**FIG. 32.3** Afferent nerves in airways. Slowly adapting receptors (SARs) are found in airway smooth muscle, whereas rapidly adapting myelinated (RAR) and unmyelinated C-fibers are present in the airway mucosa.

## Rapidly adapting receptors

Myelinated fibers in the epithelium, particularly at the branching points of proximal airways, show rapid adaptation. Rapidly adapting receptors (RARs) account for 10–30% of the myelinated nerve endings in the airways. These endings are sensitive to mechanical stimulation and to mediators such as histamine. The response of RAR to histamine is partly due to mechanical distortion consequent on bronchoconstriction, although if this is prevented by pre-treatment with isoprenaline the RAR response is not abolished, indicating a direct stimulatory effect of histamine. It is likely that mechanical distortion of the airway may amplify irritant receptor discharge.

RAR with widespread arborizations are very numerous in the area of the carina, where they have been termed "cough receptors" as cough can be evoked by even the slightest touch in this region. RAR respond to inhaled cigarette smoke, ozone, serotonin, and prostaglandin $F_{2\alpha}$, although it is possible that these responses are secondary to the mechanical distortion produced by the bronchoconstrictor response to these irritants. Neurophysiological studies using an *in vitro* preparation in guinea pig trachea and bronchi show that a majority of afferent fibers are myelinated and belong to the A$\delta$-fiber group. Although these fibers are activated by mechanical stimulation and low pH, they are not sensitive to capsaicin, histamine, or bradykinin [6, 7].

## C-Fibers

There is a high density of unmyelinated (C-fibers) in the airways and they greatly outnumber myelinated fibers. In the bronchi C-fibers account for 80–90% of all afferent fibers in cats. C-fibers play an important role in the defense of the lower respiratory tract. C-fibers contain neuropeptides, including SP, NKA, and CGRP, that confers a motor function on these nerves. Bronchial C-fibers are insensitive to lung inflation and deflation but typically respond to chemical stimulation. *In vivo* studies suggest that bronchial C-fibers in dogs respond to the inflammatory mediators histamine, bradykinin,

serotonin, and prostaglandins. They are selectively stimulated by capsaicin given either by intravenously or by inhalation and are also stimulated by $SO_2$ and cigarette smoke. Since these fibers are relatively unaffected by lung mechanics, it is likely that these agents act directly on the unmyelinated endings in the airway epithelium. In the *in vitro* guinea pig trachea preparation C-fibers are stimulated by capsaicin and by bradykinin, but not by histamine, serotonin, or prostaglandins (with the possible exception of prostacyclin) [6].

RARs and C-fibers are sensitive to water and hyperosmotic solutions, with RARs showing a greater sensitivity to hypotonic and C-fibers to hypertonic saline. *In vitro* guinea pig trachea preparation A$\delta$ fibers and C-fibers are stimulated by water and by hyperosmolar solutions; a small proportion of A$\delta$ fibers are also stimulated by low-chloride solutions, whereas the majority of C-fibers are [8]. C-fibers are activated by capsaicin, which acts through vanilloid or TRPV1 receptors, for which small molecule inhibitors are now in development [9].

## Cough

Cough is an important defense reflex, which may be triggered from either laryngeal or lower airway afferents and is an important symptom of asthma and COPD [10]. There is debate about which are the most important afferents for initiation of cough and this may be dependent on the stimulus. Thus RARs are activated by mechanical stimuli (e.g. particulate matter), bronchoconstrictors and hypotonic saline and water, whereas C-fibers are more sensitive to hypertonic solutions, bradykinin, and capsaicin. In normal humans inhaled capsaicin is a potent tussive stimulus and this is associated with a transient bronchoconstrictor reflex that is abolished by an anticholinergic drug. It is not certain whether this is due to stimulation of C-fibers in the larynx, but as these are very sparse it is likely that bronchial C-fibers are also involved. Citric acid is commonly used to stimulate coughing in experimental challenges in human subjects; it is likely that it produces cough by a combination of low pH (which

stimulates C-fibers) and low chloride (which may stimulate laryngeal and lower airway afferents). Inhaled bradykinin causes coughing and a raw sensation retrosternally which may be due to stimulation of C-fibers in the lower airways. Bradykinin appears to be a relatively pure stimulant of C-fibers [6]. Prostaglandins $E_2$ and $F_{2\alpha}$ are potent tussive agents in humans and also sensitize the cough reflex [11, 12].

## Afferent nerves in airway disease

Airway afferent nerves may become sensitized in inflammatory airway diseases, resulting in increased symptoms, such as cough and chest tightness (Fig. 32.4). Cough is a prominent symptom of asthma and COPD, and there is evidence that cough sensitivity is increased [13]. This may be due to senitization of afferent nerves in the airways as a result of inflammatory mediators produced during asthma

and COPD. $PGE_2$ is a potent sensitizer of airway sensory nerves and is increased in asthma and COPD. Bradykinin is also a potent afferent nerve sensitizer [7]. Chronic inflammation may lead to neural hyperesthesia through mechanisms that may involve cytokines and neurotrophins [5]. Neurotrophins, such as nerve growth factor (NGF), may result in proliferation of airway sensory nerves and a change in the nerve phenotype, with a reduced threshold of activation and increased expression of neuropeptides [14].

## Neurotrophins

The role of neurotrophins in airway diseases is increasingly recognized (Fig. 32.5) [15]. NGF, brain-derived neurotrophic factor, and neurotrophins 3 and 4/5 are nerve-related cytokines that play an important role in the function, proliferation, and survival of autonomic nerves. In sensory nerves

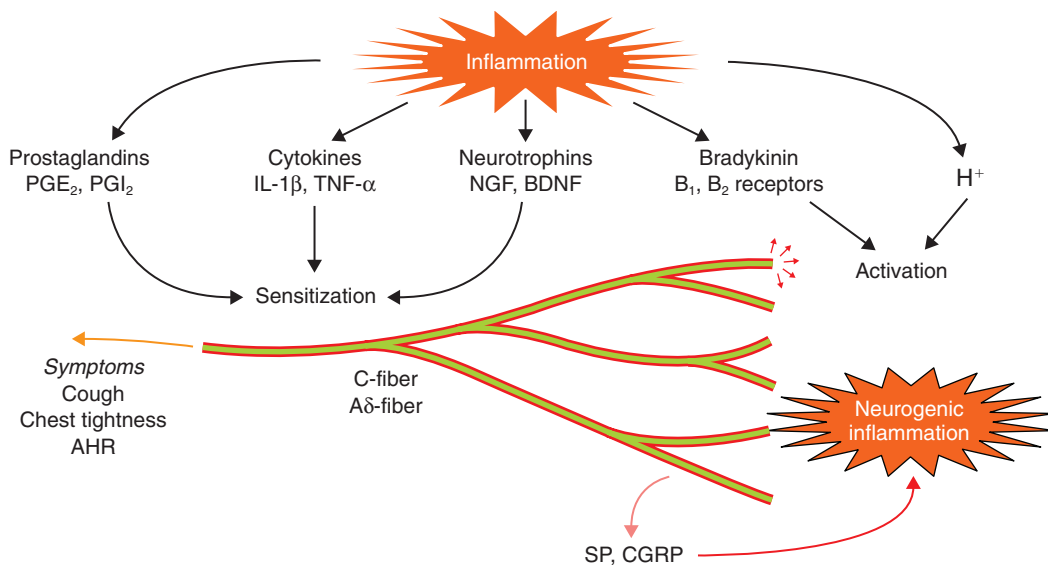

**FIG. 32.4** Airway hyperaesthesia. Increased sensitivity of airway nerves induced by inflammation as a result of sensitization and activation of airway sensory nerves, resulting in increased symptoms and possibly neurogenic inflammation through the release of neuropeptides, such as substance P (SP) and calcitonin gene-related peptide (CGRP). AHR: airway hyperresponsiveness.

**FIG. 32.5** Neurotrophin effects in airways. NGF is released from mast cell and epithelial cells and has effects of airway afferent nerves, which may lead to cough and airway hyperresponsiveness. NGF also promotes the growth of mast cells through its receptor TrkA and is chemotactic for eosinophils.

neurotrophins increase responsiveness and may also lead to expression of tachykinins. Neurotrophins may be produced by inflammatory cells, such as mast cells, lymphocytes, macrophages, and eosinophils, as well as structural cells, such as epithelial cells, fibroblasts, and airway smooth muscle cells [16]. Although neurotrophins have predominant effects on neuronal cells they may also act as growth factors for inflammatory cells such as mast cells, as well as increasing chemotaxis and survival of eosinophils [4]. NGF induces airway hyperresponsiveness in various animal models of asthma, including guinea pig, mice, and rats and this is blocked by antibodies to NGF or its receptor TrkA [15]. In guinea pig NGF enhances airway hyperresponsiveness by increasing the release of SP from sensory nerves [17] and increases sensory nerve activation [4]. The role of neurotrophins in human asthma is uncertain. However, NGF levels are increased in bronchoalveolar lavage fluid of asthmatic patients and there is a further increase after allergen challenge [18]. Blocking NGF or its receptors may therefore have some therapeutic potential. A decoy TrkA receptor which blocks NGF *in vivo* reduces airway hyperresponsiveness in animal models [19].

## CHOLINERGIC NERVES

Cholinergic nerves are the major neural bronchoconstrictor mechanism in human airway and are the major determinant of airway caliber in humans.

## Cholinergic control of airways

Cholinergic nerve fibers arise in the nucleus ambiguous in the brain stem and travel down the vagus nerve and synapse in parasympathetic ganglia which are located within the airway wall. From these ganglia short post-ganglionic fibers travel to airway smooth muscle and submucosal glands (Fig. 32.6). In animals, electrical stimulation of the vagus nerve causes release of ACh from cholinergic nerve terminals, with activation of muscarinic cholinergic receptors on smooth muscle and gland cells, which results in bronchoconstriction and mucus secretion. Prior administration of a muscarinic receptor antagonist, such as atropine, prevents vagally induced bronchoconstriction.

## Non-neuronal cholinergic system

There is increasing evidence that ACh is also synthesized and released from several non-neuronal cells, including airway epithelial cells and fibroblasts [20, 21]. Inflammatory signals may increase the synthesis of ACh and thus enhance cholinergic effects. The contribution of non-neuronal ACh to cholinergic responses in the airways is currently unknown but may play an important role in regulating the tone of small airways where cholinergic innervation is very sparse. Non-neuronal ACh may have effects on inflammatory cells through nicotinic and muscarinic receptors that are expressed on their surface [22].

FIG. 32.6 Cholinergic control of airway smooth muscle. Pre-ganglionic and post-ganglionic parasympathetic nerves release acetylcholine (ACh) and can be activated by airway and extra-pulmonary afferent nerves.

## Muscarinic receptors

Of the five known subtypes of muscarinic receptor, four have been identified by binding studies and pharmacologically in lung [23]. The muscarinic receptors that mediate bronchoconstriction in human and animal airways belong to the $M_3$-receptor subtype, whereas mucus secretion appears to be mediated by $M_1$- and $M_3$-receptors. $M_1$-receptors are also localized to parasympathetic ganglia, where they facilitate the neurotransmission mediated via nicotinic receptors (Fig. 32.7).

Inhibitory muscarinic receptors (autoreceptors) have been demonstrated on cholinergic nerves of airways in animals *in vivo*, and in human bronchi *in vitro* [24]. These pre-junctional receptors inhibit ACh release and may serve to limit vagal bronchoconstriction. Autoreceptors in human airways belong to the $M_2$-receptor subtype, whereas those on airway smooth muscle and glands belong to the $M_3$-receptor subtype [25]. Drugs such as atropine and ipratropium bromide, which block both pre-junctional $M_2$-receptors and post-junctional $M_3$-receptors on smooth muscle with equal efficacy, therefore increase in ACh release may then overcome the post-junctional blockade. This means that such drugs will not be as effective against vagal bronchoconstriction as against cholinergic agonists, and it may be necessary to re-evaluate the contribution of cholinergic nerves when drugs which are selective for the $M_3$-receptors are developed for clinical use. The presence of muscarinic autoreceptors has been demonstrated in human subjects *in vivo* [26]. A cholinergic agonist, pilocarpine, which selectively activates $M_2$-receptors, inhibits cholinergic reflex bronchoconstriction induced by sulfur dioxide in normal subjects, but such an inhibitory mechanism does not appear to operate in asthmatic subjects, suggesting that there may be dysfunction of these autoreceptors. Such a defect in muscarinic autoreceptors may then result in exaggerated cholinergic reflexes in asthma, since the normal feedback inhibition of ACh release may be lost. This might

also explain the sometimes catastrophic bronchoconstriction which occurs with β-blockers in asthma which, at least in mild asthmatics, appears to be mediated by cholinergic pathways [27]. Antagonism of inhibitory β-receptors on cholinergic nerves would result in increased release of ACh which could not be switched off in the asthmatic patient (Fig. 32.8). This explains why anticholinergics prevent β-blocker-induced asthma. The mechanisms which lead to dysfunction of pre-junctional $M_2$-receptors in asthmatic airways are not certain, but it is possible that $M_2$-receptors may be more susceptible to damage by oxidants or other products of the inflammatory response in the airways. Experimental studies have demonstrated that influenza virus infection and eosinophils in guinea pigs may result in a selective loss of $M_2$-receptors compared with $M_3$-receptors, resulting in a loss of autoreceptor function and enhanced cholinergic bronchoconstriction.

Cholinergic innervation is greatest in large airways and diminishes peripherally, although in humans muscarinic receptors are localized to airway smooth muscle in all airways [28]. In humans, studies which have tried to distinguish large and small airway effects have shown that cholinergic bronchoconstriction predominantly involves larger airways, whereas β-agonists are equally effective in large and small airways. This relative diminution of cholinergic control in small airways may have important clinical implications, since anticholinergic drugs are likely to be less useful than β-agonists when bronchoconstriction involves small airways. Normal human subjects also have resting bronchomotor tone, since atropine causes bronchodilatation.

## Cholinergic reflexes

A wide variety of stimuli are able to elicit reflex cholinergic bronchoconstriction through activation of sensory receptors in the larynx or lower airways. Activation of cholinergic reflexes may result in bronchoconstriction and an increase in

**FIG. 32.7** Muscarinic receptor subtypes in the airways. Acetylcholine (ACh) from pre-ganglionic vagal nerves activates nicotinic receptors (N) and may be facilitated by $M_1$-receptors. ACh release from pre-ganglionic nerves activate $M_3$-receptors on airway smooth muscle and feeds back to activate pre-junctional $M_2$ receptors (autoreceptors) which inhibit further ACh release.

**FIG. 32.8** Cholinergic control of airways in COPD. The normal vagal cholinergic tone has a greater effect in COPD airways because of the geometric relationship between airway diameter and resistance, so that anticholinergics are effective bronchodilators in COPD. $β_2$-Agonists are also effective and act as functional antagonists of cholinergic tone.

airway mucus secretion through the activation of muscarinic receptors on airway smooth muscle cells and submucosal glands. Cholinergic reflexes may also be activated from extrapulmonary afferents and these reflexes may also contribute to airway defenses. Esophageal reflux may be associated with bronchoconstriction in asthmatic patients. In some patients this may be due to aspiration of acid into the airways, in other cases acid reflux into the esophagus activates a reflex cholinergic bronchoconstriction (the "reflux reflex").

### Modulation of cholinergic neurotransmission

Many agonists may modulate cholinergic neurotransmission via pre-junctional receptors on post-ganglionic nerves [29]. Some receptors increase (facilitate), whereas others inhibit the release of ACh. Inflammatory mediators may influence cholinergic neurotransmission via pre-junctional receptors. For example, thromboxane and prostaglandin (PG)$D_2$ facilitate ACh release from post-ganglionic nerves in the airways. Facilitation may also occur at parasympathetic ganglia in the airways; these structures are surrounded by inflammatory cells and have an afferent neural input. Electrophysiological recordings show a prolonged potentiation of neurotransmission in ganglia after allergen exposure in sensitized guinea pigs [30].

### Role in asthma

Many of the stimuli which produce bronchospasm in asthma activate sensory nerves and reflex cholinergic bronchoconstriction in animals and there is some evidence that cholinergic tone is increased in asthmatic airways. There are several mechanisms by which cholinergic tone might be increased in asthma:

- Increased afferent stimulation by inflammatory mediators, such as histamine or prostaglandins.
- Increased release of ACh from cholinergic nerve terminals by an action on cholinergic nerve endings themselves, or by an increase in nerve traffic through cholinergic ganglia (local airway reflex).
- Abnormal muscarinic receptor expression, either via an increase in $M_3$-receptors or via reduction in $M_2$-receptors. There is no evidence for increased $M_1$- or $M_3$-receptor expression in asthmatic lungs [31], but there is functional evidence for a defect in $M_2$-receptor function that may be secondary to the inflammatory process.
- Decrease in the neuromodulators (VIP, NO) that have a "braking" effect on neurotransmission.

The effect of ACh on asthmatic airways is exaggerated, as a manifestation of non-specific hyperresponsiveness of the airways. Anticholinergic agents will only counteract the cholinergic reflex component of bronchoconstriction, which are less prominent in human airways than animal studies had indicated. By contrast $\beta_2$-agonists reverse bronchoconstriction irrespective of the mechanism, since they act as functional antagonists and always have a much greater bronchodilator effect than anticholinergic drugs. Vagal tone increases the airway narrowing further, and for geometric reasons will have a greater effect on airway resistance in narrowed airways. This may explain why anticholinergics are often of greater use in chronic asthmatics with a major element of fixed airway obstruction.

### Role in COPD

The structural narrowing of the airways in COPD means that even normal vagal tone will exert a greater effect on airway caliber than in normal airways (Fig. 32.8). This may account for the efficacy of anticholinergics as bronchodilators in COPD, as cholinergic tone is the only reversible element and have similar or even greater effects than $\beta_2$-agonists. In addition, cholinergic mechanisms may account for the mucus hypersecretion of chronic bronchitis.

## ADRENERGIC CONTROL

The airways are also under adrenergic control, which includes sympathetic nerves (which release noradrenaline), circulating catecholamines (predominantly adrenaline) and $\alpha$- and $\beta$-adrenoceptors (Fig. 32.9). The fact that $\beta$-adrenergic antagonists cause bronchoconstriction in asthmatic patients, but not in normal individuals, suggests that adrenergic control of airway smooth muscle may be abnormal in asthma.

### Sympathetic innervation

Although sympathetic bronchodilator nerves have been demonstrated in several species, including cats, dogs, and guinea pigs, most evidence suggests that adrenergic nerves do not control human airway smooth muscle directly. However, sympathetic nerves may influence cholinergic tone of airway smooth muscle via adrenoceptors localized to parasympathetic ganglia and pre-junctionally on post-ganglionic nerves [29], and sympathetic nerves may play an important role in the regulation of airway blood flow and in mucus secretion.

### $\beta$-Adrenoceptors

$\beta$-Adrenoceptors regulate many aspects of airway function, including airway smooth muscle tone, mast cell mediator release, and plasma exudation. The possibility that $\beta$-receptors are abnormal in asthma has been extensively investigated. The suggestion that there is a primary defect in $\beta$-receptor function in asthma has not been substantiated and any defect in $\beta$-receptors is likely to be secondary to the disease, perhaps as a result of inflammation or as a consequence of adrenergic therapy. Some studies have demonstrated that airways from asthmatic patients fail to relax normally to isoproterenol, suggesting a possible defect in $\beta$-receptor function in airway smooth muscle [32]. Whether this is due to a reduction in $\beta$-receptors, a defect in receptor coupling, or some abnormality in the biochemical pathways leading to relaxation, is not yet known, although the density of $\beta$-receptors in airway smooth muscle appears to be normal [33] and there is no reduction in the density of $\beta_1$- or $\beta_2$-receptors in asthmatic lung, either at the receptor or at the mRNA level [31].
**FIG. 32.9** Adrenergic control of airway smooth muscle. Sympathetic nerves release norepinephrine (NE), which may modulate cholinergic nerves at the level of the parasympathetic ganglion or post-ganglionic nerves, rather than directly at smooth muscle in human airways. Circulating epinephrine (E) is more likely to be important in adrenergic control of airway smooth muscle.

There is some evidence that proinflammatory cytokines may affect $\beta_2$-receptor function. IL-1$\beta$ reduces the bronchodilator effect of isoprenaline *in vitro* and *in vivo* and this appears to be due to uncoupling of $\beta_2$-receptors due to increased expression of the inhibitory G protein, $G_i$ [34, 35]. However, studies of $\beta_2$-receptor expression in asthmatic airways obtained by biopsy have demonstrated only small defects in coupling after local allergen challenge [36].

## $\alpha$-Adrenoceptors

$\alpha$-Receptors which mediate bronchoconstriction have been demonstrated in airways of several species, and may only be demonstrated under certain experimental conditions. There is now considerable doubt about the role of $\alpha$-receptors in the regulation of tone in human airways, however, since it has proved difficult to demonstrate their presence functionally or by autoradiography [37]. $\alpha$-Adrenoceptor antagonists are not effective as bronchodilators, but it is possible that $\alpha$-receptors may play an important role in regulating airway blood flow, which may indirectly influence airway responsiveness.

## NANC NERVES AND NEUROPEPTIDES

Neural responses that are not blocked by a combination of adrenergic and cholinergic antagonists are known as nonadrenergic non-cholinergic (NANC) nerves. These NANC responses appear to be due to the release of neurotransmitters from classical autonomic nerves, which include neuropeptides, nitric oxide (NO), and adenosine triphosphate (ATP). In the airways both inhibitory NANC (bronchodilator) and excitatory NANC (bronchoconstrictor) nerves have been described.

## i-NANC nerves

i-NANC nerves which mediate bronchodilatation have been described in may species, including humans, in whom they are of particular importance in the absence of any direct sympathetic innervation of airway smooth muscle [38]. The neurotransmitter for these nerves in some species, including guinea pigs and cats, is VIP and related peptides. The i-NANC bronchodilator response is blocked by $\alpha$-chymotrypsin, an enzyme, which very efficiently degrades VIP and by antibodies to VIP. However, although VIP is present in human airways and VIP is a potent bronchodilator of human airways *in vitro*, there is no evidence that VIP is involved in neurotransmission of i-NANC responses in human airways, and $\alpha$-chymotrypsin that completely blocks the response to exogenous VIP has no effect on neural bronchodilator responses [39]. It is likely that VIP and related peptides may be more important in neural vasodilatation responses and may result on increased blood flow to bronchoconstricted airways.

The predominant neurotransmitter of human airways is NO. NO synthase inhibitors, such as $N^G$-L-arginine methyl ester, virtually abolish the i-NANC response [40]. This effect is more marked in proximal airways, consistent with the demonstration that nitrergic innervation is greatest in proximal airways. NO appears to be a co-transmitter with ACh, and NO acts as a "braking" mechanism for the cholinergic system by acting as a functional antagonist to ACh at airway smooth muscle [41] (Fig. 32.10).
**FIG. 32.10** Nitric oxide (NO) and vasoactive intestinal peptide (VIP) may modulate cholinergic neural effects mediated via acetylcholine (ACh). In inflammation NO may be removed by superoxide anions ($O_2^-$) generated form inflammatory cells and VIP by mast cell tryptase, therefore diminishing their "braking" effects, resulting in exaggerated cholinergic bronchoconstriction.

**TABLE 32.1** Neuropeptides in the respiratory tract.

| Neuropeptide | Localization |
| --- | --- |
| Vasoactive intestinal peptide | Parasympathetic |
| Peptide histidine isoleucine/methionine | (+ Afferent) |
| Peptide histidine valine-42 | |
| Helodermin | |
| Helospectins I and II | |
| PACAP-27 | |
| Galanin | |
| Substance P | Afferent |
| Neurokinin A | (C-fibers) |
| Neuropeptide K | |
| Calcitonin gene-related peptide | |
| Gastrin-releasing peptide | |
| Secretoneurin | |
| Nociceptin | |
| Neuropeptide Y | Sympathetic |
| Opioids? | |
| Somatostatin | Afferent/uncertain |
| Enkephalin | |
| Endomorphins Cholecystokinin octapeptide | |

## Airway neuropeptides

Many neuropeptides are localized to sensory, parasympathetic, and sympathetic neurones in the human respiratory tract (Table 32.1). These peptides have potent effects on bronchomotor tone, airway secretions, bronchial circulation, and on inflammatory and immune cells [1]. Although the precise physiological roles of each peptide are not yet fully understood, clues are provided by their localization and functional effects. Recently the development of specific neuropeptide receptor antagonists has provided important new insights into the roles of these neurotransmitters. Many of the inflammatory and functional effects of neuropeptides are relevant to asthma and there is compelling evidence for the involvement of neuropeptides in the pathophysiology and symptomatology of asthma and COPD.

Although classically neuropeptides are released from autonomic nerves, there is increasing evidence that these peptides may be synthesized and released from inflammatory and non-neural structural cells, particularly in disease. Inflammatory cytokines may increase the expression of neuropeptide genes in inflammatory cells, so that inflammatory become a major source of the neuropeptide at the inflammatory site. For example, both VIP and SP have been localized to human eosinophils and SP to macrophages [42, 43].

## Neuropeptides and airway inflammation

Neuropeptides have multiple inflammatory and immune effects on the airways, thereby intensifying the ongoing inflammation [44]. In turn, inflammatory mediators may amplify or sometimes dampen neuropeptide effects. Inflammatory mediators may increase the release of neuropeptides from sensory and other nerves, may increase the expression of neuropeptide genes in neural and inflammatory cells, may increase the expression of neuropeptide receptors and may decrease the degradation of neuropeptides.

## Vasoactive intestinal peptide and related peptides

VIP-immunoreactive nerves are widely distributed throughout the respiratory tract in humans and there is also evidence for the presence of several closely related peptides (peptide histidine methionine, peptide histidine valine, helodermin, helospectins I and II, and pituitary adenylate cyclase activating peptide (PACAP-38) and PACAP-27 which have

**TABLE 32.2** Effects of tachykinins on airways.

| Effect | Neurokinin receptor |
| --- | --- |
| Bronchoconstriction (small > large airways) | $NK_2$, $NK_1$ |
| Plasma exudation | $NK_1$ |
| Bronchial vasodilatation | $NK_1$ |
| ↑ Neurotransmission (ganglia, cholinergic nerves) | $NK_1$, $NK_2$, $NK_3$ |
| Cough (peripheral and central mechanisms) | $NK_1$, $NK_2$, $NK_3$ |
| Mucus secretion (submucosal glands and goblet cells) | $NK_1$ |
| ↑ Adhesion molecules (ICAM-1, E-selectin) | $NK_1$ |
| Activation of inflammatory cells (macrophages, T-lymphocytes, eosinophils) | $NK_1$, $NK_2$ |
| Angiogenesis | $NK_1$ |
| Fibroblast activation | $NK_1$, $NK_2$ |

similar functional effects. VIP may be localized to para-sympathetic and sensory nerves. It is a potent vasodilator, a bronchodilator, increases mucus secretion and may have anti-inflammatory effects. In some species it is a mediator of neurogenic bronchodilatation, but this is not the case in human airways. A defect in VIP has been proposed in asthma, but there is little evidence for this [45].

## Tachykinins

SP and NKA, but not NKB, are localized to C-fibers are abundant in rodent airways, but are sparse in human airways [46]. Tachykinins are also be expressed human macrophages, which also express tachykinin receptors. Tachykinins have many different effects on the airways which may be relevant to asthma and these effects are mediated via $NK_1$-receptors (preferentially activated by SP) and $NK_2$-receptors (activated by NKA) (Table 32.2). Tachykinins constrict smooth muscle of human airways *in vitro* via $NK_2$-receptors. Tachykinin receptors are widely distributed in human airways, with localization predominantly to airway smooth muscle, mucus-secreting cells and bronchial cells [47]. NKA causes bronchoconstriction after both intravenous and inhaled administration in asthmatic subjects. Mechanical removal of airway epithelium potentiates the bronchoconstrictor response to tachykinins, largely because the neutral endopeptidase (NEP), which is a key enzyme in the degradation of tachykinins in airways is strongly expressed on epithelial cells [48].

SP stimulates mucus secretion from submucosal glands in human airways *in vitro* and is a potent stimulant to goblet cell secretion in guinea pig airways via activation of $NK_1$-receptors. $NK_1$-receptors also mediate the increased

plasma exudation and the vasodilator response to tachykinins. Tachykinins may activate alveolar macrophages and monocytes to release inflammatory cytokines, such as IL-6. Tachykinins also enhance cholinergic neurotransmission by facilitating acetylcholine release at cholinergic nerve terminals and by enhancing ganglionic transmission.

Tachykinins are subject to degradation by at least two enzymes, angiotensin-converting enzyme (ACE), and NEP. ACE is predominantly localized to vascular endothelial cells and therefore degrades intravascular peptides, whereas NEP is important for degrading tachykinins in the airways. The activity of NEP may therefore determine tachykinin responsiveness in the airways. Inhibition of NEP by phosphoramidon or thiorphan potentiates bronchoconstriction *in vitro* in animal and human airways and after inhalation *in vivo*. The activity of NEP is reduced by mechanical removal of the epithelium, virus infections, cigarette smoke, and hypertonic saline. Several of the stimuli known to induce bronchoconstrictor responses in asthmatic patients have been found to reduce the activity of airway NEP [49].

## Calcitonin gene-related peptide

CGRP-immunoreactive nerves are abundant in the respiratory tract of several species and is co-stored and co-localized with SP in afferent nerves. CGRP is a potent vasodilator, which has long-lasting effects and potently dilates bronchial vessels *in vitro* and *in vivo*. It is possible that CGRP may be the predominant mediator of arterial vasodilatation and increased blood flow in response to sensory nerve stimulation in the bronchi. CGRP may be an important mediator of airway hyperemia in asthma. CGRP has variable effects on airway smooth muscle tone and appears to act indirectly through the relapse of other constrictors, such as endothelin. Like tachykinins, CGRP is chemotactic for eosinophils.

## Neurogenic inflammation in airway disease

Sensory nerves may be involved in inflammatory responses through the antidromic release of neuropeptides from nociceptive nerves or C-fibers via a local (axon) reflex [50] (Fig. 32.11). The phenomenon is well documented in several organs, including skin, eye, gastrointestinal tract, and bladder. Neurogenic inflammation occurs in the respiratory tract and may contribute to the inflammatory response in asthma. Neurogenic inflammation is well documented in the airways of rodents, and there is good evidence that tachykinins contribute to the airway hyperresponsiveness in several animal models of asthma, using capsaicin depletion or specific tachykinin antagonists. However, although it was proposed several years ago that neurogenic inflammation and peptides released from sensory nerves might be important as an amplifying mechanism in asthmatic inflammation, there is little evidence to date to support this idea.
**FIG. 32.11** Axon reflex in asthma. Possible neurogenic inflammation in asthmatic airways via retrograde release of peptides from sensory nerves via an axon reflex. Substance P (SP) causes vasodilatation, plasma exudation and mucus secretion, whereas neurokinin A (NKA) causes bronchoconstriction and enhanced cholinergic reflexes and calcitonin gene-related peptide (CGRP) vasodilatation.

There is some evidence in support of a role for tachykinins in asthma:

- An increase in SP-immunoreactive nerves has been described in patients with severe asthma [51].
- SP and NKA levels are increased in bronchoalveolar lavage fluid and induced sputum of asthmatic patients [46].
- There is increased expression of $NK_1$- and $NK_2$-receptors in asthmatic lungs and airways [52, 53]. However this is more evidence against a role for tachykinins:
- SP-immunoreactive nerves are sparse in human airways and are not increased in lungs and biopsies from asthmatic patients [45].
- Capsaicin has no effect on human airways *in vitro*, whereas it potently constructs guinea pig airways. Similarly, inhaled capsicum causes cough and transient bronchoconstriction, but not prolonged bronchoconstriction as in rodents.
- NEP inhibitors have no different effects in patients with asthma than normal subjects [54].
- Tachykinin antagonists are so far ineffective in asthma.

Neurogenic inflammation plays a role in COPD. SP levels are elevated in induced sputum of patients with COPD [55]. Cigarette smoke activates C-fibers in airways and may result in mucus hypersecretion and goblet cell discharge [56] and tachykinins are potent stimuli of mucus secretion in human airways [57].

## Other neuropeptides

Several other neuropeptides have been identified in human airways (Table 32.1) [58], but their function is even less well defined that the neuropeptides discussed. Secretoneurin is a neuropeptide released by sensory nerves in the nose and is chemotactic for inflammatory cells such as eosinophils [59], but its role in asthma is uncertain.

## CIRCULATING VASOACTIVE PEPTIDES AND HORMONES

Airway function can be altered by vasoactive peptides and hormones that reach the lungs from the bloodstream, as well as by neurotransmitters released from nerve endings and by molecules released locally from other cells within the airway [60].

## Circulating catecholamines

Circulating epinephrine (adrenaline) is released from the adrenal medulla into the circulation. It may reduce bronchial smooth muscle tone directly by stimulating $\beta_2$-adrenergic receptors on airway smooth muscle, or indirectly by reducing acetylcholine release from cholinergic nerves. The lack of a bronchoconstrictor effect of $\beta$-antagonists in normal subjects suggests that in this group, basal concentrations of circulating

adrenaline are probably not important in the regulation of resting bronchomotor tone. In contrast, $\beta_2$-antagonists cause bronchoconstriction in some asthmatics; in the absence of an important sympathetic nerve supply to airway smooth muscle, this suggests that basal concentrations of circulating epinephrine are important in the maintenance of airway tone. The controlling influence of circulating epinephrine on airway tone might operate particularly in those patients with asthma in whom resting airway caliber is already reduced. In patients with non-asthmatic COPD, however, $\beta_2$-antagonists do not normally cause bronchoconstriction. This finding would suggest that basal concentrations of circulating adrenaline are not important in the maintenance of airway tone in COPD.

Basal epinephrine concentrations and the circadian variation in epinephrine concentrations in asthmatic patients appear to be similar to those found in normal subjects [61–63]. Although Bates *et al.* reported that plasma epinephrine levels at 10 pm were lower in patients with nocturnal asthma than in a non-nocturnal asthma group [64]; correction of the nocturnal fall in plasma epinephrine does not alter the peak expiratory flow values of patients with nocturnal asthma [65]. These findings, taken together with the report of nocturnal asthma occurring in a patient after adrenalectomy [66], suggest that a fall in plasma epinephrine at night is not a dominant factor in nocturnal asthma.

Allergen- or pharmacological-induced bronchoconstriction do not cause the release of epinephrine, which suggests that epinephrine does not appear to have an important homeostatic role in the regulation of airway caliber during bronchoconstriction to these stimuli [67, 68]. Even during acute exacerbations of asthma there may be no elevation in plasma epinephrine levels [69, 70], although very high-epinephrine concentrations have been found in some patients with acute severe asthma. The elevated epinephrine concentrations achieved after strenuous exercise [71] cause bronchodilation in both normal and asthmatic subjects [62, 63, 72] and may counteract bronchospasm induced by exercise in asthma [73]. Although a blunted catecholamine response to exercise in asthmatic patients has been reported by some investigators, [74] other studies have found no significant difference in either the peak plasma catecholamine level between normal and asthmatic subjects or in the response to increasing levels of exercise (Fig. 32.12) [71, 75, 76].

Norepinephrine, which has $\beta_1$- and weak $\beta_2$-adrenergic activity in addition to $\alpha$-adrenergic effects, acts as a neurotransmitter in the sympathetic nervous system but overspills into the circulation. The infusion of noradrenaline, producing circulating concentrations within the physiological and pathophysiological range, has no effect on airway caliber in either normal subjects or asthmatic subjects [62, 63]. The third catecholamine present in the blood, dopamine, has no influence on resting bronchomotor tone in normal or stable asthmatic subjects [77] although it may attenuate induced bronchoconstriction [78] and can decrease the rate of ventilation in animals and man [79].

**FIG. 32.12** Plasma epinephrine concentrations during the course of and for 20 min after maximal treadmill exercise in normal subjects (broken line) and asthmatic subjects (solid) (no significant difference). Reproduced from Ref. [76] with permission.

The human natriuretic peptides include atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin [82]. Most natriuretic peptides are produced primarily in the heart but are released also in other tissues, including the kidneys, lungs, and central nervous system. Specific ANP receptors have been localized to lung (including airway smooth muscle), of which some may be the ANP-$_c$ or clearance receptor subtype [83], although the receptor subtype(s) in human airway smooth muscle is unknown. In isolated human airway tissue, ANP has a direct relaxant effect and confers protection against agonist-induced contraction [84, 85]. Two principal mechanisms have been proposed for the inactivation of ANP: degradation by NEP and binding to a non-guanylyl cyclase clearance receptor (ANP-$_c$ receptor). NEP is widely distributed within the airways and plays a role in modulating the effect of ANP on airway smooth muscle [84, 85].

An intravenous infusion of exogenous ANP causes bronchodilation and attenuates bronchial reactivity to inhaled histamine and to fog challenge [86–90]. The rise in plasma ANP levels during exercise is similar to these obtained during the lowest rates of ANP infusion; these results suggest that the rise in circulating ANP levels during exercise may attenuation exercise-induced bronchospasm [76] (Fig. 32.13). Plasma ANP levels are elevated in patients with cardiac failure [91] and pulmonary hypertension secondary to COPD [92]; under these circumstances ANP may also play a protective role on the airways. Circulating ANP at physiological concentrations, however, appears unlikely to have any influence on bronchomotor tone in healthy subjects [88].

## Natriuretic peptides

Natriuretic peptides are a family of hormones that have an important role in salt and water homeostasis [80, 81].

## Angiotensin II

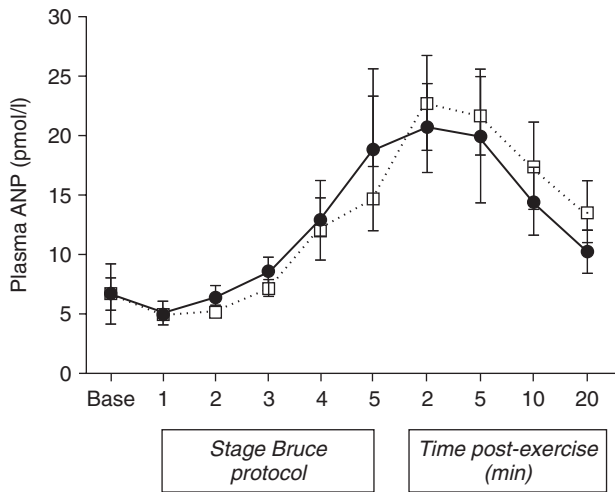
The renin-angiotensin system plays an important role in fluid and electrolyte homeostasis through the actions of the


**FIG. 32.13** Plasma ANP concentrations during exercise after maximal treadmill exercise in normal subjects (broken line) and asthmatic subjects (solid line) (no significant difference). Reproduced from Ref. [76] with permission.

octapeptide angiotensin II. Angiotensin II is formed from angiotensinogen by the action of renin and then ACE, 60–80% occurring within the pulmonary vascular endothelium. An alternative ACE-independent pathway, possibly mediated by several inflammatory proteases [93], may also cause the formation of angiotensin II.

The effect of physiological concentrations of angiotensin II on basal bronchial tone of normal individuals is not know, whereas infusion of angiotensin II in mild asthmatic patients to plasma levels found in acute asthma causes bronchoconstriction [94] (Fig. 32.14). Angiotensin II, although causing only weak contraction of isolated human and bovine bronchial rings, potentates the effects of methacholine and endothelin-1 *in vitro* [95, 96]. In patients with mild asthma, angiotensin II at subthreshold concentrations potentates methacholine-induced bronchoconstriction [96] but has no effect on endothelin- or histamine-evoked bronchoconstriction *in vivo* [97, 98]. Angiotensin II receptor antagonists reduce allergen-induced airway hyperresponsiveness and eosinophil accumulation in guinea pigs [99] and methacholine-induced bronchoconstriction in asthma [100]. These results suggest a role for angiotensin II as a putative mediator in asthma.

The renin-angiotensin system is activated in acute severe asthma, but not in stable chronic asthma [70, 94]. The mechanism of activation is unclear, but nebulized $\beta_2$-agonists cause elevation of renin and angiotensin II in normal and mild asthmatic subjects through an ACE-dependent pathway [101, 102]. This may occur via stimulation of $\beta$-adrenoceptors on juxtaglomerular cells, but the levels of angiotensin II seen in acute severe asthma are higher, suggesting the existence of an alternative pathway of angiotensin II formation. Exercise activates the renin-angiotensin system [103, 104], raising the possibility that elevated angiotensin II levels during exercise could contribute to exercise-induced bronchospasm. The renin-angiotensin system is also activated in patients with COPD and edema [105, 106].

**FIG. 32.14** Effect of infused angiotensin II (AII) on plasma levels of AII, changes in systolic blood pressure (BP) and change in $FEV_1$ from baseline values in eight asthmatic patients; *$p < 0.05$ versus placebo. Reproduced from Ref. [94] with permission.

## Adrenomedullin

Adrenomedullin is a 52-amino acid peptide that possesses vasodilator and natriuretic properties [107]. The chemical structure of adrenomedullin is similar to CGRP. Immunoreactivity to adrenomedullin is found in tissues throughout the body including the lung [108]. Adrenomedullin has a long-lasting bronchodilator action in guinea pig trachea [109, 110], inhibits IL-8 secretion from alveolar macrophages [111] and attenuates antigen-induced microvascular leakage and bronchoconstriction in guinea pigs [112]. Plasma levels of adrenomedullin are elevated in hypoxic patients with COPD [113] and in severe chronic asthma [114]. Its role in the control of airway smooth tone and inflammation in asthma or COPD, however, remains uncertain.

## Urotensin II

Urotensin II is an 11-amino acid cyclic peptide, which activates specific receptors that are widely distributed in smooth muscle [115]. It is a potent vasoconstrictor and a more potent constrictor of airway smooth muscle than endothelins [116]. Its role in regulating airway smooth muscle and vascular tone in asthma and COPD are currently unknown.

## Cortisol

Pharmacological doses of intravenous cortisol have no short-term effect on airway caliber in normal subjects [117]. Although glucocorticoids can potentate the response to catecholamines in isolated bronchial tissue, the effect occurs only at supraphysiological concentrations [118]. These results suggest that endogenous cortisol is unlikely to have an important direct modulating effect on airway tone in normal individuals.

In asthma the role of physiological concentrations of circulating cortisol in airway function is uncertain. In nocturnal asthma, the nadir in the circadian variation in plasma cortisol occurs 4h before maximal bronchoconstriction [119], although the delayed action of cortisol means that it could still have an influence on airway caliber. A reduced nadir of plasma cortisol is found in patients with nocturnal asthma compared to a group without nocturnal asthma, but this finding may have been influenced by previous corticosteroid therapy [120]. Other studies have found no direct association between plasma cortisol concentrations and nocturnal asthma [63]. Furthermore, the infusion of physiological concentrations of hydrocortisone, eliminating the fall in plasma cortisol at night, does not prevent the nocturnal fall in peak flow rate in most asthmatic patients [119], suggesting that the circulating cortisol level is not the only factor in determining nocturnal asthma. Endogenous glucocorticoids rise following allergen challenge in allergic asthmatic subjects and may play a role in the modulation of allergen-induced bronchoconstriction [121].

## Thyroid hormones

The relationship between asthma and thyroid disease provides indirect evidence of a role for thyroid hormones in maintaining airway function. The development of hyperthyroidism can be associated with deterioration in asthma control, with subsequent improvement in symptoms following appropriate treatment [122, 123]. Conversely the occurrence of hypothyroidism has been reported to be associated with improvement in asthma control, which relapses following subsequent thyroxine replacement [124]. The possible mechanisms by which thyroid hormones could influence airway smooth muscle tone and responsiveness are unclear [60].

## Sex hormones

Progesterone has an important role in reducing the contractility of uterine smooth muscle during pregnancy, and this effect may be due to its influence on gap junction formation between smooth muscle cells. It has been suggested that progesterone might cause similar effects on bronchial smooth muscle. Progesterone could influence airway smooth muscle tone by other mechanisms indirectly either by potentiating the effect of catecholamines [118] or by potentiating airway inflammation [125]. Progesterone levels and airway responsiveness do not show a clear relationship during either the pregnancy or the menstrual cycle, although changes in the levels of other hormones may obscure an effect of progesterone

on the airways [126, 127]. However, one report found that female athletes develop more severe exercise-induced asthma during the mid-luteal phase of the menstrual cycle when salivary progesterone levels were at there highest, suggesting that the menstrual cycle phase is an important determinant of the severity of exercise-induced asthma in female athletes with mild atopic asthma [128]. It is of interest that intramuscular progesterone has a beneficial effect in some women with severe menstrual asthma [129].

Estrogen possesses both immunostimulatory and immunosuppressive properties and causes increased acetylcholine activity in the lungs of animals [130], which could result in an increase or decrease in airway tone. Estrogen receptor-$\alpha$ deficient mice exhibit increased airway responsiveness, possibly due to reduced $M_2$ muscarinic receptor function and resultant increased acetylcholine release, suggesting a possible role for estrogen in regulating airway function [131]. A preliminary report suggested that estrogen treatment may have steroid-sparing effects in women with severe asthma [132].

## Glucagon

Glucagon has bronchodilator actions, but whether it has a role in the control of airway smooth tone in humans is not established [133]. Certainly intravenous glucagon has no significant bronchodilation action in patients with acute asthma [134].

## ROLE OF HUMORAL MECHANISMS IN ASTHMA AND COPD

Circulating hormones and vasoactive peptides appear to play a minor role in the physiological regulation of airway tone in normal individuals. Epinephrine is the only hormone known to influence bronchomotor tone, and it is only during strenuous exercise that concentrations are elevated sufficiently to cause bronchodilation.

Humoral mechanisms play a more important role in the regulation of airway tone in diseased states of the airways such as asthma and possibly in other disorders such as COPD, cor pulmonale, congestive cardiac failure, respiratory failure, and thyroid disease. Circulating epinephrine has a role in the maintenance of resting airway tone in asthma, perhaps particularly in those patients in whom resting airway caliber is already reduced. The elevated epinephrine and ANP concentrations achieved after vigorous exercise may act to counteract exercise-induced asthma. It has not been established in asthma whether elevated circulating angiotensin II achieved during exercise, or more particularly in acute severe asthma, contributes to bronchospasm.

## INTRODUCTION

This chapter aims to provide a brief overview of disease mechanisms to integrate some of the detailed information provided in earlier chapters into a framework with clinical relevance. Asthma and chronic obstructive pulmonary disease (COPD) are both highly complex conditions whose pathobiology remains inadequately defined. In both diseases there are many different and distinct inflammatory cells and multiple mediators with complex acute and chronic effects on the airways and airspaces. We now appreciate that these changes may vary among patients because of genetic variance in susceptibility [1]. Although our understanding of asthma pathogenesis has been enhanced by the application of new molecular, cell biological, and genetic techniques to the condition, and the key test of the acquired knowledge is the success of new specifically targeted therapies. In this area the successes have been few in asthma and are virtually absent in COPD. Thus, even though we have made considerable advances in understanding asthma, there remain many fundamental questions that need to be answered.

Our views on asthma and COPD have continued to evolve. Although it is recognized that chronic inflammation underlies the clinical syndromes, it has been hard to define the precise nature of this inflammation, much less its primary etiology. Nevertheless it is appreciated that the final consequence of this chronic inflammatory response is an abnormal *control* of airway caliber *in vivo* in asthma. In contrast, the evolution of understanding in COPD has been much slower; key insights are sought which will open up the understanding of this complex disorder (see Chapter 34).

## ASTHMA AS AN INFLAMMATORY DISEASE

It had been recognized for many years that patients who die of asthma attacks have grossly inflamed airways. The airway lumen is occluded by tenacious mucus plugs composed of plasma proteins exuded from airway vessels and mucus glycoproteins secreted from surface epithelial cells. The airway wall is edematous and infiltrated with inflammatory cells, which are predominantly eosinophils and T-lymphocytes [2]. The airway epithelium is invariably shed in a patchy manner and clumps of epithelial cells are found in the airway lumen. Occasionally there have been opportunities to examine the airways of asthmatic patients who die in accidents thought to be unrelated to their asthma. In this setting inflammatory changes have been observed but they are less marked than those observed in patients with active asthma [3]. These studies also reveal that the inflammation in asthmatic airways involves not only the trachea and bronchi, but also extends to the terminal bronchioles [4]; some investigators using transbronchial biopsies have shown inflammatory cells in the parenchyma [5].

It has also been possible to examine the airways of asthmatic patients by fiberoptic and rigid bronchoscopy, bronchial biopsy, and bronchoalveolar lavage (BAL). Direct bronchoscopic examination reveals that the airways of asthmatic patients are often erythematous and swollen, indicating acute inflammation. Lavage of the airways has revealed an increase in the numbers of lymphocytes, mast cells, and eosinophils and evidence for activation of macrophages in comparison with nonasthmatic controls. Biopsies have provided evidence for increased numbers and activation of mast cells, macrophages, eosinophils,

T-lymphocytes including regulatory T-cells, and mucin secreting cells [6–9]. These changes are found even in patients with mild asthma who have few symptoms [10], suggesting that inflammation may be found in all asthmatic patients who are symptomatic. Similar inflammatory changes have been found in bronchial biopsies of children with asthma, even at the onset of symptoms [11, 12].

## AIRWAY HYPERRESPONSIVENESS

The relationship between inflammation and clinical symptoms of asthma is not clear. There is evidence that the degree of inflammation is loosely related to airway hyperresponsiveness (AHR), as measured by histamine or methacholine challenge. However, the degree of inflammation, as measured by the number of various types of inflammatory cells in the lesion, is not closely linked to the clinical severity of asthma or AHR [13]. This suggests that other factors, such as structural changes in the airway wall, are important in mediating the clinical symptoms of asthma. The increased airway responsiveness in asthma is a striking physiological abnormality that is present even when airway function is otherwise normal. It is likely that there are several factors that underlie this increased responsiveness to constrictor agents, particularly those that act indirectly by releasing bronchoconstrictor mediators from airway cells or that modify the mechanical characteristics of the airway wall. AHR may be due to increased release of mediators (such as histamine and leukotrienes from mast cells), abnormal behavior of airway smooth muscle, thickening of the airway wall by reversible (edema), and irreversible (airway smooth muscle thickening, fibrosis) elements. Airway sensory nerves may also contribute importantly to symptoms, such as cough and chest tightness, as the nerves become sensitized by the chronic inflammation in the airways.

Although most attention has been focused on the acute inflammatory changes seen in asthmatic airways (bronchoconstriction, plasma exudation, mucus secretion), asthma is a *chronic* disease, persisting over many years in most patients. Superimposed on this chronic inflammatory state are acute inflammatory episodes, which correspond to exacerbations of asthma. It is clearly important to understand the mechanisms of acute and chronic inflammation in asthmatic airways and to investigate the long-term consequences of this chronic inflammation on airway function.

## INFLAMMATORY CELLS

Many different inflammatory cells are involved in asthma, although the precise role of each cell type is not yet certain (Fig. 33.1). It is evident that no single inflammatory cell is

**FIG. 33.1** A potential schema of Inflammation in asthma. Inhaled allergens activate sensitized mast cells by crosslinking surface-bound IgE molecules to release several bronchoconstrictor mediators, including cysteinyl-leukotrienes (*cys*-LT) and prostaglandin $D_2$ ($PGD_2$). Epithelial cells release stem-cell factor (SCF), which is important for maintaining mucosal mast cells at the airway surface. Allergens are processed by myeloid dendritic cells, which are conditioned by thymic stromal lymphopoietin (TSLP) secreted by epithelial cells and mast cells to release the chemokines CC-chemokine ligand 17 (CCL17) and CCL22, which act on CC-chemokine receptor 4 (CCR4) to attract T helper 2 (Th2) cells. Th2 cells have a central role in orchestrating the inflammatory response in allergy through the release of interleukin-4 (IL-4) and IL-13 (which stimulate B-cells to synthesize IgE), IL-5 (which is necessary for eosinophilic inflammation) and IL-9 (which stimulates mast-cell proliferation). Epithelial cells release CCL11, which recruits eosinophils via CCR3. Patients with asthma may have a defect in regulatory T-cells (T-reg), which may favor further Th2-cell proliferation.

able to account for the complex pathophysiology of asthma but some cells predominate in asthmatic inflammation. The inflammation in asthmatic airways differs strikingly from that observed in COPD, where there is a predominance of macrophages, cytotoxic (CD8$^+$) T-lymphocytes, and neutrophils, although both of these common diseases may coexist in some patients. However, although the differences in inflammation between mild asthma and COPD are well described, it is not recognized that patients with severe asthma have inflammatory changes that are similar to those of COPD, with increased numbers of neutrophils, CD4$^+$ Th1 and CD8$^+$ cells [14].

## Mast cells

Mast cells are clearly important in initiating the acute bronchoconstrictor responses to allergen and probably to other indirect stimuli, such as exercise and hyperventilation (via osmolality or thermal changes) and fog. Mast cell activation is likely to play a key role in the symptoms of asthma and during acute exacerbations. There is infiltration of airway smooth muscle by mast cells in patients with asthma that is associated with the characteristic disordered airway function of this condition [15]. Treatment of asthmatic patients with prednisone results in a decrease in the number of tryptase-only positive mast cells [16]. Furthermore, the number of mast cells in induced sputum in patients with seasonal allergic rhinitis is related to the degree of AHR [17]. There appears to be an infiltration of mast cells into airway smooth muscle of asthmatic patients and this is associated with AHR [15]. The key role of mast cells in asthma has been the subject of comprehensive reviews [7, 18]. Mast cells are maintained at the mucosal surface by the secretion of stem cell factor, which acts on c-kit receptors, by epithelial cells [19]. However, it is now clear that mast cells alone cannot account for all the pathobiological changes in asthma and that other cells, such as macrophages, eosinophils, and T-lymphocytes, play key roles in the chronic inflammatory process including induction and maintenance of AHR.

Classically mast cells are activated by allergens through an IgE-dependent mechanism. The importance of IgE in the pathophysiology of asthma has been highlighted by clinical studies with humanized anti-IgE antibodies, which inhibit IgE-mediated effects. Although anti-IgE antibody results in a reduction in circulating IgE to undetectable levels, this treatment results in minimal clinical improvement in patients with severe steroid-dependent asthma [20]. Examination of the patients receiving anti-IgE therapy with omalizumab reveals downregulated expression of IgE receptors (FcεRI) on mast cells and basophils [21]. Biopsy studies show a profound reduction in tissue eosinophilia, together with reductions in T-cell and B-cell numbers in the airway submucosa [22]. These observations suggest that treatment with anti-IgE may be more effective in early stage rather than late stage asthma; however, no clinically directive trials with omalizumab have been conducted in this population. Furthermore, unless the cost of such therapy is dramatically reduced it is unlikely that such treatment would be used in patients with mild disease.

## Macrophages

Macrophages, which are derived from blood monocytes, may traffic into the airways in asthma and may be activated by allergen via low-affinity IgE receptors (FcεRII) [23]. The enormous immunological repertoire of macrophages allows these cells to produce many different products, including a large variety of cytokines that may orchestrate the inflammatory response. Macrophages have the capacity to initiate a particular type of inflammatory response via the release of a certain pattern of cytokines. Macrophages may increase or decrease inflammation depending on the stimulus. For example, alveolar macrophages from normal and patients with mild asthma phagocytose apoptic cells resulting from lipopolysaccharide (LPS) exposure *in vitro* and produce the anti-inflammatory mediator PGE$_2$. In contrast alveolar macrophages from patients with severe asthma are impaired with respect to apoptotic cell uptake and production of PGE$_2$ [24]. These observations indicate that the severity of asthma and perhaps its chronicity can modulate the role of macrophages in asthma. It is also possible that the opposite is true, that is, patients with severe asthma are the individuals with defective macrophage function. It is established that repeated short term exposure to ozone recruits alveolar macrophages to the airways of patients with mild asthma [25] and that there is an association between the amount of carbon in alveolar macrophages, which had to be activated to ingest this material, and lung function [26]. Thus the role of alveolar macrophages appears to be to modulate the expression and severity of asthma.

## Dendritic cells

By contrast, dendritic cells (which are specialized macrophage-like cells in the airway epithelium) are very effective antigen-presenting cells and may therefore play a very important role in the initiation of allergen-induced responses in asthma [27, 28]. Dendritic cells take up allergens though their long finger-like projections, which extend into the airway lumen, process them to peptides, and migrate to local lymph nodes where they present the allergenic peptides to uncommitted T-lymphocytes, to program the production of allergen-specific T-cells. Although there is no established ways to manipulate dendritic cells, it has been shown that during experimental allergen challenge in humans that a significantly greater proportion of CD33$^+$ cells expressed the cys-LT$_1$-receptor compared with CD123$^+$ cells. Pranlukast, cys-LT$_1$-receptor antagonist, decreased the allergen-induced decrease in CD33$^+$ dendritic cells at 3 h compared with placebo treatment. Based on this finding it is reasonable to speculate that anti-leukotriene treatment could modify the initial responses to allergen exposure [29].

## Eosinophils

Eosinophil infiltration is a characteristic feature of asthmatic airways and differentiates asthma from other non-infectious inflammatory conditions of the airway. Indeed, asthma was described as "chronic eosinophilic bronchitis" as early as 1916.

Allergen inhalation results in a marked increase in eosinophils in BAL fluid at the time of the late reaction, and there is a correlation between eosinophil counts in peripheral blood or bronchial lavage and AHR. Eosinophils are linked to the development of AHR through the release of basic proteins and oxygen-derived free radicals [30, 31].

An important area of research is now concerned with the mechanisms involved in recruitment of eosinophils into asthmatic airways. Eosinophils are derived from bone marrow precursors; the Th2 cytokine IL-5 is a unique mediator of eosinophil differentiation and survival in response to allergen provocation. After allergen challenge eosinophils appear in BAL fluid during the late response, and this appearance is associated with a decrease in peripheral eosinophil counts and with the appearance of eosinophil progenitors in the circulation. The signal for increased eosinophil production is likely IL-5 derived from the inflamed airway. Eosinophil recruitment initially involves adhesion of eosinophils to vascular endothelial cells in the airway circulation, their migration into the submucosa, and their subsequent activation. The role of individual adhesion molecules, cytokines, and mediators in orchestrating these responses has been extensively investigated but since there are no pathways that are unique to eosinophils, this aspect of eosinophil biology has not been extensively probed. Adhesion of eosinophils involves the expression of specific glycoprotein molecules on the surface of eosinophils (integrins) and their expression of such molecules as intercellular adhesion molecule-1 (ICAM-1) on vascular endothelial cells. An antibody directed at ICAM-1 markedly inhibits eosinophil accumulation in the airways after allergen exposure and also blocks the accompanying hyperresponsiveness [32]. However, ICAM-1 is not selective for eosinophils and cannot account for the selective recruitment of eosinophils in allergic inflammation. Eosinophil migration may be due to the effects of lipid mediators, such as leukotrienes [33, 34] and possibly platelet-activating factor (PAF), to the effects of cytokines, such as GM-CSF and IL-5 both of which are important for the survival of eosinophils in the airways and "prime" eosinophils to exhibit enhanced responsiveness. Eosinophils from asthmatic patients show exaggerated responses to PAF and phorbol esters, compared with eosinophils from atopic nonasthmatic individuals [35]. This is further increased by allergen challenge [36, 37] suggesting that they may have been primed by exposure to cytokines in the circulation.

There are several mediators involved in the migration of eosinophils from the circulation to the surface of the airway. There are data showing that cysteinyl leukotrienes, through stimulation at the cys-$LT_1$-receptor, are in part responsible for eosinophilopoiesis in human airways [38], but other mediators such as the eotaxins, a family of chemoattractant cytokines that promote eosinophil recruitment to tissues in response to allergic provocation via CCR3 receptors also play a role [39–42]. Other potent and selective eosinophil chemoattractants include chemokines, such as CCL5 (RANTES) and CCL13 (MCP-4), that are expressed in epithelial cells [40, 43, 44] but data for their involvement in intact humans are minimal. There appears to be a co-operative interaction between IL-5, IL-13, and chemokines, so that more than one cytokine may be necessary for the eosinophilic response in airways [45, 46]. Once recruited to the airways, eosinophils

require the presence of various growth factors, of which GM-CSF and IL-5 appear to be the most important [47]. In the absence of these growth factors eosinophils undergo programmed cell death (apoptosis) [48].

A humanized monoclonal antibody to IL-5 has been administered to asthmatic patients [49]; and, as in animal studies, there is a profound and prolonged reduction in circulating eosinophils. Although the infiltration of eosinophils into the airway after inhaled allergen challenge is completely blocked, there is no effect on the response to inhaled allergen and no reduction in AHR. Anti-CCR3, anti-integrin, and antiselectin treatments are currently being considered as anti-eosinophil strategies for treatment of asthma; the results of these studies should better define the role of eosinophils as mediators of asthmatic events. Eosinophils may play a role in airway remodeling rather than AHR in asthma as anti-IL-5 treatment is able to reduce extracellular matrix deposition in asthma [50].

## Neutrophils

The eosinophil has been the recipient of current attention as an effector cell in asthma, but attention has been returning to the role of neutrophils [51, 52]. Although neutrophils are not a predominant cell type observed in the airways of most patients with mild-to-moderate chronic asthma, they appear to be a more prominent cell type in airways and induced sputum of patients with more severe asthma [53–57]. The mechanism of neutrophilic inflammation are not yet well understood, but several mediators, including CXCL8 (IL-8) are likely to be involved (Fig. 33.2). Sputum analysis shows that ~20% of asthmatics, even with mild disease, have a predominantly neutrophilic pattern of inflammation [58]. Also in patients who die suddenly of asthma, large numbers of neutrophils are found in their airways [59] although this may reflect the rapid kinetics of neutrophil recruitment compared to eosinophil inflammation. Rapid withdrawal of corticosteroids results in the appearance of neutrophils in the airways of patients with asthma [60]. There are data to suggest that monomeric IgE may mediate the appearance of neutrophils in the airways of asthmatics and may represent the anti-apoptotic activity of myeloid cell leukemia-1 protein, decreased caspase-3 activity, diminished availability of Smac from mitochondria, and sequestration of the pro-apoptic protein Bax in the cytoplasm [61]. Thus the presence of neutrophils in the airway may reflect the inflammatory microenvironment rather than indicate a causal role for this cell. Further research into the role of neutrophils especially in severe asthma is ongoing [62].

## T-lymphocytes

### Th2 cells

T-lymphocytes play a very important role in co-ordinating the inflammatory response in asthma through the release of specific patterns of cytokines, resulting in the recruitment and survival of eosinophils and in the maintenance of mast cells in the airways. T-lymphocytes are coded to express a distinctive pattern of cytokines, which are similar to that described
**FIG. 33.2** Neutrophilic inflammation in asthma. Viruses, such as rhinovirus, stimulate the release of CXCL8 (IL-8) and CXCL1 (GRO-α) from airway epithelial cells. Allergens activate dendritic cells to release IL-23, which recruits helper T-cells that secrete IL-17 (Th17 cells) to release tumor necrosis factor-α (TNF-α), which amplifies inflammation and CXCL1 and CXCL8, which recruit neutrophils into the airways. Neutrophils release more CXCL8 and also transforming growth factor-β (TGF-β), which activates fibroblasts to cause fibrosis, and neutrophil elastase and matrix metalloproteinase-9 (MMP-9) which stimulate mucus hypersecretion from goblet cells.

**FIG. 33.3** T-lymphocytes in asthma. Asthmatic inflammation is characterized by a preponderance of T helper 2 (Th2) lymphocytes over T helper 1 (Th1) cells. Regulatory T-cells (Treg) have an inhibitory effect, whereas T helper 17 (Th17) cells have a proinflammatory effects. MHC1: Class 1 major histocompatibility complex; IL: interleukin; IFN-γ: interferon gamma; TGF-β: transforming growth factor beta; IgE: immunoglobulin E, Th0: uncommitted T-cell.

in the murine Th2 type of T-lymphocytes, which characteristically express IL-4, IL-5, and IL-13 [6]. This programming of T-lymphocytes is presumably due to antigen-presenting cells such as dendritic cells, which may migrate from the epithelium to regional lymph nodes or which interact with lymphocytes resident in the airway mucosa. The naive immune system is skewed to express the Th2 phenotype; data now indicate that children with atopy are more likely to retain this skewed phenotype than are normal children [63]. There is also evidence that chitinase, a hydrolase that cleaves environmental chitin, an insect protein, plays a critical role in murine Th2 differentiation and has been identified in human tissues from patients with asthma [64, 65]. The recruitment of Th2 cells in the airway is dependent on several chemotactic mediators, including the chemokines CCL17 (TARC) and CCL22 (MDC) which act on CCR4 that are selectively expressed on Th2 cells. These CCR4 ligands show increased expression in airway epithelial cells, macrophages, and mast cells of asthmatic patients [66]. PGD$_2$, mainly derived from mast cells, is also an important chemoattractant of Th2 cells through the activation of DP$_2$-receptors (or CRTH2) [67]. There is some evidence that steroid treatment may differentially affect the balance between IL-12 expression and IL-13 expression [68]. Data from murine models of asthma [69–71] have strongly suggested that IL-13 is both necessary and sufficient for induction of the asthmatic phenotype. One of the most important areas of asthma research in the next few years will be to establish the importance of IL-13 in the induction of the Th2 phenotype and asthma in humans.

## Regulatory T-cells

A subset of CD4$^+$ T-cells expressing CD25, termed T-regulatory cells (Tregs), are capable of suppressing both Th1 and Th2-mediated adaptive immune responses, and these cells may mediate their suppressive actions through release of TGF-β or IL-10 [72]. An imbalance between allergen-specific Tregs and effector Th2 cells has been shown in allergic diseases [73]. There is some evidence that early infections or exposure to endotoxins might promote Th1-mediated responses to predominate and that a lack of infection or a clean environment in childhood may favor Th2-cell expression and thus atopic diseases [74, 75]. Indeed, the balance between Th1 cells and Th2 cells is thought to be determined by locally released cytokines, such as IL-12, which tip the balance in favor of Th1 cells, or IL-4 or IL-13, which favor the emergence of Th2 cells (Fig. 33.3).

## Th17 cells

Another subset of CD4$^+$ T-cells, known as Th17 cells, has recently been described and shown to have an important role in inflammatory and autoimmune diseases [76]. Little is known about the role of Th17 cells in asthma, but increased concentrations of IL-17A (the predominant product of Th17 cells) have been reported in the sputum of asthma patients [77]. IL-17A and the closely related cytokine IL-17F have been linked to neutrophilic inflammation by inducing the release of CXCL1 and CXCL8 from airway epithelial cells [78]. As well as IL-17, Th17 cells also produce IL-21, which is important for the differentiation of these cells and thus acts as a positive autoregulatory mechanism, but it also

inhibits FOXP3 expression and regulatory T-cell development [79, 80]. Another cytokine IL-22 is also released by these cells and stimulates the production of IL-10 and acute-phase proteins [81]. However, more work is needed to understand the role and regulation of Th17 cells in asthma, as they may represent important new targets for future therapies.

## Natural killer T-cells

A subset of CD4$^+$ T-cells termed invariant natural killer T (*i*NKT) cells, which secrete IL-4 and IL-13, has been shown to account for 60% of all CD4$^+$ T-cells in bronchial biopsies from asthmatic patients [82], but this has been disputed in another study, which failed to show any increase in *i*NKT-cell numbers in bronchial biopsies, BAL or sputum of either asthma patients or COPD patients [83]. The role of *i*NKT cells in asthma is currently uncertain as there appears to be a discrepancy between the data from murine models of asthma and humans with the disease [84].

## CD8$^+$ cells

CD8$^+$ (cytotoxic) T-cells are present in patients with more severe disease and irreversible airflow obstruction [85] and these cells may be of either the T$_C$1 or the T$_C$2 type, releasing the same patterns of cytokines as CD4$^+$ cells [86].

## B-lymphocytes

B-cells have an important role in asthma through the release of allergen-specific IgE which binds to Fc$\varepsilon$RI on mast cells and basophils and to low-affinity Fc$\varepsilon$RII on other inflammatory cells, including B-cells, macrophages, and possibly eosinophils [87]. The Th2-type cytokines IL-4 and IL-13 induce B-cells to undergo class switching to produce IgE. In both atopic asthma and non-atopic asthma, IgE may be produced locally by B-cells in the airways [88].

## Basophils

The role of basophils in asthma is uncertain, as these cells have previously been difficult to detect by immunocytochemistry [89]; indeed there may be multiple phenotypes of basophils with some able to release histamine on IgE challenge and others not able to do so [90]. Using a basophil-specific marker, a small increase in basophils has been documented in the airways of asthmatic patients, with an increased number after allergen challenge. However, these cells are far outnumbered by eosinophils [91].

## STRUCTURAL CELLS AND AIRWAY REMODELING

Structural cells of the airways, including epithelial cells, fibroblasts, and even airway smooth muscle cells are the site of influence of many of the cytokines, growth factors, and inflammatory mediators that characterize the asthmatic diathesis. Interestingly they may also be an important source of these same molecular entities [92, 93]. Although the concept is poorly defined, the idea that there are long-lasting changes in the cells that make up the airway wall and that these cells narrow the lumen and contribute to chronic airflow limitation has been termed airway remodeling. Given the absence of a clean case definition, most investigators agree that certain changes, such as thickening of the collagen layer deposited below the true basement membrane, is a critical component of this aspect of asthma [94–98]. Indeed, because structural cells far outnumber inflammatory cells they may become the major source of mediators driving chronic inflammation in asthmatic airways. For example, epithelial cells may have a key role in translating inhaled environmental signals into an airway inflammatory response and are probably a target cell for inhaled glucocorticoids and anti-leukotrienes (Fig. 33.4) [99].

FIG. 33.4 Airway epithelial cells in asthma. Airway epithelial cells may play an active role in asthmatic inflammation through the release of many inflammatory mediators, cytokines, chemokines and growth factors. TNF-α: tumor necrosis factor alpha; IL: interleukin, CCL: C-C chemokine, PDGF: platelet-derived growth factor; EGF: epidermal growth factor; FGF: fibroblast growth factor; IGF: insulin-like growth factor.

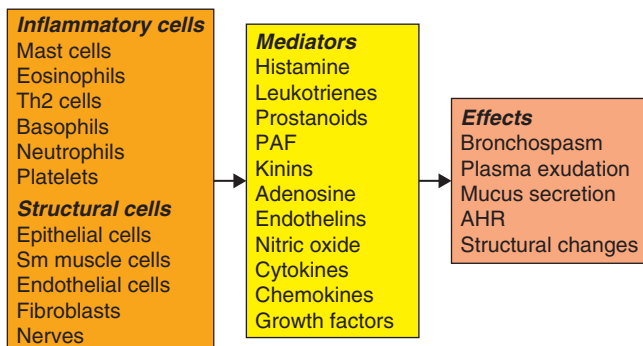
Structural changes in the airways may account for the accelerated decline in airway function seen in asthmatic patients over several years [100, 101]. Structural changes in asthmatic airways include

- increased thickness of airway smooth muscle;
- infiltration of the airway smooth muscle with mast cells
- fibrosis (which is predominantly subepithelial);
- increased mucus-secreting cells;
- increased numbers of blood vessels (angiogenesis).

It is not known if these changes are reversible with therapy. These changes may occur in some patients to a greater extent than others and may be increased by other factors such as concomitant cigarette smoking. It is likely that genetic factors will influence the extent of remodeling that occurs in individual patients.

There are good data to support the idea that mechanical deformation of the airway epithelium as a result of airway smooth muscle constriction results in the creation of a microenvironment that promotes airway remodeling. Deformed airway epithelial cells activate signaling via the epidermal growth factor receptor (EGFR) and the urokinase plasminogen activator system. Experimental data show that soluble signals generated by airway epithelial cells can influence the phenotype of fibroblasts to produce collagen similar to that found in remodeled airways [102–104]. These data could help explain why combination treatments with inhaled steroids and long-acting β-agonists are effective asthma therapies.

## INFLAMMATORY MEDIATORS

Many different mediators have been implicated in asthma. They may have a variety of effects on the airways, which could account for the pathological features of asthma (Fig. 33.5) [105, 106]. Mediators such as histamine, prostaglandins, and leukotrienes contract airway smooth muscle, increase microvascular leakage, increase airway mucus secretion, and attract other inflammatory cells. Because each mediator has many effects in the role of individual mediators in the pathophysiology of asthma is not yet clear. Although the multiplicity of mediators makes it unlikely that preventing the synthesis or action of a single mediator will have a major impact in clinical asthma, recent clinical studies with anti-leukotrienes suggest that cysteinyl leukotrienes have a clinically important effect.


## Leukotrienes

The cysteinyl leukotrienes $LTC_4$, $LTD_4$, and $LTE_4$ are potent constrictors of human airways and have been reported to increase AHR and may play an important role in asthma [107–110] (see Chapter 24). The recent development of potent specific leukotriene antagonists has made it possible to evaluate the role of these mediators in asthma. Potent $LTD_4$ antagonists protect (by about 50%) against exercise- and allergen-induced bronchoconstriction [111–114], suggesting that leukotrienes contribute to bronchoconstrictor responses. Combined treatment with an anti-histamine and an anti-leukotriene is particularly effective [115, 116] Chronic treatment with anti-leukotrienes improves lung function and symptoms in asthmatic patients, although the degree of lung function improvement is not as great as that seen with an inhaled corticosteroid. It is only through the use of specific antagonists that the role of individual mediators of asthma may be defined. In the future, pharmaceuticals with specific targets of action will be of special value in providing pathobiological insights into the basic mechanisms of asthma; their potential role in the treatment of asthma remains to be determined.

## Platelet-activating factor

Platelet-activating factor (PAF) and PAF-acetylhydrolase, the enzyme that degrades PAF, constitute a potent inflammatory mediator system that mimics many of the features of asthma, including eosinophil recruitment and activation and induction of AHR; yet even potent PAF antagonists, such as modipafant, do not control asthma symptoms, at least in chronic asthma [117–120]. However, genetic studies in Japan, where there is a high frequency of a genetic mutation which disables the PAF metabolizing enzyme, PAF-acetylhydrolase, have shown that there is an association between the presence of the mutant form of the enzyme and severe asthma [121, 122]. In addition, there are data showing that patients with a deficiency of the enzyme that degrades PAF is associated with enhanced asthma severity [123]. These data suggest that there may be certain conditions associated with a significant role for PAF in asthma.

## Cytokines

Cytokines are increasingly recognized to be important in chronic inflammation and play a critical role in orchestrating the type of inflammatory response (see Chapter 27) (Fig. 33.6) [124]. Many inflammatory cells (macrophages, mast cells, eosinophils, and lymphocytes) are capable of synthesizing

and releasing these proteins, and structural cells such as epithelial cells and endothelial cells may also release a variety of cytokines and may therefore participate in the chronic inflammatory response [125, 126]. There are number of major classes of cytokines. One class includes T-cell derived cytokines, examples of which include interferon (IFN)$\gamma$ and TNF$\alpha$ from Th1 cells and IL-4 and IL-5 from Th2 cells. Another class includes pro- and anti-inflammatory cytokines with IL-1$\beta$ and IL-10 being respective examples. Chemoattractant cytokines, such as CCL11 and CXCL8 (IL-8), and growth factors cytokines, including PDGF, TGF-$\beta$, and VEGF are other major classes. It is now clear that cytokines play a dominant role in chronic inflammation of asthma.

T-cell-derived cytokines play a key role in creating the microenvironment that lends itself to initiating and perpetuating the chronic inflammatory response of asthma [127]. The key cytokines here are Th2 cytokines, IL-3, IL-4, and IL-5. IL-3 induces eosinophilia *in vivo* and maintains mast cell viability. IL-4 induces differentiation of Th2 cells and creates the microenvironment in which IgE antibody is synthesized [128] and enhances mucin expression in goblet cells [129]. IL-5 enhances eosinophil maturation and prevents apoptosis of inflammatory cells [130]. The recently described IL-17 family of cytokines, produced by cells as a result of the action of IL-15 or IL-23 on CD4 or CD8 memory cells may be important regulators of the asthmatic response [131–133].

A lack of specific small molecule antagonists has made cytokine related research in humans difficult. Although important observations have been made using specific neutralizing antibodies [134], interventions involving immune function can be difficult.

There is increased gene expression of IL-5 in lymphocytes in bronchial biopsies of patients with symptomatic asthma [135, 136]. The role of IL-5 in eosinophil recruitment in asthma has been confirmed in a study in which administration of an anti-IL-5 antibody to asthmatic

patients was associated with a decrease in eosinophil counts in the blood and BAL fluid [49]. Interestingly in this study there was no effect on the physiology of the allergen-induced asthmatic response; although this is not the last word on eosinophils in asthma, it provides evidence that the eosinophil, as recruited by IL-5, is not the major pathogenetic cell in asthma. This has been confirmed by a study of the same antibody in symptomatic asthmatic patients, who showed no improvement in asthma control despite a profound reduction in circulating eosinophils [137]. Another Th2 cytokine produced by peripheral blood cells of patients with asthma, IL-9, may play a critical role in airway remodeling, eosinophilopoiesis, and may interact with the IL-4 receptor$_\alpha$ in mediating some of the pathobiological features of asthma [138–141].

Other cytokines, such as IL-1$\beta$, IL-6, TNF-$\alpha$, TGF-$\beta$, and GM-CSF, are released from a variety of cells, including macrophages and epithelial cells and may be important in amplifying the inflammatory response. TNF-$\alpha$ may be an amplifying mediator in asthma and is produced in increased amounts in asthmatic airways. Inhalation of TNF-$\alpha$ increased airway responsiveness in normal individuals [142]. TNF-$\alpha$ and IL-1$\beta$ both activate the proinflammatory transcription factors, nuclear factor-$\kappa$B (NF-$\kappa$B) and activator protein-1 (AP-1) which then switch on many inflammatory genes in the asthmatic airway [143]. TGF-$\beta$, through ligation of two receptors, type I and II, has been linked to tissue remodeling, and potentially to subepithelial fibrosis through the *Smad*-signaling pathway which could be a site for therapeutic intervention [144–146].

Thymic stromal lymphopoeitin (TSLP) is a cytokine that shows a marked increase in expression in airway epithelium and mast cells of asthmatic patients [66]. TSLP appears to play a key role in programming airway dendritic cells to release CCL17 and CCL22 to attract Th2 cells (Fig. 33.7) [147]. It therefore acts as an upstream cytokine which
**FIG. 33.7** Thymic stromal lymphopoetin in asthma. TSLP is an upstream cytokine produced by airway epithelial cells and mast cells in asthma that acts on immature dendritic cells to mature and release CCL17 (TARC), which attracts Th2 cells via CCR4. Th2: T helper 2; CCL: chemokine; CCR: chemokine receptor.

may play a key role in orchestrating an allergic pattern of inflammation in asthmatic airways.

## Complement

A decade ago it was postulated that complement had little role in the biology of asthma. However, studies in mice harboring a targeted deletion of the C5a receptor showed diminished bronchial hyperresponsiveness induced after allergen challenge [148]. In addition, genetic linkage studies in mice have linked regions of the mouse genome containing the gene for C5a to the phenotype of AHR [149]. Furthermore, the complement peptide C5a has been recovered from BAL fluid of patients after allergen challenge [148]. Current thinking is that complement contributes to the airway inflammation, AHR and mucus production observed in human asthma and may also prevent the formation of a Th2-directed immune response to allergens [150–152].

## Oxidative stress

In asthma, activation of epithelial cells, and resident macrophages, and the recruitment and activation of neutrophils, eosinophils, monocytes, and lymphocytes leads to the generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS). Action of many systems but primarily NADPH oxidase results in the microenvironmental availability of superoxide anions ($O_2^{\bullet-}$), which are rapidly converted to $H_2O_2$ through the catalytic action of superoxide dismutase (SOD). Hydroxyl ion ($^{\bullet}OH$) is then formed nonenzymatically; this damages tissues, particularly cell membranes by

peroxidation of their lipid membranes. Phagocytes use heme peroxidases (myeloperoxidase, MPO) or eosinophil peroxidase (EPO) to produce ROS; these moieties can also interact with nitrite ($NO_2^-$) and hydrogen peroxide ($H_2O_2$) to promote formation of RNS. Eosinophils, a key cell in asthma, have several times greater capacity to generate $O_2^{\bullet-}$ and $H_2O_2$ than do neutrophils, and the content of EPO in eosinophils is 3–10 times higher than the amount of MPO present in neutrophils [153–155].

Evidence for increased oxidative stress in asthma is provided by the increased concentrations of 8-isoprostane (a product of oxidized arachidonic acid) in exhaled breath condensates [156], and increased ethane (a product of oxidative lipoid peroxidation) in exhaled breath of asthmatic patients [156–158]. Airflow obstruction, airway hyperresponsiveness and airway remodeling have been associated with impaired SOD activity [159, 160]. Oxidative stress is increased particularly in patients with severe asthma (perhaps as a result of the neutrophilic infiltration in these patients) and this may reduce the activity of histone deacetylase (HDAC), which may account for the reduced response to corticosteroids in these patients [161, 162].

## Endothelins

Endothelins are potent peptide mediators that are vasoconstrictors, bronchoconstrictors and promote fibrosis [163, 164]. Endothelin-1 levels are increased in the sputum, serum, and BAL fluid of patients with asthma; these levels are modulated by allergen exposure and steroid treatment [165–167]. Endothelins also induce airway smooth muscle cell proliferation and promote a profibrotic phenotype and may therefore play a role in the chronic inflammation of asthma [164, 168].

## Nitric oxide

Nitric oxide (NO) is produced by several cells in the airway by NO synthases [169, 170] (see Chapter 30). Although the cellular source of NO within the lung is not known, inferences based on mathematical models suggest that it is the large airways which are the source of NO [171]. However, in patients with severe asthma NO is also derived form peripheral airways [172]. Current data indicate that the level of NO in the exhaled air of patients with asthma is higher than the level of NO in the exhaled air of normal subjects (see Chapter 30) [173–177]. The elevated levels of NO in asthma are closely linked to airway pH [178–180] and thus are more likely reflective of inflammatory mechanisms than of a direct pathogenetic role of this gas in asthma [181, 182]. The combination of increased oxidative stress and NO may lead to the formation of the potent radical peroxynitrite that may result in nitrosylation of proteins in the airways [183, 184]. Asthmatics managed by measurements of exhaled nitric oxide achieved equivalent asthma control with less inhaled corticosteroids than those managed using conventional algorithms [185]; the availability of portable devices to measure exhaled nitric oxide may allow management of asthma in manner similar to the self management of diabetics [186].

## EFFECTS OF INFLAMMATION ON THE AIRWAYS

The idea that the chronic inflammatory response results in the characteristic pathophysiological changes associated with asthma has been widely promulgated. However, biopsies from children with wheezing show many of the characteristic features of asthma [12]. Thus it is probable that some of the differences between the condition of the airways in normal and asthmatic subjects reflects the genetic makeup of the patient influenced by environmental factors such as airway infections and allergen exposures. The descriptions below present the observations without adequate evidence to support whether changes are markers for or the result of a chronic inflammatory response. The inflammatory response has many effects on structural cells of the airways resulting an amplification and perpetuation of the inflammatory response (Fig. 33.8).

### Airway epithelium

Airway epithelial cells play a critical role in asthma and link environmental influences to inflammatory responses in the airway (Fig. 33.4). Airway epithelial shedding may be important in contributing to AHR and may explain how several different mechanisms, such as ozone exposure, certain virus infections, chemical sensitizers and allergen exposure can lead to its development, since all these stimuli may lead to epithelial disruption. Epithelium may be shed because of an inflammatory milieu made up of eosinophil basic proteins, oxygen-derived free radicals, proteases released from inflammatory cells, and activated complement. Epithelial cells shed from the airway wall may be found in clumps in the BAL fluid or sputum (Creola bodies) of asthmatics, suggesting that there has been a loss of attachment to the basal layer or basement membrane. The damaged epithelium may contribute to AHR in a number of ways, including

- loss of its barrier function to allow penetration of allergens and irritants;
- loss of enzymes (such as neutral endopeptidase) which normally degrade inflammatory mediators such as kinins;
- loss of a relaxant factor (so-called epithelial-derived relaxant factor);
- edema and swelling that promotes obstruction by lumenal encroachment;
- loss of surfactant function leading to increased increased recoil of the airway;
- exposure of sensory nerves which may lead to reflex neural effects on the airway.

### Fibrosis

The basement membrane in asthma appears on light microscopy to be thickened; on closer inspection by electron microscopy it has been demonstrated that this apparent thickening is due to subepithelial fibrosis with deposition of types III and V collagen below the true basement membrane; however, the ratio of interstitial collagen fibrils to matrix is not different from that found in normal subjects [187–189]. Data from a number of investigative groups show that the thickness of the deposited collagen is related to airway obstruction

**FIG. 33.8** The complexity of asthma. The pathophysiology of asthma is complex, with participation of several interacting inflammatory cells which result in acute and chronic inflammatory effects on the airway.

and airway responsiveness [190–193]. The mechanism of the collagen deposition is not known. However, it is known that several profibrotic cytokines, including TGF-β and PDGF, and mediators such as endothelin-1, can be produced by epithelial cells or macrophages in the inflamed airway [126]. Even simple mechanical manipulations can alter the phenotype of airway epithelial cells in a profibrotic fashion [102–104, 194]. The role of airway fibrosis in asthma is unclear, as subepithelial fibrosis has been observed even in mild asthmatics at the onset of disease; it is not certain whether the collagen deposition has any functional consequences. Subepitheial fibrosis is also seen in patients with chronic eosinophilic bronchitis, who usually present with cough and have an infiltration of eosinophils in the airways but no AHR or airway obstruction [195]. This suggests that the subepithelial fibrosis seen in asthmatics is likely to be secondary to eosinophilic inflammation in the airways and may not have important functional consequences.

## Airway smooth muscle

When the concept that asthma was primarily an inflammatory disease was developed in the late 1980s to early 1990s, airway smooth muscle was thought to be predominantly a bystander tissue. That is the inflammatory process resulted in the availability of mediators that led to smooth muscle constriction and expression of an asthma phenotype. There are now substantial data to support the concept that airway smooth muscle in asthma is phenotypically different from normal airway smooth muscle and that these changes reflect the impact of the inflammatory asthmatic airway microenvironment on smooth muscle [15, 196–201]. Although some of the abnormalities identified to date in asthma impact on the contractility of individual units of airway smooth muscle, the more recently identified ones reflect differences in the ability of this tissue to proliferate or to function as an endocrine tissue (Fig. 33.9). For example, airway smooth muscle may increase in mass because of an increased tendency to proliferate due to the absence of an inhibitory transcription factor C/EBP-α [197].

Airway smooth muscle is not only influenced by the inflammatory mediators and cytokines in which it is immersed [202], but also recent studies suggest that airway smooth muscle modulates the remodeling process by secreting multiple cytokines, growth factors, or matrix proteins and by expressing cell adhesion molecules and other potential costimulatory molecules [196]. For example, increased numbers of mast cells have been identified in airway smooth muscle of patients with asthma [15, 198].

The importance of airway smooth muscle in chronic asthma was highlighted by a recent trial in which airway smooth muscle was rendered dysfunctional by bronchial thermoplasty. Although this intervention was limited to relatively large airways there was a measurable, although not overwhelming, clinical benefit [203]. The idea of manipulating the mass or contractile capacity of airway smooth muscle in asthma remains an important and unexplored avenue of asthma therapeutics [199, 204].

## Vascular responses

It has been known for decades that the subepithelial connective tissue of the asthmatic airway has many more blood vessels than are found in similar locations in normal subjects [205]. It is now recognized that bronchial vessels play a key role in the pathophysiology of asthma (Fig. 33.10). Despite this anatomic knowledge, little is known about the role of the bronchial circulation in asthma. This is partly because of the difficulties involved in measuring airway blood flow. Recent studies using an inhaled absorbable gas have demonstrated increased airway mucosal blood flow in asthma [206–208].

The bronchial circulation may also play an important role in regulating airway caliber, since an increase in the vascular volume may contribute to airway narrowing. Vascular blanching of the skin is used to measure the potency of topical steroids and a similar mechanism may be involved with the effects of inhaled steroids in asthma [207, 209]. Increased airway blood flow may be important in removing inflammatory mediators from the airway, and may play a role in the development of exercise-induced asthma [210]. Increased shear stress due to high expiratory pressures may lead to gene transduction and enhanced production of nitric oxide by type III (endothelial) NO synthase [211, 212]; there are *in vivo* experimental data in sheep that support the importance of this mechanism [213]. There may also be an

increase in the number of blood vessels in asthmatic airways as a result of angiogenesis in response to VEGF [214–216].

Microvascular leakage is an essential component of the inflammatory response and many of the inflammatory mediators implicated in asthma produce this leakage [217, 218]. There is a good evidence for microvascular leakage in asthma, and it may have several consequences on airway function, including increased airway secretions, impaired mucociliary clearance, formation of new mediators from plasma precursors (such as kinins), and mucosal edema which may contribute to airway narrowing and increased AHR [219–221].

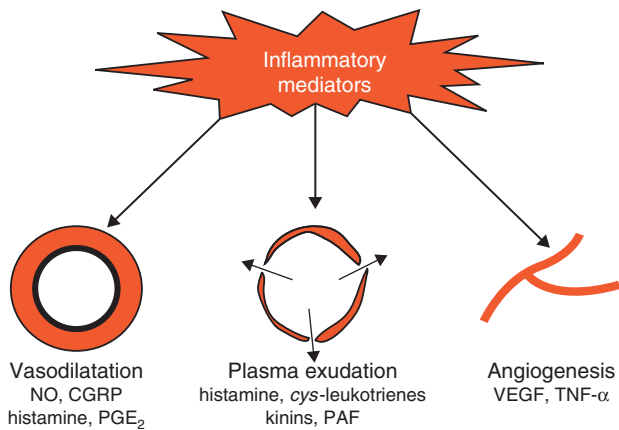

**FIG. 33.10** Vascular abnormalities in asthma. Allergic inflammation has several vascular effects, including vasodilatation, plasma exudation from post-capillary venules and new vessel formation (angiogenesis). NO: Nitric oxide; CGRP: calcitonin gene-related peptide; PGE$_2$: prostaglandin E$_2$; PAF: platelet-activating factor; VEGF: vascular-endothelial growth factor; TNF-α: tumor necrosis factor-alpha.

## Mucus hypersecretion

Mucus hypersecretion is a common inflammatory response in secretory tissues and is an important component of the inflammatory response in asthma (Fig. 33.11). Increased mucus secretion contributes to the viscid mucus plugs which occlude asthmatic airways, particularly in fatal asthma. There is evidence for hyperplasia of submucosal glands which are confined to large airways, and of increased numbers of epithelial goblet cells in patients with asthma, especially those with severe asthma [8]. One of the major mucin genes, MUC5AC is induced by complement factor C3a [222], NO [223], TNF-α [224], EGF family ligands [225], or neutrophil elastase [226]. Since both neutrophils and enhanced expression of mucin genes have been found in great profusion in the airways of patients with severe asthma [52], it is tempting to speculate that the neutrophils may have led to the enhanced mucin gene expression. Thus enhanced mucin expression in epithelial cells can be viewed as an indicator of the inflammatory state of the airways. These findings are not limited to cell culture, since in intact humans with asthma, exercise-induced bronchospasm is associated with enhanced expression of MUC5AC [227]. It is highly likely that methods to manipulate mucin gene expression in response to inflammatory stimuli will be identified and could be of value in the treatment of asthma as well as COPD.

## Neural effects

Neural mechanisms play an important role in the pathogenesis in asthma as discussed in Chapter 32 [228]. Autonomic nervous control of the airways is complex; in addition to classical cholinergic and adrenergic mechanisms,

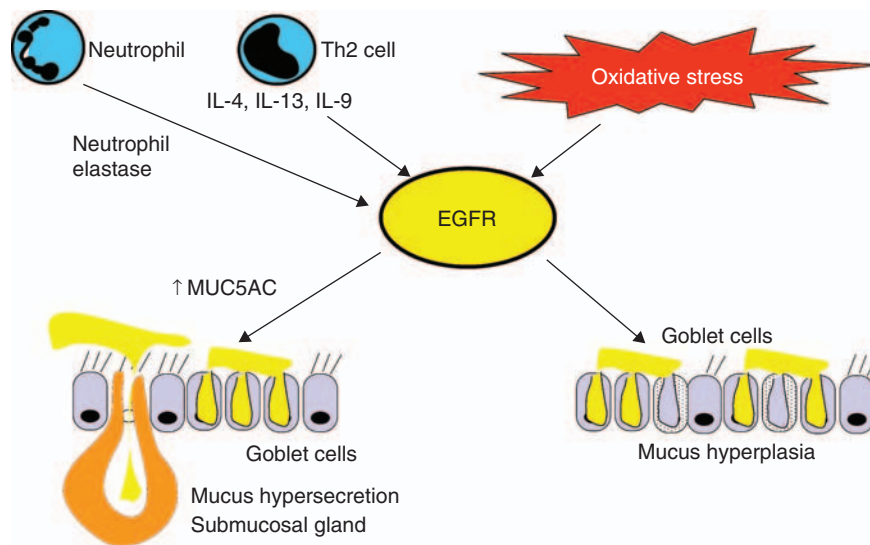

**FIG. 33.11** Mucus hypersecretion in asthma. Increased mucus secretion in asthma may be stimulated by neutrophils through the release of neutrophil elastase, T helper 2 (Th2) cytokines and oxidative stress. This may be mediated via epidermal growth factor receptors (EGFR) which may result in mucus hyperplasia and increased expression of the mucin gene MUC5AC. Mucus hypersecretion is also enhanced by neural mechanisms through the release of acetylcholine (ACh) and substance P (SP).

nonadrenergic noncholinergic (NANC) nerves and several neuropeptides have been identified in the respiratory tract [229–231]. Many studies have investigated the possibility that defects in autonomic control may contribute to AHR in asthma, and abnormalities of autonomic function, such as enhanced cholinergic and $\alpha$-adrenergic responses or reduced $\beta$-adrenergic responses, have been proposed. Current thinking suggests that these abnormalities are likely to be secondary to the disease, rather than primary defects [228]. It is possible that airway inflammation may interact with autonomic control by several mechanisms.

