANCE

THE MECHANICS OF WRITING PRESCRIPTION ORDERS

The written prescription consists of the superscription, the inscription, the subscription, the signa, and the name and signature of the prescriber, all contained on a single form (Figure A-1). The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (or *recipe*). The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded. The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: “make a solution,” “mix and place into 30 capsules,” or “dispense 30 tablets.” The *signa* or *Sig* is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., these generally are written in English. Many physicians continue to use Latin abbreviations; for example, “1 cap tid pc,” will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations only mystifies the prescription, which can hinder proper patient-physician communication and may lead to errors. Since the pharmacist always writes the label in English (or as appropriate in the language of the patient), the use of such abbreviations or symbols is unnecessary and discouraged.

The instruction “take as directed” should be avoided; Such directions can only be seen as inadequate by the pharmacist, who must determine the intent of the physician before dispensing the medication, and who shares the responsibility for safe and proper use of the medication by the patient. The best directions to the patient include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain,” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions would begin with “take” or “give”; for externally applied products, the word “apply”; for suppositories, “insert”; and for eye, ear, or nose drops, “place” is preferable to “instill.”

Prescriptive Authority

In many states in the U.S., health care practitioners other than M.D. and D.O. physicians (*e.g.*, physician’s assistants, nurse practitioners, and pharmacists) can write prescriptions in certain circumstances.

Avoiding Confusion

Units of measure can lead to confusion and medication errors. Older systems of measure such as minims for volume (15 minims = 1 mL) and grains for weight (1 grain = 60 mg) are obscure and should not be used. Doses always should be listed by metric weight of active ingredient; doses for liquid medications should include the volume. Writing “ μg ” for micrograms can very easily be misinterpreted as milligrams (mg). Thus, if abbreviated, micrograms should be written “mcg” and milligrams as “mg”; a zero should be used before a decimal (0.X mg, rather than .X mg) but not after (use X mg rather than X.0 mg). The metric system should be used in place of common household measurements such as “dropperful” and “teaspoon” in the patient directions, and both the doctor and the pharmacist should be sure that the patient understands the measurement prescribed. For medical purposes, a “teaspoon” or “teaspoonful” dose is considered to be equivalent to 5 mL and a “tablespoon” to 15 mL, but the actual volumes held by ordinary household teaspoons and tablespoons vary too widely to be used reliably for measurement of medications. Prescribing oral medications in “drops” likewise can cause problems when accuracy of dose is important unless the patient understands that only the calibrated dropper provided by the manufacturer or pharmacist should be used to dispense the medication. Thus, one possible dosage for a pediatric iron product would be more accurately written “15 mg (0.6 mL) three times daily” instead of “one dropperful three times daily.”

Abbreviations can cause dispensing errors. A prescription intending every-other-day dosing (qod) may be miswritten as “od” by the physician for “other-day dosing”; the pharmacist will interpret “od” as the abbreviation of the Latin for “right eye.” Once-daily dosing at bedtime (qhs) may be misinterpreted as “qhr” for every hour. The use of slash marks (/) to separate names and doses

FIGURE A-1 The prescription. The prescription must be carefully prepared to identify the patient and the medication to be dispensed, as well as the manner in which the drug is to be administered. Accuracy and legibility are essential. Use of abbreviations, particularly Latin, is discouraged, as it leads to dispensing errors. Inclusion of the purpose of the medication in the *subscription* (e.g., “for control of blood pressure”) can prevent errors in dispensing. For example, the use of losartan for the treatment of hypertension may require 100 mg/day (1.4 mg/kg per day), whereas treatment of congestive heart failure with this angiotensin II–receptor antagonist should not generally exceed 50 mg/day. Including the purpose of the prescription can also assist patients in organizing and understanding their medications. Including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.

can result in the incorrect drug or dose being dispensed; the slash mark may be interpreted as a letter or number. When medications are measured in units or international units, the abbreviation “U” or “IU” must NOT be used; this can lead to errors such as misinterpretation of “U” as zero or four, or “IU” as 10 or 14. The word “unit” should be written as such. Drug products available in the U.S. that are dosed in units (*e.g.*, *corticotropin*) or international units (*e.g.*, heparin) are “harmonized” by those responsible for drug standardization to avoid errors in dosing (*see* Drug Standards and Classification, below). *The critical message is that practitioners in the U.S. must write out the Rx fully in English if errors are to be avoided.*

Proper Patient Information

The patient’s name and address are needed on the order to assure that the correct medication goes to the correct patient and also for identification and recordkeeping purposes. For medications whose dosage involves a calculation, pertinent factors such as the patient’s weight, age, or body surface area also should be listed on the prescription.