There is a close interaction between airway inflammation and airway nerves (Fig. 33.12). Inflammatory mediators may act on various prejunctional receptors on airway nerves to modulate the release of neurotransmitters [232, 233]. Thus thromboxane and $PGD_2$ facilitate the release of acetylcholine from cholinergic nerves in canine airways, whereas histamine inhibits cholinergic neurotransmission at both parasympathetic ganglia and postganglionic nerves via histamine $H_3$-receptors. Inflammatory mediators may also activate sensory nerves, resulting in reflex cholinergic bronchoconstriction or release of inflammatory neuropeptides. Inflammatory products may also sensitize sensory nerve endings in the airway epithelium, so that the nerves become hyperalgesic. Hyperalgesia and pain (dolor) are cardinal signs of inflammation, and in the asthmatic airway may mediate cough and chest tightness, which are such characteristic symptoms of asthma. The precise mechanisms of hyperalgesia are not yet certain, but mediators such as prostaglandins, certain cytokines, and neurotrophins may be important. Neurotrophins, which may be released from various cell types in peripheral tissues, may cause proliferation and sensitization of airway sensory nerves [234].

Bronchodilator nerves which are nonadrenergic are prominent in human airways and may be dysfunctional in asthma [235]. In human airways, the bronchodilator neurotransmitter appears to be NO [236].

Airway nerves may also release neurotransmitters which have proinflammatory effects. Thus neuropeptides such as substance P (SP), neurokinin A, and calcitonin-gene related peptide may be released from sensitized inflammatory nerves in the airways which increase and extend the ongoing inflammatory response [237]. There is evidence for an increase in SP-immunoreactive nerves in airways of patients with severe asthma [238], which may be due to proliferation of sensory nerves and increased synthesis of sensory neuropeptides as a result of nerve growth factors released during chronic inflammation – although this has not been confirmed in milder asthmatic patients [239]. There may also be a reduction in the activity of enzymes, such as neutral endopeptidase, which degrade neuropeptides such as SP [240]. Thus chronic asthma may be associated with increased neurogenic inflammation, which may provide a mechanism for perpetuating the inflammatory response even in the absence of initiating inflammatory stimuli.

## TRANSCRIPTION FACTORS

The chronic inflammation of asthma is due to increased expression of multiple inflammatory proteins (cytokines, enzymes, receptors, adhesion molecules). In many cases these inflammatory proteins are induced by transcription factors, DNA-binding factors that increase the transcription of selected target genes (Fig. 33.13) [143].

A proinflammatory transcription factor that may play a critical role in asthma is nuclear factor-kappa B (NF-$\kappa$B) which can be activated by multiple stimuli, including protein kinase C activators, oxidants, and proinflammatory cytokines (such as IL-1$\beta$ and TNF-$\alpha$) [241–243]. There is evidence for increased activation of NF-$\kappa$B in asthmatic airways, particularly in epithelial cells and macrophages [244]. Although many aspects of the asthmatic airway are influenced by the expression of transcription factors, there are data linking the mechanical deformation of the airway to expression of proinflammatory transcription factors; these findings have direct implications for the mechanism of exercise-induced asthma and may explain how this physical stimulus could

**FIG. 33.12** Neural mechanism in asthma. There is a close interaction between asthmatic inflammation and neural mechanisms.
**FIG. 33.13** Proinflammatory transcription factors in asthma. Transcription factors play a key role in amplifying and perpetuating the inflammatory response in asthma. Transcription factors, including nuclear factor kappa-B (NF-κB), activator protein-1 (AP-1), and signal transduction-activated transcription factors (STATs), are activated by inflammatory stimuli and increase the expression of multiple inflammatory genes.

**FIG. 33.14** GATA-3 in asthma. The transcription factor GATA-3 (GATA-binding protein-3) is regulated by interleukin-4 (IL-4) via STAT-6 (signal transducer and activator of transcription 6) and regulates the expression of IL-4, IL-5, IL-9, and IL-13 from T helper 2 (Th2) cells and inhibits the expression of T-bet via inhibition of STAT4. IL-33 enhances the actions of GATA-3. T-bet regulates $T_H1$-cell secretion of IL-2 and interferon-γ (IFN-γ) and has an inhibitory action on GATA-3. T-bet is regulated by IL-12 via STAT4 and by IL-27 via STAT1. This demonstrates the complex interplay of cytokines and transcription factors in asthma.

modify the inflammatory microenvironment of the airway [104, 245–247].

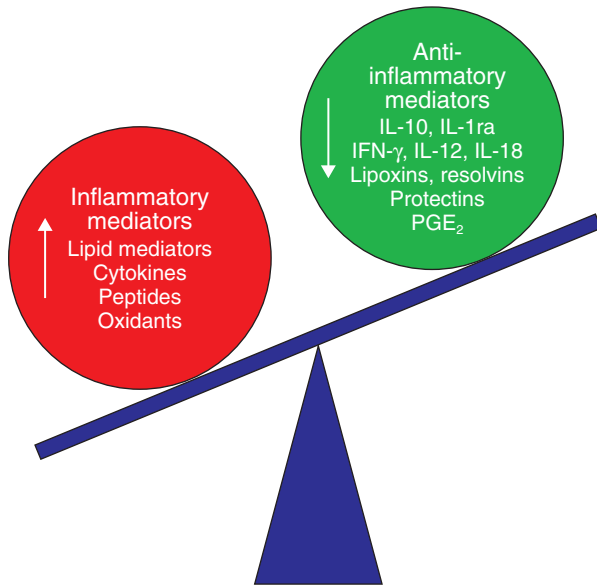
The transcription factor GATA-3 (GATA-binding protein 3) is crucial for the differentiation of uncommitted naive T-cells into Th2 cells and it regulates the secretion of $T_H2$-type cytokines [248]. There is an increase in the number of GATA-3+ T-cells in the airways of asthmatic subjects compared with normal subjects [249]. Following simultaneous ligation of the T-cell receptor (TCR) and co-receptor CD28 by antigen-presenting cells, GATA-3 is phosphorylated and activated by p38 mitogen-activated protein kinase. Activated GATA-3 then translocates from the cytoplasm to the nucleus, where it activates gene transcription [250]. GATA-3 expression in T-cells is regulated by the transcription factor STAT-6 (signal transducer and activator of transcription 6) via IL-4 receptor activation. Another transcription factor T-bet has the opposite effect and promotes Th1 cells and suppresses Th2 cells. T-bet expression is reduced in T-cells from the airways of asthmatic patients compared with nonasthmatic patients [251]. When phosphorylated, T-bet can associate with and inhibit the function of GATA-3, by preventing it from binding to its DNA target sequences [252]. GATA-3 inhibits the production of Th1-type cytokines by inhibiting STAT-4, the major transcription factor activated by the T-bet-inducing cytokine IL-12 [253] (Fig. 33.14). Nuclear factor of activated T-cells (NFAT) is a T-cell-specific transcription factor and appears to enhance the transcriptional activation of GATA-3 at the IL-4 promoter [254]. FOXP3 is a transcription factor that is expressed in Tregs, whereas the equivalent transcription factor in Th17 cells is RORγt. There appears to be a negative interaction between these transcription factors so that a reduction of Tregs in asthma may be a factor increasing Th17 cells [255].


FIG. 33.15  Anti-inflammatory mediators in asthma. There may be an imbalance between increased proinflammatory mediators and a deficiency in anti-inflammatory mediators. IL: interleukin; IL-1ra: interleukin-1 receptor antagonist; IFN-γ: interferon gamma; PGE$_2$: prostaglandin E$_2$.

exhaled breath condensates from healthy subjects but levels were significantly lower in condensates from patients with asthma exacerbations [266]. PD1 when administered before inhaled allergen challenge, in mice led to decreased airway eosinophil and T-lymphocyte recruitment, decreased airway mucus, and less of an increment in AHR than without the PD1. These data suggest that endogenous PD1 is a novel and important counterregulatory signal in allergic airway inflammation.

## IL-10

Airway and alveolar macrophages have a predominantly suppressive effect in asthma and inhibit T-cell proliferation. The mechanism of macrophage-induced immunosuppression is not yet certain, but PGE$_2$ and IL-10 secretion may contribute [267]. IL-10 inhibits many of the inflammatory mechanisms in asthma and its secretion is defective from macrophages of asthmatic patients [268]. IL-10 is secreted by a subset of Tregs and this is enhanced by specific allergen immunotherapy [267]. Interestingly treatment of asthmatic children with an inhaled corticosteroid or with montelukast increases serum levels of IL-10 [269]; these findings suggest that increasing IL-10 may be an important therapeutic approach in asthma.

## ANTI-INFLAMMATORY MECHANISMS IN ASTHMA

Although most emphasis has been placed on inflammatory mechanisms, there may be important anti-inflammatory mechanisms that may be defective in asthma, resulting in increased inflammatory responses in the airways (Fig. 33.15).

### Lipid anti-inflammatory mediators

Several lipid mediators appear to have anti-inflammatory effects, including PGE$_2$, lipoxins, resolvins, and protectins [256, 257]. There is a strong evidence supporting the role of signaling through the lipoxin A receptor as being deficient in severe asthma in general and aspirin-sensitive asthma in particular [258–263]. In addition it has now been established that presqualene diphosphate (PSDP) is an endogenous regulator of phosphatidylinositol 3-kinase (PI3K). PSDP, but not presqualene monophosphate (PSMP), directly inhibits recombinant human PI3K-γ activity and a new PSDP structural mimetic blocks human neutrophil activation and murine lung PI3K activity and inflammation [264]. Resolvin E1 (RvE1: 5S,12R,18R-trihydroxyei cosapentaenoic acid) is an anti-inflammatory lipid mediator derived from the ω-3 fatty acid eicosapentaenoic acid. RvE1 is involved in the resolution of inflammation and reduces allergic inflammation in mice exposed to inhaled allergen [265].

Another important anti-inflammatory mediator is protectin D1, a natural lipid based chemical mediator that counters leukocyte activation. PD1 has been recovered from

## GENETIC INFLUENCES

Over the past 15 years there have been multiple studies on the genetics of asthma (see Chapter 4). A number of potential asthma genes have been identified [270], but very few have been replicated in multiple populations [271]. However all the data suggest that there is not a single major asthma susceptibility gene, but rather there are multiple genes each explaining only a small proportion of the total variance in the asthma phenotype. The keys to find the most important asthma genes will be to use comprehensive methods and to replicate the findings in an individual population in multiple distinct populations.

*ADAM33* is an asthma gene, discovered by positional cloning, that has been replicated in many but not all populations tested [272]. It was initially identified in Caucasian families from the United States and United Kingdom and was associated with asthma characterized by bronchial hyperresponsiveness. There were many variants within *ADAM33* that were significantly associated with these phenotypes. Subsequently, there have been a large number of case-control and family-based association studies focused on *ADAM33*, with the majority but not all, confirming the original finding [273]. Current data suggest that *ADAM33* may be involved in lung development and remodeling.

In genome wide-association studies microarrays capable of typing 500,000 to 1 million single nucleotide polymorphisms are used to identify associations between a given phenotype and genotype. This technology has been applied to childhood asthma [274]. These investigators identified a strong statistical association between the diagnosis of

asthma in childhood in families from the United Kingdom and markers located on chromosome 17q21. The results were replicated in two European populations. They then used the genetic data to examine transcript levels in immortalized lymphocytes from children harboring the implicated variants and showed a strong association between variants in *ORMDL3* and asthma. *ORMDL3* is a member of a family of genes that encode endoplasmic reticulum proteins of unknown function. If these studies are replicated, then the community of asthma researchers will need to determine how variants in the function of this gene could lead to childhood asthma.

An area of importance is the relationship between clinical responses to anti-asthma treatments and genotype at various drug targets [275]. For example, there are known to be a number of SNPs in the $\beta_2$-adrenoceptor gene that result in structural changes in the $\beta_2$-receptor structure associated with functional changes in isolated cell systems [276]. These are related to the acute response to bronchodilator aerosols acting via this receptor [277, 278] and with deleterious effects of chronic use of albuterol [279, 280]. In a double blind randomized controlled trial, the first in a non-malignant condition where genotype at a specific locus was an entry criterion, those patients harboring the alleles encoding for homozygous expression of arginine rather than glycine at the 16th amino acid in the $\beta_2$-adrenergic receptor had diminished morning and evening peak flow and lower $FEV_1$ after the regularly scheduled use of albuterol than when albuterol was used on an "as needed only" basis [281]. In a retrospective analysis of two other randomized clinical trials similar changes have been observed by some groups [282] but not by others [283]. However, other retrospective analyses of long-acting $\beta_2$-agonists have not demonstrated a functional effect of these SNPs [284]. Similarly, there are genetically based functional variants in the regulation of the ALOX-5 gene [285]. Although these variants were originally associated with the response to anti-leukotriene treatment [286], current studies suggest that it is not these variants per se, but variants in the ALOX-5 gene in general that may confer differences in treatment response [287].

## UNANSWERED QUESTIONS

As a syndrome much about asthma remains an enigma. Although we have reasonably effective treatments and a general idea of it pathophysiology, there are still many unanswered questions about its pathobiology.

*Why is the prevalence of asthma increasing throughout the world as a consequence of Westernization?*
It is clear that allergic diseases appear as societies become more Westernized, but what environmental factors are responsible is not known. It is likely that several factors are operating together [288]. Among the factors identified to date are diet (reduced intake of antioxidants, reduced unsaturated fats), lack of early childhood infections (with consequent tendency to develop Th2-driven responses), greater exposure to allergens in the home (tight housing, mattresses,

central heating providing more favorable environment), cigarette smoking (pregnancy and early childhood exposure), and possibly air pollution due to road traffic. The role of exposures to pets in early childhood remains unresolved and because of confounding will be difficult to ascertain using an epidemiological approach.

*Why does asthma once established become chronic in some individuals but remain intermittent and episodic in others?*
Is there a genetic difference among people or an environmental difference among stimuli that results in full resolution of airway obstruction in some patients and the failure for this to occur in others? For example, occupational asthma due to chemical sensitizers, such as toluene diisocyanate, may remit if the patient is removed from exposure to the sensitizer within 6 months of development of asthma symptoms, whereas longer exposure is often associated with persistent asthma even when avoidance of exposure is complete [289, 290]. This suggests that once inflammation is established it may continue independently of a causal mechanism, whereas in others this self perpetuation does not occur.

*Are there different types of asthma, each characterized by a common genetic background with its attendant immunological and inflammatory response?*
Asthma remains a syndromic diagnosis. How can we get beyond a physiological and descriptive definition to one in which the primary disease pathobiology, for each of the many asthma syndromes, can be developed?

*How does inflammation of the airways translate into clinical symptoms of asthma?*
Airway thickening, as a consequence of the inflammatory response, may contribute to increased responsiveness to spasmogens [193, 291]. However, there is no obvious relationship between the inflammatory response in airways and asthma severity; patients with mild asthma may have a similar eosinophil response to patients with severe asthma, suggesting that there are other factors that determine clinical severity. The nature of these "factors" remains elusive, but we must identify them if we are to make true scientific progress.

*How important are genetic factors (genetic polymorphisms) in determining the phenotype of asthma?*
Asthma is a complex genetic disease but likely one in which there is both differences among individuals in the genes that pre-dispose to asthma and a requirement for more than one genetic variant in a given person for asthma to be manifest. Since each "asthma gene" may account for such a small proportion of the total genetic variance in asthma, how can we use genetics to develop better asthma diagnostics? How can we use genetics to help stratify patients to achieve uniform cohorts for clinical trials?

*Are asthma and atopy causally related or just closely linked?*
Much of our understanding of asthma derives from study of models of allergy. Although these models are of great value in defining the pathobiology of asthma, how closely will they relate to the human disease?

## INTRODUCTION

COPD is a complex inflammatory disease that involves multiple interacting cells and mediators and various tissue destruction and repair mechanisms leading to structural changes that result in progressive airflow limitation with little reversibility. The preceding chapters discuss details of the individual inflammatory cells and mediators and the structural changes that are found in COPD. The links between the cellular and molecular mechanisms, the pathology, the physiological abnormalities, and symptoms are still not well understood. This is complicated by the fact that there is heterogeneity of the disease, with some patients showing a predominant emphysema pattern, whereas in others small airway disease predominates, although many patients have a mixed pattern, as cigarette smoking is a common causal mechanism. There are differences in the degree of mucus hypersecretion between patients and in the frequency of infective exacerbations. Finally it is nowrecognized that COPD affects extrapulmonary organs, such as skeletal muscle, as well as increasing the prevalence of common comorbid diseases, such as cardiovascular disease and lung cancer, which together are the commonest cause of death in patients with COPD.

The definition of COPD adopted by the Global initiative on Obstructive Lung Disease (GOLD) encompasses the idea that COPD is a chronic inflammatory disease and much of the recent research has focused on the nature of this inflammatory response [1]. COPD is an obstructive disease of the lungs which slowly progresses over many decades leading to death from respiratory failure unless patients die of co-morbidities such as heart disease and lung cancer before this stage. Although the commonest cause of COPD is chronic cigarette smoking, some patients, particularly in developing countries, develop the disease from inhalation of wood smoke from biomass fuels or other inhaled irritants [2]. However, only about 25% of smokers develop COPD of at least moderate severity [3], although as many as half will develop abnormal lung function [4], suggesting that there may be genetic or host factors that predispose to its development, although these have not yet been clearly identified (see Chapter 4). The disease is thought to be relentlessly progressive and, to date, only smoking cessation has been demonstrated to reduce the rate of decline in lung function, although as the disease becomes more severe there is less effect of smoking cessation and lung inflammation persists. However, it is not yet clear that all patients with mild and moderate COPD show progression. Some patients may have small lungs due to abnormalities in lung development due to fetal or early childhood influences and develop symptoms of COPD as a result of the normal decline in lung function with aging but starting from a lower peak (Fig. 34.1). These patients may end up with airflow obstruction without abnormal inflammatory changes.

## AIRFLOW LIMITATION

Airflow limitation in COPD may be the result of three different pathological mechanisms (Fig. 34.2):

1. Thickening and fibrosis of small airways (chronic obstructive bronchiolitis) which is presumed to be due to the effect of chronic inflammation.
FIG. 34.1 Small airways in COPD patients. The airway wall is thickened and infiltrated with inflammatory cells, predominately macrophages and CD8[+] lymphocytes, with increased numbers of fibroblasts. In severe COPD there are also lymphoid follicles, which consist of a central core of B-lymphocytes, surrounded by T-lymphocytes and thought to indicate chronic exposure to antigens (bacterial, viral, or autoantigens). Similar changes are also reported in larger airways. The lumen is often filled with an inflammatory exudate and mucus. There is peribronchial fibrosis, and, resulting in progressive and irreversible narrowing of the airway. Airway smooth muscle may be increased slightly.

FIG. 34.2 Mechanisms of airflow limitation in COPD. Small airways are obstructed as a result of loss of alveolar attachments, thickening and distortion of the airway wall as a result of inflammation and fibrosis and occlusion of the airway lumen by mucus and inflammatory exudate.

**2.** Emphysema results in expiratory airway collapse for two reasons: Disruption of alveolar attachments permits small airways to close on expiration due to lack of elastic support; in addition, loss of lung elastic recoil decreases the intralumenal pressure, which also predisposes to small airway collapse, particularly with forced exhalation.

**3.** Luminal obstruction with mucus and plasma exudate as a result of inflammation.

All three mechanisms may contribute to air trapping and lung hyperinflation, resulting in dyspnea and exercise limitation [5] (Fig. 34.3) (see Chapter 5). The relative roles of emphysema and small airway disease in causing airflow limitation are debated, but recent studies with measurements of emphysema by computerized tomography show that varying severity of emphysema can be present with similar impairment of $FEV_1$, although there may be abnormalities in diffusion capacity and hypoxia [6]. The variable association of emphysema with airflow limitation has focused increased attention on small airways in COPD, but it is difficult to measure small airway function in patients and novel imaging and physiological approaches are needed [7].

## ETIOLOGIC FACTORS

### Inhalational exposures

The most important etiologic risk factors for the development of COPD are inhalational exposures and cigarette smoke is by far the most important of these. Exposures other than cigarette smoking, however, also contribute to the risk for COPD. Such exposures can both cause COPD independently of cigarette smoking and can increase the risk for COPD in the presence of concurrent cigarette smoking. Exposures leading to COPD include a range of both environmental fumes and dusts. Coal dust, for example, alone can lead to airflow limitation. Use of biomass for home cooking can result in significant inhalational exposure and a marked increased risk for the development of COPD [8]. Such exposure is a currently a major risk factor for COPD in parts of the developing world. Passive cigarette smoke exposure also is related to symptoms of cough and sputum production and is likely a risk factor for the development of airflow limitation [9].
**FIG. 34.3** Mechanism of dyspnea in COPD. The airway narrows on expiration but in normal individuals the elasticated alveolar attachments prevent closure so that the alveoli empty. In COPD there is a loss of elastin fibers as a result of elastases, which means that even in mild COPD small airways close to a greater extent. As COPD becomes more severe, the thickness of small airways increases and alveolar attachments may be disrupted so that peripheral airway may close during expiration. This results in air trapping and hyperinflation, leading to dyspnea and reduced exercise capacity.

Some exposures which represent risk factors for the development of COPD, for example intravenous drug abuse and cadmium may act through pathways distinct from the more common inhalational exposures. Intravenous drug abuse may lead to the development of COPD by a vascular mechanism, and cadmium, which can cause emphysema without inflammation, may act by altering the repair response. These rare causes of COPD are particularly instructive as they indicate that a variety of mechanisms may lead to altered lung structure and function. To what degree such mechanisms are involved in the more common etiologies of COPD remains to be determined.

It is likely that the varied inhalational exposures, which lead to COPD, share the ability to initiate some of the same pathogenetic mechanisms. This may account for some of the similarities of the disease induced by cigarette smoke and other environmental exposures. Most exposures, however, are complex and contain many candidate toxins. Importantly, not all exposed individuals will develop COPD. Genetic factors, most of which remain to be defined, can affect risk.

## Infections

Infections play a key role in COPD exacerbations (see Chapter 37). Up to two-thirds of exacerbations can be associated with a potential infectious pathogen, about half being bacterial and half being viral. Individuals with frequent exacerbations have been demonstrated to have an inferior quality of life as assessed by the St. George's Respiratory Questionnaire. The suggestion has also been made that individuals with frequent exacerbations experience a more rapid decline in lung function [10]. Damage induced by infections and the ensuing inflammatory process may make the airways more susceptible to subsequent infection [11].

Infections also have been related to increased risk for the development of COPD. A history of severe childhood viral infection has been associated with reduced lung function and with increased respiratory symptoms in some studies. There are several, non-exclusive, possible explanations for these associations. First, there might be an increased diagnosis of severe infections in children who have underlying airways responsiveness which itself may be a risk factor. Second, viral infections may be related to another factor such as socioeconomic status or birth weight which itself is related to COPD. Viral infections, moreover, may directly contribute to the development of COPD. In this regard, viral infections may result in incorporation of viral DNA into airway cells which could alter the response to subsequent exposures increasing the risk for COPD. In contrast, a more recent study failed to show an accelerated rate of decline among adults age 35–45 who had a history of childhood infections. However, another study did not demonstrate an accelerated rate of decline in adults aged 35–45 who had childhood infections [12].

Animal studies suggest the incorporation of adenoviral DNA can amplify the inflammatory response induced when airway epithelial cells are exposed to cigarette smoke and increased levels of adenoviral DNA have been detected in the lungs of patients with COPD compared to control patients [13]. In addition, HIV infection has also been related to the development of emphysema [14]. HIV-induced pulmonary inflammation may play a role, although weight loss associated with HIV infection has also been suggested as a possible mechanism.

## Nutrition

Nutritional status, independent of concurrent viral infection, is also likely a risk factor for the development of COPD. The famine and resulting starvation in the Warsaw ghetto in World War II was associated with the development of emphysema. Reduced body weight, often expressed as body mass index, is a poor prognostic sign in individuals with established COPD. Underweight individuals with COPD, moreover, appear to be at risk for the development of emphysema. The association of starvation and anabolic/catabolic status with the development of COPD, particularly with emphysema, is also supported by experimental studies in animals.

## Birth weight, lung growth, and development

Low birth weight has been associated with the development of COPD although this association remains controversial. Low birth weight has also been associated with increased

risk for asthma and with reduced lung function in both childhood and young adulthood. In this regard, reduced maximal attained lung function may identify individuals who are at increased risk for the development of COPD. While some of these results are controversial it remains possible that developmental problems associated with low birth weight represent a risk factor for the development of COPD.

## Aging

COPD is a disease of the elderly. While decrements in lung function can be observed at any age and decline in lung function can begin in young adulthood, clinically significant COPD is unusual before the fifth or sixth decade of life and is most common even later [15]. Lung function also declines with normal aging and compliance increases. Associated with this process are changes in alveolar structure including increased size and number of alveolar pores together with enlargement in alveolar spaces. These changes, which are sometimes termed "senile emphysema," resemble, in at least some features, clinical emphysema. This suggests the concept that aging may lead to emphysema or may accelerate its development. Further supporting a connection between COPD and aging, circulating lymphocytes in smokers have reduced telomere length [16] and chronic exposure to cigarette smoke can induce senescence in cells cultured *in vitro* [17]. In addition, fibroblasts cultured from the lungs of COPD patients proliferate more slowly and also show markers of senescence [18, 19]. Finally, emphysema spontaneously develops in mice with genetic forms of accelerated aging [20, 21]. Taken together, these observations support the concept that COPD may represent a form of accelerated senescence in the lung.

## Reactive airways

Asthma and increased airways reactivity have been identified as risk factors for the development of COPD. This relationship was originally proposed by Orie and colleagues and termed the Dutch hypothesis. Asthmatics, as a group, experience accelerated loss of lung function as do smokers with increased airways reactivity. Whether airways reactivity results from an inflammatory process, which, in turn, also leads to loss of lung function in COPD or whether the airways reactivity directly causes COPD remains undetermined.

## Genetics

It is likely that many genetic factors interact with and increase (or decrease) the risk for developing COPD. Family studies have demonstrated an increased risk of COPD within families with COPD probands. Some of this risk may be due to shared environmental factors, but several studies in diverse populations also suggest shared genetic risk (see Chapter 4).

To date the only well-defined genetic risk factor is deficiency of alpha-1 protease inhibitor (PI). Severe deficiency in this major circulating inhibitor of serine proteases is associated with development of emphysema in non-smokers, although not all deficient individuals are affected. In smokers, alpha-1 PI deficiency is associated with the accelerated development of emphysema and mortality. A number of other genetic factors, while not unequivocally established, have been suggested to be related to risk for COPD (see Chapter 4).

## Tissue remodeling

Peribronchial fibrosis and narrowing contributes to airflow limitation in chronic bronchitis. The mechanisms which lead to this process are unknown. However, injury of the small airways, either directly by inhaled toxins such as cigarette smoke or indirectly by the action of inflammatory mediators likely initiates repair processes [22]. In this regard, the airway epithelium has considerable capacity to mediate repair. Following mechanical injury, for example, airway epithelial cells from the edge of the wound rapidly flatten and migrate to cover the defect.

*In vitro* studies suggest that fibronectin and transforming growth factor (TGF)-β produced by the epithelial cells present in the wound may help direct these processes. The newly recruited cells then replicate and undergo an orderly sequence of differentiation. It is likely that these processes often can restore both anatomic structure and airway function. In addition to the epithelial cells, mesenchymal cells (fibroblasts and myofibroblasts) are also activated in the repair response. The wave of accumulation and replication of epithelial cells which occurs 24 h after mechanical injury is followed about 2 days later by the accumulation and proliferation of mesenchymal cells. Under normal circumstances, these cells disappear over the next few weeks.

However, as in many tissues, repair in the airways can result in the excessive deposition of fibrotic extracellular matrix, and like most scars, these contract [22]. If this were to happen circumferentially around an airway, airway narrowing would result. In this context, airway epithelial cells can also produce factors which drive fibroblast recruitment, matrix production and remodeling. Interestingly, the fibrotic process may be driven by some of the same mediators which may also lead to epithelial repair such as TGF-β and fibronectin. Consistent with a role for these mediators, both TGF-β and fibronectin have been reported in the airways and bronchoalveolar lavage (BAL) fluid in asthma and chronic bronchitis. While the processes which regulate airway repair following injury are only partly delineated, it seems likely that disordered repair processes can lead to tissue remodeling with altered airway structure and function.

Altered repair mechanisms may contribute to the development of emphysema [22]. In this context, the net tissue loss which characterizes emphysema may result from inadequate repair in the face of injury. Several lines of evidence support this concept. First, several animal models of emphysema have been developed in which lung destruction is induced either by exposure to large concentrations of neutrophil elastase (NE), to cigarette smoke or to other

similar insults. Such injury is characterized by a rapid loss of lung connective tissue consistent with tissue destruction taking place. These models, however, are also associated with a rapid onset of new connective tissue synthesis. In many cases, total tissue matrix macromolecule concentration is restored to normal or increased levels within a few weeks of tissue injury. Similarly, in mild human emphysema, lung collagen content has been reported to be increased consistent with initiation of matrix molecule production.

The concept that repair processes initiated in model systems of emphysema serve to mitigate the severity of the resulting emphysema is supported by studies in which repair processes are disrupted. For example, starvation can greatly potentiate the development of emphysema following elastase exposure in rats [23]. Similarly, inhibition of matrix macromolecule cross-linking can also exacerbate the development of emphysema. In this context, cigarette smoke can interfere with repair processes by a number of mechanisms. Smoke can inhibit parenchymal cell recruitment, proliferation, matrix production, and tissue remodeling [22]. Smoke can also interfere with matrix macromolecule cross-linking [24]. It is possible, therefore, that smoke can lead to the development of emphysema by three interacting mechanisms: (1) by initiating an inflammatory response which causes tissue destruction; (2) by interfering with the defenses which normally protect tissues from injury during inflammation; and (3) by disrupting the repair processes which have the potential for restoring tissue architecture in the face of injury.

Several lines of evidence suggest that tissue repair or maintenance may be abnormal in emphysema. Reduced VEGF and VEGF receptors in the lungs of patients with COPD and, in an animal model, that interruption of VEGF signaling can lead to the development of emphysema through apoptosis [25]. Fibroblasts from patients with COPD proliferate more slowly [18] and are deficient in several *in vitro* measures of tissue repair [26].

## Pathogenesis: Integrating concepts

Taken together, the currently available data suggest that the majority of COPD results from exposures to noxious agents. These, in turn, lead to activation of inflammatory processes within the lower respiratory tract. Damage to lung structures results both from the exposures and, more importantly, from the ensuing inflammatory responses. Inflammation and injury also activate repair responses. Some individuals, either on a genetic or on a developmental basis, appear to be particularly sensitive to the injurious effects of exposures and inflammation. Similarly, individuals likely differ in their ability to repair lung injury, differences which reflect both genetic and acquired (e.g. nutritional) heterogeneity. The following sections will review briefly the cells and mediators believed to play a role in COPD.

## COPD AS AN INFLAMMATORY DISEASE

Both the small airway remodeling and narrowing and the emphysema are believed to be due to chronic inflammation in the lung periphery. Quantitative studies have shown that the inflammatory response in small airways and lung parenchyma increases as the disease progresses [27] (see Chapter 6). There is a specific pattern of inflammation in COPD airways and lung parenchyma with increased numbers of macrophages, T-lymphocytes, with predominance of CD8$^+$ (cytotoxic) T-cells, and in more severe disease B-lymphocytes with increased numbers of neutrophils in the lumen [28] (Fig. 34.4). The inflammatory response in COPD involves both innate and adaptive immune responses. Multiple inflammatory mediators are increased in COPD and are derived from inflammatory cells and structural cells of the airways and lungs [29]. A similar pattern of inflammation is seen in smokers without airflow limitation, but in COPD this inflammation is amplified and even further amplified during acute exacerbations of the disease which are usually precipitated by bacterial and viral infections (Fig. 34.5). The molecular basis of this amplification of inflammation is not yet understood but may be, at least in part, genetically determined. Cigarette smoke and other irritants in the respiratory tract may activate surface macrophages and airway epithelial cells to release chemotactic factors that then attract circulating leukocytes into the lungs. Amongst chemotactic factors, chemokines predominate and therefore play a key role in orchestrating the chronic inflammation in COPD lungs and its further amplification during acute exacerbations [30]. These might be the initial inflammatory events occurring in all smokers. However in smokers who develop COPD this inflammation progresses into a more complicated inflammatory pattern of adaptive immunity and involves T- and B-lymphocytes and possibly dendritic cells along with a complicated interacting array of cytokines and other mediators [31].

## Differences from asthma

Histopathological studies of COPD show a predominant involvement of peripheral airways (bronchioles) and lung parenchyma, whereas asthma involves inflammation in all airways (particularly proximal airways) but usually without involvement of the lung parenchyma [32]. In COPD there is narrowing of bronchioles, with fibrosis and infiltration with macrophages and T-lymphocytes, along with destruction of lung parenchyma and an increased number of macrophages and T-lymphocytes, with a greater increase in CD8$^+$ than CD4$^+$ (helper) cells [27] (Fig. 34.6). Bronchial biopsies show similar changes with an infiltration of macrophages and CD8$^+$ cells and an increased number of neutrophils in patients with severe COPD. BAL fluid and induced sputum demonstrate a marked increase in macrophages and neutrophils. In contrast to asthma, eosinophils are not prominent except during exacerbations or when patients have concomitant asthma [32, 33]. In contrast to the epithelial fragility of asthma, the airway epithelium in patients with COPD may be metaplastic, as a result of the chronic release of epithelial growth factors such as epithelial growth factor (EGF) from these cells. Another difference between COPD and asthma is the pattern of fibrosis, with subepithelial fibrosis (sometimes called basement membrane thickening) as a very characteristic feature of asthma,
**FIG. 34.4** Inflammatory cells and mediators involved in COPD. Inhaled cigarette smoke and other irritants activate epithelial cells and macrophages to release several chemotactic factors that attract inflammatory cells to the lungs, including CC-chemokine ligand 2 (CCL2), which acts on CC-chemokine receptor 2 (CCR2) to attract monocytes, CXC-chemokine ligand 1 (CXCL1) and CXCL8, which act on CXCR2 to attract neutrophils and monocytes (which differentiate into macrophages in the lungs) and CXCL9, CXCL10, and CXCL11, which act on CXCR3 to attract T helper 1 (Th1) cells and type 1 cytotoxic T-cells (Tc1 cells), both of which release interferon-γ (IFN-γ). These inflammatory cells together with macrophages and epithelial cells release proteases, such as matrix metalloproteinase 9 (MMP9), which cause elastin degradation and emphysema. Neutrophil elastase also causes mucus hypersecretion. Epithelial cells and macrophages also release transforming growth factor-β (TGF-β) and fibroblast growth factors (FGF), which stimulate fibroblast proliferation, resulting in fibrosis in the small airways as well as the proinflammatory cytokines tumor necrosis factor-α (TNF-α), IL-1β and IL-6 which amplify inflammation. Mucus hypersecretion is stimulated by epithelial growth factor (EGF) and TGF-α.

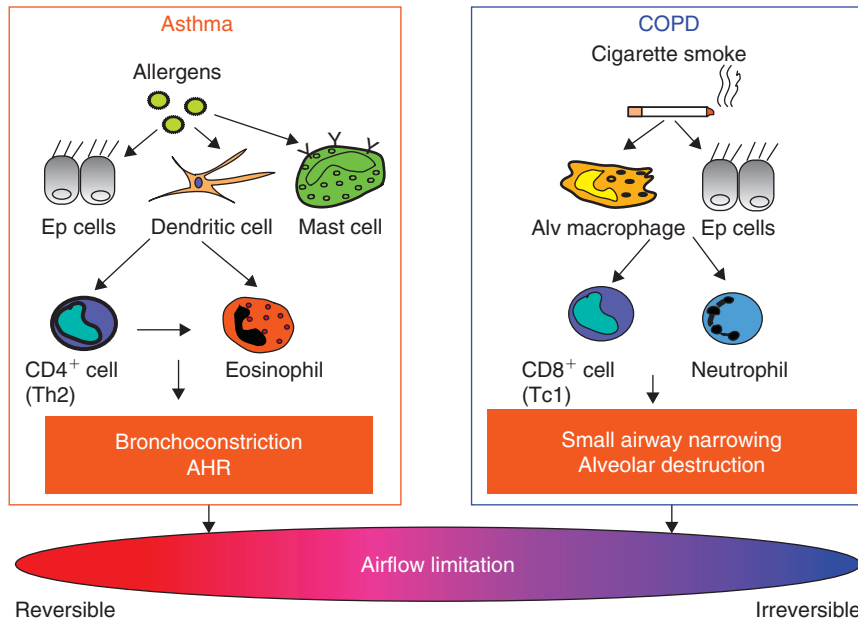
**FIG. 34.5** Amplification of lung inflammation in COPD. Normal smokers have a mild inflammatory response, which represents the normal (probably protective) reaction of the respiratory mucosa to chronic inhaled irritants. In COPD this same inflammatory response is markedly amplified, and this amplification increases as the disease progresses. It is further increased during exacerbations triggered by infective organisms. The molecular mechanisms of this amplification are currently unknown, but may be determined by genetic factors or possibly latent viral infection. Oxidative stress is an important amplifying mechanism and may increase the expression of inflammatory genes through impairing the activity of histone deacetylase-2 (HDAC2), which is needed to switch off inflammatory genes.


**FIG. 34.6** Differences in inflammation between COPD and asthma. Left panel shows that inflammation in asthma is driven by allergens resulting in activation of mast cells, dendritic cells and epithelial cells and leading to the recruitment of T helper 2 (Th2) cells and eosinophils. This results in airway hyperresponsiveness, the defining physiologic defect in asthma. Right panel shows that COPD is driven by inhaled irritants such as cigarette smoke, which results in activation of epithelial cells and macrophages, which recruit neutrophils and T-lymphocytes into the lung, resulting in small airway narrowing (chronic obstructive bronchiolitis) and alveolar destruction (emphysema).

whereas in COPD fibrosis is found mainly around small airways (peribronchiolar fibrosis). The airway smooth muscle layer in asthma may be thickened as a result of hypertrophy and hyperplasia of airway smooth muscle cells, whereas this layer is not very much increased in patients with COPD [34]. Mucus hypersecretion is a feature of asthma and COPD, with hyperplasia of goblet cells and submucosal glands [35] (see Chapter 17).

Although the inflammatory picture in asthma and COPD differs, in patients with severe asthma there are greater similarities between the two diseases, with increased neutrophils, CD8$^+$ cells, and similar patterns of mediators in severe asthma as in COPD [31].

## INFLAMMATORY CELLS

For many years, it was believed that the inflammatory reaction in the lungs of smokers consisted of neutrophils and macrophages and those proteinases from these cells were responsible for the lung destruction in COPD. More recently it has been recognized that there is a prominent T-cell infiltration in the lungs of patients with COPD, with a predominance of CD8$^+$ T-cells, although CD4$^+$ (helper) T-cells are also numerous. Although abnormal numbers of inflammatory cells have been documented in COPD, the relationship between these cell types and the sequence of their appearance and their persistence are not yet understood in detail [28]. Most studies have been cross-sectional, based on selection of patients with different stages of the disease, and comparisons have been made between smokers without airflow limitation (normal smokers) and those with COPD who have smoked a similar amount. There are no serial studies; selection biases (such as selecting tissue from patients suitable for lung volume reduction surgery) may

give misleading results. Nonetheless, there is a progressive increase in the numbers of inflammatory cells in small airways and lung parenchyma as COPD becomes more severe even though the patients with most severe obstruction have stopped smoking for many years [27], indicating the existence of mechanisms which perpetuate the inflammatory reaction in COPD. This is in contrast to many other chronic inflammatory diseases, such as rheumatoid arthritis, where the inflammation tends to diminish in severe disease. The inflammation of COPD lungs involves both innate immunity (neutrophils, macrophages, eosinophils, mast cells, NK cells, γδ-T-cells, and dendritic cells) and adaptive immunity (T- and B-cells).

The inflammation in the airways of COPD patients does not seem to disappear after smoking cessation, even after a period of several years [36, 37].

### Epithelial cells

Epithelial cells are activated by cigarette smoke to produce inflammatory mediators, including tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF) and CXCL8 (IL-8). Epithelial cells in small airways may be an important source of TGF-β, which then induces local fibrosis. Airway epithelial cells are also important in defense of the airways, with mucus production from goblet cells, and secretion of antioxidants, antiproteases, and defensins (see Chapter 16). It is possible that cigarette smoke and other noxious agents impair these innate and adaptive immune responses of the airway epithelium, increasing susceptibility to infection. The airway epithelium in chronic bronchitis and COPD often shows squamous metaplasia, which may result from increased proliferation of basal airway epithelial cells but the nature of the growth factors involved in epithelial cell proliferation, cell cycle, and differentiation in

COPD are not yet known. Epidermal growth factor receptors (EGFR) show increased expression in airway epithelial cells of smokers and may contribute to basal cell proliferation, resulting in squamous metaplasia and an increased risk of bronchial carcinoma [38].

## Mesenchymal cells

Mesenchymal cells, including fibroblasts, myofibroblasts, and smooth muscle cells, are the major structural cells responsible for the production and maintenance of the interstitial connective tissue. As such, they play a major role in the tissue remodeling that characterizes the structural alterations of COPD. In addition, mesenchymal cells can also produce inflammatory mediators and may play a role in persistent inflammation in asthma and possibly COPD. Fibroblasts from the lung parenchyma of patients with COPD proliferate more slowly [18] and are less active in chemotaxis and contraction of extracellular matrix [26]. This suggests that deficient repair could contribute to the development of emphysema. Conversely, a "pro-fibrotic" phenotype has been reported in fibroblasts from various fibrotic diseases [39, 40]. Whether such cells play a role in the airways fibrosis in COPD is unknown.

## Neutrophils

Increased numbers of activated neutrophils are found in sputum and BAL fluid of patients with COPD [41], yet are relatively little increased in the airways or lung parenchyma. This may reflect their rapid transit through the airways and parenchyma. The role of neutrophils in COPD is not yet clear, however, neutrophil numbers in induced sputum are correlated with COPD disease severity [41] and with the rate of decline in lung function [42]. Smoking has a direct stimulatory effect on granulocyte production and release from the bone marrow and survival in the respiratory tract, possibly mediated by GM-CSF and G-CSF released from lung macrophages [43]. Smoking may also increase intravascular neutrophil retention in the lung. Neutrophil recruitment to the airways and parenchyma involves adhesion to endothelial cells and E-selectin which is up-regulated on endothelial cells in the airways of COPD patients [44]. Adherent neutrophils then migrate into the respiratory tract under the direction of neutrophil chemotactic factors. There are several chemotactic signals that have the potential for neutrophil recruitment in COPD, including leukotriene (LT)$B_4$, CXCL8, and related CXC chemokines, including CXCL1 (GRO-$\alpha$) and CXCL5 (ENA-78), which are increased in COPD airways [45] (Fig. 34.7). These mediators may be derived form alveolar macrophages T-cells and epithelial cells, but the neutrophil itself may be a major source of CXCL8. Neutrophils from the circulation marginate in the pulmonary circulation and adhere to endothelial cells in the alveolar wall before passing into the alveolar space. The neutrophils recruited to the airways of COPD patients are activated as there is increased concentration of granule proteins, such as myeloperoxidase (MPO) and human neutrophil lipocalin, in the sputum supernatant [46].

**FIG. 34.7** Neutrophils in COPD. Neutrophils are attracted to the lungs of COPD patients by neutrophil chemotactic mediators, such as leukotriene $B_4$ (LTB$_4$) and the chemokines CXCL1 (also known as GRO-$\alpha$) and CXCL8 (also known as IL-8). Activated neutrophils release more LTB$_4$ and CXCL8 to attract even more neutrophils, reactive oxygen species, such as superoxide anions (O$_2^-$), and myeloperoxidase (MPO). They also release the serine proteinases NE, cathepsin G, and proteinase-3, as well as the matrix metalloproteinases (MMP)-8 and MMP-9. These proteinases stimulate mucus hypersecretion and elastolysis, resulting in emphysema.

Neutrophils secrete serine proteases, including NE, cathepsin G, and proteinase-3, as well as matrix metalloproteinase (MMP)-8 and MMP-9, which may contribute to alveolar destruction. Neutrophils have the capacity to induce tissue damage through the release of serine proteases and oxidants. However, while neutrophils have the capacity to cause elastolysis, this is not a prominent feature of other pulmonary diseases where chronic airway neutrophilia is even more prominent, including cystic fibrosis and bronchiectasis. This suggests that other factors are involved in the generation of emphysema. Indeed neutrophils are not a prominent feature of parenchymal inflammation in COPD. It is likely that airway neutrophilia is more linked to mucus hypersecretion in chronic bronchitis. Serine proteases from neutrophils, including NE, cathepsin G, and proteinase-3 are all potent stimulants of mucus secretion from submucosal glands and goblet cells in the epithelium. There is a marked increase in neutrophil numbers in the airways in acute exacerbations of COPD accounting for the increased purulence of sputum. This may reflect increased production of neutrophil chemotactic factors including LTB$_4$ and CXCL8 [47, 48].

## Macrophages

Macrophages appear to play a pivotal role in the pathophysiology of COPD and can account for most of the known features of the disease [49] (Fig. 34.8). There is a marked increase (5- to 10-fold) in the numbers of macrophages in airways, lung parenchyma, BAL fluid, and sputum in patients with COPD. A careful morphometric analysis of macrophage numbers in the parenchyma of patients with emphysema showed a 15-fold increase in the numbers of macrophages in the tissue and alveolar space compared with normal smokers [50]. Furthermore, macrophages are localized to sites of alveolar wall destruction in patients with
**FIG. 34.8** Macrophages in COPD. Macrophages may play a pivotal role in COPD as they are activated by cigarette smoke extract and secrete many inflammatory proteins that may orchestrate the inflammatory process in COPD. Neutrophils may be attracted by CXCL8, CXCL1 and leukotriene B$_4$ (LTB$_4$), monocytes by CCL2, and CD8$^+$ lymphocytes by CXCL10 and CXCL11. Release of elastolytic enzymes including matrix metalloproteinases (MMP) and cathepsins cause elastolysis, and release of transforming growth factor (TGF)-β1 and connective tissue growth factor (CTGF). Macrophages also generate reactive oxygen species (ROS) and nitric oxide (NO) which together form peroxynitrite and may contribute to steroid resistance.

emphysema and there is a correlation between macrophage numbers in the parenchyma and severity of emphysema [51]. Macrophages may be activated by cigarette smoke extract to release inflammatory mediators including TNF-α, CXCL8 and other CXC chemokines, CCL2 (MCP-1), LTB$_4$, and reactive oxygen species (ROS), providing a cellular mechanism that links smoking with inflammation in COPD. Alveolar macrophages also secrete elastolytic enzymes, including MMP-2, MMP-9, MMP-12, cathepsins K, L and S, and NE taken up from neutrophils [52]. Alveolar macrophages from patients with COPD secrete more inflammatory proteins and have a greater elastolytic activity at baseline than those from normal smokers and this is further increased by exposure to cigarette smoke [52]. Macrophages demonstrate this difference even when maintained in culture for 3 days and therefore appear to be intrinsically different from the macrophages of normal smokers and non-smoking normal control subjects [52]. The predominant elastolytic enzyme secreted by alveolar macrophages in COPD patients is MMP-9. Most of the inflammatory proteins that are up-regulated in COPD macrophages are regulated by the transcription factor nuclear factor-κB (NF-κB) which is activated in alveolar macrophages of COPD patients, particularly during exacerbations [53].

The increased numbers of macrophages in smokers and COPD patients may be due to increased recruitment of monocytes from the circulation in response to the monocyte-selective chemokines CCL2 and CXCL1, which are increased in sputum and BAL of patients with COPD [45]. Monocytes from patients with COPD show a greater chemotactic response to GRO-α than cells from normal smokers and non-smokers, but this is not explained by an increase in CXCR2 [54]. Interestingly, while all monocytes express CCR2, the receptor for CCL2, only ~30% of monocytes express CXCR2. It is possible that these CXCR2 expressing monocytes transform into macrophages that are more inflammatory. Macrophages also release the chemokines CXCL9, CXCL10, and CXCL11, which are chemotactic for CD8$^+$ Tc1 and CD4$^+$ Th1 cells, via interaction with the chemokine receptor CXCR3 expressed on these cells [55].

The increased numbers of macrophages in COPD are mainly be due to increased recruitment of monocytes, as macrophages have a very low proliferation rate in the lungs. Macrophages have a long survival time so this is difficult to measure directly. However, in macrophages from smokers, there is markedly increased expression of the anti-apoptotic protein Bcl-X$_L$ and increased expression of p21$^{CIP/WAF1}$ in the cytoplasm [56]. This suggests that macrophages may have a prolonged survival in smokers and patients with COPD. Once activated, macrophages will increase production of ROS, nitric oxide, and lysosomal enzymes and will increase secretion of many cytokines, including TNF-α, IL-1β, IL-6, CXCL8, and IL-18 among others. This activated macrophage response increases the efficiency of killing of organisms but may promote tissue damage and further inflammation.

Corticosteroids are ineffective in suppressing inflammation, including cytokines, chemokines, and proteases, in patients with COPD [57]. *In vitro* the release of CXCL8, TNF-α, and MMP-9 macrophages from normal subjects and normal smokers are inhibited by corticosteroids, whereas corticosteroids are ineffective in macrophages from patients with COPD [58]. The reasons for resistance to corticosteroids in COPD and to a lesser extent macrophages from smokers may be the marked reduction in activity of histone deacetylase-2 (HDAC2) [59], which is recruited to activated inflammatory genes by glucocorticoid receptors (GRs) to switch off inflammatory genes. The reduction in HDAC activity in macrophages is correlated with increased secretion of cytokines like TNF-α and CXCL8 and reduced response to corticosteroids. The reduction of HDAC activity in COPD patients may be mediated through oxidative stress and peroxynitrite formation [60].

## Eosinophils

While eosinophils are the predominant leukocyte in asthma, their role in COPD is much less certain. In some studies, increased numbers of eosinophils have been described in the airways and BAL of patients with stable COPD, whereas

others have not found increased numbers in airway biopsies, BAL or induced sputum. The presence of eosinophils in patients with COPD predicts a response to corticosteroids and may indicate coexisting asthma [33]. Increased numbers of eosinophils have been reported in bronchial biopsies and BAL fluid during acute exacerbations of chronic bronchitis [61]. Surprisingly the levels of eosinophil basic proteins in induced sputum are as elevated in COPD, as in asthma, despite the absence of eosinophils, suggesting the eosinophils may have degranulated and are no longer recognizable by microscopy [46]. Perhaps this is due to the high levels of NE that have been shown to cause degranulation of eosinophils.

## Dendritic cells

Dendritic cells play a central role in the initiation of the innate and adaptive immune response and it is believed that they provide a link between them [62]. The airways and lungs contain a rich network of dendritic cells that are localized near the surface, so that they are ideally located to signal the entry of foreign substances that are inhaled. Dendritic cells can activate a variety of other inflammatory and immune cells, including macrophages, neutrophils, T- and B-lymphocytes so dendritic cells may play an important role in the pulmonary response to cigarette smoke and other inhaled noxious agents. However, there does not appear to be an increase in dendritic cells in the airways of COPD patients, in contrast to asthma patients [63].

## T-lymphocytes

There is an increase in the total numbers of T-lymphocytes in lung parenchyma, peripheral and central airways of patients with COPD, with the greater increase in $CD8^+$ than $CD4^+$ cells [27, 55]. There is a correlation between the numbers of T-cells and the amount of alveolar destruction and the severity of airflow obstruction. Furthermore, the only significant difference in the inflammatory cell infiltrate in asymptomatic smokers and smokers with COPD is an increase in T-cells, mainly $CD8^+$, in patients with COPD. There is also an increase in the absolute number of $CD4^+$ T-cells albeit in smaller numbers, in the airways of smokers with COPD and these cells express activated STAT-4, a transcription factor that is essential for activation and commitment of the Th1 lineage and IFN-$\gamma$ [64].

The ratio of $CD4^+$ and $CD8^+$ cells are reversed in COPD. The majority of T-cells in the lung in COPD are of the Tc1 and Th1 subtypes [55]. There is a marked increase in T-cells in the walls of small airways in patients with severe COPD and the T-cells are formed into lymphoid follicles, surrounding B-lymphocytes [27].

The mechanisms by which $CD8^+$, and to a lesser extent $CD4^+$ cells, accumulate in the airways and parenchyma of patients with COPD is not yet understood [65]. However, homing of T-cells to the lung must depend upon some initial activation (only activated T-cells can home to the organ source of antigenic products), then adhesion and selective chemotaxis. $CD4^+$ and $CD8^+$ T-cells in the lung of COPD patients show increased expression of CXCR3,

**FIG. 34.9** T-lymphocytes in COPD. Epithelial cells and macrophages are stimulated by interferon-$\gamma$ (IFN-$\gamma$) to release the chemokines CXC-chemokine ligand 9 (CXCL9), CXCL10, and CXCL11, which together act on CXC-chemokine receptor 3 (CXCR3) expressed on T helper 1 (Th1) cells and type 1 cytotoxic T (Tc1) cells to attract them into the lungs. Tc1 cells, through the release of perforin and granzyme B, induce apoptosis of type 1 pneumocytes, thereby contributing to emphysema. IFN-$\gamma$ released by Th1 and Tc1 cells then stimulates further release of CXCR3 ligands, resulting in a persistent inflammatory activation.

a receptor activated by the chemokines CXCL9 (Mig), CXCL10 (IP-10), and CXCL11 (I-TAC), all of which are increased in COPD [66]. There is increased expression of CXCL10 by bronchiolar epithelial cells and this could contribute to the accumulation of $CD4^+$ and $CD8^+$ T-cells, which preferentially express CXCR3 [67] (Fig. 34.9). $CD8^+$ cells are typically increased in airway infections and it is possible that the chronic colonization of the lower respiratory tract of COPD patients by bacterial and viral pathogens is responsible for this inflammatory response. It is possible that cigarette-induce lung injury may uncover previously sequestered autoantigens or cigarette smoke itself may damage lung interstitial and structural cells and make them antigenic [68]. The role of increased numbers of $CD4^+$ cells in COPD, particularly in severe disease is also unknown [50]; however, it is now clear that T-cell help is required for the priming of cytotoxic T-cell responses, for maintaining $CD8^+$ T-cell memory and for ensuring $CD8^+$ T-cell survival. It is also possible that $CD4^+$ T-cells have immunological memory and play a role in perpetuating the inflammatory process in the absence of cigarette smoking. In a mouse model of cigarette-induced emphysema there is a predominance of T-cells which are directly related to the severity of emphysema [69].

The role of T-cells in the pathophysiology of COPD is not yet certain, although they have the potential to produce extensive damage in the lung. $CD8^+$ cells have the capacity cause cytolysis and apoptosis of alveolar epithelial cells through release of perforins, granzyme B, and TNF-$\alpha$ [70, 71]. There is an association between $CD8^+$ cells and apoptosis of alveolar cells in emphysema [72]. Apoptotic

cells are potential sources of antigenic material that could reach the DC and perpetuate the T-cell response. In addition $CD8^+$ T-cells also produce a number of cytokines of the Tc1 phenotype including TNF-$\alpha$, lymphotoxin, and IFN-$\gamma$, and there is evidence that $CD8^+$ in the lungs of COPD patients expresses IFN-$\gamma$ [73]. All these cytokines would enhance the inflammatory reaction in the lung besides the direct killing by $CD8^+$ cells. COPD has been considered an autoimmune disease triggered by smoking, as previously suggested [68] and the presence of highly activated oligoclonal T-cells in emphysema patients supports this [74]. There is evidence for anti-elastin antibodies in experimental models of COPD and in COPD patients [75]. In addition to activated Th1 cells there is some evidence for an increase in Th2 cells that express IL-4 in BAL fluid of COPD patients in COPD patients [76].

NK cells are also increased in COPD lungs and may contribute to epithelial cell apoptosis in emphysema [77]. Invariant NK T-cells are $CD4^+$ cells that release IL-4 but are not increased in COPD [78].

## MEDIATORS OF INFLAMMATION

Many inflammatory mediators have now been implicated in COPD, including lipids, free radicals, cytokines, chemokines, and growth factors [29]. These mediators are derived from inflammatory and structural cells in the lung and interact with each other in a complex manner.

### Lipid mediators

The profile of lipid mediators in exhaled breath condensates of patients with COPD shows an increase in prostaglandins and leukotrienes [79]. There is a significant increase in $PGE_2$ and $PGF_{2\alpha}$ and an increase in $LTB_4$ but not cysteinyl leukotrienes. This is a different pattern to that seen in asthma, in which increases in thromboxane and cysteinyl leukotrienes have been shown. The increased production of prostanoids in COPD is likely to be secondary to the induction of cyclo-oxygenase-2 (COX2) by inflammatory cytokines and increased expression of COX2 is found in alveolar macrophages of COPD patients. $LTB_4$ concentrations are also increased in induced sputum and are further increased in sputum and exhaled breath condensate during acute exacerbations [47]. $LTB_4$ is a potent chemoattractant for neutrophils, acting through high affinity $BLT_1$-receptors. A $BLT_1$-receptor antagonist reduces the neutrophil chemotactic activity of sputum by ~25% [80]. Recently $BLT_1$-receptors have been identified on T-lymphocytes and there is evidence that $LTB_4$ is involved in recruitment of T-cells.

### Oxidative stress

Oxidative stress occurs when ROS are produced in excess of the antioxidant defense mechanisms and result in

harmful effects including damage to lipids, proteins, and DNA. There is increasing evidence that oxidative stress is an important feature in COPD [81] (see Chapter 25). Inflammatory and structural cells that are activated in the airways of patients with COPD produce ROS, including, neutrophils, eosinophils, macrophages, and epithelial cells. Superoxide anions ($O_2^-$) are generated by NADPH oxidase and converted to hydrogen peroxide ($H_2O_2$) by superoxide dismutases (SODs). $H_2O_2$ is then dismuted to water by catalase. $O_2^-$ and $H_2O_2$ may interact in the presence of free iron to form the highly reactive hydroxyl radical (OH). $O_2^-$ may also combine with NO to form peroxynitrite, which also generates OH. Oxidative stress leads to the oxidation of arachidonic acid and the formation of a new series of prostanoid mediators called isoprostanes, which may exert significant functional effects including bronchoconstriction and plasma exudation [82] (Fig. 34.10).

The normal production of oxidants is counteracted by several antioxidant mechanisms in the human respiratory tract [81]. The major intracellular antioxidants in the airways are catalase, SOD, and glutathione, formed by the enzyme $\gamma$-glutamyl cysteine synthetase, and glutathione synthetase. In the lung intracellular antioxidants are expressed at relatively low levels and are not induced by oxidative stress, whereas the major antioxidants are extracellular. A transcription factor Nrf2 plays a key role in switching on several genes for antioxidants in response to oxidative stress and there is evidence that Nrf2 knock-out mice are more susceptible to developing emphysema after cigarette smoke exposure [83, 84]. Extracellular antioxidants, particularly glutathione peroxidase, are markedly up-regulated in response to cigarette smoke and oxidative stress. Extracellular antioxidants also include the dietary antioxidants vitamin C (ascorbic acid) and vitamin E ($\alpha$-tocopherol), uric acid, lactoferrin, and extracellular superoxide dismutase (SOD3), which is highly expressed in human lung, but its role in COPD is not yet clear.

ROS have several effects on the airways and parenchyma and increase the inflammatory response. ROS activate NF-$\kappa$B, which switches on multiple inflammatory genes resulting in amplification of the inflammatory response. The molecular pathways by which oxidative stress activates NF-$\kappa$B have not been fully elucidated, but there are several redox-sensitive steps in the activation pathway. Oxidative stress results in activation of histone acetyltransferase activity which opens up the chromatin structure and is associated with increased transcription of multiple inflammatory genes [85]. Exogenous oxidants may also be important in worsening airway disease. There is considerable evidence for increased oxidative stress in COPD [81]. Cigarette smoke itself contains a high concentration of ROS. Inflammatory cells, such as activated macrophages and neutrophils, also generate ROS, as discussed earlier. There are several markers of oxidative stress that may be detected in the breath and several studies have demonstrated increased production of oxidants, such as $H_2O_2$, 8-isoprostane, and ethane, in exhaled air or breath condensates, particularly during exacerbations [47].

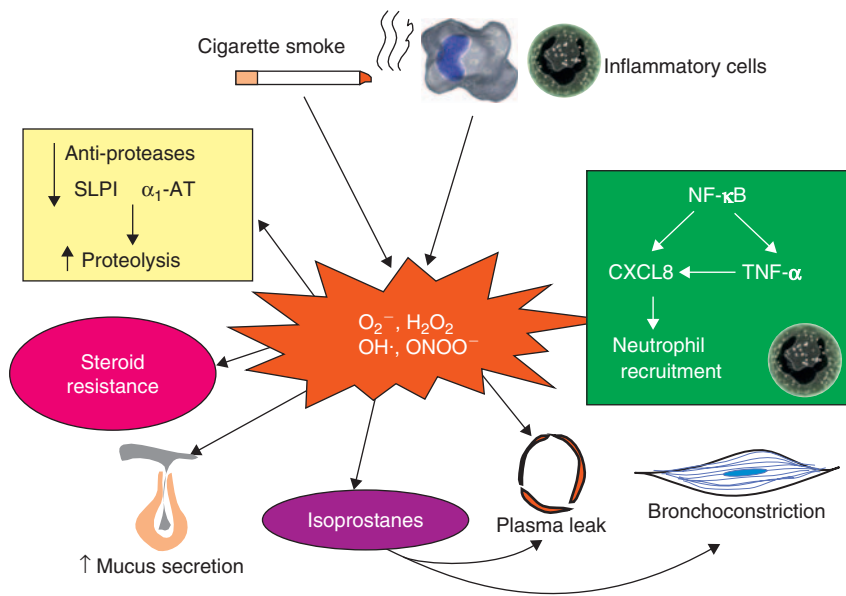
The increased oxidative stress in the lung epithelium of COPD patient may play an important pathophysiological role in the disease by amplifying the inflammatory response in COPD. This may reflect the activation of


**FIG. 34.10** Oxidative stress in COPD. Oxidative stress plays a key role in the pathophysiology of COPD and amplifies the inflammatory and destructive process. Reactive oxygen species from cigarette smoke or from inflammatory cells (particularly macrophages and neutrophils) result in several damaging effects in COPD, including decreased anti-protease defenses, such as α1-antitrypsin (AT) and secretory leukoprotease inhibitor (SLPI), activation of nuclear factor-κB (NF-κB) resulting in increased secretion of the cytokines CXCL8 and tumor necrosis factor-α (TNF-α), increased production of isoprostanes and direct effects on airway function. In addition recent evidence suggests that oxidative stress induces steroid resistance.

**FIG. 34.11** Mechanism of corticosteroid resistance in COPD. Stimulation of normal alveolar macrophages activates nuclear factor-κB (NF-κB) and other transcription factors to switch on histone acetyltransferase leading to histone acetylation and subsequently to transcription of genes encoding inflammatory proteins, such as tumor necrosis factor-α (TNF-α) and CXCL8 (IL-8). Corticosteroids reverse this by binding to glucocorticoid receptors (GRs) and recruiting histone deacetylase-2 (HDAC2). This reverses the histone acetylation induced by NF-κB and switches off the activated inflammatory genes. In COPD patients cigarette smoke activates macrophages, as in normal subjects, but oxidative stress (acting in part through the formation of peroxynitrite) impairs the activity of HDAC2. This amplifies the inflammatory response to NF-κB activation, but also reduces the anti-inflammatory effect of corticosteroids as HDAC2 is now unable to reverse histone acetylation.

NF-κB and AP-1, which then induce a neutrophilic inflammation via increased expression of CXC chemokines, TNF-α, and MMP-9. Oxidative stress may also impair the function of antiproteases such as α$_1$-antitrypsin and SLPI, and thereby accelerates the breakdown of elastin in lung parenchyma. Corticosteroids are much less effective in COPD than in asthma and do not reduce the progression or mortality of the disease. Alveolar macrophages from patients with COPD show a marked reduction in responsiveness to the anti-inflammatory effects of corticosteroids, compared to cells from normal smokers and non-smokers [58]. In patients with COPD there is a marked reduction in activity of HDAC and reduced expression of HDAC2 in alveolar macrophages and peripheral lung tissue [59], which is correlated with increased expression of inflammatory cytokines and a reduced response to corticosteroids. This may result directly or indirectly from oxidative stress and is mimicked by the effects of H$_2$O$_2$ in cell lines [86] (Fig. 34.11).

## Nitrative stress

The increase in exhaled nitric oxide (NO) is less marked in COPD than in asthma, partly because cigarette smoking reduces exhaled NO. Recently exhaled NO has been partitioned into central and peripheral portions and this shows reduced NO in the bronchial fraction but increased NO in the peripheral fraction, which includes lung parenchyma and small airways [87] (see Chapter 30). The increased peripheral NO in COPD patients may reflect increased expression of inducible NO synthase in epithelial cells and macrophages of patients with COPD [88]. NO and superoxide anions combine to form peroxynitrite which nitrates certain tyrosine residues in proteins and there is increased expression of 3-nitrotyrosine in peripheral lung and macrophages of COPD patients [88]. There is tyrosine nitration of HDAC2 which may lead to impaired activity and degradation of this enzyme, resulting in steroid resistance [86].

## Inflammatory cytokines

Cytokines are the mediators of chronic inflammation and several have now been implicated in COPD [29, 89]. There is an increase in concentration of TNF-$\alpha$ in induced sputum in stable COPD with a further increase during exacerbations [41, 48]. TNF-$\alpha$ production from peripheral blood monocytes is also increased in COPD patients and has been implicated in the cachexia and skeletal muscle apoptosis found in some patients with severe disease. TNF-$\alpha$ is a potent activator of NF-$\kappa$B and this may amplify the inflammatory response. Unfortunately anti-TNF therapies have not proved to be effective in COPD patients. IL-1$\beta$ and IL-6 are proinflammatory cytokines that may amplify the inflammation in COPD and may be important for systemic effects.

## Chemokines

Chemokines are small chemotactic cytokines that play a key role in the recruitment and activation if inflammatory cells through specific chemokine receptors. Several chemokines have now been implicated in COPD and have been of particular interest since chemokine receptors are G-protein coupled receptors, for which small molecule antagonists have now been developed [30, 89]. CXCL8 concentrations are increased in induced sputum of COPD patients and increase further during exacerbations [41, 48]. CXCL8 is secreted from macrophages, T-cells, epithelial cells, and neutrophils. CXCL8 activates neutrophils via low affinity specific receptors CXCR1, and is chemotactic for neutrophils via high affinity receptors CXCR2, which are also activated by related CXC chemokines such as CXCL1. CXCL1 concentrations are markedly elevated in sputum and BAL fluid of COPD patients and this chemokine may be more important as a chemoattractant than CXCL8, acting via CXCR2 which are expressed on neutrophils and monocytes [45]. CXCL1 induces significantly more chemotaxis of monocytes of COPD patient compared to those of normal smokers and this may reflect increased turnover and recovery

of CXCR2 in monocytes of COPD patients [54]. CXCL5 shows a marked increase in expression in airway epithelial cells during exacerbations of COPD and this is accompanied by a marked up-regulation of epithelial CXCR2.

CCL2 is increased in concentration in COPD sputum and BAL fluid [45] and plays a role in monocyte chemotaxis via activation of CCR2. CCL2 appears to cooperate with CXCL1 in recruiting monocytes into the lungs. The chemokine CCL5 (RANTES) is also expressed in airways of COPD patients during exacerbations and activates CCR5 on T-cells and CCR3 on eosinophils, which may account for the increased eosinophils and T-cells in the wall of large airways that have been reported during exacerbations of chronic bronchitis. As discussed earlier, CXCR3 are up-regulated on Tc1 and Th1 cells of COPD patients with increased expression of their ligands CXCL9, CXCL10, and CXCL11.

## Growth factors

Several growth factors have been implicated in COPD and mediate the structural changes that are found in the airways (see Chapter 29). TGF-$\beta$1 is expressed in alveolar macrophages and airway epithelial cells of COPD patients and is released from epithelial cells of small airways. TGF-$\beta$ is released in a latent form and is activated by various factors including MMP-9. TGF-$\beta$ may play an important role in the characteristic peribronchiolar fibrosis of small airways, either directly or through the release of connective tissue growth factor (Fig. 34.12). TGF-$\beta$ down-regulates $\beta_2$-adrenergic receptors by inhibiting gene transcription in human cell lines and may reduce the bronchodilator

FIG. 34.12 Transforming growth factor (TGF)-$\beta$ in COPD. TGF-$\beta$ is released in a latent form that may be activated by matrix metalloproteinase-9 (MMP-9). It may then cause fibrosis directly through effects on fibroblasts or indirectly via the release of connective tissue growth factor (CTGF). TGF-$\beta$ may also down-regulate $\beta_2$-adrenoceptors on cells such as airway smooth muscle to diminish the bronchodilator response to $\beta$-agonists.
FIG. 34.13 Epidermal growth factor receptors (EGFR) in COPD. EGFR play a key role in the regulation of mucus hypersecretion, with increased expression of mucin genes (MUC5AC, MUCB) and differentiation of goblet cells and hyperplasia of mucus-secreting cells. These effects are mediated via the activation of mitogen-activated protein (MAP) kinases. EGFR are activated by transforming growth factor-α (TGF-α), which is in turn activated by tumor necrosis factor-α converting enzyme (TACE), activated via release of oxidants from cigarette smoke and neutrophils. EGFR may also be activated by EGF.

FIG. 34.14 Protease-anti-protease imbalance in COPD. In COPD the balance appears to be tipped in favor of increased proteolysis, either because of an increase in proteases, including NE, cathepsins, and matrix metalloproteinases (MMP), or a deficiency in antiproteases, which may include α$_1$-antitrypsin, elafin, secretory leukoprotease inhibitor (SLPI), and tissue inhibitors of matrix metalloproteinases (TIMPs).

response to β-agonists in airway smooth muscle. TGF-β is also a potent anti-inflammatory molecule and TGF-β1 deficient mice die early from overwhelming inflammation, which occurs even in germ-free animals [90]. In contrast, mice deficient in Smad3, a TGFβ signal transducing molecule are resistant the development of fibrotic lung disease but spontaneously develop emphysema [91].

Alveolar macrophages produce TGF-α in greater amounts than TGF-β and this may be a major endogenous activator of epithelial growth factor receptors (EGFR) that play a key role in regulating mucus secretion in response to many stimuli, including cigarette smoke. Cigarette smoke activates TNF-α converting enzyme on airway epithelial cells which results in the shedding of TGF-α and the activation of EGFR, resulting in increased mucus secretion [92, 93] (Fig. 34.13).

VEGF is a major regulator of vascular growth and is likely to be involved in the pulmonary vascular remodeling that occurs as a result of hypoxic pulmonary vasoconstriction in severe COPD. There is increased expression of VEGF in pulmonary vascular smooth muscle of patients with mild and moderate COPD but paradoxically a reduction in expression in severe COPD with emphysema [94]. Inhibition of VEGF receptors using a selective inhibitor induces apoptosis of alveolar endothelial cells in rats, resulting in emphysema and this appears to be driven by oxidative stress [25] and may be mediated via the sphingolipid ceramide [95]. In addition, VEGF is also an important proinflammatory cytokine produced by epithelial and endothelial cells, macrophages, and

activated T-cells, which acts by increasing endothelial cell permeability, by inducing expression of endothelial adhesion molecules and via its ability to act as a monocyte chemoattractant. VEGF also stimulates the expression of CXCL10 and its receptor CXCR3. Thus VEGF is acts as an intermediary between cell-mediated immune inflammation and the associated angiogenesis reaction.

## Proteinases

An imbalance between proteinases that degrade connective tissue and anti-proteinases has long been postulated in COPD (Fig. 34.14). There has been debate about which are the most important proteinases involved in emphysema. While previous attention focused on NE, more recently a role of MMP has been recognized (see Chapter 28). MMP-9 appears to be particularly important in degrading elastin fibers in lung parenchyma and is secreted in large amounts by alveolar macrophages of COPD patients [52, 96]. MMP-9 also activates TGF-β accounting for the simultaneous occurrence of lung destruction and fibrosis in COPD (Fig. 34.15). In the mouse, MMP-12 appears to play a key role in the development of cigarette smoke-induced emphysema as MMP-12 derived elastin fragments are major factors driving macrophage recruitment [97]. A role for MMP-1 has also been suggested in both human and animal studies [98].

## SYSTEMIC MANIFESTATIONS

It is now recognized that COPD involves organs outside the lung, but the mechanism for these systemic effects of COPD are not well understood (see Chapter 44). Inflammatory cytokines, such as TNF-α and IL-6, may spill over from the lung periphery into the systemic circulation, where they may have detrimental effects on
**FIG. 34.15** Connective tissue destruction and fibrosis coexist in COPD. Matrix metalloproteinase-9 (MMP-9) is the major elastolytic enzyme released by alveolar macrophages and is generated from an inactive precursor pro-MMP-9. MMP-9 causes elastolysis directly, but also releases chemotactic peptides that attract neutrophils, which release neutrophil elastase. The elastolytic effect of neutrophil elastase is enhanced as MMP-9 inactivates its specific anti-proteinase $\alpha_1$-antitrypsin, resulting in emphysema. MMP-9 also activates transforming growth factor-$\beta$ (TGF-$\beta$) from a latent precursor and this leads to fibrosis of small airways. TGF-$\beta$ also plays a role in activating MMP-9, so the interplay between these mediators leads to tissue destruction and fibrosis simultaneously, as observed in COPD lungs.

## CONCLUSIONS

Cigarette smoke exposure induces a florid inflammatory response in the lung involving structural and inflammatory cells and a large array of inflammatory mediators. The interaction of these complex steps eventually leads to airway remodeling and obstruction and emphysema, albeit variable among individual smokers. Of interest, the main difference between smokers who develop COPD and the ones who do not seems to be the presence of an adaptive immune response with CD8+, CD4+, and B-cells, which express obvious signs of being activated effector cells. It is likely that genetic and epigenetic factors (such as histone acetylation) are involved in determining the progression of the inflammatory cascade, as this is supported by animal models, where different strains appear to have different sensitivities to cigarette smoke. COPD is a complex inflammatory disease and the interactions between different inflammatory cells and mediators are still uncertain. The role played by structural cells in responding to inflammatory cell-mediated injury and the degree to which it is deficient in COPD remains to be fully defined. More research into these mechanisms is needed in order to identify novel targets that may lead to the discovery of more effective therapies that are able to prevent disease progression and reduce the high mortality of this common disease [102].

**FIG. 34.16** Systemic features of COPD and co-morbidities. Inflammation in the lungs may spill over into the systemic circulation resulting in systemic inflammatory effects and exacerbation of cardiovascular diseases and skeletal muscle wasting. Increased concentrations of interleukin-6 (IL-6) and tumor necrosis factor-$\alpha$ (TNF-$\alpha$) are found in systemic circulation of patients with severe COPD and these may directly result in skeletal muscle atrophy. IL-6 releases the acute phase protein C-reactive protein (CRP) which is associated with increased cardiovascular disease risk [101]. Cigarette smoke also contributes to increased cardiovascular risk.

skeletal muscle function and endothelial function [99] (Fig. 34.16). IL-6 causes the release of the acute phase protein C-reactive protein, which is increased in the circulation of patients with COPD and correlates with disease severity [100]. Skeletal muscle wasting is a feature of severe COPD and this may in part be due to systemic inflammation but is more likely due to disuse atrophy as a result of impaired exercise performance.

## HISTORY

### Introduction

Allergy, that is type I IgE-mediated sensitization and sequelae to predominantly inhaled allergens, has become increasingly recognized as important in the pathogenesis of asthma. The development of this increased recognition is briefly outlined focusing on identification of allergy and its mechanisms, on the relevance of allergen in the pathogenesis of asthma, and on increased prevalence of the condition(s).

### Allergy

Although *rose catarrh* (likely actually due to grass pollen) had been known for some time, the first comprehensive clinical description of allergic rhinitis is attributed to John Bostock in 1819 [1]. The disease was given the medical name *catarrhus aestivus* (summer cold) but was recognized in the lay literature as *hay fever*, a label which persists to this day. This disease was felt to be limited to the middle and upper classes, and a major prevailing hypothesis was that it was due to the effects of summer heat and/or sunshine [1]. Grass pollen had been suggested as a potential cause, but this was not confirmed until the elegant experiments of Charles Blackley in 1873 [2]. The term *allergy* (different from normal) was coined by Von Pirquet in 1906 [3]. In 1912, allergy skin testing was first used in the investigation of this type of hypersensitivity [4]. With the mistaken belief that pollen contained a toxin, the concept of pollen immunization was introduced by Dunbar [5] and popularized

by Noon in 1911 [6, 7]. Prausnitz and Kustner disproved the toxin hypothesis by the demonstration of passive transfer of allergic sensitivity using the injection of the serum of a sensitized individual into the skin of a nonsensitized subject [8] – the basis of the so-called PK test. Coca demonstrated that a heat labile serum factor that could not be precipitated from serum by the usual methods was the case of this sensitivity and, in 1923, he coined the terms *atopy* (strange disease) and *atopic reagin* as the name for this serum factor [9]. Reaginic antibody was eventually identified as IgE by Ishizaka in 1967 [10]. The complete allergen response, including allergen presenting cells, lymphocytes (T-helper 2 or Th2 and B cells), mast cells, basophils, and mediators, is still being elucidated.

### Allergy and asthma

The recognition of allergens as potential causes of asthma parallels the recognition of allergy. Classic asthma symptoms were a major component of Bostock's original description of *catarrhus aestivus* [1]. Pollen, both ragweed [11] and grass [2], was specifically shown to provoke attacks of asthma in the 1870s. Cat, horse, and house-dust mite were identified as relevant asthma producing allergens in the early part of the 20th century [12], and more recently fungal spore sensitivity has been identified as a risk factor for asthma [13]. Asthma became lumped with the atopic diseases by many in the early part of the 20th century. However, the very influential Osler's textbook had stated that asthma was a *neurosis* [14], an opinion that continued to hold weight for many years. The opposing view, namely that asthma was primarily an atopic allergic disease,

was argued by Cooke and colleagues [15]. This controversy persisted well into the 20th century. The identification of allergen-induced late asthmatic responses [16], allergen-induced airway hyperresponsiveness[1] [17], and allergen-induced airway inflammation [18], that is features that define clinical asthma, has led to allergens becoming recognized as important position in the pathogenesis of asthma. Although still a subject of some controversy [19], many investigators now regard the majority, that is 75–80%, of nonselected asthmatics as being atopic [20, 21].

## Prevalence

There has been a striking increase in the prevalence of allergic rhinitis from the beginning to the end of the 19th century [22]. Within this time, frame allergic disease has gone from rare in the early 1800s to a common disorder by 1900. A case can be made that this is at least in part related to earlier under-recognition of a condition whose symptoms (rhinitis, wheezing) resemble other conditions believed to have been more common, and whose symptoms are often so mild as to potentially go unreported at a time when there were many more serious diseases to be concerned with. As early as 1873, Blackley noted the rising prevalence of allergic disease and felt that this could not adequately be explained by increased recognition which he admitted did play a role [2]. The prevalence of atopic disease and asthma in particular has continued to increase throughout the 20th century with more objective data to support these trends. The reasons for the remarkable increase in the prevalence of atopy and asthma are not completely understood. Genetics play a role in determining the presence and severity of atopy, however, large changes in prevalence over a short period cannot be due to genetics and therefore must be due to one or more environmental factors. One hypothesis is that increased exposure to allergens, particularly indoor allergens in modern air-tight homes, may lead to increased atopy and asthma [23]. This has been demonstrated prospectively in Papua New Guinea where blanket introduction was followed by house-dust mites, house-dust mite sensitivity, and an asthma epidemic [24]. Another intriguing hypothesis is the *hygiene hypothesis* [25]. This hypothesis suggests that early childhood infections drive the immune system toward the T helper 1 (Th1) paradigm that suppresses or reduces the Th2 arm of the immune system. Control/prevention of infections will remove this Th2 suppression and lead to an increased prevalence of Th2-related atopic disease. The evidence for this, including family size studies and epidemiologic studies related to infection, is stronger for atopy than for asthma alone [25]. Other factors related to lifestyle issues including diet and level of activity may be important [23].

---

[1]The term "airway (hyper)responsiveness" throughout this chapter, unless otherwise stated, refers to the nonallergic (hyper)responsiveness to histamine, cholinergic agonists, exercise, etc., which is a characteristic feature of symptomatic asthma.

## ATOPY

Atopy is the tendency to develop IgE antibodies to commonly encountered environmental allergens by natural exposure in which the route of entry of allergen is across intact mucosal surfaces [26]. The recognized familial nature of atopy is due to complex (multiple gene) inheritance (genetic heterogeneity) [21, 27]. The remarkable relatively short-term increase in atopic prevalence indicates that environmental factors are also important [22–25]. The pathophysiologic basis for subjects developing atopy is uncertain and is the topic of a recent symposium [28]. An old hypothesis favoring allergen handling perhaps at the mucosal surface [29] rather than increased capacity to produce IgE has not been excluded.

The prevalence of atopy in random populations, defined as the presence of positive(s) on prick skin testing with a small battery of common relevant allergens, ranges from 30% to almost 50% [30–32]. The peak period of sensitization is in the third decade; thereafter the prevalence falls [26]. Our experience with a random young population would suggest that about 50% of atopic (skin test positive) subjects will have symptoms referable to atopy, which will include asthma in about 50% [32]. Thus, atopy is common, affecting about one in three, with about one in six having symptomatic atopy and about one in twelve having atopic asthma; the prevalences will be proportionately higher in populations with a higher prevalence of atopy.

## ALLERGENS

Inhaled complete allergens that provoke asthma by IgE-mediated mechanisms are soluble organic high molecular weight (20,000–40,000 MW) protein or protein-containing molecules, which may be derived from any phylum of either the plant or the animal kingdoms (including bacteria) [33, 34]. The structural characteristics that make a protein allergenic have been recently reviewed [35]. In clinical nonoccupational settings, the important inhalant allergens fall into four groups; pollen, fungal spores, animal danders, and household arthropods (mite and insects) [36].

Pollen allergens that trigger asthma are predominantly from wind-pollinated plants, namely trees, grass, and weeds [36]. The relevant allergens and seasonal fluctuations will vary with geography and climate, with tree pollens predominant in spring months, grasses in summer, and weeds in late summer and autumn [34]. Although whole pollen grains may have limited access to the lower respiratory tract [37], the relationship of pollen to clinical asthma is convincing [36].

Atmospheric fungal spores of many groups of fungi are smaller and more respirable than pollen, and are recognized as causing atopic sensitization [13]. Their role in triggering asthma is less certain than pollen [34, 36]. Fungal spore types and seasons will also vary with geographic and climatic (temperature and humidity) conditions. Fungal spores are associated with decaying vegetation resulting in a late summer and autumn peak for common fungal spores, *Alternaria*, *Cladosporium*, *Aspergillus*, *Sporobolomyces*, etc. [34]. A spring

peak for atmospheric fungal spores may be seen in some areas especially where late melting of snow cover leads to so-called snow mold [34]. Thus, atmospheric fungal spores may be responsible for fall or spring–fall asthma symptoms. Fungi may also be present inside living areas in moist basements, food storage areas, and waste receptacles [34]. *Aspergillus* may cause a distinct clinical syndrome, allergic bronchopulmonary aspergillosis, which will be covered separately.

Household animals [34], particularly cats and dogs, but also small mammals (gerbils, hamsters, rabbits, etc.) and birds, may release allergens in secretions (e.g. saliva) or excretions (e.g. urine, feces). Large animals, particularly horses, may also provoke atopic sensitivity. House dust, due to its content of mite antigens from various *Dermatophagoides* species or insect antigens such as cockroach [38], is an important source of atopic sensitization. *Dermatophagoides* spp., in particular, are likely the most important cause of atopic sensitization worldwide. Again, climatic conditions are important, since areas of low indoor relative humidity do not favor growth of house-dust mites [34, 39].

Other allergens are encountered less frequently, often in occupational settings, and include various plant parts [castor bean, cocoa bean, tobacco leaf, psyllium (laxative), vegetable gums, etc.], insect dusts, bacterial enzymes, and in the very highly sensitized even atmospheric molecular levels of foods (e.g. cooking fish) [34].

## INHALED ALLERGENS

### Patterns of airway response

Airway responses to inhaled allergens have been assessed by the somewhat artificial inhalation tests in the laboratory with aqueous allergen extracts [17, 40, 41]. Nevertheless, the results of such challenges, especially the late sequelae, appear to be clinically relevant [42, 43], and allergen inhalation tests allow study of both the pharmacology and the pathophysiology of allergen-induced asthma. Airway responses to allergen can be divided into early and late sequelae. The early asthmatic response (EAR) is an episode of airflow obstruction which is maximal 10–20 min after allergen inhalation and resolves spontaneously in 1–2 h [17, 40, 41, 44]. The late sequelae include the late asthmatic response (LAR) [16, 17, 40, 41, 43–46], airway hyperresponsiveness [17, 41, 42], recurrent nocturnal asthma [46], and airway inflammation [18, 47]. The LAR is an episode of airflow obstruction which develops after spontaneous resolution of the EAR between 3 and 5 h after exposure, occasionally earlier, rarely later [17, 40, 41,43,44,45]. Resolution usually begins by 6–8 h but may require in excess of 12 h [41, 43, 44]. Modest late responses respond well to bronchodilators [48]; unpublished observations suggest bronchodilators may be required often (e.g. up to 2 h). More severe late airway obstruction is not always completely reversible by bronchodilator [44]. Examples of early and late responses are shown in Fig. 35.1. Allergen-induced increase in airway responsiveness (e.g. to histamine/methacholine) occurs

**FIG. 35.1** Early and dual asthmatic responses to allergen. The top graph shows an isolated EAR following ragweed pollen inhalation and the bottom graph a dual asthmatic response (in another subject) following grass pollen inhalation. Modified and reproduced from Ref. [49] with permission.

following both experimental [17, 41, 42, 47] and natural [42, 50, 51] allergen exposure. This is correlated with the occurrence and severity of the late response, often appearing with small, previously ignored, late responses (5–15% $FEV_1$ (1-s forced expiratory volume) fall) [17, 41]. Airway responsiveness develops between 2 [52] and 3 h [53–55] after exposure, is present at 7–8 h [17, 41, 52], and may persist for days, occasionally worsening despite the return of airway caliber to baseline [41] (Fig. 35.2). As expected [56], the increased airway responsiveness is associated with symptoms of asthma [17, 41], including recurrent nocturnal asthma [46]. Both the LAR [18, 47] and the increased airway responsiveness [47] are associated with increases in airway inflammation. The occurrence of seasonal increases in airway responsiveness [42, 50, 51], and airway inflammation [57] provides support for both the relevance of the bronchoprovocation model and the importance of the inflammation in the pathogenesis of the late sequelae.
**FIG. 35.2** Allergen-induced increase in nonallergic airway responsiveness to inhaled histamine. A dual asthmatic response, with spontaneous recovery, occurred after a single inhalation of ragweed pollen extract. Airway responsiveness to inhaled histamine, expressed as the provocation concentration causing a 20% FEV1 fall (PC20), increased after allergen exposure, and was associated with asthma symptoms on exposure to nonallergic stimuli. Reproduced from Ref. [49] with permission.)

## Pharmacology

Pharmacologic inhibition of airway responses to inhaled allergen has been studied for both its therapeutic relevance and further understanding of the pathophysiology of the responses.

Inhaled $\beta_2$-agonists are the best inhibitors of the EAR [45, 58–61] due to a combination of effects on smooth muscle and on mediator release [62, 63]. Despite the latter, intermediate acting inhaled $\beta_2$-agonists (salbutamol, terbutaline, etc.) do not inhibit the LAR [45, 58, 59, 61] or the increased airway responsiveness [61]. The long acting inhaled $\beta_2$-agonists salmeterol and formoterol completely inhibit or mask all aspects of the allergen-induced airway response [64, 65], likely due to functional antagonism rather than anti-inflammatory effect [65]. Regular use of inhaled $\beta_2$-agonists for a week or more increases the EAR [66, 68, 69], the LAR [69, 70, 184], mast cell mediator release [69], and allergen-induced airway inflammation [69, 70]. A larger dose of allergen can be administered after an inhaled $\beta_2$-agonist and will lead to a larger LAR [71]. These features, failure to inhibit the LAR, enhanced airway responses, and ability to tolerate a larger dose of allergen, may be relevant in $\beta_2$-agonist-worsened asthma control [72].

Muscarinic blockers cause variable minor inhibition of the EAR [60, 73–75] and no inhibition of the LAR [73, 75]. Allergen-induced airway hyperresponsiveness appears uninfluenced by anticholinergics [75]. The enhanced airway responsiveness to histamine following allergen inhalation is no more responsive to atropine than it was prior to allergen inhalation [76].

Ingested theophylline offers partial protection against both the EAR and the LAR [77–80] and variable protection against the induced airway hyperresponsiveness [78–80]. It is not clear whether this is a functional antagonist or an anti-inflammatory effect.

Inhaled sodium cromoglycate (SCG) given prior to allergen exposure inhibits both the EAR and LAR [44, 45, 58, 61, 78, 81], as well as the allergen-induced increased responsiveness to both histamine [61] and methacholine [78]. Nedocromil sodium appears to have similar effects on allergen-induced asthmatic responses [82]. SCG given after the EAR will slightly delay but not inhibit the LAR [67].

The leukotriene pathway can be altered in several ways. Leukotriene receptor antagonists (LTRAs) are the most commonly used leukotriene modifiers. LTRAs provide protection against both EAR [83–85] and LAR [83, 84]. In addition, 5-lipoxygenase inhibitors [86] or 5-lipoxygenase activating protein inhibitors [87] provide some protection. Recently, the combination of desloratadine ($H_1$ blocker) and montelukast (LTRA) has shown a synergistic effect regarding inhibition of the EAR [85]; hence, studies on the LAR are required.

A single dose of inhaled corticosteroid, given prior to allergen, has no influence on the EAR but provides effective and often complete inhibition of the LAR [44, 45, 58, 61, 66, 67, 81, 82, 89, 90, 91, 92]. A single dose given after the EAR will inhibit the LAR [67]. Longer treatment periods with inhaled corticosteroids will partially inhibit the EAR as well [68, 91, 92]. Corticosteroid-induced improvement in airway responsiveness [68, 93, 94] provides only partial explanation [68]. Reduction in mucosal mast cells [95–97] is likely more important.

$H_1$ blockers partially inhibit the early portion of the EAR [45, 58, 98–100]. Newer $H_1$ blockers may also show some inhibition of the LAR [100]; hence, further studies are necessary. Ingested antiallergic drugs such as ketotifen and repirinast have produced variable effects on allergen-induced asthma [101–107]. Most studies have failed to show any significant protection [101, 102, 106, 107]. Nonsteroidal anti-inflammatory agents (cyclooxygenase inhibitors), particularly indomethacin, appear to have no effect or perhaps enhance the EAR [108]; there is conflicting evidence regarding the late response [88, 109, 110]. Allergen-induced increase in airway responsiveness appears to be partially inhibited by indomethacin [88]. A thromboxane synthetase inhibitor had no effect on allergen-induced early or late responses or increased airway responsiveness [111]. A platelet-activating factor antagonist proved ineffective against allergen-induced asthma [112]. Inhaled furosemide provides inhibition of both EAR and LAR [113]. Allergen injection therapy has produced variable results in modulating the EAR [114, 115] but may be particularly effective versus the LAR [116]. A novel recombinant anti-IgE molecule directed against the Fc component of IgE is very effective at inhibiting both the EAR [117] and the LAR [118]. Anti-IL-5 [119] and IL-12 [120] suppressed allergen-induced eosinophilia with little effect on allergen-induced airways hyperresponsiveness (AHR) casting some doubt on the causal relationship between inflammation and AHR.

## Mechanisms

The mechanisms of allergen-induced asthmatic responses have been studied in humans by indirect means. Animal studies, *in vitro* studies on excised human tracheobronchial smooth muscle, drug-inhibition studies and, more recently, bronchoalveolar lavage (BAL), and induced sputum, have all been used to assess mechanisms. The EAR is due to the allergen-IgE mast cell acute mediator release including histamine [121], prostaglandins [122], and leukotrienes [123] and is primarily bronchospastic. Individual mediator blockers are only partially effective in inhibiting the EAR [83, 84, 85, 98, 99], however, an *in vitro* study on human tracheal smooth muscle demonstrated complete inhibition of the EAR by combined $H_1$ blocker, cyclooxygenase inhibitor, and lipoxygenase inhibitor [124]. The pathogenesis of the LAR is not so clear. An outdated hypothesis that late responses were type III precipitin-mediated responses [44], controversial at that time [58], has been disproved since both cutaneous [125, 126] and pulmonary [118, 127] late responses are IgE mediated. Animal studies have documented the requirement for inflammatory cells (eosinophils, neutrophils) in the LAR [128, 129] and induced airway hyperresponsiveness [130–132]. This has been confirmed in humans using BAL [18, 133] and induced sputum [47, 84]. The precise role of the chemokines and their cellular origin in the recruitment of inflammatory cells are a topic of current research [134–136].