Prescribers often commit errors in dosage calculations that can be prevented. When prescribing a drug whose dosage involves a calculation based on body weight or surface area, it is good practice to include both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg per day)” to allow another health care professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling these prescriptions. In hospitals and some clinic settings, medication orders for antibiotics or antiseizure medications that are sometimes difficult to adequately dose (*e.g.*, *phenytoin*) can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the Controlled Substances Act of 1970, as erasures on a prescription easily can lead to dispensing errors or diversion of controlled substances.

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure A–1). When using institutional blanks that do not bear the physician’s information, the physician always should print his or her name and phone number on the face of the prescription to clearly identify the prescriber and facilitate communication with other health care professionals if questions arise. U.S. law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Agency (DEA) registration number of the physician.

The date of the prescription is an important part of the patient’s medical record, and it can assist the pharmacist in recognizing potential problems. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The U.S. Controlled Substances Act requires that all orders for controlled substances (Table A–1) be dated and signed on the day issued and prohibits filling or refilling orders for schedule III or IV substances more than 6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills the patient may have. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician. A statement such as “refill prn” (refill as needed) is inappropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are desired, “zero” (rather than “0”) should be written in the refill space to prevent alteration of the doctor’s intent. Refills for controlled substances are discussed below.

Concern about the rising cost of health care has favored the dispensing of so-called “generic” drugs. A drug can be called by its generic name (in the U.S., this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most states in the U.S., pharmacists have the authority to dispense generic drugs rather than brand-name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this is generally unnecessary since the FDA requires that generic medications meet the same bioequivalence standards as their brand-named counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted as stated on the prescription. Substituting generic medications is discouraged for drugs with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential noncompliance may occur.

Table A-1

Controlled Substance Schedules

Schedule I (examples: heroin, methylene dioxymethamphetamine, lysergic acid diethylamide, mescaline, and all salts and isomers thereof):

1. High potential for abuse.
2. No accepted medical use in the U.S. or lacks accepted safety for use in treatment in the U.S. May be used for research purposes by properly registered individuals.

Schedule II (examples: morphine, oxycodone, fentanyl, meperidine, dextroamphetamine, cocaine, amobarbital):

1. High potential for abuse.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to severe psychological or physical dependence.

Schedule III (examples: anabolic steroids, nalorphine, ketamine, certain schedule II substances in suppositories, mixtures, or limited amounts per dosage unit):

1. Abuse potential less than substances in schedule I or schedule II.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to moderate or low physical dependence or high psychological dependence.

Schedule IV (examples: alprazolam, phenobarbital, meprobamate, modafinil):

1. Abuse potential less than substances in schedule III.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to limited physical or psychological dependence relative to substances in schedule III.

Schedule V (examples: buprenorphine, products containing a low dose of an opioid plus a non-narcotic ingredient such as codeine + guaifenesin cough syrup or diphenoxylate + atropine tablets):

1. Low potential for abuse relative to schedule IV.
 2. Has a currently accepted medical use in the U.S.
 3. Some schedule V products may be sold in limited amounts without a prescription at the discretion of the pharmacist; however, if a physician wishes a patient to receive one of these products, it is preferable to provide a prescription.
-

Choice of Drug Product

It cannot be assumed that a drug's therapeutic promise or popularity is proof of its overall efficacy or safety. Prescribers must rely on unbiased sources when seeking drug information (*see* Chapter 5).

Electronic Prescription Writing

Both government and healthcare businesses have called for the widespread use of electronic medical records by 2014 to help lower costs, reduce medical errors, improve quality of care, and provide better information for patients and providers. Electronic prescriptions are a central part of this strategy; while no national standard for either the technology or format of this record exists, electronic prescriptions are being used in many parts of the country. The advantages of electronic prescription writing include convenience for the prescriber (*e.g.*, use of hand-held devices permits prescribing at the time of therapeutic decision making); convenience for the patient, and electronic screening for appropriate drug choices, interactions with existing therapy, *etc.* The high probability that electronic prescription writing will reduce medication errors is, in and of itself, justification to make the change from current practice. Whatever the specific format of the electronic prescription, the essential features of writing the prescription described here are unchanged.

THE PRESCRIPTION AS A COMMODITY

Prescribers must be aware that patients may visit their doctor to "get a prescription." Indeed, in an era when the time spent between physician and patient is ever shorter, patients may view a trip to the doctor that does not result in a new prescription as a failed visit or a lost opportunity. Similarly,

physicians may feel that they have fulfilled their role if the patient leaves with a prescription. Physicians must be careful to educate their patients about the importance of viewing medicines as only to be used when really needed and that remaining on a particular medicine when their condition is stable may be preferable to seeking the newest medications available.

PRESCRIPTION DRUG ADVERTISING

The benefits of direct-to-consumer (DTC) advertising of drugs, including internet advertising, are controversial. DTC advertising has alerted consumers to the existence of new drugs and the conditions they treat but has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues), which has led to higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide evidence-based drug information to their patients.

ERRORS IN DRUG ORDERS

The Institute of Medicine (IOM) estimates that between 44,000 and 98,000 deaths annually in the U.S. result from medical errors. While there is some debate about this estimate, it is clear that medication errors are common and result in significant adverse effects, including death. Databases of anonymously reported errors are maintained jointly by the Institute for Safe Medication Practices (ISMP), the U.S. Pharmacopeia Medication Errors Reporting Program (USP MERP), and the FDA's MedWatch program. Adverse drug events occur in ~3% of hospitalizations, and this number is larger for special populations such as those in pediatric and neonatal intensive care units.

By examining aspects of prescription writing that can cause errors and by modifying prescribing habits accordingly, the physician can improve the chance that the patient will receive the correct prescription, whether in a hospital or an outpatient setting. Vigilance for common problems that can occur with medication orders and improved communication among physicians, pharmacists, and other healthcare professionals can reduce medication errors. Areas of particular concern in the preparation of medication orders in both the institutional and outpatient settings are summarized below:

- All orders should be written using metric measurements of weight and volume.
- Arabic (decimal) numerals are preferable to Roman numerals; in some instances, it is preferable for numbers to be spelled out.
- Use leading zeros (0.125 mg, not .125 mg); never use trailing zeros (5 mg, not 5.0 mg).
- Avoid abbreviating drug names since this leads to numerous errors due to sound-alike names. For instance, NEUMEGA, an interleukin-11 product abbreviated IL-11, can be dispensed as PROLEUKIN, an interleukin-2 derivative, if Roman rather than Arabic numerals are used.
- Avoid abbreviating directions for drug administration; write directions out clearly in English.
- Some drug names sound alike when spoken and may look alike when spelled out. The USP MERP maintains a current list of drug names that can be confused (<http://www.usp.org>), including over 750 pairs of potentially confusing names that could lead to prescribing or dispensing errors harmful to patients. The alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- The single most important measure to prevent dispensing errors based on sound-alike or look-alike drug names is for the physician to provide the patient's diagnosis on the prescription order. For instance, an order for administration of *magnesium sulfate* must not be abbreviated "MS," as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient's diagnosis can prevent this error.
- Poor handwriting is a well-known and preventable cause of dispensing errors. Both physician and pharmacist share in the responsibility to prevent adverse drug events by writing prescriptions clearly and questioning intent whenever an order is ambiguous or potentially ambiguous.

Controlled Substances

DEA regulates each step of the handling of controlled substances from manufacture to dispensing. State agencies may impose additional regulations such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. The most stringent law always takes precedence, whether it is federal, state, or local. Substances that come under the jurisdiction of the Federal Controlled

Substances Act (CSA) are divided into five schedules (Table A-1); individual states may have additional schedules. Criminal offenses and penalties for misuse generally depend on the schedule of a substance as well as the amount of drug in question.

Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances.

PRESCRIPTION ORDERS FOR CONTROLLED SUBSTANCES

To be valid, a prescription for a controlled substance must be issued for a *legitimate medical purpose* by an *individual practitioner* acting in the *usual course of his or her professional practice*. An order that does not meet these criteria, such as a prescription issued as a means to obtain controlled substances for the doctor's office use or to maintain addicted individuals, is not considered a legitimate prescription and thus does not protect either the issuing physician or the dispensing pharmacist. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even when not mandated by local law.

Execution of the Order

Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner; they should be signed as one would sign a legal document. Preprinted orders are not allowed in most states, and presigned blanks are prohibited by federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician's staff, but the prescriber is responsible for the signature and any errors that the order may contain.

Oral Order

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician or by trusted staff in the same manner as a prescription for a noncontrolled substance, although it is in the physician's best interest to keep his or her DEA number as private as reasonably possible (*see Preventing Diversion*, below). Schedule II prescriptions may be telephoned to a pharmacy only in *emergency* situations. To be an emergency: (1) immediate administration is necessary; (2) no appropriate alternative treatment is available; and (3) it is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 hours. If mailed, the prescription must be postmarked within 72 hours. The pharmacist must notify the DEA if this prescription is not received.

Refills

No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

Preventing Diversion

Prescription blanks often are stolen and used to sustain abuse of controlled substances and to divert legitimate drug products to the illicit market. To prevent such diversion, prescription pads should be protected in the same manner as one would protect a personal checkbook. A prescription blank should never be pre-signed for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept in a locked, secure location except when in use. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies; some areas have systems in place to allow the rapid dissemination of such information.