## Allergens as a cause of asthma

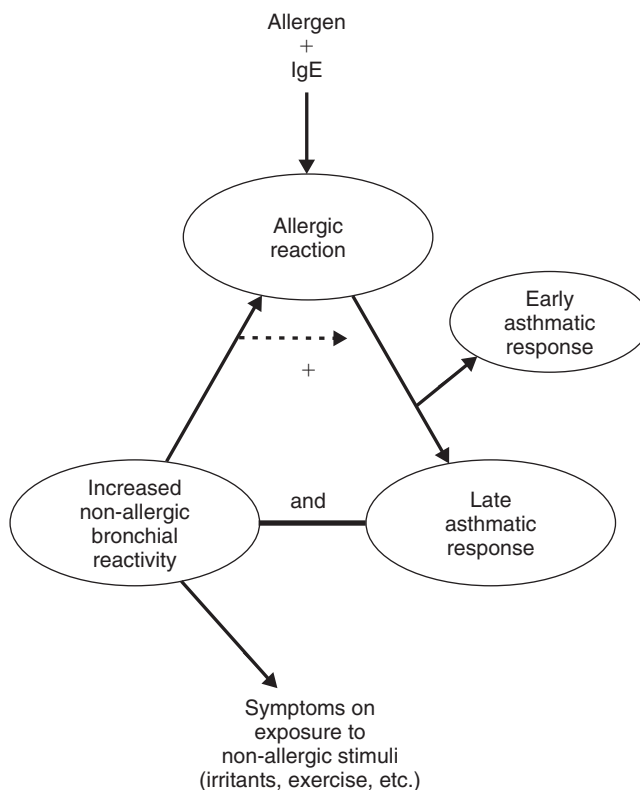
The importance of allergens as a *cause* of asthma (i.e. symptomatic airway hyperresponsiveness and airway inflammation [137], which was hypothesized several years ago [49] (Fig. 35.3), is now generally accepted [138]. The lines of reasoning include the high prevalence of atopy amongst asthmatics [20, 21], the correlation of both airway hyperresponsiveness and asthma with atopy in epidemiologic population studies [32,139–144] (Fig. 35.4), the relationship of both seasonal [42, 50, 51, 145, 146] and indoor [23, 24, 39] allergen exposure to symptoms and airway hyperresponsiveness, and their


**FIG. 35.3** Diagram of hypothesis explaining development and maintenance of perennial allergen-induced asthma. Reproduced from Ref. [49] with permission.
**FIG. 35.4** Degree of atopy (various scales) from nonatopic (0) to highly atopic (highest number) on the horizontal axis versus prevalence of airway hyperresponsiveness (%) on the vertical axis from four population studies [20, 140–142]. Reproduced from Ref. [143] with permission.

reduction with allergen avoidance [147, 183]. It is speculated that, in sensitized individuals, the duration and magnitude of airways allergic exposure, if not suppressed pharmacologically, may lead not only to transient but also to persistent airway hyperresponsiveness and clinical asthma [49]. This is supported by parallel observations in animals [148] and in human occupational asthma [149, 150].

## INGESTED/INJECTED ALLERGENS

Isolated asthma caused by allergens introduced via routes other than inhalation is uncommon but has been reported [151, 152]. Ingested allergens [152] (foods, drugs) or injected allergens [153] (hyposensitization injections, intradermal allergen tests, drugs, insect bites, and stings) can produce IgE-mediated hypersensitivity reactions. Most often, these produce systemic allergen reactions [151, 153] (violent gastrointestinal upset, urticaria, angioedema, laryngeal edema, anaphylactic shock, with or without bronchospasm). However, occasionally such exposures produce reactions that appear to be centered primarily in the lung [152, 154]. It is likely that these represent systemic allergen reactions in subjects with pre-existing asthma and high levels of airway hyperresponsiveness who develop disproportionately severe bronchospasm. Some cases of food/bite/sting-induced *asthma* may actually represent laryngeal spasm or edema which has been misdiagnosed. Although relatively uncommon, allergen (asthmatic or otherwise) responses to both ingested and injected allergens occur rapidly and can be exceedingly severe. We have seen subjects with sudden severe asthma due to foods (nuts, shellfish) and two subjects with sudden onset status asthmaticus circumstantially linked to unrecognized black fly bites.

## CLINICAL FEATURES

### Clinical presentation

Allergic asthma usually begins at a young age, between about 2 and 20, but can develop at any time. A positive family history of asthma or atopy is common. Other atopic symptoms are often present and include food sensitivity (infancy), childhood eczema, urticaria, conjunctivitis, and allergic rhinitis. Asthma or asthma exacerbations should correlate with allergen exposure or seasons. Spring, summer, or fall exacerbations suggest fungal spore or pollen sensitivity whereas winter exacerbations are typical of indoor allergen sensitivity but may also occur in nonatopic asthmatics. The polyallergic subject may show little seasonal variability. Because of the gradual onset of airway inflammation and hyperresponsiveness, allergen-induced asthma exacerbations are usually of gradual onset often lagging behind and persisting beyond allergen exposure. An acute exposure–symptom relationship may be lacking. For these reasons, the patient and physician may miss the importance of allergens. When present, nonrespiratory,

particularly ocular or cutaneous and, to a lesser extent, nasal symptoms will bear a much closer relationship to exposure and may provide an important historical clue to sensitization. Irritant- and exercise-induced bronchospasm are symptomatic of underlying airway hyperresponsiveness and, consequently, can be due to (often unrecognized) allergen exposure that may not be acutely temporally related.

Sudden severe symptoms can occur following inhaled allergen exposure if the exposure is marked, if the individual is highly sensitized, or if previous asthma symptoms/airflow obstruction have been either under-perceived or ignored. However, genuinely sudden asthma exacerbations raise the possibility of ingested or injected allergen (foods, drugs, bites, stings, allergen shots); this clinical scenario should prompt an aggressive historical review for relevant clues. Non-IgE-mediated responses to ASA and NSAIDs, β-adrenergic blockers, food additives (e.g. metabisulphites), or cholinesterase inhibiting insecticides are included in the differential diagnosis of sudden severe asthma.

## Diagnosis

The diagnosis of allergic asthma rests predominantly on the historical features noted above. The inquiry into possible allergens should not stop with the home but must include work, school, social, and recreational exposures. Because of the frequently subtle exposure–symptom relationships, non-respiratory symptoms related to allergen exposure should be sought. Following completion of a complete history, allergen prick-skin testing with a small series of relevant allergens should be done.

## Treatment

The treatment of allergen-induced asthma is the same as for asthma in general and is outlined elsewhere in this book. The pathophysiologic and clinical features outlined above stress the importance of environmental control. The possibility that chronic allergen exposure might lead to permanent pathology suggests that therapeutic strategies that are largely effective by preventing the allergic response and sequelae (allergen avoidance, cromones, anti-IgE) will be less effective if their introduction is delayed.

## Allergic bronchopulmonary mycoses

A distinctive clinical syndrome occurs when atopic individuals have organisms, against which they have IgE antibodies, growing in their airways. The prototype, by far the commonest of these "allergic bronchopulmonary mycoses," is allergic bronchopulmonary aspergillosis (ABPA) usually caused by *Aspergillus fumigatus* [155–158]. Other fungi, including *Helminthosporium* [159, 160], *Curvularia* and *Drechslera* [160, 161], *Stemphylium* [162], *Candida* [163], *Fusarium* [164], and rarely bacteria such as *Pseudomonas* [165], may cause a similar syndrome. The syndrome that these organisms can produce involves complex immunologic and mechanical pathogenesis.

The pathogenesis of ABPA initially involves acquisition of IgE-mediated type I hypersensitivity to the fungus. *Aspergillus* fungal spores released from decaying vegetation, particularly in the autumn germinate and grow in the airway provoking reduced airway caliber and mucous hypersecretion leading to mucous plugs containing fungal hyphae producing "cast-like" outlines of the bronchial tree. The chronic high-level allergen exposure leads to very high levels of both allergen-specific and total serum IgE, an intense peripheral and bronchial eosinophilia, and in most, but not all, to the development of IgG precipitating antibodies. Other immunologic responses including cell-mediated immunity may be stimulated. The continuous airways allergic reaction will lead to exacerbation of asthma while the other immunologic reactions may be responsible for bronchial and parenchymal damage that includes (proximal) bronchiectasis and (upper lobe) interstitial pulmonary fibrosis. Fleeting or fixed pulmonary infiltrates may be produced by immunologic reactions within the lung, by the mechanical effect of obstruction of major bronchi by mucous plugs, or both.

ABPA is a fairly common condition in some areas; the precise prevalence is not certain. Amongst asthmatics, the prevalence of type I (IgE) sensitivity to *Aspergillus* may approximate 25% [166–168], and the prevalence of type III (IgG) sensitivity to *Aspergillus* is approximately half of this [169, 170]. By contrast, on the dry Canadian prairies, *Aspergillus* skin sensitivity is uncommon, and we have seen no new cases of ABPA in over 20 years. Other organisms (e.g. *Helminthosporium*) are involved only rarely. The clinical picture is generally that of a subject with pre-existent atopy, and usually previous asthma, presenting with exacerbation of asthma accompanied by the expectoration of characteristic firm brown plugs [155]. Pulmonary infiltrates with eosinophils with or without fever may be seen. Chronic disease may manifest as bronchiectasis with chronic or recurrent pulmonary infection or pulmonary fibrosis with progressive dyspnea or both [155, 156].

The two features that must be present in all subjects with ABPA are type I hypersensitivity to the *Aspergillus* and the presence of *Aspergillus* in the airways. However, it is not always possible to grow the organism [171]. Specific IgG precipitating antibodies are found in about 90% of cases [157]. Other features that are commonly seen include intense peripheral and bronchial eosinophilia [171], marked elevations of total serum IgE [172], and transient pulmonary infiltrates [155–158]; these all tend to correlate with activity of disease. Chronic changes in established or recurrent disease include radiographic demonstration of an unusual and essentially pathognomonic *proximal* bronchiectasis [173] and, in more severe cases, progressive upper lobe interstitial pulmonary fibrosis similar to tuberculosis and other upper lobe scarring conditions [156]. The computerized tomographic scan may be particularly helpful as an adjunct to the diagnosis of ABPA [174, 175]. ABPA is a common complication of cystic fibrosis [176]; the 2% prevalence in one observational cohort was felt to represent under recognition [177]. Atopic skin testing has been suggested as a useful screen in this population [176], however, may not be reliable [178]; specific skin tests, allergen-specific IgE, total IgE, and precipitins are recommended in this population [178].

Allergic bronchopulmonary infestations with *Aspergillus* or other fungal organisms are not true infections; progression to invasive fungal infections or mycetoma formation is uncommon. Treatment is directed against the asthma and the immunologic abnormalities; intensive asthma treatment with systemic corticosteroids in doses sufficient to suppress clinical and laboratory features of the disease is indicated [171, 179, 180]. Total serum IgE may be useful to predict exacerbations [180]. With such treatment, the prognosis is favorable; however, under-treatment can lead to substantial, even severe, permanent bronchopulmonary damage. Itraconazole has been reported to be effective in reducing corticosteroid requirements in ABPA [181] and may be useful in cystic fibrosis [176]. However, a recent Cochrane Database report concludes there is insufficient information available to recommend the use of azoles (itraconazole, ketoconazole) in this condition [182].

## SUMMARY

1. The majority of subjects with asthma are atopic.

2. Allergen-induced airway hyperresponsiveness and airway inflammation point to allergens as a *cause* of asthma (i.e. symptomatic airway hyperresponsiveness with inflammation).

3. The remarkable rise in the prevalence of atopy ("hygiene" hypothesis, airtight home/indoor allergen exposure hypothesis, other hypotheses or some combination) over the past 200 years may explain in whole or in part the rising prevalence of asthma.

4. Chronic/recurrent allergen exposure may lead to persistent asthma.

5. This provides a plausible basis to suggest that early prophylactically or actively anti-inflammatory therapeutic strategies should improve long-term outcomes in allergic asthma.

6. This also provides a rationale to speculate re-*primary* prevention of (allergic) asthma.

## OCCUPATIONAL ASTHMA

### Definition

A proposed definition of occupational asthma (OA) should take into account at least two essential aspects of the condition. First, it should reflect the fact that OA shares the clinical, functional, and pathological features of asthma, that is variable, spontaneously or as a result of treatment, symptomatic airway caliber, hyperresponsiveness, and inflammation of the airways. Second, it should state that OA is caused by the workplace in which, in most cases, an agent has been identified. The definition of OA which has been retained in a textbook on OA reads as follows: "OA is a disease characterized by variable airflow limitation and/or airway hyperresponsiveness and/or inflammation due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace" [1]. Within this definition, two types of OA are distinguished by whether they appear after or without a latency period.

### Agents that cause OA and the pathophysiological mechanisms

Over 300 agents in the workplace have been implicated in causing asthma [2]. Table 36.1 shows a list of the more common agents responsible for OA. The agents can be divided into two groups according to the pathogenic mechanisms: those that give rise to asthma by immunological mechanisms and those by nonimmunological mechanisms. Agents in the former group can cause asthma by immunoglobulin (Ig)E-dependent or IgE-independent mechanisms. Irritant-induced asthma (IIA) is a type of OA caused by an apparently nonimmunological mechanism [3].

### Agents that induce OA by immunological mechanisms

#### Agents that induce asthma by IgE-dependent mechanisms

The agents causing OA by IgE-dependent mechanisms include both high molecular weight compounds (>10kDa) and some low molecular weight compounds (<10kDa). High molecular weight compounds are usually proteins or polysaccharides and induce specific IgE antibodies. Some low molecular weight agents, such as platinum [4] and acid anhydrides [5], can also induce specific IgE antibodies by acting as haptens, which combine with a body protein to form complete antigens. There is evidence to support the fact that the asthmogenic potency of a compound is determined to a certain extent by its chemical structure [6, 7]. Often, agents such as trimellitic anhydride and isocyanates can modify body proteins, an important step toward becoming a hapten, and thus stimulate the immune system.

These agents often affect atopic subjects. The inhaled occupational sensitizer can bind to specific IgE antibodies on the surface of mast cells, basophils, and possibly macrophages and eosinophils. The mechanism of asthma induction by these sensitizers is similar to nonoccupational allergens [8].

#### Agents that induce asthma by IgE-independent mechanisms

The agents that give rise to OA through IgE-independent mechanisms are mostly low molecular weight compounds such as isocyanates and

**TABLE 36.1** Agents that cause immunologically mediated occupational asthma.

| | Common sources of exposure |
| --- | --- |
| *High molecular weight agents* | |
| Animal-derived material | Animal, poultry and insect work, veterinary medicine, fishing and fish processing, laboratory work |

| Chlorine | Pulp and paper mills |
| Acetic acid | Hospital setting |
| Isocyanates | Spray paint |

For further information see Ref. [2].

plicatic acid (the agent responsible for Western red cedar asthma) [8]. In subjects with both isocyanate and Western red cedar asthma, specific IgE antibodies have been found in only a small proportion proven to have the disease [9] although, if present in high concentrations, they appear specific for the disease [10] though, apparently, not causal for the disease [11]. It is still uncertain whether the presence of specific IgG antibodies is a marker of the disease or merely of exposure. In Western red cedar asthma, the significance of the presence of specific IgE antibodies is not clear since anti-IgE antibodies failed to inhibit the release of histamine by plicatic acid from granulocytes of patients with the disease [12].

Studies of both isocyanate and Western red cedar asthma have demonstrated that T-lymphocytes might play a direct role in mediating the inflammatory response in the airways [13, 14]. In patients with isocyanate-induced asthma, the majority of T-cell clones derived from bronchial mucosa of subjects were found to be CD8$^+$ T-lymphocytes that produced IL-5 [13]. Among patients with Western red cedar asthma, peripheral blood lymphocytes released IL-5 and IFN-$\gamma$ after stimulation with plicatic acid in sensitized subjects [14]. Animal studies have shown that diisocyanate-induced asthma is driven primarily by CD4$^+$ T-cells and is dependent upon the expression of Th2 cytokines. However, animal models are not always reflective of human responses [15].

A more recent study of bronchial biopsies taken after specific inhalation challenge testing from patients suspected of diisocyanate-induced asthma showed a striking absence of C and IL-4 mRNA-positive cells in bronchial biopsy specimens irrespective of whether the response was positive or negative indicating the absence of IgE involvement at least in a proportion of patients with diisocyanate-induced asthma [11].

Toluene diisocyanate was also found to induce production of proinflammatory cytokines and chemokines from bronchial epithelial cells through the epidermal growth factor receptor and p38 mitogen-activated protein kinase pathways [16].

## Agents that induce OA by nonimmunological mechanism

Irritant-induced asthma is apparently a nonimmunologically induced type of asthma. There seems to be a dose-dependent relationship between exposure and likelihood of permanent disability/impairment [3, 17–19].

## Pathology

### Immunologically mediated OA

There is no difference between the pathology of the airways of patients with occupational and those with nonoccupational asthma. Studies of bronchoalveolar lavage (BAL) fluid have shown influx of eosinophils and neutrophils and a marked increase in albumin concentration during late asthmatic reaction after inhalation challenge with isocyanates [20]. In patients with Western red cedar asthma, increases in eosinophils and epithelial cells, as well as in albumin, histamine, and LTE4,

have also been found in the BAL fluid [21]. Irrespective of the sensitizing agent, the pathological features in the airways are similar. There is subepithelial fibrosis, hypertrophy of airway smooth muscle, edema of the airway wall, accumulation of inflammatory cells, mostly eosinophils, and obstruction of the airway lumen by exudate and/or mucus in patients with OA [22]. Cessation of exposure to the sensitizing agent is associated with a decrease in the number of inflammatory cells in the airway mucosa [23]. In isocyanate-induced asthma, some reversal of the subepithelial fibrosis has been found [24] but airway eosinophilia and neutrophilia may persist. Studies of induced sputum of patients with OA after cessation of exposure for a mean interval of 8.7 years indeed showed that some subjects still had increased levels of neutrophils and eosinophils in induced sputum [25].

### Nonimmunologically induced asthma

The mechanism of IIA is not known. IIA is a "big bang" phenomenon. Exposure to a high level of the irritant leads to acute sloughing of the epithelium [3]. There are some differences between the pathological features of IIA and those of immunologically mediated asthma. In general, subepithelial fibrosis is more evident in IIA [26]. In the acute phase, the airway epithelium is extensively damaged and the submucosa infiltrated by mononuclear cells [27]. One study reported fewer T-lymphocytes in the airway mucosa in IIA than in allergen-induced asthma [28].

## Epidemiology: Frequency and determinants

### Frequency

OA has become one of the two most common occupational lung diseases in developed countries (the other is

mesothelioma) [29]. Estimates of incidence of OA have been made using registers based on mandated or voluntary physician reporting, medicolegal statistics, and various national or disability registers. There are considerable between-country differences in the estimated incidence of OA ranging from 22 per million per year in the United Kingdom to 187 per million per year in Finland. The differences are likely due in part to the methods used to derive these estimates. However, community-based studies on population-attributable risk (PAR) of occupational exposure for asthma carried out in countries involved in the European Community Respiratory Health Survey using similar methodology have shown considerable variation from 5% in Spain to 41% in New Zealand depending on the local industries, options for employment, and the population's susceptibility [30–32]. Studies in the United States of adult patients with new-onset asthma have shown that about 8% reported a history of exposure to sensitizers at work and 13% when irritants were included [33, 34]. The generally accepted PAR of occupational exposure for asthma is around 9–15% [35, 36].

Table 36.2 summarizes the findings from selected cross-sectional studies for various workplaces [37–46]. There is considerable variation in the prevalence of OA in different industries, ranging from 2% in latex-exposed workers to 50% among detergent-enzyme workers [37]. While the between-workforce differences can be due to varying data collection methodology, different definitions used for OA, and intensity of exposure, it is quite possible that the asthmogenic potential of the agents is different.

Few longitudinal studies have been carried out in high-risk apprenticeship programs including baking [47, 48] and students (bakers, animal health technicians and veterinarians, dental hygienists, welders, spray painters) exposed to various high [49, 50] and low [51, 52] molecular weight agents. This model is particularly interesting because it assesses young individuals who have not been previously exposed to the relevant

**TABLE 36.2** Prevalence and determinants of work-related asthma: results of selected studies.

| Exposure/Industry | No. | Latency (months) | Work-related asthma (%) | Smoking (%) | Atopy (%) |
|---|---|---|---|---|---|
| | | | **Prevalence** | | |
| *High molecular weight compounds* | | | | | |

For further information see Ref. [1].

workplace allergens and can best evaluate the natural history of sensitization, symptoms, and disease even after beginning of exposure and even after removal of exposure.

## Host determinants

Atopy (defined as positive skin test to one or more common allergens) has been shown to be associated with sensitization to some high molecular weight agents but not others (Table 36.2). The positive predictive value of atopy in various studies of OA is low: 34% in animal laboratory workers [53, 54] and 7% in psyllium workers [55]. Moreover, over 40% of young adults have positive skin-test reactions to common allergens. These findings do not justify routine screening for atopy in high-risk workplaces.

The relationship between smoking and OA is complex and findings of studies are often contradictory [56]. It appears that the effect of smoking is dependent on the type of occupational agent. An interaction between smoking and atopy has been found in OA in animal laboratory handlers [54] and in workers exposed to tetrachlorophthalic anhydride [54]; atopic smokers had the highest prevalence of sensitization and nonatopic nonsmokers, the lowest. Among platinum workers, smoking, not atopy, is the most important risk factor for sensitization [43]. Cigarette smoke probably acts as an adjuvant to promote IgE sensitization [57]. When agents cause OA by IgE-independent mechanisms, as in the cases of isocyanate-induced asthma and Western red cedar asthma, both atopy and smoking are unimportant [58].

Studies of genetics of OA has proven to be difficult because of the small numbers of patients with asthma due to one type of occupational agents and the difficulties of getting appropriate controls. Nevertheless, there have been some studies showing association between HLA class II genes and several types of OA such as isocyanate-[59], trimellitic anhydride-[60], Western red cedar-[61], and platinum-induced asthma [62]. However, such findings should be considered as preliminary [63] and this type of testing cannot be used for screening of susceptible subjects. Exposure to diisocyanates increases reactive oxygen species which are taken up by the glutathione S-transferase enzyme [64]. Individuals with the glutathione S-transferase M1 null gene had a two-fold increase risk of diisocyanate-induced asthma [65]. The combination of GSTM1 null and GTM3 AA phenotype was strongly associated with lack of diisocyanate-specific IgE antibodies and with late asthmatic reaction [65].

## Exposure factors

Improved industrial hygiene techniques have resulted in the ability to measure several low molecular weight compounds such as isocyanates, formaldehyde, and amines [66]. Immunochemical techniques for quantitating aeroallergens have been developed and used in a number of workforce-based studies [67, 68].

Several studies have shown that there is a dose-response relationship between the level of exposure to occupational agents and the prevalence of sensitization and/or nonallergic bronchial hyperresponsiveness and/or asthma. These include exposure to high molecular weight allergens such as α-amylase [69], animal laboratory allergen [70], and low molecular weight compounds such as Western red cedar [71], acid

anhydride [44], and colophony [72]. As a result, a "permissible exposure limit" has been proposed for a few occupational agents [67]. The minimum concentration of occupational allergen that causes sensitization may be one to two orders of magnitude greater than the concentration for eliciting symptoms. Once an individual is sensitized to an agent, a minute dose can trigger an attack of asthma. Concomitant environmental exposures, such as low levels of irritants and cigarette smoke, may enhance sensitization to some occupational agents. Further studies are required in this area.

## Diagnosis

All asthmatic subjects should be questioned regarding possible exposure to causal agents in their current or previous workplaces. It has been estimated that approximately 5% of all asthmatics seen in a specialized asthma clinic may suffer from OA. Also, it has to be remembered that because affected subjects could be left with permanent asthma after removal from the workplace, their current asthma symptoms could result from previous exposure to occupational causal agents. Physicians should be aware that certain workplaces have a high risk of exposing subjects to asthma-causing agents. Information on workplaces at risk and on all agents causing OA is available on the web site ASMANET.COM as prepared and reviewed by Henriette Dhivert-Donnadieu and on ASTHMA-WORKPLACE.COM. Safety data sheets (SDS) on all products used in the workplace can be obtained from employers and/or from safety agencies. However, these SDS do not necessarily report all products present in the workplace. Although flour and isocyanates are still the most frequent causes of OA, many other high and low molecular weight agents emerge every year on the list of agents that often cause OA.

Clinical questionnaires should be sensitive although, in general, they are not very specific tools [73, 74]. Exposure to a known causal agent at work and the presence of asthma should be sufficient to alert the physician to the possibility of OA even though the temporal relationship between exposure and symptoms may seem discordant. The possibility of the presence of nasal or conjunctival symptoms should be addressed. Ocular and nasal symptoms often accompany or even precede, in the case of high molecular weight agents, the occurrence of OA. Moreover, ocular and nasal symptoms are good predictors of OA in the case of high molecular weight agents [74].

Skin-prick tests can be done with extracts derived from specific high molecular weight agents although these extracts are not generally standardized. The presence of immediate skin sensitivity only indicates the presence of sensitization and does not confirm the diagnosis of OA. The target organ, in this case the bronchial, should be shown to be hyperresponsive. This can be done through the assessment of nonallergic airway responsiveness. The combination of positive skin-test reaction to a relevant occupational allergen and nonallergic airway hyperresponsiveness in a subject means that there is an ~80% likelihood that he/she has OA [55]. Nonallergic airway hyperresponsiveness can be shown either by assessing the response to bronchodilators if there is airway obstruction, or by estimating the degree of bronchoconstrictive response to a pharmacological agent. If the worker is still

employed, nonallergic airway responsiveness should be evaluated on a working day after a minimum period of 2 weeks at work. The absence of nonallergic airway hyperresponsiveness in a subject when still working and exposed to the agent(s) suspected of causing OA virtually excludes OA.

Serial measurement of peak expiratory flow rates (PEF) in the diagnosis and management of asthma [75, 76] has been used since the late 1970s in the investigation of OA [77]. Workers are asked to measure and register their PEF at least four times a day and to record their medication, symptoms, and whether they are at work or away from work. Although monitoring of PEF has been found to be a useful tool in the investigation of OA [77], there are several pitfalls including generally unsatisfactory compliance [78] and tracing, analysis and interpretation of results, for which computerized methods have been suggested. [79]. In our hands, while positive tracings are most likely associated with confirmed diagnosis, negative graphs cannot exclude OA [80]. Adding markers of airway inflammation (exhaled NO, induced sputum) for a period at work and off work improves the accuracy of diagnosis [81].

Exposing individuals to the potential causal agent(s) in a hospital laboratory, or at the workplace under careful supervision, is a good method to confirm OA. This method was first proposed in the 1970s by Professor Jack Pepys at the Brompton Hospital in London, UK [82]. However, such tests require the expertise of highly trained personnel and can only be done in specialized centers. They should be performed in a dose-response manner, exposing subjects to increasing concentrations but nonirritant levels of the agent with serial monitoring of $FEV_1$ following exposure for at least 8 h [83].

The investigation of OA is a stepwise procedure, as illustrated in Fig. 36.1.

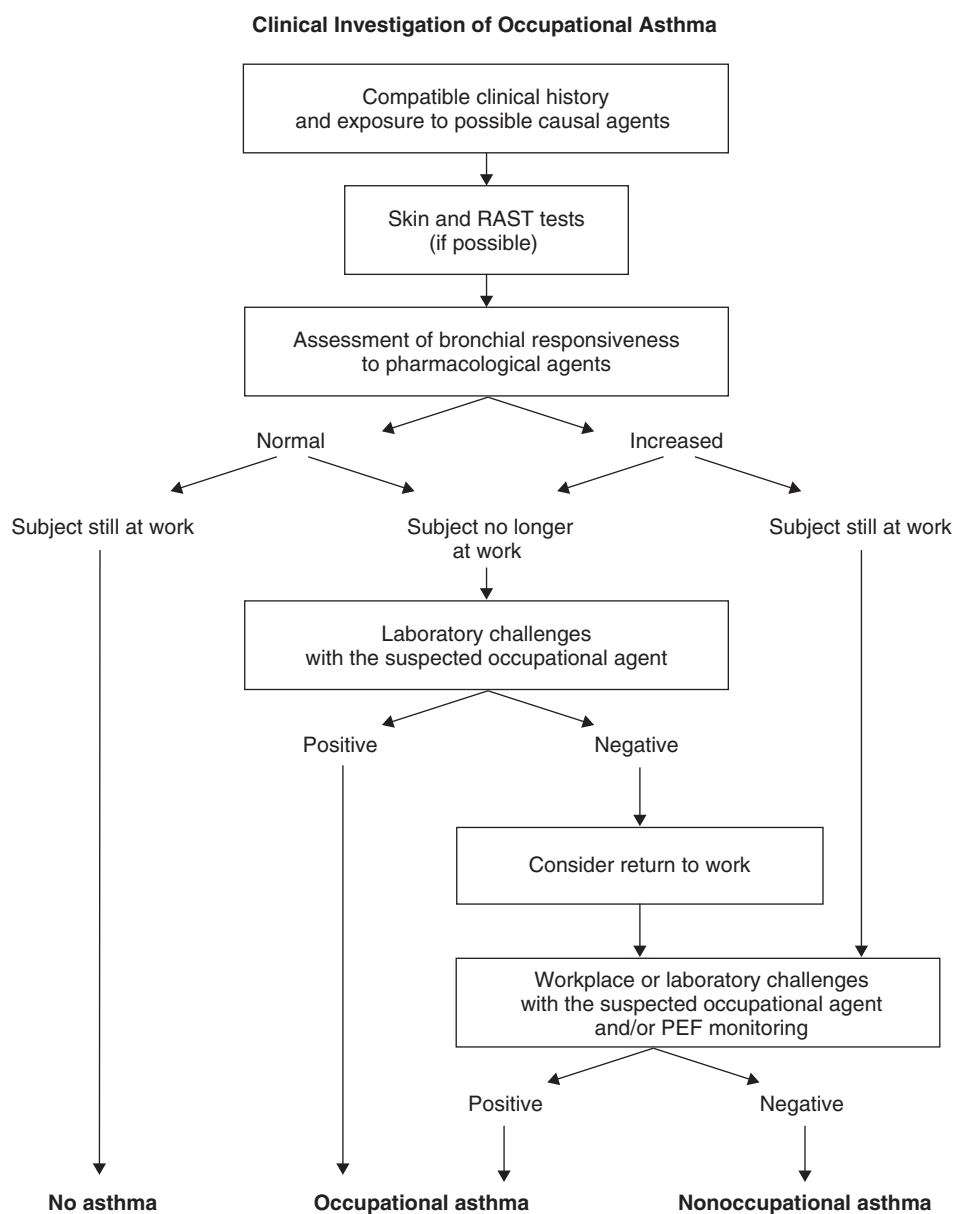
**Clinical Investigation of Occupational Asthma**


**FIG. 36.1** Flow chart for the investigation of OA.

## Management and compensation

Physicians may be asked to screen for OA in subjects exposed to known causal agents or in a workplace where cases of OA have been identified. These surveillance programs may include preemployment testing and periodic assessment. A cost-effectiveness examination of such programs needs to be done. Preemployment testing to document the baseline status may include a questionnaire, spirometry with assessment of nonallergic airway responsiveness, and skin testing to work-related allergens in the case of exposure to high molecular weight allergens. Workers with preexisting asthma should not be excluded as there is no reason to believe that asthmatic subjects are more likely to develop OA than anyone else. It is difficult to recommend the frequency for screening assessments. It has been estimated that 40% of subjects with OA due to low molecular weight agents develop their symptoms during the first year of exposure, while the corresponding figure for high molecular weight agents is 20% [84]. After that, there is a progressive reduction in the rate of development of OA.

Prevention is relevant in high-risk workplaces where inhalational accidents leading to IIA can occur. Assessment of airway responsiveness should also be considered as a preemployment test so that if an accident occurs comparisons are possible [85].

Once the diagnosis of OA is confirmed, subjects should be advised to avoid exposure to the causal agent. Whereas wearing cartridge masks does not apparently reduce symptomatology or functional abnormalities [86], helmet masks may eliminate exposure completely and may be considered in some instances. Treatment with inhaled steroids, while keeping the subject at work, improves the asthma but not to the extent of removal from exposure complemented by inhaled steroids [87], especially when steroids are given early after removal [88]. Subjects with OA whose symptoms persist after removal from exposure should be treated in the same way as patients with non-OA.

As for OA with a latency period, there might be functional recovery in the 2 years following the inhalation accident leading to IIA [89]. Steroids may be beneficial [90].

Patients with OA should be offered suitable help in finding another job where there is no further exposure to the causal agent, either with the same employer or another one. Subjects aged 55 or over should be offered early retirement, and young subjects should be retrained for a new job, all with financial compensation. Compensation boards or similar medicolegal agencies should offer these programs to workers and assess their cost-effectiveness. The time needed to make a diagnosis of OA and to implement a program is generally too long, causing hardship to the subjects [91, 92]. It has been estimated that during the 1990s, a single case of OA in Québec cost approximately C$50,000, a figure that is currently C$75,000 [91].

Because OA can lead to permanent impairment/disability, subjects should be reassessed periodically. The first assessment should take place 2 years after removal from exposure, when a plateau of improvement can occur, as in the case of a high molecular weight agent such as snow crab [93], although improvement can also occur at a later stage though at a slower pace [94]. The three main criteria for assessing impairment/disability for asthma are: (1) airway caliber; (2) airway responsiveness to a bronchodilator if airway obstruction is present or to a bronchoconstrictor if it is not the case; (3) the need for medication, which is a reflection of the clinical severity of asthma [95]. Adding evaluation of persistent airway inflammation may help in this assessment [96].

## Conclusion

Asthma is a common respiratory occupational ailment. Whereas improvement in diagnostic tools and pathophysiological mechanisms still need to be considered, emphasis should be put on prevention programs through identification and application of permissible respirable levels and of affected subjects at an early stage of sensitization or disease to prevent long-term sequelae of permanent asthma.

## COPD

In most patients, COPD is caused by chronic inhalation of polluted air, specifically, air contaminated by proinflammatory agents. The air can be polluted by personal choice (e.g. cigarette smoking), or by exposure sources in the ambient or work environment. Many patients may have been exposed to multiple sources, and the relative contributions of each may be impossible to disentangle. COPD is the symptomatic and functional consequence of chronic exposure to these polluted air sources. Therefore, it seems appropriate to pose a definition for occupational COPD that allows it to coexist with "smoking-induced COPD" or "urban air pollution-induced COPD." For the purpose of this section, we will define occupational COPD as "the existence of COPD in a patient with a history of chronic exposure to proinflammatory agents in workplace air." This definition is useful for clinical management and public health prevention as it points to the potential for eliminating or modifying occupational risk factors for the disease. Additional challenges with defining occupational COPD for legal or compensation purposes will be discussed below.

## Epidemiology: Frequency and determinants

The general population prevalence of occupational COPD is difficult to estimate due to the lack of occupational exposure information in most population-based studies. After reviewing all available published evidence from general population epidemiologic studies, an *ad hoc* committee of the American Thoracic Society recently estimated the contribution of occupational exposure to the overall population burden of COPD to be at least 15% [97]. A 2001 study of 517 lifetime nonsmokers referred to a hospital pulmonary function laboratory estimated the PAR among nonsmokers from occupational exposure to be 23.6% for bronchitis and 29.6% for obstructive lung disease [98].

Occupational COPD is associated with chronic exposure to mineral and/or metal particulate matter and fumes,

organic particulate matter, combustion products, irritant gases, and various combinations of these exposures. Evidence for this has emerged primarily from epidemiological studies, some of which are listed in Fig. 36.2.

## Mineral particulate

Prevalence rates for COPD with airflow obstruction among miners range from 6% to 20% among nonsmokers, and up to 60% among smokers [104–107]. Exposure-response relationships are also seen. Airflow obstruction was seen among 10.5% of nonsmoking British coal miners exposed to low dust levels and 20.6% of those exposed to medium and high dust levels [106]. Similarly, among nonsmoking US underground coal miners the corresponding rates were 7.4% in the lower dust exposure category and 14.3% in the higher dust exposure category [108, 109]. Chronic bronchitis symptoms related to mining exposures are persistent even after cessation of exposure, as was seen among former Swedish iron ore miners after an average of 16 years of not being exposed [110].

Mine dust with greater crystalline silica content appears to produce even higher COPD rates. Among South African gold miners the estimated effect of dust exposure on airflow obstruction was approximately ten times greater than that seen among coal miners [107, 111]. COPD mortality is significantly increased (in a dose-related fashion) among workers exposed to silica, especially in the presence of silicosis [112, 113]. COPD has also been clearly demonstrated in association with asbestos exposure [114–118]. From the evidence to date, airflow obstruction appears more pronounced among workers installing or handling asbestos products than among miners [116]; however, only a few studies have looked specifically for airflow obstruction in these populations. Among miners and millers of wollastonite (another fibrous dust) significant dose-response relationships for cumulative dust and airflow obstruction were seen in both nonsmokers and smokers [119]. COPD is also linked to particulate exposure (with and without crystalline silica) in other industries, such as quarrying, carbon black manufacturing [120–122], and cement manufacturing [123].

## Metal fumes, irritant gases, combustion products

Exposure to metal fumes, irritant gases, and combustion products appears to augment the effect of exposure to dust alone on COPD. This has been seen in mining and smelter workers [124, 125], workers in rubber manufacturing [126, 127], welders [128–132], tunnel workers [133], and fire fighters [134–137]. There is some evidence that the risk of airflow obstruction in welders and smelter workers may be higher among atopic workers, raising the possibility that at least some of the excess airflow obstruction seen in these groups may be related to asthma [130]. Indeed, as discussed above in the section on OA, several metal fumes and irritant gases are recognized risk factors for OA.

## Organic dusts

Although organic dust exposure is also associated with asthma and hypersensitivity pneumonitis, there is increasing evidence that chronic respiratory symptoms and nonasthmatic airflow obstruction are caused in part by exposure to both "allergenic" and "nonallergenic" organic dusts. For example, a recent study of nonasthmatic cedar sawmill workers found that the annual decline in FVC was significantly related to cumulative

**FIG. 36.2** Prevalence rates for airflow obstruction (defined as $FEV_1$/FVC % below the lower 95% confidence limit, based on age) among nonsmokers, aged 50 and over, exposed to mixed dusts and fumes and organic dusts, compared with a blue-collar control population [100] and to "expected rates" [101]; from studies conducted by the UBC Occupational Lung Diseases Research Unit [99, 102, 103].

dust exposure, even when the average dust exposure was well below the accepted limit [138]. Studies of sawmill and furniture workers exposed to wood dusts from species not currently known to cause asthma also show exposure-related airflow obstruction [139–144]. Generally, in these studies, the excess airflow obstruction linked to dust exposure is similar among nonsmokers and smokers.

There is also considerable evidence confirming a link between grain dust and COPD in both smokers and nonsmokers, with consistent dose-response relationships found [145–150]. Among retired grain workers, moderate to severe airflow obstruction was found in 40% of nonsmokers and 50% of smokers [151].

Mixed exposure to grains, other animal feeds, and animal by-products are found in animal confinement buildings, and there is growing evidence that exposure to these environments leads to COPD. There is clear evidence of excess chronic bronchitis among farmers and workers in poultry and swine confinement buildings, with prevalence rates remarkably consistent across studies at about 25–35% [99, 152–157]. Evidence for nonasthmatic chronic airflow obstruction in this industry is mixed [99, 157] although the majority of studies indicate reductions in airflow rates associated with duration of exposure [155, 158, 159]. COPD was found among 17% of 105 European farmers who had never smoked and who worked in animal confinement buildings, with 10% having moderate or severe disease by GOLD criteria. The highest disease prevalence was seen in farmers with the highest dust and endotoxin exposure levels [160].

## Relationship between cigarette smoking and occupational exposures

The research indicates that occupational exposure plays a clinically important role in the development of COPD in exposed workers. Among aluminum smelter workers, the impact of a 30-year working career with particulate exposure at the permitted level was about the same as smoking, 75 g/week [161]. Among tunnel workers exposed to dust and diesel exhaust, the decline in $FEV_1$ associated with each year of tunnel work was twice that associated with each pack year of cigarette smoking [133]. Among fire fighters, the cumulative impact of "being a fire fighter" on longitudinal decline in $FEV_1$ was about half as strong as the impact of cigarette smoking [162].

Cigarette smoking and dust exposure appear to exert their effect on airways in a roughly additive fashion regardless of the dust type [106, 111, 138] although there is a suggestion that the effect is more than additive in patients with marked airflow obstruction, and in the presence of high crystalline silica [163].

## Natural history

Most research suggests that the natural history of COPD is similar regardless of the source of the polluted air. However, there is growing evidence that there may be a link between early rapid decline in airflow rates due to occupational exposures and later airflow obstruction. This has been seen in

British [106], US [108], and Italian [164] coal miners, among workers exposed to asbestos [165, 166], and grain [151, 156].

## Assessment of exposure

The relevant exposure for COPD is that to which the patient was exposed in the past. Therefore, the best clinical tool for assessing this is a detailed occupational history, augmented by specific inquiry about exposures to dusts, gases, and fumes. In fact, research has shown that a positive response to the simple question "have you been exposed to dusts, gases, or fumes at work?" is linked to a more rapid decline in $FEV_1$ and increased prevalence of chronic bronchitis in population studies [167, 168]. Ideally, the occupational history should be reviewed by a professional with knowledge of the typical occupational exposures in the region. However, evidence has shown that the patient is also a reliable source of information about exposure duration and intensity. For each main job, the patient should be asked what year the job began and ended (to estimate duration of exposure); whether or not there was noticeable dust, fumes, or gas exposure; and if so, how often (to estimate intensity of exposure).

Although it is not possible to provide a clear answer to the question, "How much exposure is necessary before one should suspect an occupational contribution to COPD?" most research indicates that the relevant exposure duration is measured in years (or even decades), not months or days. Many patients will have held more than one job, and exposure duration should be summed over all jobs with relevant exposures. Time spent in irregular work environments should also be considered (e.g. in the armed forces, in prison, during extended periods of casual or temporary employment) as hazardous exposures are common in these situations. Dust and fume exposures are seldom present every day, all day, so patients should be asked whether exposure occurred most days, only a few times a month, or only seldom (i.e. a few days a year). Exposure that occurred at least a few times a month should be considered relevant.

Clinicians should be cautious about assuming that workplace exposures within "safe" limits were not high enough to produce disease. Many of the studies discussed above found significant airflow obstruction among workers exposed at or below regulated allowable limits. It is useful to consider the example of grain dust, which in many countries (including Canada and much of the United States) is still regulated with reference to the "nuisance dust" standard, despite overwhelming evidence that this standard is unacceptable. The American Conference of Governmental and Industrial Hygienists has adopted the term "particulate not otherwise classified" rather than nuisance dust, to indicate "that all materials are potentially toxic and to avoid the implication that these materials are harmless" and to emphasize that "although these materials may not cause fibrosis and systemic effects, they are not biologically inert" [169].

## Occupational COPD among women

There is growing evidence that COPD mortality and morbidity is rising among women relative to men and it has

been hypothesized that this may be linked to an increase in tobacco exposure or susceptibility among women [170, 171]. However, other evidence indicates that smoking rates among adult women have declined in parallel with men since the 1980s, at least in Western countries [172], suggesting that other factors must also be contributing to the apparent COPD increase among women. Environmental (or domestic occupational) exposure to biomass particulate matter (from indoor cooking) has been strongly linked to COPD among women in developing countries. The potential impact on COPD of women's work and changing occupational environments has only been explored in a few very recent studies, but there is some evidence of possible differential susceptibility to biological dusts among women. In a 20-year follow-up study of Chinese cotton textile workers, nonsmoking men demonstrated a small improvement in airflow rates after cessation of exposure (reduced decline in $FEV_1$), whereas no such improvement was seen among women, despite higher dust and endotoxin exposures among men [173]. Among a random sample of Australians, employment in a job with exposure to biological dust was a strong and a significant risk factor for COPD among women (sevenfold increase in risk); this effect was not seen in men (no increased risk) [174]. Jobs with biological dust exposure held by women in this study included health care professions, food and textile workers, artists, and cleaners. An analysis of data from the US National Health and Nutrition Examination Survey [175] indicated an increased risk for COPD, using GOLD criteria (compared to the population as a whole) among women in personal services, agriculture, textiles, rubber and plastics industries, and sales-related jobs. These very preliminary findings require further investigation to understand and quantify the potential role of occupational exposures in contributing to the growing prevalence of COPD among women. They do point, however, to the importance of considering occupational risks even among female patients with jobs not traditionally considered "dusty" or "industrial."

## Management and compensation

When the clinician sees a patient (male or female) with chronic nonspecific airflow limitation (regardless of whether or not that patient is a smoker), it is useful to consider the possibility that occupational exposures may have contributed to the disease. This is important as continued occupational exposure may contribute to a worsening of the disease (in the patient, or in others in that workplace), if no preventive action is taken. For the patient still exposed to particulate or irritant gases or fumes, a recommendation should be made to reduce or eliminate the potential for the exposure. For the patient no longer exposed (or no longer working), it is important to record and report the disease as "potentially occupational" in order that public health officials can assess the role of the occupational exposure and use this information to direct prevention activities in the workplace.

Whether or not a patient with occupational COPD is entitled to compensation or disability, benefits will depend on the specific requirements of the compensation or insurance carrier. These requirements vary broadly. Disability

evaluation should be carried out without reference to the question of etiology, as the level of disability or impairment is unaffected by the cause. The decision to attach the label "possibly occupational" to the diagnosis should also be based on the occupational history. Although requirements vary among jurisdictions, it should be the attending physician's role to raise the possibility of occupational etiology, not to make the final determination in law. General guidance can be found in the following statement from the BC Workers' Compensation Board policy manual: "Since workers' compensation … operates on an enquiry basis rather than on an adversarial basis, there is no onus on the worker to prove his or her case. All that is needed is for the worker to describe his or her experience of the disease and the reasons why they suspect the disease has an occupational basis. Then it is the responsibility of the Board to research the available scientific literature and carry out any other investigations into the origin of the worker's condition which may be necessary."

That said, unfortunately, physicians do find themselves called upon by legal tribunals, to quantify the relative contribution of occupational exposure to COPD. This can be extremely difficult, if not impossible, in the absence of detailed exposure information and the expertise to interpret it. A useful benchmark may be the research among smelter workers, discussed earlier in this section, that found the effect of working for 30 years at today's "accepted" exposure concentration had an impact on airflow of about the same magnitude as a similar duration of cigarette smoking.

## Prevention

Some evidence suggests that a rapid decline in $FEV_1$ (but still in the "normal" range) in young exposed workers may be associated with a worse prognosis. Therefore, although these workers are unlikely to seek treatment, if such a patient is encountered (e.g. as a result of routine screening or for other reasons) the index of concern should rise. The evidence is not strong enough to suggest that such a worker should be removed from exposure, but the patient should be made aware of his or her excess decline in lung function and the potential role of occupational exposure should be explored.

Global prevention of occupational COPD will require increased recognition of the disease (by physicians, by regulators, and by employers), and a willingness by regulators and employers to act to reduce exposure to particulates and irritant gases and fumes in the work environment. Primary care and pulmonary physicians can play a major role in prevention by increasing the recognition of the disease, by reporting it, even if just as "suspect" or "possible" occupational COPD, to the local agency responsible for occupational disease prevention.

# Infections

**Simon D. Message and Sebastian L. Johnston**

Department of Respiratory Medicine, National Heart and Lung Institute, Imperial College London, London, UK

## INTRODUCTION

Asthma and chronic obstructive pulmonary disease (COPD) are common diseases and both result in significant morbidity and mortality. Although they share some clinical features and although they may coexist in the same individual, they are distinct disease syndromes with different pathogenetic mechanisms. In each case much of the morbidity and mortality is associated with exacerbations of disease, in response to a variety of trigger factors. A common feature of asthma and COPD is the important role of infection in triggering exacerbations. Infections have also been implicated in the etiology of the two diseases. This chapter will review the epidemiological evidence implicating infectious pathogens as triggers and will discuss the mechanisms of interaction between the host–pathogen response and preexisting airway pathology that result in an exacerbation.

## ASTHMA

Asthma affects 20–33% of children in the United Kingdom [1]. It is a multifaceted syndrome involving atopy, bronchial hyperreactivity, and IgE and non-IgE-mediated acute and chronic immune responses. The asthmatic airway is characterized by an infiltrate of eosinophils and of T-lymphocytes expressing the type 2 cytokines IL-4, IL-5, and IL-13. Trigger factors associated with acute exacerbations of asthma include exposure to environmental allergens, especially animals, molds, pollens and mites, cold, exercise, and drugs. The link between

respiratory infection and asthma exacerbations is well established although incompletely understood. In the 1950s this association was attributed to bacterial allergy [2] but it is now clear that the majority of exacerbations are due to viral rather than bacterial infection.

## Epidemiology

Viral respiratory tract infections are a major cause of wheezing in infants and in adult patients with asthma. Their role may have been underestimated in early epidemiological studies because of difficulties in isolation and identification [3]. The introduction of PCR to such studies has implicated viral infection in the majority of asthma exacerbations.

Indirect evidence from population studies has established a significant correlation between the seasonal variation in wheezing episodes in young children and peaks of virus identification [4]. Seasonal patterns of identification of respiratory viruses are associated with peaks in hospital admissions for both children and adults with asthma indicating a role for such infections in severe asthma attacks [5]. Direct evidence implicating viral infection in asthma exacerbations has been provided by studies showing an increased rate of virus detection in individuals suffering asthma attacks. Viruses have been detected in 80–85% of asthma exacerbations in children [4–10] and in 75–80% in adults [11–14]. The highest rates of identification are in those studies where subjects were followed prospectively allowing collection of clinical specimens early in the course of the illness, where PCR-based methods of diagnosis were used instead of or in addition to serology and culture, and where the methodology used

allowed for detection of rhinoviruses. The rate of detection of viruses between exacerbations when individuals are asymptomatic is only of the order of 3–12%. In contrast a study of transtracheal aspirates in adult asthmatics during exacerbations [15] yielded sparse bacterial cultures with no correlation to clinical illness and no difference from those of normal subjects.

In almost all studies of asthmatics, the predominant viruses are rhinoviruses (RV), influenza, RSV, and parainfluenza viruses. RV alone are detected in around 50% of virus-induced asthma attacks. Adenoviruses, enteroviruses, metapneumoviruses, bocaviruses, and coronaviruses are also detected but less frequently. Influenza is only found during annual epidemics.

## Experimental virus infection

The effects of respiratory virus infection in the nasal mucosa and upper respiratory tract have been extensively investigated. The effects of such viruses in the lower respiratory tract have been studied but detailed knowledge of the pathogenetic mechanisms involved in asthma exacerbations remains limited. Experimental respiratory virus infection in human volunteers is limited to mild disease by concerns of safety [16]. Most such studies have therefore focused on the experimental innoculation of rhinovirus in allergic rhinitic or mild asthmatic individuals and normal control subjects [17–28]. Such studies provide a useful model of natural virus infection in asthma and offer the advantages of patient selection and monitoring, under controlled conditions before, during, and after infection, of administration of active and placebo medication, of ability to sample the lower airway with timing from onset of infection accurately defined and the study of RV-induced effects including asthma symptomatology, lung function, and airway pathology/immunology.

Recent epidemiological evidence confirms a synergistic interaction between virus infection and allergen exposure in precipitating hospital admissions for asthma [29, 30]. Other trigger factors that may interact with infection include air pollution. A study of asthmatic children demonstrated an increased risk of developing an asthmatic episode within 7 days of an upper respiratory tract infection if the nitrogen dioxide level was greater than $28\,\mu g/m^3$ [9, 31].

Most studies of experimental virus infection in allergic subjects are performed outside the relevant season for allergen exposure. One attempt to provide a model combining allergen exposure and virus infection utilized RV infection in subjects with allergic rhinitis. Individuals received three high dose allergen challenges in the week prior to innoculation to try to mimic combined allergen exposure and virus infection [32]. Interestingly, prior allergen challenge in this model, somewhat unexpectedly, appeared to protect against an RV cold with delayed nasal leukocytosis, increased generation of the proinflammatory cytokines IL-6 and IL-8 and a delayed, less severe clinical course. There was an inverse correlation between nasal lavage eosinophilia and the severity of cold symptoms. The explanation proposed by the authors of this study is that limited high dose allergen challenge may not reproduce the effects of chronic low dose

allergen exposure and may stimulate the production of anti-inflammatory mediators such as IL-10 or antiviral cytokines such as IFN-γ or TNF-α. In work by de Kluijver *et al.* the effects of a 10-day period of low dose allergen exposure in house-dust mite sensitive and/or experimental RV16 infection were studied. No synergistic or additive effects were observed as regards lung function parameters [33]. Further development of models of experimental combined allergen exposure and virus infection is clearly required.

We have recently adopted the approach of infecting asthmatic volunteers with RV and then sending them home to continue their normal allergen exposure in the natural environment [34]. We investigated physiologic, virologic, and immunopathologic responses to experimental rhinovirus infection in blood, induced sputum, and bronchial lavage in 10 atopic mild asthmatic and 15 nonatopic normal volunteers. Rhinovirus infection induced significantly greater lower respiratory symptoms, lung function impairment, increases in bronchial hyperreactivity, and eosinophilic lower airway inflammation in asthmatic compared to normal subjects. We also saw trends to increased neutrophils and lymphocytes in the lower airway in asthmatics, and coincident reductions in blood lymphocytes, suggesting trafficking to the airway. In asthmatic, but not normal subjects, virus load was significantly related to lower respiratory symptoms, bronchial hyperreactivity, and reductions in blood total and $CD8^+$ lymphocytes and lung function impairment was significantly related to neutrophilic and eosinophilic lower airway inflammation. This study demonstrated increased rhinovirus-induced clinical illness severity in asthmatic compared to normal subjects, provided evidence of strong relationships between virus load, lower airway virus-induced inflammation, and asthma exacerbation severity and suggests that this approach could provide a very good model in which to examine asthma exacerbation pathogenesis as well as treatment interventions.

## Rhinovirus infection of the lower airway

Whereas other respiratory viruses such as influenza, parainfluenza, RSV, and adenovirus are well recognized causes of lower airway syndromes such as pneumonia and bronchiolitis and are capable of replication in the lower airway, until recently there was uncertainty as to whether RV infection occurred in the lower airway or solely in the upper respiratory tract. Although the possibility of nasopharyngeal contamination cannot be ruled out, RV has been detected in lower airway clinical specimens such as sputum [35], tracheal brushings [26], and BAL [36] by both RT-PCR and culture. RV has been cultured in cell lines of bronchial epithelial cell origin [37] and replication has been demonstrated in primary cultures of bronchial epithelial cells [38–40]. The preference of RV for culture at 33°C rather than 37°C has been used as an argument against lower airway infection but there is now evidence that replication does occur at lower airway temperatures [41]. Finally the use of *in situ* hybridization has conclusively demonstrated RV replication in bronchial biopsies of subjects following experimental infection [38] and recent immunochemistry data suggests a preference for basal cells [42]. These data

confirm that RV infection of the lower airway does occur and directly implicate lower airway infection in the pathogenesis of asthma exacerbations.

## A mouse model of rhinovirus-induced asthma exacerbation

Investigation into the pathogenesis of rhinovirus infections and rhinovirus-induced asthma exacerbations has been severely hampered for the ~50 years since their discovery, as it has been believed that rhinoviruses only infect humans and chimpanzees. However, a mouse model of rhinovirus infection has recently been successfully developed for the first time. New methods of purification and concentration of rhinoviruses, were used to show that for the minor group of rhinoviruses (the ~10% that use the LDL receptor as their mode of entry into cells), wild-type BALB/c mice can be successfully infected and that most of the disease-related outcomes observed in humans were reproduced in this unique new model. These outcomes include induction of both innate and acquired immune responses, induction of mucin synthesis and secretion, induction of both acute neutrophilic and prolonged lymphocytic airway inflammation, and induction of chemokines responsible for chemoattraction of neutrophils, lymphocytes and dendritic cells as well as a range of proinflammatory cytokines. Mice transgenic for a chimera of ICAM-1, the receptor for the major group (~90%) of rhinoviruses, in which the rhinovirus-binding domains were human, but the remainder of the molecule mouse were then developed. This transgenic mouse was then able to be infected by major group strains, thus generating mouse models capable of being infected by all rhinovirus serotypes. Finally an established mouse model of allergic airway inflammation was used to demonstrate that rhinovirus infection of this model resulted in rhinovirus-induced exacerbation of allergic airway inflammation. The asthma-related outcomes exacerbated by infection in this model include exacerbation of airway hyperresponsiveness, exacerbation of mucin synthesis and secretion (MUC5AC and MUC5B), exacerbation of neutrophilic, eosinophilic, and lymphocytic airway inflammation, and augmented induction of both Th1 (IFN-$\gamma$) and Th2 (IL-4 and -13) cytokines. The development of this novel mouse model of rhinovirus-induced asthma exacerbations, should allow mechanisms of disease to be investigated *in vivo* and true causation be established *in vivo*. [43].

## Physiological effects of experimental rhinovirus infection

Subjects with asthma and/or allergic rhinitis exhibit increased pathophysiological effects as a result of RV infection as compared to nonatopic, nonasthmatic controls. With detailed monitoring, it is possible to detect reductions in both peak flow [44] and home recordings of $FEV_1$ [24] in atopic asthmatic patients in the acute phase of experimental RV16 infection. There is an enhanced sensitivity to histamine and allergen challenge after RV16 innoculation in nonasthmatic atopic rhinitic subjects [19, 45]. RV16

increases asthma symptoms, coinciding with an increase in the maximal bronchoconstrictive response to methacholine up to 15 days after infection [20]. There is also a significant increase in sensitivity to histamine in asthmatic subjects after RV16 infection, most pronounced in those with severe cold symptoms [25] and our recent study confirmed that these reductions in lung function and increases in symptoms and airway hyperresponsiveness were observed only in asthmatic, but not in normal subjects [34].

## Components of the antiviral immune response

Current concepts of a typical antiviral immune response, as reviewed in detail elsewhere [46, 47], result from research in human volunteers and patients but also in experimental animals, especially inbred mice. Results of animal studies may not be directly applicable to the outbreed human population but ethical considerations often limit direct investigation of the human immune system. All immune responses are a combination of nonspecific (innate) and specific (adaptive) immunity.

Nonspecific or innate [48] elements include: phagocytes such as neutrophils and macrophages that engulf and destroy viruses; natural killer (NK) cells that recognize and destroy virus-infected cells on the basis of reduced HLA class I expression; cells including NK cells, neutrophils, macrophages, mast cells, basophils, epithelial cells that release cytokines, such as interferons, with immunoregulatory or antiviral actions; components of body fluids such as complement, defensins, and surfactant proteins that are capable of neutralizing viruses independently of, or in combination with, antibodies.

### Complement

Some viruses may also cause complement-mediated damage. Complement components bind to epithelial cells both *in vitro* and *in vivo* during RSV infections. C3a and C5a are increased in human volunteers infected with influenza A virus [49]. There is little information on the role of complement in immunity to RV. Recent data suggests that the RV 3C protease cleaves the complement factors C3 and C5 which may interfere with the destruction of virus-infected cells [50]. For other viruses, for example influenza, the complement system forms an important link between the innate and specific immune systems. Mice deficient for the third component of complement are highly susceptible to primary influenza, showing reduced priming of T-helper cells and cytotoxic T-cells in lung draining lymph nodes and severely impaired recruitment into the lung of virus-specific $CD4^+$ and $CD8^+$ effector T-cells producing IFN-$\gamma$ [51]. Activation of the complement cascade may be necessary for the function of other innate antiviral proteins such as serum mannose-binding protein [52]

### Defensins

The $\alpha$ and $\beta$ defensins are small cationic antimicrobial peptides which have the capacity to kill bacteria, fungi, and enveloped viruses by disruption of the microbial membrane.

*In vivo* they are probably most important in phagocytic vacuoles and on the surface of skin and mucosal epithelia. In addition to their direct antibiotic role, defensins are increasingly being found to have immunomodulatory actions [53] and to play a role in cell recruitment through activation of certain chemokine receptors, for example hBD3 and CCR6 on dendritic cell (DC).

Specific immunity involves production of antibody by B-lymphocytes and the activities of cytotoxic T-cells following processing and presentation of viral antigens by additional cells of the immune system, the most important of which are probably dendritic cells. Immunological memory modifies the overall response to reinfection by previously encountered virus and alters the timing and magnitude of contributions due to different components.

## Time course of innate and adaptive immunity in primary and secondary infections

In primary infection, viruses replicate in the respiratory tract reaching peak levels at around days 2–4. At this time type I interferons are first detected, peaking around days 2–3 and falling to become undetectable once active replication has ceased. Interferons activate NK cells, first detectable around day 3 and peaking around day 4. In addition to destruction of virally infected cells NK cells release cytokines including IFN-$\gamma$ that activate additional inflammatory cells in the airway including macrophages. Such nonspecific immune mechanisms are essential in early defense against virus in the first few days. In addition, the innate immune system plays a role in stimulating specific immunity and may influence the nature of the specific response, for example whether this is characterized by type 1 or type 2 cytokines.

Meanwhile, viral antigens are processed locally and in regional lymph nodes by dendritic cells and presented to T-cells. CD4$^+$ and CD8$^+$ T-cells are detectable from around day 4 then generally decline as infection resolves to become undetectable by day 14. However, memory CD4$^+$ and CD8$^+$ responses may persist for life. T-cell recruitment is dependent on the production of chemokines and on alterations in the expression of adhesion molecules on the endothelium of inflamed tissues. Time is also required to generate B-cell responses. Mucosal IgA may be detected around day 3, serum IgM from days 5–6 and IgG days 7–8, increasing in amount and avidity over the next 2–3 weeks. IgA falls normally to low or undetectable levels over 3–6 months. Serum IgG may remain detectable for life. Specific immune mechanisms such as CD8$^+$ T-cells and immunoglobulin are responsible for the eradication of infectious virus usually by 7–10 days after infection.

Secondary infection with the same virus results in rapid mobilization of B- and T-cell specific immunity with an earlier T-cell peak coinciding with the NK cell peak around days 3–4. If reinfection is with the same serotype a rapid increase in levels of preexisting neutralizing antibodies may limit viral replication to such an extent that infection is clinically silent. Because this results in fewer infected cells

there is relatively less activation of nonspecific immunity and it may be difficult to detect a CD8$^+$ T-cell response.

Following experimental infection of seronegative subjects with RV2 [54] serum-specific antibodies are detectable at 1–2 weeks, reach a maximum at 5 weeks, persist for at least a year and may remain elevated many years after infection. Local specific antibody levels may be lost more rapidly. High levels of serum neutralizing antibody or specific IgA protect against reinfection with the same rhinovirus serotype. However, since it appears relatively late, recovery from illness for seronegative hosts which usually occurs at 7–10 days must be due to other components of the immune response. In seropositive subjects preexisting serum neutralizing antibodies to RV39 and to RV-Hanks modify experimental infections in human subjects [55, 56]. Local IgA and IgG passing from the vasculature into the pulmonary interstitium contribute to viral clearance. However, the 100+ RV serotypes mean that repeated infection with RV to which an individual lacks appropriate antibodies is common.

T-cell responses to RV demonstrate MHC class I restricted cross-reactivity between serotypes due to specificity for conserved epitopes within the capsid proteins VP 1–3 [57]. RV16- and RV49-specific T-cell clones from human peripheral blood demonstrate recognition of both serotype specific and shared viral epitopes [58]. Vigorous proliferation of and IFN-$\gamma$ production by PBMC in response to RV16 in seronegative subjects is associated with reduced viral shedding after inoculation [59], thus T-cells responses also appear protective.

## Interactions between virus infection and asthmatic airway inflammation

The interaction of respiratory virus infection and chronic asthmatic airway inflammation results in respiratory symptoms that are more severe than those suffered by nonasthmatic individuals [34, 60] and case-control studies have demonstrated clear synergistic interactions between virus infection and allergen exposure in increasing risk of exacerbation [29, 30]. The detailed immunological mechanisms underlying this interaction are currently being investigated, but recent data suggest deficient production of type I ($\beta$), type II ($\gamma$), and type III ($\lambda$) IFNs, as well as Th1 cytokines (IL-12) and anti-inflammatory cytokines (IL-10), are likely to increase virus-induced lower airway inflammation [34, 61, 62]. These deficiencies are also accompanied by augmented production of Th2 cytokines suggesting that perhaps allergen-induced inflammation is also increased in the pathogenesis of virus-induced asthma exacerbations.

Bronchial inflammation is likely therefore a central event for virus-induced asthma exacerbations. The processes involved include interacting cascades from the complement, coagulation, fibrinolytic, and kinin systems of the plasma as well as cell-derived cytokines, chemokines, and arachidonic acid metabolites. Our understanding of the interaction of viruses with these cascades in asthma is incomplete and it is likely that different viruses interact with each system to different extents. However, it is reasonable to believe that in all cases the initial trigger of the inflammatory reactions is epithelial cell–virus interaction.

**TABLE 37.1** Current hypotheses for the pathogenesis of virus-induced asthma exacerbations.

| | |
|---|---|
| Epithelial disruption | Reduced ciliary clearance |
| | Increased permeability |
| | Loss of protective functions |
| |    Kinins |
| Mediator production | Complement |
| | Arachidonic acid metabolites |
| | Nitric oxide |
| | Reactive oxygen products |
| | Cytokines |
| Induction of inflammation | Chemokines |
| | Immune cell activation |
| | Adhesion molecule induction |
| | Impaired innate IFN production |
| Immune dysregulation | Impaired apoptosis |
| | Impaired Th1 immunity |
| | Impaired IL-10 production |
| | Augmented Th2 immunity |
| | Increased total IgE |
| IgE dysregulation | Antiviral IgE production |
| | Airway smooth muscle |
| Airway remodeling | Fibroblasts |
| | Myofibroblasts |
| | Growth factors |
| | Increased cholinergic sensitivity |
| Alterations of neural responses | Neuropeptide metabolism |
| |    modulation |
| | β-adrenergic receptor dysfunction |

Table 37.1 summarizes some of the current hypotheses proposed to explain the mechanisms of exacerbation of asthma following respiratory virus infection. The evidence supporting these hypotheses is reviewed in detail below.

## The role of the airway epithelial cell

The airway epithelium is an important component of antiviral defense. In addition to its function as a physical barrier to the entry of viruses, the responses of epithelial cells (EC) following viral infection, whether or not this results in destruction of the cell, contribute to both innate and adaptive antiviral immune responses. Information regarding the effects of RV on EC comes from *in vivo* studies and from *in vitro* models using either cultured primary airway EC or cell lines of epithelial cell origin such as A549, BEAS-2B, and H292.

EC contribute to the immune response following virus infection through the production of cytokines and chemokines (Fig. 37.1). They may also act as antigen presenting cells particularly during secondary respiratory viral infections. Epithelial cells express MHC class I and the costimulatory molecules B7-1 and B7-2 and this expression is upregulated *in vitro* by RV16 [63] (Fig. 37.2).

The extent of epithelial cell destruction observed in the airway varies according to virus type. Influenza typically causes extensive necrosis [64], whereas RV causes little or only patchy damage. Destruction of epithelial cells results in both an increase in epithelial permeability, and increased penetration of irritants and allergens, and exposure of the extensive network of afferent nerve fibers. Both effects may contribute to increased bronchial hyperresponsiveness.

**FIG. 37.1** Airway epithelial cells participate in the immune response to respiratory virus, producing a variety of cytokines and chemokines with actions on other cells. In addition the migration of inflammatory cells is aided by the upregulation of adhesion molecules and interferons help to establish an antiviral state in neighboring epithelial cells. Upregulation of MHC class I may facilitate presentation of viral antigens.
**FIG. 37.2** Preexisting asthmatic airway inflammation may modify a predominantly Th1 antiviral immune response, favoring a Th2 or mixed response which may provide less efficient viral clearance and result in prolonged virus-induced inflammation, increased associated immunopathology and increased tissue damage.

*In vivo* RV causes some shedding of infected ciliated EC [65], but the extent of viral infection of the epithelium may be incomplete even in the nose [66]. *In vitro* studies exposing monolayer cultures of nasal epithelial cells to respiratory viruses at $10^3$–$10^4$ TCID$_{50}$/ml demonstrate no detectable CPE (carboxypeptidase E) with RV or coronavirus in contrast to the extensive destruction with influenza and adenovirus [67]. *Ex vivo* infection of cells from both the upper and the lower respiratory tract suggest that less than 10% of cells in the epithelium are infected by RV [68], however the extent of virus-induced epithelial damage may be considerably greater in asthmatic than in normal subjects, as asthmatic epithelium has been shown to be much more susceptible *in vitro* [61]. *In vivo* studies of degrees of epithelial damage would be technically challenging, but could generate interesting findings.

## Receptors for entry of RV into host cells

Viruses enter into and replicate within airway EC. Entry is dependent on the interaction with host cell surface proteins which function as receptors. In the case of the major group RV this is ICAM-1 [69] and infection can be blocked by antibodies to ICAM-1 or with soluble ICAM-1 [37]. There is relatively limited expression of ICAM-1 in airway epithelium prior to RV infection [70] and this may explain the

patchy nature of infection. The upregulation of ICAM-1 in the asthmatic airway is one possible explanation for the increased severity of RV infection in asthma. RV upregulates expression of its own receptor ICAM-1 both *in vitro* and *in vivo*. Following experimental infection with RV, ICAM-1 expression is upregulated in nasal epithelium within 24h, declining by day 5 [71]. RV has similar effects on EC from the lower airway. RV has been shown to upregulate ICAM-1 in primary bronchial EC *in vitro* [72] and ICAM-1 is upregulated in bronchial biopsies following experimental infection of asthmatic subjects with RV16 [73].

There are two forms of ICAM-1: membrane bound (mICAM-1) which favors viral infection by acting as a virus receptor and soluble (sICAM-1) which binds virus outside the cell and can thereby inhibit virus infection. RV infection of EC is reported to alter the balance in favor of further infection by inducing mRNA for mICAM-1 whilst suppressing that of sICAM-1 [74]. The LDL receptor is the receptor for the minor group RV. RV2 infection of primary human tracheal EC (PHTEC) is blocked by an antibody to the LDL receptor and is also reported to upregulate LDL-R expression [48].

ICAM-1 expression by human nasal EC is upregulated *in vitro* by exposure to a number of inflammatory cytokines and mediators including IL-1β, IL-8, IFN-γ, TNF-λ, and the eosinophil-derived proteins MBP and ECP [75]. IL-1β in particular may be important in RV-induced induction of

ICAM-1. Antibodies to IL-1β but not TNF-α decreased viral replication and ICAM-1 expression by PHTEC [76]. Not all respiratory epithelial cell lines behave in the same way as primary EC – for example A549 cells express ICAM-1 at lower levels constitutively and show upregulation by IFN-γ and TNF-α but not by ECP or MBP. The effect of IFN-γ is complex. Whilst IFN-γ upregulates ICAM-1 in uninfected cells this cytokine inhibits ICAM-1 upregulation by RV14 in H292 cells and its presence results in reduced viral titers [72, 77].

A preexisting elevation of ICAM-1 expression in the asthmatic airway may contribute to increased symptom severity of RV infection. Type 2 cytokines (IL-4, IL-5, IL-13) upregulate ICAM-1 in H-292 cells [78]. Allergen challenge results in upregulation of ICAM-1 on conjunctival and nasal EC in atopics [79]. In nasal brushing EC from atopics, basal ICAM-1 levels were increased relative to nonatopics and elevated in the relevant allergen season. Nasal EC from atopics showed further upregulation after *in vitro* culture with allergen. The highest basal ICAM-1 was found on nasal polyp EC and this was increased further after RV14 infection. Viral titers after RV14 infection were significantly higher for polyp EC than for nonatopic and atopic nonpolyp EC [80].

Modification of EC ICAM-1 expression is therefore of possible therapeutic benefit. *In vitro* RV increases expression of ICAM-1 and VCAM-1 in primary bronchial EC (PBEC) cultures and in A549 cells via a mechanism involving NF-κB [5, 81, 82]. One of the actions of corticosteroids is inhibition of NF-κB [83]. In both A549 cells and in PBEC pretreatment with three corticosteroids, hydrocortisone, dexamethasone, and mometasone furoate inhibits RV16-induced increases in ICAM-1 surface expression, mRNA, and promoter activation without alteration of virus infectivity or replication. Dexamethasone suppresses ICAM-1 in PHTEC and inhibits RV infections [84]. Dexamethasone does not inhibit infection of PHTEC by minor group RV2 [85]. Disappointingly, a study of inhaled corticosteroids in asthmatics prior to experimental RV infection failed to show reduced virus-induced ICAM-1 expression in bronchial biopsies [73] but it is possible that a longer course and/or a higher dose of inhaled steroid or administration of oral steroids might have demonstrated a significant effect.

Other drugs which affect EC ICAM-1 include reducing agents [86], the H₁ receptor antagonists desloratidine/loratidine which inhibit RV-induced ICAM-1 upregulation in HPBEC and in A549 cells [87] and erythromycin which inhibits infection of PHTEC by both major group RV14 and minor group RV2 through effects including ICAM-1 reduction, blockage of RV RNA entry into endosomes and small reductions in LDL receptor expression [88].

## RV induction of EC production of cytokines and chemokines

EC can activate and recruit a variety of other cell types such as lymphocytes, eosinophils, and neutrophils through the production of chemokines and cytokines (Fig. 37.1). Such cells are important components of the antiviral response but may also contribute to airway inflammation and dysfunction in asthma.

## Type 1 interferons

Interferons (IFN) play an important role in innate resistance to viruses [89], acting on virus-infected cells and surrounding cells to produce an antiviral state characterized by the expression and antiviral activity of IFN-stimulated genes (ISGs). There are three main types of IFN, type 1 (IFN-α, IFN-β, IFN-ω, IFN-τ), type 2 (IFN-γ) and the recently discovered type 3 (IFN-λs [90, 91]). EC can produce both type 1 and type 3 IFNs. There are 14 IFN-α genes but only 1 IFN-β gene. IFN-β synthesis involves NF-κB, ATF/JUN and the interferon regulatory factors (IRFs) (up to 10 of which are currently identified), activation of which occurs in response to virus-specific signals including dsRNA, a product of the replication of ssRNA viruses such as RV, RSV, and influenza.

IFN-β and IFN-α4 are expressed early through the action of IRF3. Activation of the IFN intracellular signaling pathway is required for induction of IRF7 which is required for transcription of the full range of IFNs. DNA microarray analysis has shown that following binding to their receptors on target cells IFNs trigger a complex signaling pathway (mainly JAK-STAT) resulting in the transcription of hundreds of ISGs [92].

Several ISGs have been well studied. These include the dsRNA-activated serine/threonine protein kinase (PKR) which reduces cellular mRNA translation and transcriptional events, two enzymes involved in mRNA degradation, 2′5′oligoadenylate synthetase (OAS) and RNase L, the myxovirus resistance (Mx) proteins and RNA-specific adenosine deaminase (ADAR) which is involved in RNA editing. These ISGs inhibit virus replication at a number of levels and not surprisingly, viruses have evolved mechanisms to resist the actions of IFNs, for example blocking of PKR by the influenza NS1 protein [93]. IFNs also upregulate cellular expression of MHC class I and II molecules therefore increasing antigen presentation to CD8⁺ and CD4⁺ T-cells and enhancing cellular immune responses.

One recent study has examined type 1 interferon production by primary bronchial epithelial cells from normal and asthmatic subjects infected *ex vivo* with RV [40]. Asthmatic EC following infection released a higher titer of virus into culture supernatant and exhibited impaired apoptosis and a greater degree of necrotic cell death, favoring release of virus from dying cells. This was accompanied by lower concentrations of IFN-β after infection. Addition of IFN-β to asthmatic ECs inhibited virus replication to levels observed in ECs from normal subjects. This study suggests that the production of IFN-β is deficient in asthmatic ECs and that replacement/augmentation of IFN-β to boost the innate immune response could be a novel approach to treatment of virus-induced asthma exacerbations [94].

## Type III interferons

A new family of interferons, called type III IFN-λs, and characterized by three elements: λ1, λ2, and λ3, also termed IL-29, IL-28A, and IL-28B, has recently been described

[90, 91]. The three highly homologous IFN-λ proteins demonstrate limited (about 20%) homology to type I IFNs [95]. Human IFN-λs bind to a unique heterodimeric receptor (IFN-λR), composed of CRF2-12 (also designated IFN-λR1), and CRF2-4 (also designated IL-10R2) shared with other class II cytokine-receptor ligands including IL-10, IL-22, and IL-26 [90].

Viral infection induces upregulation of IFN-λ mRNA in epithelial cells, peripheral blood mononuclear cells (PBMCs), and dendritic cells [90, 91, 96–99]. IFN-λs exhibit some similar biological properties to type I IFNs: they induce Jak/STAT pathways that lead to the upregulation of several antiviral proteins and enzymes including 2′,5′-OAS and MxA, have antiviral activity *in vitro* [90, 91, 97] and have also exhibited antviral activity in an *in vivo* model of vaccinia virus-infected mice [100]. Based on current knowledge, it thus appears that both IFN-α/-β and IFN-λ ligand-receptor systems can independently induce an antiviral state by engaging similar participants of the antiviral response, though the signaling pathways involved in IFN-λ production are currently largely unknown. Recent data suggest that IFN-λ may be involved in antiviral responses against RV. *In vitro* RV infection of a bronchial epithelial cell line (BEAS-2B) led to IFN-λ production and this cytokine demonstrated a dose-dependent antiviral effect against RV [62]. Moreover, IFN-λ production occurred after *in vitro* infection of primary bronchial epithelial cells, macrophages, and BAL cells from healthy volunteers.

We have recently investigated the production of IFN-λs in response to RV in primary bronchial ECs and in BAL cells (90% macrophages) from normal and asthmatic subjects [62]. Production of IFN-λ1 and IFN-λ2–3 was deficient in ECs and BAL cells from asthmatic subjects after *in vitro* RV infection and induction of IFN-λs by RV infection of ECs was strongly inversely related to RV replication. To determine whether IFN-λ production was important in determining responses to RV infection *in vivo*, the same volunteers were then experimentally infected with RV16, the severity of symptoms and reductions in lung function were monitored and the virus load was determined in BAL. *In vitro* production of IFN-λs by RV infection of BAL cells was strongly inversely correlated with both common cold symptoms and *in vivo* virus load and strongly positively correlated with severity of falls in lung function, in asthmatic and normal volunteers experimentally infected with RV16. Asthmatic patients, in whom *in vitro* IFN-λ production in BAL cells was significantly lower than in normal subjects, exhibited increased common cold symptoms and reductions in lung function and virus load after *in vivo* RV16 infection. In marked contrast normal subjects had robust IFN-λ responses, less severe cold symptoms, lower virus load, and no significant changes in lung function. These results document the importance of IFN-λ in the host defense against RV infection *in vitro* and *in vivo* and indicate that deficient IFN-λ production is likely to be important in the pathogenesis of virus-induced asthma exacerbations.

## Proinflammatory cytokines and chemokines

Viral infection of the respiratory tract results in significant changes in the pattern of cytokine expression by a number of cell types, by both cells of the immune system, which may be increased in number and activation status, and by cells often considered to be structural but which in fact contribute significantly to the immune response such as EC. Efficient orchestration of the immune response by cytokines is essential for eradication of virus. Modification of cytokine expression in the airway may contribute to the increased severity of virus infection in asthma.

*In vitro* studies of bronchial EC lines or macrophages have demonstrated the production of a wide range of proinflammatory cytokines such as IL-1, IL-6, IL-11, IFN-α, IFN-γ, TNF-α, and granulocyte-macrophage colony stimulating factor (GM-CSF) and the chemokines IL-8, ENA-78, RANTES, and IP-10 and macrophage inflammatory protein (MIP)-1α in response to RV and RSV [37, 101–103]. *In vivo* these cytokines can be found in nasal lavage in association with RV infection [104].

The specific roles of individual cytokines in the human lower airway during viral infection are not well understood, but increasing information is becoming available. Such cytokines and chemokines activate and recruit a variety of other cells including lymphocytes, eosinophils, and neutrophils. IL-1, TNF-α, and IL-6 share proinflammatory properties such as the induction of the acute phase response and the activation of both T- and B-lymphocytes. IL-1 enhances the adhesion of inflammatory cells to endothelium, facilitating chemotaxis [105]. TNF-α is a potent antiviral cytokine but *in vitro* increases the susceptibility of cultured epithelial cells to infection by RV14 through upregulation of ICAM-1 [37]. IL-6 has been shown to stimulate IgA-mediated immune responses. IL-11 may also be important in virus-induced asthma [106]. It appears to cause bronchoconstriction by a direct effect on bronchial smooth muscle [102]. Production of this cytokine by human stromal cells *in vitro* is increased by RV14, RSV, and parainfluenza type 3 but not by cytomegalovirus (CMV), herpes simplex virus (HSV)-2 or adenovirus. *In vivo* IL-11 is elevated in nasal aspirates from children with colds, levels correlating with the presence of wheezing.

Similarly the chemokine MIP-1α is increased in nasal secretions during natural viral exacerbations of asthma [107]. Studies in MIP-1α knock-out mice suggest that it mediates pneumonitis due to influenza [108]. The other chemokines IL-8 and ENA-78, will recruit and activate neutrophils, while RANTES and IP-10 will do the same for lymphocytes [103].

Viral upregulation of cytokines and chemokines may be mediated through certain key transcription factors. Increases in IL-6 and IL-8 production by cultured epithelial cells due to RV was dependent on NF-κB [82, 107, 109] and further upstream, protein kinase R (PKR)-mediated RV-induced RANTES, IL-8, and IL-6 [110]. Rhinovirus induction of IL-8 was shown to require IkappaB kinase-beta (IKKβ) and the transcription factor NF-IL-6 as well as NF-κB. Similar observations have been made with regard to the induction of IL-1, -6, -8, -11, and TNF-α by RSV [111, 112], thus the potential role of inhibition of NF-κB in this context has generated considerable interest.

In addition to the induction of IL-1α and IL-1β RV infection results in substantial increases in IL-1ra both *in vivo* and *in vitro*. This is a relatively late effect, occurring

48–72 h after infection and may contribute to symptom resolution [113].

## Kinins and nitric oxide

A multitude of inflammatory mediators are generated or act on the epithelial surface. Bradykinin, a-nine-amino acid peptide generated from plasma precursors as part of the inflammatory process has been shown to be present in nasal secretions of RV-infected individuals [114]. Bradykinin given intranasally is able to reproduce some of the symptoms of the common cold such as sore throat and rhinitis [115]. Although the presence of kinins in the lungs of virus-infected individuals has not been reported they are present in both the upper and lower airways in allergic reactions [114–118].

Nitric oxide (NO) is produced by diverse sources including epithelial, endothelial, and smooth muscle cells. In human airways NO appears to be important in relaxation of the human airway smooth muscle [119]. Nitric oxide (NO) may be important in a range of respiratory diseases [120] including asthma [121] and in virus infection [122]. NO is produced both by the constitutive enzymes, nitric oxide synthase (NOS)1, and NOS3 and by the inducible, calcium-independent NOS2 expressed by airway EC [123] and macrophages.

In asthma there is increased NOS2 expression and an elevated level of exhaled NO [124] that falls with corticosteroid therapy; the level of exhaled NO correlates with sputum eosinophilia and methacholine responsiveness [125]. In contrast in stable COPD, exhaled NO levels are not different from normal subjects [126] although there may be an increase during exacerbations [127]. In fact *in vitro* cigarette smoke reduces cytokine-induced NOS2 mRNA expression in the LA-4 murine cell line, in A549 cells and in PHBEC [128].

The relative importance of the beneficial antimicrobial activity of NO versus the potentially disadvantageous suppression of IFN-γ may be dependent on the specific pathogen. NOS2 knock-out mice show an increased susceptibility to infections [129], perhaps because release of NO may be important for NK cell-mediated target cell killing [130]. However NO may also possess antiviral activity. *In vitro* RV induces NOS expression in HPBEC [131]. There is increased expression of NOS2 mRNA in cultured HPBEC after RV16 infection [132]. NO inhibits RV-induced production of IL-6, IL-8, and GM-CSF and viral replication in a human respiratory epithelial cell line [132, 133]. RSV also induces NOS2 and increases nitrite levels in supernatant from A549 cells, from HPBEC culture and in BAL fluid from RSV-infected BALB/c mice, effects opposed by IL-4 and dexamethasone but unaffected by IL-13 or IFN-γ [134]. Replication of RSV in Hep2 cells is inhibited following transfection with a retroviral construct containing NOS and this inhibition is abolished by the NOS inhibitor, NG-methyl-l-arginine [135]. Replication of influenza A and B in Mabin Darby kidney cells is severely impaired by the NO donor, *S*-nitroso-*N*-acetylpenicillamine [136].

Overall there is evidence that *in vivo* increased lower airway NO production may be of benefit in virus-induced asthma exacerbations. Work in a guinea pig model suggests that one mechanism for increased airway hyperresponsiveness during respiratory virus infection is through inhibition of NOS enzymes and a loss of NO-related relaxation of airway smooth muscle [137]. Studies of human asthmatics would also suggest that NO has a protective role in virus-induced exacerbations. Following experimental RV16 infection patients with the greatest increase in exhaled NO had smaller increases in histamine airway responsiveness [131].

In experimental animals parainfluenza virus-induced hyperreactivity correlates with a deficiency in constitutive NO production [137]. Increased levels of exhaled NO are found in nonasthmatic volunteers following natural colds [138] as well as in asthmatic patients after experimental RV infection [131]. In the latter study, an inverse association between NO increase and worsening of airway hyperresponsiveness was demonstrated arguing in favor of a protective role for this substance. This is further supported by the observation that NO reduces cytokine production and viral replication in an *in vitro* model of RV infection [133]. Interestingly, studies of viral upper respiratory tract infections have failed to demonstrate an increase in nasal NO after experimental RSV, RV, and influenza infections [139]. In normal subjects experimental influenza infection increased oral NO 8 days postinfection but had no effect on nasal NO [140]. This raises the possibility that during respiratory virus infection induction of NO is selective for the lower respiratory tract.

## Signaling pathways

The responses of airway EC to virus infection are consequences of the interactions between virus and the intracellular signaling pathways of the host cell [141]. Knowledge of the mechanisms involved for rhinoviruses is currently very limited. Activation of signaling pathways may be dependent on cell surface receptor (ICAM-1, LDL-R) binding or may occur during viral replication within the cell. The need for replicative virus is demonstrated by the inhibition of RV induction of EC cytokines after UV inactivation. One product of replication, common to ssRNA viruses such as RV and also RSV and influenza, is dsRNA, which has been shown to activate components of signaling pathways including dsRNA-dependent protein kinase PKR, IKKβ, NF-κB, and p38 mitogen-activated protein kinase with resultant induction of IL-6, IL-8, and RANTES [110, 142]. Activation of EC by dsRNA may be direct or indirect through the interferon system as discussed above. It has also been reported that dsRNA and virus infections activate EC through binding to TLR3 [143, 144].

## Effects of viruses on airway smooth muscle cells

Studies utilizing isolated rabbit tissues and human cultured airway smooth muscle cells suggest that, for RV16, exposure to the virus may have a direct effect on smooth muscle cells, resulting in increased contractility to acetylcholine and impaired relaxation to isoproterenol. This effect is dependent on ICAM-1 and appears to involve an autocrine signaling mechanism including upregulation of production of

IL-5 and IL-1β by the airway smooth muscle itself [145]. A more recent study demonstrated that RV induction of IL-6 and IL-8 was increased in smooth muscle cells from asthmatic compared to normal subjects [146]. Whether rhinovirus reaches airway smooth muscle cells in sufficient quantity to produce a significant effect by this mechanism *in vivo* is as yet unknown. The effects of other respiratory viruses on smooth muscle require further investigation.

## The cellular immune response to virus infection in the lower airway

A variety of leukocytes show changes in number, site of accumulation, and activation state in response to virus infection. Since these cells are also implicated in asthmatic inflammation of the lower airway they provide potential sites of interaction between the immunopathologies of virus infection and asthma.

## Monocytes/macrophages

Alveolar macrophages are present in large numbers in the lower airway. They make up around 90% of the cells seen in BAL from normal volunteers [28]. They are ideally placed for early phagocytosis of virus particles and are likely to play an important role in the immune response through antigen presentation to T-cells and through the production of cytokines and other mediators. RV has been shown to enter human monocytes and macrophages which express high levels of the major RV receptor ICAM-1. It has not been possible to demonstrate RV replication within alveolar macrophages although low grade productive infection has been shown in the monocyte cell line THP-1 [147]. Replication also occurred in THP-1-derived macrophages but was limited in monocyte-derived macrophages which are relatively resistant to viral replication at least partly because of higher levels of type I interferon production [148]. RV entry into monocytes results in activation and the production of both IL-8 [147] and TNF-α [149]. In monocyte and THP-1-derived macrophages RV induction of TNF-α is NF-κB dependent [148].

A recent study reported that infectious but not UV-inactivated RV-increased TNF-α and IL-8 release by macrophages derived from resected lung tissue. Interestingly, infectious rhinovirus-impaired LPS and lipoteichoic acid-induced TNF-α and IL-8 secretion by macrophages as well as the macrophage phagocytic response to labeled bacterial particles [150]. This RV-induced impairment of cytokine responses to bacterial LPS and lipoteichoic acid and of phagocytosis in alveolar macrophages could lead to impairment of antibacterial host defense may have important implications in the pathogenesis of exacerbations of respiratory diseases including both asthma [151] and COPD [152]. In contrast, infection of human monocytes *in vitro* with influenza A causes alterations in structure and activation status and the production of IL-1β IL-6, TNF-α IFN-α, and IFN-β [153], effects dramatically potentiated by subsequent exposure to bacterial LPS.

## Dendritic cells

Dendritic cells are key cells in IFN production, as well as in antigen presentation both of allergens and pathogens with a capacity to induce both primary and secondary immune responses. They may also play a role in the regulation of the type of T-cell-mediated immune response [154]. RV infection has been shown to induce production of the dendritic cell attracting chemokine MIP-3α [43] and to increase in number in the lung during RSV infection [155], suggesting they are recruited to the lung during respiratory virus infections. However, they have also been shown to be produced from local precursors during RSV infection [156]. Plasmacytoid dendritic cells are likely protective against infection as they have been shown to limit virus replication in RSV infections, as well as reducing airway inflammation and airway hyperresponsiveness [157]. In contrast, others have reported induction of the high affinity IgE receptor on dendritic cells during Sendai virus infection, and linked this with induction of mucus cell metaplasia and airway hyper-reactivity [158]. There is thus increasing knowledge of the immunobiology of these cells during respiratory infections but their role in the context of viral exacerbations of asthma remains unclear and further studies are needed.

## Lymphocytes

Bronchial biopsies demonstrate increases in cells positive for CD3, CD4, and CD8 within the epithelium and submucosa of both normal and asthmatic subjects following experimental RV infection [21] and we have recently demonstrated a trend toward increased numbers of lymphocytes in BAL from asthmatic compared to normal subjects ($p = 0.06$)[34]. Such increases coincided with peripheral blood lymphopenia, and reductions in blood total lymphocytes and CD8$^+$ T-cells correlated strongly with virus load only in asthmatic subjects[34] suggesting increased recruitment of T-cells to the asthmatic airway may be important in the context of asthma exacerbations. Since T-cells are believed to be key cells in the pathogenesis of asthma the effects of viruses on T-cells are of particular importance.

T-cell recruitment into the airway is at least partly under the influence of chemokines, including those whose production by EC is upregulated by viruses. The nature and the effectiveness of the specific immune response may be influenced by the balance of chemokine production by airway EC. This balance may in turn be influenced by preexisting chronic inflammation as found in asthma.

Studies of cloned T-cells suggest that Th1 and Th2 cells show differential expression of chemokine receptors. There is increased expression of CXCR3 (receptor for IP-10, I-TAC, and Mig) and CCR5 (MIP-1β) in human Th1 cells and increased expression of CCR4 (TARC and MDC) and to a lesser extent CCR3 (eotaxin and MCP-3) in Th2 cells, with selective migration of cells in response to the appropriate chemokines. CCR1 (RANTES, MIP-1α, MCP-3) and CCR2 (MCP-1, -2 ,-3, -4) were found on both Th1 and Th2 cells [159]. Bronchial biopsies from asthmatics show high levels of expression of CCR4 and significant levels of CCR8 by T-cells [160].

Increased recruitment of T-cells to the airway as a result of virus-induced chemokine production by EC could amplify preexisting allergic inflammation. If the asthmatic airway microenvironment influences the pattern of chemokine expression following virus infection then this could alter the Th1/Th2 balance of the antiviral immune response.

## CD4$^+$ T-cells

The CD4$^+$ T-cell response to virus infection is thought to be of the T-helper 1 (Th1) type. It is thought that an effective antiviral immune response is characterized by the production of type 1 cytokines such as IFN-$\gamma$. IFN-$\gamma$, in addition to IFN-$\alpha$, IFN-$\beta$, and IFN-$\lambda$ from monocytes and macrophages, plays a role in establishing an "antiviral state" in neighboring cells. IFN-$\gamma$ has a complex role in the pathogenesis of asthma. It appears to increase basophil and mast cell histamine release [161] but on the other hand inhibits the expression of type 2 cytokines. Production of IFN-$\gamma$ is increased in PBMC [162] and in nasal secretions [104] during RV colds and in human and animal models of influenza, parainfluenza, and RSV infection [119, 163, 164]. There are exceptions where the antiviral response exhibits a Th2 character or a mixture of Th1/Th2. In animal models of RSV, different proteins of the virus may induce either Th1 or Th2 type responses and priming with such proteins prior to infection with whole virus can influence the character, effectiveness, and associated immunopathology of the immune response [165].

Asthma is believed to be characterized by type 2 inflammation. Many studies have demonstrated mutual inhibition of Th1 and Th2 cells [166, 167]. It is therefore possible within an airway with a preexisting type 2 allergic asthmatic microenvironment that there may be inhibition of the normal effective type 1 antiviral immune response or that the system may be skewed toward type 2 responses.

Papadopoulos *et al*. have shown that type 1 responses to RV are deficient in individuals with asthma [168]. PBMC taken from asthmatics and exposed *in vitro* to RV show lower levels of IFN-$\gamma$ and IL-12 and higher levels of IL-4 and IL-10 in culture supernatants than cells from normal subjects. The IFN-$\gamma$/IL-4 ratio was three times lower in the asthmatic group [168].

In a study by Gern *et al*. of experimental RV16 infection in subjects with allergic rhinitis or asthma, the balance of airway Th1 and Th2 cytokines in induced sputum induced by viral infection was found to be related to clinical symptoms and viral clearance. Although protein could not be detected in sputum due to the presence of inhibitors of the ELISA assay used, there were increases in mRNA, as determined by semi-quantitative RT-PCR, for both IL-5 and IFN-$\gamma$. An inverse correlation was demonstrated between the ratio of IFN-$\gamma$ mRNA to IL-5 mRNA and peak cold symptoms. In addition subjects with RV16 still detectable 14 days after inoculation had lower IFN-$\gamma$/IL-5 ratios during the acute phase of the cold than those subjects who had cleared the virus [169].

We have recently investigated the production of type 1 and type 2 cytokines from BAL cells in asthmatic and normal subjects. We found that production of the type 1 cytokines IL-12 and IFN-$\gamma$ were suppressed in the asthmatics, while production of the type 2 cytokines IL-4, -5 and, -13 were all increased [34]. Importantly CD4$^+$ T-cell production of IFN-$\gamma$ was strongly inversely correlated with virus load and reductions in lung function in the asthmatic subjects when they then underwent RV experimental infection, suggesting that CD4$^+$ T-cell production of IFN-$\gamma$ is protective in the context of RV-induced asthma [34]. Conversely, CD4$^+$ T-cell production of each of IL-4, -5, and -13 was positively correlated with lower respiratory symptom severity, suggesting CD4$^+$ T-cell production of each of IL-4, -5, and -13 are associated with more severe exacerbations. These data are novel and important, but causal roles cannot be established in such human challenge studies. Investigation of the possible causal role of each these cytokines *in vivo* is now required using the newly developed mouse model [43].

## CD8$^+$ T-cells

CD8$^+$ T-cells are important effector cells in specific cell-mediated antiviral immunity. They also demonstrate polarization of cytokine production, the major Tc1 cytokine again being IFN-$\gamma$ and are believed to regulate CD4 Th1/Th2 balance [170]. In a murine asthma model induction of bystander CD4$^+$ Th2 responses to ovalbumin resulted in a switch of virus-peptide specific lung CD8$^+$ T-cells to production of Tc2 cytokines including IL-5 with, after virus peptide challenge, induction of airway eosinophilia [171]. If this occurs in man it suggests a means whereby CD8 antiviral function could be inhibited at the same time as CD8 amplification of allergic inflammation through IL-5 induction of airway eosinophilia. The role of CD8$^+$ T-cell production of type 1 and type 2 cytokines in virus-induced asthma exacerbations requires investigation.

## $\gamma\delta$-TCR$^+$ T-cells

$\gamma\delta$-TCR$^+$ T-cells are a minor subset of T-cells expressing receptors distinct from the $\alpha\beta$ receptors found on the majority of T-cells involved in adaptive immunity. There appear to be at least two types of $\gamma\delta$-TCR$^+$ T-cells. The first type is found in the lymphoid tissue of all vertebrates and displays highly diversified receptors. The second type, intraepithelial $\gamma\delta$-TCR$^+$ T-cells, display receptors of limited diversity. It has been suggested that this second subset recognize molecules expressed only by nearby infected cells. Candidate ligands are heat-shock proteins, MHC class IB molecules and unorthodox nucleotides and phospholipids. Antigen is recognized directly rather than as processed peptide presented by MHC. Recognition of molecules expressed as a consequence of infection rather than pathogen-specific molecules themselves would place $\gamma\delta$-TCR$^+$ T-cells at the intersection of innate and adaptive immunity [172].

However, exaggerated responses to various pathogens and self tissues have been found in studies of mice deficient in $\gamma\delta$-TCR$^+$+ T-cells rather than deficiencies in control of pathogens. Such work has suggested that at least some $\gamma\delta$-TCR$^+$+ T-cells have a regulatory role in modulating immune responses [173], a function consistent with their demonstrated ability to secrete regulatory cytokines when activated.

It has been reported that $\gamma\delta$-TCR$^+$ T-cells are more numerous in the asthmatic airway [174]. A recent study found a greater capacity for production of IL-5 and IL-13 in bronchoalveolar lavage $\gamma\delta$-TCR$^+$ T-cells from asthmatic subjects [175]. If virus infection results in the release of molecules from epithelial cells that activate $\gamma\delta$-TCR$^+$ T-cells in the respiratory mucosa, such cells could provide a source of type 2 cytokines that influence the nature of the subsequent immune response. The role of $\gamma\delta$-TCR$^+$ T-cells in virus-induced asthma exacerbations requires investigation.

## Eosinophils

Eosinophils are increased in bronchial epithelium in biopsies taken from normal and asthmatic volunteers following experimental RV infection; in a small study eosinophilic inflammation persisted for up to 6 weeks in asthmatic subjects [21] and in our recent study eosinophil numbers in the BAL were significantly (threefold) increased in asthmatic compared to normal subjects during the acute RV infection and correlated significantly with reductions in lung function only in the asthmatic subjects [34]. In allergic rhinitis experimental RV infection increases BAL eosinophils following segmental allergen challenge, again persisting for 6 weeks [28], and increased levels of ECP are found in the sputum of RV-infected subjects [23] and during naturally occurring acute exacerbations of asthma [13]. Eosinophils accumulate in the airway under the influence of IL-5, GM-CSF, IL-8, RANTES, and eotaxin [176]. Of these only IL-5 has not been shown to be produced by airway EC *in vitro* after infection by RV. Expression of RANTES is increased in nasal secretions of children with natural virus-induced asthma [107]. RANTES is upregulated in primary nasal EC cultures by RSV [177] and RV [178]. GM-CSF is important in bone marrow eosinophil production and in eosinophil survival [176] but levels are not increased during viral upper respiratory tract infections [107, 179, 180]. Levels of eotaxin in nasal lavage rise after experimental RV16 infection [181]. These data suggest a pathogenic role for eosinophils in virus-induced asthma. However, a protective role is also possible. In allergic rhinitic subjects, infected with RV after high dose allergen challenge, the severity and duration of cold symptoms were inversely related to the NL eosinophil count prior to infection [32]. Eosinophils may contribute to viral antigen presentation. Eosinophils pretreated with GM-CSF bind RV16 via ICAM-1 and present viral antigen to RV16-specific T-cells, inducing proliferation and secretion of IFN-$\gamma$ [182]. Eosinophils have antiviral actions in parainfluenza-infected guinea pigs [183]. EDN and ECP have ribonuclease activity and reduce RSV infectivity [184]. The role of the eosinophil in the antiviral immune response thus requires further evaluation.

## Mast cells/basophils

These cells are important sources of inflammatory mediators, characteristic of allergic inflammation in asthma. Mast cell basal and stimulated histamine release increases after virus infection [185]. Airway mast cell numbers are upregulated

in a rat model of parainfluenza infection. Several viruses can enhance basophil IgE-mediated histamine release, but the role of this cell in human asthma is controversial.

Mast cells are also important sources of inflammatory mediators. Their function and localization suggest an early interaction with viruses. Leukotriene (LT) C$_4$ is among the mediators responsible for the late phase of bronchospasm in asthma. During RSV infection increased levels of LTC$_4$ were found in the nasopharyngeal secretions of infants [186]. Levels correlated well with the symptoms of the disease with concentrations in infants presenting with bronchiolitis being fivefold higher than in those with only upper respiratory tract symptomatology. Cultured alveolar macrophages can be infected with parainfluenza virus and respond with an increase in arachidonic acid metabolism. Several of the products of this pathway are known inducers of airway constriction, including LTC$_4$, LTD$_4$, PGF$_{2\alpha}$, and thromboxanes and/or stimulants of mucous secretion such as PGF$_{2\alpha}$, LTB$_4$, and 5-hydroxyeicosa-tetraenoic acid [187]. RV infection has been shown to induce prostaglandin and LT synthetic enzymes in bronchial biopsies in normal subjects, as well as trends for increased numbers of mast cells ($p = 0.07$) bronchoalveolar lavage fluid cysteinyl-leukotriene levels ($p = 0.13$), but these outcomes have not been studied in asthmatic subjects [188].

## Neutrophils

Neutrophils are recruited early during respiratory viral infection in response to the production of IL-8, Gro-$\alpha$, and ENA-78 by EC and activated neutrophils are a prominent feature of severe asthma. Induced sputum IS in asthmatics and nonasthmatics demonstrates a significant increase in neutrophils at day 4 of a natural cold, correlating with sputum IL-8 [189]. Similar results were obtained in IS taken 2 and 9 days after experimental RV16 infection in asthmatics. Intracellular staining demonstrated an increase in cells positive for IL-8 at day 2 attributable to increased IL-8 positive neutrophils [25]. The chemokine IL-8 is a potent chemoattractant for neutrophils but also acts on lymphocytes, basophils, and primed eosinophils. Increased IL-8 has been found in NL from children with natural colds [104]. Experimental RV16 infection of asthmatics resulted in elevated NL IL-8, correlating with cold/asthma symptom scores and histamine PC20 [25]. IS from asthmatics with exacerbations has both elevated IL-8 and neutrophilia [23, 190]. A study of experimental infection in asthmatic children also demonstrated elevated IL-8 and neutrophilia in NL during the acute infection and levels of neutrophil myeloperoxidase correlated with symptom severity [191]. In asthma, exacerbations in asthmatic adults [13] those with virus infection had increased sputum neutrophils and increased neutrophil elastase and more severe clinical disease. Such studies suggest a prominent role for the neutrophil in tissue damage during virus-induced asthma.

## Natural killer cells

Natural killer (NK) cells are an important part of the innate immune response, their function being the elimination of

a variety of target cells including virus-infected cells and the modulation of adaptive immunity toward viruses [192]. Cell killing by NK cells may occur through natural killing, antibody-dependent cellular cytotoxicity (ADCC), or apoptotic killing of Fas-positive target cells via membrane bound FasL. The ability to directly kill virus-infected cells is regulated by a balance between inhibitory and activating receptors [193]. Killer inhibitory receptors (KIRs), Ig-like receptors that recognize HLA-A, -B, or -C molecules, and the lectin-like CD94/NKG2A receptor that interacts with HLA-E allow NK cells to recognize cells expressing normal self MHC class I [194]. Loss of inhibition occurs if potential target cells have lost class I expression following virus infection or if they display abnormal class I/peptide complexes.

NK cells are rapid and efficient producers of cytokines such as IFN-$\gamma$, important both in early viral infection in the antigen-independent activation of antigen presenting cells such as macrophages, dendritic cells, and epithelial cells, and for biasing the development of CD4$^+$ Th1 and CD8$^+$ Tc1 cells. Cytokines and chemokines shown to enhance the activities of NK cells *in vitro* and *in vivo* include IFN-$\alpha$/-$\beta$, IFN-$\gamma$, TNF-$\alpha$, IL-2, IL-12, IL-15, IL-18, MIP-1$\alpha$ MIP-1$\beta$, MCP-1, 2, 3, and RANTES. Transforming growth factor (TGF)-$\beta$ and IL-10 inhibit NK cell activity [195]. Type 2 cytokines may also modulate NK function, increasing NK type 2 activities and decreasing NK type 1 activities. Human NK cells cultured in medium supplemented with IL-4 differentiated into NK type 2 cells, secreting IL-5 and IL-13 and when cultured in the presence of IL-12, differentiated into NK type 1 cells secreting IL-10 and IFN-$\gamma$. IL-4 and IL-13 have also been shown to suppress IL-2-induced cytolytic and proliferative activities and IFN-$\gamma$ production of human NK cells [196]. NK cell production of IL-5 is enhanced by IL-4 and reduced by IL-10 and IL-12 [197]. In a mouse model of asthma, intracellular staining of NK cells has demonstrated IL-5 production and depletion of NK cells resulted in reduced airway eosinophilia [198].

The function of NK cells in the asthmatic airway is as yet unexplored. It may be that, in an airway environment rich in type 2 cytokines, that NK type 1 function and effective antiviral activity are inhibited. If this is the case then a key component of the early immune response would be deficient and viral clearance would be impaired. In addition, if NK type 2 function is favored by the asthmatic microenvironment, production of type 2 cytokines by NK cells in response to virus infection might be one mechanism for amplification of allergic inflammation. These hypotheses are as yet untested in human studies of experimental virus infection.

## B-lymphocytes and interaction of viruses with IgE-dependent mechanisms

An elevated serum total and allergen-specific IgE are features of "extrinsic" or atopic asthma. IgE-mediated mechanisms are certainly important in the pathophysiology of extrinsic asthma. Recent studies suggest a similar airway pathology in both extrinsic and "intrinsic" nonatopic asthma [199] where there is an absence of specific serum IgE and negative skin prick tests to aeroallergens. It has been suggested that there may be the production of local IgE to as yet unknown environmental allergens in intrinsic asthma.

Upregulation of total IgE or virus-/allergen-specific IgE locally or systemically during respiratory virus infection would be expected to contribute to the duration and severity of symptoms of an asthma exacerbation.

Intranasal challenge with RV39 results in an increase in total serum IgE in allergic rhinitic subjects but no increase in preexisting allergen-specific IgE [200]. In children with asthma, during infection with influenza A there was no change in total IgE but increases were observed in specific serum IgE to house dust mite and in *ex vivo* proliferative and IL-2 responses of lymphocytes challenged with house dust mite allergen [201]. In a study of RSV infection in infants the development of serum RSV-specific IgE occurred more frequently in atopics and correlated with clinical wheezing, histamine levels in nasal secretions, and hypoxia [202]. There is no information as yet on the presence of local virus-specific IgE in the airway during asthma exacerbations.

## COPD

Increasing interest in the clinical features and pathogenesis of COPD reflects the worldwide importance of the disease. More than 14 million patients are affected in the United States alone. It is predicted to become the third leading cause of death worldwide by 2020 [203]. National and global initiatives have been launched and management guidelines have been published [204, 205].

The frequency of exacerbations is a major factor in the quality of life of patients with COPD [206]. The typical clinical features of an exacerbation include increased dyspnea, wheezing, cough, sputum production, and worsened gas exchange. Although noninfectious causes of exacerbations such as allergy, air pollution, or inhaled irritants including cigarette smoke may be important, acute airway infections are the major precipitants [207]. The infection and consequent host inflammatory response result in increased airway obstruction.

### Epidemiology

It is likely that two-thirds to three-quarters of COPD exacerbations may be caused by viral infections. In a study of 186 patients rhinoviruses, influenza virus, parainfluenza virus, and coronavirus were significantly associated with COPD exacerbations [208]. Between 60% and 70% of exacerbations are associated with preceding symptoms of a common cold. The frequency of exacerbations requiring hospitalization is higher in the winter. One explanation for this could be the increased frequency of respiratory viruses at this time of the year. A recent study of 321 exacerbations in 83 patients with moderate to severe COPD using new diagnostic methods including RT-PCR shows a high incidence of viral infection [209]. Viruses were detected in nasal aspirates at exacerbation in almost 40% of cases. Rhinovirus

was the most common, occurring in 58% of cases where a virus was present. The presence of virus was associated with increased dyspnea, cold symptoms, and sore throat and with prolonged recovery from exacerbation. Earlier studies relying on serology and virus culture quote lower virus detection rates of 15–20% [208, 210–212]. Other studies of more severe exacerbations using more comprehensive PCR methods confirmed the importance of virus infection, with viruses being detected in around 50% of exacerbations [152, 213]. Because these studies all involve sampling relatively late in the course of illness, it is likely that these detection rates underestimate the true importance of virus infections.

The role of bacteria in precipitating exacerbations is also somewhat controversial. Bacteria may have a primary role in the development of an exacerbation and/or represent a secondary superinfection of an initial viral process. Various bacterial species are present in the airways of 25–40% of patients, even when the COPD is stable but increased frequency of recovery of bacteria during exacerbations ($\sim$55%) as well as higher bacterial loads during exacerbations both suggest that they play an important role in a significant number [152, 214, 215]. Significant bacterial infection has been suggested when there is an abundance of neutrophils in the sputum [216] and when the sputum is purulent and green (due to neutrophil myeloperoxidase) [217]. Bacteria may contribute to the pathogenesis of an exacerbation due to increased bacterial loads of bacteria already colonizing diseased airways, however in addition to this, acquisition of new bacterial strains has also been shown to be important, increasing the risk of exacerbation over twofold [218].

The major bacterial organisms associated with COPD exacerbations are nontypable *Haemophilis influenzae*, *Streptococcus pneumoniae*, and *Moraxella (Branhamella) catarrhalis* [219, 220]. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* may play a part [221, 222]. Evidence also suggests that in more severe patients with a baseline $FEV_1$ of 35% predicted or less, gram-negative bacteria especially *enterobacteriaceae* and *pseudomonas* play an important part in acute exacerbations [223].

Recent studies have addressed the role of coinfection with both bacteria and viruses – one study showed this to occur in 25% of exacerbations, and that patients with dual infection had more marked lung function impairment and longer hospitalizations [152]. Another reported that exacerbations with both cold symptoms (a marker of putative viral infection) and a bacterial pathogen, the $FEV_1$ fall was greater and symptom count was higher than those with a bacterial pathogen alone [224]. Thus even in exacerbations in which viruses are detected, bacteria can also contribute to exacerbation severity.

Although the results of placebo-controlled trials show conflicting results, overall the effects of antibiotic treatment also support an etiological role for bacteria in exacerbations in some patients. A meta-analysis of nine studies showed a small overall benefit when antibiotics were used for COPD exacerbations [225]. The largest study included 362 exacerbations in 173 outpatients [216]. Compared with placebo, the rate of symptom resolution and improvement of peak expiratory flow during exacerbations was slightly but significantly faster when patients were treated with co-trimoxazole, amoxicillin, or doxycycline. More importantly, treatment

failures as defined by respiratory deterioration were nearly twice as likely in the placebo group. Benefit from antibiotics was most evident for patients with most symptoms (dyspnea, increased sputum volume, and sputum purulence).

Guidelines for the use of antibiotics in acute exacerbations of COPD are unclear because of the difficulties in defining the role of bacterial infection in an individual case. The American Thoracic Society statement on COPD [205] suggests using antibiotics if there is evidence of infection (fever, leukocytosis, CXR changes) but not all patients with bacterial bronchial infection have fever (this is more common in viral infection or pneumonia) and few have CXR changes. The European Respiratory Society recommends antibiotics if the sputum is purulent, using standard antibiotics as first line, and sputum culture if these fail [226].

## Evidence for a role for bacterial infection in pathogenesis/progression of COPD

Bacterial infection has a definite role in the pathogenesis of other chronic lung diseases such as cystic fibrosis and bronchiectasis where bacterial infection is chronic, causing not only acute exacerbations but also influencing long-term prognosis [207].

In these diseases chronic bacterial infection occurs as the host immune response is unable to clear the bacteria, the continuous infection leads to continuous inflammatory responses and continuous tissue damage [207]. Host and bacterial factors attract and activate neutrophils, which produce proteinases and reactive oxygen species. Lung antiproteinase defenses are overwhelmed. Both proteinase enzymes and reactive oxygen species cause damage to the epithelium, stimulating mucus production and impairing mucociliary clearance. Neutrophil elastase stimulates epithelial cell production of the chemokine IL-8 which attracts further neutrophils and in addition impairs phagocytosis by destroying antibody and cleaving complement receptors from neutrophils and complement components from bacteria. Neutrophils are also stimulated by cigarette smoke.

Identification of bacteria during exacerbation is also associated with increased levels of inflammatory mediators in BAL and/or sputum. These include reactive oxidant species, IL-8, TNF-$\alpha$, neutrophil elastase, $LTB_4$, and myeloperoxidase and many others. These clearly have potential to cause considerable tissue damage, as well as further recruitment and activation of inflammatory cells. COPD patients, particularly those at the more severe end of the disease spectrum, may also be chronically colonized by bacteria between exacerbations, bacterial numbers then increasing during exacerbations. In a study using bronchoscopic protected brush specimens [214] 10 of 40 COPD patients were colonized with bacteria when stable. During exacerbations 50% had bacteria present and when present, bacterial numbers were greater. When protected brush specimens were taken during severe acute exacerbations of COPD requiring ventilation [227] bacteria were detected in 50% but it was not possible to distinguish patients more likely to have bacteria on the basis of clinical features or other investigations.

The major bacterial pathogens isolated during bronchial infections all form part of the commensal flora in the nasopharynx. Bronchial infections occur in patients with abnormal airways with reduced host defenses. Persistence of bacteria within the bronchial tree may come about through toxins that impair mucociliary clearance, enzymes that breakdown local immunoglobulin, products that alter immune effector cell function, adherence to mucus and damaged epithelium, or other mechanisms of avoiding immune surveillance [207, 228].

Bacterial colonization in the stable state represents an equilibrium in which the number of bacteria present in the bronchial tree is contained by the host defenses but not eliminated. During an exacerbation this equilibrium is upset and bacterial numbers increase, inciting an inflammatory response. Change will usually occur because of a change in the host rather than altered virulence of the bacteria, for example as a result of viral infection.

## Evidence for a role for viruses in pathogenesis/progression of COPD

Exacerbations associated with viral infections also have increased levels of many inflammatory mediators also found in bacterial exacerbations including TNF-$\alpha$, IL-8, neutrophil elastase, myeloperoxidase, and LTB$_4$. In contrast to bacterial exacerbations where neutrophils and neutrophil products predominate, during a viral exacerbation both neutrophils and eosinophils are present and eosinophil products such as ECP are also increased [152]. Other mediators implicated include ENA-78, RANTES, and endothelin–1 [229].

It has also been suggested that persistent virus infection contributes to the progression of COPD. In particular, adenovirus appears to persist in a latent form in which viral proteins are produced without replication of complete virus. Such latent infection may amplify lung inflammation due to cigarette smoke [230]. Adenoviral E1A DNA persists in human lungs from patients with COPD compared with patients of similar age, sex, and smoking history who do not have COPD [231]. The E1A protein has been demonstrated in airway epithelial cells from smokers [232]. It is able to amplify many host genes through attachment to the DNA-binding sites of transcription factors [233]. Airway epithelial cells transfected with E1A produce excess inflammatory cytokines such as IL-8 [234] and surface adhesion molecules such as ICAM-1 [235] after *in vitro* challenge by an NF-κB-dependent mechanism [236].

RSV has been identified in induced sputum from patients with stable COPD. These individuals have a higher plasma fibrinogen and serum IL-6, a higher pCO$_2$ and increased frequency of exacerbations [209]. This suggests either that low grade persistent RSV infection contributes to COPD severity or that patients with more severe COPD are less able to clear RSV from the airway.

The immunology of virus infection in COPD is not well understood. Less data is available than for virus infection in asthma since this has not been a major subject of human experimental infection studies. In a small safety study of four patients, inoculation with low dose RV16 resulted in symptomatic colds, viral replication, significant increases in lower respiratory tract symptoms, and reductions in PEF and FEV$_1$ typical of an acute exacerbation of COPD [237]. Further studies are clearly needed in view of the increasing evidence for a major role for viruses in causing COPD exacerbations.

## Therapy for infective exacerbations of asthma and COPD

Currently much of the treatment of infective exacerbations of asthma and COPD is symptomatic, consisting of increased bronchodilators, either short-acting $\beta_2$-agonists in inhaled or intravenous form or anticholinergics or theophyllines, or supportive in the form of oxygen and in severe cases noninvasive or invasive ventilatory measures. Corticosteroids are widely used in inhaled or oral form for their anti-inflammatory actions. The effects of corticosteroids are the result of actions at many points in various inflammatory cascades. Whilst this undoubtedly contributes to their beneficial effects it also results in significant local and systemic side effects, in particular if oral steroid treatment is prolonged or frequent. In addition systemic steroids may interfere with the antiviral immune response resulting in reduced viral clearance [238].

In persistent asthma, control of disease is achieved predominantly with inhaled corticosteroids. There is a role for additional drugs such as long-acting $\beta_2$-agonists and leukotriene antagonists. The long-acting $\beta_2$-agonists in particular appear to increase the effectiveness of inhaled corticosteroids allowing the dose needed to achieve control to be reduced [239]. There is also evidence that these drugs in combination with inhaled corticosteroids may further reduce exacerbation frequency [240]. The leukotriene antagonists appear to be most effective in treating or preventing exacerbations in children [241, 242].

Regular corticosteroid treatment is however only partially effective at preventing exacerbations. In adult asthma inhaled steroids reduce exacerbation frequency by only 40% [243]. In school age children inhaled steroids are ineffective at reducing exacerbation frequency, duration, or severity [244]. In preschool age children with virus-induced wheeze oral steroids are ineffective even in those with primed eosinophils [245].

Specific antibiotic therapy is available for bacterial infections and is indicated where there is good evidence of such infection or when the exacerbation is severe and bacterial involvement is a possibility.

However, as discussed above the majority of infective asthma exacerbations are of viral rather than bacterial origin and viruses are also common in exacerbations of COPD.

## Vaccination

The success of vaccination to prevent respiratory virus infections has been limited by significant variation within the major virus types causing disease. There are 102 serotyped strains of rhinovirus and several more that have not been serotyped and no effective vaccine has been introduced. A decavalent vaccine [246] developed in the 1970s was

ultimately of limited efficacy. The influenza viruses display antigenic shift and drift. Vaccines must be modified every 2–3 years to cover the strains prevalent at the time. Vaccination against RSV experienced a major setback in the 1960s when the use of formalin-inactivated virus in young babies resulted in increased disease severity following subsequent virus infection [247]. Eighty percent of vaccinated children required hospitalization when subsequently infected with RSV, as compared to 5% of controls. The lungs of two vaccinated children who died contained eosinophilic infiltrates. It has been suggested that formalin inactivation may have modified epitopes within the RSV G and F surface glycoproteins, resulting in a modified immune response to subsequent infection with enhanced immunopathology [248]. Vaccinated individuals demonstrate a number of differences from individuals who have suffered natural RSV infection including a lack of specific mucosal antibodies and deficient neutralizing and fusion-inhibiting serum antibodies [249]. There are also differences in the cell-mediated immune response with some vaccinated individuals demonstrating peripheral eosinophilia and exaggerated lymphocytic proliferative responses to RSV [250]. To protect against RSV infection a successful vaccine would need to provide more effective protection than natural infection, which is itself frequently followed by reinfection [251], and would have to be administered early in infancy to have an effect on infant bronchiolitis.

## Treatment for virus-induced asthma exacerbations

Simple nonspecific treatments for the common cold do exist although their efficacy is debated. Vitamin C and zinc gluconate [252] both may shorten the duration of a cold by 1–2 days. The inhalation of humidified hot air provides symptomatic relief [253]. Nasal IFN-$\alpha$ is an effective treatment for the common cold [254] but must be given either prior to or shortly after exposure to the virus. It is also expensive and is associated with significant local side effects such as bleeding and discharge. These problems have limited its clinical use. However IFN therapy for virus-induced asthma exacerbations may be more useful in view of the deficiencies identified by recent studies. Further because of the large number of viruses producing similar clinical syndromes, the general antiviral properties of IFNs would provide significant advantage over the use of specific antiviral drugs.

## Antivirals

Specific antiviral agents exist for influenza. Amantidine and rimantidine are effective against influenza A. The use of amantidine has been limited by CNS side effects such as dizziness and insomnia; fewer such side effects are seen with rimantidine. Both drugs are indicated during epidemics for treatment and prophylaxis in high risk groups including asthmatics. Neither is active against influenza B. Two neuraminidase inhibitors, zanamivir and oseltamivir, are active against both influenza A and B [255–257]. These agents are effective in preventing infection when used as prophylaxis

during the influenza season and, as treatment, they reduce the duration of illness if started within 36–48 h of the onset of illness. Zanamivir must be given by inhalation whereas oseltamivir can be given orally. Ribavirin is a nucleoside analog active against RSV *in vivo* and also against influenza *in vitro*. Nebulized ribavirin therapy is licensed for use in hospitalized infants and children in the first 3 days of RSV bronchiolitis. It is however expensive and of unproven benefit on clinical outcome. Because of its toxicity it is not appropriate for asthma. RSV enriched immunoglobulin was effective as prophylaxis for infants at high risk of RSV bronchiolitis [258] but has been superseded by RSV neutralizing monoclonal antibodies [259].

## Antirhinoviral agents

RV are a major target for drug treatment. It has been estimated that rhinoviruses result in 6–10 colds per year in young children [260]. As yet no effective agent is available for clinical use. Capsid-binding/canyon inhibitors block RV binding to host cell receptor (ICAM-1 in the case of the major group). One example in phase 3 clinical trials is pleconaril (Picovir). These drugs can be extremely potent but their clinical usefulness is often limited by toxicity, the need for rapid initiation of therapy and the possible development of resistance. Alternative targets include soluble ICAM-1 which inhibits major rhinovirus infection and conserved viral enzymes such as protein 3D, the RNA-dependent RNA transcriptase, protein 2C, the associated ATP-helicase, and the cysteine protease 3C.

## New approaches

Alternative approaches to direct antiviral therapy are suppression of virus-induced inflammation, or strategies that promote innate or type 1 immune responses in individuals with excessive type 2 responses. Understanding the complexities of the antiviral immune response, in particular how it may be altered in the context of preexisting chronic airway diseases such as asthma is an essential first step. Further work is needed to elucidate the important sites of interaction between the immunological networks of asthma and of virus infection. Greater knowledge is required if we are to identify key targets for therapeutic intervention, the aim of which will be to minimize immunopathology whilst maintaining or enhancing the host anti-viral immune response.

## OVERVIEW

There are substantial differences in the pulmonary response between those with asthma and those with chronic obstructive pulmonary disease (COPD) when exercise is used as a stimulus. For the person with asthma, exercise is a stimulus for bronchodilatation and for bronchoconstriction and the airway response varies according to resting lung function, duration and intensity of exercise, and the temperature and water content of the air inspired. The stimulus for exercise-induced bronchoconstriction (EIB) relates to the thermal and osmotic consequences of water loss by evaporation from the airway surface when large volumes of air need to be conditioned in a short time. For most asthmatics however, EIB can be well controlled with treatment and the emphasis has moved from exercise as a stimulus for provoking attacks of asthma to exercise for the potential benefits to health and lifestyle. For those with COPD, exercise does not usually provide a dehydrating stimulus sufficient to provoke EIB simply because the subjects cannot ventilate at a rate sufficient to achieve significant loss of water from the airway surface. Some people with COPD however do demonstrate the airway hyperresponsiveness of asthma in response to inhaling aerosols of hyperosmolar agents such as saline or mannitol. The more classic response exercise provides to the patient with COPD is dynamic hyperinflation that increases end-expiratory lung volume (EELV) and decreases inspiratory capacity (IC). This strategy serves to reduce expiratory flow limitation and increase tidal volume but at a cost of greater respiratory effort that contributes to exercise limitation. As with treatment of asthma there has been a marked improvement in treatment of COPD in recent years. Although treatment has not allowed patients with COPD to achieve normal exercise performance, as asthmatics have done, exercise has become an important intervention in the management of patients with COPD.

## EXERCISE AND THE PERSON WITH ASTHMA

The cardiopulmonary response to exercise in asthmatics is extremely variable. When expiratory flow rates and airways resistance are normal, at rest and during exercise, the cardiopulmonary response to exercise is not significantly different to healthy subjects [1]. Asthmatics however commonly have a higher ventilatory equivalent (ventilation per unit of oxygen consumption) compared with non-asthmatics although this can normalize following physical training [2]. Asthmatic children with moderate to severe asthma have reduced aerobic capacity, endurance time, and cardiac function [3], particularly at high altitude [4]. Expiratory flow limitation and hyperinflation are likely contributors to the increased work of breathing and shortness of breath in some people with asthma.

Physical inactivity is thought to contribute to the development of "asthma" because bronchial smooth muscle can become stiff and hyperresponsive without the benefit of periodic stretch from the increased tidal volume of exercise [5]. There are many reports of asthmatic children being physically inactive and unfit, particularly those who are obese or overweight, but being unfit is not a universal finding in asthmatic children [1]. Neither body mass index nor baseline lung function predicted exercise limitation in children with asthma [6].

## LUNG FUNCTION AND GAS EXCHANGE DURING AND AFTER EXERCISE

It is the propensity for airway resistance and arterial oxygen tension to change rapidly in response to exercise that is of primary physiological importance to a person with asthma

**FIG. 38.1** Changes in forced expiratory volume during and after exercise. The severity of the response is assessed by the fall in $FEV_1$ after exercise expressed as a percentage of the pre-exercise value. A normal response is usually regarded as a fall less than 10% of baseline. A value less than 10–25% is mild, 25.1–49.9% as moderate, and 50% or more as severe. The values refer to the severity of EIB in those not taking an ICS. In those taking ICS a value greater than 30% would be generally accepted as severe.

([7–9], Figs 38.1 and 38.2). There are three phases of changes in the airway resistance (Raw) to exercise. During exercise of variable intensity, Raw decreases when exercise intensity is increased and increases when exercise intensity is reduced [10]. During intense steady-state exercise there is an early phase in which Raw falls rapidly. This is not due to release of nitric oxide or due to prostaglandins (PGs) [11, 12] but maybe due to tidal volume stretch reducing bronchial smooth muscle tone [13]. This early fall in Raw during exercise is followed by a slow and progressive rise in Raw after the first few minutes, then on the cessation of 6–8 min of vigorous exercise there is a marked increase in Raw. It is common for the increase in Raw to be associated with a fall in peak expiratory flow (PEF) or $FEV_1$ from pre-exercise level of 10% or more within the first 5 min. The terms commonly used to describe these changes in lung function following exercise are EIB or exercise-induced asthma (Fig. 38.1).

In "untrained" asthmatics with moderate airflow limitation at rest (% predicted $FEV_1 > 75\%$), the fall in Raw or bronchodilatation of the first few minutes of exercise is associated with an increase in arterial oxygen tension ($PaO_2$) [7, 8, 14] (Fig. 38.2). After exercise ceases the $PaO_2$ falls in concert with the reduction in lung function and as a result of ventilation–perfusion inequality [7, 15, 16]. Carbon dioxide levels in asthmatics usually, but not always, remain within normal limits (<40 mmHg) both during exercise and after exercise [8, 15]. Recovery to pre-exercise lung function occurs spontaneously over 30–60 min, or usually within 10 min in response to a bronchodilator, with $PaO_2$ increasing with the improvement in lung function. The lung function and gas exchange changes

**FIG. 38.2** Mean values for PEF expresses as a percentage of predicted, arterial oxygen tension ($PaO_2$ mmHg), arterial saturation ($SaO_2$ %), arterial carbon dioxide tension ($PaCO_2$ mmHg), pH, and base excess (BE) at baseline, during, and after exercise after placebo (broken line) and 70 min later after pre-medication with terbutaline sulfate (1250 μg – 20 min after exercise, and another 1250 μg – 50 min later). The time between exercise tests was 90 min. The data are from the study of Ref. [8].

associated with EIB can sometimes be extreme, and deaths in young athletes, though uncommon, have been reported [17].

Differences from this classic pattern of gas exchange described above have been reported in some "trained" asthmatics with good lung function (i.e. $FEV_1$ 94% predicted) exercising at higher workloads for longer periods than 8 min. In one study, 8 of 21 asthmatic subjects were unable to sustain their $SaO_2$ above 94% during 11 min of strenuous treadmill exercise ($VO_2$ maximum range from 39.9 to 61.8 ml/min/kg). The low $SaO_2$ was attributed to a widened alveolar-arterial oxygen gradient ($A-aO_2$) and ventilatory insufficiency that resulted in a significant increase in $PaCO_2$ in some subjects [9]. It was not possible to predict from pre-exercise lung function or blood gases which asthmatic subject would desaturate in response to exercise. In these "trained" asthmatics, who were not taking inhaled corticosteroids (ICS), the arterial hypoxemia, expiratory flow limitation, and dynamic hyperinflation during exercise occurred at lower metabolic rates than would be sometimes documented in highly "trained" healthy subjects [9]. The findings have significant implications for untreated asthmatics wishing to participate in competitive high endurance sports and support the policy that athletes with asthma would benefit from having objective tests [18].

## PHYSICAL TRAINING AND EIB

The aim of exercise training in an asthmatic who is "unfit" is to increase the exercise intensity and thus the threshold of ventilation that will provoke EIB [2]. Exercise training in an unfit asthmatic results in an increase in maximum oxygen uptake per kilogram and a reduction in ventilatory equivalent and a modest improvement in maximum heart rate [19]. Since ventilation determines severity of EIB for an individual, physical fitness should be encouraged, and at an early age.

It is important to know fitness does not eliminate potential for EIB [20], but becoming fit will increase the workload to provoke EIB. Physical training does not improve any parameters of lung function including PEF, $FEV_1$, FVC, or maximum ventilation [19]. It is for this reason that treatment of the airway inflammation is recommended so that an asthmatic has the best opportunity to perform normally at any level of competition [21].

## FACTORS WITH POTENTIAL TO INFLUENCE THE ASTHMATIC RESPONSE TO EXERCISE

There are many endogenous factors that have the potential to impact on the airway response to exercise in asthmatics. These include severity of the underlying airway inflammation, the associated bronchial smooth muscle responsiveness and increased vascular permeability, the degree of atopy, and the pre-exercise lung function in relation to predicted normal. Other factors include age and fitness of the subject, and body mass index, particularly for its potential to impact on functional residual capacity.

The intervention that has the greatest influence on these factors is the medication being taken by the asthmatic subject, either daily as with ICS, long acting $\beta_2$-agonist (LABA), or leukotriene receptor antagonists (LTRA), or prophylactically before exercise as with short acting $\beta_2$ agonists (SABA), sodium cromoglycate (SCG), or nedocromil sodium [8, 22–26]. Treatment of airway inflammation and prevention of bronchoconstriction during and after exercise can lead to improved gas exchange (Fig. 38.2) and normal exercise performance [8]. Diets that include reduction in sodium intake [27], and supplementation with omega 3 free fatty acids [28] have been reported to reduce severity of EIB but their effect on gas exchange has not been reported.

Many young people with self-reported exercise symptoms are diagnosed clinically as having EIB but fail to demonstrate EIB on objective testing and may thus be over treated [29, 30]. In contrast, many young fit and clinically "well controlled" asthmatics with normal lung function can have a significant reduction in lung function and gas exchange abnormalities after exercise. Some may have become tolerant to the protective effects of $\beta_2$-agonists [23], and others may be receiving too low a dose of inhaled steroids [25] (Fig. 38.3). These are reasons why exercise is and should remain a concern for people with asthma.

## DETERMINANTS OF EIB

The most important external determinants of the severity of the airway response to exercise in asthmatics are the level

**FIG. 38.3** Maximum percent fall in $FEV_1$ from baseline after 8 min of running exercise breathing dry air exercise in two groups of young adults with repeatable EIB, that is, 15% or more fall in $FEV_1$ at baseline. The fall is shown at baseline and after treatment with an ICS in a dose of 40 and 160 μg in one group and 80 and 320 μg in another for a duration of 1, 2, and 3 weeks. Reproduced from the study of Ref. [25].

of ventilation reached and sustained during exercise and the water content of the inspired air [31]. Thus exercise load is very important [32]. Whilst temperature of the air inspired during exercise can influence severity of EIB, it is of less importance than the absolute water content. Inspiring air close to body temperature and fully saturated with water prevents EIB.

That hyperpnea of dry air at high ventilation rates is required to provoke EIB suggests that severity of EIB depends on the rate at which generations of airways are recruited into the air conditioning process [33]. This concept explains why, for an individual, EIB occurs more often and more severely the drier and cooler the inspired air and the more rapid the increase in ventilation. It may also explain why EIB may be reported for the first time in athletes when they have reached their full ventilatory capacity in their early twenties and can achieve ventilation rates of 100l/min or more [34]. It also explains why patients with COPD are unlikely to have EIB provoked by exercise, that is, they cannot reach high enough ventilation during exercise.

At the very high ventilation chronically achieved by cross-country skiers, rowers, and cyclists, a large surface area of airways including very small airways (<1 mm in diameter) will be used to condition the air. If very small airways become dehydrated and sustain injury then the restorative process of plasma exudation [35] that follows may explain pathogenesis of EIB [34]. If exposure to plasma-derived products occurs regularly then the contractile properties of the bronchial smooth muscle may be altered over time [36]. In allergic

subjects repeated exposure to plasma may induce passive sensitization of the bronchial smooth muscle *in vivo* [34], increasing its sensitivity to mast cell mediators [37]. In healthy subjects mast cells are more abundant in the smaller airways compared with the larger airway [38]. Thus they are well positioned to release histamine and other mediators that increase the plasma exudation from post-capillary venules.

## STIMULUS AND MECHANISM OF EIB

The stimulus for exercise to provoke the airways of asthmatics to narrow is the loss of water from the airway surface that occurs in conditioning large volumes of air in a short time (Fig. 38.4). That is why EIB occurs more often when the exercise is intense [32, 39] and performed in a dry environment [40]. It is also the reason that eucapnic voluntary hyperpnea of dry air (EVH) is an excellent surrogate for exercise to provoke EIB [41]. The mechanism whereby the loss of water causes airway narrowing relates to the thermal (cooling) and osmotic consequences of dehydration of the airway surface and the underlying mucosa [42].

The thermal hypothesis proposes that EIB is a vascular event. Thus cooling of the airway surface from conditioning inspired air causes vasoconstriction of the bronchial vessels and a reactive hyperemia follows immediately after

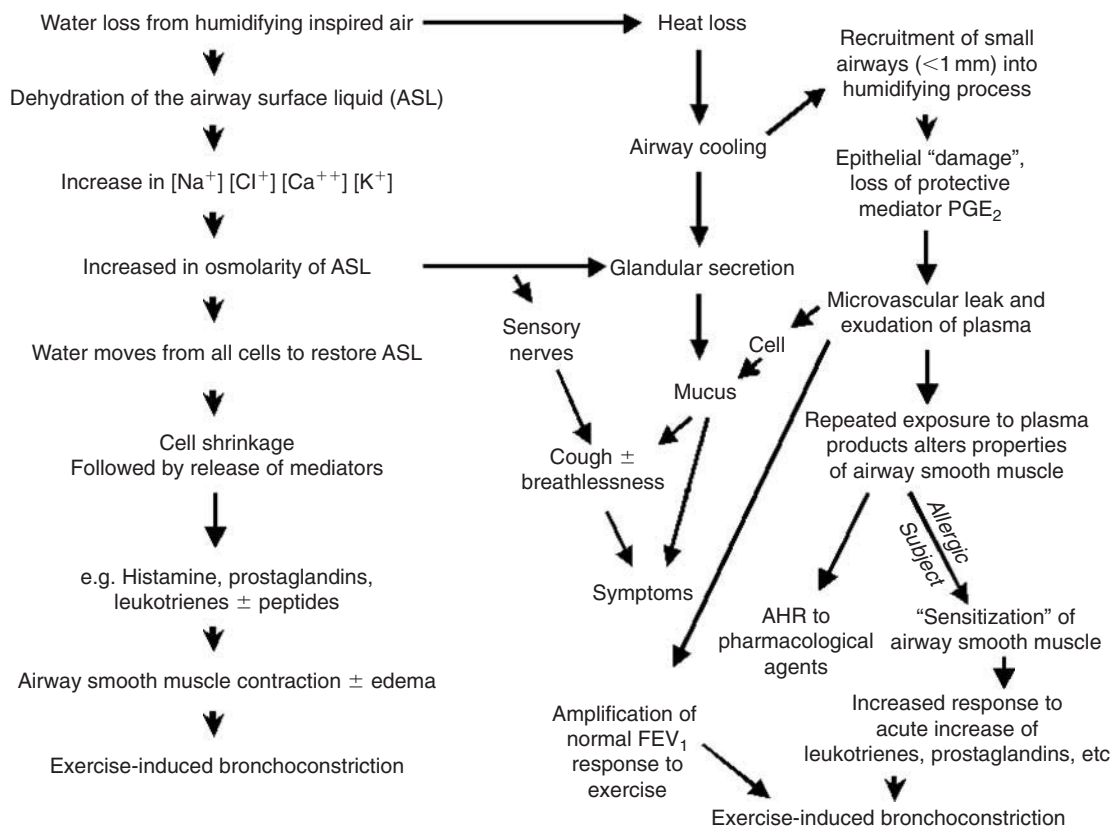

**FIG. 38.4** The events that lead to EIB in people with asthma and events proposed to contribute to the pathogenesis of EIB and airway hyperresponsiveness in people exercising strenuously. Reproduced from Ref. [34].

exercise when ventilation falls and the airways re-warm rapidly [43]. The mechanical events of vascular engorgement, amplified by edema, serve to narrow the airways.

The osmotic hypothesis of EIB proposes that a transient increase in osmolarity of the airway surface liquid occurs in response to evaporative water loss, and that the cooler and drier the air inspired the greater the surface area that will become dehydrated and hyperosmotic [31, 44]. It is the hyperosmolarity of the airway surface liquid and the underlying mucosa that provides the appropriate microenvironment for release of mediators [45, 46]. In contrast to the thermal hypothesis, the osmotic hypothesis proposes airway

narrowing occurs as a result of the contraction of bronchial smooth muscle by mediators [31]. The same mediators may increase vascular permeability and exudation of plasma, an event that would serve to normalize osmolarity.

Healthy subjects have the same burden to condition the air inspired during exercise as asthmatics. That water replacement to the airway surface is compromised at a high ventilation (at least for the first 5–6 min) in both healthy and asthmatic subjects has been demonstrated by an acute reduction in mucociliary clearance during hyperpnea of dry, but not warm humid air ([47], Fig. 38.5).

The difference in the lung function response to exercise between healthy subjects and asthmatic subjects is likely due to the bronchial smooth muscle of asthmatics being hyperresponsive and having a greater abundance of mast cells and their mediators close by [48]. Thus treatment that reduces the source (e.g. ICS), or production (fish oil diet), of mediators or their release ($\beta_2$-agonists, SCG, nedocromil sodium), or their contractile action on smooth muscle ($\beta_2$-agonists, leukotriene antagonists, histamine antagonists), are effective in inhibiting or preventing EIB [22-28] (Fig. 38.6).

**FIG. 38.5** Mean values for the percentage (%) mucociliary clearance of a radionuclide from the airways at baseline and following 6 min of hyperpnea in asthmatic and healthy subjects. Hyperpnea with dry air but not humid air caused a significant reduction in mean mucociliary clearance in the asthmatics suggesting the loss of water from the airway surface exceeded the rate of replacement and dehydration occurred. Redrawn data from Ref. [47].

## OPTIMIZING PROTOCOLS TO IDENTIFY EIB

The benefit of optimizing an exercise protocol as a provocative stimulus for inducing an attack of asthma is that it provides a simple and inexpensive method to monitor treatment of asthma and can be utilized by both the patient and their doctor [49].

An exercise load that increases heart rate to 95% predicted maximum [32], and ventilation to $>17.5 \times FEV_1$ in l/min within a few minutes, and one that can be sustained for at least 6–8 min whilst breathing dry air, is more likely to provoke EIB than protocols using a lower intensity of

**FIG. 38.6** Schematic diagram of the mast cell showing the stimulus for the release of mediators such as prostaglandin $D_2$ ($PGD_2$), histamine and $LTC_4$ and the mode of action of various pharmaceutical agents in preventing or inhibiting EIB.

**TABLE 38.1**  Challenge tests that can be used as a surrogate for exercise to identify EIB.

The surrogate stimuli (eucapnic voluntary hyperpnea with dry air, hyperosmolar aerosols of salt or mannitol) are easy to perform.

- These stimuli can be easily repeated for monitoring the response to treatment.
- These stimuli are more potent than exercise so false negative results are less likely.
- Some tests (e.g. mannitol) are portable and provide a common operating standard and can be performed at the point of care.
- Less expensive in manpower than field testing.

exercise for a longer duration [50]. There are, however, difficulties in achieving optimal conditions to provoke EIB, particularly in fit young adults with normal lung function. For this reason many laboratories have abandoned exercise in preference to using EVH or other surrogates to identify EIB (Table 38.1).

The protocol for EVH requires the subject to ventilate dry air containing 5% $CO_2$ for 6 min [51]. An "untrained" person can easily hyperventilate at $21 \times FEV_1$ l/min for 6 min without respiratory muscle fatigue and a "trained subject" can usually achieve and maintain a ventilation of $30 \times FEV_1$ l/min [52].

Other surrogates used to identify EIB include inhalation of aerosols of 4.5% saline or dry powder mannitol that increase osmolarity and cause release of mediators [53–56]. Some patients with COPD have been shown to have asthmatic responses to hyperosmolar agents [57, 58] even though they occasionally asthmatic responses to dry air challenge [59].

## REFRACTORINESS TO THE BRONCHO-CONSTRICTING EFFECTS OF EXERCISE

Protocols that use a progressive increase in workload (e.g. 10 or 20 W increments each minute) to maximum working capacity are inappropriate to identify EIB likely due to refractoriness developing at the lower workloads. This was recognized many years ago when these protocols became popular in laboratories for assessing both heart disease and lung disease in children and adults. Similarly submaximal exercise for 20 min [60], or multiple warm up sprints of 30 s duration [61], induce refractoriness to an optimal stimulus. Even when an optimal stimulus is used to provoke EIB, 50% of subjects become refractory for about 2 h [62]. Refractoriness also develops to the effects of EVH when ventilation is increased progressively [63] so single stage protocols are recommended [51].

Prostaglandins and leukotrienes (LTs) are thought to be important in protecting the airways and for inducing a state of refractoriness [64]. The evidence for this is the absence of refractoriness following treatment for a few days with clinically recommended doses of non-steroidal anti-inflammatory agents, such as indomethacin [65]. The role of these mediators

might be to increase the rate of return of water to the airway surface, probably by increasing bronchial blood flow. In this way the osmotic threshold for mediator release from mast cells may not be reached either during warm up exercise or later when an optimal exercise stimulus is used. The capacity of the epithelium to produce and release protective mediators may also be related to the extent to which the epithelium is injured in response to the hyperpnea of dry air [66]. It is also likely that the increase in tidal volume causes stretch on the bronchial smooth muscle reducing the "latch state" and making it less responsive to a subsequent stimulus [13].

## INFLAMMATORY MARKERS AND EXERCISE AND EIB

Exercise can enhance transcription of two genes coding for 5-lipoxygenase (ALOX5) and ALOX5-activating protein leading to increased levels of $LTB_4$ and leukotriene $C_4$ ($LTC_4$) in plasma [67]. Leukotrienes sustain bronchoconstriction following exercise in asthmatics [68] and they may contribute to EIB in elite athletes [34]. A mast cell-derived mediator of importance in EIB is prostaglandin $D_2$ ($PGD_2$), usually reported as its metabolite $9\alpha$, $11\beta\text{-}PGF_2$ [69]. Histamine is a less potent mediator of EIB, but unlike the PGs and LTs it is preformed in mast cells and thus is likely to contribute to the reduction in lung function that occurs immediately after exercise [9, 70]. It is however, the LTs and PGDs that sustain the fall in lung function after exercise and this is the reason that antihistamines are not useful as a single therapy for controlling EIB in most asthmatics [71].

The role of neuropeptides in EIB has not been well studied although the data are supportive and fluctuations in osmolarity of the airway surface could stimulate their release [72]. Recent data suggest an association between increase in neurokinin A levels in induced sputum and cysteinyl LTs in sputum following exercise in subjects with EIB [73].

Eosinophils are a potential source of LTs and increased numbers in sputum [74] and blood [75] are associated with presence of EIB independently of the presence of atopy. An acute increase in the percentage of eosinophils has been reported after exercise [76, 77].

The percentage of columnar epithelial cells in sputum relates to severity of EIB [66], and the concentration of these cells is higher in asthmatic subjects with EIB compared with asthmatics without EIB [78].

The severity of EIB is related to the degree of atopy. This is unsurprising in that atopy is an indirect marker of IgE on mast cells and it is the mediators from these cells that are implicated in EIB. The presence of IgE on mast cells renders them less stable to hyperosmotic stress [45].

The severity of EIB is also related to concentration of expired nitric oxide (eNO) although this appears to be true only for atopic subjects and thus may be an epiphenomenon [79]. A value for eNO $\leq 25$ ppb has a negative predictive value of 100% for EIB but a positive predictive value of only 28% [80]. Severity of EIB is related to markers of vascular permeability and vascular endothelial growth factor [81].

## EXERCISE AND THE PERSON WITH COPD

COPD is characterized by airway inflammation and air-flow limitation that is not fully reversible. Despite optimal medical management, people with COPD have significant abnormalities in exercise capacity and ability to participate in everyday life. Often, the presenting symptom is breathlessness on exertion. Breathlessness during activity is evident in everyday life and varies with disease severity, with those with mild disease only experiencing breathlessness at high levels of exertion, whereas those with moderate to severe COPD becoming breathless during everyday tasks. In terms of the World Health Organization descriptors [82], the "impairments" (i.e. the physiological and anatomical changes) resulting from COPD lead to "activity limitation" (inability to perform daily tasks or activities), and "participation restriction" (inability to contribute fully in societal roles such as work and recreation).

The impairments that lead to exercise intolerance and activity limitation are related to the effects of COPD on the ventilatory, cardiovascular, and muscular systems.

### Ventilatory limitations to exercise

#### Flow limitation and altered mechanics of breathing

The increased airway resistance and expiratory flow limitation that occurs in COPD results in hyperinflation at rest. This alters the length–tension relationship of the respiratory muscles (i.e. muscles are in a more shortened position) which places them at a mechanical disadvantage. During exercise, ventilation increases (via increases in tidal volume and inspiratory and expiratory flow rates) to meet the metabolic demands. The need for increased flow rates in the presence of expiratory flow limitation results in further hyperinflation during exercise (i.e. dynamic hyperinflation) which is measured as a decrease in IC, the corollary of which is an increase in end-expiratory lung volume EELV (Fig. 38.7). Such dynamic hyperinflation further impacts on respiratory muscle length–tension relationships as well as limiting the tidal volume response to exercise, resulting in a greater respiratory effort to achieve a given tidal volume ($V_T$) (Fig. 38.8).

At low levels of exercise, dynamic hyperinflation may enable higher flow rates and greater tidal volume than would have been possible without dynamic hyperinflation, allowing exercise to continue. With increasing intensity of exercise the inability to further increase ventilation due to expiratory flow constraints becomes a limiting factor. A measure of this ventilatory limitation is the ratio of peak exercise ventilation to maximum voluntary ventilation ($V_E$/MVV). A $V_E$/MVV ratio above 0.9, while heart rate and other physiological functions are below maximal capacity, suggests severe ventilatory constraints to exercise [83]. However, since the estimate of MVV is usually obtained from resting measures this approach to the determination of ventilatory limitation may be imprecise.

Altered mechanics of breathing in COPD may also impact on the capacity for arm exercise, especially in those

**FIG. 38.7** Tidal flow-volume loops at rest and at peak exercise in COPD. Dynamic hyperinflation is evident by the shift of the exercise flow-volume loop towards TLC. The reduction in IC indicates an increase in EELV.

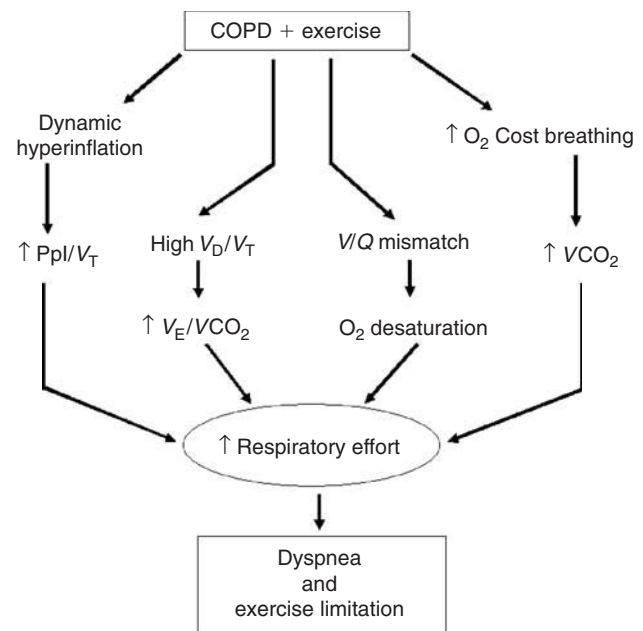

**FIG. 38.8** Ventilatory factors leading to dyspnea and exercise limitation in COPD. Ppl: pleural pressure as a measure of inspiratory effort; $V_T$: tidal volume; $V$CO₂: carbon dioxide production; O₂: oxygen; V/Q: ventilation/perfusion; $V_E$: ventilation; $V_D$: dead space.

with severe hyperinflation. Arm elevation reduces the ability of the accessory muscles to contribute to breathing due to involvement in the arm task [84]. This shifts more of the respiratory work to the diaphragm which is already shortened due to hyperinflation, and thus is less effective in

responding to the added respiratory load. Dynamic hyperinflation during arm exercise [85–87] and a higher EELV with arms elevated [86] may also contribute to exercise limitation, although this has not been examined in detail.

### Increased work of breathing

Compared to the healthy population, respiratory muscle work during exercise is greater in people with COPD to overcome the increased airway resistance. In addition, due to dynamic hyperinflation, elastic work increases as tidal volume ($V_T$) nears total lung capacity (TLC). It has been shown that the oxygen consumption of the respiratory system in COPD during exercise may be 35–40% of total body oxygen consumption ($\dot{V}O_2$) [88]. Such a large oxygen demand by the respiratory muscles may lead to a higher carbon dioxide production ($\dot{V}CO_2$) for a given level of lower limb exercise, further increasing ventilation, as well as possible diversion of blood flow from the lower limb muscles to meet respiratory muscle requirements. Indirect evidence for blood flow diversion comes from studies in healthy subjects [89] and in COPD [90].

### Gas exchange abnormalities

Gas exchange abnormalities arise from alveolar and capillary bed destruction leading to increased physiological dead space (i.e. a high dead space to tidal volume ratio ($V_D/V_T$) and ventilation–perfusion ($V/Q$) mismatch. The high $V_D/V_T$ means that there is an increased requirement for ventilation for a given level of $\dot{V}CO_2$, while the $V/Q$ mismatch results in oxygen desaturation which may further increase ventilatory demand [83]. An added consequence of hypoxia is increased ventilatory drive resulting from early onset of lactic acidosis.

The above anatomical and physiological changes (i.e. the impairments) in the ventilatory system that result in dyspnea and exercise limitation are depicted in Fig. 38.8.

### Cardiovascular constraints to exercise

Besides ventilatory constraints to exercise, people with COPD commonly have coexisting cardiovascular constraints. Cardiac output may be reduced due to a reduction in right ventricular stroke volume related to (1) increased pulmonary vascular resistance from hypoxic vasoconstriction and/or loss of capillary bed and vascular restructuring; (2) a reduction in right heart pre-load from decreased venous return consequent to hyperinflation [91]. Such reductions in cardiac output may limit blood supply, and thus oxygen availability, to the exercising muscles, with consequent early onset of lactic acidosis [92] adding to the constraints to exercise in COPD.

### Skeletal muscle dysfunction and exercise

Skeletal muscle dysfunction in COPD may occur as a consequence of deconditioning related to inactivity caused by exertional dyspnea. In approximately 40% of patients with COPD the main symptom limiting exercise is leg fatigue. Besides deconditioning, other factors such as malnutrition, skeletal muscle myopathy, low levels of anabolic hormones, systemic inflammation, corticosteroid use, aging, and

hypoxia may contribute to skeletal muscle dysfunction [93]. The physiological abnormalities evident in skeletal muscle of people with COPD are reduced oxidative enzyme capacity [94], reduced muscle fiber capillarization [95], atrophy of Type I [96] and Type IIa muscle fibers. Combined, these abnormalities result in lactic acidosis at lower levels of exercise and a reduced exercise endurance capacity compared to healthy people [97, 98]. Muscle mass and strength are also reduced in people with COPD. Importantly, some of these abnormalities can be partially reversed by exercise training.

Interestingly, skeletal muscle dysfunction is less evident in arm muscles compared to leg muscles in COPD [99] and therefore limitation of upper limb exercise capacity is more likely due to alterations in mechanics of breathing, described previously, than to skeletal muscle dysfunction. Maintenance of arm skeletal muscle function has been attributed to the requirements to continue performing upper limb tasks for daily functional activities, while lower limb activity can be more easily reduced, leading to deconditioning. However, further research is required to validate this.

## INTERVENTIONS TO IMPROVE EXERCISE CAPACITY IN COPD

Interventions that can either decrease ventilatory demand or that can increase ventilatory capacity may improve the ability of people with COPD to exercise.

### Interventions that reduce ventilatory demand

#### Exercise training

Lower limb endurance exercise training is effective in improving exercise capacity and quality of life and reducing exertional dyspnea in people with COPD [100], largely due to physiological changes that decrease ventilatory demand at a given level of exercise. These physiological changes include increases in muscle fiber capillarization [101], mitochondrial density, and muscle oxidative/metabolic capacity [102–104]. Such training adaptations improve the aerobic capacity of the muscle, delaying the onset of lactic acidosis and, as such, reduce the ventilatory requirements for exercise at equivalent pretraining work rates [92]. This is reflected in the ability of people with COPD to perform equivalent work rates for longer after training as well as achieving higher peak work rates [92] and translates into a reduction in "activity limitation" and "participation restriction" and improved quality of life.

The endurance exercise prescription in terms of the mode of training (cycle, treadmill, etc.) the intensity (high or low), duration of a training session, frequency of training, and the length of the program has generated a great deal of research, much of which is outlined in the major recent guidelines of on Pulmonary Rehabilitation [105–109] and Chapter 58. Information on the practical application of exercise training in COPD patients can be accessed through the Pulmonary Rehabilitation Toolkit (http://www.pulmonaryrehab.com.au).

It should be noted that while exercise training is considered the key component to achieve changes in exercise capacity and quality of life, exercise training often occurs as part of a comprehensive pulmonary rehabilitation program which includes education, anxiety and dyspnea management, smoking cessation support, and nutritional advice. These additional components of pulmonary rehabilitation may enhance the outcomes of training regimen.

In addition to lower limb training, endurance training of the upper limb using either supported arm exercise (arm cranking) or unsupported arm exercise (free weights) has been shown to reduce ventilatory demand and improve arm exercise capacity [110, 111]. Such improvements are task specific [112], therefore exercise mimicking daily activities, which are mostly unsupported arm tasks, are recommended for inclusion in exercise training programs [108, 109].

### Supplemental oxygen

During exercise gas exchange abnormalities result is oxygen desaturation in COPD patients with severe disease, with consequent increases in ventilation (through earlier production of lactate) and higher dyspnea levels [83]. Acute oxygen supplementation during exercise in COPD reduces ventilatory demand for an equivalent work rate as well as reducing EELV [113] and exercise-induced pulmonary hypertension [114], and improving leg blood flow [90]. All these factors contribute to an increased exercise capacity and reduced dyspnea. However, no significant relationship has been found between exercise desaturation on room air and improvement in exercise capacity with supplemental oxygen [114, 115], suggesting that responses to oxygen supplementation need to be assessed on an individual basis.

The effect of oxygen supplementation during exercise training in COPD subjects who desaturate during exercise has been equivocal, with most studies showing no greater improvement in exercise capacity compared with exercise training on room air [109]. However, one study of oxygen supplementation during exercise training in nonhypoxaemic COPD subjects, demonstrated significantly greater improvements in endurance exercise time in the oxygen trained group, most likely related to the higher training intensities achieved [116]. Further studies are required to validate the effectiveness of similar exercise training protocols using supplemental oxygen in COPD subjects who desaturate during exercise.

### Strength training

Although strength training does not results in reduced ventilatory demand per se it had been included in this section, since the short bouts of this form of exercise induce lower ventilatory demand and dyspnea compared to endurance training and are usually well tolerated by people with COPD [117].

Reductions in skeletal muscle strength are evident in people with COPD and may affect their ability to perform functional activities as well as increase the risk of falls; however, the latter has not been specifically studied in the COPD population. Whether improvements in muscle strength gained by resistance training programs [118] translate into improved exercise capacity is not clear. Significant improvements in cycle endurance capacity were demonstrated in studies comparing strength training with no intervention

[119, 120]. However, the gains in endurance capacity from strength training were small compared to those that could be elicited from endurance training [119, 120].

## Interventions that increase ventilatory capacity

### Bronchodilator therapy

In general, lung function is poorly correlated with exercise capacity in COPD. However, as one of the main factors limiting exercise in COPD is expiratory flow limitation, medications such as inhaled anticholinergic and $\beta_2$-sympathomimetic agents, that reduce airway resistance, may improve exercise capacity in COPD. Bronchodilator medication delivered prior to exercise has been shown to decrease resting hyperinflation and dynamic hyperinflation during exercise, which correlated strongly with improved exercise capacity in severe COPD despite minimal change in spirometry [121]. A recent study of bronchodilator therapy prior to exercise combined with supplemental oxygen during exercise has shown an additive effect on exercise endurance, due to the combined physiological effects of reduced hyperinflation and reduced ventilatory drive [122].

### Non-invasive ventilation

In people with severe COPD, positive pressure non-invasive ventilation reduces respiratory muscle load and prolongs the tolerance to lactic acid accumulation resulting in a reduction in dyspnea and improved exercise duration [123]. Exercise training using non-invasive ventilation in such patient groups, especially those with a ventilatory limitation to exercise, enabled higher training intensities to be achieved resulting in a reduction in lactate at equivalent workloads and greater improvements in exercise capacity in the intervention group [124–126]. The clinical significance of this form of intervention in terms of improvements in functional capacity and quality of life, as well as the cost-effectiveness has yet to be determined.

### Lung volume reduction surgery

Lung volume reduction surgery (LVRS), the removal of areas of emphysematous lung tissue, increases static lung recoil, thus reducing flow limitation and dynamic hyperinflation [127]. Combined with post-operative exercise training, LVRS improved exercise capacity for both lower limbs [128] and upper limbs [129]. The improvements in exercise capacity were additional to those gained from pre-surgery exercise training. LVRS is mostly effective in selected patients with upper-lobe emphysema and persistent low exercise capacity after an exercise training program.

### Body positioning

The lean forward position with shoulder girdle fixation is often adopted by people with COPD when breathless. Leaning forward has been shown to reduce accessory muscle activity, increase transdiaphragmatic pressure, increase maximum inspiratory pressures, and reduce dyspnea at rest in COPD subjects with severe disease [130, 131], presumably by

increased abdominal pressure improving the length–tension relationship of the diaphragm in people who are hyperinflated. Shoulder girdle fixation allows the accessory muscles to function with reverse origin and insertion (i.e. rather than acting to move the arm on a fixed torso these muscles can act to move the ribs in an inspiratory direction). Shoulder girdle fixation has been shown to improve MVV, potentially reducing the ventilatory constraint to exercise [132]. Some evidence that the lean forward position with shoulder fixation can enhance exercise capacity in people with COPD comes from studies of rollator walking which have shown improved functional exercise capacity and a reduction in dyspnea [132, 133].

### Breathing strategies

Pursed-lip breathing is another strategy adopted spontaneously by people with severe COPD to prolong active expiration and limit airway collapse. Pursed-lip breathing at rest has been shown to reduce EELV [134] which could potentially increase ventilatory capacity. However, volitional pursed-lip breathing during exercise has not been shown to increase exercise capacity in people with COPD [135]. The variable response to volitional pursed-lip breathing during exercise suggests that benefit may only occur in those who spontaneously adopt pursed-lip breathing.

### Respiratory muscle training

Respiratory muscle weakness is evident in a subgroup of people with COPD. The impact of inspiratory muscle weakness on exercise capacity is unclear and may only be important if such weakness reduces ventilatory capacity such that it is a factor limiting exercise. Improvements in exercise capacity gained with inspiratory muscle training are significantly less than those gained with lower limb endurance training [136]. However, a number of studies have shown that the addition of inspiratory muscle training to a lower limb training program improved functional exercise capacity above that gained from lower limb training alone [137, 138]. Inspiratory muscle training for people with COPD may only be of benefit in those with suspected or proven respiratory muscle weakness [108] and current guidelines do not support routine inclusion of this type of training for people with COPD [109].

# Atmospheric Pollutants

**Jon Ayres**

Department of Environmental and
Occupational Medicine, Liberty Safe
Work Research Centre, University of
Aberdeen, Aberdeen, UK

In the 1940s and 1950s, air pollution was a fact of life in industrialized cities, but the true extent of its health risks was not appreciated until the London Fog Incident of 1952 [1], which caused 4000 excess deaths largely from cardiac disease, bronchitis, or pneumonia. At the time, it was believed that the combination of particles and $SO_2$ was the cause of such effects, but subsequent reanalysis of these historical data suggested that the acidity of the aerosol could have been the major contributor to mortality [2]. As the Clean Air Act of 1956 began to reduce black smoke levels, day-to-day changes in pollution had progressively less impact on symptoms in chronic bronchitis [3] and the advice given to Government was that air pollution would never again represent a risk to human health, even though studies of urban compared with rural areas showed a higher prevalence of productive cough in urban areas [4]. However, by the late 1970s such reassurance was being questioned as vehicle-generated air pollution was being shown to impact on human health.

## CURRENT POLLUTANT EXPOSURES

The air pollutants relevant to asthma and chronic obstructive pulmonary disease (COPD) are:

- sulfur dioxide ($SO_2$)
- nitrogen dioxide ($NO_2$)
- ozone
- particles

Levels of these pollutants vary worldwide and health-based air quality standards have been produced by many individual countries or agencies (Table 39.1). These give an indication of the levels to which populations are currently exposed, although levels exceeding these are commonplace in large cities. The time frame for these standards varies between pollutants. For example, the UK air quality standard for $SO_2$ is 100 ppb over a 15-min sampling time frame, because of its ability to cause acute bronchoconstriction in asthma, whereas the standard for ozone is based on 8 h, being the timescale in which ozone is formed during sunlight.

## Sources of gaseous pollutants

The main source of $SO_2$ is the burning of fossil fuel in coal-fired power stations, domestic fires, or industrial processes with a variable contribution from sulfur-containing engine fuels. $NO_2$ is largely derived from vehicle emissions, although the highest individual exposures are from gas appliances indoors. Ozone is a secondary pollutant formed by the action of ultraviolet light on components of vehicle exhaust.

## Sources of particulate pollutants

The main sources of particles are vehicle emissions. Particles are often measured by a reflectance method, black smoke (BS) which, while simple and cheap has been superceded by a mass measure of particles either using a high volume filter system or a TEOM (tapered element oscillating microbalance). This produces measures such as $PM_{10}$ (particles broadly <10 μm in diameter) or $PM_{2.5}$ (<2.5 μm in diameter), depending on the size of the air inlet. There is some evidence that at least part of the toxic fraction of particles resides in the ultrafine

**TABLE 39.1** Air quality standards.

| | WHO (2005 revision) | EC | UK |
|---|---|---|---|
| *Sulfur dioxide* | | | |
| 10 min | 500 μg/m³ | | |
| 15 min | – | | 100 ppb (286 μg/m³) |
| 24 h | 125 μg/m³ (interim target 1) 20 μg/m³ (AQS) | | |
| Annual | Now not needed as adherence to the 24-h standard will control annual exposures | 48.8 ppb if smoke >60 μg/m³ | |
| | | 67.5 ppb if smoke <60 μg/m³ | |
| *Nitrogen dioxide* | | | |
| 1 h | 200 μg/m³ | 70.6 ppb (133 μg/m³)[a] | 150 ppb (282 μg/m³) |
| Annual | 40 μg/m³ | 26.2 ppb (49 μg/m³)[b] | |
| *Ozone* | | | |
| 8 h moving average | 100 μg/m³ | 55 ppb (110 μg/m³) | 50 ppb (100 μg/m³) |
| *Particles* | | | |
| 24-h mean | $PM_{10}$ 50 μg/m³ $PM_{2.5}$ 25 μg/m³ | $PM_{10}$ 80 μg/m³ | $PM_{10}$ 50 μg/m³ [c] |
| Annual mean | $PM_{10}$ 20 μg/m³ $PM_{2.5}$ 10 μg/m³ | | |

EC: European Community; UK: United Kingdom; WHO: World Health Organization.

fraction (<100 nm). The relevance of the surface chemistry of particles in terms of health effects is now recognized and the need for a measure of particle surface area has arisen. This is difficult, but particle numbers can be used as a surrogate measure, and there is some evidence that this metric relates to health effects.

## Exposures

Exposure of an individual to pollutants is only very crudely estimated by levels obtained from sentinel monitoring sites, which do not take into account indoor levels of pollutants and factors, such as personal activity and preexisting lung disease, which will affect the amount of a given pollutant inhaled.

Particles, once emitted, agglomerate to produce secondary particles of varying size and shape and undergo chemical reactions depending on the emission source and the atmosphere into which they are emitted. There are marked differences in the deposition of particles by size both regionally in the lung and with respect to the airway level at which deposition occurs. Larger particles (>10 μm in diameter) mostly impact in the upper airways with those in the respirable range (<7.2 μm) penetrating deeper (Fig. 39.1). The belief that ultrafine particles (<1 μm) do not remain in the lung and are simply breathed out again leaving none

in the lung is now not held. Once penetrating to the distal lung, some particles will deposit and will either be taken up by alveolar macrophages or become interstitialized.

Deposition of gases will depend on, amongst other things, gas solubility, minute ventilation, and the presence of airflow obstruction. The endogenous antioxidant systems (largely urate in the nose and glutathione nitrate/nitrite in the lower respiratory tract) will, up to certain concentrations, counteract the proinflammatory effects of oxidant gases (ozone and $NO_2$) thus also altering the exposure of the epithelium to the inhaled gas.

## ASSESSING THE HEALTH EFFECTS OF AIR POLLUTANTS

### Health effects of air pollution

Exposure to air pollutants can result in:

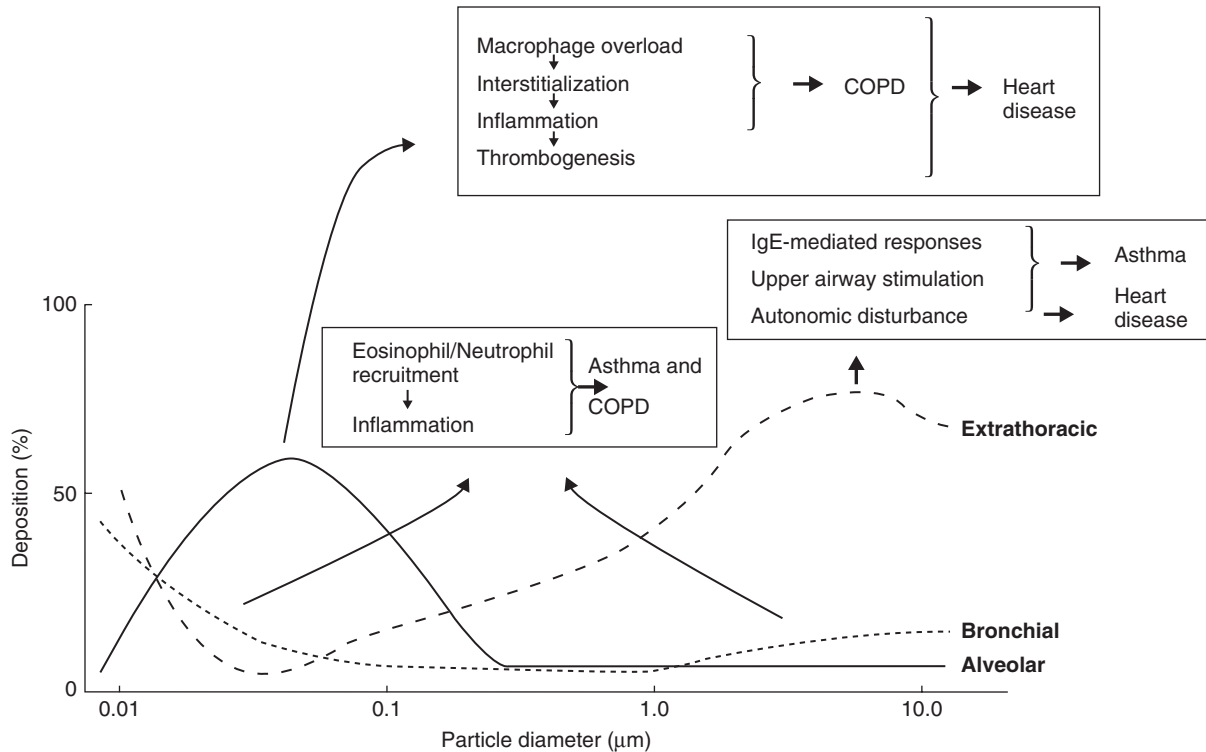
- acute, or day-to-day effects;
- chronic effects;
- latent effects.


**FIG. 39.1** Deposition of particles at various levels of the respiratory tract by particle size and likely mechanisms of health effect.

Acute effects occur in patients with preexisting disease, while chronic effects may impact on patients who are apparently disease-free prior to exposure. The major at-risk groups for acute effects are patients with asthma or COPD, although both deaths and hospital admissions for patients with cardiac disease increase on days of higher particulate levels [5]. While the cardiac effects will not be covered here, the frequent coincidence of coronary heart disease and COPD means that patients with COPD may be affected by air pollution more through their cardiac than their pulmonary disease.

## Methods of assessment of health effects

- Epidemiological studies provided the first evidence of and quantified, to an extent, the adverse health effects of air pollution. Time series studies of routinely collected data (mortality, hospital admissions) and panel studies of putative susceptible groups (asthma, COPD) have provided information across a range of severities.

- Experimental studies in man have relied on controlled laboratory exposure of volunteers (almost exclusively normal subjects or patients with mild asthma) to specific pollutants, on *in vitro* work on cells obtained from nasal or bronchoalveolar lavage (BAL) and studies of cultured cell monolayers.

- Animal studies can be used for the study of more prolonged exposures than is possible with man. Experimental and animal studies both have the benefit of being able to study specific, controlled exposures of single or combined pollutant exposures.

- Computer modeling can predict outcomes providing the specific exposure characteristics of the pollutant(s) and recognized coexposures (e.g. meteorological variables) and host factors (e.g. exercise) are known.

Most health effects of air pollutants are respiratory although in COPD these are limited to mortality and hospital admissions as there are no contemporary panel studies of well-characterized patients with COPD and little human challenge evidence. In asthma, in contrast, there is a substantial body of evidence ranging from hospital admissions to challenge studies.

## Responses to an air pollutant

Individual response to an air pollutant is affected by many factors (Table 39.2). Where possible these need to be allowed for when assessing the effects of a specific pollutant, usually by complex statistical manipulation of the data [6]. The observation of an effect will depend on whether there is a threshold for an effect which will always be present at an individual level but which may be more difficult to determine for populations.

**TABLE 39.2** Factors affecting response to air pollutants.

| | |
|---|---|
| Pollutant | Degree of exposure (concentration)<br>Duration of exposure |
| Coexposure | Other pollutants (both indoor and outdoor)<br>Allergens<br>Viral infections<br>Meteorological conditions (e.g. cold air)<br>Degree of physical activity<br>Cigarette smoke (both active and passive) |
| Host factors | Atopy<br>Age (infants, perhaps the elderly)<br>The fetus<br>Preexisting disease state<br>Use of treatment (e.g. bronchodilators)<br>Airflow obstruction<br>Bronchial hyperresponsiveness |

## CHRONIC EFFECTS OF AIR POLLUTION

The importance of a possible chronic effect of exposure to air pollution is that it brings more members of the population into the subpopulation susceptible to triggering by air pollutant exposure. At present, the evidence for air pollution contributing to the prevalence of both COPD and asthma is not compelling. However, it is generally believed that the chronic effects of air pollution may prove to be, at least in public health terms, more important than the acute effects. A chronic effect can best be identified either from prospective, longitudinal studies such as the US Six Cities Study [7] and the American Cancer Society Study [8], from cross-sectional studies comparing prevalence between areas of differing pollutant exposure or from life-table analysis [9]. All types of study are open to the criticism that early life pollutant exposures could have contributed to later life symptoms and morbidity, but are the best currently available methods for assessing chronic effects.

### Asthma

In some cases, serial cross-sectional studies have provided important insights into changes in respiratory disease in the face of alterations in pollutant exposures. The German pre- and post-reunification studies [10, 11] have demonstrated that, with marked reductions in black smoke and $SO_2$ levels (although no change in $NO_2$ levels) in what was previously East Germany, the prevalence of episodes of bronchitis in children has fallen. Asthma prevalence has, however, remained unchanged at a lower level than in the old West Germany, although both hay fever and eczema have begun to increase. The implications of these findings are still unclear. It is likely that the higher levels of $SO_2$ and black smoke experienced in East Germany before reunification contributed to sputum production and episodes of bronchitis, in parallel with the pattern of symptoms seen in industrialized cities in the Western world up to the 1960s. Whether these exposures

protected the airway against asthmagenic stimuli is debatable. Any such effect may take longer to be expressed than we have had time to observe to date, but the change in hay fever rates does suggest that allergic conditions may be emerging as a result of this differing exposure, although indoor exposures and possible changes in diet may also be playing a part.

The studies of Seventh Day Adventists [12] (a non-smoking population) suggest that chronic exposure to different components of the pollutant mix may result in an increased incidence of new cases of diagnosed asthma over time, but these are isolated findings in an unusual population and it is difficult to extrapolate these findings more widely.

## Chronic obstructive pulmonary disease

The evidence for pollution contributing to the prevalence of COPD is limited to studies from the early 1960s in the United Kingdom [4]. The overwhelming effect of cigarette smoking as the main cause of this condition means that contributions from other environmental exposures to initiation of COPD are difficult to quantify. The recent findings that coal-dust exposure may contribute to chronic productive bronchitis and airflow obstruction independent of cigarette smoke [13] adds some supportive evidence to the possibility that current air pollutant exposure may contribute to the prevalence of COPD, although the character of the particulate exposures is clearly greatly different both in amount and in type. There are more recent data from Germany which suggests that in women living near busy roads, COPD is more prevalent.

## ACUTE EFFECTS OF AIR POLLUTION

### Asthma

#### Panel studies
Panel studies of children with asthma, mostly from North America, have shown small day-to-day changes in peak flow and symptoms [14], the most frequently reported pollutants associated with effects being $NO_2$, ozone, and particles. On average, inhaler use and symptoms increase by around 3% for every $10\,\mu g/m^3$ rise in $PM_{10}$ with a less than 1% fall in peak flow for the same change [14]. However, not all studies show such effects and the PEACE study from Europe was essentially negative [15, 16]. Where they occur, effects are most marked in children either with more preexisting symptoms or who are atopic or both. It is not clear whether greater disease severity predicts greater effects [17]. There is some evidence to suggest that personal exposure to $NO_2$ (most of which is likely to be from indoor sources) may predispose asthmatic subjects to exacerbations in association with respiratory tract infections [18].

#### Hospital admissions
Hospital admissions for asthma have been shown to be related to air pollutant levels on a day-to-day basis both in

adults and in children [19, 20], although not consistently. This may appear to conflict with the small effects seen in the panel studies, although it can be argued that some individuals may be more likely to be admitted on days when other asthmagenic factors combine to produce an attack if they are concurrently exposed to higher levels of pollution.

## Mortality

No relationship has been shown between death from asthma and day-to-day changes in air pollution although the numbers of asthma deaths occurring in a city on a given day are so few that a small effect might yet exist.

## Episodes

Episodes of air pollution might in theory result in asthma deaths or hospitalization. The London smog of 1952 [1] resulted in many deaths from bronchitis, but no clear evidence of an effect in asthma. The more recent 1991 [21] episode in the same city (where the sources of pollutants were quite different) showed no effect on any index of asthma, suggesting that any effect that might have occurred would have been in terms of small changes in symptoms rather than severe attacks.

## Chronic obstructive pulmonary disease

### Panel studies

There is limited information on day-to-day changes in clinical state in patients with COPD. There is some evidence for changes in symptoms in relation to particles and treatment use in relation to $NO_2$ and for changes in lung function [22]. These changes were modest (the lung function change amounted to a 0.2% fall in $FEV_1$ for a $10 \mu g/m^3$ rise in $PM_{10}$) and changes were either same day effects or lagged by 24h.

### Hospital admissions

There is a consistent effect of air pollutant exposure and hospital admissions for COPD from studies across a wide range of countries. In the United States, hospital admissions increase between 1% and 3% for a $10 \mu g/m^3$ rise in $PM_{10}$ [14], while in Europe, the APHEA studies have shown smaller overall effects of around 1% [23, 24]. In most instances particles seem to be the most important pollutant, although the London study [25] showed no effect of particles, but an effect of ozone in the warmer months only. There is a range of effects however, across countries, with effects being less marked in eastern Europe and more marked in western countries (Fig. 39.2).

### Mortality

Deaths from COPD are similarly associated with pollution and the effects are usually most strongly seen at lags of around 3 days [14] mediated largely through particles, although $SO_2$ also appears to contribute in Europe. On average the increase in respiratory mortality for a $10 \mu g/m^3$ rise in $PM_{10}$ is 3.4% on a day-to-day basis [14], although in those parts of Europe where particle exposures are generally higher, this effect is less marked suggesting a tolerance effect [26, 27].

**FIG. 39.2** Relative risks for death by city from respiratory disease for a $50 \mu g/m^3$ rise in black smoke for a range of European cities (the APHEA project [26]).

## MECHANISMS OF THE EFFECTS OF AIR POLLUTANTS

## Mechanisms of damage by particles

Particles are likely to exert health effects via a number of mechanisms. One hypothesis is that macrophages become overloaded allowing particles to penetrate through the alveolar/bronchiolar wall and become interstitialized [28]. This initiates an inflammatory response which could both affect gas exchange in COPD and also release prothrombogenic cytokines, which, in an individual with a compromised coronary circulation, could lead to an acute cardiac event [29]. The inflammation may be caused through release of free radicals, perhaps because of transition metals on the particles [30, 31] although just the very small size of the particles themselves may be responsible [32]. Patients with COPD have a condition which is almost exclusively caused by cigarette smoking and many will thus have coexistent atheromatous coronary disease. It is possible, therefore, that increase in hospital admissions and deaths seen in patients with COPD associated with days of higher air pollution might not simply be due to enhancement of airway inflammation or facilitation of microbial pathogenicity, but due to cardiac decompensation.

There have been few studies of particulate challenge in asthma and none in COPD. One series of freshly generated

diesel challenges in healthy normal subjects [33] has revealed infiltration of inflammatory cells and increases in some proinflammatory cytokines, notably IL-8, albeit at high pollutant concentrations which may be of relevance in both the asthmatic and COPD settings. For asthma, there is also evidence that diesel exhaust can potentiate the local production of specific IgE in the nose with an associated shift in T-cell patterns compatible with this [34, 35].

## Mechanisms of damage by gases

### Sulfur dioxide

$SO_2$ is a highly soluble, irritant gas quickly absorbed by the respiratory tract. It is a potent bronchoconstrictor in asthma particularly with exercise, but there is marked variability in the response between individuals, individuals responding to between 200 ppb and over 1500 ppb [36]. An airway effect is only seen in normal subjects at exposures of 4–5 ppm. In asthma $SO_2$ is thought to activate rapidly adapting receptors (RAR) [37], thus leading directly to bronchoconstriction. Lower doses inhaled at rest (200 ppb) can alter autonomic balance in asthma invoking the possibility that the gas initially activates neurogenic inflammation through a RAR initiated, vagally mediated reflex which subsequently results in an autonomic modulating response which differs from that seen in normal subjects [38].

### Nitrogen dioxide

Nitrogen dioxide is an oxidant gas which at high concentrations can cause acute pulmonary edema (e.g. silo filler's disease). At levels usually experienced in ambient air (15–30 ppb as urban background levels) effects are difficult to find. At high concentrations (1000–3000 ppb usually with exercise) some changes in spirometric indices and bronchial hyperresponsiveness (BHR) have been recorded in asthmatic subjects, but these are of modest degree [39]. At these high concentrations some inflammatory markers are raised in BAL fluid after challenge in normal subjects, although there is considerable inconsistency between studies [40, 41].

At lower exposures (400 ppb) $NO_2$ has been shown to enhance the acute bronchoconstrictor effect of house dust mite allergen exposure, both at high dose [42] or as repeated smaller doses of allergen [43]. This suggests that exposure to gaseous air pollutants may exert more subtle effects than can be identified by epidemiological studies and which consequently may prove very difficult to quantify at a population level. There is no evidence that any such potentiating effects are seen in COPD, for instance with respect to viral infections.

### Ozone

Ozone is a highly reactive, oxidant gas and can cause inflammatory changes in the bronchial mucosa (largely in the terminal bronchioles) in animals at concentrations similar to those which can be experienced in ambient air (80–120 ppb) [41, 44]. With exercise, it can produce similar degrees of bronchoconstriction in both normal and asthmatic subjects although there are large interindividual variations in response

[45]. Ozone can also increase nonspecific airway responsiveness in both normal and asthmatic subjects in a dose-related manner [46]. Repeated daily exposures of asthmatic subjects to ozone lead to progressive loss of the response suggesting tolerance to its effects [47]. Ozone also potentiates the bronchoconstrictor effect of allergen in asthma either alone [48] or in combination with $NO_2$ [49]. The inflammatory response to ozone is very variable. Although most studies have shown an increase in neutrophils in BAL some, but not all, have shown increases in certain adhesion molecules and cytokines (notably IL-8) [41, 50, 51]. There are, however, marked interindividual differences and any changes in airflow so induced do not necessarily match changes in inflammatory markers which are often present at elevated levels some hours after exposure even though the cellular response has settled. There is suggestive evidence that patients with mild COPD exposed to ozone (along with exercise) at 200–300 ppb may show small decrements in both lung function and oxygen saturations although this needs confirmation with adequately powered studies [52, 53].

## SUMMARY

Air pollution can affect some patients with asthma, in terms of symptoms and hospital admissions although the picture varies between countries and perhaps according to severity. There is evidence for all components of the pollutant mix to be capable of playing a role, although the mechanisms are only just being unraveled. For patients with COPD, air pollution increases the risks of hospital admission and death, particles being the most important pollutant. Particles may exacerbate inflammation by generation of free radicals, perhaps through transition metals. Interstitialization of particles at bronchioloalveolar level may exacerbate COPD itself or induce cardiac events by release of prothrombotic cytokines. Figure 39.1 summarizes the possible mechanisms of the health effects of particles in both COPD and asthma.

At present there is no specific approach for dealing with any air pollution-induced changes in clinical state in either asthma or COPD, although increasing inhaled anti-inflammatory treatment makes intuitive sense, while avoiding exertion and other known triggers during periods of higher air pollution may also be sensible.

The overall impact on public health of these triggering events of air pollution on patients with airway diseases is significant although may prove to be swamped by the size of the chronic effects once these are adequately quantified [54, 55].

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

### Introduction

In the early part of the 20th century it was first recognized that aspirin could precipitate asthma in susceptible individuals [1]. Similar asthmatic reactions were later shown to occur with other nonsteroidal anti-inflammatory drugs (NSAIDs) [2] and patients with aspirin-induced asthma were found to be sensitive to other cyclooxygenase (COX)-1 inhibitors. Various terms have been used to describe the sensitivity to NSAIDs, including aspirin-induced asthma, aspirin-sensitive asthma, aspirin hypersensitivity, idiosyncratic reaction to aspirin, aspirin intolerance, and non-allergic hypersensitivity reactions to aspirin and NSAIDs [3].

### Prevalence

The prevalence of hypersensitivity reactions to aspirin and NSAIDs in individuals with asthma is unclear, with estimates ranging from 4.3% to 21% [4–6]. The prevalence figures are higher when determined by oral provocation testing (e.g. 21% in adults and 5% in children [6]). Oral aspirin challenges undertaken in subgroups of patients with asthma, nasal polyps, and chronic sinusitis attending specialized allergy centers provide high positive rates of 30% or greater.

### Clinical features

Aspirin-induced asthma is characterized by the development of bronchoconstriction within minutes to several hours after the ingestion of aspirin or other NSAIDs [2, 3]. The asthmatic reaction can be associated with other symptoms, including rhinorrhea, flushing, and loss of consciousness, and very rarely the attack may be fatal.

In the typical case, symptoms of chronic rhinitis are present for many years before asthma develops. The rhinitis starts as intermittent watery rhinorrhea, which develops during the second or third decade of life. The rhinorrhea becomes progressively more severe and is complicated by nasal polyp formation and sinusitis. On average 2 years later symptoms of asthma appear associated with the development of acute asthma after the ingestion of COX-1 inhibitors. Although in this group drugs may precipitate asthma, these patients continue to have nasal and asthmatic symptoms in the absence of ingesting aspirin or other NSAIDs. Respiratory symptoms are often chronic, severe, and perennial in nature. Individuals with aspirin-induced asthma are more commonly female. Skin tests to common external allergens are positive in a third to over a half of subjects. A small percentage of patients with aspirin-induced asthma also develop associated symptoms of urticaria and angioedema after ingestion of aspirin.

### Diagnosis

In most clinical circumstances, the diagnosis is based on a history of bronchoconstriction following the ingestion of a COX-1 inhibitor. It should be appreciated, however, that a history of either the presence or the absence of aspirin-induced asthma may result in both a false positive and a false negative diagnosis. For example, patients with a history of aspirin-induced asthma have a positive oral aspirin challenge in approximately 60% to over 90% of cases. A negative oral

challenge may occur in patients with a history of aspirin-induced asthma due to changing responsiveness to aspirin, a high threshold to aspirin, or a misleading history.

The only reliable method of establishing a diagnosis of aspirin-induced asthma is by aspirin challenge. Oral aspirin challenge is indicated in patients with adult asthma who require treatment with an NSAID. The oral challenge procedure has been reported to be safe, if a standardized protocol is used [3, 7]. An alternative but less widely used method of detecting aspirin-induced asthma involves administering aspirin-lysine by inhalation [7]. It is claimed that this method is safe and when compared to oral challenge the procedure is shorter and the reaction is localized to the respiratory tract. Aspirin-lysine administered as a nasal challenge has also been used to diagnose aspirin-sensitive asthma and this technique does not induce bronchoconstriction [8]. No *in vitro* test is currently available to detect aspirin-induced asthma.