Ideally, the physician's full DEA number should not be preprinted on the prescription pad; most prescriptions will not be for controlled substances and will not require the registration number, and anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write "pharmacist call to verify" or "call for registration number." This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must be advised to fill the prescription during the prescriber's office hours. Pharmacists can ascertain the likely authenticity of a physician's DEA number using an algorithm.

Another method employed by the drug-seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient's addiction is not a legitimate medical purpose.

DRUG STANDARDS AND CLASSIFICATION

The U.S. Pharmacopeial Convention, Inc. is a nongovernmental organization that promotes the public health and benefits practitioners and patients by disseminating authoritative standards and information on medicines and other health care technologies. This organization is home to the U.S. Pharmacopeia (USP), which together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. Drug monographs are published in the USP/National Formulary (USP-NF), the official drug standards compendium that organizes drugs into categories based on pharmacological actions and therapeutic uses.

The USP is also home to the USAN (The USP Dictionary of *U.S. Adopted Names and International Drug Names*). This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. The USP maintains an electronic Web site that can be accessed for useful drug naming, classification, and standards information (<http://www.usp.org>).

In the U.S., drug products are also coded under the National Drug Code. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the National Drug Code (NDC) number, identifies the labeler/vendor, product, and package size. The labeler code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer.

Drugs are also grouped by their potential for misuse under British and United Nations legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C. A separate FDA classification scheme is used to rate the risk to the fetus of drugs taken during pregnancy in five categories from Category A (safest) through Categories B, C, D, and Category X (contraindicated in pregnancy). The possible risk increases in categories B, C, and D. In Category D, for example, there is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (*e.g.*, if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

COMPLIANCE

Compliance may be defined as the extent to which the patient follows a prescribed regimen. The assumption that the patient follows directions on the prescription is unrealistic. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant with a vested interest in its success. The prescriber must promote a collaborative interaction with the patient in which each helps to determine the course of therapy. The patient's quality-of-life beliefs may differ from the clinician's therapeutic goals, and the patient will have the last word when there is an unresolved conflict. Suggestions for improving patient compliance are listed in Table A-2.

Even the most carefully prepared prescription for the ideal therapy will be useless if the patient's level of compliance is inadequate. Noncompliance, thought to occur 50% of the time, may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled. Noncompliance always should be considered in evaluating therapeutic failures.

Table A-2

Suggestions for Improving Patient Compliance

Provide respectful communication; ask patient how he takes medicine.

Develop satisfactory, collaborative relationship between doctor and patient; encourage pharmacist involvement.

Provide and encourage use of medication counseling.

Give precise, clear instructions, with most important information given first.

Support oral instructions with easy-to-read written information.

Simplify whenever possible.

Use mechanical compliance aids as needed (sectioned pill boxes or trays, compliance packaging, color-coding).

Use optimal dosage form and schedule for the individual patient.

Assess patient's literacy and comprehension and modify educational counseling as needed. Don't rely on patient knowledge about his or her disease, alone, to improve compliance.

Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).

Enlist support and assistance from family or caregivers.

Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

THE PATIENT-PROVIDER RELATIONSHIP

Patient satisfaction with the physician has a significant impact on compliance behavior and is one of the few factors that the physician can directly influence. When deciding upon a course of therapy, it can be useful to discuss a patient's habits and daily routine as well as the therapeutic options with the patient. This information can help suggest cues for remembrance, such as storing a once-daily medicine atop the books on the bedside table for a patient who reads nightly, or in the cabinet with the coffee cups if it is to be taken in the morning (noting that the bathroom can be the worst place to store a medication in terms of its physical and chemical preservation). The information also can help tailor the regimen to the patient's lifestyle. A lack of information about a patient's lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Involving patients in the control of any appropriate aspects of their therapy may improve compliance, by aiding memory, making the dosage form or schedule more agreeable or convenient, giving patients a feeling of empowerment, and emphasizing their responsibility for the treatment outcome.

Behavioral models suggest that patients are more likely to be compliant when they *perceive* that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, that the benefits outweigh the costs, and when they believe in their own efficacy to execute the therapy. Education of the patient about his or her condition alone will not improve compliance.

Pharmacists have a legal and professional responsibility to offer medication counseling in many situations—even though practice environments are not always conducive to its provision—and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient's therapy can help identify compliance and other problems and notify the physician as appropriate.