Tartrazine is a yellow dye used for coloring foods and drugs such as confectionery, soft drinks, antibiotics, and antihistamines. A number of earlier reports suggested that tartrazine caused bronchospasm in some patients with aspirin-induced asthma, but further research has failed to support any cross-reactivity between tartrazine and aspirin in patients with aspirin-induced asthma [9].

## Mechanisms

### Alterations in the arachidonic acid pathway

A characteristic feature of patients with aspirin-induced asthma is the occurrence of airway obstruction following the ingestion of drugs which inhibit COX-1, the enzyme that converts arachidonic acid into prostaglandins (PG) and

thromboxane. An abnormality in the arachidonic acid pathway in the respiratory tract of patients with aspirin-induced asthma seems to be central to the development of an asthmatic attack after the ingestion of NSAIDs (Fig. 40.1). In support of this hypothesis, the severity of bronchoconstriction induced by aspirin or other NSAIDs, such as indomethacin, flufenamic acid, and naproxen, is directly proportional to their ability to inhibit COX *in vitro*. Furthermore, specimens of nasal polyps removed from patients with aspirin-induced asthma are more sensitive to the inhibition effects of aspirin on the COX-1 pathway.

The influence of PG on bronchomotor tone may differ between patients with or without aspirin-induced asthma. The control of airway caliber in the latter group could be more dependent on the effects of PG, such as $PGE_2$, either due to its direct bronchodilator activity or indirectly by suppression of the release of bronchoconstrictor mediators. Alternately, the production of $PGE_2$ may be impaired in these individuals. In support of this later mechanism, peripheral blood mononuclear cells release reduced amounts of $PGE_2$ in patients with aspirin-induced asthma [10], although a recent clinical challenge study with aspirin found that urinary metabolites of $PGE_2$ were not altered in patients with aspirin-induced asthma [11]. The expression of the E-prostanoid (EP) 2 receptor for $PGE_2$ is reduced in nasal tissue of patients with aspirin-induced asthma [12] and polymorphisms in the promoter region of the gene coding for the EP2 gene are associated with sensitivity to aspirin [13].

The lipoxygenase pathway also appears to be abnormal in these individuals, since the synthesis of leukotriene (LT) E4 is frequently increased in aspirin-induced asthma [14], the expression of cys $LT_1$ receptors is increased in nasal inflammatory cells [15], and leukotriene $C_4$ synthase

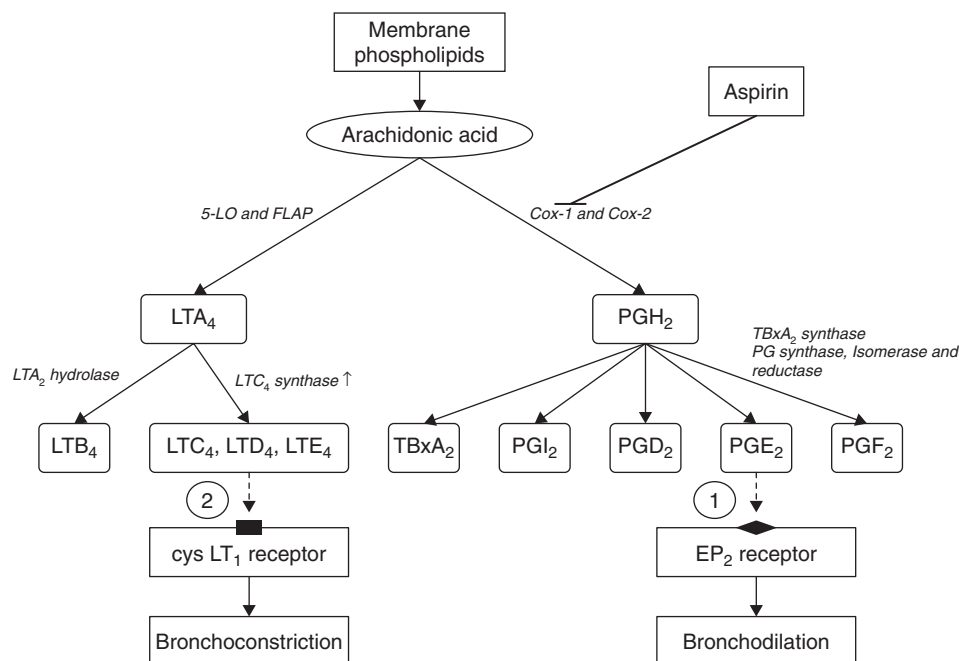

**FIG. 40.1** Biosynthetic pathways leading to the production of LT and PG. Possible mechanisms by which aspirin and NSAIDs inhibit COX-1 to induce bronchoconstriction: (1) Impaired PGE2 synthesis and/or reduced PGE2 receptor function. (2) Increased cys LT synthesis and/or increased cys $LT_1$ receptor function. 5-LO: 5-lipoxygenase; FLAP: 5-lipoxygenase-activating protein; $TBxA_2$: thromboxane $A_2$; $PGI_2$: prostacyclin.

(LTC$_4$S), an enzyme involved in the synthesis of LTs, is often overexpressed in eosinophils and in bronchial tissue [16]. Furthermore, genetic polymorphisms of LTC$_4$S promoter region have been found in some patients with aspirin-sensitive asthma [17], but this has not been confirmed in other populations [18].

Taken together, these findings point to abnormalities in the arachidonic acid pathway in patients sensitive to NSAIDs in particular impaired PGE$_2$ synthesis and actions and excessive LT synthesis and effects. There is, however, an overlap in some of the defects in the arachidonic acid pathway found in patients with aspirin-induced asthma when compared with individuals without sensitivity to NSAIDs, suggesting that the exact mechanisms underlying aspirin-induced asthma are not yet fully elucidated.

### Other mechanisms

There is no convincing evidence that aspirin-induced asthma is due to IgE-mediated mechanisms. For example, specific anti-aspiryl IgE antibodies are generally absent and skin tests to aspiryl-polylysine are negative in these patients. Basal and post-aspirin challenge complement levels are not altered in patients with aspirin-induced asthma. Inflammatory mediators are released following aspirin challenge, such as neutrophil chemotactic factor, but this is thought to be secondary to the primary biochemical events.

### Management

#### Avoidance

Patients with a history of acute bronchoconstrictor response after the ingestion of NSAIDs must be warned to avoid these drugs. If they require a simple analgesic, then acetaminophen (paracetamol) is usually safe in doses up to 500 mg. Cross-reactivity can occur with high doses of acetaminophen (paracetamol), which is a weak inhibitor of COX-1, although the respiratory reaction tends to be mild. There is considerable data to indicate that COX-2 inhibitors do not induce bronchoconstriction in individuals sensitive to aspirin [19], although a few case reports of reactions have been published.

If a patient with aspirin-induced asthma should require an NSAID for the treatment of another condition, such as arthritis, then the patient can be desensitized to aspirin. This procedure should be undertaken by doctors with experience in aspirin challenge.

#### Treatment of respiratory disease

These patients often have severe chronic asthma and nasal disease, which should be treated along similar lines to that of patients with chronic asthma who are not sensitive to NSAIDs. Pretreatment with a number of drugs, including sodium cromoglycate, the H$_1$ receptor antagonist clemastine, and ketotifen, can inhibit the bronchoconstrictor response to aspirin ingestion in patients with aspirin-induced asthma. A small percentage of patients with aspirin-induced asthma develop bronchoconstriction after an intravenous injection of hydrocortisone, and occasionally the bronchoconstriction can be severe. These patients do not react adversely to other intravenous steroids such as methylprednisolone, dexamethasone,

or betamethasone. Although cys LTs have been implicated in the pathogenesis of aspirin-induced asthma, LT receptor antagonists and a 5′-lipoxygenase' inhibitor have not been found to be any more effective than in nonsensitive asthmatic patients [20].

### Desensitization

Following the administration of oral or inhaled aspirin to patients with aspirin-induced asthma there is a refractory period to further aspirin challenge, which lasts for 2–5 days. Continued administration of aspirin on a daily basis will maintain this refractory state, and this effect has been termed desensitization. The process of outpatient desensitization is safe [21] and results in desensitization not only to aspirin but also to other NSAIDs. Those patients who react to small doses of aspirin require several aspirin challenges before desensitization is accomplished, whereas less aspirin-sensitive patients are more quickly desensitized. The process by which aspirin ingestion causes desensitization is unknown.

## β-BLOCKERS

### Nonselective and cardioselective β-blockers

Nonselective β-adrenergic receptor antagonists precipitate acute bronchoconstriction in asthma, even in individuals with mild disease [22], and attacks can be fatal. The dose of β-blockers that causes bronchospasm may be low and there are case reports of severe asthma attacks induced by eye drops of timolol, a nonselective β-blocker used to treat glaucoma [23]. Compared to individuals with asthma, patients with chronic obstructive airways disease (COPD) are less likely to develop deterioration in lung function after a nonselective β-adrenergic receptor antagonist [24], although there are a few case reports of acute bronchospasm induced by nonselective β-blockers [25]. In patients with COPD who have acute exacerbations there is no evidence that β-blockers are detrimental and may even reduce mortality [26].

A meta-analysis of 19 studies on single-dose treatment and 10 studies on continued treatment with cardioselective β$_1$-blockers concluded that this group of drugs does not precipitate bronchospasm in patients with mild to moderate reactive airway disease [27]. Nevertheless there are case reports of individuals with asthma who have developed bronchospasm due to cardioselective β-blockers [28]. Thus despite the recommendation that cardioselective β-blockers should not be withheld from patients with mild to moderate asthma [27] it seems prudent to administer these drugs with great care to patients with moderate persistent asthma and to avoid their use in individuals with severe persistent asthma [28]. A recent systematic review of 20 studies of cardioselective β-blockers given to patients with COPD found no evidence of adverse effects on lung function or on the response to β$_2$-agonists [25, 29].

Acute bronchospasm induced by a nonselective β-blocker should be treated with an inhaled anticholinergic bronchodilator such as ipratropium or oxitropium [30].

Any fall in lung function due to a cardioselective $\beta_1$-blocker can be reversed by an inhaled short-acting $\beta_2$-agonist.

## Possible mechanisms

$\beta$-blocker-induced bronchoconstriction occurs in individuals with asthma, but not in healthy subjects, which suggests that endogenous activation of $\beta$-receptors is important in maintaining airway tone in asthma against neural and inflammatory bronchoconstrictor stimuli.

### Circulating catecholamines

$\beta$-blockers could antagonize the bronchodilator effect of circulating catecholamines in patients with asthma but not in normal subjects. However, against this suggestion, circulating catecholamines are not elevated in asthmatic subjects, even in those subjects who have demonstrable bronchoconstriction after propranolol and the concentrations of adrenaline in plasma ($<0.3$ nmol/l) are too low to have a direct effect on human airway smooth muscle tone [31, 32]. $\beta$-Blockers may inhibit the action of catecholamines on some other target cell, such as airway mast cells or cholinergic nerves. Mediator release from human lung mast cells is potently inhibited by $\beta$-agonists [33]. The effect of $\beta$-blockers may, therefore, be an increase in mediator release, which may be more marked in the "leaky" mast cells of asthmatic individuals. This idea is supported by the observation that cromolyn sodium, a mast cell "stabilizer," prevents the bronchoconstriction produced by inhaled propranolol. However after intravenous propranolol, no increase in plasma histamine has been detected [34].

### Neural pathways

A more likely explanation for $\beta$-blocker-induced asthma is that there is an increase in neural bronchoconstrictor mechanisms. $\beta_2$-adrenergic receptors on cholinergic nerves in human airways may be tonically activated by adrenaline to modulate acetylcholine (ACh) release [35] and therefore to dampen cholinergic tone. Blockage of these receptors would therefore increase the amount of ACh released tonically, but this would be compensated for by the increased stimulation of prejunctional $M_2$-autoreceptors, which would act homeostatically to inhibit any increase in ACh release and therefore no increase in airway tone would occur, even with high doses of a $\beta$-blocker. By contrast, in patients with asthma $\beta$-blockers inhibit prejunctional $\beta$-receptors in the same way, increasing the release of ACh [36]; however, there may be a defect in $M_2$-receptor function in asthmatic airways, so that the increased release in ACh cannot be compensated. Thus increased ACh reaches $M_3$ receptors on airway smooth muscle. In addition, bronchoconstrictor responses to ACh are exaggerated in asthma, a manifestation of airway hyperresponsiveness, and thus two interacting amplifying mechanisms may lead to marked bronchoconstriction (Fig. 40.2). Evidence to support this hypothesis is provided by the inhibitory effect of an inhaled anticholinergic drug oxitropium bromide on $\beta$-blocker-induced asthma [30].

In patients with more severe asthma there may be an additional neural mechanism by which $\beta$-blockers may

**FIG. 40.2** Possible mechanisms of $\beta$-blocker-induced asthma. Blockade of prejunctional $\beta_2$-receptors on cholinergic nerves in normal individuals results in increased release of acetylcholine (ACh), but this is compensated by stimulation of prejunctional muscarinic $M_2$ receptors to inhibit any increase in ACh. In patients with asthma, prejunctional $M_2$ receptors are dysfunctional, so that there is a net release of ACh; ACh also has a greater bronchoconstrictor effect on the airways due to airway hyperresponsiveness.

cause bronchoconstriction. $\beta_2$-adrenergic receptors inhibit the release of tachykinins from airway sensory nerves [37], thus $\beta$-blockers may increase the release of these neuropeptides, thereby increasing bronchoconstriction and airway inflammation. While this mechanism may not be relevant in patients with mild asthma, in whom cholinergic mechanisms appear to account for the bronchoconstrictor response to $\beta$-blockers [30], it may be relevant in more severely affected asthmatic patients in whom cholinergic mechanisms do not appear to be as important.

### Inverse agonism

Another possible mechanism may be related to the recently recognized phenomenon of inverse agonism [38]. It has been found that some mutants of the $\beta$-receptor have constitutive activity and activate the coupling protein Gs, even in the absence of occupation by agonist. In this situation $\beta$-blockers function as inverse agonists and have an inhibitory effect on baseline function. It is possible that in asthmatic patients $\beta_2$-receptors are constitutively active, so that $\beta$-blockers result in adverse effects. Different $\beta$-blockers have differing potencies as inverse agonists that are unrelated to their $\beta$-blocking potency. Thus, propranolol is a potent inverse agonist whereas pindolol is not and this may relate to the different tendency of these two agents to induce asthma.

It has recently been suggested that some $\beta$-blockers with inverse agonist activity may even be beneficial in asthma when used chronically [39]. In murine models $\beta$-blockers with inverse agonist activity (nadolol and carvedilol) increased $\beta_2$-receptor expression and caused bronchodilation [40]. In a pilot open study nadolol has been reported to be safe in asthmatic patients and to reduce airway

hyperresponsiveness [41]. Further controlled studies may therefore be indicated.

## ANGIOTENSIN CONVERTING ENZYME INHIBITORS

A retrospective cohort study suggested that bronchospasm was twice as common in patients treated with angiotensin converting enzyme (ACE) inhibitors (5.5%) compared to the reference group treated with lipid-lowering drugs (2.3%) [42]. However, the prevalence of a past history of bronchospasm in patients reporting ACE inhibitor-induced bronchospasm was not significantly different from the prevalence in patients on ACE inhibitors without an adverse reaction [42]. In a controlled trial in asthmatic and hypersensitive patients (with and without cough), there was no change in lung function following administration of captopril and no increase in reactivity to histamine or bradykinin [43]. Similar findings were obtained in a group of 21 patients with asthma given ACE inhibitors for 3 weeks, although one subject developed a slight wheeze [44]. Administration of a potent ACE inhibitor (ramipril) to a group of individuals with mild asthma showed no change in lung function or bronchial reactivity to inhaled histamine, nor was there any increase in bronchoconstrictor response to inhaled bradykinin [45]. Taken together these findings suggest that ACE inhibitors are unlikely to worsen asthma in the majority of patients, although there may be occasional patients in whom this occurs. When there is a possibility that asthma has been worsened or precipitated by an ACE inhibitor, the drug should be withdrawn and an alternative agent selected. As many as 20% of hypertensive patients treated with ACE inhibitors may develop an irritant cough, although this is unrelated to the presence of underlying airway disease or atopic status.

## ADDITIVES

Several chemicals used as additives in drug preparations and food have been associated with worsening of asthma and should, where possible, be avoided. Bisulphites and metabisulphites (E220, E221, E222, E226, and E227) are antioxidants used as preservatives in several foods, including wines (especially sparkling wines), beer, fruit juices, salads, and medications. Characteristically, they produce bronchoconstriction within 30 min of ingestion and this may account for several cases of "food allergy." The mechanism of metabisulphite-induced asthma is probably explained by release of sulfur dioxide ($SO_2$) after ingestion that is then inhaled, since nebulized metabisulphite solutions generate $SO_2$ in sufficient quantities to provoke bronchoconstriction in asthmatic subjects [46]. Tartrazine (E102), a yellow dye, is used as a coloring in many foods, beverages (such as orange squash), and pharmaceutical preparations. Tartrazine

sensitivity is relatively common and may affect 4% of asthmatic individuals, especially children [9]. Ingestion of tartrazine may result in urticarial rashes and bronchoconstriction. The mechanism may depend upon mediator release from mast cells. Monosodium glutamate (MSG, E621) is added to food as a flavor enhancer. It is found in soy sauce, spices, stock cubes, hamburgers, and in Chinese restaurant food. Some people react with sweating, flushing, and numbness of the chest; in patients with asthma this may be accompanied by wheezing, which may begin several hours after the ingestion ("Chinese restaurant asthma syndrome") [47]. Precipitation of asthma symptoms by MSG is uncommon, however.

## LOCAL ANESTHETICS

Aerosols of the local anesthetics, such as bupivacaine and lignocaine (lidocaine), cause bronchoconstriction in a proportion of asthmatic patients [48, 49]. The degree of bronchial reactivity to histamine does not predict the development or extent of bronchoconstriction following lignocaine inhalation [49]. The mechanism of local anesthetic-induced bronchoconstriction is unclear. Pretreatment with anticholinergic drugs partially attenuates the bronchoconstrictor response to aerosols of local anesthetics, suggesting that they may be acting in part via a vagal reflex pathway. Inhaled local anesthetics may selectively inhibit nonadrenergic noncholinergic bronchodilator nerves and so allow unopposed vagal tone. Some evidence for this is provided by the demonstration that lignocaine inhalation blocks nonadrenergic noncholinergic reflex bronchodilation in human subjects, leading to a reflex bronchoconstrictor response [50]. It is important to be aware that some patients with asthma may develop bronchoconstriction with topical local anesthetics during fiber optic bronchoscopy. All patients with asthma should receive premedication with a bronchodilator prior to bronchoscopy.

## OTHER DRUGS

Many other drugs have been reported to lead to exacerbation of asthma in occasional patients. Bronchoconstriction may constitute part of an anaphylactic reaction to a drug, such as penicillin or to intravenous dextran or to contrast media. Other drugs, such as opiates, may cause direct degranulation of mast cells. Bronchodilator aerosols may occasionally cause a paradoxical bronchoconstriction. This is presumed to be due to the propellant (Freon) or other additives (such as oleic acid, which is used as a surfactant). The mechanism of bronchoconstriction may be via a cholinergic reflex. The treatment of paracetamol poisoning with intravenous N-acetylcysteine has been reported to exacerbate asthma. Cholinergic agents such as pilocarpine, used for the treatment of dry mouth and pyridostigmine, used to treat myasthenia gravis can induce attacks of asthma.

## INTRODUCTION

Asthma and chronic obstructive pulmonary disease (COPD) are different chronic inflammatory respiratory disorders that may share a common functional abnormality, that is, poorly reversible airflow limitation [1–4]. According to current guidelines, airflow limitation in asthma is reversible or partly reversible [1], whereas airflow limitation in COPD is poorly reversible or not reversible at all [2].

In the pathogenesis of both asthma and COPD, individual genetic susceptibility and environmental exposures are relevant for disease expression. Cigarette smoking is the major cause of COPD [2]. The causes of asthma are largely unknown, although atopy and allergen exposure have major roles [1, 2]. Asthma is a phenotypically heterogeneous disorder that, over the years, has been divided into many different clinical subtypes. In particular, asthma starting in adulthood, asthma in smokers, non-eosinophilic asthma, and asthma in obese subjects are important subtypes in the adult asthma population that are still poorly characterized and that may overlap with COPD [5–7].

The differential diagnosis between asthma and COPD is quite simple when the typical clinical and functional features of either disease are present. It is easy to recognize asthma in a young, atopic, nonsmoking subject with recurrent dyspnea, wheezing, or chest tightness and fully reversible airflow limitation. Similarly, it is easy to diagnose COPD in a subject older than 40, a smoker, who presents with chronic dyspnea, cough, sputum, and fixed airflow limitation and no history of asthma or allergic diseases.

The difficulty comes when trying to make a diagnosis of asthma or COPD in a middle-aged or elderly patient, a smoker, who may be atopic or have a history of asthma, who complains of chronic dyspnea but not wheezing, chronic cough, or sputum, and who presents with poorly reversible airflow limitation. It is also difficult to make a diagnosis of asthma or COPD in a middle-aged or elderly patient who has a clear history of atopy and asthma, bronchodilator reversibility, and recurrent wheezing, but who also smokes and has chronic cough and sputum and dyspnea that are not suppressed by inhaled steroids. In such patients, differential diagnosis might become important from a clinical and therapeutic point of view. Inhaled glucocorticosteroids are the first choice of regular medication in asthma but not in COPD, whereas regular long-acting bronchodilators are the first choice of regular medication in COPD but not in asthma. Thus, in patients with overlapping features, the differential diagnosis between asthma and COPD is important in making the decision to prescribe regular treatment with either steroids or bronchodilators.

## DEFINITIONS OF ASTHMA AND COPD

Asthma is a chronic inflammatory disease of the airways clinically characterized by recurrent respiratory symptoms as follows: dyspnea, wheezing, chest tightness, or cough associated with reversible airflow limitation. Other important features of asthma are an exaggerated responsiveness of the airways to various stimuli, and a specific chronic inflammation of the airways characterized by an increased number of CD4$^+$ Th2 lymphocytes, eosinophils, and methacromatic cells in the airway mucosa, and increased thickness of the reticular layer of the epithelial

basement membrane. Familial predisposition, atopy, and exposure to allergens and sensitizing agents are important risk factors for asthma, even though the causes of asthma – the factors responsible for the development of asthma rather than its exacerbations – remain largely undetermined [1].

COPD is a syndrome characterized by poorly reversible airflow limitation, usually progressive, and often associated with chronic respiratory symptoms, such as dyspnea and/or chronic cough and sputum [2]. COPD is associated with chronic inflammation of the airways that is remarkably different from asthmatic inflammation, and that is characterized by an increased number of $CD8^+$ Th1/Tc1 lymphocytes in the airway mucosa and neutrophils in the lumen, with no increased thickness of the reticular layer of the epithelial basement membrane [8–13]. Even though genetic and familial predisposition as well as occupational exposure are considered risk factors, cigarette smoking is by far the most important risk factor for COPD [2].

## MINIMUM REQUIREMENTS FOR THE DIAGNOSIS OF ASTHMA OR COPD

The diagnosis of asthma or COPD is based on clinical history and lung function tests, particularly peak expiratory flow (PEF) and spirometry, with assessment of spontaneous or postbronchodilator reversibility of airflow limitation. Allergy tests are also usually performed for the diagnosis of asthma, but not of COPD patients, to identify allergens responsible for asthma exacerbations and to consider the opportunity to treat the patient with immunotherapy.

## Symptoms and medical history

### Asthma

Most patients who are diagnosed with asthma seek medical attention because of respiratory symptoms. A typical feature of asthma symptoms is their variability. One or more of the following symptoms – wheezing, chest tightness, cough, and episodic shortness of breath – are reported by more than 90% of patients with asthma [14]. However, the simple presence of these symptoms is not diagnostic, because identical symptoms may be triggered by different stimuli in nonasthmatics, such as in children by acute viral infections [15]. In some asthmatics, wheezing and chest tightness are absent, and the only symptom the patient complains of may be chronic cough or cough after exercise [16]. This clinical entity is also called "cough-variant asthma;" it is particularly common in children and is often more problematic at night [17, 18]. Symptoms of asthma may be triggered or worsened by several factors, such as exercise, exposure to allergens, viral infections, and emotions. Recurrent exacerbations of respiratory symptoms, worsening of lung function requiring change of treatment, unscheduled requests for medical assistance, and sometimes hospitalization are also among the characteristic clinical features of asthma.

**TABLE 41.1** Differential diagnosis of asthma.

| Other pathologies | Gastroesophageal reflux<br>Pulmonary embolism<br>Pulmonary eosinophilia<br>Drug-induced airway hyperresponsiveness |

Asthma clusters in families and its genetic determinants appear to be linked to those of other allergic IgE-mediated diseases [19–21]. Thus, a personal or family history of asthma and/or allergic rhinitis, atopic dermatitis, or eczema increases the likelihood of a diagnosis of asthma.

Physical activity is an important cause of symptoms (wheezing and/or cough) for most asthma patients, particularly in children, and for some it is the only cause [15, 16]. Exercise-induced asthma usually develops not during exercise but 5–10 min afterward, and it resolves spontaneously within 30–45 min. Prompt relief of symptoms after the use of inhaled beta2-agonist, or their prevention by pretreatment with an inhaled beta2-agonist before exercise, supports a diagnosis of asthma. Important aspects of personal history are exposure to agents known to worsen asthma in the home (heating system, cooking system, house-dust mites), workplace conditions, air-conditioning, pets, cockroaches, environmental tobacco smoke [22–26], or even the general environment (e.g. diesel fumes in traffic [27]).

Since respiratory symptoms of asthma are nonspecific, the differential diagnosis is quite extensive, and the main goal for the physician is to consider and exclude other possible diagnoses (Table 41.1). This is even more important if the response to a trial of therapy (i.e. bronchodilators) has been negative.

Asthma is often classified by severity, but asthma severity changes over time. It also depends not only on the severity of the underlying disease but also on its responsiveness to treatment, which becomes the most important criterion in treated subjects. An asthmatic patient might be completely asymptomatic, either because he or she has mild intermittent asthma and long periods without symptoms even without treatment, or because he or she has severe asthma and is receiving full anti-asthmatic treatment, including systemic steroids.

While respiratory symptoms suggest asthma, the *sine qua non* for the objective diagnosis of asthma is the presence of reversible airflow limitation in subjects with persistent airways obstruction, and/or airway hyperresponsiveness or increased PEF variability in subjects without airways obstruction [1].

## COPD

A clinical diagnosis of COPD should be considered in any patient who has dyspnea, chronic cough, or sputum production, and/or a history of exposure to risk factors for the disease [2]. Most patients who are diagnosed with COPD seek medical attention because of respiratory symptoms, particularly dyspnea [28]. Since the early stages COPD may manifest as chronic cough and sputum production, they may be present even in smokers without airflow limitation. Cough and sputum may precede the development of airflow limitation: in fact, respiratory symptoms may be an important risk factor for the development of COPD [29, 30]. Regular production of sputum for 3 or more months in 2 consecutive years is defined as chronic bronchitis [31]. In some subjects, chronic cough may be unproductive [32–35], and airflow limitation may develop in the absence of cough. In COPD, dyspnea is characteristically persistent, unlike in asthma where it is variable and progressive [36]. In the early stages of the disease, dyspnea is noted only during the patient's usual effort; as lung function decreases, dyspnea becomes more serious and is present during everyday activities or at rest. Dyspnea is not closely correlated with arterial blood gases; for example, the typical "blue bloater" with peripheral edema, hypoxemia, and hypercapnia has generally less dyspnea than the "pink puffer," who generally does not have these blood gas abnormalities but is much more dyspneic. Wheezing and chest tightness are nonspecific symptoms of COPD and may vary on different days or over the course of a single day. Recurrent exacerbations of respiratory symptoms requiring change of treatment, unscheduled requests for medical assistance, and sometimes hospitalization are also among the characteristic clinical features of COPD.

A detailed medical history of a patient with symptoms suggestive of COPD should include exposure to risk factors (e.g. smoking and occupational or environmental exposures), family history of COPD or other chronic respiratory disease, pattern of symptoms, history of exacerbations, presence of comorbidities, medical treatment, and the patient's quality of life.

Diagnosis and assessment of the severity of COPD are mainly based on the degree of airflow limitation during spirometric measurement. Thus, according to current guidelines, the *sine qua non* for the diagnosis of COPD is the presence of poorly reversible airflow limitation, that is, the presence of a postbronchodilator forced expiratory volume in 1 s/forced vital capacity ratio ($FEV_1/FVC$) <0.70 and $FEV_1$ <80% predicted. These values confirm the presence of airflow limitation that is not fully reversible [2].

Airflow limitation in COPD is due to both small airways disease (obstructive bronchiolitis) and parenchymal destruction (emphysema), the relative contributions of which vary among patients [1, 2]. In contrast, airflow limitation in asthma is almost exclusively due to airways disease [10]. Imaging (see below), particularly thin-section computed tomography (CT), has been used to quantify emphysema by detecting areas of low attenuation. However, airflow limitation as assessed by $FEV_1$ correlates poorly with the severity of emphysema as evaluated by CT [4], possibly because small airways disease contributes significantly to airflow limitation [37]. Recent progress in CT technology

**TABLE 41.2** Differential diagnosis of COPD.

| Other airway inflammatory diseases | Asthma |
| | Bronchiectasis |
| | Diffuse panbronchiolitis |
| Infectious airway diseases | Tuberculosis |
| Cardiac diseases | Congestive heart failure |

has made it possible to detect and quantify airway abnormalities [38, 39], but more work is required before the technique can be used in clinical practice.

Studies in COPD patients recruited by experienced pulmonary specialists in hospitals [40] or by general practitioners in outpatient clinics [41] report that up to 40% of smokers/ex-smokers with chronic respiratory symptoms and clinical findings compatible with COPD do not fit the spirometric definition of COPD reported above. Thus, even when there is a clear history of COPD – chronic respiratory symptoms, exacerbations, smoking, and age >50 – a large proportion of such patients either have normal spirometric values or present with reduced lung volumes (a restrictive pattern), and thus the diagnosis of COPD cannot be confirmed [40, 41]. Clinical features of COPD correlate poorly with airflow limitation. Thus, although not yet recommended by current guidelines, proper diagnosis and assessment of the severity of COPD require more than a comprehensive approach that includes imaging [38, 39] assessment of exercise tolerance [42], body mass index [42, 43], and chronic comorbidities (e.g. chronic heart failure (CHF), arterial hypertension, metabolic syndrome) that are often associated with COPD [44, 45].

Because chronic respiratory symptoms (particularly dyspnea), clinical features, and poorly reversible airflow limitation may also be present in other pathological conditions, a careful differential diagnosis between COPD and these conditions should always be performed (Table 41.2).

## Physical examination

In mild asthma, physical examination is usually normal under stable conditions but becomes characteristically abnormal during asthma attacks. Typical physical signs of asthma attacks are wheezing on auscultation, cough, expiratory ronchi throughout the chest, and signs of acute hyperinflation (e.g. poor diaphragmatic excursion at percussion, use of accessory muscles of respiration). Some patients, particularly children, may present with a predominant nonproductive cough (cough-variant asthma). In some asthmatics, wheezing – which usually reflects airflow limitation – may be absent or detectable only on forced expiration, even in the presence of significant airflow limitation; this may be due to hyperinflation or to very marked airflow limitation. In these patients, however, the severity of asthma is mostly indicated by other signs, such as cyanosis, drowsiness, difficulty in speaking, tachycardia, hyperinflated chest, use of accessory muscles, and intercostal recession.

In the early stages of COPD, physical examination is usually normal. Current smokers may have signs of active

smoking, including an odor of smoke or nicotine staining of fingernails. In more severe COPD, prolonged expiration and wheezing and signs of hyperinflation (e.g. barrel chest and poor diaphragmatic excursion at percussion, use of accessory muscles of respiration) are usually present. Cyanosis of the lips and nail beds and signs of cor pulmonale, such as edema of the ankle or lower leg, are often present in patients with reduced oxyhemoglobin percentage. Even though clubbing of the digits may be present in patients with severe COPD and is considered a sign of COPD, it is nonspecific; in fact, its presence should alert the physician to the possible presence of other diseases, particularly lung cancer. Patients with COPD often have reduced breath sounds and wheezing during quiet breathing or after forced expiration.

Physical examination is usually not very useful in making the differential diagnosis between asthma and COPD, but it can be useful in assessing the severity of exacerbations of both asthma and COPD [46].

## Lung function tests

### Spirometry

Lung function tests play a crucial role in the diagnosis and follow-up of asthma and COPD. Spirometric measurements – $FEV_1$ and slow vital capacity (VC) or FVC – are the standard means for assessing airflow limitation. Spirometry is recommended at the time of diagnosis and for the assessment of the severity of both asthma and COPD [1, 2, 47, 48] it should be repeated to monitor the disease and when there is a need for reassessment, such as during exacerbations [3].

Poorly reversible airflow limitation is indicated by the absolute reduction of postbronchodilator $FEV_1$/VC or $FEV_1$/FVC ratios <0.7 but it should be confirmed with postbronchodilator $FEV_1$/VC values below the lower limit of normal [4, 49]. Measurements of residual volume and total lung capacity may also be useful in determining the degree of hyperinflation and/or enlargement of airspaces [1, 2, 47, 48].

In asthma, airflow limitation is usually reversible, either spontaneously or after treatment, except for moderate/severe asthma with fixed airway obstruction [1, 3, 10]. In COPD, airflow limitation is by definition not reversible (i.e. $FEV_1$/FVC does not reach 0.7 even after inhalation of a bronchodilator or a short course of long-acting beta2-agonist (LABA) and inhaled steroids). However, up to one-third of COPD patients show a significant increase in $FEV_1$ (>15%) after receiving inhaled beta-adrenergic agonists [50–54], which simulate the reversible airflow limitation observed in asthmatics.

In conclusion, while the best spirometric values are useful to define whether airflow obstruction is reversible or not (i.e. does not return within normal values), the degree of reversibility after treatment does not help to make the differential diagnosis between asthma and COPD (see below).

### Peak expiratory flow

An important tool for the diagnosis and subsequent treatment of asthma is the PEF meter [55]. PEF is the highest expiratory flow obtained during a forced expiration starting immediately after a deep inspiration from total lung capacity. PEF is a simple, reproducible index and can be measured with inexpensive and portable meters [56]. If spirometry does not reveal airflow limitation, the home monitoring of PEF for 2–4 weeks may help to detect an increased variability of airway caliber, and thus help to diagnose asthma [57]. For most asthmatic patients, PEF correlates well with $FEV_1$ [58]. Daily monitoring of PEF (at least in the morning at awakening and in the evening hours, preferably after bronchodilator inhalation) [1, 3] is also useful to assess the severity of asthma and its response to treatment, and it can help patients to detect early signs of asthma deterioration [59]. However, PEF measurements have some limitations. PEF is effort dependent and mainly reflects the caliber of large airways and may therefore underestimate the degree of airflow limitation present in peripheral airways [60]. Diurnal variability is calculated as follows:

$$\frac{PEF_{max} - PEF_{min} \times 100}{PEF_{max} + PEF_{min}/2}$$

A diurnal variability of PEF of more than 20% is diagnostic of asthma, and the magnitude of the variability is broadly proportional to disease severity. PEF monitoring may be of use not only in establishing a diagnosis of asthma and assessing its severity, but also in uncovering an occupational cause for asthma. When used in this way, PEF should be measured more frequently than twice daily, and special attention should be paid to changes occurring in and out of the workplace [55, 61–63].

Even though PEF is at least as important to prognosis as $FEV_1$ in moderate to severe COPD [64], PEF monitoring is not frequently used in COPD for various reasons. First, PEF reflects the patency of central airways, and airflow limitation in COPD starts from peripheral airways. Thus, the PEF value may underestimate airflow limitation, particularly if it occurs in peripheral airways. Second, by definition, airflow limitation is poorly reversible in COPD, and thus PEF usually does not vary significantly. Finally, there is only limited evidence to support a role for PEF in detecting COPD exacerbations [65, 66].

### Reversibility to bronchodilators

The reversibility of airflow limitation following bronchodilator therapy is no longer an accepted criterion in support of the diagnosis of asthma, or to establish the differential diagnosis between asthma and COPD [1–3]; even though there is a large increase in FEV1, and particularly its return is above the lower limit of normal values, normal expiratory flows after anti-asthma treatment strongly suggests asthma. Subjects with moderate to severe asthma may develop poorly reversible airflow limitation and have a response to treatment but not a return to normal values. Similarly, COPD patients may show a significant response to treatment, even without a return to normal expiratory flows.

In subjects with airflow limitation, an improvement in $FEV_1$ of >12–15% predicted and more than 200 ml after administration of a bronchodilator (e.g. 200 μg of inhaled salbutamol from a metered dose inhaler) is no longer considered a pathognomonic hallmark of asthma [1], or a

criterion for differential diagnosis between asthma and COPD [3, 67–69]. In fact, an incomplete response to a single administration of a bronchodilator does not exclude the possibility of reversibility to longer treatment with bronchodilators or steroids [70, 71]. Thus, more attention should be paid to the response to long-term treatment.

In COPD patients, bronchodilator reversibility testing should generally be performed at least once. Airflow limitation in COPD is usually not reversible, but the one-third of COPD patients who show a significant response to bronchodilator agents [50, 51, 53, 54, 72] are likely to benefit from treatment with glucocorticosteroids [73, 74]. The absence of a response to a bronchodilator should never be a reason to withhold bronchodilator therapy, as the response to bronchodilators in COPD is mainly symptomatic rather than functional [75–79]. Bronchodilator responsiveness is a continuous and poorly reproducible variable; thus, classifying patients as responders or nonresponders can be misleading and does not predict disease progression [68].

As recommended by recent guidelines [1], the terms "reversibility" and "variability" should refer to changes in symptoms accompanied by changes in airflow limitation, which occur spontaneously or in response to treatment. At present, however, these terms often refer only to rapid improvements in $FEV_1$ measured within minutes after inhalation of a rapid-acting bronchodilator, for example, after 200–400 µg salbutamol or salbutamol and ipratropium bromide [54, 80]. In contrast, a history of symptoms and/or functional reversibility (spontaneous or after any kind of treatment) is the essential component in the diagnosis of asthma.

The assessment of reversibility of both clinical features and functional abnormalities may be useful in obtaining the best level of asthma control achievable and/or the best lung function for individual patients [81]. Achieving and maintaining lung function at the best possible level is one of the objectives of both asthma and COPD management [1, 81, 82].

In summary, while the best spirometric values are useful to define whether airflow obstruction is reversible or not (i.e. does not return within normal values), the degree of reversibility after treatment does not help to make the differential diagnosis between asthma and COPD (see below).

## Arterial blood gases

In severe asthma and COPD and, more importantly, during acute exacerbations of both asthma and COPD, the measurement of arterial blood gases while the patient is breathing air and/or after oxygen administration is essential for the diagnosis of chronic and/or acute respiratory failure. This test should be performed in all patients with clinical signs of acute or chronic respiratory and/or heart failure [2].

## Allergy tests

The presence of allergic disorders in a patient's family history should be investigated in all patients in whom symptoms are suggestive of asthma [83]. A history provides important information about the patient's lifestyle and occupation, both of which influence exposure to allergens and the time and factors possibly involved in onset and in exacerbations of asthma [84, 85]. In asthmatics, the relationship between exposure to one or more allergens and the occurrence of asthma and/or ocular and nasal symptoms should be established [86]. Also, the relationship of symptoms to the time of the year (seasonal pollen asthma) and to the presence of pets in the home should be assessed, together with a description of the patient's living environment with special attention to carpets, pillows, and other dust collectors [87]. Identifying the presence of an allergic component in asthma adds little to the diagnosis, but it can help in identifying potential triggers and directing allergen immunotherapy [1].

Skin tests with all relevant allergens are present in the geographic area in which the patient lives are the primary diagnostic tool in determining allergic status. Deliberate provocation of the airways with a suspected allergen or sensitizing agent may also be helpful in establishing causality, especially in the workplace [63, 88]. Measurement of specific IgE is not usually more informative than a skin test, and is more expensive. Measurement of total IgE in serum has no value as a diagnostic test for atopy. The main limitation of the allergy test is that a positive test does not necessarily mean that the disease is allergic in nature or that it is causing asthma, as some individuals have specific IgE antibodies without any symptoms. The cost–benefit ratio of performing inhalation tests with allergens or other sensitizing agents should be carefully examined for each patient because of the high cost and the potential risk involved [69].

The assessment of atopy is not useful in COPD. Even though atopy may be a risk factor for both asthma and COPD [89, 90], the demonstration of atopy in COPD patients does not help in the identification of potential triggers as in allergic asthma. Allergen immunotherapy has no role in COPD.

## ADDITIONAL TESTS

While the diagnosis and assessment of severity of asthma and COPD can be fully established on the basis of clinical history and lung function tests (including arterial blood gases, see below), additional tests might be helpful to better characterize individual patients.

## Reversibility to corticosteroids

In patients with airflow limitation that is not reversed by a single dose of a short-acting bronchodilator, a 2-week treatment with oral or inhaled glucocorticosteroids and bronchodilators might be considered. Glucocorticosteroids can be administered orally (e.g. 40 mg daily prednisone) by aerosol (e.g. 2 mg daily beclomethasone, or equivalent) or both [91–93] for at least 14 days [94]. Unfortunately, patients with COPD cannot be separated into discrete groups of glucocorticosteroid responders and nonresponders, and

thus glucocorticosteroid testing is an unreliable predictor of the benefit from inhaled glucocorticosteroids in individual patients.

Because of their efficacy and infrequent adverse effects, inhaled glucocorticosteroids alone or in combination with long-acting bronchodilators are increasingly used in practice as first-choice therapy to investigate the reversibility of airflow limitation [74, 95, 96].

In most patients with a clear history of asthma or COPD, the reversibility to glucocorticosteroids confirms the diagnosis, even if significant overlap exists [10]. Asthma is usually responsive to bronchodilators and/or glucocorticosteroids, whereas COPD is usually less responsive or not responsive at all. In asthma, a combination of sputum eosinophilia and increased nitric oxide (NO) levels may be useful in predicting the response to a trial of oral steroids [97, 98], and sputum eosinophilia may also predict the response to steroids in COPD [99, 100]. However, some COPD patients may show a significant improvement in function after glucocorticosteroid treatment [73], particularly if they present with pathological abnormalities similar to those in asthma.

The simplest and potentially the safest way of identifying these COPD patients is by an *ex juvantibus* treatment trial with inhaled glucocorticosteroids [92] in combination with long-acting bronchodilators for 6 weeks to 3 months, using the same criteria for reversibility as in the bronchodilator trial ($FEV_1$ increase of 200 ml and 12%) [2, 73, 92, 101]. The response to glucocorticosteroids alone or in combination with long-acting bronchodilators should be evaluated with respect to the postbronchodilator $FEV_1$ [2, 4].

COPD patients with a response to glucocorticosteroids present some pathological features of asthma, such as a significantly higher number of eosinophils and higher levels of eosinophil cationic protein in their bronchoalveolar lavage fluid, and a thicker reticular basement membrane [73, 101].

All long-term studies in COPD have demonstrated the lack of any effect of inhaled glucocorticosteroids on the natural history of COPD, as evaluated by the decline in $FEV_1$ [2, 102–106]. Therefore, given the documented risks of chronic glucocorticosteroid therapy in both asthma [107] and COPD, such as osteoporosis [102, 108], the decision to start long-term treatment with inhaled glucocorticosteroids must be made very carefully.

In patients with poorly reversible airflow limitation due to asthma, the beneficial effects of inhaled glucocorticosteroids are likely to overcome the risks of negative systemic effects [74]. However, in patients with poorly reversible airflow limitation due to smoking, this may not be the case, particularly considering that inhaled glucocorticosteroid alone may be associated with increased mortality [109], and that inhaled glucocorticosteroid both alone and in combination with a long-acting beta2-adrenergic agonist may slightly increase the risk of pneumonia in COPD patients [109, 110].

## Exercise testing

Exercise testing is useful for assessing the degree of disability, the role of comorbidities, prognosis for survival, presence of exercise-induced hypoxemia, and response to treatment in individuals with COPD. Simple walking tests are increasingly used in the assessment of COPD patients [111]. Severe COPD might be better assessed by a composite score such as BODE (body mass index, degree of airway obstruction, severity of dyspnea, and exercise tolerance), which has been shown to be a better predictor of subsequent survival and is increasingly used in clinical assessment of patients.

## Diffusion capacity

Measurement of the diffusing capacity of the lung for carbon monoxide (Dlco) has been recommended for distinguishing asthma from COPD [112]. In asthma, Dlco is usually normal or increased [10, 113, 114]. In contrast, Dlco is usually reduced in COPD, possibly due to emphysema [10, 114, 115], but it may also be reduced in smokers without airflow limitation [116]. Dlco is lower in COPD patients than in asthmatics with incomplete reversible airflow limitation [10, 117, 118]. However, patients with severe alpha-1 antitrypsin deficiency may present with normal Dlco, despite having a significant component of fixed airway obstruction and prominent panacinar emphysema on a high-resolution CT (HRCT) scan, suggesting the limitations of measuring Dlco in these patients [119, 120].

## Airway hyperresponsiveness

In patients who have symptoms consistent with asthma but have normal lung function, bronchial provocation tests (methacholine, histamine, adenosine 5′-monophosphate, mannitol, and exercise) are helpful in measuring airway hyperresponsiveness and thereby confirming or excluding the diagnosis of active asthma [121, 122]. Methacholine is mainly used to identify bronchial hyperresponsiveness and to guide treatment. Exercise is used as a bronchial provocation test because demonstrating prevention of exercise-induced asthma is an indication for use of a drug [121].

These measurements are sensitive for a diagnosis of asthma, but they have low specificity [123]. This means that a negative test can be used to exclude a diagnosis of active asthma, but a positive test does not always mean that a patient has asthma [123]. Airway hyperresponsiveness has been described in workers who are acutely exposed to irritants [124, 125], allergic rhinitis [126–128], and other diseases with airflow limitation, such as cystic fibrosis [129–131] and COPD [132–134]. Indeed COPD, especially in current smokers, is often accompanied by airway hyperresponsiveness [135] that is no different from that in asthmatics with a similar degree of airflow limitation [10, 136]. In patients with fixed airflow limitation, a similar degree of airway hyperresponsiveness was observed in those with a history of COPD and those with a history of asthma [10]. In these patients, hyperresponsiveness might be largely due to the airflow limitation itself.

In conclusion, the measurement of airway hyperresponsiveness may be useful to confirm asthma in subjects with normal baseline lung function, but it is not useful in

the differential diagnosis between asthma and COPD, particularly when patients have a similar degree of poorly reversible airflow limitation.

## Imaging

While chest radiography may be useful to exclude diseases that may mimic asthma and COPD, it is not required in the confirmation of the diagnosis and management of asthma. The utility of chest radiography is to exclude other conditions that may imitate or complicate asthma, particularly acute asthma. Examples include pneumonia, cardiogenic pulmonary edema, pulmonary thromboembolism, tumors (especially those that result in airway obstruction with resulting peripheral atelectasis), and pneumothorax [137].

A number of novel imaging methods for assessing airway pathology in asthmatic patients have been proposed [39, 138]. Both direct and indirect signs of airway pathology have been described using HRCT. Direct signs are obtained by measuring airway or bronchial wall thickness, evaluating the ratio of bronchial diameters to adjacent pulmonary arteries, and identifying a lack of bronchial tapering. Indirect signs include foci of mucoid impaction (including the finding of a tree-in-bud configuration of small peripheral lung nodules indicative of bronchiolitis) and mosaic attenuation [139]. Mosaic attenuation is the presence of geographic zones of decreased lung density adjacent to areas of apparent increased lung density in the absence of architectural distortion or honeycombing. This finding may also be seen in patients with diffuse infiltrative lung disease or, more rarely, chronic embolic pulmonary hypertension. In most cases, reliable identification of air trapping resulting in mosaic lung attenuation requires expiratory imaging. During exhalation, areas of air trapping become accentuated, simplifying the differential diagnosis. Each of these methods has serious limitations, and in clinical practice they have not yet proved sufficiently accurate to warrant their use in diagnosing most cases in which extensive airway remodeling has occurred [140].

Airflow limitation in COPD is due to both small airways disease (obstructive bronchiolitis) and parenchymal destruction (emphysema), the relative contributions of which vary among patients [141, 142]. Thin-section CT has been used to quantify emphysema by detecting low-attenuation areas, and the role of CT in diagnosing emphysema is well established. However, airflow limitation evaluated by $FEV_1$ does not show a good correlation with the severity of emphysema as evaluated by CT [143, 144], because small airways disease appears to contribute significantly to airflow limitation [145]. Recent progress in CT technology has made it possible to detect and quantify airway abnormalities [146]. Theoretically, thin-section CT can depict the dimensions of airways as small as ~1 to 2 mm in inner diameter, suggesting that CT can be used to evaluate airway dimensions in a variety of diseases [141, 142]. Hasegawa and colleagues [38], who developed new software for measuring airway dimension using curved multiplanar reconstruction, demonstrated that airway luminal area and wall area significantly correlated with $FEV_1$ (% predicted). The correlation coefficients improved as the airways became smaller.

**TABLE 41.3** HRCT features in asthma and COPD.

| | Mild-to-persistent asthma | Severe asthma | COPD | Healthy subjects |
|---|---|---|---|---|
| Bronchial wall thickening | ++ | +++ | + | − |
| Emphysema | − | + | +++ | − |
| Bronchiectasis | +/− | ++ | − | +/− |

Scintigraphic approaches may be used to assess COPD or emphysema and to provide functional imaging. Ultrafine $^{133}$Xe gas particles are being used for ventilation scintigraphy, including single photon emission CT (SPECT). SPECT imaging has been shown to be more useful than morphologic HRCT in the evaluation of small airways disease, including pulmonary emphysema [147]. Diffusion-weighted, hyperpolarized $^3$He magnetic resonance imaging has been shown to correlate with pulmonary function tests, particularly Dlco [148]. Also, dynamic contrast-enhanced magnetic resonance imaging may detect abnormalities of the pulmonary peripheral microvasculature [149]. These techniques might be useful in the assessment of pulmonary emphysema.

The clinical application of HRCT is mandatory inCOPD patients who are candidates for volume reduction surgery and in whom the regional distribution of emphysema, particularly upper lobe emphysema, is critical for the outcome of the intervention [150–152]. HRCT features of asthma and COPD [39, 153–156] are reported in Table 41.3.

## Laboratory examinations

Circulating eosinophils: circulating eosinophilia is a feature of many different lung diseases. In some conditions, eosinophils are increased in the blood but not in the lung tissue; in other diseases, there may be significant eosinophilia in the lung tissue but not in the peripheral blood. In others, there may be lung eosinophilia without any radiographic evidence of disease, as in asthma. Churg–Strauss syndrome (CSS) is characterized by peripheral and pulmonary eosinophilia with infiltrates on chest radiograph. However, the primary features that distinguish CSS from other pulmonary eosinophilic syndromes are the presence of eosinophilic vasculitis in the setting of asthma and the involvement of multiple end organs. Therefore, in these cases it is important to establish a differential diagnosis between these diseases, which may occur without any radiographic evidence of disease. Although perceived to be quite rare, the incidence of this disease seems to have increased in the last few years, particularly in association with various asthma therapies.

Clinical presentation of COPD exacerbation includes worsening of dyspnea, increased cough and sputum, and changes in the aspect of expectorations.

## Biomarkers of respiratory bacterial infections

Although clinical criteria are still used to determine which patient should be treated with antibiotics [157], these criteria are neither sensitive nor specific enough to exclude other causes of exacerbation of respiratory symptoms in these patients. Novel biomarkers (e.g. pro-calcitonin) have been recommended for guiding antibiotic treatment both in exacerbations of COPD and pneumonia, but these studies need confirmation [158–160].

Other frequent clinical conditions may mimic the symptoms of COPD exacerbation, including congestive heart failure, pneumonia, pneumothorax, pleural effusion and pulmonary embolism [2]. However, COPD is often cited among the risk factors for acute venous thromboembolism and is an independent predictor of pulmonary embolism [161]. In a small series of patients, the prevalence of deep vein thrombosis in patients admitted with acute exacerbation of COPD was 31% [162, 163]. Similarly, on the basis of ventilation–perfusion lung scintigraphy, the prevalence of pulmonary embolism in patients admitted with acute exacerbation of COPD was as high as 20% [164]. More recently, Tillie-Leblond *et al.* [165] explored the prevalence of pulmonary embolism in a cohort of patients with COPD with unexplained dyspnea and found a rate of 25% in this population. D-dimer is a product of lysis of stabilized fibrin-clot that is considered an indirect marker of coagulation activation. Measurement of plasma D-dimer has a well established diagnostic role in acute pulmonary embolism because of its high negative predictive value [166]. The usefulness of D-dimer testing remains controversial in inpatients, in part due to a high percentage of "positive" D-dimer values among them, which is consequent to a broad spectrum of diseases (other than pulmonary embolism) and procedures related to the hospitalization. Moreover, for inpatients, a negative D-dimer reduces suspicion but its sensitivity is only 89%, unsatisfactory to exclude pulmonary embolism [167]. If the helical contrast CT angiogram is negative and ultrasound is negative, there is still a 5% false-negative rate for inpatients [168]. There are no convincing data regarding a negative CT alone for inpatients. Accordingly, CT and D-dimer evidence may add information but conventional pulmonary arteriography may still be required to make a secure diagnosis. In its absence, a "clinical" decision to treat (and suspend treatment, if contraindications supervene) may be required [169].

## Troponin and/or N-BNP

COPD and CHF are common conditions. The diagnosis of CHF can remain unsuspected in patients with COPD, because shortness of breath is attributed to COPD. Measurement of plasma B-type natriuretic peptide (BNP) levels helps to uncover unsuspected CHF in patients with COPD and clinical deterioration [170]. Amino-terminal pro-B-type natriuretic peptides (NT-proBNP) are strong and independent prognostic indicators, representing a particularly strong predictor of heart failure or death [171]. This risk is independent of all other variables, including renal function or troponin, and is proportional to the magnitude of NT-proBNP release, with higher risk observed among those with a more marked elevation of the marker. An elevated initial NT-proBNP concentration should prompt consideration of an early invasive management approach. Consideration should be given to repeating the NT-proBNP measurement after 24–72 h and again at 3–6 months because these follow-up measurements provide more long-term prognostic information than single measures at presentation. In acute ischemic heart disease, an NT-proBNP value >250 ng/l is associated with an adverse prognosis. In patients with stable coronary artery disease, measurement may be performed for prognostication purposes at 6- to 18-month intervals. In the case of clinical suspicion of disease progression, a new sample may be warranted.

## Alpha-1 antitrypsin

Severe hereditary deficiency of alpha-1 antitrypsin is usually associated with early-onset panacinar emphysema [172]. Thus, in patients who develop COPD before the age of 45 and/or who have a strong family history of COPD, alpha-1 antitrypsin should be measured; if the serum concentration is <15–20% of the normal value, the patient should be considered for alpha-1 antitrypsin augmentation therapy. Like other genetic tests, this test has no clinical value in asthma [21].

## Assessment of airway inflammation

Bronchopulmonary inflammation is markedly different in asthma and COPD [9, 12, 173–182] (Fig. 41.1).

While airway biopsies and bronchoalveolar lavage clearly distinguish between asthma and COPD in subjects with overlapping features that may provide useful information in research protocols, they are considered too invasive for the diagnosis or staging of either asthma or COPD [179, 183, 184]. In contrast, noninvasive markers of airway inflammation have been increasingly used in research protocols to differentiate asthma from COPD [183, 185].

### Sputum

Sputum induction has been widely used in the study of airway inflammation in asthma and COPD because it is a safe, reproducible, and noninvasive technique that can be used repeatedly, even during exacerbations [186–188]. Sputum findings mainly represent the bronchial compartment. Induced sputum from asthmatic patients during stable conditions is usually characterized by a higher percentage of eosinophils and metachromatic cells than that found in samples from healthy subjects [189, 190]. Sputum neutrophilia may also be present across the range of disease severity; its identification is important, as it is associated with a poor response to glucocorticosteroids [191–193].

In stable conditions, ex- or current smokers with COPD characteristically show an increased total cell number in spontaneous or induced sputum, with a predominance of neutrophils and a small percentage of eosinophils in some subjects [133, 194, 195]. In some smokers with chronic bronchitis, with or without chronic airflow limitation,
**FIG. 41.1** Photomicrographs showing bronchial biopsy specimens immunostained with anti-EG-2 (eosinophil cationic protein) from a patient with fixed airflow obstruction and a history of COPD (A) and from a patient with fixed airflow obstruction and a history of asthma (B). The two patients had a similar degree of fixed airflow obstruction. In (B), there is prominent eosinophilia beneath the destroyed epithelium that is not present in (A). Photomicrographs showing bronchial biopsy specimens stained with H&E from a patient with fixed airflow obstruction and a history of COPD (C) and from a patient with fixed airflow obstruction and a history of asthma (D). The two patients had a similar degree of fixed airflow obstruction. In (D), there is a thicker reticular layer of the epithelial basement membrane compared with (C) (from Ref. [10]).

an excess proportion of eosinophils (>3%) in lower respiratory secretions (called "eosinophilic bronchitis") can also occur [100, 186, 187]. A recent study has elegantly shown that in patients with COPD the main cells in sputum are neutrophils and macrophages, with more macrophages and eosinophils than in a sub-phenotype of patients with chronic bronchitis [196].

Analysis of sputum from patients with exacerbations of asthma or COPD has provided interesting new information. Mild exacerbations of asthma induced by tapering the dose of inhaled steroids are associated with sputum eosinophilia [197, 198]. In contrast, mild exacerbations that are spontaneous are associated with eosinophilia in about 50% of subjects, but the other 50% do not have sputum eosinophilia [199]. In children, eosinophilic airway inflammation is associated with deteriorating asthma over time. This is consistent with the hypothesis that airway inflammation has an adverse effect on the prognosis of childhood asthma and suggests a role for monitoring inflammation in asthma management [200]. Severe asthma exacerbations are associated with more prominent sputum neutrophilia [201]. Bronchial neutrophilia has also been observed in bronchial lavage fluid from asthmatics during status asthmaticus [202].

Interestingly, exacerbations of chronic bronchitis or COPD are associated with quite similar changes in sputum cell count. Mild exacerbations of chronic bronchitis or COPD are associated with eosinophilia in sputum and in biopsy specimens [203, 204], whereas severe exacerbations of COPD are associated with sputum neutrophilia [205].

Thus, at least in sputum, the changes in inflammatory cells during exacerbations may be no different in asthma and COPD. Once again, this evidence underlines the similarities between the two diseases and the difficulty in

**TABLE 41.4** History, symptoms, and results of pulmonary function tests in the differential diagnosis between asthma and COPD.

|  | Asthma | COPD |
|---|---|---|
| Onset | Mainly in childhood | In mid to late adult life |
| Smoking | Usually non-smokers | Almost invariably smokers |
| Chronic cough and sputum | Absent | Frequent (chronic bronchitis) |
| Dyspnoea on effort | Variable and reversible to treatment | Constant, poorly reversible and progressive |
| Nocturnal symptoms | Relatively common | Uncommon |
| Airflow limitation | Increased diurnal variability | Normal diurnal variability |
| Response to bronchodilator | Good | Poor |
| Airway hyperresponsiveness | In most patients, with or without airflow limitation | In most patients with airflow limitation |

making a differential diagnosis in those few cases in which clinical findings are not definitive.

Several biochemical markers have been studied in induced sputum from both asthma and COPD patients [206–210] (Table 41.4). Although some markers are markedly different in asthma and COPD, and studying

**FIG. 41.2** Exhaled breath analysis: current state of standardization, research, and clinical use (from Ref. [212]).

these markers may provide useful information in research protocols, their use in clinical practice has not been shown to be superior to simple cell counts.

### Exhaled NO

While endogenous NO may be involved in the pathophysiology of asthma and COPD [211, 212] (Fig. 41.2), exhaled NO is increased in atopic asthma [213–217] but less at lesser extent so in nonatopic asthma [218, 219]. Furthermore, exhaled NO is reduced by glucocorticosteroids [220] but not by bronchodilators [221]. Conflicting results have been obtained in COPD [222–228].

In patients with stable COPD, a partial bronchodilator response to inhaled salbutamol is associated with increased exhaled NO and sputum eosinophilia [101]. Taken together with previous findings [73], this suggests that there is a subset of patients with COPD who share some characteristics of asthmatic inflammation and who may be responsive to steroids [100].

## DIFFERENTIAL DIAGNOSIS BETWEEN ASTHMA AND COPD

In most patients, the clinical presentation and particularly the history provide the strongest diagnostic criteria to distinguish asthma from COPD (Table 41.5). Results of pulmonary function tests, particularly spirometry, that show

**TABLE 41.5** Ancillary tests in the differential diagnosis between stable asthma and COPD.

| Ancillary test | Asthma | COPD |
|---|---|---|
| Reversibility to bronchodilator and/or glucocorticosteroids | Usually present | Usually absent |
| Lung volumes Residual volume, total lung capacity | Usually normal or, if increased, reversible | Usually irreversibly increased |
| Diffusion capacity | Normal | Decreased |
| Airway hyperresponsiveness | Increased | Usually not measurable due to airflow limitation |
| Allergy tests | Often positive | Often negative |
| Imaging of the chest | Usually normal | Usually abnormal |
| Sputum | Eosinophilia | Neutrophilia |
| Exhaled NO | Increased | Usually normal |

a nearly complete reversibility of airflow limitation may help to confirm a diagnosis of asthma, and those that show poorly reversible airflow limitation may help to confirm the diagnosis of COPD (Table 41.5).

Differential diagnosis between asthma and COPD becomes more difficult in elderly patients, in whom some

features may overlap, such as smoking and atopy, and, more importantly, when the patient develops poorly reversible airflow limitation that responds only partially to treatment. In these cases, symptoms, lung function, airway responsiveness, imaging, and even pathological findings may overlap and thus may not provide solid information for the differential diagnosis. Because the differential diagnosis mainly aims to provide better treatment, it is important in these cases to undertake an individual approach and to perform additional tests. Reversibility to corticosteroids alone or in combination with long-acting bronchodilators, measurements of lung volumes and diffusion capacity, analysis of sputum and exhaled NO, and imaging of the chest may demonstrate whether asthma or COPD is the predominant cause of airflow limitation (Table 41.5). In contrast, reversibility to bronchodilator and assessment of airway hyperresponsiveness or skin testing may not be useful in these patients.

## COMORBIDITIES OF ASTHMA AND COPD

The coexistence of chronic rhinitis, nasal polyposis, and sinusitis may contribute to the severity of asthma [229, 230]. There is broad evidence to show that adequate treatment of these upper airway diseases is beneficial to asthma by mechanisms that are not clearly understood. The "one airway" concept developed by the WHO ARIA Group [231] has drawn attention to the importance of treating the whole respiratory tract while managing asthma. Gastroesophageal reflux is also occasionally associated with asthma, both in adults and in children [232], but treatment of reflux usually has little overall effect on mild to moderate asthma [233]. Two recent studies [234, 235] indicate that proton-pump inhibitors in patients with symptomatic reflux improve asthma control in severe disease. A frequent and quite important comorbidity of asthma in adults is COPD, most likely due to smoking, which is quite common in asthmatics. Smoking modifies the airway pathology of asthmatics to a COPD-like pattern and reduces the response to treatment [7]. Comorbidities may become important in severe asthmatics, whereas overall they play a less important role overall in the clinical manifestations of mild to moderate asthma [236, 237].

Recent research suggests that inflammation in COPD is not confined to the lungs, because the main risk factor, smoking, may simultaneously cause pulmonary and systemic inflammation. This may account for the observation that patients with COPD often present with one or more comorbid conditions. The most common comorbidities that have been described in association with COPD are *hypertension*, *diabetes*, coronary artery disease [238, 239], *chronic heart failure* [240], pulmonary infections, *cancer* [241], and *pulmonary vascular disease* [242, 243].

Comorbidities are highly likely to affect health outcomes in COPD. Progressive respiratory failure accounts for only about one-third of COPD-related deaths: COPD patients are more likely to die of *cardiovascular* complications or *cancer* than of respiratory failure [242]. Therefore, factors other than the progression of lung disease must play a substantial role. The number of preexisting comorbidities

in patients with COPD is associated with increased in-hospital mortality [239]. Comorbid conditions that have been associated in particular with an increased mortality risk in COPD patients include chronic renal failure, cor pulmonale [244], and *pulmonary vascular disease* [245]. Underlying heart diseases have not been consistently associated with a higher mortality risk. However, since COPD is frequently underreported, it is difficult to make an accurate estimate of how comorbid conditions influence COPD mortality or, conversely, how COPD affects the outcome of other diagnoses [242].

The complexity of chronic comorbidities applies to acute exacerbations of asthma and COPD to a similar extent. Acute exacerbations of respiratory symptoms may be present in several other acute conditions that should always be carefully considered and excluded, such as acute left ventricular failure, pulmonary thromboembolism, pneumonia, metabolic acidosis, and anemia.

Heart and Lung Institute, Imperial
College, London, UK

## INTRODUCTION

Airway inflammation is thought to be an important component of asthma, chronic obstructive pulmonary disease (COPD), and the various cough syndromes. However, it is not routinely assessed in clinical practice and much of what we know about the nature and importance of airway inflammation is derived from bronchoscopy studies. These studies are limited by the invasive nature of bronchoscopy, bronchial biopsy, and bronchoalveolar lavage so it has not been possible to study large heterogeneous populations nor has not been standard practice to assess airway inflammation in clinical practice or clinical trials.

Over the last 15–20 years there has been an explosion of interest in the assessment of airway inflammation using non-invasive means and there are now a large number of different techniques to assess airway inflammation, each with its own strengths and weaknesses (Table 42.1). Two techniques are particularly well developed and are already widely used in clinical trials and impacting on clinical practice: induced sputum, where a sputum differential and total cell count is used to determine the characteristics and intensity of the lower airway inflammatory response; and exhaled nitric oxide ($FE_{NO}$), where the concentration of nitric oxide (NO) in exhaled air is used to provide information about the presence of eosinophilic, corticosteroid responsive airway inflammation. Induced sputum has the advantage of providing measurements of the type of airway inflammation (eosinophilic versus neutrophilic) as well as its severity. The main limitation is that results are not available immediately, limiting the application of the technique in asthma monitoring. $FE_{NO}$ has the advantage of being simple to measure and provides an immediate result but it provides only limited information on the nature of the inflammatory response. The different strengths and weaknesses of the techniques suggests that they may find different roles, with $FE_{NO}$ being used mainly in primary care to facilitate diagnosis and to titrate corticosteroid therapy and induced sputum used in secondary and tertiary care, where more detailed information on the type of lower airway inflammation is necessary.

In this chapter we will review the methodology and validation of induced sputum and $FE_{NO}$ and outline other more experimental approaches to the assessment of airway inflammation. We will finish by discussing how the widespread application of induced sputum to large and heterogeneous populations of patients with airway disease has furthered our understanding of the complex relationship between airway inflammation and the clinical expression of airway disease and opened the way to a new approach to the management of airway disease based on assessment of airway inflammation (inflammometry).

## INDUCED SPUTUM

### Methodology

Sputum induction using nebulized hypertonic saline is used to collect respiratory secretions from the airways of patients who do not expectorate spontaneously. The precise mechanism leading to production of increased secretions is not known but increased production of mucous by the submucosal glands, increased vascular permeability of the bronchial mucosa and release of pro-inflammatory mediators may all contribute. Eighty to ninety percent of patients with airway disease and a similar proportion of healthy controls are able to produce a satisfactory sputum sample following hypertonic saline inhalation.

**TABLE 42.1** Comparison of methods measuring airway inflammation.

| | Ease of performing technique | Ease of analyzing result | Time to result | Cost | Influence on outcome proved | Potential use |
|---|---|---|---|---|---|---|
| Induced sputum | Simple sputum sample | Simple, but requires experience | 3–4 h | Moderate | Yes | Secondary care |
| Blood eosinophil count | Simple blood test | Simple | 30 min | Inexpensive | Suggests eosinophilic airway inflammation when raised in correct context | Secondary care |
| Eosinophil cationic protein | Urine test/sputum test/blood test | Simple | 3–4 h | Moderate | Not proven conclusively | Research |
| Exhaled nitric oxide | Very easy breathing test | Easy | Immediate | Expensive though could become cheaper | Not proven | Research Possibly primary care |
| Exhaled breath temperature | Thermometer. Complex currently but could be simplified. | Easy | Immediate | Inexpensive | Studies awaited | Research |
| Breath condensate | Cooling/freezing of exhaled air | Simple | Moderate | Inexpensive | Studies awaited | Research |
| BAL, bronchial wash, and biopsy | Biopsy- invasive | Complex | 2 days | Moderate | Yes | Secondary care |

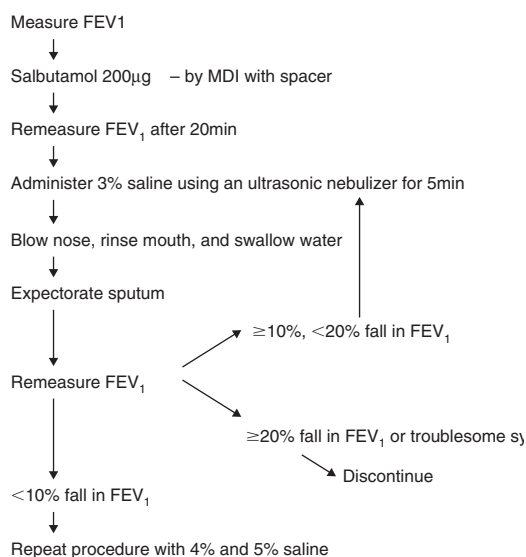
**BOX 42.1 PROTOCOL FOR SPUTUM INDUCTION USING NEBULIZED HYPERTONIC SALINE.**

Measure FEV1
↓
Salbutamol 200μg  – by MDI with spacer
↓
Remeasure FEV$_1$ after 20min
↓
Administer 3% saline using an ultrasonic nebulizer for 5min
↓
Blow nose, rinse mouth, and swallow water
↓
Expectorate sputum
↓
Remeasure FEV$_1$
→ ≥10%, <20% fall in FEV$_1$
→ ≥20% fall in FEV$_1$ or troublesome symptoms → Discontinue
↓
<10% fall in FEV$_1$
↓
Repeat procedure with 4% and 5% saline

---


A variety of protocols for sputum induction have been published and shown to be safe provided patients are pre-treated with bronchodilators and monitored carefully [1, 2]. Risk factors for bronchoconstriction include a low baseline FEV$_1$% predicted [3], overuse of short-acting $\beta_2$-agonists [4] and poor asthma control [4]. Symptomatic bronchoconstriction is unusual in patients with COPD, even those with severe airflow obstruction [5]; sputum induction has also been carried out repeatedly and safely in patients with severe asthma [6]. It is likely that higher nebulizer output, higher concentration of inhaled saline, a longer duration of saline inhalation and reduced frequency and timing of safety assessment by forced expiratory volume in 1 s or peak expiratory flow reduce safety. Higher output nebulizers have also been associated with the development of a sputum neutrophilia 24 h after sputum induction [7]. Whether this is seen with the low output nebulizers is unknown. A common and well-validated protocol is to use a relatively low output ultrasonic nebulizer (output 0.7–0.9 ml/min) delivering increasing concentrations of hypertonic saline [5, 6, 8]. The method is summarized in Box 42.1.

Once expectorated sputum should be processed within 2 h. There is evidence that sputum can be stored for up to 9 h in a refrigerator at 4°C or that sputum can be snap frozen for longer without affecting cell counts [9], although experience with these techniques is limited. The whole expectorate or selected sputum plugs can be processed. The latter approach has the advantage of producing better quality cytospins and more repeatable differential cell counts [10]. A common method used to process induced sputum is outlined in Box 42.2. The total cell count, cell viability and squamous cell contamination are assessed using a hemocytometer. Differential cell counts are determined by counting 400 leukocytes on an appropriately stained cytospin. Other biomarkers can also be measured in the sputum supernatant. Some of the molecular markers of airway inflammation that have been successfully measured in sputum are shown in Table 42.2.

---

## BOX 42.2 PROTOCOL FOR PROCESSING OF SPUTUM.

Process at 4°C within 2 h of expectoration

Select sputum (if necessary using inverted microscope)

↓

Weight and incubate with 4 × volume 0.1% dithiothreitol (DTT)

↓

Gently aspirate with pasteur pipette, vortex for 15 s

↓

Rock on bench rocker for 15 min on ice

↓

Mix with equal volume (to DTT) of Dulbecco's phosphate buffered saline (DPBS)

↓

Vortex for 15 s

↓

Filter through 48 μm nylon gauze (pre-wet with DPBS)

↓

Centrifuge 790 g 10 min  ⟶  Store supernatant at −70°C

↓   ↓

Resuspend cell pellet in DPBS    Measure fluid phase

↓

Perform total cell count and viability by trypan blue exclusion method in Neubauer hemocytometer

↓

Adjust cell suspension to $0.5-0.75 \times 10^6$ cells/ml with DPBS

↓

Prepare cytospins by placing 50 or 75 μl cell suspension in cups of cytocentrifuge and centrifuge at 450 rpm for 6 min

↓

Air dry and stain

**TABLE 42.2** Cell types and molecular markers that have been successfully measured in induced sputum.

| Cells | Effector mediators | Cellular markers | Cytokines/ chemokines |
|---|---|---|---|
| Eosinophils | Leukotrienes | Eosinophilic cationic | Interleukin-8 |
| Neutrophils | $C/D/E_4$ | protein | |
| Macrophages | Prostaglandin $D_2$ | Neutrophil elastase | |
| Lymphocytes | Histamine | | |
| Epithelial | | | |
| Mast cells | | | |

It is generally agreed that the central airways are sampled with induced sputum. This view is supported by studies showing a greater proportion of granulocytes in both sputum and bronchial samples compared with bronchoalveolar lavage [11–13] and by the demonstration that sputum induction results in greater clearance of radiolabeled aerosol from the central airways than the peripheral airway [14]. There is evidence that increasing the duration of sputum induction leads to sampling of more distal airways although, as yet, the clinical utility of this technique has not been explored [15].

## Validation

Sputum differential cell counts have been shown to correlate closely with bronchial wash cell counts [16], less closely with bronchoalveolar lavage counts [13, 16] and not at all with biopsy cell counts [17]. This may reflect sampling of different airway compartments by the different techniques and the fact that some cell types (notably eosinophils and neutrophils) are not tissue dwelling.

Normal ranges have been published for a large adult population [18–20] (Table 42.3). Age has been shown to influence differential sputum neutrophil counts, with the higher values occurring in the older age groups [20]. Sputum differential eosinophils, macrophage and neutrophil counts and the sputum supernatant concentration of eosinophilic cationic protein (ECP), cysteinyl–leukotrienes, prostanoids, and IL-8 can be measured repeatably in asthma [21–23] and in COPD [5] (Table 42.3). The differential lymphocyte and epithelial cell count and the total cell count are less repeatable [22]. Spontaneous and induced sputum have similar cell and molecular characteristics and they can be used interchangeably in asthma and COPD; there is no evidence that pre-treatment with salbutamol or a prior methacholine inhalation test influences sputum cell counts.

The sputum eosinophil count is responsive in that it increases when asthma worsens (e.g. after allergen challenge and following relevant occupational exposures [24, 25]), and decreases when asthma improves with inhaled corticosteroid (ICS) treatment [26]. Sputum and bronchoscopy studies with corticosteroids [26, 27] and anti-IL-5 [28, 29] suggest that the sputum eosinophil count is more responsive than tissue eosinophil counts. The sputum differential neutrophil count is reduced following treatment with the fixed dose combination inhaler seretide in patients with COPD [30]. There are theoretical reasons to suggest that the total neutrophil count may be a more responsive measure than the differential count since the relationship between them becomes relatively flat over a differential neutrophil count of 80% [31].

Based on what is known about the responsiveness and repeatability of the sputum eosinophil count, a 2-fold change is regarded as clinically significant [32]. A reduction of the sputum neutrophil differential cell count of 13% or more has been regarded as significant since longitudinal, observational studies suggest that a difference of this magnitude is associated with a clinically important reduction in the rate of decline in lung function in patients with COPD [33].

## Findings in disease

Clinically relevant patterns of airway inflammation include neutrophilic, eosinophilic, and mixed eosinophilic and

**FIG. 42.1** Classification based on induced sputum patterns of cellular inflammation in airway diseases.

neutrophilic (Fig. 42.1). The latter pattern is most commonly seen in COPD, refractory asthma, and in exacerbations of airway disease. A sputum neutrophilia with a raised total cell count suggests infective bronchitis, COPD, and bronchiectasis; a neutrophilia with a normal total cell count is more non-specific but is commonly seen in chronic cough and non-eosinophilic asthma. A significant minority of patients with airway disease have paucigranulocytic sputum characterized by normal sputum eosinophil and neutrophil counts (Fig. 42.1).

A raised sputum eosinophil count is the most characteristic finding in patients with asthma. 60–80% of patients with symptomatic untreated asthma and around 50% of patients taking ICS have a sputum eosinophil count above the normal range. A minority of patients with asthma of all severity grades have consistently non-eosinophilic sputum; many have a sputum neutrophilia. A raised sputum eosinophil count is not exclusive to asthma: 30–40% of patients with cough and a similar proportion of patients with COPD have a sputum eosinophilia (Fig. 42.2). Roughly a half of patients with cough and a sputum eosinophilia have evidence of variable airflow obstruction and/or airway hyperresponsiveness and meet diagnostic criteria for cough variant asthma. The remainder consistently do not and are classified as having eosinophilic bronchitis. Patients with COPD and a sputum eosinophilia may have more asthma like features such as bronchodilator reversibility, atopy, and airway hyperresponsiveness but there is too much overlap in the presence of these features to make it possible to reliably predict pathology on the basis of these tests.

## EXHALED NITRIC OXIDE

### Methodology

$FE_{NO}$ is usually measured by chemiluminescence. This uses ozone to react with NO and produce nitrogen dioxide which then emits photon in a stoichiometric relationship with the

**FIG. 42.2** Approximate prevalence of eosinophilic airway inflammation (defined as a sputum eosinophil count >1.9%) in different patient populations. Each dot represents an estimate of prevalence from a single study. Adapted from Gibson *et al*. [75].

amount of NO present in the gas sample. This technique is sensitive, allowing measurements down to 1 part per billion (ppb) [34]. $FE_{NO}$ can be measured either "offline" or "online". Online measurement involves the inhalation of NO free air immediately followed by exhalation at a steady flow directly into the measuring apparatus, whereas in offline measurements the exhaled air is collected in a Mylar® balloon and then transported to the NO analyzer.

There is now a consensus that $FE_{NO}$ is best measured before other spirometric maneuvers, at an exhaled rate of 50 ml/s maintained within 10% for >6 s, and with an oral pressure of 5–20 $cmH_2O$ to ensure velum closure [35]. The technique is simple and well within the scope of most patients in primary care, including children as young as 5 years of age [36]. Results are expressed as the NO concentration in ppb (equivalent to nanoliters/liter) based on the mean of two or three values within 10% [37]. NO output can be calculated as the product of the exhaled NO concentration in nl/l and the exhalation flow in l/min. Alveolar NO concentration can be estimated from measurement of NO output at multiple exhalation flows [38]. Alveolar NO may reflect distal lung inflammation; it is increased in patients with refractory asthma and is reduced by oral, but not inhaled, corticosteroids [39]. The clinical role of this derived measurement has not been firmly established and it will not be considered further.

## Validation

Robust estimates of $FE_{NO}$ measured using the above methods are available in children [40] and, to a lesser extent, adults [37]. $FE_{NO}$ tends to increase in healthy children to the age of 17; thereafter the values are similar to adults. There is no age effect in adults. There is conflicting data on the effects of gender [37, 40]. One study suggested fluctuations in $FE_{NO}$ in healthy pre-menopausal women related to the menstrual cycle, with peak values mid-cycle [41]. A reasonable estimate of the normal ranges of $FE_{NO}$ in adults is <30 ppb [37, 40]; this is reduced to <24 ppb when outliers are removed from the analysis and <22.4 ppb when outliers and atopics are removed. Various factors have been shown to influence $FE_{NO}$ and some do so independently of the presence of eosinophilic airway inflammation. These factors and the likely mechanism of the effect on $FE_{NO}$ are summarized in Table 42.4. Genetic factors are known to affect the production of NO: van's Gravesande *et al.* demonstrated a strong relationship between a known functional NOS3 missense sequence variant in the endothelial nitric oxide gene (G894T) and $FE_{NO}$ level in a cohort of subjects with asthma [42], and the number of alpha-1 antitrypsin (AAT) repeats in intron 20 of this gene correlate with NO levels, with a higher number of repeats associated with lower NO levels [43].

The between subject standard deviation of $FE_{NO}$ is around 25 ppb in asthma and 8 ppb in normal controls [37]. The within subject standard deviation has been estimated at 1.6–2 ppb in a range of subjects [37, 40]. $FE_{NO}$ is reduced 2- to 4-fold by corticosteroids in patients with asthma [44–46] and is increased (by about 60%) by during the late response to allergen in subjects with atopic asthma [47]. There is a dose-related effect of low dose ICS on $FE_{NO}$ but no additional benefit above a dose of budesonide of 400 μg/day [44, 48, 49]. Based on what is known about the effect of ICS on $FE_{NO}$ and the predictive value of a change in $FE_{NO}$ [50], a reasonable minimally important difference is a 60% change either way.

## Findings in disease

Any form of airway inflammation increases $FE_{NO}$ levels, including that seen in bronchiectasis, viral infection, fibrosing alveolitis, allergic rhinitis, pulmonary tuberculosis, COPD, and pulmonary sarcoidosis, although the relationship between inflammation and $FE_{NO}$ is complex as pneumonia [51], ciliary dyskinesia, and cystic fibrosis [52] have been shown to be associated with reduced $FE_{NO}$. Cross-sectionally, the relationship between $FE_{NO}$ levels and eosinophilic airway inflammation is much closer than the relationship with other markers of airway inflammation [53] and it is not clear to what extent the finding of a raised $FE_{NO}$ are a true reflection of the presence of eosinophilic airway inflammation in these conditions.

## OTHER METHODS TO MEASURE AIRWAY INFLAMMATION

## Exhaled condensate

The collection of exhaled breath condensate (EBC) and assay of inflammatory markers is the most recent development in non-invasive asthma monitoring technologies. Methodological aspects of EBC collection and analysis have been reviewed by a European Respiratory Society (ERS) working party [54]. Water vapor and respiratory droplets and particles are cooled and collected and used for conventional assay or inflammatory markers such as leukotrienes [55], 8-isoprostane [56], *pH* [57], and hydrogen peroxide [58–60]. The current methods for the collection of EBC vary primarily in the type of condensers that are employed. The physical surface properties of each condenser system may influence the condensate that is collected. Therefore it is possible that there may be variation between systems in terms of the particles

**TABLE 42.4** Factors associated with increased and decreased $FE_{NO}$.

| Factor | Effect on $FE_{NO}$ | Likely mechanism |
|---|---|---|
| Age | Increase until age 17, no effect thereafter | Increased airway size |
| Gender | Mixed evidence. If anything lower in females independent of height but not a major effect | ? Increased airway size in males |
| Height | Small increase with increasing height | Increased airway size |
| Atopy | Increased in atopic patients | Underlying eosinophilic airway inflammation, which may be asymptomatic in some |
| Smoking | Increased in non-smokers | Unclear. May depend on time of last cigarette. Relationship between $FE_{NO}$ and sputum eosinophil count lost in smokers |
| Spirometry | Transient reduction after spirometry | Unclear. $FE_{NO}$ should be done before other tests. |
| Rhinitis | Increased, independent of atopy | ? Increased eosinophilic airway inflammation |

collected. The influence of salivary contamination on EBC values may also be a problem as many of the mediators assayed are found in high concentration in saliva [61]. The measurement characteristics of some of the mediators detectable in EBC are summarized in Table 42.5.

Assessment of airway inflammation using EBC is non-invasive and feasible in almost all patients. It has the potential to provide information about different aspects of the airway inflammatory response and this information may be clinically important. However, results are not available immediately, limiting the clinical utility of the technique. Future technological advances may overcome this problem. There is evidence of significant variability in the concentration of some EBC markers and the reported relationship between the concentration of EBC markers and other inflammatory or clinical measures is variable between studies raising the possibility of unresolved methodological issues and a need for further validation work.

## Exhaled breath temperature

Exhaled breath temperature is a potential marker of airway inflammation as it is likely to reflect vascular hyperperfusion secondary to tissue inflammation and airway remodeling. Measurement of exhaled breath temperature and bronchial blood flow [62] is feasible in asthma [63] and COPD [64]. Asthma is associated with increased exhaled breath temperature presumable reflecting increased blood flow due to new vessel formation and vasodilatation. Exhaled breath temperature is not consistently increased in COPD, suggesting differences in bronchial blood flow and tissue remodeling. Whether exhaled breath temperature provides clinically important information over and above other techniques has not been established but if it does, then the simplicity of the  technique makes it an attractive option as a non-invasive marker of airway inflammation although the lack of specific information on the pattern of airway inflammation may limit its clinical value.

## Serum ECP

ECP is a product of eosinophils and there has been interest in the use of serum, sputum or urinary ECP as a non-invasive marker of eosinophilic airway inflammation. Serum ECP concentrations are higher than EDTA plasma concentration, probably because blood eosinophils continue to produce ECP *ex-vivo* in the absence of additives. Serum ECP concentrations are thought to be better at discriminating health from disease and are preferred. A standardized collection, processing, and testing method has been described [65].

Serum ECP increases with spontaneous allergen exposure or after a laboratory allergen challenge and decreases following allergen avoidance and ICS therapy. However, serum ECP is a less responsive measure than the sputum eosinophil count and $FE_{NO}$ [66, 67]. Compared with eosinophil counts, ECP measurements in either induced sputum or serum failed to reflect treatment-related changes in chronic asthma [68], supporting the view that serum ECP is not a sensitive or reliable means of evaluating eosinophilic airway inflammation. Moreover, serum ECP was found to be insensitive marker in titrating and monitoring therapy with ICS over a wide dose range in childhood asthma [69] and it does not help predict a response to corticosteroid therapy [70]. Finally, a randomized trial which compared a serum ECP based algorithm with a conventional algorithm for managing asthma found no improvement in symptom scores, in spite of increased doses of ICS [71]. These findings suggest that serum ECP is an imperfect and insensitive measure of eosinophilic airway inflammation, which provides no particular advantages over other techniques.

## NEW INSIGHTS INTO THE IMPORTANCE OF AIRWAY INFLAMMATION IN AIRWAY DISEASE

Our view of the importance of inflammation in the pathogenesis of asthma and other airway diseases has been heavily influenced by bronchoscopy studies performed over the

**TABLE 42.5** Measurement characteristics of markers assayed in exhaled breath condensate.

| | 8-isoprostane | Cysteinyl leukotrienes | Hydrogen Peroxide | pH |
|---|---|---|---|---|
| Methodology | EIA, GCMS | EIA | | De-aerated sample, pH meter |
| Normal range | ? | ? | ? | 6.8–8.1 |

*Notes*: EIA: enzyme immunoassay; GCMS: gas chromatography–mass spectrometry; NS: not significant.

last 20 years [72]. These, by necessity, were largely limited to young volunteers with mild disease. The development of a non-invasive technique to assess airway inflammation has made it possible to relate the presence of airway inflammation to objective measures of disordered airway function in larger and more heterogeneous populations than was possible with bronchoscopy studies. These studies have suggested a complex relationship between airway inflammation and the pattern and severity of airway dysfunction [8, 73, 74]. Clinicians and researchers interested in using measures of airway inflammation need to be aware of this relationship in order to fully appreciate the added value such measures provide. A number of key observations are particularly important. All have been primarily made using induced sputum as the measure of airway inflammation but they are potentially relevant to the use of $FE_{NO}$ given the close relationship between $FE_{NO}$ and eosinophilic airway inflammation.

Firstly, the presence of pattern of airway inflammation is not closely related to either the pattern or the severity of the airway dysfunction or symptoms. A raised sputum eosinophil count is seen in 60–80% of corticosteroid naive patients with asthma, 50% of corticosteroid treated patients with symptomatic asthma [75], 30–40% of patients with cough [76], and up to 40% of patients with COPD [77]. Within diagnostic groups there is a weak correlation between the presence of eosinophilic airway inflammation and the severity of symptoms or disordered airway function [73]. Thus, little can be deduced about the presence, nature and severity of airway inflammation from a standard clinical assessment.

This observation is important as it strongly implies that there is not a close causal link between eosinophilic airway inflammation and the airway dysfunction that underlies many of the day-to-day clinical manifestations of asthma. Further support for this view is provided by studies showing that treatment with anti-IL-5 markedly reduced eosinophilic airway inflammation but does not affect asthma symptoms, lung function or airway responsiveness [29, 78]. A comparative bronchial biopsy study of asthma and eosinophilic bronchitis (a condition where one sees eosinophilic airway inflammation in the absence of the abnormalities of airway function that characterize asthma) has shown that infiltration of the airway smooth muscle with mast cell is only seen in asthma [79]. Moreover, the extent of infiltration is closely related to airway hyperresponsiveness implying that it is the interaction between mast cells and airway smooth muscle that is of fundamental importance in the genesis of airway hyperresponsiveness.

Secondly, the presence of eosinophilic airway inflammation is more closely associated with a positive response to corticosteroids than other clinical measures. Moreover, a positive response to corticosteroids is seen irrespective of the pattern of airway disease in which eosinophilic airway inflammation occurs (Fig. 42.3) [26, 77, 80–82]. Thus, if the clinical questions were whether a patient with symptoms suggesting airway disease should receive corticosteroid treatment (as it often is), then the identification of eosinophilic airway inflammation would be a better basis for making this decision than the findings of other tests.

**FIG. 42.3** Mean net change in $FEV_1$ with after 2 weeks treatment with prednisone 30 mg od in 69 patients with moderate and severe COPD participating in a randomized, double blind placebo controlled trial. Patients are stratified into tertiles based on baseline sputum eosinophil count. Reproduced with permission from Brightling *et al.* [77].

Thirdly, the sputum eosinophil count is a better marker for titrating corticosteroid therapy than standard clinical measures. Studies in asthma [6, 83] and COPD [84] have shown that management strategies where decisions about corticosteroid use and dose are guided by the sputum eosinophil count results in a lower frequency of exacerbations and more economical use of corticosteroids than management guided by traditional clinical measures (Fig. 42.4). The findings of these studies, together with evidence that a sputum eosinophilia is an important and independent predictor of the occurrence of an asthma exacerbation following corticosteroid withdrawal [85, 86], suggest that eosinophilic airway inflammation is a more valid surrogate marker of preventable exacerbation risk than other currently available markers.

Fourthly, there is a clear and consistent positive correlation between a raised sputum neutrophil count and the presence of fixed airflow obstruction as reflected by a reduced post-bronchodilator $FEV_1$ and $FEV_1/FVC$. This is seen in patients with asthma [87] and COPD [88] and in COPD a raised sputum neutrophil count is associated with longitudinal decline in $FEV_1$ [33]. These findings raise the possibility of a common mechanism for the development of fixed airflow obstruction involving neutrophilic airway inflammation. Much more information is required before we can be sure that there is a causal link between neutrophilic airway inflammation and fixed airflow obstruction. In particular, there is a need for longitudinal studies evaluating the effect of reducing neutrophilic airway inflammation. Nevertheless, there is sufficient evidence to speculate that a raised sputum neutrophil count is a useful biomarker of risk of subsequent decline in lung function.

The new understanding of the importance of airway inflammation in airway disease has opened the way for a new approach to the management of airways disease in clinical practice where assessment of airway inflammation

Results: Severe exacerbations

*$p$ = 0.01
FIG. 42.4  Comparison of effects of two treatment strategies on rates of severe exacerbations of asthma. One strategy (British Thoracic Society (BTS) guidelines) utilized standard guidelines of the BTS and the other (sputum guidelines) adjusted the anti-inflammatory treatment with corticosteroids based on the eosinophil counts. Reproduced from Green et al. [6].

is used to identify risk of future adverse outcome and likely response to treatment.

## FE$_{NO}$ AS A MEANS OF MONITORING AIRWAY INFLAMMATION

The main limitations of induced sputum are that the technique is labor intensive, it requires a significant amount of training to get reliable results and results are not available immediately, limiting the application of the technique in disease monitoring. FE$_{NO}$ has the advantages of being simple to measure and providing an immediate result making it much more suitable for a monitoring tool.

FE$_{NO}$ is a reasonably robust measure of the presence of eosinophilic airway inflammation across a wide range of patients differing in atopic status, diagnosis, and medication [53]. The association is lost in current smokers [53]. As for sputum eosinophils, it has been shown that a raised FE$_{NO}$ level is a reliable indicator of a positive response to corticosteroids in a heterogeneous population of patients with symptoms suggesting airway disease [89]. This finding was independent of the clinical diagnosis at presentation, in particular the label of asthma. One corticosteroid reduction study has shown that a raised F$_E$NO is predictive of loss of asthma control [50] but two others have shown less convincing evidence for such an effect [86, 90]. The relationship between airway eosinophilia, FE$_{NO}$ levels, steroid responsiveness, and exacerbation risk raises the possibility that FE$_{NO}$ can be used as a guide to corticosteroid dose requirements. This has been investigated in a number of small studies in different populations [91–93]. The findings show a consistent trend to reduction in asthma exacerbation of around 25%, in one study this was achieved with a 40% lower mean daily dose of ICS [91]. More definitively, studies have shown that FE$_{NO}$ levels may be used to identify which patients do and do not require long-term maintenance therapy with inhaled steroids: the predictive values

for either high (>50 ppb) or low (<25 ppb) FE$_{NO}$ levels are highly significant and may be used with confidence to guide decision-making [94, 95]. More needs to be learnt about the optimum cut-points for FE$_{NO}$ as a marker of corticosteroid responsive airway disease and as a tool for asthma monitoring, but the evidence to date suggests that the use of regular FE$_{NO}$ measurements is a promising way to achieve more economical and effective use of ICS [96].

## POTENTIAL CLINICAL ROLE OF INFLAMMOMETRY

### Role in diagnosis

None of the currently available diagnostic tests are sufficiently sensitive to rule out asthma [97, 98] with the result that treatment trials are often instigated without good evidence variable airflow obstruction, airway hyperresponsiveness or airway inflammation. One study has shown that out of 263 subjects referred to a tertiary referral center with suspected asthma, 160 received an alternative diagnosis [99]. Many of these had received prolonged treatment with potentially toxic therapy before the correct diagnosis was reached. Even in tertiary referral centers the diagnosis of refractory asthma can be difficult to make with certainty [100]. The presence of a sputum eosinophilia or raised FE$_{NO}$ in asthma is sufficiently common to suggest that these findings may have a role in the diagnosis of asthma. Hunter et al. [98] showed that the sensitivity of a sputum eosinophil count outside the normal range in identifying asthma (defined as consistent symptoms with objective evidence of abnormal variable airflow obstruction) was around 80%, significantly better than PEF amplitude % mean and the acute bronchodilator response and approached the sensitivity and specificity of measurement of airway responsiveness. Smith et al. [97] have reported similar findings; in

this study a high $FE_{NO}$ concentration achieved a similarly high diagnostic accuracy. Similar results have been reported by Berkman *et al.* [101] and Dupont *et al.* [102]. $FE_{NO}$ performed less well in a community study [103], possibly because the diagnosis of asthma was less rigorous and because subjects were tested whilst taking ICS.

Arguably it matters more to patients what can be done to help them than the diagnostic label attached to them. Thus, testing strategies that identify patients who are going to respond well to corticosteroid and provide guidance on the dosing of corticosteroids might be particularly helpful. There is now compelling evidence that the presence of a sputum eosinophilia or a raised $FE_{NO}$ predicts corticosteroid responsiveness. This was first clearly demonstrated by Morrow-Brown in the 1950s who showed that patients with airway disease and a sputum eosinophilia responded to corticosteroid treatment whereas those without a sputum eosinophilia did not [104]. It has since been shown that patients with non-eosinophilic asthma respond less well to inhaled budesonide than a group with more typical sputum features [26, 105]. This is also the case with longer-term corticosteroid treatment in patients with more severe asthma [6]. A sputum eosinophilia or raised $FE_{NO}$ [91] is a predictor of a steroid response irrespective of the clinical context: patients with chronic cough respond well to inhaled corticosteroids if there is a sputum eosinophilia [80, 106] and patients with COPD with a sputum eosinophilia respond better to systemic and ICS than those without [77, 81, 107].

## Role in monitoring asthma

Once a decision is made to start corticosteroid treatment the next question is how best to titrate this therapy. Traditionally dose titration is done by assessing the clinical response to treatment and attempting to define the lowest dose of ICS that maintains this. Many patients do very well with this approach [108] but there is evidence that the use of the induced sputum eosinophil count to titrate therapy results in a lower exacerbation frequency with no overall increase in treatment, particularly in patients with more severe asthma (Fig. 42.4) [6, 83]. A number of researchers have investigated whether a similar effect is seen using $FE_{NO}$ as the monitoring tool (Table 42.6). Smith *et al.* [91] used $FE_{NO}$ measurements at a flow of 250ml/s to titrate ICS in a single blind parallel group trial involving 92 subjects with asthma. Subjects were treated according to their $FE_{NO}$ measurements or Global Initiative for Asthma (GINA) guidelines. Following a run in period the steroid dose was reduced in the $FE_{NO}$ group if the $FE_{NO}$ was <15 ppb (equivalent to an $FE_{NO}$ of about 45 ppb using an expiratory flow of 50 ml/s). In the control group, steroid reduction was based on current GINA guidelines and only occurred when the subjects had, over the course of the previous week, achieved all of the following: less than 2 night-time awakenings, a mean peak flow amplitude of <20%, bronchodilator use <4 times on 1 or 2 days, minimal asthma symptoms, and a $FEV_1$ > 90% predicted.

**TABLE 42.6** Summary of studies investigation $FE_{NO}$ as a tool for monitoring corticosteroid treatment in asthma.

| Study | Design | Population | Duration | Intervention | Reduction in exacerbation frequency | Change in ICS dose |
|---|---|---|---|---|---|---|
| Smith *et al.* [91] | Single blind, parallel group | 97 adults with mild-moderate asthma | 12 months, after an optimization phase of up to 12 months | Control: conventional measures of asthma control Intervention: $FE_{NO}$ < 15* ppb | 0.49 moderate and severe exacerbation/ patient/year in intervention and 0.9 in control ($p = 0.27$) | 40% lower in intervention group ($p = 0.003$) |
| Pijnenburg *et al.* [92] | Single blind, parallel group | 85 children with atopic asthma | 12 months | Control: control of symptoms Intervention: Control of symptoms and $FE_{NO}$ < 30 ppb | Eight courses of prednisolone in intervention and 18 in control; $p = 0.6$ | Cumulative dose over 5 visits of 4407 μg in intervention, 4332 μg in control |
| Shaw *et al.* [93] | Single blind, parallel group | 118 adults with a primary care diagnosis of asthma | 12 months | Control: control of symptoms Intervention: $FE_{NO}$ < 26 ppb | 0.42 severe exacerbation/ patient/year in control and 0.33 in intervention ($p = 0.4$) | 12% higher in intervention group ($p = 0.4$) |

*Note:* ICS: inhaled corticosteroid.
*Measured at 250 ml/s.

In the $FE_{NO}$ group the optimal dose was one dose above the dose at which the subjects $FE_{NO}$ was >15 ppb. In the control group the optimal dose was one dose above the dose at which a loss of control had occurred. These became the optimal doses at which subjects entered the final year of the study. During this stage the steroid dose was increased in the $FE_{NO}$ group if the $FE_{NO}$ was >15 ppb and in the control group the optimal dose was increased if a loss of control occurred. Although there were fewer exacerbations in the $FE_{NO}$ group, this did not reach statistical significance. However, over the year of the study the $FE_{NO}$ managed group used 40% less ICS.

A similar study in a pediatric population showed a significant improvement in airway responsiveness in children whose $FE_{NO}$ was maintained below 30 ppb when compared to a population whose corticosteroid dose was titrated using traditional measures [92]. Few exacerbations were seen with either management strategy and there was no overall reduction in corticosteroid dose.

Shaw et al. [93] took a different approach in a single blind parallel group trial of 118 adults with asthma managed in primary care. In the control group the goal of treatment was to maintain the Juniper asthma control score below 1.57 [109]; in the intervention group the aim was to achieve this and to maintain the $FE_{NO}$ between 16 and 26 ppb. Exacerbation frequency assessed over 12 months was 21% lower ($p = 0.4$) in the intervention group and there was no overall difference in corticosteroid dose over

the year. The study was underpowered to show a clinically important effect on exacerbation frequency although the effect on severe exacerbation frequency was similar to that seen by Smith et al.

The results of corticosteroid dose–titration studies with $FE_{NO}$ are therefore mixed. There is a fairly consistent finding of a small reduction in severe asthma exacerbations in patients managed with reference to $FE_{NO}$ (Table 42.6) but a much larger study will be needed to determine whether such an effect is real, and whether it can be achieved cost effectively and with no overall increase in corticosteroid therapy.

The induced sputum studies showing a reduction in exacerbation frequency have generally included a more severe patient population than the $FE_{NO}$ studies and it is possible that more clear evidence of benefit of $FE_{NO}$ monitoring would be seen in this population. In support of this, Jayaram et al. [83] noted that the benefit of sputum eosinophil directed management was much more clearly seen in patients with more severe asthma. Patients taking long-acting $\beta_2$-agonists did particularly well and it is possible that the increased dissociation between eosinophilic airway inflammation and symptoms seen after treatment with long-acting $\beta_2$-agonists [110] is an important determinate of this. $FE_{NO}$ is measurable in most patients with severe asthma and it appears to be as good a marker of eosinophilic airway inflammation as it is in less severe asthma [111], so future studies should evaluate its use in severe asthma. In a

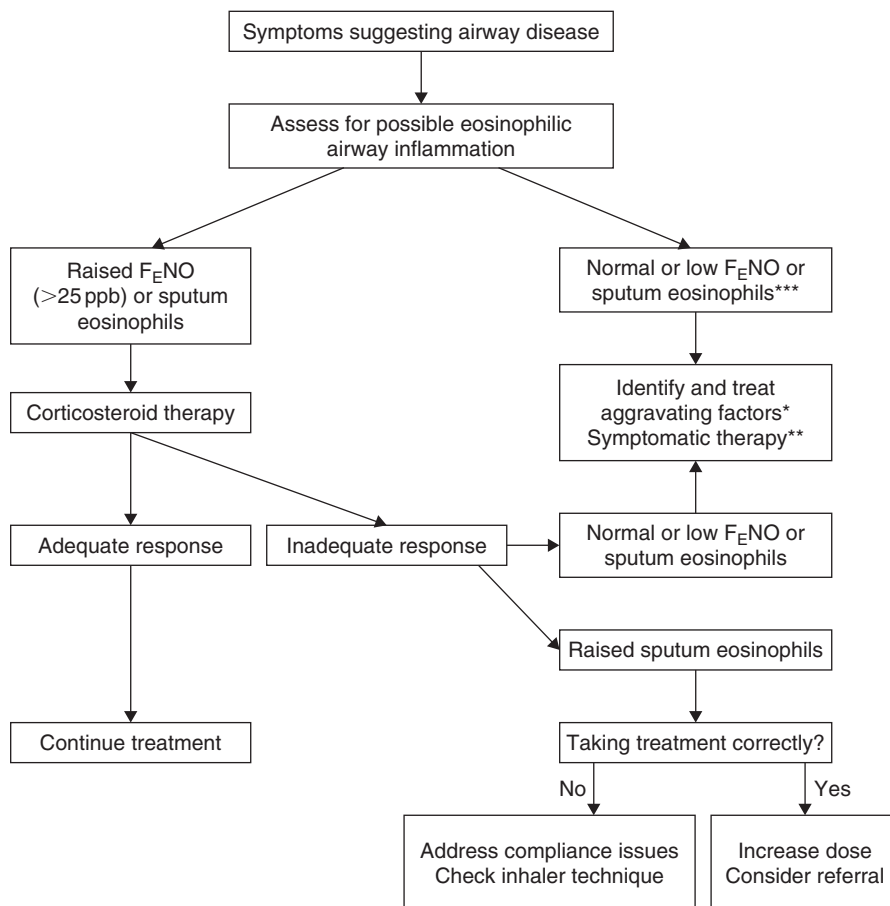

**FIG. 42.5** Suggested algorithm for assessment of patients presenting with untreated airway disease. Eosinophilic airway inflammation can be assessed using induced sputum eosinophils or $FE_{NO}$. *Potentially treatable aggravating factors include rhinitis, anxiety–hyperventilation syndrome, vocal cord dysfunction, bronchiectasis, and gastroesophageal reflux disease. **Symptomatic therapy includes short- and long-acting bronchodilator therapy, oral theophylline, and mucolytics as well as specific treatments for the aggravating factors. ***The suggested normal range for sputum eosinophils is <2% and $FE_{NO}$ in adults is <25 ppb. $FE_{NO}$ > 50 ppb is very predictive of a response to corticosteroid and a relapse when treatment is withdrawn; the interpretation of $FE_{NO}$ in the range 25–50 ppb varies between individual patients, and in some individuals different cut-points may apply. The induced sputum eosinophil count is likely to be a more reliable indicator of corticosteroid response and relapse risk when $FE_{NO}$ is in this range.

**TABLE 42.7** An approach to monitoring ICS treatment in patients with airway disease using FE$_{NO}$.

| FE$_{NO}$ | Low | Normal | Intermediate | High |
|---|---|---|---|---|
| Ppb | <5 | 5–25 | 25–50 | >50 |
| Symptoms controlled | Decrease/stop ICS | Decrease/stop ICS | No change | Increase ICS/refer |
| Symptoms uncontrolled | Decrease ICS, increase bronchodilators. Investigate for PCD and CF | Decrease/stop ICS, increase bronchodilators | Assess compliance. Increase ICS | Assess compliance. Increase ICS/refer |

*Notes*: ppb: parts per billion; PCD: primary ciliary dyskinesia; CF: cystic fibrosis.

less severe population the main impact of inflammometry might be a reduction in corticosteroid dose without loss of efficacy.

Trials evaluating FE$_{NO}$ as a monitoring tool for asthma have used a wide variety of target ranges for FE$_{NO}$ (Table 42.6). Since than there has been an increase in our understanding of the relationship between FE$_{NO}$ and eosinophilic airway inflammation an there is now a consensus that an FE$_{NO}$ of <25 ppb is a sensitive indicator of the absence of eosinophilic airway inflammation [93, 96] and is therefore an appropriate cut off for a reduction in ICS [112]. Conversely, an FE$_{NO}$ above 50 ppb is a specific marker for the presence of eosinophilic airway inflammation [93, 96] and a good response to corticosteroids is consistently seen above this value [89]. These therefore would appear to be the most appropriate values for a reduction and an increase in corticosteroid dose. Values lying between 25 and 50 ppb are indeterminate and clinical criteria should be used to guide corticosteroid treatment. A suggested approach to interpretation of FE$_{NO}$ values in the diagnosis and monitoring of asthma is outlined in Fig. 42.5 and Table 42.7.

## FUTURE DIRECTIONS

Recently it has become possible to investigate the contribution of the distal lung in the inflammatory process in asthma and other airway diseases by measurement of FE$_{NO}$ at different expiratory flows [38]. Lehtimaki *et al*. have used this method to demonstrate that patients with nocturnal symptoms have elevated alveolar NO concentrations [113] and that alveolar NO concentration does not fall in response to treatment with ICS [114]. Patients with refractory asthma have a raised alveolar NO concentration which is reduced by oral but not ICS [39] suggesting that it reflects corticosteroid responsive inflammation in a site that can't be accessed by ICS. Induced sputum may also have a role in investigating proximal and distal airway inflammation as there is evidence that distal airways are sampled with increasing output and duration of nebulized hypertonic saline [15]. The clinical utility of these methods has not been explored. They could provide useful information on the need for a systemic rather than an inhaled approach to anti-inflammatory treatment with agents such as prednisolone, anti-IgE, and perhaps anti-IL-5.

There is an urgent need for a non-invasive technique capable of providing accurate information on the characteristics of the lower airway inflammatory response from an easily accessible sample. The technique should be capable of providing an immediate result and be useable in acute as well as outpatient settings. Whether FE$_{NO}$ or EBC analysis as it currently stands are ideal for this purpose is doubtful. Refinements of breath analysis, or perhaps identification of novel biomarkers in urine or blood are perhaps most likely to advance this area. Work already done with induced sputum provide a strong scientific rationale for the use of these markers as a means of defining risk and likely treatment response.

# Quantitative Imaging of the Lung

CHAPTER

**43**

**Harvey O. Coxson**

Department of Radiology, James Hogg iCAPTURE Centre for Cardiovascular and Pulmonary Research, University of British Columbia, Vancouver, BC, Canada

## INTRODUCTION

Imaging of the lung has always played a very important role in pulmonary medicine. The advent of quantitative imaging allowed lung researchers to move beyond descriptive studies in the lung and actually apply measurements that could be applied to humans generally and disease conditions specifically. Weibel was one of the first researchers to meticulously measure the lung and open up a whole new field of pathologic research known as quantitative stereology [1–6]. These techniques have undergone some modification over the last 40 years, with the proliferation of computers, but the basic principles remain unchanged today. Unfortunately, pathologic techniques have some considerable drawbacks most notably that they require the tissue from either resected or autopsy specimens. The second limitation is that they are histologic examinations and because of their depth of scale require an extensive amount of work to cover a small region of the lung. However, pathology and histology are still considered the gold standard by which all other measuring devices are judged and remains the cornerstone of quantitative analysis.

Today the search for quantitative imaging techniques that are not as invasive as pathology and allow the investigator to obtain multiple measurements over time is becoming very important. With the explosion worldwide of chronic lung diseases and, therefore, our need to accurately measure the structure of the lung and possibly any changes due to the pathogenic mechanism or interventions is key. It is for these reasons that medical imaging has become so popular and the introduction of the computed tomography (CT) scanner by Hounsfield has changed the way

that we look at organs today. As the CT scanner developed and images became easier in terms of time and financial considerations, it has become one of the first lines of clinical medicine. The CT technology is now so pervasive that nearly every hospital has at least one CT scanner and the technology behind CT has changed so much that now images of entire organs can be obtained in less time than it took to acquire one image in the original CT scanner. Of course many other techniques have also started to proliferate including magnetic resonance imaging, which provides not only anatomic information, but also some functional information as well. This chapter will focus on these non-invasive quantitative measurements of lung structure specifically as they apply to lung structure and the changes involved in chronic obstructive pulmonary disease (COPD). This chapter will start with an examination of CT since it is the most popular both in terms of market penetration of the CT scanner, and quantitative methodologies. The other major focus of this chapter will be hyperpolarized magnetic resonance (MR) imaging since it is a growing field and potentially has some valuable insights. This chapter will also divide COPD into two separate sections based on widely accepted phenotypic expressions of the disease, emphysema and small airways disease because the exact pathogenesis of COPD is still unknown and it varies widely between individuals.

It has been established that the root cause of COPD is an exaggerated inflammatory response that, in susceptible people, results in either a destruction of lung tissue (emphysema) or a remodeling of the airway wall structure. Both of these processes result in changes to the function of the lung that termed COPD, but the exact role and contribution of these two processes varies between individuals and is thought

to be under genetic control. Therefore, studies of COPD must take into account the differences in these pathogenic pathways particularly as therapeutic interventions are developed because it is very likely that a specific intervention for the inflammatory response in airway walls may be the exact wrong intervention for the destructive components of emphysema.

## QUANTITATIVE MEASUREMENTS OF THE LUNG IN COPD

### Emphysema analysis

In brief, CT images are obtained by passing a beam of X-rays through the body and measuring their absorbance which, in biological tissues, is directly proportional to the density of tissue. This apparent absorbance of X-rays is converted to a relative scale known as the Hounsfield Unit (HU) scale which is a linear scale based on the attenuation water. In the Hounsfield scale the apparent attenuation of water is set at 0 HU while the absorbance of air is −1000 HU. The CT scan is a transaxial image so each of the pixels, or picture elements, in the image has an X and a Y dimension. However, the X-ray beam and detector system of the scanner also has at width which gives the CT scan a "slice thickness" making the pixel of the CT image more appropriately known as a voxel or volume element. In a classic conventional CT scan the slice thickness was 10 mm which allowed adequate coverage of the lung using the shortest breath hold maneuver. The X-ray detectors then became thinner so that images could be acquired down to 1 mm in thickness, which combined with a high spatial frequency reconstruction algorithm, became known as the high-resolution CT scan (HRCT). CT scanners have seen immense growth over the last 10–15 years as the introduction of slip ring technology allowed continuous acquisition of images while the patient moved through the gantry, the helical or spiral CT scan, to the sub-division of the X-ray detector into multiple elements allowing for multiple slice acquisitions simultaneously, the multi-detector row or multi-slice CT scanner.

The normal human lung is approximately 80 % airspace and 20% tissue and blood [1] and CT densitometry studies have shown that the normal human lung has a symmetrical distribution of X-ray attenuation values around a mean of approximately −800 HU [7–10]. This distribution of X-ray attenuation values was the first quantitative feature of the CT scan that was exploited to quantify structural changes in disease states because changes in the quantity of tissue and gas in the lung causes changes in the shape of this distribution. Independently, investigators led by Hayhurst [11] in Edinburgh and Müller [12] in Vancouver found that the extent of emphysema quantified pathologically was directly correlated to either the percentage of lung voxels with attenuation values less than a HU specific threshold value, "density mask" [12, 13], or the actual HU value at the lowest 5th percentile of the frequency distribution curve [14]. While both of these techniques are similar in idea they are different in

application and have led to numerous disagreements in the literature concerning their applicability.

Since these initial studies CT scanners have undergone remarkable changes as described above. The initial description of the "density mask" technique found that for CT scans that were 10 mm thick and reconstructed using a low spatial frequency reconstruction algorithm, emphysematous holes greater than 5 mm in diameter correlated well with a threshold value of −910 HU (Fig. 43.1). This means that the percentage of lung voxels with attenuation values less than −910 HU was correlated with the percentage of the lung occupied by holes greater than 5 mm in diameter [12, 13]. Coxson and colleagues took this analysis a step further and found that by estimating the average maximal lung inflation for a subject (based on a 6 l TLC and 1000 g lung mass) they found that a cut-off value of 6.0 ml gas per gram of tissue (−856 HU) estimated the extent of emphysematous holes between 2 and 5 mm in size [15].

As CT scanner technology changed threshold values have also had to change. Gevenois and co-workers re-examined the "density mask" technique using 1 mm thick CT slices

**FIG. 43.1** (A) This figure shows a CT scan from a subject with relatively severe emphysema indicated by the arrows. (B) The voxels with attenuation values less than −950 HU or below the threshold or "density mask" are highlighted on the CT scan.

reconstructed using a high spatial frequency reconstruction algorithm and found that the best correlation between lung pathology and CT was obtained using the −950 HU threshold value [16, 17]. Furthermore, the lowest 5th percentile was also redefined to be the lowest 15th percentile [18, 19]. Finally with the advent of multi-detector row CT scanners that obtain multiple CT images at the same time and acquire these images helically while the subject is moving through the CT gantry. Madani and colleagues found that the best correlations with pathology were obtained using the −960 HU threshold and all percentile points below the lowest 18th percentile correlated with macroscopic and microscopic measures of emphysema, although the strongest correlation with the lowest first percentile [20].

Uses of the "density mask" and percentile method have proliferated in the literature in recent years. The "density mask" technique has been used to measure the extent of emphysema in very severe subjects undergoing lung volume reduction surgery (LVRS) [15, 21–23] or other therapeutic interventions such as retinoic acid treatment [24]. It has also been used to describe differences in the extent of disease in males and females and has reported that for a given level of obstruction males have more "emphysema" than females [25]. It has also even been used to investigate emphysema like changes in lung structure in subjects with Anorexia Nervosa and found that the subjects with the lowest body mass index had the lowest diffusing capacity for carbon monoxide and also had X-ray attenuation values that were similar to heavy smokers and normally attributed to emphysema [26].

The percentile technique has also been applied to LVRS studies [27] and numerous studies of $\alpha_1$-antitrypsin deficiency [18, 19, 27–30]. These investigators have shown that the lowest 15th percentile point is a robust threshold and allows subjects to be compared over time and is less susceptible to minor changes that may be induced by the CT scanner or the size of the breath the subject takes during the scan [18, 28, 30].

Having a robust metric of lung change is an extremely important tool because with the proliferation of CT scanners and the continuous changing of the devices by manufacturers it makes it very difficult come up with a metric that changes with the disease process and not just the with features of the scanner. Therefore, when conducting longitudinal studies all aspects of the scan must be considered, including patient parameters such as breath size and motion during the scan, but also calibration of the scanner, slice thickness, reconstruction algorithm, type of scanner and radiation dose. In a longitudinal study of subjects with $\alpha_1$ deficiency, Parr *et al*. noticed a drift in density mask measurements which they managed to trace back to calibration of the CT scanner [31]. They found that while the water calibration of the scanner was performed routinely, there was no attempt to calibrate the scanner to air and therefore the change they were observing in lung density was due entirely to the scanner and not the disease. For this reason the authors had to develop a correction factor for their CT scans to take into account this shift in X-ray attenuation values [31]. In another study, Boedeker *et al*. found that even when all other aspects, such as scanner type, size of breath, etc. were carefully controlled, the reconstruction

algorithm could make up to a 15% (average 9.4%) difference in the extent of emphysema measured using a "density mask" technique [32]. Their data showed that some reconstruction algorithms, described as "over-enhancing," improve spatial resolution by over-enhancing the difference between lung voxels; thereby changing the frequency distribution of the apparent X-ray attenuation values within the CT image and ultimately the number of voxels below a certain cut-off value [32]. Other investigators have looked at the effect of dose, and scanner manufacturer. Using a phantom, Stoel found that there were significant differences between single and multi-slice scanners [33]. In this study they reported that there were more errors in the volume measurements of single slice scanners than multi-slice and the higher degree of apparent random error in the density measurements led them to conclude that only multi-slice CT scanners should be used in clinical multi-center studies. Madanai *et al*. recently examined the effect of slice thickness and radiation dose on measurements of emphysema. In this study the authors used one multi-slice CT scanner and acquired images using different radiation doses (mA) and then reconstructed the images using different slice thicknesses [34]. They found that there were significant correlations between their metrics of emphysema, either threshold cut-offs or percentile technique, however X-ray dose had an effect on the threshold cut-off measurements but not percentile method while slice thickness had a significant effect of both threshold and percentile techniques. In a similar study, Yuan and colleagues compared two multi-slice CT scanners as well as changes in radiation dose and showed that there was no difference between the techniques in terms of volume measurements if scanner or dose was changed [35]. However, there were differences in mean lung density between scanners and, most importantly, large differences in the extent of emphysema measured using either the threshold or the percentile technique when the X-ray dose was changed [35]. Therefore, the conclusions of all of these studies are that if you intend to use CT as a measurement of emphysema in a longitudinal and/or multi-center study you must pay careful attention to the details. A multi-slice scanner should be use for these studies and if you are to use a Toshiba scanner a correction factor must be applied to the X-ray attenuation values. Furthermore, the radiation dose must be carefully monitored because this factor alone can have large effects on the emphysema measurements. In conclusion, the CT scanner can be used to measure emphysema, but it must be treated like all other measuring tools and all of the parameters must be carefully monitored.

An aspect of emphysema measurements that has been largely overlooked in the literature is some type of emphysema hole size measurement. While it has been shown that there are decent correlations between the threshold cut-off and the percentile techniques and pathologic measurements of emphysema, these techniques do not provide any information on the size or location of the emphysematous hole (Fig. 43.2). This is an area that needs more research because the number of publications using these types of techniques is very small. One of the first attempt to quantify hole size used a technique known as the "fractal" or "cluster" analysis [36, 37] whereby the size of low attenuation areas, as defined by the number of connected voxels below a given
**FIG. 43.2** This figure shows the voxels identified as below −950 HU in two different subjects, one with predominately smaller holes (A) and one with predominately large holes (B). A cluster analysis can be used to separate the subjects with large holes from the one with smaller holes.

threshold, is correlated to the number of these low attenuating areas. Mishima validated this technique using an "elastic spring" model and showed that as the emphysema become more extensive the holes become larger and they decrease in number [36]. They also found that in subjects with COPD but similar percentage emphysema as control subjects the "fractal" measurement was lower in the COPD subjects suggesting that while they had the same "extent" of emphysema the emphysematous lesions tended to be larger in subjects with COPD. This study was follow-up by another study that examined the size and location of the lesion in subjects undergoing lung volume reduction surgery. This study showed that that subjects with large upper lung region lesions have the best outcome following LVRS [37]. The National Emphysema Treatment Trial (NETT) applied a similar technique to their study subjects and found that there was a good correlation between the radiologist assessed hole size and the computer assessed metric [22]. Furthermore, the size and location of these lesions, large lesions located in the apical regions of the lung, seemed to have a predictive effect on survival following surgery [22]. More complex techniques that quantify multiple features within the CT scan, such as the adaptive multiple feature method, have reported decent results in disease stratification including the ability to separate smokers from non-smokers in the absence of other disease [38]. However, the disadvantage of these new "texture" analysis techniques is that they often use complex mathematical terminology to describe the lung rather than anatomic or physiologic terminology that are more commonly used in medicine and have not been validated using pathologic assessment of the underlying lung structure. Finally, the location of the emphysema seems to be important as well as

indicated by the NETT study and the emphysematous hole size studies above [22, 37]. Nakano first showed that emphysema located in the upper-outer regions of the lung predicted better outcome following surgery, presumably because it is more accessible to surgical resection than those with more centrally located or diffuse disease [39]. The studies of location of emphysema and the effect that it has on lung function are sparse in the literature, but it is hoped that with the widespread use of multi-slice CT scanners that these types of studies will shed more light on the pathogenesis of emphysema (Fig. 43.3).

Finally, there is great interest in using CT scans in multi-center studies as an end point for a therapeutic intervention. This has already been accomplished in studies such as the NETT trial but the work of Dirksen really adds importance to this approach. In a small study of $\alpha_1$-antitrypsin deficient subjects, Dirksen found that there was no significant change in the functional or structural (assessed using CT) characteristics over the course of the study [28]. However, when the authors performed a power calculation of their data they found that to show a difference in $FEV_1$ the authors would have had to study 550 subjects but to show a difference using CT the authors would only have had to study 130 [28]. These data add further credence to the important role that CT scans can play in clinical intervention studies.

In conclusion, these studies all show that CT measurements of emphysema are correlated with pathologic measurements of emphysema. Furthermore, these measurements can be used to follow disease progression, possibly with more sensitivity than the traditional metrics of $FEV_1$, and that size and location of the disease is important. Also, these techniques can be used to measure early or small changes in the lungs
**FIG. 43.3** This figure shows a three dimension analysis of emphysema in a subject with predominately upper lobe emphysema. The trans-axial images (A) show more highlighted regions (arrows) in the upper lobes while the coronal images (B) show quite clearly that there are more highlighted voxels in the upper lobes (arrows) than the lower lobes (arrow heads). A cluster analysis (C) that highlights the connected regions clearly shows larger clusters in the upper lobes. Images were created using the Pulmonary Workstation 2.0 software (VIDA Diagnostics Inc.).

of early disease subjects and can be used to compare differences in disease between genders. Overall, the assessment of emphysema using CT has a long and well developed history and is now starting to be applied in more and more longitudinal studies. However, it is important to keep in mind that CT, like any measuring device, must be used properly. The CT scanners must be comparable and the CT image acquisition techniques must be comparable. It has been shown that low dose studies can be performed in these groups of subjects, but because dose effects the measurements of emphysema the dose must be kept constant throughout the study.

## Airway analysis

Of course assessing the emphysema is only one part of the analysis of the structural changes that cause the chronic

airflow limitation because it has long been recognized that the site of major airflow limitation is the small airways [40]. There have been numerous investigations of small airway dimensions and COPD that have confirmed the importance of the remodeling in these structures, but once again, these rely on histologic specimens [40–45]. The introduction of CT scanning peaked investigators interest in measuring airways non-invasively so several methods were implemented to manually trace the airway walls using the CT images printed on film, similar to how it was accomplished using histology. However, one thing that became immediately apparent was that optimal measurement of airway lumen using this technique required very specific display settings. For example, it was found that an accurate measurement of wall area required the use of a window level of −450 HU and a window width of 1000–1400 HU [46–49]. Unfortunately, these display settings produce images that are too dark for optimal visualization of the lung parenchyma and so are never used clinically. Furthermore, because the technique is cumbersome, time consuming, and associated with considerable intra- and interobserver variability, this approach was quickly abandoned [47–49].

Since the CT scan is a digital image and contains gray scale information attention quickly turned to using automated airway analysis techniques. McNitt-Gray *et al.* found that the lumen area could be accurately measured using a threshold cut off of −500 HU [50] which was further validated using excised formalin fixed pig lungs by King and co-workers who reported that a threshold of −577 HU produced the least error in the measurements [51]. However, these techniques just measured the airway lumen so attention turned to using the X-ray attenuation values of the CT scan to measure both the airway lumen and wall. One of the more common techniques is the "Full-Width-At-Half-Maximum" ("half-max") method (Fig. 43.4) where the distribution of apparent X-ray attenuation values along a ray projected from a central point of the lumen to the parenchyma is measured. The distance between the point at which the attenuation is half way between the local minimum in the lumen or parenchyma and the maximum within the wall is considered to be wall thickness [52, 53]. Unfortunately, the shape of this curve is dependant on various parameters including: the reconstruction algorithm used to create the image, partial volume averaging due to field of view and orientation of the airway within the CT image and the inevitable blurring of edges that occurs due to the point spread function of the CT scanner. Validation studies show that the CT scans over-estimate airway wall area and underestimate lumen area and that these errors become very large in small airways [52, 54]. Furthermore, this algorithm requires that the airway being analyzed on CT is cut in cross section. While it is relatively easy for observers to find airways cut in cross section, because the CT slice has a thickness, typically on the order of 1 mm, the airway observed on CT may or may not have actually been cut in cross section (Fig. 43.5). This is another source of error within the airway wall measurements and makes them especially unreliable as the airways approach the resolution of the CT scanner. For these reasons investigators have developed numerous other algorithms to measure these airways such as the "maximum-likelihood method" whereby
**FIG. 43.4** This figure shows a CT scan (A) from which an airway is chosen and displayed using a magnified view (B). The measurement of the airway wall dimensions is performed by using the Full-Width-At-Half-Maximum method whereby the length of the rays is determined by choosing the halfway point between the minimum X-ray attenuation value in the lumen or lung parenchyma and the maximum value within the airway wall. The lumen area and the internal perimeter of the airway wall are measured using the internal boundary of the rays (shown by arrowhead) and the wall area and the outer perimeter are measured by the external boundary of the rays (arrow).

**FIG. 43.5** This figure shows the same airway from gross pathology (A), histology (B) and from the pre-operative CT scan (C). From this image some of the measuring artifacts can be seen including the fact that the airway may not actually be cut in cross section in the CT scan because the airway is slightly different shape in the CT and can be seen to not be in perfect cross section in the gross pathology section. Secondly, the resolution issues can clearly be seen as the actual pixels are visible in the CT scan and the image appears very pixilated. All of the scale bars are 5 mm in length.

the attenuation threshold along each ray is matched to an ideal calculated ray [54], the "score-guided erosion algorithm" [51] where airway wall edges are found using an edge finding algorithm that assumes that airways are circular and have a relatively high density compared to the surrounding parenchyma, and an algorithm where ellipses are fit to the airway lumen and wall [55].

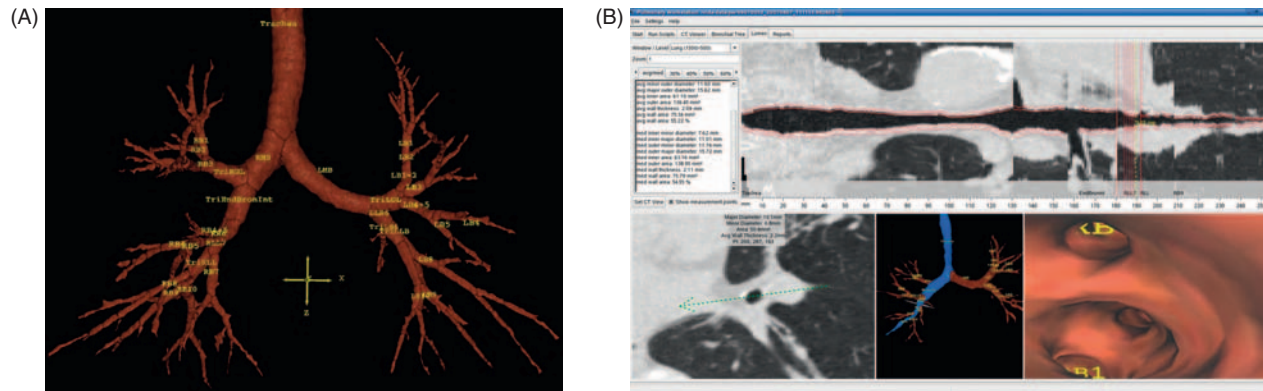
Because it is well recognized that airway wall remodeling plays a very important role in COPD there is great interest in non-invasive measurement of airway wall dimensions. However, the applications of these techniques have so far been very limited. One of the first papers published in this field was a study by Nakano and co-workers [53] who evaluated the right apical segmental bronchus of asymptomatic smokers and COPD subjects. The authors chose this airway to measure because it is routinely cut in cross section on transaxial CT scans, and they could compare the same airway across all subjects. The authors also measured the extent of emphysema using a threshold technique and correlated the emphysema and airway wall dimension data with pulmonary function data. The data from this study showed that the thickening in this large airway correlated with $FEV_1$ percent predicted, FVC percent predicted and RV/TLC while the emphysema correlated with $FEV_1$, FEV/FVC ratio and the $DL_{CO}$. Furthermore, a multiple regression analysis suggested that, for a given $FEV_1$, subjects with more extensive emphysema had less airway wall thickening than those with less extensive emphysema [53]. Obviously a segmental airway is unlikely to be the major source of airflow limitation in subjects with COPD. Furthermore, it is questionable whether any of the airways that can be observed using CT are the airways responsible for the airflow limitation. Since histology is considered the gold standard for small airway wall remodeling, Nakano compared the measurements of wall area obtained using CT (average diameter of 3.2 mm) to those obtained using histology of small airways (1.27 mm diameter) in resected specimens [56]. These data show a significant association ($R^2 = 0.57$, $p = 0.001$) between the


**FIG. 43.6** This figure shows multi-planar reformatted reconstructions of the airway tree (A). Using these new software tools it is now possible to segment the airway tree from the lung parenchyma and, using a pre-defined pathway, reconstruct it as a long straight tube and obtain measurements at a cross section to the center line of the airway at any point along the pathway (B). Images were created using the Pulmonary Workstation 2.0 software (VIDA Diagnostics Inc.).

dimensions of the smaller and larger airways. The authors conclude that, at least for COPD, measuring airway dimensions in the larger bronchi, which are more accurately assessed by CT, can provide an estimate of small airway remodeling. It is likely that the same pathophysiologic process, which causes small airway obstruction, also takes place in larger airways where it has less functional effect.

Recently focus has turned away from measurements of airways cut in cross section on transaxial CT images to what is thought to be a true cross section of the airway obtained by multi-planar reformats of three-dimensional airway data. Multi-slice scanners can now obtain CT images with resolution in the Z dimension that approaches that of the X–Y dimensions, although most studies still use CT slices with 1–1.25 mm slice thickness. Investigators can now segment the airway tree in three dimensions starting in the trachea and projecting out to the fifth or sixth generation (Fig. 43.6). Also, this technique allows the investigator to section the airway at any place and any angle that they choose. Of course this technique assumes that the voxel dimension in the Z dimension is small, that is 1 mm or less, or the assumptions inherent to the re-format become too large. Another important advance to this technique is that now investigators can know exactly where they are in the airway tree and if they wish to compare the airway size of a specific airway between individuals and over time they have the landmarks to do so and no longer have to count on random selections of airways. While random airway selections have their advantages in that you have an overall picture of airways within a subject they also have their drawbacks. For example, investigators often normalize airway wall dimensions between individuals by comparing the percent of the total airway (lumen + wall) that is occupied by wall, the so called Wall Area Percent (WA%). This is a very good estimate of wall area between subjects but it assumes that you are comparing equal sized airways because in large airways the WA% is always small because the wall area is such a small fraction of the total airway. On the other hand, in small airways, the WA% is always large because now the lumen is very small and the wall starts to occupy a much

larger fraction of the total airway. Therefore, you can potentially measure a statistical difference in WA% between individuals, because there is an inflammatory process occurring in the airway wall that is making the wall area bigger, or you could simply be comparing big airways to small airways due to improper sampling. The new three-dimensional reconstruction technique can avoid that trap by allowing investigators to compare the exact airway between individuals and over time. That was one of the original goals of the Nakano paper where they measured the right apical segmental bronchus only, but it is now better achieved and in smaller airways using current CT and image analysis technology.

This approach was recently put to the test by Hasegawa and co-workers [57] who used multi-slice CT scans to measure the right apical and basal segmental bronchus at different branch points along its pathway. These authors were not able to verify the findings of Nakano by comparing the right apical segmental bronchus to $FEV_1$ however, they did show that as they moved more distally, to the sixth generation of the airway tree, the correlation with $FEV_1$ improved. The authors concluded that the airflow limitations are more strongly associated with the dimensions of the distal airways than the proximal ones and demonstrate that these new three-dimensional techniques can be used to obtain measurements from a specific location within a specific airway [57]. Also, it once again shows the importance of airway measurements in understanding COPD.

## Hyperpolarized noble gas imaging of the lung

Other techniques such as MR imaging of the lung are becoming very attractive techniques particularly because they do not expose the subject to any ionizing radiation. This has always been a strong point of MR, but factors such as the small nuclear spin polarization at thermal equilibrium and the field inhomogeneity problems associated with the lung have greatly limited the application of this technique [58]. However, the last few years have seen resurgence in

MR imaging research because of the introduction of hyperpolarized noble gases. Research has shown that by exposing noble gases such as $^{129}$Xenon or $^3$Helium to a laser you can hyperpolarize the gas by aligning more of their magnetic moments into the same orientation. This allows the gas to be used as a contrast agent within the lungs during an MR scan and has allowed investigators to measure the ventilation of the lung [59, 60], the size of the alveolus airspace [61] and airway dimensions [62, 63]. The most well established of these techniques is the measurement of alveolar size by a technique known as the "Apparent Diffusion Coefficient" or ADC. This technique works on the principle that gas molecules will move, or diffuse, within a given volume such as the alveolus of the lung. In the normal lung the airspaces are much smaller so that the movement of Helium is restricted but in emphysema where the airspaces become much larger. Several studies have correlated the ADC with spirometry measurements in animal models, normal volunteers and in subjects with airflow limitations emphysema [60–62, 64–69]. In a recent study Woods *et al.* showed that there was a very good correlation between the ADC and alveolar size measured using either the surface area to volume ratio of the lung parenchyma or the mean linear intercept and that the ADC was able to separate emphysematous lung from normal lung with greater sensitivity than histology [61].

Other investigators have shown that it is possible to create three-dimensional reconstruction of the airway lumen to the seventh-generation of airways [62, 63]. While this is an interesting technique it does not provide measurements of airway wall thickness and so the applicability is still uncertain.

Finally, while it appears that hyperpolarized gas MR has some very powerful applications in the study of COPD, the technique its self is very limited by availability of a hyperpolarized helium or xenon source and the extremely technical nature and cost of the procedure. While it is an exciting and innovative technique, it is very likely that hyperpolarized gas MR will remain a research tool for the immediate future.

## CONCLUSION

In conclusion, the last 20 years have seen a large amount of growth in both the interest and the application of non-invasive quantitative imaging of the lung. As long as the scanners are treated properly it is now possible to obtain reliable quantitative information on the extent of emphysema, the size of the emphysematous lesions and airway wall dimensions. The advent of multi-slice CT scanners has opened up new avenues of research into regional distribution of disease and specific tagging and measurements of airways. On the downside CT imaging has some inherent limitations: particularly concerning radiation exposure to the subject and the standardization and quality control of the CT scan parameters. Hyperpolarized gas MR imaging has come a long ways in the last several years and has made some important steps to provide both quantitative structure

and functional information. However, because of technical and financial reasons CT is currently the only readily accessible, relatively non-invasive technique that provides quantitative structural data *in vivo*. The proper application of these techniques should produce valuable information on the pathogenesis of COPD and the effects of new therapeutic interventions.

## INTRODUCTION

Single organ diseases can have systemic manifestations. Acute diseases, such as urinary tract infections or pneumonia can cause septic shock, multiple organ failure, and eventually, death. Likewise, chronic diseases like cancer, heart failure, or chronic obstructive pulmonary disease (COPD), to name only a few, are associated with systemic manifestations as well. In a much more relentless way than in acute conditions, systemic manifestations in chronic diseases influence the course of the disease, and eventually, contribute to death. This chapter reviews the systemic manifestations associated to two chronic respiratory diseases, COPD, and asthma, and discusses their potential implications for the management and treatment of these patients.

## SYSTEMIC MANIFESTATIONS OF COPD

The COPD guidelines published jointly by the American Thoracic Society (ATS) and European Respiratory Society (ERS) in 2004 were the first to explicitly recognize that "*although chronic obstructive pulmonary disease (COPD) affects the lungs, it also produces significant systemic consequences*" [1]. More recently, the last update of the Global Obstructive Lund Disease (GOLD) initiative published in 2006 incorporates and extends this concept by defining COPD as "*a preventable and treatable disease with some significant extra-pulmonary effects that may contribute to the severity in individual patients*" [2]. It is interesting to note that the systemic manifestations of the disease

are quoted in this update even before stating that "*its pulmonary component is characterized by air-flow limitation that is not fully reversible*" [2]. This highlights the clinical relevance of these extra-pulmonary effects because: (1) they contribute to disease progression independently of airflow obstruction. In fact, it is likely that important clinical outcomes, such as mortality or health status, among others, eventually result from the interplay between the intra-pulmonary and extra-pulmonary effects that occur in COPD (Fig. 44.1) [3]; and (2) they constitute novel therapeutic targets [4]. Table 44.1 presents the systemic manifestations of COPD identified so far.

### Nutritional abnormalities

Unexplained weight loss occurs in about 50% of patients with severe COPD, but it can also be seen in patients with mild to moderate disease (10–15%) [5]. It is a poor prognostic indicator [6, 7] and interestingly, it is independent of other traditional indices, such as the volume of air exhaled in the first second of a forced spirometry maneuver ($FEV_1$) or the arterial partial pressure of oxygen [6]. Therefore, weight loss identifies a new systemic domain of COPD that needs to be taken into consideration in their clinical management. In this context, Celli *et al.* have recently proposed a composite index (the BODE index) that includes body weight (assessed by the body mass index, BMI), the degree of airflow obstruction (assessed by the $FEV_1$ value expressed as percentage of the reference value), the level of dyspnea experienced by the patient (assessed by the modified Medical Research Council scale), and their exercise capacity (assessed by the 6-min walking test), that predicts survival much more accurately than $FEV_1$ alone [8]. This approach has the

historical merit of being the first to assess COPD multidimensionally, but it is likely that the BODE index may be modified in the future by the inclusion of other relevant domains of the disease, such as the degree of inflammation [9], the number and severity of exacerbations episodes [10], and/or the severity of lung hyperinflation [11], to name only a few.

## Skeletal muscle dysfunction

Unexplained weight loss in COPD is mostly due to skeletal muscle atrophy [12, 13]. Further, the remaining muscle mass is often dysfunctional [14]. This combination contributes significantly to reduce the exercise capacity (thus, health status) of patients with COPD [14] and is likely to contribute to the BODE index discussed earlier. The mechanisms underlying skeletal muscle abnormalities in COPD are not precisely defined, but they are probably multiple and interdependent, including sedentarism, malnutrition, systemic inflammation, and tissue hypoxia among others [13].

In this context, systemic inflammation is probably a key contributor [15]. Several molecular abnormalities have been described. On the one hand, a number of cytokines, particularly TNF-$\alpha$, activate the transcription factor NF-$\kappa$B, upregulate the inducible form of the nitric oxide synthase (iNOS) and facilitate the degradation of myosin heavy chains through the ubiquitin–proteasome complex [16]. On the other hand, these same cytokines have the potential to promote apoptosis (programmed cell death) in skeletal muscle cells, and this has been shown to occur in patients with COPD and low body weight [17]. Finally, abnormalities of the sarcoplasmic–endoplasmic reticulum calcium adenosine triphosphatase 2 (SERCA2) have been described by Morlá *et al*. [18]. These investigators found that the expression of SERCA2 was significantly lower in COPD patients with low BMI (another domain captured by the BODE index discussed earlier) and, interestingly, related to iNOS [18]. All these molecular abnormalities are likely to contribute to skeletal muscle atrophy and dysfunction in COPD [19, 20].

## Cardiovascular disease

Cardiovascular disease (CVD) is another clinically relevant systemic manifestation of COPD [21]. Despite the fact that tobacco smoking is a major risk factor for both COPD and CVD, recent investigations have shown that the risk of CVD is higher among those smokers who develop COPD as compared to those who do not develop it [21]. For instance, Sin *et al*. reported that when the lowest quintile of $FEV_1$ is compared with the highest quintile, the risk of cardiovascular mortality increases by approximately 75% both in men and in women, and that the presence of symptoms of chronic bronchitis increases the risk of coronary deaths by 50% [22]. Further, the presence of ventricular arrhythmias increases the

risk of coronary events two-fold, suggesting that the cardiovascular effects of COPD are amplified in those who have underlying cardiac rhythm disturbances [22]. Sin *et al*. calculated that, for every 10% decrease in $FEV_1$, all-cause mortality increases by 14%, CVD mortality by 28%, and nonfatal coronary event increases by 20%, and concluded that COPD is a powerful, independent risk factor for CVD morbidity and mortality [22]. These findings were later confirmed in a large ($n = 11,493$), retrospective cohort study in health-care databases maintained by the government of Saskatchewan (Canada). Curkendall *et al*. found that persons diagnosed and treated for COPD have a significantly increased risk for hospitalizations and deaths due to CVD [23]. The mechanism(s) for the synergy between COPD and CVD are still under investigation, but the low-grade persistent systemic inflammation that characterizes COPD is likely to contribute significantly [21, 24] by causing endothelial dysfunction [25, 26].

## Depression

In patients with severe COPD ($FEV_1$ <50% reference value), the prevalence of depression was 25.0% whereas it was 19.6% in patients with mild to moderate COPD and 17.5% in controls [27]. When results were adjusted for demographic variables and comorbidity, the risk for depression was 2.5 times greater for patients with severe COPD than for controls [27].

## Osteoporosis

Osteoporosis in COPD might develop possibly due to a number of factors related or not related to the disease, including age, sedentarism, smoking, steroid use, and systemic inflammation [28, 29]. In a study by Jorgensen *et al*., 68% of patients with severe COPD ($FEV_1$ 33% of reference value) had osteoporosis or osteopenia and the use steroids could not explain this high prevalence [30]. The occurrence of fractures, as a consequence of osteoporosis, can contribute to the disability and mortality of patients with COPD and add to the economic burden of the disease [31]. Randomized placebo-controlled trials are required to assess the effect of intervention, such as bisphosphonates, hormone replacement, calcium supplementation, on the prevention and treatment of osteoporosis and fractures in these patients [31]. Interestingly, very recently Sabit and coworkers have described a link between CVD and osteoporosis in patients with COPD [32]. These authors found that arterial stiffness and serum inflammatory mediators were particularly increased in patients with osteoporosis suggesting that age-related bone and vascular changes occur prematurely in COPD [32].

## Metabolic syndrome

The metabolic syndrome is characterized by the presence of abdominal obesity, atherogenic dyslipidemia, raised blood pressure, presence of insulin resistance, and prothrombotic and inflammatory states that predispose to CVD [33]. It is frequently present in patients with COPD [34].

For instance, its prevalence in patients with moderate to severe COPD ($FEV_1$ 43% of reference value) who participated in a cardiopulmonary rehabilitation program was 47%, whereas it was 21% in controls [33].

Insulin resistance and diabetes mellitus are a key components of the metabolic syndrome [33]. In the Nurses' Health Study (a prospective cohort that included 103,614 female nurses) during 8 years of follow-up, a total of 2,959 new cases of type 2 diabetes were identified [35]. The risk of type 2 diabetes was significantly higher (multivariate relative risk 1.8) for patients with COPD, suggesting that COPD may be a risk factor for developing type 2 diabetes [35]. Authors speculated that systemic inflammation in these patients might contribute to the increased risk of type 2 diabetes [35].

## Systemic inflammation

The systemic manifestations of COPD reviewed earlier have been often related to the presence of systemic inflammation in these patients [34]. Many different studies have now provided convincing evidence that COPD is associated with increased levels of several pro-inflammatory cytokines (such as TNF-$\alpha$ and its soluble receptors soluble (sTNF-R55 and sTNF-R75)), interleukins 6 (IL-6) and 8 (IL-8), acute phase reactants (such as C-reactive protein, CRP), oxidative stress and activations of several inflammatory cells (such as neutrophils, monocytes, and lymphocytes) [13, 36]. Gan and associates conducted a meta-analysis encompassing all these previous studies and showed beyond doubt that COPD is associated with systemic inflammation [15]. Interestingly, other chronic conditions such as chronic heart failure, asthma (reviewed later), obesity, diabetes, and the normal process of aging are also associated with a similar low-grade systemic inflammatory process [37–39].

Many questions related to systemic inflammation in COPD remain unanswered [3]. For instance, we do not know if systemic inflammation occurs in all patients with COPD or only in a subgroup of them. Also, because all studies carried out so far are cross-sectional, we do not know the quantitative and qualitative longitudinal variation of systemic inflammation in a given patient, although recent data by Pinto Plata *et al*. indicate that, in the absence of an episode of exacerbation, CRP values tend to be relatively stable [40, 41]. In contrast, systemic inflammation (like pulmonary inflammation) appears to burst during the episodes of exacerbation of the disease [42–46].

The origin of systemic inflammation in COPD is unclear. It is possible that the pulmonary inflammation that characterizes COPD "spills-over" into the systemic circulation and/or contribute to activate the inflammatory cells during their transit through the pulmonary circulation [13]. Yet, several observations appear to contradict this hypothesis. For instance, Vernooy *et al*. could not find any relationship between the levels of soluble TNF-$\alpha$ (and its receptors) and IL-8 measured in induced sputum and in plasma of 18 COPD patients [47]. More recently, Hurst *et al*. were also unable to find such relationships for individual cytokines, albeit overall, global pulmonary inflammation correlated with global systemic inflammation [48]. Another mechanism of systemic inflammation in COPD is smoking.

It can cause by itself, that is, in the absence of COPD, systemic inflammation [49]. However, Vernooy *et al.* found that former smoker patients with COPD also had systemic inflammation [47]. Interestingly, the persistence of inflammation after smoking cessation occurs also in the lungs of patients with COPD [9, 50] and has actually raised the possibility that the pathogenesis of COPD may include an auto-immune component [51]. Another potential mechanism of systemic inflammation in COPD is the lung hyperinflation that occurs as a consequence of the chronic airflow obstruction that characterizes the disease [52], because it can stimulate the production of cytokines from the lungs [53–55]. Importantly, if this was the case, systemic inflammation in COPD should be responsive to bronchodilator therapy. This hypothesis is testable. In fact, in support of this possibility is the very recent observation that patients undergoing lung volume reduction surgery (a surgical procedure aimed at, basically, reduce lung hyperinflation) present a reduced incidence of episodes of exacerbation of COPD, which are characterized by a burst of inflammation [56]. Other potential origin of systemic inflammation in COPD is the skeletal muscle, which, as discussed above, is often abnormal and dysfunctional in these patients. In support of this possibility, Rabinovitch *et al.* have shown that, contrary to healthy subjects, systemic inflammation increases after muscular exercise in patients with COPD [57]. It has to be considered also that the bone marrow is the site of production of inflammatory cells and that smoking, as well as air pollution, can stimulate their release from the bone marrow [58–60]. Finally, the possibility that bone marrow abnormalities can contribute to systemic inflammation in COPD has not been studied systematically, but a recent study by Palange *et al.* showed that circulating hemopoietic progenitors (CD34+ cells) were significantly reduced in COPD patients as compared to controls and that CD34[+] cell counts correlated with exercise capacity and severity of airflow obstruction [61]. Two final considerations deserve comment when considering the origin of systemic inflammation in COPD. First, the normal aging process is also associated with low-grade systemic inflammation [62, 63], and COPD is an age-related disease [39]. Further, smoking has been shown to enhance telomeric loss (a marker of cell aging) (Fig. 44.2) [64], and evidence for cell senescence has been recently identified in the lung parenchyma of patients with emphysema [65, 66]. Thus, a better understanding of the mechanisms of lung aging and their relationship with the pathogenesis of COPD in general, and to systemic inflammation in particular, may be very valuable in this setting. Second, even in subjects with lung function values within the normal range ($FEV_1$ values above 80% predicted), an inverse linear relationship exists between CRP concentrations and $FEV_1$ [67]. This relationship occurs also in never-smoker individuals, suggesting that systemic inflammation may be linked to early perturbations of pulmonary function [67]. Whether systemic inflammation precedes or follows lung function changes requires longitudinal studies.

Irrespective of its origin, an intriguing possibility about systemic inflammation in COPD is that it may "feed back" to the lungs and contribute to enhance the chronic destructive process that characterizes the disease. In other words, a systemic manifestation of COPD may contribute to the core pulmonary domain of the disease. It is possible,

**FIG. 44.2** Relationship between relative telomeric length (RTL), a marker of biological ageing, and chronological age in never smokers (*panel A*) and smokers with (closed symbols) and without COPD (open symbols) (*panel B*). Panel C shows the relationship between RTL and $FEV_1$ in smokers with (closed symbols) and without COPD (open symbols). For further explanations, see text. Reproduced from Ref. [64].

although not proven, that systemic oxidative stress [68] and the increased plasma levels of pro-inflammatory cytokines (most notably TNF-α [69]) can contribute to the pathogenesis of lung damage in COPD because, first, the inhibition of the vascular endothelial growth factor (VEGF) receptors cause lung cell apoptosis and emphysema [70], second, oxidative stress and apoptosis interact and cause emphysema due to VEGF receptor blockade [71], and third, endothelial

cell death and decreased expression of VEGF and the VEGF receptor KDR/FLK-1 occur in patients with smoking-induced emphysema [72].

## Therapeutic implications

The systemic manifestations of COPD discussed earlier offer new opportunities for therapy because they constitute novel targets beyond the traditional therapies in COPD (broncho-dilators, inhaled steroids), which aimed at improving lung function [2]. For instance, malnutrition and poor skeletal muscle performance can be improved by diet supplementation and adequate rehabilitation programs [2, 73]. Tissue hypoxia and the associated systemic manifestations are potentially treatable by domiciliary oxygen therapy [74, 75]. Likewise, those systemic manifestations of COPD related to systemic inflammation may be responsive to anti-inflammatory therapy. Sin and coworkers showed that withdrawal of inhaled corticosteroids in patients with COPD increased the plasma levels of CRP by about 30% and that 2 weeks of treatment with inhaled fluticasone (or oral prednisolone) reduced them by about 50% [76]. If low-grade chronic systemic inflammation is really a relevant mechanism in the pathogenesis of many of the systemic effects of COPD described earlier, then it is likely that the biological effects described by Sin *et al.* may well be clinically relevant. In fact, a retrospective study has suggested that the risk of acute myocardial infarction in COPD patients was reduced by 32% in those receiving low doses of inhaled steroids [77]. The recently published, study, TORCH has explored the potential beneficial effect on survival of the combination of salmeterol and fluticasone propionate (versus placebo) in patients with moderate and severe COPD [78]. Strictly speaking, the *p* value of the study did not reach the predetermined level of statistical significance, but this occurred only after adjusting for the potential effect of the interim analysis performed. In absolute terms, there was a reduction in the risk of death of 17.5% in the patients receiving the combination of a salmeterol and fluticasone propionate [78], a reduction that is in the same order of magnitude as that provided by statins. Unfortunately, no measurement of systemic inflammation was obtained in these subjects, so the interpretation of these results is still open [78]. Other therapeutic alternatives, such as the use of the antioxidant N-acetyl-cysteine [79, 80], anti-TNF-$\alpha$ or other cytokine antibodies, NF-$\kappa$B blockers and i-NOS inhibitors, among others, require large and rigorously conducted clinical trials before entering clinical practice but, as recently reviewed [81, 82], they may be interesting alternatives. Finally, other systemic manifestations of COPD may deserve specific therapy. For instance, because patients with COPD are at increased risk of developing depression, particularly those with severe airflow obstruction, living alone, with airflow reversibility, respiratory symptoms, and physical impairment [27], it is important to reduce symptoms and improve physical functioning both (rehabilitation) as well as use anti-depressants drugs if needed. Likewise, as the prevalence of osteoporosis and osteopenia is increased in severe COPD, it is necessary to select the individuals at risk and to initiate prophylaxis or treatment for the disease [30].

## SYSTEMIC MANIFESTATIONS OF ASTHMA

Although often overlooked, asthma is frequently associated with systemic manifestations. The link between asthma and rhinitis, sinusitis, or allergic dermatitis is a good examples [83]. However, other potential systemic manifestations of asthma (Table 44.2) have been less extensively studied than those of COPD discussed earlier. Several features can contribute to explain this. First, asthma tends to be a disease of young (otherwise healthy) individuals [84], whereas COPD is rarely diagnosed before the sixth decade of age in individuals who often have other comorbidities [2, 85]. Second, lung disease is reversible in asthma but mostly irreversible in COPD [86]. It is plausible that the chronicity of the disease may favor the development of abnormalities in other distant organs. Finally, available therapies (mostly inhaled steroids with or without long-acting bronchodilators) are very effective in the vast majority of asthmatics [84] whereas, interestingly, the same therapy is considerably less effective in patients with COPD [2].

## Systemic inflammation

Airway inflammation is a key pathologic mechanism in asthma [84]. As in COPD, there may be cross-communication between the airways and the bone marrow in patients with asthma through inflammatory mediators that can eventually lead to systemic inflammation [83]. Sauleda *et al.* were the first to report that the activity of cytochrome oxidase (CytOx), the terminal enzyme of the mitochondrial respiratory chain, was abnormally increased in circulating lymphocytes of patients with asthma (as compared to those with COPD, arthritis and/or healthy subjects) [87] (Fig. 44.3). This was a totally unexpected and serendipitous observation because the goal of that study was to investigate if the observation made previously by these same investigators of increased CytOx activity in skeletal muscle of patients with COPD [88] could be reproduced in other cell types and other chronic inflammatory diseases. As shown in Fig. 44.2, CytOx activity was higher in COPD than in healthy subjects (as previously observed in skeletal muscle [88]), but its activity was one order of magnitude greater in patients
**FIG. 44.3** Cytochrome oxidase activity in circulating lymphocytes of healthy subjects and patients with COPD, asthma and rheumatoid arthritis. Reproduced from Ref. [87].

with asthma [87] (Fig. 44.3). The mechanisms and implications of these findings were unclear, but authors speculated that they were likely to reflect activation of circulating lymphocytes (thus systemic inflammation) in these conditions [87]. Other studies that were published later, provided further evidence of systemic inflammation in asthma. Jousilahti *et al*. found that the age-adjusted odds ratios of asthma increased in proportion to the levels of several inflammatory markers in plasma (CRP, serum amyloid-A, and fibrinogen), and that this association was independent of smoking, the waist-to-hip ratio (a marker of central obesity), and symptoms of chronic bronchitis [89]. Silvestri *et al*. reported that patients with severe asthma had higher circulating neutrophil and eosinophil number, as well as increased serum levels of IL-8 and TNF-$\alpha$, than controls and that there was a positive correlation between circulating neutrophil counts, plasma TNF-$\alpha$ levels, and exhaled nitric oxide (a well-established marker of pulmonary inflammation in asthma) as well as between TNF-$\alpha$ and IL-8 plasma levels and the degree of airflow obstruction (FEV$_1$, % of reference) [90]. Higashimoto *et al*. found that the systemic inflammatory profile of patients with asthma was similar to that of patients with COPD, including increases in serum CRP, fibrinogen, TNF-$\alpha$, IL-6, and the tissue inhibitor of matrix metalloproteinase TIMP-1 [91]; interestingly, however, serum TGF-$\beta$1 levels were higher in asthma patients than in COPD patients [91]. Finally, the latest US National Health and Nutrition Examination Survey in 8020 adults found that those with asthma have higher levels of CRP in plasma, suggesting that this may be a clinically useful marker for asthma severity and control [92]. From all these studies, therefore, it is clear that asthma is also associated with systemic inflammation. Like in COPD, thus, it is possible that systemic inflammation in asthma contributes to some (or all) the systemic manifestations reviewed later.

## Obesity

At variance with COPD, where unexplained weight loss is frequent (see above), in patients with asthma, a relationship with obesity has been suggested [93, 94]. For instance, the

First National Health and Nutrition Examination Survey studied 14,407 subjects, aged 25–74, followed-up during a mean of 10 years and found that, both at baseline and during the follow-up, increasing BMI was associated with increased prevalence of asthma [95]. Other studies have shown that obesity precedes and predicts the onset of asthma, increased obesity leads to more severe asthma, weight reduction improves asthmatic symptoms, and obesity co-occurs with intermediate asthma phenotypes [93, 94]. These observations suggest that obesity and asthma may be causally related through immunologic and inflammatory, hormonal, genetic, and/or nutritional mechanisms [93].

## Diabetes mellitus

It is unclear whether or not asthma and type 1 diabetes mellitus are related (and the direction of such potential relationship). Contrary to findings in COPD, the Nurses' Health Study could not detect an increased risk of type 2 diabetes among asthmatic patients [35]. Yet, other authors have suggested an inverse relationship between asthma and type 1 diabetes mellitus (DM1) [96]. It has been hypothesized that because, according to the "hygiene hypothesis," the risk of asthma decreases with infections early in childhood by shifting the Th2 profile, common at birth, to the Th1 phenotype, the latter may favor the development of DM1 [96]. Thus further research is required to find out whether or not asthma and DM1 are related.

## Cardiovascular disease

Several pieces of evidences indicate that the risk of CVD is increased in asthmatics [97]. Schanen *et al*. reported that asthma was an independent risk factor for incident stroke (but not coronary heart disease) in a cohort of 13,501 adults followed during 14 years [98]. In an even larger cohort (74,342 participants in the Canadian Community Health Survey), Dogra *et al*. found that asthmatics were 43% more likely to have heart disease and 36% more likely to have high blood pressure than non-asthmatics [97]. Interestingly, the age of onset of asthma did not influence this relationship significantly [97]. Finally, Wu *et al*. reported increases in multiple inflammatory markers of atherosclerosis in patients with asthma [86]. Thus, available evidence supports the concept that CVD risk is increased in patients with asthma.

## Skeletal muscle abnormalities

Skeletal muscle abnormalities are uncommon (or at least, seldom studied) in patients with asthma, at variance with COPD (see above). In one of the rare studies that have addressed this issue, Picado *et al*. could not find significant differences between oral steroid-dependent asthmatics and age- and sex-matched steroid naïve asthmatics in respiratory and skeletal muscle strength, endurance time, or fiber-type composition [99].

## Osteoporosis

A recent systematic review of the literature by Kearney *et al.* found that patients with asthma (and COPD, as discussed earlier) are at risk of osteoporosis, particularly those treated with high doses of corticosteroids [100].

## Depression and panic disorders

Depression and panic disorders are frequent in patients with asthma. Schneider *et al.* found that about 4% of asthmatics visited in primary care suffered from major depressive disorder, 23% from minor depressive disorder, and 8% from panic disorder [101]. Further, the presence of depression predicted hospitalization within the subsequent year (odds ratios, OR 6.1) and panic disorder predicted unscheduled emergency home visits (OR 4.8). Likewise, McCauley *et al.* found that 125 out of 767 adolescents with asthma (16.2%) reported significant anxiety and depressive disorders in the last 12 months, and this was related to functional status [102]. Overall, these results indicate that the impact of psychiatric comorbidity on health outcomes for patients with asthma is substantial [103]. Interestingly, the frequency of symptoms of anxiety and depression is greater among asthma patients (particularly those with uncontrolled asthma) than among patients with COPD [104].

## Inflammatory bowel disease

The prevalence of asthma is particularly increased in patients with inflammatory bowel disease. Berstein *et al.* found that patients with ulcerative colitis (*n* = 3879) and Crohn's disease (*n* = 4193) had a significantly greater likelihood of having arthritis, asthma, bronchitis, psoriasis, and pericarditis than population controls, and that asthma was the most common comorbidity in Crohn's disease patients [105]. The reasons for these associations are unknown but shared inflammatory mechanisms have been postulated [83].

## Therapeutic implications

Inhaled steroids (with or without long-acting bronchodilators) are very effective in patients with asthma [84]. They reduce local inflammation and improve pulmonary function but their effects upon the systemic manifestations of asthma are less well studied [83]. In the context of the systemic manifestations of asthma, oral medications, such as leukotriene receptor antagonists, can block the action of cysteinyl leukotrienes and thus improve both asthma and rhinitis and other conditions systemically linked with asthma [83]. Other potential treatments include receptor-blocking molecules and synthesis inhibitors related to eicosanoid inflammation [83]. Further, as depression and panic disorders are frequent in patients with asthma and both are predictive of health-care resources utilization, specific psychiatric interventions may reduce inappropriate health-care utilization and avoid adverse outcomes [101].

## INTRODUCTION

Chronic obstructive pulmonary disease (COPD) and asthma are inflammatory disorders of the lung, characterized by airflow limitation and symptoms of dyspnea and cough [1]. In both of these conditions spirometric parameters are usually abnormal with a forced expiratory volume in one second ($FEV_1$) to forced vital capacity (FVC) ratio of less than 80%. In asthma, this ratio may normalize following administration of a bronchodilator, whereas in COPD, there is little or no reversibility of lung function [1]. Although these disorders are distinct and have different pathophysiologies, in both conditions, cardiovascular complications are frequently observed. For instance, in patients with COPD, the risk of cardiovascular hospitalizations and mortality including those related to ischemic heart disease, stroke, arrhythmias, heart failure, and sudden death is two to three times higher than those without COPD [2]. In mild to moderate cases of COPD, the leading causes of hospitalization are cardiovascular events, accounting for approximately 50% of all cases [3]. In this chapter, we will review the epidemiological evidence and explore the potential mechanistic link(s) between obstructive airways diseases and cardiovascular comorbidities.

## EPIDEMIOLOGY

### Reduced lung function and CVD

One of the defining features of asthma and COPD is reduced $FEV_1$ in addition to a reduced $FEV_1$ to FVC ratio. There have been many studies that have evaluated the relationship between $FEV_1$ and cardiovascular diseases (CVD) in various populations. Almost universally, these studies have shown that reduced $FEV_1$, regardless of the cause, is a significant risk factor for CVD. As an example, in the First National Health and Examination Survey Epidemiologic Follow-up Study ($n = 1861$), Sin and colleagues found that individuals in the lowest quintile of $FEV_1$ (i.e. reduced lung function) had the highest risk for cardiovascular mortality (relative risk, RR, 3.36; 95% confidence interval, CI, 1.54–7.34), while individuals in the highest $FEV_1$ quintile had the lowest risk. The mortality risk was particularly notable for deaths related to ischemic heart disease (RR, 5.65; 95% CI, 2.26–14.13). The CVD risk was slightly lower in $FEV_1$ quintiles 2 and 3 but still significantly higher than that for the lowest quintile group (RR, 2.00, 95% CI, 1.03–3.89 for quintile 2; and RR, 2.22; 95% CI, 1.23–4.01 for quintile 3) suggesting that the relationship between reduced $FEV_1$ and CVD is linear [2]. Similar findings were observed when the analysis was limited to nonsmokers suggesting that the relationship between reduced $FEV_1$ and CVD is independent of the effects of cigarette smoking.

In another population-based study, the SALIA Cohort (Study on the influence of Air pollution on Lung function, Inflammation and Aging) investigators found that the RR of cardiovascular mortality of women with $FEV_1$ less than 80% of predicted was 3.79 (95% CI, 1.64–8.74) at 5 years and 1.35 (95% CI, 0.66 to 2.77) at 12 years of follow-up compared with women who had normal lung function [4]. In a Norway study, the investigators found that the risk of CVD mortality increased by 7% with every 10% decrease in $FEV_1$ (as percent

[b]Female values.

[c]Although 12,866 participants were originally enrolled in the study, only 7368 participants had an acceptable pulmonary function testing.

[d]Although the smoking-adjusted RR was reported, its 95% CI was not provided; thus, the adjusted data could not be used for the meta-analysis.

predicted) over a 26-year follow-up [5]. In the Honolulu Heart Program, which prospectively followed 5924 healthy, middle-aged men for up to 18 years, Curb and colleagues found that the individuals in the lowest $FEV_1$ quintile had a 1.93-fold increase in the risk of cardiovascular mortality compared to those in the best $FEV_1$ quintile (RR, 1.93; 95% CI, 1.46–2.54) [6]. In the Tecumseh Cohort Study, Higgins and colleagues observed that individuals with $FEV_1$ values less than 2.0l had a fivefold increase in the risk for CVD mortality compared with those with $FEV_1$ greater than this value (RR, 5.03; 95% CI, 3.07–8.22) [7]. In the Harvard Six Cities Study, Speizer and colleagues reported a RR of 2.74 (95% CI, 1.93–3.90) in women and 1.42 (95% CI, 1.07–1.90) in men, comparing the lowest $FEV_1$ quartile to the highest quartile [8]. Schunemann and colleagues reported a RR of 1.96 (95% CI, 0.99–3.88) in women and 2.11 (95% CI, 1.20–3.71) in men, once again comparing the lowest $FEV_1$ quintile to the highest quintile [9]. Hole and colleagues reported a RR of 1.88 (95% CI, 1.44–2.47) in women and 1.56 (95% CI, 1.26–1.92) in men, comparing the lowest to the highest quintile of $FEV_1$ [10]. Overall, these large population-based studies showed that reduced $FEV_1$ is an important, independent risk factor for CVD morbidity and mortality (pooled RR, 1.99; 95% CI, 1.71–2.29) even among nonsmokers where the RR is 1.67 (95% CI, 1.35–2.01) [2]. The relationship between reduced $FEV_1$ and cardiovascular mortality appears to be similar between men (RR, 1.64; 95% CI, 1.48–1.84) and women (RR, 2.14; 95% CI, 1.75–2.59). In general, when the lowest quintile of $FEV_1$ is compared with the highest quintile, the risk of cardiovascular mortality increases by ~75% in both men and women [2]. Taken together, these population-based studies clearly support the notion that CVD risk increases as $FEV_1$ decreases (Table 45.1).

The population attributable risk of ischemic cardiac deaths imposed by reduced $FEV_1$ was estimated by Hole *et al.* [10]. They showed that when the lowest quintile of $FEV_1$ was compared with the highest quintile, the population attributable risk for deaths related to ischemic heart disease was 26% (95% CI, 19–34%) in men and 24% (95% CI, 14–34%) in women, independent of the effects of cigarette smoking. The magnitude of the mortality burden attributed to reduced $FEV_1$ in this model was similar to that imposed by hypercholesterolemia. In the same study, comparison of total serum cholesterol (between the lowest

to the highest quintile levels) produced a population attributable risk of 21% in men and 25% in women for deaths related to ischemic heart disease [10] (Fig. 45.1). In certain populations, reduced $FEV_1$ may be responsible for 20–30% of deaths related to ischemic heart disease [10].

The risk of CVD in those with reduced $FEV_1$ is amplified by the presence of another risk factor for CVD such as hypertension. In the "Malmo Born in 1914" Study, the risk of cardiac events defined as fatal or nonfatal myocardial infarction, was only 10% higher in individuals who had reduced $FEV_1$ but without hypertension [19]. The risk nearly tripled (RR, 2.9; 95% CI, 1.8–4.5) when subjects had both reduced $FEV_1$ and hypertension together. The incidence of stroke was nearly fourfold higher (RR, 3.8; 95% CI, 1.9–7.6) when subjects had both reduced $FEV_1$ and hypertension. In contrast, reduced $FEV_1$ alone was not associated with increased risk of stroke (RR, 1.2; 95% CI, 0.70–2.2) [19]. In the same cohort, Engstrom and colleagues found that individuals who had reduced $FEV_1$ and ventricular dysrhythmia on the baseline electrocardiogram (ECG) experienced a twofold increase in the risk of coronary events (RR, 2.31; 95% CI, 1.28–4.20) [20]. In contrast, reduced $FEV_1$ alone in the absence of ventricular ectopy was not significantly associated with coronary events (RR, 1.24; 95% CI, 0.67–2.27). Similarly, ventricular ectopy by itself was not associated with coronary events (RR, 1.16; 95% CI, 0.58–2.33).

## The relationship between rate of $FEV_1$ decline and CVD

Another important physiologic phenotype associated with COPD is accelerated decline in lung function over time [21]. Individuals who experience rapid decline in $FEV_1$ are two times more likely to experience COPD-related hospitalizations and mortality [22]. They are also more likely to experience CVD events. In the Malmo "Men Born in 1914" Study, the cardiovascular event rate among smokers in the high, middle, and low thirds with regard to the decline in $FEV_1$ was 56.0, 41.0, and 22.7 events per 1000 person-years, respectively (*p* for trend = 0.01) [23]. The Baltimore Longitudinal Study of Aging showed that individuals who experienced the most rapid decline in $FEV_1$ over 16 years were three to five times more likely to die from a cardiac

**FIG. 45.1** Population attributable risk of reduced $FEV_1$ on mortality from ischemic heart disease in men [10].

cause of death than those who had the slowest decline in $FEV_1$ [24]. In lifetime nonsmokers, accelerated decline in $FEV_1$ was associated with a 5- to 10-fold increase in the risk for cardiac deaths. In the US National Study of Coal Workers' Pneumoconiosis, a longitudinal health survey of male underground coal miners, Beeckman and colleagues found that workers who had an accelerated decline in $FEV_1$ (defined as $FEV_1$ decline of 60 ml/year or greater) were more likely to develop incident asthma or COPD compared to individuals with a slower $FEV_1$ decline. Importantly, the former group had nearly 50% excess mortality than the latter group (RR of all-cause mortality, 1.45), driven mostly by excess CVD deaths (RR, 1.90) and pulmonary causes of mortality (RR, 3.20) [25].

## The relationship between $FEV_1$ to FVC ratio and CVD

Reduced $FEV_1$/FVC ratio is a more specific indicator of airways disease than is reduced $FEV_1$ alone in the general population. Using data from the Third National Health and Nutrition Examination Survey in the United States [26], Sin and Man found that individuals with severe airflow obstruction (defined as $FEV_1$ >50% of predicted and $FEV_1$/FVC ratio ≥70%) were twice as likely to have ECG evidence of probable or possible myocardial infarction than individuals with normal lung function. In the "Men Born in 1914 Study," Engstrom *et al.* found that compared to subjects in the highest $FEV_1$/FVC quintile (ratio ≥77.3%), those in the lowest $FEV_1$/FVC (≤66.3%) quintile were 73% more likely to experience coronary events ($p = 0.01$) [20]. The risk for frequent or complex ventricular arrhythmia was 83% higher in the lowest $FEV_1$/FVC quintile compared with the highest quintile. As with $FEV_1$, reduced $FEV_1$ to FVC ratio may have a modifying effect on CVD. In the study by Engstrom *et al.*, reduced $FEV_1$/FVC ratio by itself was a modest independent risk factor for coronary events (RR, 1.30). Presence of arrhythmias in those with normal $FEV_1$/FVC was not associated with coronary events (RR, 1.01). However, the combination of reduced $FEV_1$/FVC ratio and presence of arrhythmias increased the risk of coronary events by over twofold (RR, 2.43; 95% CI, 1.36–4.32) [20]. These data suggest that airflow obstruction impacts synergistically on the diseased heart to make it more vulnerable to acute coronary events.

## COPD and CVD

The Lung Health Study (LHS) is one of the largest COPD cohorts that studied the effects of smoking cessation and inhaled anticholinergic drugs on disease progression in patients with mild COPD (Global Initiative for Chronic Obstructive Lung Disease, GOLD, Stages 1 and 2) [27]. Although the initial study was designed as a 5-year trial, the follow-up was subsequently extended to 14.5 years. The latter was called Lung Health Study-3 (LHS-3) [28]. In this study, the LHS investigators confirmed the benefits of smoking cessation in retarding disease progression and attenuating morbidity and mortality [28]. Notably in this

study, the leading cause of hospitalization was CVD [3] and the leading cause of mortality was lung cancer [28]. CVDs accounted for nearly half of all hospitalizations and 22% of all deaths, while lung cancer accounted for 33% of all deaths. In contrast, only 8% of the cohort died from respiratory failure [28]. These data are a sobering reminder of the importance of CVD and cancer in patients with mild COPD.

Even in more advanced disease (GOLD Stages 3 and 4), CVD and lung cancer are important causes of morbidity and mortality. In TORCH (Towards a Revolution in COPD Health) study, a 3-year randomized controlled trial that assessed the effects of salmeterol/fluticasone in severe COPD ($FEV_1$ <60% of predicted), CVDs accounted for 26% and cancer accounted for 21% of all deaths [29]. In an analysis of data from the Kaiser Permanente Medical Group, Sidney and coworkers found that having COPD increased the risk of hospitalization for cardiac arrest and ventricular fibrillation by 2.8 fold, atrial fibrillation by 2.1 fold, angina by 2 fold, myocardial infarction by 87%, congestive heart failure by nearly 4 fold, stroke by 39%, pulmonary embolism by 2.7 fold, and other CVD by 86%, independent of age, sex, and history of hypertension, hyperlipidemia, and diabetes [30]. Curkendall and colleagues reported similar findings using a completely different cohort [31]. On average, for every 10% decrease in $FEV_1$, all-cause mortality increases by 14%, cardiovascular mortality increases by 28%, and nonfatal coronary event increased by almost 20%, after adjustments for relevant confounders such as age, sex, and smoking status [3].

In COPD, there are two major phenotypes: emphysema and small airways disease. Emphysema can be determined noninvasively using quantitative computerized tomography (CT) scanning [32]. McAllister and coworkers used this method and found a significant relationship between emphysema severity as assessed by quantitative CT scanning of the lungs and arterial stiffness as measured by pulse wave velocity [33]. Arterial stiffness is a good surrogate of atherosclerosis and a robust predictor of future CVD risk [34].

## The relationship between asthma and CVD

Although most of the attention has been directed at the relationship between COPD and CVD, there is emerging literature supporting the notion that asthma is also a risk factor for CVD. In one study from Sweden, Toren and colleagues estimated the risk of mortality in patients with asthma. Compared to the expected mortality, the mortality rate among patients with severe asthma, defined as one who needed daily treatment of oral corticosteroids for at least a year, was twofold higher (RR, 2.1, 95% CI, 1.8–2.5) [35]. The RR of ischemic cardiac deaths was also nearly twofold higher (RR, 1.9, 95% CI, 1.4–2.4) with women having a particularly high RR at 2.5 (95% CI, 1.7–3.3) [35]. In another population-based study, Musk and colleagues found that patients with asthma had excess mortality compared to the rest of the population (standardized mortality ratio, SMR, for all causes of death 1.6 for men ($p < 001$) and 1.7 for women ($p < 0.001$)). The risk of ischemic cardiac death was also elevated (SMR, 1.3) but only in the older age group [36]. A Canadian study found that patients with

self-reported asthma were 43% more likely to have heart disease and 36% more likely to have hypertension compared to nonasthmatics [37]. Using the Northern California Kaiser Permanente database, a large Health Maintenance Organization providing to over 3 million people, Iribarren and colleagues found that patients with asthma defined based on self-report or hospitalization for asthma had a 24% increase in the risk for coronary heart disease hospitalization or death adjusted for confounders such as age, race/ethnicity, education level, smoking status, white blood cell count, hypertension and diabetes, and occupational exposures. The relationship was particularly strong in women [38].

However, there are some dissenting studies. For instance, Belli and coworkers failed to find a significant association between asthma and mortality in an elderly group of individuals. In this study, the risk of cardiovascular mortality was similar between those with and without asthma [39]. Similarly, in the Atherosclerosis Risk In Communities (ARIC) Study, Zureik and colleagues found that compared with individuals without asthma, those with (ever) asthma (defined by self-report) had similar RR of coronary heart disease (RR, 0.87; 95% CI, 0.66–1.14). The RR using a time-dependent analysis was 0.88 (95% CI, 0.69–1.11). However, they found that individuals with asthma had increased risk of stroke (RR, 1.43; 95% CI, 1.03–1.98 using a time-dependent analysis) [40].

One of the characteristic physiologic signs in asthma is bronchial hyperresponsiveness (BHR). Zureik and colleagues used data from the European Community Respiratory Health Survey to determine the relationship between BHR and carotid intima-media thickness, which is a marker of atherosclerosis [41] and a risk factor for stroke [42]. They found that in men but not in women who demonstrated BHR (defined as a 20% fall in baseline $FEV_1$ with methacholine exposure of 4 mg or less) the mean carotid intima-media thickness was greater compared to men who did not have BHR (0.68 ± 0.11 in men with BHR versus 0.62 ± 0.09 mm in men without BHR, $p = 0.002$) [43]. Although the mechanism for this observation is not completely known, a recent study indicates that BHR is associated with systemic inflammation, as measured by circulating C-reactive protein (CRP) [44].

## POSSIBLE MECHANISMS

While the epidemiological link between COPD (and to lesser extent with asthma) and cardiovascular events is solid, the mechanism(s) that underpin this relationship are far from certain.

### The inflammation theory

It is well recognized and accepted that both asthma and COPD are inflammatory conditions associated with both lung and systemic inflammation, though the content and the nature of the inflammatory process differs between the two conditions [1]. It is postulated that the inflammatory process starts in the lungs and then "spills" into the systemic circulation through the rich network of capillary beds in the pulmonary microcirculation [45]. The rate of spillage is heavily influenced by inflammation (which generally increases permeability of the vasculature) and by underlying parenchymal disease. It is believed (though not proven) that in asthma and in COPD, proinflammatory cytokines and chemokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1β, IL-6, and others, escape into the systemic circulation from the lungs inducing a systemic inflammatory response in the liver, bone marrow, and other organs [46]. In asthma, the inflammatory process in the lungs is thought to reflect an "allergic" or "atopic" response to environmental allergens, while in COPD, it is thought to be an abnormal (exaggerated) response to cigarette smoke and other irritants. Systemic inflammation is believed to contribute to plaque build-up in coronary and cerebral vasculature and to their rupture during periods of stress [47].

Consistent with the systemic inflammation theory, CRP levels in COPD patients have been associated with CVD and all-cause morbidity and mortality [48]. In LHS, for instance, the risk of all-cause and CVD mortality over 7 years of follow-up increased as a function of CRP levels. Compared to the lowest CRP quintile group (mean level 0.21 mg/l), the highest CRP quintile (mean level 7.1 mg/l) had a mortality risk that was 1.8 times higher, adjusted for sex, race, age, body mass index, pack-years of smoking, biochemically validated smoking status (i.e. continued smokers, sustained quitters, or intermittent quitters), rate of descent in $FEV_1$ (in quintiles), and predicted $FEV_1$ (in quintiles). The risk of fatal and nonfatal CVD also increased along the CRP gradient. Compared to the lowest quintile, the highest CRP quintile group experienced a 1.5-fold increase in fatal and nonfatal cardiovascular events [49].

## DISTURBANCE OF NEUROHUMORAL TONE

Patients with severe COPD have a perturbed neurohumoral regulatory system, leading to excess sympathetic nervous activity and reduced vagal tone [50], which is inversely related to their oxyhemoglobin saturation. Accordingly, COPD patients have raised resting heart rate and have an increased risk of rhythm disturbances and ectopic beats [19], which may increase their risk for CVD events. Metaiodobenzylguanidine (MIBG), an analog of guanethidine, has similar metabolism to norepinephrine in systemic nervous tissues [51]. MIBG has been used to image the heart for assessment of cardiac sympathetic activity. Increased sympathetic nervous activity leads to reduced cardiac to mediastinal activity ratio in the delayed images [51]. In a group of 28 COPD patients and 7 control subjects, COPD patients demonstrated reduced cardiac accumulation of MIBG and a higher washout rate from the heart than control subjects, indicating excess activity of the sympathetic nervous system with increased norepinephrine turnover [52]. Interestingly, the MIBG accumulation rate correlated significantly with the intensity of dyspnea as reported by these patients ($p < 0.05$). Consistent with

the MIBG data, COPD patients had higher plasma nore-pinephrine levels than did the control subjects (449 versus 69 pg/ml; $p < 0.01$). There is little information on whether or not patients with mild or moderate COPD have disturbed neurohumoral regulatory system. However, there is emerging data to indicate that in mild disease, patients are frequently exercise limited by an abnormal cardiovascular response to exercise (e.g. reduced anaerobic threshold). In contrast, subjects without COPD are limited mainly from leg muscle fatigue [53]. These data suggest that even in mild COPD, cardiac performance may be perturbed.

Whether certain inhaled drugs commonly used in COPD and asthma worsen cardiac status is very controversial. Pharmacoepidemiological studies have linked the use of short- or long-acting bronchodilators with increased risk of cardiovascular events in COPD and asthma. In one study, the use of ipratropium bromide, a short-acting anticholinergic medication, was associated with a 60% increase in adjusted mortality compared with nonuse among 827 patients with COPD [54]. In the LHS in which one-third of the participants were assigned in a random fashion to usual care; another one-third to special intervention (for smoking cessation) in addition to ipratropium bromide; and the remaining subjects to special intervention (for smoking cessation) in addition to placebo puffers, ipratropium bromide was associated with a 26% increase in the risk of cardiovascular events compared with placebo. The risk of fatal cardiovascular events was even higher (relative risk, 2.6). Although this study was underpowered to detect cardiovascular events, these data, nonetheless, raised concerns that ipratropium bromide may increase cardiovascular morbidity and mortality in COPD [3].

There is a scarcity of cardiovascular safety data on tiotropium. In the 1-year clinical trials, the risk of heart rate and rhythm disturbance disorders, such as arrhythmias, atrial fibrillation, and tachycardia, were about twofold higher in those assigned to tiotropium ($n = 550$ patients) compared with those assigned to placebo ($n = 371$). However, these events were rare occurring in only 4.4% of this carefully selected group of COPD patients [55]. Nevertheless, tiotropium should be used with caution in patients with COPD who also have coexisting rhythm disorders.

A systematic review and meta-analysis showed that a single dose of a $\beta_2$-agonist caused an increase in heart rate of 9 beats/min and reduced serum potassium by 0.36 mmol/l compared with placebo [56]. The use of short-acting $\beta_2$-agonist has been associated with increased cardiovascular events. Au and colleagues, for example, studied 630 patients with unstable angina or myocardial infarction and 10,486 control subjects enrolled in 7 Veterans Administration Medical Centers, and found that compared with subjects who did not fill a short-acting $\beta_2$-agonist, patients who had filled one $\beta_2$-agonist prescription in the 3 months prior to their index date had ~70% increase in the risk for an acute coronary event [57]. Importantly, the excess risk was limited to those patients who had a prior history of CVD; their risk was over threefold higher than those who did not use $\beta_2$-agonists. Additionally, new users of $\beta_2$-agonists had a sevenfold increase in the risk of cardiovascular events. Overall, treatment with short-acting $\beta_2$-adrenoceptor agonists was associated with a 2.5-fold increase in the risk of adverse

cardiovascular events, which included ventricular tachycardia, myocardial infarction, and sudden deaths [56]. The exact mechanisms by which these medications may potentially increase cardiovascular morbidity and mortality are unknown. Future studies are needed to validate these initial epidemiologic observations and to determine the potential mechanisms by which these medications may increase cardiovascular risk in susceptible COPD and asthmatic patients.

## CAN HEART-PROTECTIVE DRUGS REDUCE COPD MORBIDITY?

In view of the intrinsic link between COPD and CVD, some have suggested that cardioprotective drugs may have beneficial effects in COPD. There have been no randomized controlled studies that have carefully and prospectively tested this hypothesis. There are, however, several epidemiological studies that have generated promising data. For instance, Mancini and coworkers conducted a time-matched nested case-control study using administrative health data in Quebec to determine whether or not statins (hydroxymethylglutaryl CoA reductase inhibitors), angiotensin-converting enzyme (ACE) inhibitors, and/or angiotensin receptor blockers (ARB) could improve survival in COPD. They found that the combined use of statins and ACE or ARBs was associated with a 34% reduction in hospitalization for COPD, a 61% reduction in myocardial infarction, and a 58% reduction in all-cause mortality [58]. Similar findings were noted by an independent group in Japan [59]. One of the major limitations of the previous two studies was that the diagnosis of COPD was not confirmed by spirometry. A Norweigan group using a retrospective cohort of 854 patients with spirometry confirmed COPD (mean $FEV_1$, 48% of predicted) demonstrated that treatment with statins following hospitalization for COPD was associated with a 43% reduction in all-cause mortality. Interestingly, in the same study, inhaled corticosteroids, which are anti-inflammatory drugs, were also associated with reduced mortality [60], a finding that has been observed in other epidemiological studies [61, 62 ] but not in a randomized controlled trial [63]. Low-dose inhaled corticosteroid therapy has been associated with reduced risk of myocardial infarction, arrhythmias, and CVD mortality [64–66]. Other groups have shown that beta-blockers may also reduce mortality in COPD patients but the overall magnitude of the benefit appears to be small [67]. Moreover, they (especially noncardioselective beta-blockers) are associated with a slight increase in the risk for COPD hospitalizations [68]. Thus, for safety reasons, in general, only cardioselective beta-blockers in low doses should be employed in COPD [69].

## SUMMARY

Cardiovascular events are common complications in COPD and asthma. While the mechanisms linking these disorders

have not been well established, the epidemiological evidence is strong. Reduced lung function (regardless of the cause) increases the risk of cardiovascular hospitalization by twofold may contribute up to 25% of all ischemic cardiac deaths. In mild to moderate COPD, cardiovascular events are the leading cause of hospitalization and the second leading cause of mortality (trailing only behind lung cancer). System inflammation and neurohumoral disturbances are the leading putative mechanisms for the association. There are emerging data that cardioprotective drugs may also have salutary effects in COPD. However, these promising observations must be validated in clinical trials before they can be routinely recommended in patients with obstructive airways disease.

# Allergen Avoidance

## INTRODUCTION

Senitization to inhalant allergens is a major risk factor for asthma, rhinitis, and eczema [1, 2]. Exposure of individuals with established allergic disease to high levels of sensitizing allergens causes exacerbation of symptoms and worsening of the underlying inflammatory process [3–10]. Complete cessation of exposure leads to the improvement in disease control. For example, patients with seasonal allergic rhinitis have no symptoms in the absence of exposure to pollen, and moving atopic asthmatics into low-allergen environments such as hospitals [11] or high-altitude sanatoria [12–14] improves markers of asthma severity.