Elderly patients often face a number of barriers to compliance related to their age. Such barriers include increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and an increased number of concurrent medicines used (both prescription and over-the-counter), whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects.

voriconazole for, 806
- oropharyngeal
clotrimazole for, 809
fluconazole for, 804
inhaled glucocorticoids and,
466, 466*t*
itraconazole for, 802, 804
nystatin for, 811
- vulvovaginal
butoconazole for, 810
clotrimazole for, 809
miconazole for, 809
nystatin for, 811
terconazole for, 810
tioconazole for, 810
- Cannabinoids
for nausea/vomiting, 649
pharmacological effects, 396–397
tolerance, dependence, and
withdrawal, 397, 397*t*
- Cannabis sativa*, 649
- Canrenone, 495*t*
- CAPASTAT (capreomycin), 791
- Capecitabine
metabolism, 874
pharmacokinetics, 875
therapeutic uses, 854*t*, 876
toxicity, 876
- CAPOTEN (captopril), 520
- Capreomycin, 785*t*, 791
- CAPROGEL (aminocaproic acid),
1109
- Capsaicin, 1094
- Capsid, 812
- Captopril
dosage, 520
for heart failure, 563*t*, 566–567
for hypertension, 554
pharmacokinetics, 520
- CARAC (5-fluorouracil), 1087
- CARAFATE (sucralfate), 626
- Carbachol
chemistry, 117*f*
ophthalmic uses, 1104*t*, 1107
pharmacological properties, 116,
116*t*
- Carbamazepine
adverse effects, 326–327
in bipolar disorder, 317
CYPs and, 324*t*, 326
for diabetes insipidus, 506
in Huntington's disease, 346
interactions, 327
with delavirdine, 847
with hepatic microsomal
enzymes, 324*t*
with itraconazole, 803*t*
with lamotrigine, 331
with macrolides, 773
with phenytoin, 325
with warfarin, 958
mechanisms of action, 319, 321*f*,
326
metabolism, 48
for neuralgia, 327
pharmacokinetics, 326
pharmacological effects, 326
plasma concentrations, 327
for seizures, 327
therapeutic uses, 327
tolerance, 327
toxicity of/poisoning with, 326
vasopressin and, 501, 504–505, 509
- Carbapenems, 748–749
- Carbaryl, 127
- CARBATROL (carbamazepine), 326
- Carbencillin
adverse effects, 739
antimicrobial activity, 738–739
chemistry, 731*t*
pharmacological properties, 729,
731*t*, 739
- Carbenicillin indanyl, 731*t*
- Carbenoxolone, 628
- Carbidopa, for Parkinson's disease,
340*t*
- Carbinoxamine maleate, 408*t*
- CARBOCAINE (mepivacaine), 247
- Carbon dioxide (CO₂), 258–259
- Carbonic anhydrase inhibitors,
477–481, 479*f*, 480*t*
absorption and elimination, 480*t*
adverse effects, 480
chemistry, 480*t*
CNS effects, 480
contraindications, 480
excretory effects, 478*t*, 479
mechanisms of action, 477, 479*f*
ophthalmic effects, 479–480
ophthalmic uses, 1106
renal hemodynamic effects, 478*t*,
479
therapeutic uses, 480–481
- Carboplatin (CBDCA, JM-8)
mechanisms of action, 867, 868
pharmacokinetics, 868
resistance to, 867
therapeutic uses, 854*t*, 868
toxicity, 860*t*, 868
- Carboxylesterase superfamily, 48
- Carboxymethylcellulose, 642, 1114
- Carboxypenicillins, 738–739
- Carcinogens
chemical, 1117–1118
FDA regulations, 1115
genotoxic, 1117
nongenotoxic, 1117–1118
screening, 1118
- Carcinoid tumors
octreotide for, 200, 644
streptozocin for, 854*t*, 865
- Cardiac arrhythmias
drug-induced, 579–580*t*, 591
electrophysiology
cardiac action potentials, 578,
581*f*
impulse propagation, 582
intracellular homeostasis
mechanisms, 582
refractoriness, 582
ethanol consumption and, 376
mechanisms, 582–584, 585–586*t*
afterdepolarization, 583
enhanced automaticity, 583
reentry, 583–584
triggered automaticity, 583
therapeutic approach, 590–592
by mechanism, 585–586*t*
- Cardiac cells, action potential
behaviors, 578, 581*f*
- Cardiac glycosides
adverse effects, 573, 596
electrophysiological actions, 573,
596
for heart failure, 573
interactions, 597
with ACE inhibitors, 525
with loop diuretics, 487
with spironolactone, 496
with thiazide diuretics, 489
mechanisms of action, 572–573,
572*f*
pharmacokinetics, 573, 596–597
pharmacological effects, 596
toxicity, 573
- Cardiomyopathy
doxorubicin and, 889
ethanol consumption and, 376
- Cardiopulmonary bypass, heparin
therapy in, 953
- Cardiopulmonary resuscitation,
epinephrine in, 168
- Cardiovascular system
ACE inhibitors and, 522–523
acetylcholine and, 114–115
 α adrenergic receptor antagonists
and, 170
 β adrenergic receptor antagonists
and, 176, 186, 538
amphetamine and, 164
angiotensin II and, 517*f*, 518
anticholinesterase agents and, 130
antipsychotics and, 305, 310
aspirin and, 441
barbiturates and, 272–273
Ca²⁺ channel antagonists and,
532–533, 534–535*t*, 536
corticosteroids and, 1029
COX-2 inhibitors and, 420, 438
desflurane and, 236
dobutamine and, 159
dopamine and, 157
eicosanoids and, 421
enflurane and, 235
epinephrine and, 153*t*, 154
estrogens and, 998, 1000, 1001
ethanol consumption and, 375–377
etomidate and, 230
ganglionic blocking and, 146–147
halothane and, 233–234
histamine receptors and, 404
isoflurane and, 235
isoproterenol and, 152*f*, 158–159
ketamine and, 231–232
kinins and, 414
leukotrienes and, 421