In occupational asthma, cessation of exposure to an allergen may be associated with a dramatic improvement in symptoms, and sometimes cure, but only *early* in the natural history of the disease [15]. However, exposure over a longer period can result in asthma becoming persistent in spite of removal from exposure. This early "window of opportunity" appears variable between individuals and may explain why environmental control is ineffective in some circumstances. It suggests that any allergen avoidance strategy must achieve an early and major reduction in exposure and be targeted to individuals likely to benefit.

## ALLERGEN AVOIDANCE MEASURES

Allergen avoidance measures are usually not specific to any given allergen, or even environmental contaminant. For example, measures against house dust mite allergen will also impact on levels of microbial products such as endotoxin and glucan. This may have unanticipated consequences and may alter the effectiveness of allergen avoidance on allergic disease.

When designing effective methods to reduce personal exposure, the aerodynamic characteristics and distribution of allergens have to be taken into account [16]. Mite and cockroach allergens are contained within particles >10 μm diameter and become airborne after vigorous cleaning, whereas substantial cat and dog allergen circulates in the air on small particles (<5 μm diameter) [17–19]. Consequently, pet allergic patients often develop wheezing, sneezing, or itchy eyes immediately on entering a home with a pet, but mite and cockroach-sensitized asthmatics are unaware of the relationship between exposure and symptoms. Air filtration units have little effect on personal exposure to mite or cockroach but may be useful in removing airborne pet allergens.

## Mite allergen avoidance

Reduction of mites and mite allergens in the home can be achieved by a number of measures (Table 46.1; for review see Ref. [16]).

### Bed and bedding

The greatest exposure to mite allergen is in bed at night, and synthetic quilts provide much greater risk than feather cover does. The most effective mite allergen avoidance measure is to cover the mattress, duvet, and pillows with impermeable encasings (or get rid of the quilt if it is not covered). Finely woven fabrics are the most effective covers [20]. Sheets should be washed weekly, and blankets should be washed regularly in a hot cycle (above 55°C) to kill the mites [21].

**TABLE 46.1** Practical measures for reducing house dust mite, pet, fungal, and cockroach allergen levels.

---

*House dust mite*

Bed and bedding
- Encase mattress, pillow, and quilt in allergen impermeable covers (preferably finely woven fabric)
- Wash all bedding weekly. Use hot cycle (55–60°C) if possible

Replace carpets with hard flooring (e.g., linoleum or wood)
Minimize upholstered furniture/replace with leather furniture
Replace curtains with blinds
Minimize dust accumulating objects; keep in closed cupboards
Remove soft toys (if impossible, hot wash/freeze soft toys)
Reduce indoor humidity if possible

---

*Cat/dog*

Remove cat/dog from the home

---

*Fungi*

Reduce indoor humidity if possible
Use HEPA air filters in main living areas and bedrooms
Use Fungicides on heavily contaminated surfaces
Minimize upholstered furniture
Replace carpets with hard flooring (e.g., linoleum or wood)
Ensure regular inspection of heating and air conditioning units to prevent contamination

---

*Cockroaches*

Remove food and water sources
Use suitable pesticide in bait form
Remove all dead carcasses and frass
Wash down all surfaces, floors, and walls with detergent
Seal cracks in walls and plaster work to reduce further access
Wash all bedding, clothing, and curtains

---

**FIG. 46.1** Air filtration with HEPA units results in only moderate reduction in personal exposure to cat allergen (assessed by intranasal air filters). From Ref. [28] with permission.

## Carpets and upholstered furnishings

Fitted carpets should be removed and replaced with hard floor coverings (e.g., wooden or linoleum floor) since they are impossible to clean (vacuuming provides substantial personal exposure). Exposing carpets to direct sunlight, steam cleaning, use of acaricides or tannic acid, freezing with liquid nitrogen, etc. are only partially effective [21]. Allergen reduction in upholstered furniture is impossible, without impermeable (leather or PVC) covers. Fabric curtains can be replaced with venetian blinds. Soft toys can be frozen then washed to kill mites and remove allergens.

## Controlling humidity

Mites live in beds because of the high levels of humidity; but reducing relative humidity of indoor air may be insufficient to reduce humidity in the middle of a mattress [22, 23]. This depends on the local climate, housing design, and effectiveness of dehumidification. Central mechanical ventilation heat recovery units are effective in areas where outdoor humidity is low and home insulation is good, but not where outdoor humidity is high and homes are poorly insulated. Portable dehumidifiers are generally inadequate [24].

Major reductions in personal exposure are possible, but single measures are unlikely to work. A stringent environmental control regime combining several measures can achieve and maintain a low-allergen environment [25], but this will be expensive and require long-term discipline – this may be beyond many patients.

## Pet allergen avoidance

Cat and dog allergen levels are low in homes without a pet [16]. After permanent removal of a pet, allergen levels remain high for months [26]. Pet-sensitized children exposed to pets may lose lung function in early life which may never be recovered [3]. Almost all pet owning and pet-sensitized asthmatics continue keeping their pets, in spite of asthma which is hard to control.

Air cleaning units with high-efficiency particulate arrest (HEPA) filters can reduce the airborne concentration of cat and dog allergens in homes with pets [27], but field studies demonstrated that the magnitude of reduction in personal exposure is small (Fig. 46.1) [28]. Washing pets produces a modest reduction in airborne allergen [29, 30] but needs to be done more than twice a week [31] and is unlikely to translate into clinical benefit.

In experimental chambers, vacuum cleaners with built-in HEPA filters and double thickness bags do not leak pet allergens. However, in real life (actually vacuuming a carpet for which they were designed!) intranasal air samplers have shown a fivefold increase in the amount of cat allergen inhaled while using a range of brand new high-efficiency vacuum cleaners (Fig. 46.2) [32]. Data from experimental chamber studies are not a relevant index of personal exposure in a real-life situation and thus cannot be used to recommend high-efficiency vacuum cleaners to allergy sufferers.

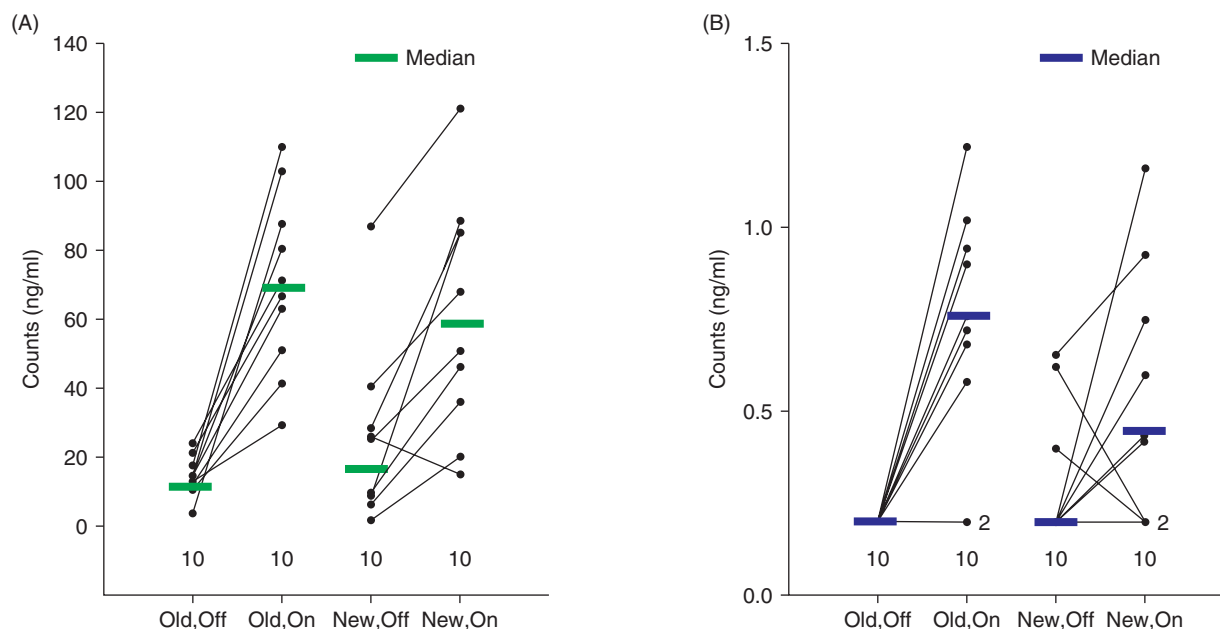
Pet removal is the only effective advice to patients with pet allergy who experience symptoms on exposure.


**FIG. 46.2** Vacuum cleaning and cat allergen exposure: Fel d 1 bearing particle counts (halo units; (A) and Fel d 1 level (ELISA; (B). Vacuum cleaners are grouped into either control (old) or unused (new). Each value is the median (range) of the observations in each cell (2 observers × 10 homes). There is a fivefold increase in the amount of cat allergen inhaled while using a range of brand new high-efficiency vacuum cleaners. From Ref. [32] with permission.

## Cockroach allergen reduction

Physical and chemical procedures can control cockroach populations in infested houses [33–35]. Several pesticides are available, in either a gel or a bait form. Elimination of food and water sources, sealing holes in plasterwork and floors, and household cleaning (of contaminated floors, surfaces, and bedding) are essential. Successful treatments reduce exposure in ~2 weeks, have maximal effect within 1 month, and reduce populations for up to 6 months. Discipline in cleaning and repeat treatments are critical.

## ALLERGEN AVOIDANCE IN THE TREATMENT OF ALLERGIC DISEASE

Vulnerable patients are bombarded with advertisements for allergen avoidance, often with spurious or exaggerated claims for extremely expensive vacuum cleaners, dehumidifiers, etc. We have a duty to only recommend clinically effective controls, which are relevant to specific patients, often relevant to their geographical location. The questions that remain controversial are whether home environmental changes are adequate, can be sustained in real life sufficient to impact disease, and how to identify those patients who will benefit [36].

## Mite allergen avoidance

Recent updates of the Cochrane meta-analysis reported no effect of the interventions and concluded that current methods of mite allergen avoidance should not be recommended to mite-sensitive asthmatics [37, 38]. The authors concluded that they were unable to demonstrate any clinical benefit to mite-sensitive patients with asthma of measures designed to reduce mite exposure (Figs 46.3 and 46.4). The most recent meta-analysis [37] included 3002 patients included into 54 trials, which is more than doubling the number of patients since the first such review [39]. The authors suggested that allergen avoidance methods did not adequately reduce mite antigen levels but also stressed that mite-sensitive asthmatic patients are usually sensitized to other allergens, so that successful elimination of only one allergen may have limited benefit, whatever its success [37]. Recent Cochrane review of dehumidification showed no satisfactory studies.

In *adults* with asthma, three older studies (98 study participants in total) suggested improvements in bronchial reactivity with mite allergen avoidance in mite-sensitive patients [40–42]. In contrast, the largest randomized double-blind, placebo-controlled SMAC trial assessed the effectiveness of mite-impermeable bed covers as a single intervention, in over 1000 adult asthmatics. There was no improvement in any of the outcome measures [morning peak expiratory flow rate, PEFR, during the first 6 months or 12 months (Fig. 46.5), the proportion of patients who are able to discontinue inhaled steroids during the second 6 months of the study, symptoms scores, quality of life, etc.] [43]. Over two-thirds had positive mite-specific IgE and one in four beds had mite allergen levels >10 μg/g Der p 1. In a *post-hoc* analysis of the subgroup of 130 patients with high mite-specific IgE (≥10 kU$_A$/l) and high mite allergen exposure (>10 μg/g Der p 1 in mattress dust), there was no difference between active and placebo groups. This was confirmed by a study in 55 adult patients with asthma who

**FIG. 46.3** Cochrane meta-analysis reported no effect of the interventions. House dust mite reduction versus control, outcome: asthma symptoms score.

were sensitized to mite (mite-specific IgE > 0.7 kU$_A$/l) and exposed to high levels of dust mite allergen in their mattresses (Der p 1 > 2μg/g) [44]. Recent Dutch studies have given opposing results [45]. In asthma in adults, a single intervention with allergen-impermeable encasings for the mattress, duvet, and pillows is ineffective in long-term management, even in individuals who are highly allergic to dust mite and exposed to high levels of mite allergens.

In contrast, several studies in *children* with asthma have indicated that environmental interventions may improve airway reactivity [46], lung function [47], reduce acute Emergency Room visits [48], and substantially reduce maintenance inhaled steroids [49]. The Inner-City Asthma Study assessed individually tailored environmental interventions [50]. A total of 937 children aged 5–11 years with uncontrolled moderate/severe asthma and at least one positive skin test were recruited from seven inner city areas of the USA. Mattress and pillow encasings and a high-filtration vacuum cleaner were supplied to all homes, and products required for specific interventions (e.g., a HEPA air filter for the reduction in passive smoke exposure) were supplied free of charge (the control group had no placebo interventions). Children in the intervention group had significantly fewer days with asthma symptoms, and fewer emergency room visits [50] (Fig. 46.5). An additional period of 34 symptom-free days over 2 years was obtained at a cost of $2000/child (Fig. 46.6) [51].

### Rhinitis

A Cochrane systematic review of mite avoidance measures in the management of perennial allergic rhinitis published in 2001 reported that the quality of studies was poor and found no evidence of benefit [52]. In the very large SMAC

**FIG. 46.4** Cochrane meta-analysis reported no effect of the interventions. House dust mite reduction versus control, outcome PC20 (provocative concentration for 20% fall in $FEV_1$).

(A) All patients — Peak expiratory flow rate (l/min) vs Baseline, 6 month, 12 month. Control group, Active-intervention group.

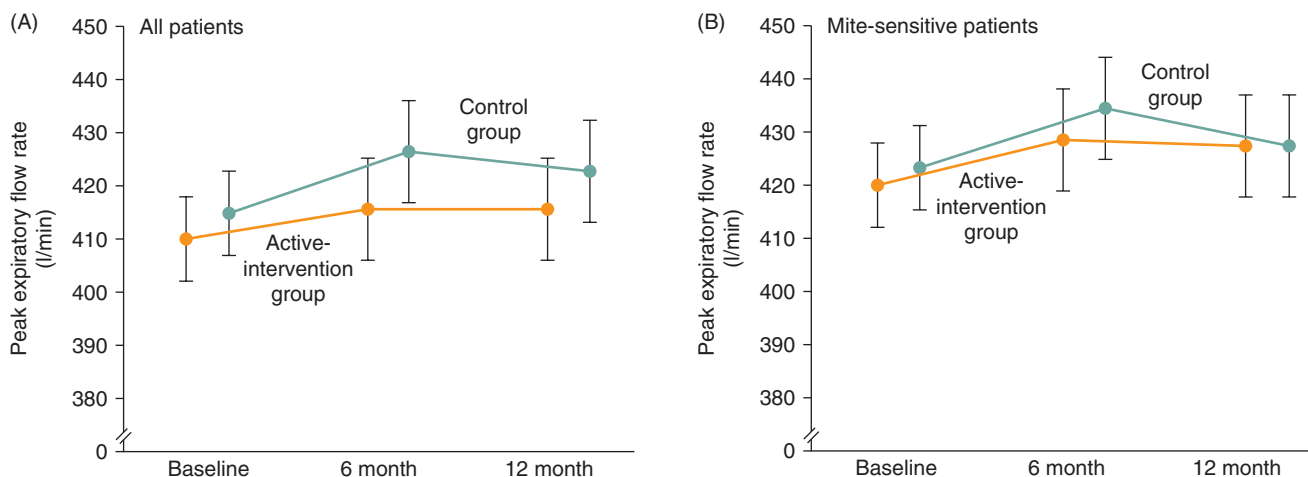
(B) Mite-sensitive patients — Peak expiratory flow rate (l/min) vs Baseline, 6 month, 12 month. Control group, Active-intervention group.


**FIG. 46.5** No effect of covering mattress, pillow, and quilt with allergen-impermeable covers amongst adults with asthma. Mean morning peak expiratory flow rate in the active–intervention and control groups at base line, 6 months, and 12 months among all patients (A) and among mite-sensitive patients (B). From Ref. [43] with permission.
**FIG. 46.6** Environmental control is effective amongst children with asthma. Mean maximal number of days with symptoms for every 2-week period before a follow-up assessment during the 2 years of the study. The difference between the environmental intervention and control group was significant in both the intervention year ($p < 0.001$) and the follow-up year ($p < 0.001$). From Ref. [50] with permission.

study [40], there was no difference in rhinitis symptoms between active bedding and control groups (data unpublished). A further large randomized, double-blind, placebo-controlled study has since confirmed this [53].

### Eczema

There are as yet no systematic reviews assessing the effect of mite avoidance measures in patients with eczema. Two small studies [54, 55] compared mite-impermeable encasings $+/-$ acaricides with controls and failed to show any improvement in eczema. In contrast, an earlier study in which half of the study population were children, with a more comprehensive environmental intervention which included a combination of bed covers, acaricides, and high-filtration vacuum cleaners for 6 months, demonstrated a significantly greater improvement in the severity score and area affected by eczema in the active compared to the control group [56].

### Pet allergen avoidance

While experience suggests that clinical improvement can occur when a pet to whom a patient is sensitized is removed [57], it rarely happens. There have been three small studies of cat and dog allergen avoidance with the pet still in home with contrasting outcomes [58, 59], A Cochrane Airways review emphasized the lack of evidence on the clinical effectiveness of pet allergen avoidance [59]. Larger studies are needed before definitive recommendations can be made.

### Food allergen avoidance

It is difficult to get patients to comply with food allergen avoidance. The beneficial effects of food avoidance in food-allergic patients without other allergic disorders are unambiguous, this approach being indeed the mainstay of their treatment. Some controversy still exists, however, regarding the role of exclusion diets in patients with combined eczema and food sensitivity. The few small studies on this issue, most investigating the impact of an elemental diet, showed no or limited benefit [60, 61].

## Summary on the use of allergen avoidance in the treatment of asthma

There is no evidence to support the use of simple single allergen avoidance methods amongst adults with asthma; with respect to the effects of a multifaceted intervention, there are as yet no adequately powered studies based upon which to make an informed decision in this age group. In contrast, the majority of studies in children suggest that allergen avoidance may be of benefit.

Until unequivocal evidence for all age groups is obtained, we suggest the following pragmatic approach:

- Single avoidance measures ineffective
  - use a comprehensive environmental control regime aiming to achieve a complete cessation of exposure, or as great a reduction in personal exposure as possible
- Tailor the intervention to the patient's sensitization and exposure status
  - if unable to assess the exposure, use the level of allergen-specific IgE antibodies or the size of skin test wheal as an indicator
- Start the intervention as early in the natural history of the disease as possible.

## ALLERGEN AVOIDANCE IN THE PREVENTION OF ALLERGIC DISEASE

The consistent finding of an association between allergic sensitization and childhood asthma raises the question as to whether reducing exposure to allergens early in life can reduce the risk of subsequent development of sensitization and/or symptoms of allergic disease.

### Secondary prevention

Secondary preventive measures are designed to halt the progression of disease in individuals who are at high risk for the development of allergic disease, but who have not yet developed specific symptoms (e.g., prevention of asthma in individuals with eczema, rhinitis, or evidence of allergen senitization). The evidence for effective secondary prevention measures is scarce and only a small number of secondary prevention trials using allergen avoidance measures have been conducted (most research to date has focused on primary and tertiary prevention).

The multicentre Study on the Prevention of Allergy in Children in Europe (SPACE) secondary prevention study

investigated the protective effect of mite avoidance in high-risk allergic children (family history of atopy asthma, rhinitis, eczema, but not sensitized to mite). In one study, 636 young children aged 1.5–5 years were randomized to mite-impermeable mattress covers and specific mite avoidance advice versus general advice only [62]. The rate of senitization to mite after 1 year was reduced in the active group. A similar study and intervention including 242 children aged 5–7 years was reported by another group [63]. After 1 year, fewer children were newly sensitized to mite in the active group, with a trend for fewer wheezing symptoms.

These two studies indicate that senitization to mite can be prevented by allergen avoidance in the short term; however, further follow-up of these children is essential to show whether this effect can be sustained, as well as to ascertain its impact on the natural history of allergic disease.

## Primary prevention

So, does successful reduction in exposure to allergens early in life prevent the development of sensitization and allergic disease? This topic has been a subject of several recent review articles [64, 65]. Seven "primary prevention" studies are ongoing, all focussed on children at high risk of developing allergic disease (e.g., both parents atopic, single parent atopic, mother with asthma, etc.). The studies used different environmental control approaches (e.g., four combined dietary intervention with environmental control). Different outcomes were assessed at different ages. While the results are not directly comparable, they do provide interesting and complementary data.

Isle of Wight was the first primary prevention study [66–69]. A complex intervention involved avoidance of both food and dust mite allergens until age 9 months. Mothers who were breast-feeding their children were asked to avoid allergenic foods, and these foods were not introduced into the infant's diet until after 9 months of age. Infants who were not breast-fed were given a hydrolyzed formula. Environmental control comprised of the application of acaricide to carpets and upholstered furniture. Infants in both groups slept on polyvinyl-covered mattresses with vented head area. Mite allergen levels at age 9 months were lower in the active than in the control group but were still higher than levels seen in most studies.

By age 8 years in the active group, sensitization to mite was reduced by more than 50%, and current wheeze, nocturnal cough, wheeze with bronchial hyper-responsiveness, and atopy were lower in the multivariate analysis. [69]. However, due to the study design it is impossible to determine which intervention is responsible.

The Canadian Primary Prevention Study (CaPPS) exemplifies the complexity of adherence to multifaceted interventions [70, 71]. Compliance with mattress encasings and acaricides was excellent. Mite allergens were significantly reduced in the parental bed throughout the study, while child's mattress levels were low in both groups. However, despite advice, there was no reduction in the use of carpets and in pet ownership in the active group compared to controls. There was a significant reduction in "probable asthma" and "rhinitis without colds" at age 2 in

the active group. At age 7, physician-diagnosed asthma was reduced in the intervention group compared to the control group (14.9% versus 23.0%) [71], but there was no difference in allergic rhinitis, eczema, atopy, and bronchial hyper-responsiveness [71].

In the Study on the Prevention of Allergy in Children in Europe (SPACE), the multifaceted intervention included both inhalant and food allergens, studied in new born children from Austria, Germany, and UK [72, 73]. Mattress covers were applied to the infants' bed. Mothers were advised to breast-feed, and hypoallergenic formula was recommended as an alternative (Austria and Germany, but not UK). Parents were advised to delay the introduction of allergenic foods. At age 2, no differences were found between the control and the intervention groups in the prevalence of mite sensitization or respiratory symptoms.

The Childhood Asthma Prevention Study (CAPS) is a multicentre, parallel group, randomized controlled trial in Sydney, Australia [74–77]. Children from at-risk families were randomized into four groups (mite avoidance with placebo dietary intervention, mite avoidance with active dietary intervention, active dietary intervention alone, no mite avoidance; placebo dietary intervention, no mite avoidance). A significant reduction in the very high baseline mite levels was achieved in the mite intervention group; the dietary intervention consisted of omega 3 fatty acids supplementation. At age 3 and 5 years, there was a significant reduction in sensitization to house dust mite in the active mite allergen avoidance group, but no significant differences in wheeze were found with either intervention [75]. At 5, the prevalence of eczema was higher in the active mite avoidance group (26% versus 19%) [76].

In the Primary Prevention of Asthma in Children Study (PREVACS) in the Netherlands, children were recruited during the prenatal period and randomized to either a control group (receiving usual care) or an intervention group in which families received instruction from nurses on how to reduce exposure of newborns to mite, pet and food allergens, and passive smoking. This study was not effective in reducing asthma-like symptoms in high-risk children during the first 2 years of life, and although a modest effect was observed at age 2 years, no significant differences in the total and specific IgE were found between the groups [78].

The Prevention and Incidence of Asthma and Mite Allergy (PIAMA) is a multi-centre, population-based cohort study of >4000 children in the Netherlands [79, 80]. Nested within this cohort is an intervention study amongst 810 high-risk infants who were randomly allocated to receive active or placebo mite-proof encasings for the mattress and pillows of the parental and infant beds. Advice was given to the active group to wash bedding regularly at more than 60°C. Baseline mite allergens levels were low in both groups, and even lower in the active group at 1 year, there was little change in the absolute value [79]. At age 2 and 4 years, sensitization and allergic symptoms were similar in both groups [79, 80].

The Manchester Asthma and Allergy Study (MAAS) is a whole population birth cohort study of >1000 children, with a nested environmental intervention study in the high-risk group. Children with two atopic parents who had no pets in their home were randomly allocated before birth to

an extremely stringent environmental control ($n = 145$) or normal regime ($n = 146$) [81, 82]. This included mite proof encasings to the parental mattress, duvet and pillows by 16th week of pregnancy; mite proof cot and carry cot mattresses; advice to hot wash bedding weekly at over 55°C, supply of a high-filtration vacuum cleaner, carpets removed from the nursery and a vinyl cushion floor fitted, acaricide for carpets with high mite allergen levels, hot washable toy. No attempt was made to introduce placebo devices into the control homes. A substantial and sustained reduction in exposure to mite, cat and dog allergens was observed in the homes of children in the active group.

At age 3, children in the intervention group were significantly and *more* frequently sensitized to dust mite compared to controls (risk ratio 2.85) [82]. However, lung function (assessed by the measurement of specific airway resistance) was markedly and significantly better amongst children in the intervention group. Since there was no difference between the groups in infant lung function at age 4 weeks [82], the difference had occurred between 4 weeks and 3 years of age. Thus, in MAAS stringent environmental control was associated with *increased* risk of mite senitization but better lung function at age 3 years.

## CONCLUSIONS

- Established adult asthma: there is little evidence to support the use of simple physical or chemical methods as single interventions to control dust mite or pet allergen levels (e.g., mattress encasings, acaricides, or HEPA filters). While it remains possible that a multifaceted intervention in carefully selected patients could have some benefit, this has not as yet been addressed in an adequately designed study in adults. There are serious concerns about the effectiveness and sustainability outside the context of a clinical trial. There is inadequate evidence to advise allergen avoidance in adults.

- In childhood asthma, several smaller trials of allergen-impermeable bed encasings as a single intervention in asthmatic children reported benefits, as did a large study of a more comprehensive environmental intervention in children living in poor quality housing.

- The reasons for the apparent differences in response between adults and children are not clear, but the situation may be analogous to that observed in the occupational asthma, where early intervention is associated with a better long-term outcome.

- In the prevention of allergic disease, the clinical outcomes reported from different intervention studies appear inconsistent and often confusing. Much longer follow-up is required before we can be sure that the interventions do not cause harm. There is very unlikely to be a "one-size-fits-all" strategy for primary prevention which will be applicable to the whole population; Specific environmental interventions will be designed and targeted to genetically susceptible individuals [83, 84].

# Smoking Cessation

**Michael A. Chandler and Stephen I. Rennard**

**University of Nebraska Medical Center, Omaha, NE, USA**

## INTRODUCTION

Cigarette smoking is a chronic relapsing disorder with secondary complications including atherosclerotic cardiovascular disease, chronic obstructive pulmonary disease (COPD), and lung cancer. Smoking remains the leading cause of preventable death in the world [1]. Tobacco control policies and smoking cessation therapies have been shown to be effective deterrents and treatments (Fig. 47.1). This chapter will outline the epidemiology, pathophysiology, and treatment of cigarette smoking with particular emphasis on current pharmacotherapies including nortriptyline, clonidine, nicotine replacement, bupropion, and varenicline.

## THE GLOBAL TOBACCO EPIDEMIC

Cigarette smoking led to five million premature deaths worldwide in 2000 [2] (Fig. 47.2). Due to declines in smoking prevalence, smoking-related mortality is trending downward in developed countries like the United States and United Kingdom; however, other developing countries are experiencing dramatic increases in mortality [3]. In China, smoking is attributed to a million deaths annually, a figure that is still on the rise [4]. India is expected to achieve this dubious milestone by 2010 [5]. Barring alterations in present tobacco use, the tobacco epidemic will lead to an estimated one billion deaths this century alone [1].

## A HETEROGENEOUS DISEASE

Heterogeneity in the susceptibility to and persistence of cigarette smoking is governed by genes, environment, and gene by environment interactions [6]. Genes that modulate neurotransmitter signaling, best characterized for dopamine and opiod signaling, have been implicated [7, 8]. Polymorphisms in the enzymes that metabolize nicotine into inactive metabolites like cotinine

and 3-hydroxycotinine also play a role. For example, slow metabolizers are less likely to become smokers. Nevertheless, they comprise about 20% of total smokers but are likely to smoke fewer cigarettes, perhaps because they "overdose" experiencing higher levels of nicotine for greater duration. The opposite is true for fast metabolizers [9]. Environmental cues, such as social prohibition or acceptance of smoking, also impact smoking prevalence. These factors and their interplay lead to a broad spectrum of smoking behaviors.

## NICOTINE ADDICTION

Nicotine as an addictive euphoriant is comparable to amphetamines, cocaine, or opiates [10]. Nicotinic acetylcholine receptors in the central nervous system regulate downstream neurotransmitter release. For example, nicotine addiction appears to be mediated by nicotine-stimulated dopamine release in the mesolimbic system, a pathway involved in endogenous reward and behavioral consolidation [11, 12]. Additionally, smokers habitually smoke during common situations, for example, when driving or socializing or after eating or during stressful conversations. This leads to classic or "Pavlovian" conditioning, which is potentiated by nicotine [13].

The interplay between these neurophysiologic and psychologic forces leads to addiction for roughly 85% of smokers [14] (Fig. 47.3). The presence of addiction is further evidenced by a well-defined withdrawal syndrome upon smoking cessation. Features of this syndrome include dysphoria, insomnia, irritability, anxiety, diminished concentration, restlessness, increased appetite, decreased heart rate, and weight gain [15]. Craving for smoking often persists years following cessation and may wane in frequency but not in intensity, a feature that

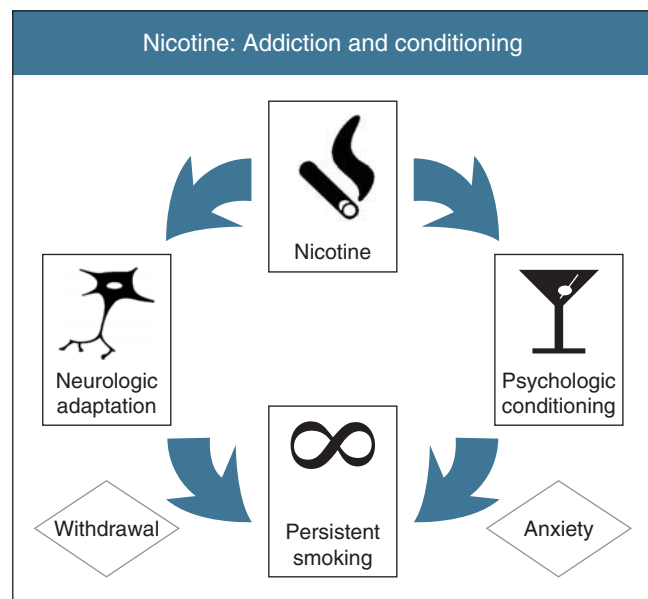

**FIG. 47.3** Biopsychosocial model of nicotine addiction.

resembles a grief response. Insights such as these have led to our current understanding of tobacco dependence as a chronic relapsing disorder requiring recurrent therapy.

## SPECTRUM OF COMPLICATIONS

Smoking leads to about one-third of deaths from coronary artery disease (CAD), the most common cause of morbidity

**TABLE 47.1** The 5 A's: brief smoking cessation strategies for routine practice. The 5 R's: generating or reinforcing motivation to quit smoking.

| Step | Action |
| --- | --- |
| *Five A's* | |
| Ask about smoking | Systematically assess smoking status Smoking should be a vital sign |
| Advise all smokers to stop | Give a clear, strong, and personalized message to stop smoking |
| Assess willingness to stop | Determine whether the smoker is ready to stop currently or soon. Provide assistance to motivated smokers; motivate those unwilling to stop |
| Assist motivated smokers to stop | Help smoker with a quit plan, counseling, pharmacotherapy and additional materials |
| Arrange follow-up | Follow up soon after the quit date. Assess success and difficulties. Consider referring for a more intensive intervention if there is relapse |
| *Five R's* | |
| Relevance | Encourage the patient to indicate why quitting is personally relevant |
| Risks | Ask the patient to identify potential negative consequences of tobacco use |
| Rewards | Ask the patient to identify potential benefits of stopping tobacco use |
| Roadblocks | Ask the patient to identify barriers to quitting |
| Repetition | Apply 5 R's whenever interacting with unmotivated or relapsed smokers |

Adapted from Ref. [45] and *http:ahrq.gov/clinic/tobacco/5rs.htm*.

and mortality in the developed world [8, 16, 17]. Active and passive smoke exposure leads to increases in oxidative stress, vascular inflammation, blood coagulability, platelet aggregation, and thrombus formation as well as reduced oxygen delivery and coronary vasoconstriction [16, 18]. Heart disease risk drops off significantly after 1–2 years of cessation and normalizes at 3–5 years [18, 19].

COPD and cigarette smoking are closely linked. Smoking directly damages the lung and triggers a cascade of secondary inflammation and impaired repair that leads to ongoing damage [20]. These effects lead to COPD in roughly 50% of active smokers and 7% of passive smoke exposed individuals [21–23]. Exposure *in utero* or in adolescence compromises subsequent lung growth and predisposes to COPD [24–27].

In countries where smoking is common, the risk of lung cancer increases 20-fold leading to 90% of lung cancers [28]. Smoking has been clearly linked to genetic and epigenetic alterations that promote carcinogenesis [16, 29, 30].

## PUBLIC HEALTH RESPONSE

Smoking prevention and cessation should reduce the prevalence of smoking and, thus, prevent millions of premature deaths [3]. Public health measures (advertisement bans, indoor smoking bans and measures to increase cigarette purchase price) increase smoking cessation and reduce tobacco use and passive smoke exposure [31–33]. While smoking

trends have been decreasing in the United States, recent estimates suggest this decrease has slowed and nearly stopped with a current smoker rate of 20.8% [34]. Public health initiatives and tobacco control programs in the United States remain underfunded and susceptible to having monies withdrawn and allocated to support other programs or to cover budget deficits. Despite ample evidence supporting the achievements and returns to society of such programs, they are transient fixtures in public health [35]. Nevertheless, many states have continued to push for total bans on smoking and 24 states have been successful. Internationally, several countries now too have similar laws prohibiting smoking nationwide.

## SMOKING CESSATION: BEHAVIORAL INTERVENTION

Smoking abstinence rates at 6–12 months in motivated quitters without behavioral or pharmacologic therapy approach 3–5% [36]. Even minimal behavioral therapy delivered by a medical practitioner increases this abstinence rate to 5.5–7.5% [37].

The "5A's" provides general guidelines to smoking cessation in clinical practice (Table 47.1) [38]. The "stages of change" model predicts smoking abstinence at 1 year and has become a useful tool in tailoring behavioral tobacco cessation efforts [40] (Fig. 47.4). In this model, smokers are regarded as "precontemplators" who are not thinking of

**FIG. 47.4** Transtheoretical model of change. Adapted from Ref. [39].

accounted for in future cessation trials. All tobacco cessation attempts should supplement behavioral interventions with pharmacotherapy as described below.

## SMOKING CESSATION: PHARMACOTHERAPY

Because the subject characteristics and the support offered differ across clinical trials, the most conventional means to assess the effect of pharmacotherapy is the quit rate relative to placebo.

When compared to placebo, pharmacotherapy doubles or triples quit rates achieved by nonpharmacological means (Table 47.2). The relatively high placebo quit rates seen in many clinical trials, which are higher than the rates noted above for minimal advice, are likely due to selection of highly motivated individuals for entry.

### Nicotine replacement therapy

Smokers who quit not only lose the euphoric effects of nicotine but frequently experience symptoms related to nicotine withdrawal [4]. Nicotine replacement therapy (NRT), the most widely used tobacco cessation agent, may partially ameliorate these ill effects and is central to American and British guidelines [1, 5–7]. NRT is given at doses sufficient to temper withdrawal without providing the reinforcing effects of bolus nicotine. NRT almost doubles the untreated quit rate regardless of whether behavioral counseling is applied [8, 9]. Smoking abstinence rates at 6–12 months with combined NRT and limited behavioral therapy approach 17% (range 12–34%) [43, 47–50]. However, a single round of NRT does not prevent relapse. About one-third of quitters will relapse by 4 years whether NRT is employed or not – a result consistent with our current understanding of tobacco dependence as a chronic relapsing disorder requiring recurrent therapy [7, 8].

Nicotine gums, lozenges, patches, nasal sprays, and inhalers are equally efficacious whereas heavy smokers may benefit from higher doses [9, 15–19, 51]. The patch and nasal spray are beneficial for up to 2 and 3 months, respectively. Other forms of NRT are used for 3–6 month courses [9]. There is no benefit to tapering of NRT versus abrupt withdrawal [9]. Physician-prescribed NRT appears to be more effective than voluntary over-the-counter NRT [9]. The cost of 6 weeks of NRT is comparable to that of smoking one pack per day and diminishes as the course progresses.

Nicotine is metabolized by the liver so that NRT with gum or lozenge is dependent on absorption through the buccal mucosa. Moreover, nicotine is poorly absorbed at low oral pH; thus, gum or lozenge use should be deferred during and 15 min after snacks or meals and should not be used with acidic beverages [52–54]. Oral irritation, indigestion, and diarrhea, which likely result from swallowed drug, are the most common side effects [52, 53].

Transdermal nicotine patches require no special technique for application, have no restrictions regarding dosage

quitting, "contemplators" who are considering quitting, or "preparers" who are ready to trial cessation. Precontemplators and contemplators may be advanced by discussing the "5R's" (Table 47.1) [38]. With physician guidance, preparers create a smoking cessation plan including a quit date. At this stage, smokers should be advised to inform others of the impending quit attempt and counseled to avoid places or situations with close associations to smoking. The quit date marks their graduation into the action then maintenance stages, marked by initial and chronic tobacco cessation, respectively. Attempts to bypass stages generally decrease the likelihood of success. Inpatient or outpatient episodes of acute illness are an exception to this and represent windows of opportunity when smokers are more liable to quit [41, 42]. The chronic, relapsing nature of cigarette smoking means patients often will cycle through stages several times before achieving stable abstinence [39]. Additional counseling advice may be reviewed elsewhere [38, 39].

More intensive behavioral therapies like group or individual counseling sessions improve the odds of cessation when compared to minimal advice (odds ratio 1.44, 95% CI = 1.24–1.67) [37]. Many smokers, however, are unwilling to participate in more intensive programs. Augmenting behavioral support with additional healthcare personnel, follow-up visits, or even a brief phone call increases quit rates but is not consistently covered by private or public health insurance [37, 38].

The majority of patients will relapse in the first 6–12 months. Reasons for relapse should be reviewed and

**TABLE 47.2** Pharmacotherapies for smoking cessation.

| Product | Time peak venous nicotine blood level | Common side effects | Dosage | Duration | Odds ratio 1-year smoking abstinence versus placebo |
|---|---|---|---|---|---|
| Nicotine gum or lozenge | 25–30 min | Oral irritation, indigestion, diarrhea | 1 piece every 1–2 h as needed, then taper <br> Daily maximum: 24 pieces gum or 20 lozenges | 3 months | 1.80 |
| Nicotine nasal spray | 5–15 min | Nasal irritation | 1 inhalation, each nostril, every 1–2 h as needed, then taper <br> Daily maximum: 40 doses (80 sprays) | 3 months | 2.03 |
| Nicotine inhaler | 15 min | Oropharyngeal irritation | Multiple inhalations over 20 min every 1–2 h as needed, then taper <br> Daily maximum: 16 cartridges | 3 months | 2.14 |
| Nicotine patch | 6–12 h | Vivid nightmares | 1 patch daily for 16 or 24 h | 2 months | 2.16 |
| Bupropion | NA | Insomnia, lowered seizure threshold | 150 mg daily for 3 d, then 150 mg twice daily | 3 months* | 1.83 |
| Varenicline | NA | Nausea | 0.5 mg daily increasing to 1 mg twice daily | 3 months* | 3.22 |

Derived from manufacturers' product data sheets and Refs [43–46].

*Efficacy may be increased by extending duration of therapy beyond 3 months.

timing with oral intake, and are associated with fewer gastrointestinal complaints. They also have the lowest addiction potential, likely due to their slow pharmacokinetics [55]. Patches are often used at night to treat morning withdrawal symptoms; however, this may lead sleep disturbances, particularly vivid dreams or nightmares [56]. Skin irritation occurs in up to 54% of patch users but is generally mild and self-limited [57]. Rotating the site of patch application is recommended to minimize irritation.

Nicotine nasal spray delivers an aqueous solution of nicotine to the nasal mucosa and produces the most rapid rise in plasma nicotine concentration amongst various forms of NRT [58]. This may lead to prolonged nicotine dependence. For example, the rate of continued use after 12 months in clinical trials ranges from 3% to 13% for nicotine nasal spray versus 1% and 8% for nicotine gum [9, 59]. The most common side effect is nasal irritation that persists in up to 81% of patients after 3 weeks of use [60].

The nicotine inhaler is composed of a mouthpiece and a plastic, nicotine-containing cartridge that releases nicotine upon inhalation. Mild mouth or throat irritation and cough occurs with initial use in one-third of cases and wanes with time [61]. While named an "inhaler" nicotine does not effectively reach the lower respiratory tract with this device and absorption is mostly through the mouth and pharynx. Nevertheless, patients with severe airway reactivity should consider alternate forms of NRT as inhaled nicotine may cause bronchospasm.

Serious side effects are extremely rare despite short- and long-term NRT use by millions of smokers over the past two decades [9, 59]. Patients suffering acute cardio-vascular events should defer NRT use; otherwise, NRT appears safe in patients with known cardiovascular disease [9, 58–65]. Though not recommended, concurrent smoking and NRT use does not appear to enhance cardiac risk [66]. Nicotine crosses the placenta and is excreted in breast milk. While animal studies link various fetal and reproductive toxicities to nicotine exposure, NRT is devoid of the hazardous compounds present in tobacco smoke [67]. Ongoing tobacco smoking is the single largest modifiable risk for pregnancy-related morbidity and mortality and pregnant smokers have additional motivation to quit [68]. Thus, NRT is a reasonable alternative to ongoing smoking, should behavioral intervention fail. Nicotine gum and lozenge are considered safer in this population than other forms of NRT by the US Food and Drug Administration (USFDA) [28, 29, 60, 61, 67–70].

## Bupropion

Bupropion is an atypical antidepressant that has been used as a smoking cessation agent for over a decade [71]. It is believed to block the reuptake of dopamine, serotonin, and norepinephrine and thereby treat occult depression, withdrawal dysphoria, and addiction [44, 72]. Smoking cessation

rates with bupropion (19% versus placebo) are comparable to rates with NRT (17% versus placebo) by indirect comparison [68].

The standard dose of sustained-released bupropion used for tobacco cessation is 150 mg twice daily. A meta-analysis comparing standard-dose to low-dose bupropion (150 mg once daily) did not demonstrate a benefit to standard therapy but was underpowered to establish equivalency [71, 73, 74]. Nonetheless, low-dose therapy remains a reasonable alternative to discontinuation in patients who experience side effects at standard doses. Bupropion is taken for up to 12 weeks though longer courses may be beneficial. One randomized, placebo-controlled trial found that ongoing use of bupropion decreased weight gain (3.8 versus 5.6 kg) and relapse rates in quitters at 1 year of treatment [75]. This benefit was lost 1 year after drug discontinuation. Two subsequent studies found no benefit in relapse rates in quitters 1 year after cessation with limited duration bupropion (3–6 months) at standard or low doses [76, 77].

Insomnia, the most common side effect, occurs in roughly one-third of patients. Bupropion may cause seizures in 1 patient per 1000 at standard doses leading to its contraindication in persons predisposed to or suffering from seizure disorders [44, 72, 78]. Bupropion, like other antidepressants, increases the risk of suicidality in patients under age 24 with psychiatric disorders, though this does not preclude its use in carefully monitored settings if the benefits are felt to outweigh the risks [79]. The USFDA considers bupropion in the same risk category as nicotine gum and lozenge when used by pregnant women [28, 29, 78]. A higher rate of spontaneous abortions has been identified in prospective trials of bupropion users who were pregnant or planning a pregnancy [78, 80].

## Other antidepressants

Nortriptyline, which is not approved by the USFDA for smoking cessation, is suggested for consideration for off-label use in United States and United Kingdom guidelines [38]. Quit rates with nortriptyline are comparable to those of NRT and bupropion therapy per indirect meta-analysis and direct head-to-head comparison [44]. It is worth noting that the most recent studies in the aforementioned meta-analysis failed to show benefit. Side effects include nausea, sedation, and anticholinergic symptoms. No benefit has been found with selective serotonin reuptake inhibitors including fluoxetine, sertraline, and paroxetine, nor with serotonin-norepinephrine uptake inhibitors including venlafaxine, in either individual studies or meta-analyses [44].

## Clonidine

Clonidine, an $\alpha$-2 adrenergic and imidazoline agonist used for the treatment of essential hypertension, has been suggested for off-label use for smoking cessation [1]. Clonidine reduces withdrawal symptoms; however, only one of six randomized, placebo-controlled studies selected for recent meta-analysis found a statistically significant benefit [81]. Inclusion of this study raised the pooled odds ratio at 3 months up to 1.89 versus placebo. This second- or third-line drug may be useful in quitters with intense withdrawal symptoms, but clear benefit beyond 3 months of smoking cessation has not been established. Dry mouth and sedation, the most common side effects, occur in two-thirds of cases [81]. Postural hypotension is also common. Clonidine should be tapered off to avoid rebound hypertension.

## Varenicline

Varenicline is the first nicotine receptor partial agonist approved for smoking cessation by the USFDA [82]. As mentioned above, neuronal nicotinic acetylcholine receptors stimulate the mesolimbic dopamine release that leads to subsequent nicotine addiction. Varenicline is a partial agonist of one such nicotinic receptor, the $\alpha4\beta2$ nicotinic receptor. As a partial agonist, varenicline elicits less dopamine release than nicotine and blunts subsequent nicotine-induced dopamine release [83]. This leads to less intense craving in the absence of nicotine and less intense pleasure in the presence of nicotine [84–87]. By eroding the reinforcing properties of smoking, varenicline continues to capture quitters weeks after the onset of therapy, an effect that seems to differ from other pharmacotherapies [85, 86]. Cessation rates up to 44% have been documented in clinical trials [88, 89]. In a meta-analysis of four randomized, placebo-controlled trials encompassing 3300 participants, the number-needed-to-treat for ongoing smoking abstinence with varenicline was 8 versus 15 and 20 for bupropion and NRT, respectively [88]. Trials subsequent to this analysis continue to demonstrate the efficacy and safety of varenicline [86, 87, 90, 91].

Nausea occurs in up to one-third of patients [88]. This is limited by the initial dose titration and in clinical trials led to discontinuation rates of 2.5–7.6% [88]. Dose should be adjusted for renal disease (creatinine clearance <30 ml/min) [89]. At doses 36–50 times the recommended daily maximum, low birthweight and subsequent reproductive toxicity, but not teratogenicity, were demonstrated. Thus, varenicline is USFDA pregnancy category C, the same risk category as nicotine gum, nicotine lozenge, and bupropion.

In 2007, the FDA informed health care providers about suicidal thoughts and aggressive and erratic behavior in patients treated with varenicline, even non-quitters [92]. This has lead to recommendations that physicians and caregivers monitor for neuropsychiatric symptoms such as agitation, behavior change, depressed mood, suicidal ideation, and suicidal behavior.

## Combination therapy

Supplementing *trans*-dermal nicotine with short-acting NRT products, such as nicotine gum, nasal spray, or inhaler, increases the likelihood of cessation by 40% compared to the use of the same products independently [43]. Using bupropion or nortriptyline in combination with NRT has not been shown to be beneficial by meta-analysis [44]. The efficacy of combination therapy with varenicline and either NRT or bupropion is unknown at present.

## Cost-effectiveness

Consumer expense, lost productivity, and direct and indirect medical costs compound the burden of morbidity and mortality inherent with cigarette smoking. Despite this understanding, many practitioners reserve pharmacotherapy for refractory cases in an effort to minimize costs. Smoking cessation is cost-effective, regardless of cessation method used, statistical analysis utilized, and geographic or socioeconomic strata examined [93–95]. Thus, current guidelines suggest that all individuals who are willing to make a serious quit attempt should be given the best opportunity to achieve success, including pharmacological support [96].

In the United States in 2000, the cost per life-year saved with NRT and bupropion was cost $1914 to $11,217, a relative bargain. During this time period, the cost per quality-adjusted life-year saved with lovastatin, a popular drug used for the primary prevention of cardiovascular disease, was $56,415 to $438,780 [93]. Subsequent studies support the cost-effectiveness of varenicline [94]. In the near future, gene testing to predict treatment responses may offer additional cost reduction [97].

## HARM REDUCTION

Harm reduction is an alternative strategy for the smoker who cannot, or will not, quit. It is designed to mitigate the medical complications of smoking without achieving full abstinence. In theory, this could be achieved by pharmacotherapy with nicotine or other agents or by substitution of less toxic tobacco products [98]. A similar strategy may also reduce the exposure to secondhand smoke among children of smokers. To date, however, there are no demonstrated health benefits of a harm reduction approach. Even if a harm reduction approach were to benefit individual smokers, the effect of such interventions in a population is difficult to predict. Some individuals may use reduction as a bridge to cessation. Others may opt not to quit but to reduce. These uncertainties have led to considerable debate and controversy.

## FUTURE DIRECTIONS

A number of novel smoking cessation pharmacotherapies have followed in the wake of recent insights into nicotine addiction. Several cannabinoid receptor antagonists are in development. One such cannabinoid receptor antagonist, rimonobant, demonstrated efficacy but did not lead to drug approval due to concerns of toxicity [45]. A nicotine vaccine that stimulates the production of antibodies against nicotine has demonstrated efficacy in Phase II trials [99]. Other potential targets for smoking cessation drugs under investigation include the $\gamma$-amino butyric acid $\beta$ receptor, the $\mu$-opioid receptor, and the $\beta2$ nicotinic receptor.

Finally, pharmacogenomics studies continue to cast light on the mechanisms behind variations in individual response to specific pharmacological agents. Research in this area will help tailor maximally effective smoking cessation pharmacotherapy.

# $\beta_2$-Adrenoceptor Agonists

**Ian P. Hall**

**Division of Therapeutics and Molecular Medicine, University Hospital of Nottingham, Nottingham, UK**

## INTRODUCTION

$\beta_2$-Agonists have been the mainstay bronchodilator agents used for the treatment of asthma and chronic obstructive pulmonary disease (COPD) since the development of inhaled isoprenaline (isoproterenol) preparations in the 1960s. While the initial preparations were marketed at relatively high doses and had little $\beta_2$-selectivity, the side-effect profile of these agents was markedly improved by the development of short-acting $\beta_2$-selective agents such as salbutamol (albuterol) and terbutaline. More recently, long-acting $\beta_2$-selective agents have assumed an increasingly important role in the management of asthma and COPD.

## MECHANISM OF ACTION

$\beta_2$-Agonists bind to the $\beta_2$-adrenoceptor which is present in the cell membrane of a number of airway cells including airway smooth muscle, airway epithelial cells, inflammatory cells including mast cells, vascular and endothelium and vascular smooth muscle [1]. However, the major site of action of $\beta_2$-agonists in the airways is the airway smooth muscle cell. Following binding of $\beta_2$-agonist to the $\beta_2$-adrenoceptor on airway smooth muscle, a signaling cascade is triggered which results in a number of events, all of which contribute to relaxation of airway smooth muscle (Table 48.1) [2, 3].

The majority of these events are dependent on elevation of cell cyclic adenosine monophosphate (AMP) content, which is brought about following binding of $\beta_2$-agonist to the $\beta_2$-adrenoceptor by stimulation of adenylyl cyclase as a result of activation of the G protein coupled to the $\beta_2$-adrenoceptor, Gs [4]. This exists as a heterotrimeric complex but following stimulation of the $\beta_2$-adrenoceptor Gs dissociates releasing free $\alpha$-subunits that are able to stimulate adenylyl cyclase. Adenylyl cyclase exists in a number of different isoforms although there is at least some evidence suggesting that adenylyl cyclase VI is important in airway smooth muscle; however, most of the other adenylyl cyclase isoforms are also present in this tissue [5]. Adenylyl cyclase catalyzes the formation of cyclic AMP from adenosine triphosphate (ATP). Cyclic AMP is able to convert protein kinase A from an inactive form to the active form in which the catalytic and regulatory subunits dissociate. The catalytic subunit of protein kinase A then phosphorylates key targets within the cell bringing about the majority of the physiological effects of $\beta_2$-adrenoceptor stimulation. However, there is at least some evidence to suggest that cyclic AMP-independent actions may also occur; for example, direct stimulation by Gs$\alpha$ of the BKCa channel present in the airway smooth muscle cell membrane has

**TABLE 48.1** Mechanisms underlying airway smooth muscle relaxation by $\beta_2$ adrenoceptor agonists.

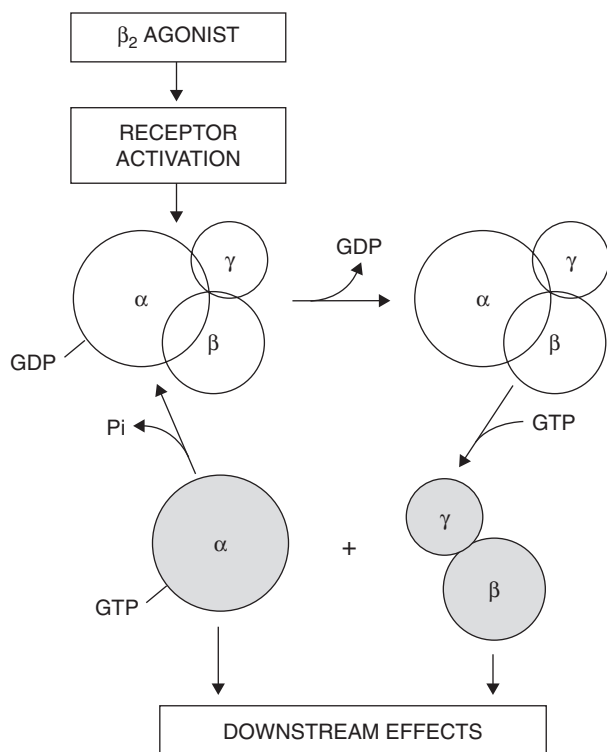
- Inhibition of spasmogen-induced inositol 1,4,5 trisphosphate production
- Inhibition of spasmogen-induced rises in intracellular free calcium
- Activation of calcium-activated $K^+$ channels
- Alteration of sensitivity of contractile apparatus
- Increased extrusion/re-uptake of calcium from cytoplasm
- Hyperpolarization of cell membrane


**FIG. 48.1** G-protein regulatory cycle of activation and deactivation for transmission of the signal from receptor to effector. When GDP is bound, the heterotrimeric G-protein is inactive, receptor stimulation causes conformational change in both the receptor and the G-protein which decreases GDP binding affinity. GTP is abundant in the cell and replaces GDP; the active conformation of the $G\alpha$ subunit dissociates from $\beta\gamma$. This activated state remains until GTP is hydrolysed to GDP whereby the subunits reassociate.

**FIG. 48.2** Cross-sectional view of transmembrane spanning domains of the $\beta_2$-adrenoreceptor core. The $\beta_2$ agonist ligand is shown sitting in the binding pocket in the receptor. Key amino acid residues for binding of ligand are shown. Amino acids in transmembrane domain IV are implicated in salmeterol exocite binding.

been described [2]. This is relevant because the BKCa channel (the calcium activated potassium channel) is thought to be important in modulating changes in cell membrane potential following stimulation with $\beta_2$-agonist, and thus can contribute to the relaxant response of $\beta_2$-adrenoceptor stimulation.

The intracellular effects of $\beta_2$-adrenoceptor stimulation are relatively short lived. Cyclic AMP is broken down by phosphodiesterase isoenzymes present in the cell, with type 3 and type 4 phosphodiesterase activities believed to be the most important in regulating cyclic AMP content in airway smooth muscle and type 4 phosphodiesterase being physiologically important in many inflammatory cells including eosinophils. Continued stimulation by $Gs\alpha$ is prevented by the free $Gs\alpha$ rapidly reassociating with $\beta\gamma$ to reconstitute the heterotrimeric Gs complex (Fig. 48.1).

## STRUCTURE AND FUNCTIONAL RELATIONSHIPS OF $\beta_2$-AGONISTS AND THE $\beta_2$-ADRENOCEPTOR

The $\beta_2$-adrenoceptor is a member of the G protein coupled receptor superfamily with the typical seven transmembrane spanning domains (Fig. 48.2) [6, 7]. The binding site for $\beta_2$-agonists consists of residues in at least three of the $\alpha$-helices that pass through the cell membrane. The prolonged duration of action of salmeterol is believed to be due to the binding of the lipophilic tail to residues deep in the fourth transmembrane domain [8, 9]. This process is essentially irreversible. The explanation for the prolonged duration of action of formoterol is less clear although it has been proposed that because of its lipophilicity formoterol partitions in the cell membrane which forms a reservoir allowing prolonged interaction with the receptor [10]. The most commonly used $\beta_2$-agonists in clinical practice are listed in Table 48.2.

All the clinically important $\beta_2$-agonists consist of a benzene ring with a chain of two carbon atoms and either an amine head or a substituted amine head. If a hydroxyl (OH) group is present at positions 3 or 4 on the benzene ring, the structure is a catechol nucleus and hence the agent a catecholamine. If these hydroxyl groups are substituted or repositioned, the drug is generally less potent than the synthetic catecholamine isoprenaline, which is a full agonist at $\beta_2$-adrenoceptors. This potential disadvantage may be outweighed by the relative resistance of substituted catecholamines to metabolic degradation by the enzyme catechol-*O*-methyltransferase (COMT). Examples of such

agents are salbutamol and terbutaline with salbutamol only being a partial agonist. As mentioned above, the prolonged duration of action of salmeterol is due to a long side chain substitution which is believed to bind to an additional site in the fourth transmembrane spanning domain of the receptor. Substitutions on the $\alpha$ carbon atom help block oxidation by monoamine oxidase (MAO).

The effects of catecholamines such as adrenaline (epinephrine), noradrenaline (norepinephrine), and isoprenaline are terminated by uptake into either sympathetic nerve endings (uptake 1) or other innervated tissues such as smooth muscle (uptake 2). The dominant enzyme present in innervated tissues is COMT whereas the dominant metabolic degradation route in sympathetic nerve endings is through oxidation by MAO. In addition to degradation, exogenously administered $\beta_2$-agonists can be conjugated to sulfates or glucuronides in the liver, or the lung. Following ingestion the drugs are partially conjugated during first past metabolism which accounts for roughly 50% of the metabolism of the short-acting drug salbutamol.

## CLINICAL PHARMACOLOGY OF β2-AGONISTS

### General pharmacology

$\beta_2$-Adrenoceptor agonists are predominantly used in the treatment of airflow obstruction because of their bronchodilator properties. These differ markedly between asthma and COPD (Table 48.3); indeed, reversibility of airflow obstruction with inhaled $\beta_2$-agonist is often used as a diagnostic marker of asthma and helps distinguish asthma from COPD in patients where the distinction is in doubt (e.g., chronic "asthmatics" who have smoked, or previous smokers who develop symptoms of wheeze in later life). However, in addition to reversing airflow obstruction in asthmatic individuals $\beta_2$-agonists also protect against bronchoconstrictor challenge [11]. Because of this latter effect, $\beta_2$-agonists have been considered to have potential anti-inflammatory actions (see below). *In vitro* $\beta_2$-agonists prevent mediator release from inflammatory cells including mast cells, an effect which if present in human airways would be expected to reduce airway inflammation [12, 13]. However, the concentrations of these agents required to demonstrate these effects are in general much higher than those seen in the lungs *in vivo*.

**TABLE 48.3** $\beta_2$-agonists in asthma and COPD.

| Asthma | COPD |
|---|---|
| Bronchodilator response greater than 15% change in FEV$_1$ | Bronchodilator response less than 15% change in FEV$_1$ |
| Bronchodilator hyperreactivity present | Bronchial hyperreactivity usually absent |
| $\beta_2$-agonist protects against nonspecific airway challenge | |
| Marked symptomatic benefit with $\beta_2$-agonist | Small or moderate symptomatic benefit with $\beta_2$-agonist |
| Effective in long-term management | No disease-modifying effects |

bronchiectasis, although the magnitude of these effects is generally much smaller. In normal individuals bronchodilator responses are generally only observable by measuring specific airway conductance. This contrast between the marked effects of $\beta_2$-agonists in asthmatic patients and the minimal effects in normal individuals led early investigators to hypothesize that a primary defect in the $\beta_2$-adrenoceptor signaling pathway was the actual cause of asthma. This hypothesis would not explain many of the inflammatory features present in the disease, but interest in the potential for a primary abnormality of $\beta_2$-adrenoceptors to contribute in part to the pathophysiology of asthma resurfaced following the description of polymorphic variation within the $\beta_2$-adrenoceptor (see below).

In addition to having a bronchodilator action, $\beta_2$-agonists in asthmatics protect against bronchoconstrictor stimuli [14–17]. One feature demonstrated by most (but not all) asthmatics is nonspecific airway hyperreactivity to inhaled irritant challenge including allergen. The most frequently used stimuli are histamine and methacholine although abnormal responses are also seen to exercise, allergen, and other challenges. The inhaled dose of histamine and other agents which required to provoke a 20% fall in FEV$_1$ (PC$_{20}$) is increased markedly (usually by about three doubling doses) by previous treatment with a short-acting $\beta_2$-agonist. While a degree of such bronchial hyperreactivity can also be demonstrated in other diseases including COPD, bronchiectasis, cystic fibrosis, and left ventricular failure, this is usually far less marked than in asthmatic subjects.

## SHORT-TERM EFFECTS OF β2-AGONISTS IN ASTHMA AND COPD

As mentioned above, the ability of $\beta_2$-adrenoceptor agonists to reverse airflow obstruction is a hallmark of asthma, with reversibility >15% being considered diagnostic. $\beta_2$-Agonists do produce a measurable bronchodilator effect in normal individuals and in patients with other diseases characterized by airflow obstruction such as COPD and

## LONG-TERM EFFECTS OF β2-AGONISTS IN ASTHMA AND COPD

While regular treatment of inhaled or nebulized $\beta_2$-agonist is frequently used in the management of moderate or severe COPD, despite relatively small improvements in symptoms, controversy has reigned over the long-term use of regular $\beta_2$-agonist in the management of asthma [18, 19]. This controversy originated from discussions following epidemics of

asthma deaths in New Zealand in the late 1960s and late 1970s which were linked to the prescribing of high-dose isoprenaline and fenoterol, respectively. Several studies subsequently concentrated on the possibility that tachyphylaxis may develop as a result of inhaled $\beta_2$-agonists in asthma. In general, studies attempting to demonstrate tachyphylaxis to the bronchodilator effects of $\beta_2$-agonists have failed to identify clinically important loss of responsiveness although small effects have been observed when looked for carefully (see for example, Ref. [20]). However, in contrast, the bronchoprotective effects of $\beta_2$-agonists against nonspecific airway challenge show tachyphylaxis that generally develops within 24h [21, 22]. Thus, the magnitude of the protective effect against exercise, histamine challenge, or methacholine challenge is reduced in magnitude compared with the level of initial protection following administration of $\beta_2$-agonist for periods of over 24h. However, there is still overall protection against bronchoconstrictor challenge even if this is less than the protection seen in the initial hours after treatment. Thus, while it seems clear that tachyphylaxis develops to the bronchoprotective effects of $\beta_2$-agonists against nonspecific airway challenge, this is only partial, and one would presume that patients would still be better despite this tachyphylaxis than if they were not taking $\beta_2$-agonist at all. The main concern therefore has revolved around patients taking intermittent treatment or in those discontinuing treatment. Small rebound increases in airway reactivity have been demonstrated following the cessation of $\beta_2$-agonist therapy [23]. Clinical studies comparing regular (e.g., four times a day) short-acting $\beta_2$-agonist versus "as required" $\beta_2$-agonist have not shown clinically important differences despite earlier reports that asthma control deteriorated following regular treatment [24, 25]. None the less, there is no reason to suppose that regular treatment is better than "as required" usage which remains the preferred way of prescribing $\beta_2$-agonists in asthma.

The controversy regarding $\beta_2$-agonists resurfaced with the introduction into the marketplace of long-acting $\beta_2$-agonists (LABAs). There were initial concerns that LABAs might worsen asthma control in asthmatics in general, but most asthmatics respond well to LABAs. At least for salmeterol, this might initially seems surprising, given the fact that salmeterol is a partial agonist and essentially binds irreversibly with the $\beta_2$-adrenoceptor. The issue of LABA safety has recently resurfaced, following a large study examining efficacy of salmeterol in asthma (the SMART study [26]). In this study, there were a small number of deaths and severe exacerbations in the salmeterol treatment group which led to premature termination of the study and a subsequent black box warning from the FDA which was later extended to all LABAs. The explanation for these findings is unclear, although it is possible that reduced compliance with inhaled corticosteroids may have played a role. The other commonly used LABA, formoterol, has undergone recent studies which has led to a license in the UK for use as an "as required" agent (in a combination inhaler with inhaled budesonide).

Although mild COPD is often treated with "as required" $\beta_2$-agonist, regular high-dose inhaled or nebulized $\beta_2$-agonists have been much more widely used in COPD than in asthma. While small improvements in lung function

and symptomatic improvement have been demonstrated in severe COPD, the overall effect on lung function has generally been small, which is hardly surprising given the fixed nature of the airflow obstruction in the majority of patients. There have been no data suggesting deterioration in lung function following chronic administration of high doses of $\beta_2$-agonist in COPD (these would be difficult to observe in short-term studies in any case) although there have been concerns about other effects of high doses of $\beta_2$-agonist in this setting. In particular, high-dose nebulized $\beta_2$-agonists are known to cause hypokalaemia and both supraventricular and ventricular arrhythmias [27], and there have been concerns that these may occur in patients on regular high-dose nebulized bronchodilator therapy for either asthma or COPD at home.

## $\beta_2$-ADRENOCEPTOR POLYMORPHISM IN ASTHMA AND COPD

As mentioned above, the identification of polymorphic variation within the gene for the $\beta_2$-adrenoceptor reawakened interest in the possibility that primary abnormalities of $\beta_2$-adrenoceptor signaling pathways may be involved in the pathogenesis of these airway diseases. The gene for the $\beta_2$-adrenoceptor is situated on chromosome 5q31-33 in a region showing linkage to intermediate phenotypes for asthma and/or atopy [28]. The $\beta_2$-adrenoceptor gene and its immediate controlling regions show a high degree of polymorphic variation with nine single nucleotide type polymorphisms (SNPs) having been identified within the coding region of the gene and a further eight in the immediate 5 prime untranslated region (reviewed in Ref. [29]). Of the nine coding region polymorphisms, five are degenerate (i.e. do not alter the amino acid code of the receptor) [30]. However, the other four all result in single amino acid substitutions. While the polymorphism at codon 34 (Val34Met) is rare and appears to have no functional effects, the other three nondegenerate polymorphisms appear to produce functional alteration in receptor behavior. Thus, the rare Thr164Ile polymorphism results in reduced affinity for catechol ligands and an altered receptor sequestration profile [31]. Interestingly, Thr164 is very close to the salmeterol binding site within the fourth transmembrane spanning domain of the receptor, and it seems likely that the isoleucine 164 substitution may alter the binding characteristics of salmeterol to the $\beta_2$-adrenoceptor. However, the allelic frequency of this polymorphism is only around 2–3% in Caucasian populations, hence homozygous individuals are very rare and to date have not been adequately studied.

In contrast, the two N-terminal polymorphisms at codon 16 (Arg16Gly) and 27 (Gln27Glu) are common. While neither alter agonist binding properties of the receptor, both result in altered downregulation profiles following long-term agonist exposure. Thus, the Gly16 and Gln27 forms of the receptor show increased receptor downregulation following agonist exposure while the Glu 27 form of the receptor appears to be partially protected from downregulation

[9]. These effects have been shown both in transformed cell systems and in primary cultures of human airways smooth muscle. Of the 5 prime untranslated region polymorphisms, the strongest evidence for possible functional effects is for the −47 T-C SNP which alters the terminal amino acid in a short open reading frame that codes for the β-upstream peptide (also known as the β$_2$-adrenoceptor 5 prime leader cistron); this peptide is believed to be important in maintaining a "brake" on receptor expression, and the Cys19Arg polymorphism in this peptide may possibly increase translational inhibition of the β$_2$-adrenoceptor [32, 33].

The role of β$_2$-adrenoceptor polymorphism has been extensively studied in asthma but less so in COPD. A recent major study in UK 1958 birth cohort [34] failed to demonstrate an association between β$_2$-adrenoceptor polymorphism and asthma *per se,* although weak association with IgE and the degree of bronchial hyperresponsiveness have previously been described in some (but not in all) studies [35]. These effects may, in part, be due to linkage disequilibrium with other important genes on chromosome 5q such as the nearby Th2 cytokine locus. The possibility that these polymorphisms may contribute to the development of COPD has not been reported upon to date, although studies in this area are currently in progress.

The other potential importance of β$_2$-adrenoceptor polymorphism is in pharmacogenetic studies. The possibility that β$_2$-adrenoceptor polymorphism may predict treatment response, particularly following long-term exposure to agonists due to the altered downregulation profile of individuals carrying particular genotypes (e.g., Gly16, Gln27), has been studied by a number of groups. Initial studies demonstrated an association between Gly16 and subsensitivity to the bronchodilator effects of formoterol following chronic dosing and also a reduced bronchodilator response to salbutamol [20, 36]. Gly16 has also been shown to be associated with nocturnal asthma. Two relatively large studies, one retrospective and one prospective, suggested that treatment with regular (four times a day) salbutamol (albuterol) resulted in poorer outcome in Arg16Arg asthmatics (15% of the Caucasian population) [37, 38]. However, salbutamol is not currently used in most countries in this way, and the asthmatics studied were not on inhaled corticosteroids, so the clinical relevance of these observations is unclear. More recently, a small retrospective study suggested that these effects may extend to LABAs [39], although subsequently a larger retrospective analysis of pharma-funded studies suggests that this does not extend to patients on combined LABA/inhaled steroid preparations [40]. In general, therefore, it appears that the effects of these polymorphisms upon treatment response to these drugs used as recommended in national guidelines are likely to be relatively small and of doubtful clinical significance overall. It is also possible that the combination of groups of polymorphisms around this region (i.e. the haplotype of an individual at this locus) may be the main determinant of functional effects rather than single polymorphisms in isolation [41]. It will be interesting to determine whether these polymorphisms are relevant to treatment response in COPD; intuitively, one might imagine that this could be the case given the higher doses of agents used in COPD although, to date, no published data are available on this issue.

## INTRODUCTION

The major prescribed long-acting muscarinic antagonist (LAMA) is now tiotropium bromide (Spiriva) that is a once daily inhaled therapy for symptomatic management of chronic obstructive pulmonary disease (COPD). Indeed, tiotropium is recommended on a regular daily basis by the Global Obstructive Lung Disease (GOLD) guidelines (2007) for moderate (Stage II), severe (Stage III), and very severe (Stage IV) COPD to prevent or reduce symptoms, improve exercise performance, and decrease exacerbations [1, 2] (Fig. 49.1). Tiotropium has been the subject of a number of recent reviews that address the clinical development process from research to clinical practice, and their

| Stage | I | II | III | IV |
|---|---|---|---|---|
| Post-bronchodilator FEV$_1$ (% predicted) | Mild >80% | Moderate 50–80% | Severe 30–50% | Very severe <30% |

• Avoidance of risk factors SMOKING CESSATION
• Influenza vaccination

Short-acting bronchodilator if needed

• Add regular treatment with one or more long-acting bronchodilators, including tiotropium
• Pulmonary rehabilitation

Add regular treatment with inhaled corticosteroids if repeated exacerbations

• Long-term oxygen therapy (LTOT) if respiratory failure
• Consider surgical options

Based on GOLD 2007

**FIG. 49.1** Treatment of COPD at different GOLD stages.

place in the management of patients with COPD [3–7]. Certain articles have centered on review and meta-analyses of experience in clinical studies [8–10]. This chapter will consider the pharmacology, biochemistry, and potential anti-inflammatory actions of anticholinergic bronchodilators, including possible anti-inflammatory actions, as well as clinical trial evidence for the safety and efficacy of these therapies. Important outcome measures for LAMAs involve considerations of effects on symptoms, lung function, dynamic hyperinflation and exercise responses, quality of life, health economics, exacerbations, survival, and the natural history of COPD. We shall then discuss clinical trials that have assessed combined inhaled LAMAs and LABAs, as well as combinations of LAMAs, LABAs, and ICSs. Finally, we shall look to the future with novel LAMAs such as glycopyrrolate and aclidinium bromide (Almirall).

## PLANT ORIGINS OF ANTICHOLINERGICS

Herbal remedies have been used since ancient times to treat human disease; and the leaves, roots, and seeds of many plants contain anticholinergic agents [11–16] (Fig. 49.2). Ayurvedic medicine sources from India at around 450 AD describe the use of *Datura stramonium* (thorn-apple or jimson weed) extract for the relief of asthma. Atropine and scopolamine represent parent anticholinergic agents, and are alkaloids found in *Datura* species as well as *Atropa belladonna* (deadly nightshade). After serving in India, General Gent in 1802 recommended the smoking of *Datura* to relieve bronchial complaints.

In the last century, plant extracts have largely been replaced by synthetic chemicals, and in the late 1970s

**FIG. 49.2** Botanical origin of anticholinergics. (A) The black berries of *Atropa belladonna* (deadly nightshade) contain the deadly plant alkaloid, atropine. Atropine is a competitive antagonist to acetylcholine at muscarinic receptor sites, $M_1$, $M_2$, and $M_3$. Atropine, when taken orally, causes blocked vagal innervation of the heart (tachycardia), decreased mucus secretion and bronchial smooth muscle relaxation in the respiratory system, mydriasis (pupillary dilation), decreased salivation with dry mouth, decreased gut motility and acid secretion, bladder wall relaxation, and decreased sweating. (B) *Hyosyamus niger* is the plant source of scopolamine (hyosine) that was employed by the notorious Dr Crippen to murder his wife in London in 1910. (C) *Datura stramonium* (thorn-apple or jimsonweed) is the source of stramonium which was inhaled to alleviate respiratory disorders. These images are taken from the Wikimedia Commons, free public domain.
The plant alkaloids are represented by atropine. Ipratropium and tiotropium are synthetic anticholinergic agents that contain a positively charged quaternary nitrogen moiety (highlighted in green). This ensures local action following inhalation, without systemic absorption.

**FIG. 49.3** Structure of anticholinergics (see text on figure).

short-acting synthetic anticholinergic drugs were introduced: ipratropium bromide (4 times a day) and oxitropium bromide (3 times a day). These have largely been superseded by tiotropium bromide (Spiriva®) that is administered once daily from the HandiHaler and was licensed in most of the European Union in 2002, while a license in the USA was obtained in 2003.

## MOLECULAR STRUCTURES

The parent compounds for anticholinergic therapy are the plant alkaloids atropine and scopolamine (Fig. 49.3). Atropine methyl nitrate, ipratropium bromide, oxitropium bromide, and tiotropium bromide share a quaternary ammonium structure [17–19]. Quaternary ammonium compounds are poorly absorbed from respiratory or pharyngeal mucosal surfaces, and they have minimal oral bioavailability, ensuring that systemic anticholinergic effects are kept to a minimum.

## MUSCARINIC RECEPTOR PHARMACOLOGY

Anticholinergics are muscarinic receptor antagonists, inhibiting cholinergic reflex bronchoconstriction and reducing vagal cholinergic tone, which is the main reversible component in COPD. Normal airways have a small degree of vagal cholinergic tone, but because the airways are patent this has no perceptible effect and does not reduce airflow. When the airways are irreversibly narrowed in COPD, vagal cholinergic tone has a much greater effect on airway resistance for geometric reasons, so when this increased constriction is relieved by an anticholinergic drug, there is a perceptible improvement in airflow. In addition, anticholinergics may reduce mucus hypersecretion [20] (Fig. 49.4). Anticholinergics have no apparent effect on pulmonary vessels, and therefore do not cause a fall in $Pao_2$, as may sometimes be seen with $\beta_2$-agonists and theophylline.

The existence of several subtypes of muscarinic receptor in human airways has suggested that more selective muscarinic antagonists may have advantages over non-selective agents, such as ipratropium bromide and oxitropium bromide [21, 22] (Fig. 49.4).

- $M_1$-receptors are localized to parasympathetic ganglia, and their blockade results in reduced reflex bronchoconstriction.

- $M_2$-receptors located at cholinergic nerve terminals inhibit the release of acetylcholine, thus acting as autoreceptors.

- $M_3$-receptors mediate the bronchoconstrictor and mucus secretion action of acetylcholine in human airways. The most important effects of anticholinergics appear to be mediated through blockage of $M_3$-receptors.

Non-selective anticholinergics, such as atropine and ipratropium bromide, act on $M_1$-, $M_2$-, and $M_3$-receptors [17]. Blockage of $M_1$- and $M_3$-receptors leads to bronchodilatation. However, by blocking pre-junctional $M_2$-receptors

this leads to an increase in acetylcholine release and this may work against the post-junctional blockade of $M_3$-receptors, making these antagonists less efficient. It has been difficult to develop $M_3$-selective antagonists [23].

Tiotropium bromide is a quaternary ammonium derivative like ipratropium bromide and is a long-acting anticholinergic drug that has unique kinetic selectivity for $M_1$ and $M_3$ muscarinic receptors [17, 24, 25]. Tiotropium has similar affinity for the five types of muscarinic receptors, $M_1$ to $M_5$. In the airways, tiotropium has a high affinity and dissociates very slowly from $M_1$- and $M_3$-receptors in human lung and produces long-term blockade of cholinergic neural bronchoconstriction in human airway smooth muscle, but much more rapidly from $M_2$-receptors giving a unique kinetic selectivity for $M_1$- and $M_3$-receptors [26, 27].

## ANTI-INFLAMMATORY ACTIONS

There has been major recent progress in understanding cholinergic systems mediated by muscarinic acetylcholine receptors [28–30] as well as nicotinic pathways [31] (Fig. 49.4). In particular, lymphocytes have been found to express a variety of cholinergic receptors [32], and acetylcholine/muscarinic receptor signaling involving epithelial and inflammatory cells has been documented in both asthma and COPD. Interestingly, anticholinergic may benefit asthmatics with COPD-like inflammation in asthma, viral hyperreactivity [33], and emergency asthma [34]. In guinea pigs tiotropium inhibits allergen-induced airway remodeling [35, 36], while muscarinic receptors mediate lung fibroblasts proliferation [37]. Tiotropium has been shown to suppress acetylcholine-induced release of chemotactic mediators *in vitro* with a special activity on $LTB_4$ [38]. A recent clinical study did not show an anti-inflammatory effect on sputum inflammatory markers during exacerbations of COPD [39], but this study was flawed by the methodology of detection of sputum IL-6 and IL-8. This was because the supernatants were formed after liquefaction of sputum with dithiothreitol, and this agent can denature cytokines and thus lower detectable levels on immunoassay.

## TIOTROPIUM DELIVERY

Tiotropium is licensed in Europe as a bronchodilator for the maintenance treatment of COPD but may have a role in the chronic treatment of severe asthma, as well as in acute severe emergency room asthma. Tiotropium is present in capsules containing 22.5 µg tiotropium bromide monohydrate equivalent to 18 µg tiotropium. These capsules are administered in the HandiHaler, a specialized dry powder inhalation system [40]. As with all inhaled therapy, attention to effective drug delivery and training in inhaler technique is essential. COPD patients may have difficulty in coordinating a Metered Dose Inhaler (MDI), and breath-activated Dry Powder Inhalers
The mechanism of vagally mediated reflex bronchoconstriction is induced by irritants and non-specific stimuli acting on irritant receptors. Pre- and postganglionic parasympathetic nerves release acetylcholine (ACh). Preganglionic nervefibers from the vagus nerve relay in parasympathetic ganglia in the airway wall, and short postganglionic pathways release ACh to cause bronchoconstriction and mucus secretion. Cholinergic muscarinic receptors are present on inflammatory cells, airway smooth muscle, fibroblasts, submucosal gland cells, and epithelial cells. The role of cholinergic receptors on inflammatory cells and inflammatory mediators remains controversial (?).

**FIG. 49.4** Cholinergic control of airways (see text on figure).

(DPI) have advantages in elderly subjects. HandiHaler requires low inspiratory flow rates to evacuate the capsule and so can be used by patients with severe COPD. The capsule begins to vibrate at 15 l/min and evacuates with concomitant clinical effect at 20 l/min. The delivered dose that leaves the HandiHaler is 10 µg. The contents of one capsule of tiotropium bromide should be inhaled once daily with the HandiHaler at the same time of the day.

Patient performance with the HandiHaler was found in a clinical study to be superior to that with a MDI [41].

## PHARMACOKINETICS

Tiotropium bromide provides a bronchodilator effect for over 24 h with a plasma concentration of ~2 pg/ml. After inhalation of a 10-µg dose there is a rapid absorption with a peak plasma concentration within 5 min of 6 pg/ml, followed by a rapid fall within 1 h to the steady state level of 2 pg/ml and a terminal half-life of 5–6 days that is independent of the dose [24]. It has been calculated that this concentration would occupy <5% muscarinic receptors, perhaps accounting for the very low incidence of systemic side effects. There is no evidence for accumulation of tiotropium after repeated administration. The pharmacokinetics and tissue distribution of tiotropium in the rat and dog have also been described [42]. Following dry powder inhalation, the absolute bioavailability of 19.5% suggests that the lung fraction is highly bioavailable. Since tiotropium is a quaternary ammonium compound, it is poorly absorbed from the gastrointestinal tract (10–15%). Food is not expected to influence absorption.

Tiotropium at a level of 72% to plasma proteins shows a volume of distribution of 32 l/kg. At steady state, tiotropium plasma levels in COPD patients at peak were 17–19 pg/ml when measured 5 min after inhalation of an 18-µg dose, and steady state trough plasma concentrations were 3–4 pg/ml. The extent of biotransformation is small, with urinary excretion of 74% of unchanged substance after an intravenous dose to young healthy volunteers. Tiotropium should be used with care in patients with moderate-to-severe renal insufficiency [43]. The termination half-life of tiotropium is between 5 and 6 days following inhalation. Tiotropium has linear pharmacokinetics in the therapeutic range after both intravenous administration and dry powder inhalation.

## ONSET AND DURATION OF ACTION

Tiotropium bromide is given as 18 µg once daily, usually in the morning or at noon. In studies of patients with COPD, single doses of tiotropium bromide give an almost immediate bronchodilator response that is preserved for over 24 h [44]. Approximately 70% of the improvement in $FEV_1$ is seen after 48 h, which is judged to be the steady state, while continued improvements can be expected beyond the first week of therapy [45], while dyspnea and health-related quality of life improve over the longer term. Interestingly in patients with and without short-term bronchodilator responses, long-term benefits of treatment with tiotropium are found in COPD patients [46]. Tiotropium was found to improve significantly in lung functions in African-American patients with COPD [47].

In contrast, ipratropium and oxitropium bromide have a slower onset of action than $\beta_2$-agonists, with a peak effect being obtained in between 30 and 90 min. Ipratropium bromide has a duration of 6–8 h, while oxitropium is claimed to maintain bronchodilation for 8 h, although this could be due to a higher dose of oxitropium [17]. On the basis of the duration of action, ipratropium bromide is given four times daily, while oxitropium bromide is given three times daily.

## CLINICAL STUDIES

A comprehensive range of clinical studies have been performed with tiotropium up to registration with the drug regulatory authorities, and other studies that investigate the effects of tiotropium on exacerbations and the natural history of COPD are ongoing (Table 49.1).

Single-dose relationships of tiotropium bromide have been determined with nebulized doses of up to 160 µg in patients with COPD [23, 44], as well as doses of up to 80 µg from a DPI in asthma [72] (Fig. 49.5). In the open label first study in patients prolonged bronchodilation without significant adverse events was noted in COPD [44], and in a randomized placebo-controlled crossover design a clear dose response could be demonstrated between for tiotropium at single doses of between 10 and 80 µg [44]. In addition, in the single dose study in patients with asthma, tiotropium mediated bronchoprotection against the constrictor effects of methacholine [72].

A 1-week study in patients with COPD demonstrated that ~70% of the bronchodilator effect of tiotropium are obtained after two doses, and that the $FEV_1$ steady state is reached within 48 h [45]. A 4 week study of tiotropium at doses of up to 36 µg given daily at noon found comparable responses at doses from 9 to 36 µg, representing a flat dose response curve, with little dose dependency in terms of spirometric outcomes [49]. On this basis, a dose of 18 µg was selected for use in long-term studies, since the 36 µg dose increased the incidence of dry mouth without significantly increasing $FEV_1$.

The Dutch Tiotropium Study Group has undertaken a 13-week study with 288 patients with COPD, in which tiotropium at 18 µg from the HandiHaler administered once daily was significantly more effective than ipratropium administered four times daily [61]. The US Tiotropium Study Group also undertook a 13-week multicenter study, but compared tiotropium with placebo, and found significant improvements in lung function ($FEV_1$ and PEFR), symptoms, as-needed albuterol/salbutamol usage and physician global assessment [48].

Long-term studies with tiotropium bromide in moderate-to-severe COPD have demonstrated significant improvement in lung function, symptoms, and health-related quality of life, as well as a reduction in exacerbations [50, 62] (Fig. 49.6). These studies confirm that the positive effects seen in 4- and 13-week studies are extended to 1 year and suggest that tolerance does not occur in this period [73]. In the study from the Dutch/Belgian Tiotropium Study Group,

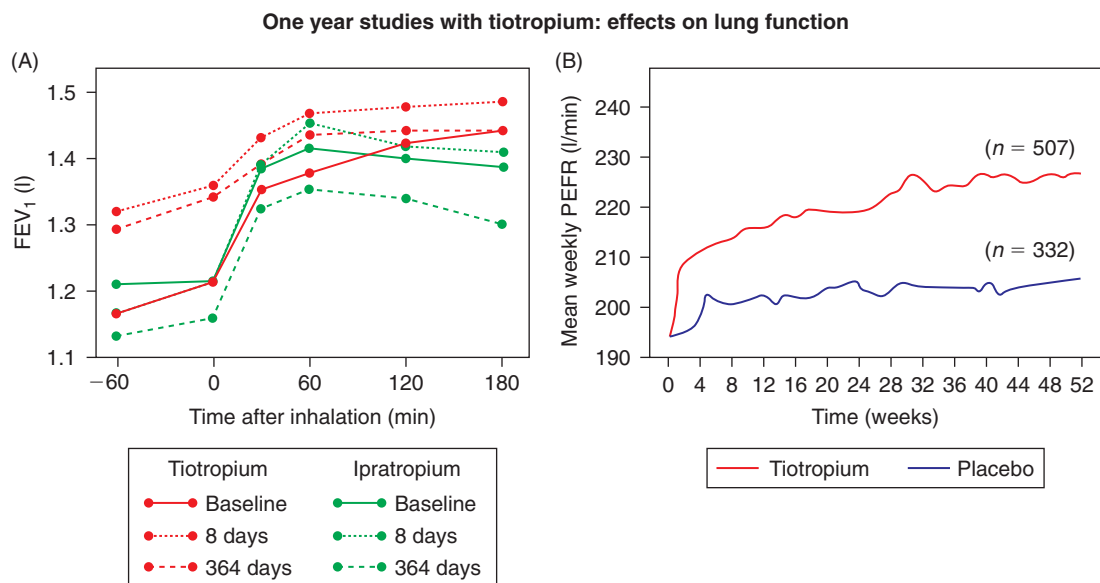
## Tiotropium: Single dose study in COPD

Increase in adjusted mean improvement in FEV₁ from test day baseline
Adapted from Fig.1, Ref. [44]

**FIG. 49.5** Single-dose study of tiotropium in COPD (see text on figure).

## One year studies with tiotropium: effects on lung function



(A) Effects on trough FEV₁ following inhalation of tiotropium or ipratropium (Adapted from Ref. [62]).

(B) Effects on mean weekly morning peak expiratory flow rates (PEFR) following inhalation of tiotropium or placebo (Adapted from Ref. [50]).

**FIG. 49.6** One year studies with tiotropium (see text on Figure).

tiotropium was effective in improving lung function, dyspnea, exacerbations and health-related quality of life, and improved trough FEV₁ at 1 year [62]. In this study tiotropium was found to be more effective than ipratropium inhaled four times a day. In a separate placebo-controlled multicenter study from Casaburi and colleagues, tiotropium also showed significant effects on the Transition Dyspnea Index (TDI) as well as health status assessed by the disease-specific St. George's Respiratory Questionnaire (SGRQ) and the generic Short Form (SF) 36 [50].

## EFFECTS OF TIOTROPIUM ON OUTCOMES IN COPD

### Bronchodilatation, symptoms of dyspnea

Bronchodilators lessen airway smooth muscle tone and reduce dynamic hyperinflation, to cause relatively rapid relief of symptoms and improved exercise tolerance [74–76]. Relaxation of airway smooth muscle tone causes an increase in $FEV_1$, but in COPD these changes are generally small (<10%). Bronchodilator efficacy in COPD is generally assessed as the $FEV_1$ measured by spirometry. Symptomatic improvement may be greater than changes in $FEV_1$, especially in moderate-to-severe COPD [62], and tiotropium causes improvement in dyspnea [50, 77, 78].

### Dynamic hyperinflation

Improved exercise performance may be a conspicuous feature of bronchodilator usage in COPD [54]. Reduced dynamic hyperinflation with a reduction in residual volume (RV) and functional residual capacity (FRC) but improved resting inspiratory capacity (IC) [54] contributes markedly to symptomatic benefits, since this makes breathing more comfortable and dyspnea is lessened on exertion [56,79]. Improvement of exercise tolerance is aided by the combination of tiotropium and pulmonary rehabilitation [80]. Other effects of anticholinergics are to increase mucociliary clearance and decrease mucous production. However, improved respiratory muscle function is unlikely at the dose of tiotropium used clinically.

### Exacerbations

The reader is recommended to consult a recent review on the effect of tiotropium on exacerbations and hospitalizations [81].

- The 1-year tiotropium registration studies demonstrated that tiotropium causes a decreased incidence of exacerbations when compared with placebo [46, 50, 62].
- Following this, Niewoehner and colleagues prospectively demonstrated significant tiotropium effects on reducing COPD exacerbations, and may reduce related healthcare utilization [59].
- The MISTRAL (*Mesure de L'Influence de Spiriva sur les Troubles Aigus à Long Terme*) study studied 500 patients with COPD treated with tiotropium for a 1-year period in comparison with a placebo group [58].
- The INSPIRE (Investigating New Standards for Prophylaxis in Reduction of Exacerbations) study compares salmeterol in addition to fluticasone (SF) in a combination inhaler compared with tiotropium [82]. This study found no difference in exacerbation rates between the two arms, with more patients failing to complete the study while receiving tiotropium, yet more cases of pneumonia were reported in the salmeterol/fluticasone

arm. In addition, a small significant beneficial effect was found on health status with an unexpected finding in lower death in SF-treated patients [83].

### Natural history of COPD

There is little evidence that bronchodilators, including tiotropium, modify the rate of decline in lung function ($FEV_1$) in COPD [84]. It is very important to assess whether chronic therapy with tiotropium can affect the natural history of COPD, which can be defined by the annual rate of decline in post-bronchodilatory $FEV_1$. A rather unsatisfactory attempt to assess effects of tiotropium on longitudinal effects of lung function was made by pooled analysis of two 1-year tiotropium studies [85]. These studies have the problem that lung function should be measured at the end of chronic tiotropium therapy, with a sufficiently large time interval to have no lingering bronchodilatory or other effects of tiotropium.

The UPLIFT (Understanding the Potential Long-Term Impacts on Function with Tiotropium) study is currently evaluating the long-term effects of 4 years of therapy with tiotropium on the rate of decline in lung function, health status, and frequency of exacerbations [86]. The UPLIFT study measures trough $FEV_1$, as well as $FEV_1$, 90 min after maximal bronchodilator administration and includes a spectrum of patient-centered outcomes [87].

### Costs and health economics

Health outcomes have been found to be positive following treatment of COPD patients with once daily tiotropium for 6 months [53], and similar results have been found after 1 year of treatment with tiotropium [88], and in comparison with treatment with ipratropium over a year [89]. In a probabilistic Markov model to assess the cost-effectiveness of bronchodilator therapy in COPD, tiotropium was associated in terms of exacerbations with maximum expected net benefit for plausible values of the ceiling ratio [90].

### Sleep quality

Sustained LAMA therapy with tiotropium improves sleeping oxygen saturation in COPD without affecting sleep quality [57]. Tiotropium does not appear to abolish circadian variation in airway caliber [52].

## COMPARISON OF TIOTROPIUM WITH SALMETEROL AND FORMOTEROL

A 6-month clinical trial in 623 patients with COPD has demonstrated superior effects of tiotropium on bronchodilation, dyspnea, and health-related quality of life compared to salmeterol [51]. In other studies with tiotropium being given once daily, while salmeterol was given twice daily, tiotropium has been shown to be superior in terms of daytime spirometric efficacy [63] and exacerbations and health outcomes [53].

In comparison with formoterol, tiotropium was better in terms of lung function, although a combination of both drugs was most effective [64]. The benefits of tiotropium over formoterol have also been demonstrated in single-dose studies [65].

## COMBINATION STUDIES WITH TIOTROPIUM

Combination bronchodilator products have already been demonstrated to have advantages over a single class of bronchodilator, so that both short-acting and long-acting $\beta_2$-agonists may be combined with anticholinergics, and additional oral theophylline may have benefit. Combination bronchodilator inhalers with an anticholinergic and a short-acting $\beta_2$-agonist, such as Combivent (ipratropium bromide + salbutamol), are a convenient a and more effective way of giving bronchodilators [91–93]. Tiotropium bromide has additive effects with both short- and long-acting $\beta_2$-agonists (LABAs) [94].