- Cardiovascular system (*Cont.*):
 local anesthetics and, 245
 muscarinic receptor agonists and,
 114–115, 117
 muscarinic receptor antagonists
 and, 120–121
 nicotine and, 145
 nitrates and, 528–530
 nitrous oxide and, 238
 norepinephrine, 152*f*, 153*t*, 156
 NSAIDs and, 437*t*, 438
 opioids and, 355
 oral contraceptives and, 1009
 oxygen inhalation and, 254
 platelet-activating factor and,
 425–426
 propofol and, 229
 prostaglandins and, 421
 salicylates and, 441
 scopolamine, 120
 serotonin (5-HT) in, 192–193
 sevoflurane and, 237
 thiopental and, 228
 thyroid hormones and, 985
 tricyclic antidepressants and, 292
 vasopressin and, 505
- CARDIZEM (diltiazem), 535*t*
 CARDOVAR (trimazosin), 171*t*
 CARDURA (doxazosin), 171*t*
 Carmustine (BCNU)
 for cutaneous T-cell lymphoma,
 1087
 dosage, 865
 mechanisms of action, 865
 pharmacokinetics, 865
 therapeutic uses, 854*t*, 865
 toxicity, 860, 860*t*, 1087

 Vertigo, histamine H₁ receptor antagonists for, 411
 Very-low-density lipoprotein (VLDL)
 characteristics, 603–606, 604r
 metabolism, 606
 VEXOL (rimexolone), 1107
 VFEND (voriconazole), 805
 VIADUR (leuproflide), 975r
 VIAGRA (sildenafil), 531
 VIBRAMYCIN (doxycycline), 665
 VICODIN (hydromorphone), 368r
 Vidarabine, 1101r
 VIGAMOX (moxifloxacin), 1100r
 Vinblastine
 dermatologic uses, 1089
 dosage, 882
 interaction with itraconazole, 803r
 mechanisms of action, 858f
 pharmacokinetics, 882
 therapeutic uses, 855r, 881, 882
 toxicity, 882
 Vinca alkaloids, 855r, 881–884
 VINCASAR PFS (vincristine), 882
 Vincristine
 dosage, 882–883
 interactions
 with itraconazole, 803r
 with nucleoside reverse transcriptase inhibitors, 844
 with nucleoside reverse transcriptase inhibitors, 844
 mechanisms of action, 858f
 pharmacokinetics, 882
 resistance to, 881
 therapeutic uses, 855r, 861, 881, 882
 toxicity, 882, 883
 vasopressin secretion and, 501
 Vinorelbine
 dosage, 883
 pharmacokinetics, 882
 therapeutic uses, 855r, 881, 882
 toxicity, 882, 883
 VIOXX (rofecoxib), 420
 VIP (vasoactive intestinal peptide), 86, 112, 501
 VIRA-A (vidarabine), 1101r
 Viral load, in HIV infection, 838
 VIRAZOLE (ribavirin), 815r
 VIROPTIC (trifluridine), 815r
 Viruses. *See also* Antiviral agents; *specific viruses*
 DNA, 812, 814f
 replication, 812, 814f
 structure, 812
 Visceral afferent fibers, 85–86
 Visceral larva migrans, 695
 Viscoelastic substances, 1108
 VISICOL (sodium phosphate), 640
 VISINE MOISTURIZING (tetrahydrozoline), 1105r
 VISKEN (pindolol), 178
 VISTARIL (hydroxyzine pamoate), 408r
 VISTIDE (cidofovir), 815r
 VISUDYNE (verteporfin), 1112
 Vitamin(s)
 deficiencies, ophthalmic effects, 1113r
 ethanol consumption and, 378
 Vitamin A, 1112–1114, 1113r
 Vitamin B₁, 1113r
 Vitamin B₆ (pyridoxine)
 for altretamine neurotoxicity, 864
 deficiency, ophthalmic effects, 1113r
 with isoniazid, for tuberculosis, 785, 940
 with pyrazinamide, for tuberculosis, 940
 for sideroblastic anemia, 940

- Vitamin B₁₂
 absorption, distribution, and excretion, 943–944, 943f
 chemistry, 942, 942f
 daily requirements, 944
 deficiency, 944–945, 1113r
 folic acid and, 940–942, 941f
 functions, 943
 metabolism, 940–942, 941f
 sources, 943
 therapeutic uses, 945
- Vitamin C, 1113r
- Vitamin D
 absorption, fate, and excretion, 1063
 chemistry, 1062
 D₂, 1062, 1068
 D₃, 1062, 1068
 daily requirements, 1063
 deficiency, 1067
 ethanol consumption and, 379
 forms, 1069
 for hyperparathyroidism, 1068
 interactions
 with thiazide diuretics, 489
 mechanisms of action, 1064–1065
 metabolic activation, 1063, 1063f, 1064f
 for osteoporosis, 1072
 overdose, 1066, 1067
 physiologic actions, 1064
 therapeutic uses, 1069
- Vitamin D receptor, polymorphisms, 66r
- Vitamin E, 1113r
- Vitamin K
 absorption, fate, and excretion, 964
 chemistry, 964
 deficiency, 958, 964, 1113r
 functions, 963, 964
 pharmacological actions, 964
 requirements, 964
 therapeutic uses, 965–966
 warfarin actions and, 956, 957f
 for warfarin reversal, 958
- Vitiligo
 PUVA for, 1081
 tacrolimus for, 1088
- VITRASERT (ganciclovir), 824
- VITRAVENE (fomivirsen), 815r
- Vitreous substitutes, 1109, 1110r
- VIVACTIL (protriptyline), 281r
- VIVELLE (estradiol), 999
- VOLTAREN (diclofenac), 451
- VOLTAROL (diclofenac), 451
- VOLTAROL-XR (diclofenac), 451
- Volume of distribution, 8–9, 9f
- Vomiting. *See* Nausea/vomiting
- Von Hippel-Lindau (VHL) protein, 928
- Von Willebrand factor, 505
- Von Willebrand's disease, desmopressin for, 509
- Voriconazole
 absorption, distribution, and excretion, 805
 adverse effects, 806
 chemistry, 805f
 dosage, 806
 interactions, 806
 mechanisms of action, 799f
 in pregnancy, 806
 therapeutic uses, 806
- Vorzole, 1004
- VUMON (teniposide), 890
- VYTORIN (simvastatin/ezetimibe), 615
- W**
- Waldenström's macroglobulinemia
 chlorambucil for, 863
 cladribine for, 880
 fludarabine for, 880
- Warfarin
 absorption, distribution, and excretion, 957
 adverse effects, 958–959
 chemistry, 955–956, 956f
 dosage, 957
 interactions, 958
 with amiodarone, 596
 with chloramphenicol, 769
 with cholestyramine, 616
 with griseofulvin, 807
 with indomethacin, 447
 with itraconazole, 803r
 with macrolides, 773
 with NSAIDs, 439
 with phenytoin, 323
 with proton pump inhibitors, 623
 with quinine, 676
 with rifabutin, 794
 with statins, 613
 with voriconazole, 806
 mechanisms of action, 956–957
 pharmacogenetics, 958, 1119
 sensitivity to, 958
 teratogenic effects, 959, 964
 therapeutic uses, 959
- Water channel–containing vesicles, 501
- Water homeostasis, vasopressin and, 499, 504, 504f
- Wegener's granulomatosis, cyclophosphamide for, 916, 1087
- Weight gain, antipsychotics and, 310
- WELLBUTRIN (bupropion), 284r
- WELLFERON (interferon- α), 815r
- Whooping cough. *See* Pertussis
- Wilms' tumor, dactinomycin for, 887
- Wilson's disease, 1129, 1130
- WINRHO SDF (Rho(D) immune globulin), 922r
- WINSTROL (stanozolol), 1017f
- Withdrawal syndrome, 388–389. *See also specific agents*
- Wobble position, 57
- Wolff-Parkinson-White syndrome
 mechanisms, 583, 585r
 pharmacotherapy, 585r
- Wucheria bancrofti*, 696. *See also* Lymphatic filariasis
- WYAMINE SULFATE (mephentermine), 162
- WYICILLIN (penicillin G procaine), 734
- WYTENSIN (guanabenz), 163–164
- X**
- XALATAN (latanoprost), 1103
- XANAX (alprazolam), 268r
- Xenobiotics, 3
- Xenon, 224r, 239
- Xeroderma pigmentosa, isotretinoin for cancer chemoprevention in, 1080
- Xerophthalmia, 1113
- Xerosis, 1113
- Xerostomia, muscarinic receptor agonists for, 117–118
- XIBROM (bromfenac), 1107
- XIGRIS (drotrecogin alfa), 955
- Ximelagatran, 959
- XOLAIR (omalizumab), 468
- XOPENEX (levbuterol), 464
- XYLOCAINE (lidocaine), 246
- Y**
- YENTREVE (duloxetine), 123
- ⁹⁰Y-ibritumomab tiuxetan, 902r, 903r, 905
- YODOXIN (iodoquinol), 685
- Yohimbe, 174–175
- Z**
- ZADITOR (ketotifen hydrochloride), 1108
- Zafirlukast
 for asthma, 467–468
 chemistry, 467f
 interaction with warfarin, 958
 pharmacokinetics, 467
 toxicity, 467
- Zalcitabine
 adverse effects, 843, 845
 chemistry, 841f
 interaction with ganciclovir, 824
 mechanisms of action, 845
 pharmacokinetics, 842r, 845
- Zaleplon, 265, 269–270
- ZANAFLEX (tizanidine), 164
- Zanamivir, 815r
 absorption, distribution, and excretion, 829
 adverse effects, 829
 antiviral activity, 828
 chemistry, 828r
 mechanisms of action, 829
 therapeutic uses, 829
- ZANOSAR (streptozocin), 865
- ZANTAC (ranitidine), 624
- ZARONTIN (ethosuximide), 327
- ZAROXOLYN (metolazone), 491r
- ZEBETA (bisoprolol), 179
- ZEGERID (omeprazole), 623
- ZELNORM (tegaserod), 635
- ZEMPLAR (paricalcitol), 1068
- ZEMURON (rocuronium), 138r
- ZENAPAX (daclizumab), 919
- ZENTEL (albendazole), 695
- ZESTRIL (lisinopril), 520
- ZETIA (ezetimibe), 620
- ZEVALIN (⁹⁰Y-ibritumomab tiuxetan), 905
- Zidovudine (AZT)
 adverse effects, 843, 844, 930
 chemistry, 841f, 844
 for HIV infection, 839r, 844
 for HIV prophylaxis, 844
 interactions
 with ganciclovir, 824
 with interferons, 832
 with probenecid, 819
 with rifabutin, 794

- mechanisms of action, 843*f*, 844
- pharmacokinetics, 842*t*
- resistance to, 843
- Zileuton
 - chemistry, 467*f*
 - withdrawal from market, 420
- ZINACEF (cefuroxime), 743*t*
- Zinc deficiency, ophthalmic effects, 1113*t*
- Zinc oxide, 1092
- Zinc undecylenate, 811
- ZINECARD (dexrazoxane), 888
- Ziprasidone, 307*t*, 309*t*
- ZITHROMAX (azithromycin), 772
- ZOCOR (simvastatin), 614
- ZOFRAN (ondansetron), 647
- ZOLADEX (goserelin), 975*t*
- Zoledronate (zoledronic acid)
 - adverse effects, 1071
 - for cancer chemotherapy, 899
 - for hypercalcemia, 1068, 1071
- Zollinger-Ellison syndrome, 624, 632
- Zolmitriptan, 195*f*
 - absorption, fate, and excretion, 196
 - contraindications, 197
 - for migraine, 197
- ZOLOFT (sertraline), 283*t*
- Zolpidem, 265, 267, 269–270
- ZOMETA (zoledronate), 899
- ZOMIG (zolmitriptan), 195
- ZONALON (doxepin), 1082
- ZONEGRAN (zonisamide), 332
- Zonisamide, 321*f*, 324*t*, 332–333
- Zopiclone, 267, 269
- ZOSTRIX (capsaicin), 1094
- ZOSYN (piperacillin–tazobactam), 750
- ZOVIRAX (acyclovir), 815*t*
- ZYFLO (zileuton), 467
- ZYLOPRIM (allopurinol), 459
- ZYMAR (gatifloxacin), 1100*t*
- Zymogen, 949
- ZYPREXA (olanzapine), 200
- ZYRTEX (cetirizine), 409*t*
- ZYVOX (linezolid), 780