An important study demonstrated that adding tiotropium to formoterol causes improvements in airflow obstruction, resting hyperinflation, and use of rescue salbutamol [70] (Fig. 49.7). Concomitant treatment with nebulized formoterol and tiotropium provided benefits in patients with COPD [71], and the combination of formoterol and tiotropium is complementary in treating acute exacerbations of COPD [66].

Combined LABAs and ICS in a single inhaler are licensed for asthma and COPD, with the combination of salmeterol and fluticasone available as Seretide or Advair (GlaxoSmithKline) [95], with formoterol and budesonide as Symbicort (AstraZeneca) [96]. Recently, there have been studies to show the benefits of triple therapy with the combination of salmeterol/fluticasone and tiotropium [67, 69]. However, addition of salmeterol/fluticasone to tiotropium did not statistically influence rates of COPD exacerbation in a study of 449 patients over 1 year of treatment [68].

## TIOTROPIUM IN ASTHMA

Anticholinergics are less useful in asthma than in COPD, as inhaled $\beta_2$-agonists are generally more effective [5]. However, with regard to allergen-induced airway remodeling in guinea pigs, tiotropium and budesonide have similar inhibitory efficacy [35]. Patients with concomitant asthma and COPD have been shown to benefit from tiotropium [97], and in patients with severe asthma adding salmeterol/tiotropium to patients with fluticasone has benefits [98]. Tiotropium could reduce chronic viral inflammation and may be helpful in acute severe asthma [34]. Hence, tiotropium is likely to be effective as an additional bronchodilator in patients with severe disease, especially when there is an element of fixed airflow limitation. It is likely that patients with severe asthma will benefit from the addition of tiotropium to combination inhalers containing long-acting $\beta_2$-agonists and corticosteroids, but clinical trials are needed to document this.

Mean FEV$_1$ and Inspiratory Capacity (IC) before (24 h baseline) and at the end of 2-week treatment periods, adjusted for period, center, and patient within center.

## SAFETY OF TIOTROPIUM

A pooled clinical trial analysis (meta-analysis) of tiotropium safety has been carried out on a population of 4435 patients receiving inhaled tiotropium [99]. Dyspnea, dry mouth, COPD exacerbation, and upper respiratory tract infections were the most commonly reported adverse events. A careful study demonstrated that tiotropium does not retard mucus clearance from the lungs [55].

A cohort study using UK primary care databases found that tiotropium and LABAs had similar risks of total mortality and cardiovascular endpoints [100], while the SPRUCE primary care study showed benefits and not adverse effects when adding tiotropium to COPD care [101]. Detailed electrocardiography (ECG) monitoring has been performed in COPD patients receiving tiotropium with ECGs performed up to six times during 12 months of treatment [102], and tiotropium was not associated with any cardiac safety concerns in a separate ECG analysis in COPD patients [103].

Side effects of anticholinergics are pharmacologically predictable and dose dependent, and inhaled delivery means that systemic adverse effects are less likely. However,

COPD patients are older and more likely to have comorbidities than patients with asthma, so they have a greater risk of developing adverse reactions to therapy. Side effects of tiotropium bromide are very uncommon as tiotropium acts topically and there is virtually no systemic absorption. This limits the type of adverse anticholinergic effects seen with atropine; and extensive experience has shown inhaled anticholinergics to be a remarkably safe class of drug.

- Dry mouth may be associated with dental caries
- Cough, pharyngitis, upper respiratory infections
- Ocular effects: narrow angle glaucoma is a recognized adverse effect of nebulized anticholinergics and tiotropium may cause eye pain, blurred vision, visual halos, and conjunctival and corneal congestion (redness).
- Taste disturbance: a bitter metallic taste has been reported by some patients.
- Immediate hypersensitivity reactions may occur.
- CNS: headache, nervousness, irritation, dizziness.
- Theoretical systemic anticholinergic effects: prostatic hypertrophy, urinary retention, bladder disorders, constipation, tachycardia, cardiac arrhythmias, palpitations.
- Renal and hepatic impairment: patients can use tiotropium bromide at the recommended dose.

## NEW ANTICHOLINERGICS

There have been considerable efforts from the pharmaceutical industry to develop novel bronchodilators, and especially LABAs and LAMAs, for COPD [104, 105]. Glycopyrrolate has been used extensively systemically for decades to control salivation as a pre-anesthetic agent and causes bronchodilation on isolated guinea pig trachea [106, 107]. Interestingly, glycopyrrolate is a quaternary ammonium derivative which has minimal mucosal absorption and systemic toxicity when inhaled, causing prolonged bronchodilation in patients with asthma [106] and a family of anticholinergics based on glycopyrrolate have been synthesized [108]. A variant on this agent is racemically pure R,R-glycopyrrolate as a LAMA [109], while an inhaled glycopyrrolate derivative, NVA-237, is currently being developed by Novartis (license from Arakis and Ventura). An oral selective M3-selective M3-cholinergic receptor antagonist that was studied in patients with COPD (OrM3, Merck) has apparently been discontinued in clinical development [110]. However, Phase 3 studies have been successfully carried with the inhaled LAMA, aclidinium bromide (LAS-34273, Almirall), that is likely to be licensed in the near future. Recently there have been efforts to develop a combined muscarinic antagonist and beta-agonist in a single molecule: Theravance describes this as a MABA. In the future we can expect LABAs and LAMAs to be combined in single inhalers (eg. indacaterol-glycopyrrolate) and there may be the possibility of 3 agents in a single inhaler (LABA, LAMA, ICS).

# Theophylline

**Peter J. Barnes**

National Heart and Lung Institute
(NHLI), Clinical Studies Unit,
Imperial College, London, UK

## INTRODUCTION

Theophylline remains one of the most widely prescribed drugs for the treatment of asthma and chronic obstructive pulmonary disease (COPD) worldwide, since it is inexpensive and widely available. In many industrialized countries, however, theophylline has become a third-line treatment that is only used in poorly controlled patients. This has been reinforced by various national and international guidelines on asthma therapy. Some have even questioned whether theophylline is indicated in any patients with asthma [1], although others have emphasized the special beneficial effects of theophylline which still give it an important place in management of asthma [2]. The frequency of side-effects at the previously recommended doses and the relatively low efficacy of theophylline have recently led to reduced usage, since inhaled $\beta_2$-agonists are far more effective as bronchodilators and inhaled corticosteroids have a greater anti-inflammatory effect. Despite the fact that theophylline has been used in asthma therapy for over 70 years, there is still considerable uncertainty about its molecular mode of action in asthma and its logical place in therapy. Recently, novel mechanisms of action that may account for the effectiveness of theophylline in severe asthma have been elucidated [3]. Because of problems with side effects, there have been attempts to improve on theophylline, and recently there has been increasing interest in selective phosphodiesterase (PDE) inhibitors, which have the possibility of improving the beneficial and reducing the adverse effects of theophylline.

## CHEMISTRY

Theophylline is a methylxanthine similar in structure to the common dietary xanthines caffeine and theobromine. Several substituted derivatives have been synthesized, but none has any advantage over theophylline [4]. The 3-propyl derivative, enprofylline, is more potent as a bronchodilator and may have fewer toxic effects; however, its clinical development was halted because of hepatic toxicity problems [5]. Many salts of theophylline have also been marketed, the most common being aminophylline, the ethylene diamine salt used to increase solubility at neutral pH, so that intravenous administration is possible. Other salts, such as choline theophyllinate, do not have any advantage and others, such as acepifylline, are virtually inactive [4].

## MOLECULAR MECHANISMS OF ACTION

Although theophylline has been in clinical use for more than 70 years, its mechanism of action at a molecular level and its site of action remain uncertain, although there have been important recent advances. Several molecular mechanisms of action have been proposed, many of which appear to occur only at higher concentrations of theophylline than are effective clinically (Table 50.1).

**TABLE 50.1** Proposed mechanisms of action of theophylline.

| |
|---|
| PDE inhibition (non-selective) |
| Adenosine receptor antagonism ($A_1$-, $A_{2A}$-, $A_{2B}$-receptors) |
| Inhibition of nuclear factor-κB (↓ nuclear translocation) |
| Inhibition of phosphoinositide 3 kinase-δ |
| ↑ IL-10 secretion |
| ↑ Apoptosis of inflammatory cells |
| ↓ Poly(ADP-ribose)polymerase-1 (inhibits cell death) |
| ↑ Histone deacetylase activity (↑ efficacy of corticosteroids) |

**FIG. 50.1** Effect of PDE inhibitors in the breakdown of cyclic nucleotides in airway smooth muscle and inflammatory cells. AC: adenylyl cyclase; ATP: adenosine triphosphate; cAMP: cyclic adenosine monophosphate; cGMP: cyclic guanosine monophosphate; GC: guanylyl cyclase; Gs: stimulatory G-protein; GTP: guanosine triphosphate; PDE: phosphodiesterase; R: receptor.

## PDE inhibition

Theophylline is a weak and nonselective inhibitor of PDEs, which break down cyclic nucleotides in the cell, thereby leading to an increase in intracellular cyclic 3′5′ adenosine monophosphate (AMP) and cyclic 3′,5′ guanosine monophosphate (GMP) concentrations (Fig. 50.1); however, the degree of inhibition is small at concentrations of theophylline which are therapeutically relevant. Thus, total PDE activity in human lung extracts is inhibited by only 5–10% by therapeutic concentrations of theophylline [6]. There is convincing *in vitro* evidence that theophylline relaxes airway smooth muscle by inhibition of PDE activity, but relatively high concentrations are needed for maximal relaxation [7]. Similarly, the inhibitory effect of theophylline on mediator release from alveolar macrophages appears to be mediated by inhibition of PDE activity in these cells [8]. There is no evidence that airway smooth muscle or inflammatory cells concentrate theophylline to achieve higher intracellular than circulating concentrations. Inhibition of PDE should lead to synergistic interaction with β-agonists, but this has not been convincingly demonstrated *in vivo* or in clinical studies; however, this might be because the relaxation of airway smooth muscle by β-agonists may involve direct coupling of β-receptors via a stimulatory G-protein to the opening of potassium channels, without the involvement of cyclic AMP [9].

At least 11 isoenzyme families of PDE have now been recognized, and some (PDE3, PDE4, PDE5) are important in smooth muscle relaxation [10]; however, there is no convincing evidence that theophylline has any greater inhibitory effect on the PDE isoenzymes involved in smooth muscle relaxation. It is possible that PDE isoenzymes may have an increased expression in asthmatic airways, as a result of either the chronic inflammatory process or the therapy. Elevation of cyclic AMP by β-agonists may result in increased PDE activity, thus limiting the effect of β-agonists. Indeed, alveolar macrophages from asthmatic patients appear to have increased PDE activity [11]. This would mean that theophylline might have a greater inhibitory effect on PDE in asthmatic airways than in normal airways. Support for this is provided by the lack of bronchodilator effect of theophylline in normal subjects, compared to a bronchodilator effect in asthmatic patients [12].

Inhibition of PDEs is likely to account for some of the moist frequent side effects of theophylline, including nausea and vomiting (PDE4), palpitations and cardiac arrhythmias (PDE3), and headaches (PDE4).

## Adenosine receptor antagonism

Theophylline is a potent inhibitor of adenosine receptors at therapeutic concentrations. Both $A_1$- and $A_2$-receptors are inhibited, but theophylline is less effective against $A_3$-receptors, suggesting that this could be the basis for its bronchodilator effects [13]. Although adenosine has little effect on normal human airway smooth muscle *in vitro*, it constricts airways of asthmatic patients via the release of histamine and leukotrienes, suggesting that adenosine releases mediators from mast cells [14]. The receptor involved appears to be an $A_3$-receptor in rat mast cells [15, 16], but in humans there is evidence for the involvement of an $A_{2B}$-receptor [17, 18]. Adenosine causes bronchoconstriction in asthmatic subjects when given by inhalation [19]. The mechanism of bronchoconstriction is indirect and involves release of histamine from airway mast cells [14, 20]. The bronchoconstrictor effect of adenosine is prevented by therapeutic concentrations of theophylline [19]; however, this only confirms that theophylline is capable of antagonizing the effects of adenosine at therapeutic concentrations and does not necessarily indicate that this is important for its anti-asthma effect. Adenosine antagonism is likely to account for some of the side effects of theophylline, such as central nervous system stimulation, cardiac arrhythmias (both via blockade of $A_1$-receptors), gastric hypersecretion, gastroesophageal reflux, and diuresis. A novel AMP receptor, $P2Y_{15}$, has been identified which is more potently inhibited by theophylline [21], although the function of these receptors has been questioned.

## IL-10 release

IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in COPD [22]. IL-10 release is increased by theophylline, and this effect may be mediated via PDE inhibition [23], although this has not been seen at the low doses that are effective in asthma [24].

## Effect on gene transcription

Theophylline prevents the translocation of the proinflammatory transcription factor, nuclear factor-κB (NF-κB), into the nucleus, thus potentially reducing the expression of inflammatory genes in asthma and COPD [25]. Inhibition of NF-κB appears to be due to a protective effect against the degradation of the inhibitory protein I-κBα, so that nuclear translocation of activated NF-κB is prevented [26]. However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.

## Effect on kinases

Theophylline directly inhibits phosphoinositie-3-kinases, with greatest potency for the PI3K (p110)-δ subtype (IC$_{50}$ 75 μM) [27], a subtype of the enzyme that has been implicated in responses to oxidative stress [28]. However, it is a relatively weak effect against the PI3K-γ subtype (IC$_{50}$ 800 μM), which is involved in chemotactic responses of neutrophils and monocytes. The inhibitory effect of theophylline on PI3K-δ may account for the ability of theophylline to reverse corticosteroid resistance, which may be of critical importance for its clinical effects in severe asthma and COPD.

## Effects on apoptosis

Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in COPD. Theophylline promotes inhibits apoptosis in neutrophils *in vitro* [29]. This is associated with a reduction in the anti-apoptotic protein Bcl-2 [30]. This effect is not mediated via PDE inhibition but in neutrophils may be mediated by antagonism of adenosine A$_{2A}$-receptors [31]. Theophylline also induces apoptosis of T-lymphocytes thus reducing their survival, and this effect appears to be mediated via PDE inhibition [32]. Theophylline also inhibits the enzyme poly(ADP-ribose)polymerase-1 (PARP-1), which is activated by oxidative stress and leads to a reduction in nicotine adenine diamine levels resulting in an energy crisis that leads to cell death [33].

## Other effects

Several other effects of theophylline have been described, including an increase in circulating catecholamines, inhibition of calcium influx into inflammatory cells, inhibition of prostaglandin effects, and antagonism of tumor necrosis factor-α. These effects are generally seen only at high concentrations of theophylline which are above the therapeutic range and are therefore unlikely to contribute to the anti-inflammatory actions of theophylline. Despite intense efforts, it has been difficult to find any molecular mechanisms that can account for the anti-inflammatory effects of theophylline in asthma and COPD. Although several potential mechanisms have been demonstrated *in vitro*, there is little evidence that these occur at plasma concentrations of 5–10 mg/l where clinical benefit and anti-inflammatory effects are seen. A novel mechanism of action involving activation of histone deacetylases (HDAC) has been described which, in contrast to the proposed molecular mechanisms discussed above, is seen at therapeutically relevant concentrations [3].

## HDAC activation

Expression of inflammatory genes is regulated by the balance between histone acetylation and deacetylation [34]. In asthma multiple inflammatory genes are activated through proinflammatory transcription factors, such as NF-κB, leading to histone acetylation and increased transcription. This process is reversed by the recruitment of HDAC to the activated inflammatory gene promoter site within the nucleus. Corticosteroids suppress inflammation by recruiting HDAC2 to activated inflammatory genes, thus switching off their expression [35] (see Chapter 53). This molecular mechanism is defective in COPD patients as HDAC2 activity and expression are markedly reduced, thus accounting for the steroid resistance of COPD [36]. There is also a defect in HDAC2 function in patients with severe asthma and in asthmatic patients who smoke [37, 38]. We have shown that theophylline is an activator of HDACs and enhances the anti-inflammatory effect of corticosteroids, as well as reversing steroid resistance in cells from COPD patients [39, 40] (Fig. 50.2). This action of theophylline is seen at low plasma concentrations (optimally 5 mg/l) and is completely independent of PDE inhibition and adenosine antagonism. The effect of theophylline is completely blocked by an HDAC inhibitor called trichostatin A and by knocking out HDAC2 using interference RNA [41]. The reason why theophylline selective activates HDAC activity is not yet known but appears to be indirect through the activation of kinase and phosphatase pathways in the cell that are activated by oxidative stress and involved in the regulation of HDAC2 activity. This effect of theophylline is seen particularly in the presence of oxidative and nitrative stress, and this accounts for why theophylline is effective particularly in severe asthma, where oxidative and nitrative stress are greatest. Increased reactive oxygen species and nitric oxide from increased expression of inducible nitric oxide synthase result in the formation of peroxynitrite radicals. Peroxynitrite is unstable and nitrates tyrosine residues in proteins, which may result in altered protein function. 3-Nitrotyrosine adducts are increased in asthmatic airways [42]. Peroxynitrite is also increased in COPD lungs [43] and is associated with tyrosine nitration and inactivation of HDAC2 [44]. Theophylline also appears to reduce the formation of peroxynitrite, and this provides
**FIG. 50.2** Theophylline directly activates HDACs which deacetylate core histones that have been acetylated by the histone acetyltransferase (HAT) activity of co-activators, such as CREB binding protein (CBP). This results in suppression of inflammatory genes and proteins, such as granulocyte-macrophage colony stimulating factor (GM-CSF) and IL-8 that have been switched on by proinflammatory transcription factors, such as nuclear factor-$\kappa$B (NF-$\kappa$B). Corticosteroids also activate HDACs, but through a different mechanism resulting in the recruitment of HDACs to the activated transcriptional complex via activation of the glucocorticoid receptors (GR) which function as a molecular bridge. This predicts that theophylline and corticosteroids may have a synergistic effect in repressing inflammatory gene expression.

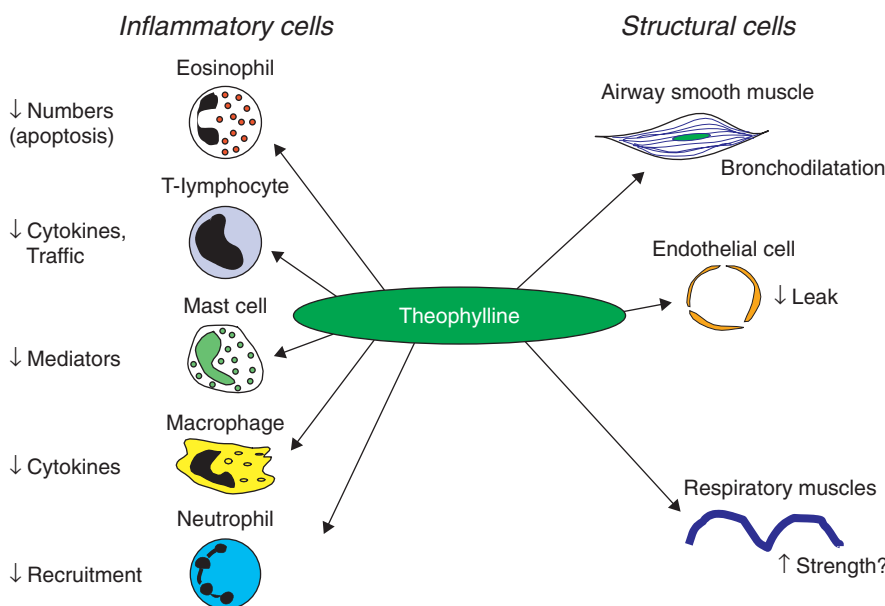

**FIG. 50.3** Multiple cellular effects of theophylline.

a further mechanism for increasing HDAC2 function in asthma [45].

## CELLULAR EFFECTS

Theophylline has several cellular effects that may contribute to its clinical efficacy in the treatment of asthma (Fig. 50.3).

### Airway smooth muscle effects

The primary effect of theophylline is assumed to be the relaxation of airway smooth muscle; as *in vitro* studies have shown, it is equally effective in large and small airways [46]. In airways obtained at lung surgery ~25% of preparations fail to relax with a $\beta$-agonist but all relax with theophylline [47]. The molecular mechanism of bronchodilatation is almost certainly related to PDE inhibition, resulting in an increase in cyclic AMP [7]. The bronchodilator effect of theophylline is reduced in human airways by the toxin charybdotoxin, which inhibits large conductance $Ca^{2+}$-activated $K^+$ channels (maxi-K channels), suggesting that theophylline opens maxi-K channels via an increase in cyclic AMP [48]. Theophylline acts as a functional antagonist and inhibits the contractile response of multiple spasmogens. In airways obtained at post-mortem from patients who have died from asthma, the relaxant response to $\beta$-agonists is reduced, whereas the bronchodilator response to theophylline is no different from that seen in normal airways [49]. There is

evidence that $\beta$-adrenoceptors in airway smooth muscle of patients with fatal asthma become uncoupled [50], and theophylline may therefore have a theoretical advantage over $\beta$-agonists in severe asthma exacerbations. However, theophylline is a weak bronchodilator at therapeutically relevant concentrations, suggesting that some other target cell may be more relevant for its anti-asthma effect. In human airways the $EC_{50}$ for airway smooth muscle relaxation by theophylline is $\sim 1.5 \times 10^{-4}$M, which is equivalent to 67 mg/l assuming 60% protein binding [47], that is above the therapeutic range. As discussed above, it is important to consider the possibility that PDE activity may be increased in asthmatic airways, so that theophylline may have a greater than expected effect.

*In vivo* intravenous aminophylline has an acute bronchodilator effect in asthmatic patients, which is most likely to be due to a relaxant effect on airway smooth muscle [51]. The bronchodilator effect of theophylline in chronic asthma is small in comparison with $\beta_2$-agonists, however. Several studies have demonstrated a small protective effect of theophylline on histamine, methacholine, or exercise challenge [52–55]. This protective effect does not correlate well with any bronchodilator effect, and it is interesting that in some studies the protective effect of theophylline is observed at plasma concentrations of <10 mg/l. These clinical studies suggest that theophylline may have anti-asthma effects that are unrelated to any bronchodilator action.

## Anti-inflammatory effects

There is increasing evidence that theophylline has anti-inflammatory effects in asthma and that these are seen at lower plasma concentrations than are needed for bronchodilatation. Theophylline inhibits mediator release from chopped human lung [56], although high concentrations are necessary and it is likely that this effect involves an increase in cyclic AMP concentration due to PDE inhibition. Theophylline also has an inhibitory effect on superoxide anion release from human neutrophils [57] and inhibits the feedback stimulatory effect of adenosine on neutrophils *in vivo* [58]. At therapeutic concentrations *in vitro*, theophylline may *increase* superoxide release via an inhibitory effect on adenosine receptors, since endogenous adenosine may normally exert an inhibitory action on these cells [59]. Similar results are also seen in guinea pig and human eosinophils [60]. At therapeutic concentrations there is an increased release of superoxide anions from eosinophils, which appears to be mediated via inhibition of adenosine $A_2$-receptors and is mimicked by the adenosine antagonist 8-phenyltheophylline. Inhibition of eosinophil superoxide generation occurs only at high concentrations of theophylline ($>10^{-4}$M) which are likely to inhibit PDE. Similar results have also been obtained in human alveolar macrophages [8]. Macrophages in bronchoalveolar lavage fluid from patients taking theophylline have been found to have a reduced oxidative burst response [61], but there is no reduction in the release of the proinflammatory cytokines TNF-$\alpha$ or GM-CSF [62]. Theophylline inhibits neutrophil chemotaxis via inhibition of adenosine $A_{2A}$-receptors, and this may be relevant in severe asthma [63].

*In vivo* theophylline inhibits mediator-induced airway microvascular leakage in rodents when given in high doses [64], although this is not seen at therapeutically relevant concentrations [65]. Theophylline has an inhibitory effect on plasma exudation in nasal secretions induced by allergen in patients with allergic rhinitis, although this could be secondary to inhibition of mediator release [66].

In allergen challenge studies, chronic oral treatment with theophylline reduces the late response to allergen [67]. This has been interpreted as an effect on the chronic inflammatory response and is supported by a reduced infiltration of eosinophils into the airways after allergen challenge following low doses of theophylline [68]. In patients with nocturnal asthma low-dose theophylline inhibits the influx of neutrophils and, to a lesser extent, eosinophils seen in the early morning [69]. Chronic treatment with low-dose theophylline reduces the numbers of eosinophils in bronchial biopsies, bronchoalveolar lavage and induced sputum of patients with mild asthma [62]. However, these effects are less than those expected with low doses of inhaled corticosteroids, and there is no reduction of exhaled nitric oxide, indicating a lesser effect on suppression of inflammation than corticosteroids.

In patients with COPD, theophylline reduces the proportion of neutrophils in induced sputum and reduces the concentration of IL-8, suggesting that it may have an anti-inflammatory effect unlike corticosteroids [70, 71]. Since patients with severe asthma may have increased neutrophils in the airways [72, 73], this may provide a mechanism whereby theophylline is effective as an add-on therapy to high does of inhaled corticosteroids in these patients.

## Immunomodulatory effects

T-lymphocytes are now believed to play a central role in coordinating the chronic inflammatory response in asthma. Theophylline has been shown to have several actions on T-lymphocyte function, suggesting that it might have an immunomodulatory effect in asthma. Theophylline has a stimulatory effect on suppressor (CD8$^+$) T-lymphocytes which may be relevant to the control of chronic airway inflammation [74, 75], and has an inhibitory effect on graft rejection [76]. *In vitro* theophylline inhibits IL-2 synthesis in human T-lymphocytes, an effect that is secondary to a rise in intracellular cyclic AMP concentration [77]. At high concentrations theophylline inhibits proliferation in CD4$^+$ and CD8$^+$ cells, an effect that is mediated via inhibition of PDE4 [78]. Theophylline also inhibits the chemotactic response of T-lymphocytes, an effect that is also mediated through PDE inhibition [79]. In allergen-induced airway inflammation in guinea pigs, theophylline has a significant inhibitory effect on eosinophil infiltration [80], suggesting that it may inhibit the T-cell-derived cytokines responsible for this eosinophilic response. Theophylline has been reported to decrease circulating concentrations of IL-4 and IL-5 in asthmatic patients [81]. In asthmatic patients low-dose theophylline treatment results in an increase in activated circulating CD4$^+$ and CD8$^+$ T-cells, but a decrease in these cells in the airways, suggesting that it may reduce the trafficking of activated T-cells into the airways [82]. This is

supported by studies in allergen challenge, where low-dose theophylline decreases the number of activated CD4$^+$ and CD8$^+$ T-cells in bronchoalveolar lavage fluid after allergen challenge, and this is mirrored by an increase in these cells in peripheral blood [83]. These effects are seen even in patients treated with high does of inhaled corticosteroids, indicating that the molecular effects of theophylline are likely to be different from those of corticosteroids. Theophylline induces apoptosis of T-lymphocytes, thus reducing their survival [32]. This effect may be mediated via PDE4 inhibition so may not be relevant to clinical doses of theophylline. The therapeutic range of theophylline was based on measurement of immediate bronchodilatation in response to the acute administration of theophylline [51]. However, it is possible that the nonbronchodilator effects of theophylline, which may reflect some anti-inflammatory or immunomodulatory effect, may be exerted at lower plasma concentrations and that different molecular mechanisms may be involved [84].

## Extrapulmonary effects

It has been suggested that theophylline may exert its effects in asthma via some action outside the airways. It may be relevant that theophylline is ineffective when given by inhalation until therapeutic plasma concentrations are achieved [85]. This may indicate that theophylline has effects on cells other than those in the airway.

An effect of theophylline which remains controversial is its action on respiratory muscles. Aminophylline increases diaphragmatic contractility and reverses diaphragm fatigue [86]. This effect has not been observed by all investigators, and there are now doubts about the relevance of these observations to the clinical benefit provided by theophylline [87].

## PHARMACOKINETICS

There is a close relationship between the acute improvement in airway function and the serum theophylline concentration. Below 10 mg/l therapeutic effects (at least in terms of rapid improvement in airway function) are small, and above 25 mg/l additional benefits are outweighed by side effects, so that the therapeutic range was usually taken as 10–20 mg/l (55–110 μM) [4]. It is now apparent that nonbronchodilator effects of theophylline may be seen at plasma concentrations of <10 mg/l and that clinical benefit may be derived from these lower concentrations of theophylline. This suggests that it may be necessary to redefine the therapeutic range of theophylline based on anti-asthma effect, rather than the acute bronchodilator response that requires a higher plasma concentration. The dose of theophylline required to give therapeutic concentrations varies among patients, largely because of differences in clearance. In addition, there may be differences in bronchodilator response to theophylline and, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilatation [88].

Theophylline is rapidly and completely absorbed, but there are large inter-individual variations in clearance, due to

**TABLE 50.2** Factors affecting clearance of theophylline.

| Increased clearance |
| --- |
| Enzyme induction (rifampicin, phenobarbitone, ethanol) |
| Smoking (tobacco, marijuana) |
| High protein, low carbohydrate diet |
| Barbecued meat |
| Childhood |
| **Decreased clearance** |
| Enzyme inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, zileuton) |
| Congestive heart failure |
| Liver disease |
| Pneumonia |
| Viral infection |
| Vaccination (immunization) |
| High carbohydrate diet |
| Old age |

differences in hepatic metabolism (Table 50.2). Theophylline is metabolized in the liver by the cytochrome P450 microsomal enzyme system, and a large number of factors may influence hepatic metabolism. Theophylline is predominantly metabolized by the CYP1A2 enzyme, while at higher plasma concentrations CYP2E1 is also involved [89].

## Increased clearance

Increased clearance is seen in children (1–16 years), and in cigarette and marijuana smokers. Concurrent administration of phenytoin and phenobarbitone increases activity of P450, resulting in increased metabolic breakdown, so that higher doses may be required.

## Reduced clearance

Reduced clearance is found in liver disease, pneumonia, and heart failure and doses need to be reduced to half and plasma levels monitored carefully [90]. Decreased clearance is also seen with certain drugs, including erythromycin, certain quinolone antibiotics (ciprofloxacin, but not ofloxacin), allopurinol, cimetidine (but not ranitidine), serotonin uptake inhibitors (fluvoxamine), and the 5-lipoxygenase inhibitor zileuton, which interfere with CYP1A2 function. Thus, if a patient on maintenance theophylline requires a course of erythromycin, the dose of theophylline should be halved. Viral infections and vaccinations (immunizations) may also reduce clearance, and this may be particularly important in children. Because of these variations in clearance, individualization of

theophylline dosage is required and plasma concentrations should be measured 4h after the last dose with slow-release preparations, when steady state has usually been achieved. There is no significant circadian variation in theophylline metabolism [91], although there may be delayed absorption at night, which may relate to the supine posture [92].

## ROUTES OF ADMINISTRATION

### Intravenous

Intravenous aminophylline has been used for many years in the treatment of acute severe asthma. The recommended dose is now 6 mg/kg given intravenously over 20–30 min, followed by a maintenance dose of 0.5 mg/kg/h. If the patient is already taking theophylline, or there are any factors that decrease clearance, these doses should be halved and the plasma level checked more frequently.

### Oral

Plain theophylline tablets or elixir, which are rapidly absorbed, give wide fluctuations in plasma levels and are not recommended. Several effective sustained-release preparations now available are absorbed at a constant rate and provide steady plasma concentrations over a 12–24h period [93]. Although there are differences between preparations, these are relatively minor and of no clinical significance. Both slow-release aminophylline and theophylline are available and are equally effective (although the ethylene diamine component of aminophylline has very occasionally been implicated in allergic reactions). For continuous treatment, twice daily therapy (~8 mg/kg b.i.d.) is needed, although some preparations are designed for once daily administration. For nocturnal asthma, a single dose of slow-release theophylline at night is effective [94, 95], and more effective than an oral slow-release β-agonist preparation. Once optimal doses have been determined, plasma concentrations usually remain stable, providing no factors which alter clearance are introduced.

### Other routes

Aminophylline may be given as a suppository, but rectal absorption is unreliable and proctitis may occur, so this route should be avoided. Inhalation of theophylline is irritating and ineffective [85]. Intramuscular injections of theophylline are very painful and should never be given.

## CLINICAL USE

### Acute exacerbations

Intravenous aminophylline has been used in the management of acute severe asthma for over 50 years, but this use has been questioned in view of the risk of adverse effects compared with nebulized β2-agonists. In patients with acute asthma, intravenous aminophylline is less effective than nebulized β2-agonists [96] and should therefore be reserved for those who fail to respond to β-agonists. In a meta-analysis of 27 studies which looked at addition of intravenous aminophylline to nebulized β2-agonists, there is no evidence for significant benefit in adults [97] or children [98]. This indicates that aminophylline should not be added routinely to nebulized β-agonists. Indeed, addition of aminophylline only increases adverse effects. Several deaths have been reported after intravenous aminophylline. In one study of 43 asthma deaths in southern England, there was a significantly greater frequency of toxic theophylline concentrations (21%) compared with matched controls (7%) [99]. These concerns have lead to the view that intravenous aminophylline should be reserved for the few patients with acute severe asthma who fail to show a satisfactory response to nebulized β2-agonists. When intravenous aminophylline is used, it should be given as a slow intravenous infusion with careful monitoring of vital signs, and plasma theophylline concentrations should be measured prior to and after infusion.

Aminophylline similarly has no place in the routine management of COPD exacerbations [100, 101].

### Chronic asthma

In most guidelines for asthma management theophylline is recommended as an additional bronchodilator if asthma remains difficult to control after high doses of inhaled corticosteroids. The introduction of long-acting inhaled β2-agonists has further threatened the position of theophylline, since the side effects of these agents may be less frequent than those associated with theophylline, and long-acting inhaled β2-agonists are more effective controllers than theophylline [102]. Whether theophylline has some additional benefit over its bronchodilator action is now an important consideration. In chronic asthma oral theophylline appears to be as effective as cromolyn sodium in controlling young allergic asthmatics [103] and provides additional control of asthma symptoms even in patients talking regular inhaled steroids [104]. In one study a group of adolescent patients with severe asthma who were controlled with oral and inhaled steroids, nebulized β2-agonists, inhaled anticholinergics, and cromolyn, in addition to regular oral theophylline, withdrawal of the oral theophylline resulted in a marked deterioration of asthma control which could not be controlled by further increase in steroids and only responded to reintroduction of theophylline [105]. This suggests that there may be a group of severe asthmatic patients who particularly benefit from theophylline. In a controlled trial of theophylline withdrawal in patients with severe asthma controlled only on high doses of inhaled corticosteroids, there was a significant deterioration in symptoms and lung function when placebo was substituted for the relatively low maintenance dose of theophylline [82]. There is also evidence that addition of theophylline improves asthma control to a greater extent than β2-agonists in patients with severe asthma treated with high-dose inhaled steroids [106].

This suggests that theophylline may have a useful place in the optimal management of moderate-to-severe asthma and appears to provide additional control above that provided by high-dose inhaled steroids [107, 108].

Theophylline may be a useful treatment for nocturnal asthma, and a single dose of a slow-release theophylline preparation given at night may provide effective control of nocturnal asthma symptoms [94, 109]. There is evidence that slow-release theophylline preparations are more effective than slow-release oral β-agonists and inhaled β-agonists in controlling nocturnal asthma [95, 110, 111]. Theophylline has equal efficacy to salmeterol in controlling nocturnal asthma, but the quality of sleep is better with salmeterol compared to theophylline [112]. The mechanism of action of theophylline in nocturnal asthma may involve more than long-lasting bronchodilatation and could involve inhibition of some components of the inflammatory response, which may increase at night [69].

## Add-on therapy

Several studies have demonstrated that adding low-dose theophylline to inhaled corticosteroids in patients who are not controlled gives better asthma control than doubling the dose of inhaled corticosteroids. This has been demonstrated in patients with moderate-to-severe and mild asthma [113–115]. Interestingly, there is a greater degree of improvement in forced vital capacity than in $FEV_1$, possibly indicating an effect on peripheral airways. Since the improvement in lung function was relatively slow, this suggests that the effect of the added theophylline may be having an anti-inflammatory rather than a bronchodilator effect, particularly as the plasma concentration of theophylline in these studies was <10 mg/ml. These studies suggest that low-dose theophylline may be preferable to increase the dose of inhaled steroids when asthma is not controlled on moderate doses of inhaled steroids; such a therapeutic approach would be much less expensive than adding long-acting inhaled β$_2$-agonists. However, theophylline is a less effective option than adding a long-acting inhaled β$_2$-agonist [102].

## Chronic obstructive pulmonary disease

Theophylline may also benefit patients with COPD and increases exercise tolerance [116, 117]. Theophylline reduces air trapping, suggesting an effect on peripheral airways, and this may explain why some patients with COPD may obtain considerable symptomatic improvement without any increase in spirometric values [118]. Although the effect of theophylline on respiratory muscle weakness was believed to be important in contributing to symptomatic improvement in patients with COPD [86], this seems unlikely as several investigators have failed to confirm any effect on respiratory muscle function at therapeutic concentrations of theophylline [87]. The demonstration that low doses of theophylline reduce neutrophils in induced sputum of patients with COPD suggests that theophylline may have some anti-inflammatory effect [71, 119]. In COPD macrophages *in vitro* theophylline restores HDAC activity to normal and

thus reverses corticosteroid resistance [40]. It also reduces nitrative stress in macrophages from patients with COPD, whereas high doses of an inhaled corticosteroid are without effect [45]. This suggests that corticosteroids may be useful in reversing corticosteroids resistance in patients with COPD, but long-term clinical trials are now needed to confirm this [120, 121].

## Interaction with β$_2$-agonists

If theophylline exerts its effects by PDE inhibition, a synergistic interaction with β-agonists would be expected. Many studies have investigated this possibility, but while there is good evidence that theophylline and β-agonists have additive effects, true synergy is not seen [122]. This can now be understood in terms of the molecular mechanisms of action of β-agonists and theophylline. β-Agonists may cause relaxation of airway smooth muscle via several mechanisms. Classically, they increase intracellular cyclic AMP concentrations, which were believed to be an essential event in the relaxation response. It has recently become clear that β-agonists may cause bronchodilatation, at least in part, by opening maxi-K channels in airway smooth muscle cells [9, 48]. Maxi-K channels are opened by low concentrations of β$_2$-agonists which are likely to be therapeutically relevant. There is now evidence that β-receptors may be coupled directly to maxi-K channels via the α-subunit of $G_s$ [123], and therefore may induce relaxation without any increase in cyclic AMP, thus accounting for a lack of synergy.

Repeated administration of β$_2$-agonists may result in tolerance; however, this may be explained by downregulation of β$_2$-receptors, an additional mechanism may involve upregulation of PDE enzymes (especially PDE4D) which then break down cyclic AMP more readily [124]. Theophylline may therefore theoretically prevent the development of tolerance. However, in a clinical study theophylline failed to prevent the development of tolerance to the bronchoprotective effect of salmeterol in asthmatic patients [125].

## SIDE EFFECTS

There is no doubt that theophylline provides clinical benefit in obstructive airway disease, but the main limitation to its use is the frequency of adverse effects [126]. Unwanted effects of theophylline are usually related to plasma concentration and tend to occur when plasma levels exceed 20 mg/l; however, some patients develop side-effects even at low plasma concentrations. To some extent side effects may be reduced by gradually increasing the dose until therapeutic concentrations are achieved.

The commonest side effects are headache, nausea and vomiting, abdominal discomfort, and restlessness. There may also be increased acid secretion, gastroesophageal reflux, and diuresis. There has recently been concern that theophylline, even at therapeutic concentrations, may lead to behavioral disturbance and learning difficulties in school children [127],

although it is difficult to design adequate controls for such studies. At high concentrations convulsions and cardiac arrhythmias may occur and, as stated previously, there is concern that intravenous aminophylline administered in the emergency room may be a contributory factor to the deaths of some patients with severe asthma [99].

Some of the side-effects of theophylline (central stimulation, gastric secretion, diuresis, and arrhythmias) may be due to adenosine receptor antagonism ($A_{1A}$ receptors), and these may therefore be avoided by PDE inhibitors, as discussed above. The commonest side effects of theophylline are nausea and headaches, which may be due to inhibition of certain PDEs (e.g. PDE4 in the vomiting center) and cardiac arrhythmias due to inhibition of PDE3 [128].

## FUTURE OF THEOPHYLLINE

Although theophylline has recently been used much less in developed countries, there are reasons for thinking that it may come back in fashion for the treatment of chronic asthma and COPD, with the recognition that it may have an anti-inflammatory and immunomodulatory effect when given in low doses (plasma concentration 5–10 mg/l) [3]. At these low doses the drug is easier to use, side effects are uncommon, and the problems of drug interaction are less of a problem, thus making the clinical use of theophylline less complicated. Theophylline appears to have an effect that is different from those of corticosteroids, and it may therefore be a useful drug to combine with low-dose inhaled steroids. The molecular mechanism of anti-inflammatory effects of theophylline is now becoming clearer, and it seems likely that there is a synergistic interaction with the anti-inflammatory mechanism of corticosteroids through restoration of HDAC activity. This interaction may underlie the beneficial effects of theophylline when added to inhaled corticosteroids. This may be particularly appropriate in patients with more severe asthma in whom corticosteroids are less effective as there may be a reduction in HDAC activity in these patients [37] as well as in smoking asthmatics patients and patients with COPD. As slow-release theophylline preparations are cheaper than long-acting inhaled $\beta_2$-agonists and leukotriene modifiers, this may justify the choice of low-dose theophylline as the add-on therapy for asthma control. In addition, compliance with oral therapy is likely to be greater than with inhaled therapies [129]. This suggests that low-dose theophylline may find an important place in modern asthma management in patients with moderate asthma as well as with severe asthma.

# Corticosteroids

**Peter J. Barnes**

**National Heart and Lung Institute (NHLI), Clinical Studies Unit, Imperial College, London, UK**

Corticosteroids (also known as glucocorticosteroids, glucocorticoids, steroids) are by far the most effective controllers used in the treatment of asthma and the only drugs that can effectively suppress the characteristic inflammation in asthmatic airways. By contrast, they are ineffective in suppressing pulmonary inflammation in COPD. After the discussion of the mechanism of action and pharmacology of corticosteroids their current use in the treatment of asthma and COPD will be described.

## MECHANISMS OF ACTION

There have been major advances in understanding the molecular mechanisms whereby corticosteroids suppress inflammation, based on recent developments in understanding the fundamental mechanisms of gene transcription [1, 2]. Corticosteroids activate and suppress many genes relevant to understanding their action in asthma and in other allergic diseases (Table 51.1).

### Cellular effects

At a cellular level, corticosteroids reduce the numbers of inflammatory cells in the airways, including eosinophils, T-lymphocytes, mast cells, and dendritic cells (Fig. 51.1). These effects of corticosteroids are produced through inhibiting the recruitment of inflammatory cells into the airway by suppressing the production of chemotactic mediators and adhesion molecules and by inhibiting the survival in the airways of inflammatory cells, such as eosinophils, T-lymphocytes, and mast cells. Epithelial cells may be the major cellular

target for inhaled corticosteroids, which are the mainstay of modern asthma management. Inhaled corticosteroids suppress many activated inflammatory genes in airway epithelial cells (Fig. 51.2). Epithelial integrity is restored by regular inhaled corticosteroids. The suppression of mucosal inflammation is relatively rapid with a significant reduction in eosinophils detectable within 6 h and associated with reduced airway hyperresponsiveness [3, 4]. Reversal of airway hyperresponsiveness

**TABLE 51.1** Effect of corticosteroids on gene transcription.

Increased transcription

- Lipocortin-1
- $\beta_2$-Adrenergic receptors
- Secretory leukocyte inhibitory protein
- IκB-α (inhibitor of NF-κB)
- Anti-inflammatory or inhibitory cytokines
- IL-10, IL-12, IL-1 receptor antagonist
- Mitogen-activated protein kinase phosphatase-1 (MKP-1, inhibits MAP kinase pathways)

Decreased transcription

- Inflammatory cytokines
  IL-2, IL-3, IL-4, IL-5, IL-6, IL-11, IL-13, IL-15, TNF-α, GM-CSF, SCF
- Chemokines
  IL-8, RANTES, MIP-1α, eotaxin
- Inflammatory enzymes
  Inducible nitric oxide synthase (iNOS), inducible cyclo-oxygenase (COX-2) inducible phospholipase $A_2$ (cPLA$_2$)
- Inflammatory peptides
  Endothelin-1
- Mediator receptors
  Neurokinin (NK$_1$)-, bradykinin (B$_2$)-receptors
- Adhesion molecules
  ICAM-1, VCAM-1
**FIG. 51.1** Cellular effects of corticosteroids.

**FIG. 51.2** Inhaled corticosteroids may inhibit the transcription of several "inflammatory" genes in airway epithelial cells and thus reduce inflammation in the airway wall. NF-κB: nuclear factor κB; AP-1: activator protein-1; GM-CSF: granulocyte-macrophage colony stimulating factor; IL-1: interleukin-1; iNOS: inducible nitric oxide synthase; NO: nitric oxide; COX-2: inducible cyclooxygenase; cPLA$_2$: cytoplasmic phospholipase A$_2$; PG: prostaglandin; ET: endothelin; ICAM: intercellular adhesion molecule.

may take several months to reach a plateau, probably reflecting recovery of structural changes in the airway [5].

## Glucocorticoid receptors

Corticosteroids diffuse across the cell membrane and bind to glucocorticoid receptors (GR) in the cytoplasm [2]. There is only one form of GR that binds corticosteroids termed GR-α. GR-β is an alternatively spliced form of GR that interacts with DNA but not with corticosteroids, so may act as a dominant negative inhibitor of glucocorticoid action by interfering with the binding of GR to DNA [6]. Whether GR-β is involved in steroid resistance in asthma is controversial [7]. Activated

GRs rapidly translocate to the nucleus where they produce their molecular effects. A pair of GRs (GR homodimer) bind to glucocorticoid response elements in the promoter region of steroid-responsive genes and this interaction switches on (and sometimes switches off) gene transcription (Fig. 51.3). Examples of genes that are activated by corticosteroids include genes encoding β$_2$-adrenergic receptors and the anti-inflammatory proteins secretory leukoprotease inhibitor and mitogen-activated protein kinase phosphatase-1 (MKP-1), which inhibits MAP kinase pathways. These effects may contribute to the anti-inflammatory actions of corticosteroids [8, 9]. GR interaction with negative GREs may suppress gene transcription and it is thought that this may be important in mediating many of the side effects of corticosteroids. For example, corticosteroids inhibit the expression of osteocalcin that is involved in bone synthesis [10].

## Switching off inflammation

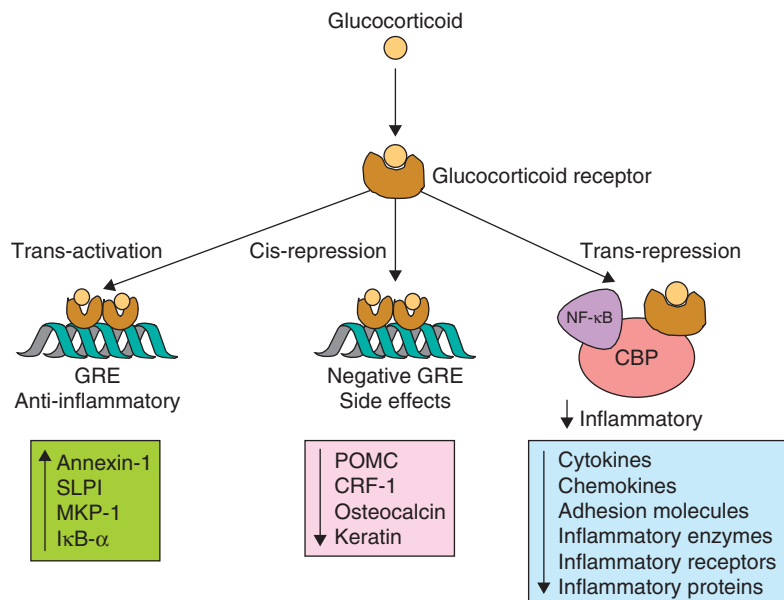
The major action of corticosteroids is to switch off multiple activated inflammatory genes that encode for cytokines, chemokines, adhesion molecules, inflammatory enzymes, and receptors [11]. These genes are switched on in the airways by proinflammatory transcription factors, such as nuclear factor-κB (NF-κB) and activator protein-1, both of which are activated in asthmatic airways and switch on inflammatory genes by interacting with coactivator molecules, such as CREB-binding protein, that have intrinsic histone acetyltransferase (HAT) activity, resulting in acetylation of core histones, which opens up the chromatin structure so that gene transcription is facilitated [12]. In artificial overexpression systems, activated GR may directly interact with NF-κB and AP-1 to inhibit their activity, but this does not appear to occur in asthmatic patients treated with inhaled corticosteroids [13]. Glucocorticoid-activated GR also interact with coactivator molecules and this inhibits the interaction of NF-κB with coactivators, thus reducing histone acetylation [1, 14]. Reduction of histone


**FIG. 51.3** Corticosteroids may regulate gene expression in several ways. Glucocorticoids enter the cell to bind to glucocorticoid receptors in the cytoplasm that translocate to the nucleus. GR homodimers bind to glucocorticoid-response elements (GRE) in the promoter region of steroid-sensitive genes, which may encode anti-inflammatory proteins. Less commonly, GR homodimers interact with negative GREs to suppress genes, particularly those linked to side effects of corticosteroids. Nuclear GR also interact with coactivator molecules, such as CREB-binding protein (CBP), which is activated by proinflammatory transcription factors, such as nuclear factor-κB (NF-κB), thus switching off the inflammatory genes that are activated by these transcription factors. SLPI: secretory leukoprotease inhibitor; MKP-1: mitogen-activated kinase phosphatase-1; IκB-α: inhibitor of NF-κB; GILZ: glucocorticoid-induced leucine zipper protein; POMC: proopiomelanocortin; CRH: corticotrophin releasing factor.

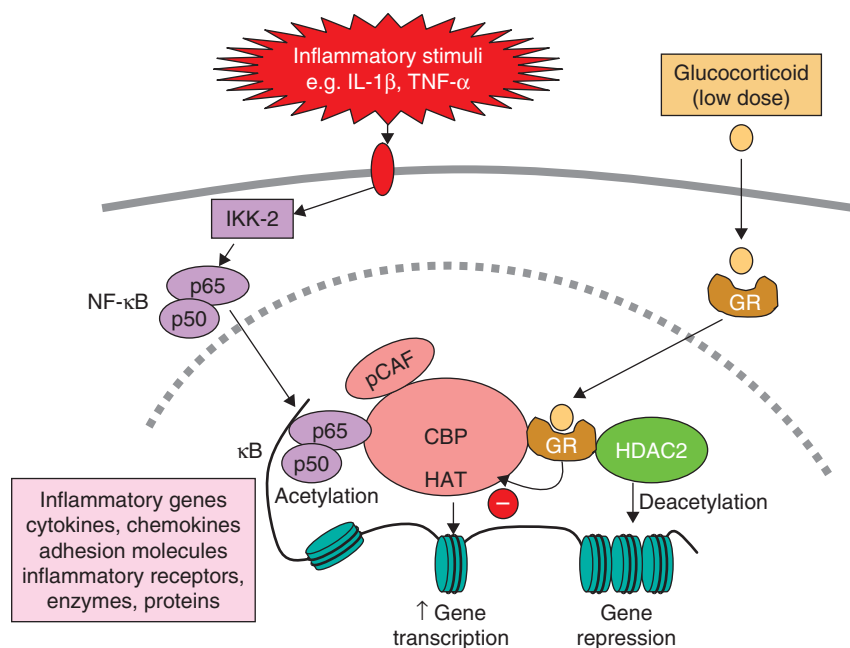

**FIG. 51.4** Corticosteroid suppression of activated inflammatory genes. Inflammatory genes are activated by inflammatory stimuli, such as interleukin-1β (IL-1β) or tumor necrosis factor-α (TNF-α), resulting in activation of IKK2 (inhibitor of I-κB kinase-2), which activates the transcription factor, nuclear factor κB (NF-κB). A dimer of p50 and p65 NF-κB proteins translocates to the nucleus and binds to specific κB recognition sites and also to coactivators, such as CREB-binding protein (CBP) or p300/CBP-activating factor (pCAF), which have intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of core histone H4, resulting in increased expression of genes encoding multiple inflammatory proteins. Glucocorticoid receptors (GR) after activation by glucocorticoids translocate to the nucleus and bind to coactivators to inhibit HAT activity directly and recruiting histone deacetylase-2 (HDAC2), which reverses histone acetylation leading in suppression of these activated inflammatory genes.

acetylation also occurs through the recruitment of histone deacetylase-2 (HDAC2) to the activated inflammatory gene complex by activated GR, thereby resulting in effective suppression of all activated inflammatory genes within the nucleus (Fig. 51.4). This accounts for why corticosteroids are so effective in the control of asthmatic inflammation, but also why they are safe, since other activated genes are not affected.

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on mitogen-activated kinase signaling pathways through the induction of MKP-1 and this may inhibit the expression of multiple inflammatory genes [8, 9]. Some inflammatory genes, for example granulocyte-macrophage colony stimulating factor,

have an unstable mRNA that is rapidly degraded by certain RNAses but stabilized when cells are stimulated by inflammatory mediators. Corticosteroids reverse this effect, resulting in rapid degradation of mRNA and reduced inflammatory protein secretion [15]. This may be through the inhibition of proteins that stabilize mRNAs of inflammatory proteins, such as tristetraprolin [16].

## Corticosteroid resistance

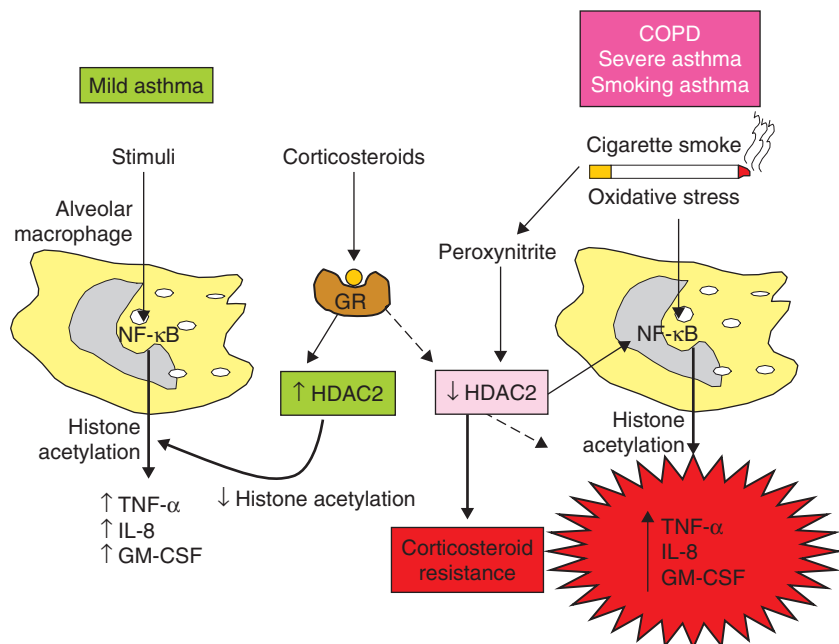
Patients with severe asthma have a poor response to corticosteroids, which necessitates the need for high doses and a few patients are completely resistant. All patients with COPD show corticosteroid resistance. Asthmatics who smoke are also


FIG. 51.5 Mechanism of corticosteroid resistance in COPD, smoking asthma, and severe asthma. Stimulation of mild asthmatic alveolar macrophages activates nuclear factor-κB (NF-κB) and other transcription factors to switch on histone acetyltransferase leading to histone acetylation and subsequently to transcription of genes encoding inflammatory proteins, such as tumor necrosis factor-α (TNF-α), interleukin-8 (IL-8), and granulocyte-macrophage colony stimulating factor (GM-CSF). Corticosteroids reverse this by binding to GR and recruiting HDAC2. This reverses the histone acetylation induced by NF-κB and switches off the activated inflammatory genes. In COPD patients and smoking asthmatics cigarette smoke generates oxidative stress (acting through the formation of peroxynitrite) and in severe asthma and COPD intense inflammation generates oxidative stress to impair the activity of HDAC2. This amplifies the inflammatory response to NF-κB activation, but also reduces the anti-inflammatory effect of corticosteroids, as HDAC2 is now unable to reverse histone acetylation.

relatively corticosteroid-resistant and require increased doses of corticosteroids for asthma control [17]. Several molecular mechanisms have now been identified to account for corticosteroid resistance in severe asthma and COPD [18]. In patients with COPD, smoking asthmatics, and severe asthma there is a reduction in HDAC2 activity and expression, which prevents corticosteroids switching off activated inflammatory genes (Fig. 51.5) [19–21]. In steroid-resistant asthma other mechanisms may also contribute to corticosteroid insensitivity, including reduced translocation of GR as a result of phosphorylation by p38 MAP kinase [22] and abnormal histone acetylation patterns [23]. A proposed mechanism is an increase in GR-β, which prevents GR binding to DNA, but there is little evidence that this would be sufficient to account for corticosteroid insensitivity as the amounts of GR-β are too low [7].

## INTERACTION WITH β₂-ADRENERGIC RECEPTORS

Inhaled β₂-agonists and corticosteroids are frequently used together in the control of asthma and it is now recognized that there are important molecular interactions between these two classes of drugs (Fig. 51.6) [24]. As discussed above, corticosteroids increase the gene transcription of β₂-receptors, resulting in increased expression of cell surface receptors. This has been demonstrated in human lung *in vitro* [25] and nasal mucosa *in vivo* after topical application of a glucocorticoid [26]. In this way corticosteroids protect against the downregulation of β₂-receptors after long-term administration [27]. This may be important for the non-bronchodilator effects of β₂-agonists, such as mast cell stabilization. Corticosteroids may also enhance the coupling of β₂-receptors to G-proteins, thus enhancing β₂-agonist effects and reversing the uncoupling of β₂-receptors that may occur in response to inflammatory

mediators, such as IL-1β through a stimulatory effect on a G-protein-coupled receptor kinase [28].

There is also evidence that β₂-agonists may affect GR and thus enhance the anti-inflammatory effects of corticosteroids. β₂-Agonists increase the translocation of GR from cytoplasm to the nucleus after activation by corticosteroids [29]. This effect has now been demonstrated in sputum macrophages of asthmatic patients after an inhaled glucocorticoid and inhaled long-acting β₂-agonist (LABA) [30]. This suggests that β₂-agonists and glucocorticoid enhance each others beneficial effects in asthma therapy.

## PHARMACOKINETICS

Prednisolone is readily and consistently absorbed after oral administration with little interindividual variation. Prednisone is converted in the liver to the active prednisolosne. Enteric coatings to reduce the incidence of dyspepsia delay absorption but not the total amount of drug absorbed. Prednisolone is metabolized in the liver and drugs such as rifampicin, phenobarbitone, or phenytoin, which induce CYP450 enzymes, lower the plasma half-life of prednisolone [31]. The plasma half-life is 2–3h, although its biological half-life is approximately 24h, so that it is suitable for daily dosing. There is no evidence that previous exposure to steroids changes their subsequent metabolism. Prednisolone is approximately 92% protein bound, the majority to a specific protein transcortin and the remainder to albumin; it is the unbound fraction which is biologically active. Corticosteroid-resistant asthma is not explained by impaired absorption or metabolism of steroids, but is due to reduced anti-inflammatory actions of corticosteroids, as discussed above. Measurement of plasma concentrations of prednisolone are useful in monitoring compliance with inhaled corticosteroids and in assessing whether a poor
**FIG. 51.6** Interaction between corticosteroids and LABA. Corticosteroids have anti-inflammatory effects but also increase the numbers of $\beta_2$-receptors, whereas $\beta_2$-agonists, as well as inducing direct bronchodilation, act on GR to increase the anti-inflammatory effects of corticosteroids.

therapeutic response to corticosteroids is due to poor absorption or increased metabolism.

## Inhaled delivery

The pharmacokinetics of inhaled corticosteroids is important in relation to systemic effects [32, 34]. The fraction of steroid which is inhaled into the lungs acts locally on the airway mucosa, but may be absorbed from the airway and alveolar surface. This fraction therefore reaches the systemic circulation (Fig 51.7). The fraction of inhaled steroid which is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver before reaching the systemic circulation (first-pass metabolism). Budesonide and fluticasone propionate (FP) have a greater first-pass metabolism than beclomethasone dipropionate (BDP) and are therefore less likely to produce systemic effects at high inhaled doses. The use of a large volume spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of corticosteroids, although this effect is minimal in corticosteroids with a high first-pass metabolism [35]. Mouth rinsing and discarding the rinse has a similar effect and this procedure should be used with high dose dry powder steroid inhalers, since spacer chambers cannot be used with these devices. The ideal inhaled corticosteroid with optimal therapeutic index should have high lung bioavailability, negligible oral bioavailability, low systemic absorption, high systemic clearance, and high protein binding [36].

A recently introduced corticosteroid ciclesonide is an inactive prodrug that is activated by esterases in the lung to the active metabolite des-ciclesonide [37]. This may reduce oropharyngeal side effects as esterases appear to be less active in this site than in the lower airways. Ciclesonide is also claimed to be effective as a once daily therapy.

## SYSTEMIC STEROIDS

Hydrocortisone is given intravenously in acute severe asthma. While the value of corticosteroids in acute severe asthma

**FIG. 51.7** Pharmacokinetics of inhaled glucocorticoids. GI: gastrointestinal.

has been questioned, others have found that they speed the resolution of attacks. There is no apparent advantage in giving very high doses of intravenous steroids (such as methylprednisolone 1 g) as this only increases the risk of side effects, such as hyperglycemia and increased susceptibility to infections. Intravenous steroids are indicated in acute asthma if lung function is < 30% predicted and in whom there is no significant improvement with a nebulized $\beta_2$-agonist. Intravenous therapy is usually given until a satisfactory response is obtained and then oral prednisolone may be substituted. Oral prednisolone (40–60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer [38, 39]. High doses of inhaled corticosteroids may also substitute for a course of oral steroids in controlling acute exacerbations of asthma. High dose FP (2000 μg daily) was as effective as a course of oral prednisolone in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency room setting, although this route of delivery is more expensive [40, 41]. Although doubling the dose of inhaled corticosteroids was recommended for mild exacerbations of asthma, this does not appear to be useful [42, 43], but a fourfold increase in dose appears to be effective [44]. Inhaled steroids have no proven effect in the management of severe acute asthma in a hospital setting [45], but trials with nebulized steroids, which can deliver large doses, are underway.
**FIG. 51.8** Chemical structures of inhaled glucocorticoids.

Maintenance treatment with oral steroids are reserved for patients who cannot be controlled on maximum doses of other therapy, the dose being titrated to the lowest which provides acceptable control of symptoms. For any patient taking regular oral steroids objective evidence of steroid responsiveness should be obtained before maintenance therapy is instituted. Short courses of oral steroids (30–40 mg prednisolone daily for 1–2 weeks) are indicated for exacerbations of asthma, and the dose may be tailed off over 1 week once the exacerbation is resolved (although the tail-off period is not strictly necessary, patients often find it reassuring).

## INHALED CORTICOSTEROIDS

There is no doubt that the early use of inhaled corticosteroids has revolutionized the management of asthma, with marked reductions in asthma morbidity and improvement in health status. Inhaled steroids are now recommended as first-line therapy for all patients with persistent asthma [46]. Several topically acting corticosteroids are now available for inhalation (Fig. 51.8). Inhaled corticosteroids are very effective in controlling asthma symptoms in asthmatic patients of all ages and severity. Inhaled corticosteroids improve the quality of life of patients with asthma and allow many patients to lead normal lives, improve lung function, reduce the frequency of exacerbations, and may prevent irreversible airway changes. They were first introduced to reduce the requirement for oral corticosteroids in patients with severe asthma and many studies have confirmed that the majority of patients can be weaned off oral corticosteroids [32].

## USE IN ASTHMA

### Studies in adults

As experience has been gained with inhaled corticosteroids they have been introduced in patients with milder asthma, with the recognition that inflammation is present even in patients with mild asthma. Inhaled anti-inflammatory drugs have now become first-line therapy in any patient who needs to use a $\beta_2$-agonist inhaler more than two to three times a week and this is reflected in national and international guidelines for the management of chronic asthma. In patients with newly diagnosed asthma an inhaled corticosteroid (budesonide 600 μg twice daily) reduced symptoms and $\beta_2$-agonist inhaler usage and improved lung function. These effects persisted over the 2 years of the study, whereas in a parallel group treated with inhaled $\beta_2$-agonists alone there was no significant change in symptoms or lung function [47]. In another study, patients with mild asthma treated with a low dose of inhaled corticosteroid (budesonide 400 μg daily) showed less symptoms and a progressive improvement in lung function over several months and many patients became completely asymptomatic [48]. There was also a significant reduction in the number of exacerbations; in patients with mild asthma a low dose of corticosteroids (budesonide 400 μg daily) significantly reduces exacerbation by around 40% over a 3-year period [49]. Although the effects of inhaled corticosteroids on AHR may take several months to reach a plateau, the reduction in asthma symptoms occurs much more rapidly and reduced inflammation is seen within hours [3, 4].

High dose inhaled corticosteroids may be used for the control of more severe asthma. This markedly reduces the need for maintenance oral corticosteroids [50]. With the use

of add-on therapies, particularly LABA, most patients can now be controlled on much lower doses of inhaled corticosteroids so that high doses are needed in only a few patients with severe disease. Inhaled corticosteroids are the treatment of choice in nocturnal asthma, which is a manifestation of inflamed airways, reducing nocturnal awakening and reducing the diurnal variation in airway function.

Inhaled corticosteroids effectively control asthmatic inflammation but must be taken regularly. When inhaled corticosteroids are discontinued there is usually a gradual increase in symptoms and airway responsiveness back to pretreatment values [51]. Reduction in the dose of inhaled corticosteroids is associated with an increase in symptoms and this is preceded by an increase in exhaled NO and sputum eosinophils [52, 53].

## Studies in children

Inhaled corticosteroids are equally effective in children. In an extensive study of children aged 7–17 years there was a significant improvement in symptoms, peak flow variability, and lung function compared to a regular inhaled $\beta_2$-agonist which was maintained over the 22 months of the study [54], but asthma deteriorated when the inhaled corticosteroids were withdrawn [55]. There was a high proportion of dropouts (45%) in the group treated with inhaled $\beta_2$-agonist alone. Inhaled corticosteroids are also effective in younger children. Nebulized budesonide reduces the need for oral corticosteroids and also improved lung function in children under the age of three [56]. Inhaled corticosteroids given via a large volume spacer improve asthma symptoms and reduce the number of exacerbations in preschool children and in infants.

## Dose-response studies

Surprisingly, the dose-response curve for the clinical efficacy of inhaled corticosteroids is relatively flat and, while all studies have demonstrated a clinical benefit of inhaled corticosteroids, it has been difficult to demonstrate differences between doses, with most benefit obtained at the lowest doses used [57, 58]. This is in contrast to the steeper dose response for systemic effects, implying that while there is little clinical benefit from increasing doses of inhaled corticosteroids the risk of adverse effects is increased. However, the dose-response effect of inhaled corticosteroids may depend on the parameters measured and, while it is difficult to discern a dose response when traditional lung function parameters are measured, there may be a dose-response effect in prevention of asthma exacerbations. Thus, there is a significantly greater effect of budesonide 800 μg daily compared to 200 μg daily in preventing severe and mild asthma exacerbations [59]. Normally, a fourfold or greater difference in dose has been required to detect a statistically significant (but often small) difference in effect on commonly measured outcomes such as symptoms, PEF, use of rescue $\beta_2$-agonist and lung function and even such large differences in dose are not always associated with significant differences in response. These findings suggest that pulmonary function tests or symptoms may have a rather low sensitivity in the assessment of the effects of inhaled corticosteroids. This is obviously important for the interpretation of clinical comparisons between different inhaled corticosteroids or inhalers. It is also important to consider the type of patient included in clinical studies. Patients with relatively mild asthma may have relatively little room for improvement with inhaled corticosteroids, so that maximal improvement is obtained with relatively low doses. Patients with more severe asthma or with unstable asthma may have more room for improvement and may therefore show a greater response to increasing doses, but it is often difficult to include such patients in controlled clinical trials.

More studies are needed to assess whether other outcome measures such as AHR or more direct measurements of inflammation, such as sputum eosinophils or exhaled NO, may be more sensitive than traditional outcome measures such as symptoms or lung function tests [60–63]. Higher doses of inhaled corticosteroids are needed to control AHR than to improve symptoms and lung function, and this may have a better long-term outcome in terms of reduction in structural changes of the airways [64]. Measurement of sputum eosinophils to adjust the dose of inhaled corticosteroids may reduce the overall dose requirement for inhaled corticosteroids and exacerbations [65, 66]. Monitoring of exhaled nitric oxide also reduces the requirement for corticosteroids but is not yet practical in clinical practice [67].

## Prevention of irreversible airway changes

Some patients with asthma develop an element of irreversible airflow obstruction, but the pathophysiological basis of these changes is not yet understood. It is likely that they are the result of chronic airway inflammation and that they may be prevented by treatment with inhaled corticosteroids. There is some evidence that the annual decline in lung function may be slowed by the introduction of inhaled corticosteroids [68] and this is supported by a 5-year study of low dose budesonide in patients with mild asthma [69, 70]. Increasing evidence also suggests that delay in starting inhaled corticosteroids may result in less overall improvement in lung function in both adults and children [71, 73]. These studies suggest that introduction of inhaled corticosteroids at the time of diagnosis is likely to have the greatest impact [72, 73]. So far there is no evidence that early use of inhaled corticosteroids is curative and even when inhaled corticosteroids are introduced at the time of diagnosis, symptoms and lung function reverts to pretreatment levels when corticosteroids are withdrawn [71].

## Reduction in mortality

In a retrospective review of the risk of mortality and prescribed antiasthma medication, there was a significant protection provided by regular inhaled corticosteroid therapy [74]. By contrast, asthma mortality appears to increase with increasing usage of short-acting $\beta_2$-agonists, reflecting the fact that increased rescue therapy is a marker of poor asthma control [75]. The increase in use of rescue therapy should result in an increase in the maintenance dose of inhaled corticosteroids. The long-acting inhaled $\beta_2$-agonist salmeterol is

associated with a small increase in asthma mortality, but the excess deaths appear to be related to underuse of inhaled corticosteroids [76].

## Comparison between inhaled corticosteroids

Several inhaled corticosteroids are currently prescribable in asthma, although their availability varies between countries. There have been relatively few studies comparing efficacy of the different inhaled corticosteroids, and it is important to take into account the delivery system and the type of patient under investigation when such comparisons are made. Because of the relatively flat dose-response curve for the clinical parameters normally used in comparing doses of inhaled corticosteroids, it may be difficult to see differences in efficacy of inhaled corticosteroids. Most comparisons have concentrated on differences in systemic effects at equally efficacious doses, although it has often proved difficult to establish dose equivalence. There are few studies comparing different doses of inhaled corticosteroids in asthmatic patients. Budesonide has been compared with BDP and in adults and children it appears to have comparable antiasthma effects at equal doses, whereas FP appears to be approximately twice as potent as BDP and budesonide [58]. Studies have consistently shown that FP and budesonide have less systemic effects than BDP, triamcinolone, and flunisolide [33]. The new inhaled corticosteroids mometasone and ciclesonide are claimed to have less systemic effects [77, 78].

## Clinical application

Inhaled corticosteroids are now recommended as first-line therapy for all patients with persistent symptoms. Inhaled corticosteroids should be started in any patient who needs to use a $\beta_2$-agonist inhaler for symptom control more than three times weekly. It is conventional to start with a low dose of inhaled corticosteroid and to increase the dose until asthma control is achieved. However, this may take time and a preferable approach is to start with a dose of corticosteroids in the middle of the dose range (400μg twice daily) to establish asthma control. Once control is achieved (defined as normal or best possible lung function and infrequent need to use an inhaled $\beta_2$-agonist) the dose of inhaled corticosteroid should be reduced in a stepwise manner to the lowest dose needed for optimal control. It may take as long as 3 months to reach a plateau in response and any changes in dose should be made at intervals of 3 months or more. When daily doses of ≥800μg daily are needed, a large volume spacer device should be used with a metered dose inhaler (MDI) and mouth washing with a dry powder inhaler in order to reduce local and systemic side effects. Inhaled corticosteroids are usually given as a twice daily dose in order to increase compliance. When asthma is unstable four times daily dosage is preferable [79].

The dose of inhaled corticosteroid should be increased to 2000μg daily if necessary, but higher doses may result in systemic effects. It may be preferable to add a low dose of oral corticosteroid, since higher doses of inhaled corticosteroids are expensive and have a high incidence of local side effects. Nebulized budesonide has been advocated in order to give an increased dose of inhaled corticosteroid and to reduce the requirement for oral corticosteroids [80], but this treatment is expensive and may achieve its effects largely via systemic absorption. The dose of inhaled corticosteroid should be the minimal dose that controls asthma and once control is achieved the dose should be slowly reduced [81].

## USE IN COPD

Patients with COPD have a poor response to corticosteroids in comparison to asthma with little improvement in lung function. High doses of inhaled corticosteroids have consistently been shown a reduction (20–25%) in exacerbations in patients with severe disease and this is the main clinical indication for their use [82]. However, several large studies have shown that corticosteroids fail to reduce the progression in COPD (measured by annual fall in $FEV_1$) [83] and they have not been found to reduce mortality in a large study [84]. These results are likely to reflect the resistance of pulmonary inflammation to corticosteroids in COPD patients as a result of the reduction in HDAC2 [21].

## ADD-ON THERAPY

Previously it was recommended to increase the dose of inhaled corticosteroids if asthma was not controlled, on the assumption that there was residual inflammation of the airways. However the dose-response effect of inhaled corticosteroids is relatively flat, so that there is little improvement in lung function after increasing the dose of inhaled corticosteroids. An alternative strategy is to add some other class of controller drug and this is more effective than increasing the dose of inhaled corticosteroids for most patients [85].

### LABA

In patients who are not controlled on BDP 200μg twice daily, addition of salmeterol 50μg twice daily was more effective than increasing the dose of inhaled corticosteroid to 500μg twice daily, in terms of lung function improvement, use of rescue $\beta_2$-agonist and symptom control [86]. This has been confirmed in several other studies [87]. Similar results have been found with another long-acting inhaled $\beta_2$-agonist formoterol, which in addition reduced the frequency of mild and severe asthma exacerbations in patients with mild, moderate, and severe persistent asthma [59, 88]. Analysis of several studies clearly show that adding a LABA is more effective than increasing the dose of inhaled corticosteroids in terms of improving asthma control and reducing exacerbations [89]. These studies showing the great efficacy of combined corticosteroids and LABA compared to increased doses of LABA have led to the development of fixed combinations of corticosteroids and

LABA, such as FP/salmeterol and budesonide/formoterol, which may be more convenient for patients. These fixed combination inhalers also ensure that patients do not discontinue their inhaled corticosteroids when a long-acting bronchodilator is used. For patients with mild persistent asthma, combination inhalers are no more effective than the inhaled corticosteroids alone in controlled trials [90], but may have an advantage in the real world where adherence to regular inhaled corticosteroids is very low.

Recently, studies have demonstrated that when formoterol combined with budesonide is used as a reliever therapy this gives better control of asthma compared to the normally used short-acting $\beta_2$-agonist as a rescue therapy with either the same dose of combination inhaler or a high dose of inhaled corticosteroids as maintenance treatment [91, 92]. This advantage is particularly striking in terms of reducing the number of severe exacerbations. When formoterol was used as the reliever therapy this reduce exacerbations to a greater extent than the short-acting $\beta_2$-agonist terbutaline but the combination was even more effective [93]. This suggests that the "as required" use of inhaled corticosteroids contributes to the marked reduction in acute exacerbations. The mechanisms by which corticosteroids as required improve asthma control and reduce exacerbations are not completely understood, but exacerbations of asthma evolve over several days when patients take increasing amounts of rescue medication [94]. During this time there is increasing inflammation of the airways, as may be measured by exhaled nitric oxide and sputum eosinophils [52]. Taking the inhaled corticosteroid at the same time as the formoterol to relieve symptoms may suppress this evolving inflammation, particularly since corticosteroids appear to have a relatively rapid onset of effect in suppressing airway inflammation [95].

LABA/corticosteroid inhalers are also more effective in COPD patients than either treatment alone and reduce exacerbations and improve symptoms [96, 97]. They are more effective than LABA alone in reducing exacerbations [98]. This may be explained by molecular interactions between LABA and corticosteroids as discussed above. However, there is a reduction in COPD mortality although this fails to reach significance in one large study (TORCH) [84], although this has been seen in another smaller study (INSPIRE) [99].

## Theophylline

Addition of low doses of theophylline (giving plasma concentrations of <10 mg/l) are more effective than doubling the dose of inhaled budesonide, either in mild or in severe asthma [100–102]. However, this is less effective than using a long-acting inhaled $\beta_2$-agonist as an add-on therapy [103]. Theophylline has not been examined as an add-on therapy in COPD patients but there are theoretical reasons to believe that low dose theophylline may reverse corticosteroid resistance in COPD (see Chapter 52).

## Antileukotrienes

Antileukotrienes have also been used as an add-on therapy in asthma [104, 105], although this is less effective than

addition of LABA [106–108]. There is no role of antileukotrienes in COPD patients.

## SIDE EFFECTS

The efficacy of inhaled corticosteroids is now established in short- and long-term studies in adults and in children, but there are still concerns about side effects, particularly in children and when high inhaled doses are used. Several side effects have been recognized (Table 51.2).

## Local side effects

Side effects due to the local deposition of the inhaled corticosteroid in the oropharynx may occur with inhaled corticosteroids, but the frequency of complaints depends on the dose and frequency of administration and on the delivery system used.

The commonest complaint is of hoarseness of the voice (dysphonia) and may occur in over 50% of patients using MDI. Dysphonia is not appreciably reduced by using spacers, but may be less with dry powder devices. Dysphonia may be due to myopathy of laryngeal muscles and is reversible when treatment is withdrawn [109]. For most patients it is not troublesome but may be disabling in singers and lecturers.

Oropharyngeal candidiasis (thrush) may be a problem in some patients, particularly in the elderly, with concomitant oral corticosteroids and more than twice daily administration [110]. Large volume spacer devices protect against this local side effect by reducing the dose of inhaled corticosteroid that deposits in the oropharynx.

## Infections

There is no evidence that inhaled corticosteroids, even in high doses, increase the frequency of infections, including tuberculosis, in the lower respiratory tract in asthmatic

**TABLE 51.2** Side effects of inhaled corticosteroids.

| Local side effects |
| --- |

|    Psychiatric disturbances |

patients. Recently several large controlled studies have shown that high dose ICS increase physician-diagnosed pneumonias, either used alone or in combination with a LABA [83, 98] and this has been confirmed in an epidemiological study of hospital admissions for pneumonia amongst COPD patients [111].

## Systemic side effects

The efficacy of inhaled corticosteroids in the control of asthma is undisputed, but there are concerns about systemic effects of inhaled corticosteroids, particularly as they are likely to be used over long periods and in children of all ages [33, 112]. The safety of inhaled corticosteroids has been extensively investigated since their introduction 30 years ago [32]. One of the major problems is to decide whether a measurable systemic effect has any significant clinical consequence and this necessitates careful long-term follow-up studies. As biochemical markers of systemic corticosteroid effects become more sensitive, then systemic effects may be seen more often, but this does not mean that these effects are clinically relevant. There are several case reports of adverse systemic effects of inhaled corticosteroids, and these may be idiosyncratic reactions, which may be due to abnormal pharmacokinetic handing of the inhaled corticosteroid. The systemic effect of an inhaled corticosteroid will depend on several factors, including the dose delivered to the patient, the site of delivery (gastrointestinal tract and lung), the delivery system used, and the individual differences in the patient's response to the corticosteroid. Recent studies suggest that systemic effects of inhaled corticosteroid are less in patients with more severe asthma, presumably as less drug reaches the lung periphery [113, 114].

The systemic effect of an inhaled corticosteroid is dependent on the amount of drug absorbed into the systemic circulation. Approximately 80–90% of the inhaled dose from an MDI deposits in the oropharynx and is swallowed and subsequently absorbed from the gastrointestinal tract. Use of a large volume spacer device markedly reduces the oropharyngeal deposition, and therefore the systemic effects of inhaled corticosteroids, although this is less important when oral bioavailability is minimal, as with FP. For dry powder inhalers similar reductions in systemic effects may be achieved with mouth washing and discarding the fluid. All patients using a daily dose of ≥800μg of an inhaled corticosteroid should therefore use either a spacer or a mouthwash to reduce systemic absorption. Approximately 10% of an MDI enters the lung and this fraction (which presumably exerts the therapeutic effect) may be absorbed into the systemic circulation. As the fraction of inhaled corticosteroid deposited in the oropharynx is reduced, the proportion of the inhaled dose entering the lungs is increased. More efficient delivery to the lungs is therefore accompanied by increased systemic absorption, but this is offset by a reduction in the dose needed for optimal control of airway inflammation. For example, a multiple dry powder delivery system, the Turbuhaler, delivers approximately twice as much corticosteroid to the lungs as other devices, and therefore has increased systemic effects. However this is compensated for by the fact that only half the dose is required.

## Adrenal suppression

Corticosteroids may cause hypothalamic–pituitary–adrenal (HPA) axis suppression by reducing corticotrophin (ACTH) production, which reduces cortisol secretion by the adrenal gland. The degree of HPA suppression is dependent on dose, duration, frequency, and timing of corticosteroid administration. Measurement of HPA axis function provides evidence for systemic effects of an inhaled corticosteroid. Basal adrenal cortisol secretion may be measured by a morning plasma cortisol, 24h urinary cortisol, or by plasma cortisol profile over 24h. Other tests measure the HPA response following stimulation with tetracosactrin (which measures adrenal reserve) or stimulation with metyrapone and insulin (which measure the response to stress). There are many studies of HPA axis function in asthmatic patients with inhaled corticosteroids, but the results are inconsistent as they have often been uncontrolled and patients have also been taking courses of oral corticosteroids (which may affect the HPA axis for weeks) [32]. BDP, budesonide, and FP at high doses by conventional MDI (>1600μg daily) give a dose-related decrease in morning serum cortisol levels and 24h urinary cortisol, although values still lie well within the normal range. However, when a large volume spacer is used doses of 2000μg daily of BDP or budesonide have little effect on 24h urinary cortisol excretion. Stimulation tests of HPA axis function similarly show no consistent effects of doses of 1500μg or less of inhaled corticosteroid. At high doses (>1500μg daily) budesonide, and FP have less effect than BDP on HPA axis function. In children no suppression of urinary cortisol is seen with doses of BDP of 800μg or less. In studies where plasma cortisol has been measured at frequent intervals there was a significant reduction in cortisol peaks with doses of inhaled BDP as low as 400μg daily, although this does not appear to be dose related in the range 400–1000μg . The clinical significance of these effects is not certain, however.

## Bone metabolism

Corticosteroids lead to a reduction in bone mass by direct effects on bone formation and resorption and indirectly by suppression of the pituitary–gonadal and HPA axes, effects on intestinal calcium absorption, renal tubular calcium reabsorption, and secondary hyperparathyroidism [115]. The effects of oral corticosteroids on osteoporosis and increased risk of vertebral and rib fractures are well known, but there are no reports suggesting that long-term treatment with inhaled corticosteroids is associated with an increased risk of fractures. Bone densitometry has been used to assess the effect of inhaled corticosteroids on bone mass. Although there is evidence that bone density is less in patients taking high dose inhaled corticosteroids, interpretation is confounded by the fact that these patients are also taking intermittent courses of oral corticosteroids. Changes in bone mass occur very slowly and several biochemical indices have been used to assess the short-term effects of inhaled corticosteroids on bone metabolism. Bone formation has been measured by plasma concentrations of bone-specific alkaline phosphatase, serum osteocalcin, or procollagen peptides. Bone resorption may be assessed by urinary hydroxyproline after a 12-h fast, urinary calcium excretion, and pyridinium cross-link excretion. Inhaled corticosteroids, even at doses

up to 2000μg daily, have no significant effect on calcium excretion, but acute and reversible dose-related suppression of serum osteocalcin has been reported with BDP and budesonide when given by conventional MDI in several studies. Budesonide consistently has less effect than BDP at equivalent doses and only BDP increases urinary hydroxyproline at high doses. With a large volume spacer even doses of 2000μg daily of either BDP or budesonide are without effect on plasma osteocalcin concentrations, however. Urinary pyridinium and deoxypyridinoline cross-links, which are a more accurate and stable measurement of bone and collagen degradation, are not increased with inhaled corticosteroids (BDP > 1000μg daily), even with intermittent courses of oral corticosteroids. It is important to monitor changes in markers of bone formation as well as bone degradation, as the net effect on bone turnover is important. There is no evidence that inhaled corticosteroids increase the frequency of fractures. Long-term treatment with high dose inhaled corticosteroids has not been associated with any consistent change in bone density. Indeed, in elderly patients there may be an increase in bone density due to increased mobility.

## Connective tissue effects

Oral and topical corticosteroids cause thinning of the skin, telangiectasiae, and easy bruising, probably as a result of loss of extracellular ground substance within the dermis, due to an inhibitory effect on dermal fibroblasts. There are reports of increased skin bruising and purpura in patients using high doses of inhaled BDP, but the amount of intermittent oral corticosteroids in these patients is not known. Easy bruising in association with inhaled corticosteroids is more frequent in elderly patients [116] and there are no reports of this problem in children. Long-term prospective studies with objective measurements of skin thickness are needed with different inhaled corticosteroids.

## Cataracts

Long-term treatment with oral corticosteroids increases the risk of posterior subcapsular cataracts and there are several case reports describing cataracts in individual patients taking inhaled corticosteroids [32]. In a recent cross-sectional study in patients aged 5–25 years taking either inhaled BDP or budesonide no cataracts were found on slit-lamp examination, even in patients taking 2000μg daily for over 10 years [117]. A slight increase in the risk of glaucoma in patients taking very high doses of inhaled corticosteroids has also been identified [118].

## Growth

There has been particular concern that inhaled corticosteroids may cause stunting of growth and several studies have addressed this issue. Asthma itself (as with other chronic diseases) may have an effect on the growth pattern and has been associated with delayed onset of puberty and deceleration of growth velocity that is more pronounced with more severe disease [119]. However, asthmatic children appear to grow for longer, so that their final height is normal. The effect of asthma on growth make it difficult to assess the effects of inhaled corticosteroids on growth in cross-sectional studies, particularly as courses of oral corticosteroids is a confounding factor. Longitudinal studies have demonstrated that there is no significant effect of inhaled corticosteroids on statural growth in doses of up to 800μg daily and for up to 5 years of treatment [32]. A meta-analysis of 21 studies, including over 800 children, showed no effect of inhaled BDP on statural height, even with higher doses and long duration of therapy [120] and in a large study of asthmatics treated with inhaled corticosteroids during childhood there was no difference in statural height compared to normal children [121]. Another long-term follow-up study showed no effect of corticosteroids on final height in children treated over several years [122]. Short-term growth measurements (knemometry) have demonstrated that even a low dose of an oral corticosteroid (prednisolone 2.5mg) is sufficient to give complete suppression of lower leg growth. However inhaled budesonide up to 400μg is without effect, although some suppression is seen with 800μg and with 400μg BDP. The relationship between knemometry measurements and final height are uncertain since low doses of oral corticosteroid that have no effect on final height cause profound suppression.

## Metabolic effects

Several metabolic effects have been reported after inhaled corticosteroids, but there is no evidence that these are clinically relevant at therapeutic doses. In adults, fasting glucose and insulin are unchanged after doses of BDP up to 2000μg daily and in children with inhaled budesonide up to 800μg daily. In normal individuals high dose inhaled BDP may slightly increase resistance to insulin. However, in patients with poorly controlled asthma high doses of BDP and budesonide paradoxically decrease insulin resistance and improve glucose tolerance, suggesting that the disease itself may lead to abnormalities in carbohydrate metabolism. Neither BDP 2000μg daily in adults nor budesonide 800μg daily in children have any effect on plasma cholesterol or triglycerides.

## Psychiatric effects

There are various reports of psychiatric disturbance, including emotional lability, euphoria, depression, aggressiveness and insomnia, after inhaled corticosteroids. Only eight such patients have so far been reported, suggesting that this is very infrequent and a causal link with inhaled corticosteroids has usually not been established.

## Pregnancy

Based on extensive clinical experience inhaled corticosteroids appear to be safe in pregnancy, although no controlled studies have been performed. There is no evidence for any adverse effects of inhaled corticosteroids on the pregnancy, the delivery, or on the fetus [123]. It is important to recognize that poorly controlled asthma may increase the incidence of perinatal mortality and retard intrauterine growth, so that more effective control of asthma with inhaled corticosteroids may reduce these problems.

## Side effects in COPD

Patients with COPD are elderly and are likely to have increased systemic side effects from inhaled corticosteroids as they have several additional risk factors. There have been

fewer studies of systemic side effects in COPD patients. However, a systematic review found no reduction in bone mineral density or increase in fractures in COPD patients treated for up to 3 years with inhaled corticosteroids [83]. An epidemiological study showed an increase in cataracts which are more common in an elderly population [124]. Many patients with COPD suffer from comorbidities, including hypertension, metabolic syndrome and diabetes, and may therefore have a worsening of these conditions, but this has not yet been systematically investigated.

## SYSTEMIC CORTICOSTEROIDS

Oral or intravenous corticosteroids may be indicated in several situations. Prednisone is converted in the liver to the active prednisolone. In pregnant patients prednisone is preferable as it is not converted to prednisolone in the fetal liver, thus diminishing the exposure of the fetus to corticosteroids. Enteric-coated preparations of prednisolone are used to reduce side effects (particularly gastric side effects) and give delayed and reduced peak plasma concentrations, although the bioavailability and therapeutic efficacy of these preparations is similar to uncoated tablets. Prednisolone and prednisone are preferable to dexamethasone, betamethasone, or triamcinolone, which have longer plasma half-lives and therefore an increased frequency of adverse effects.

### Short courses

Short courses of oral corticosteroids (30–40 mg prednisolone daily for 1–2 weeks or until the peak flow values return to best attainable) are indicated for exacerbations of asthma, and the dose may be tailed off over 1 week once the exacerbation is resolved. The tail-off period is not strictly necessary, but some patients find it reassuring.

### Maintenance corticosteroids

Maintenance oral corticosteroids are only needed in a small proportion of asthmatic patients (approximately 1%) with the most severe asthma that cannot be controlled with maximal doses of inhaled corticosteroids (2000 µg daily) and additional bronchodilators. The minimal dose of oral corticosteroid needed for control should be used and reductions in the dose should be made slowly in patients who have been on oral corticosteroids for long periods (e.g. by 2.5 mg per month for doses down to 10 mg daily and thereafter by 1 mg per month). Oral corticosteroids are usually given as a single morning dose, as this reduces the risk of adverse effects since it coincides with the peak diurnal concentrations. There is some evidence that administration in the afternoon may be optimal for some patients who have severe nocturnal asthma [125]. Alternate day administration may also reduce adverse effects, but control of asthma may not be as good on the day when the oral dose is omitted in some patients.

Intramuscular triamcinolone acetonide (80 mg monthly) has been advocated in patients with severe asthma as an alternative to oral corticosteroids [126, 127]. This may be considered in patients in whom compliance is a particular problem, but the major concern is the high frequency of proximal myopathy associated with this fluorinated corticosteroid. Some patients who do not respond well to prednisolone are reported to respond to oral betamethasone, presumably because of pharmacokinetic handling problems with prednisolone.

## Acute severe asthma

Intravenous hydrocortisone is given in acute severe asthma, with a recommended dose of 200 mg intravenously. While the value of corticosteroids in acute severe asthma has been questioned, others have found that they speed the resolution of attacks [128]. There is no apparent advantage in giving very high doses of intravenous corticosteroids (such as methylprednisolone 1 g). Indeed, intravenous corticosteroids have occasionally been associated with an acute severe myopathy [129]. No difference in recovery from acute severe asthma was seen whether intravenous hydrocortisone in doses of 50, 200, or 500 mg 6 hourly were used [130], and another placebo-controlled study showed no beneficial effect of intravenous corticosteroids [131]. Intravenous corticosteroids are indicated in acute asthma if lung function is <30% predicted and in whom there is no significant improvement with nebulized β2-agonist. Intravenous therapy is usually given until a satisfactory response is obtained and then oral prednisolone may be substituted. Oral prednisolone (40–60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer [38, 128]. Oral prednisolone is the preferred treatment for acute severe asthma, providing there are no contraindications to oral therapy. There is some evidence that high doses of nebulized corticosteroids may also be effective in acute exacerbations of asthma, with a more rapid onset of action [132].

# Mediator Antagonists

**Kian Fan Chung and
Peter J. Barnes**

**National Heart and Lung Institute
(NHLI), Clinical Studies Unit,
Imperial College, London, UK**

## INTRODUCTION

Inflammatory mediators contribute to the pathophysiology of asthma and chronic obstructive pulmonary disease (COPD) (see Chapters 23–27) suggesting that antagonists of mediator receptors or inhibitors of their synthesis would be beneficial in treatment. However, because a large number of mediators are involved and many mediators share similar effects on the airways, inhibitors of single mediators may have had little or no clinical benefit to date. This may underlie the fact that despite many years of continuing efforts by pharmaceutical companies, only one class of mediator antagonists, the anti-leukotrienes, has become established in the treatment of asthma, representing the first new class of therapy for asthma introduced in more than 40 years. So far, there has been no mediator antagonists introduced for the treatment of COPD. In addition to reviewing the anti-leukotrienes, we will also review other classes of mediator antagonists that have failed to show beneficial effects or those currently under-investigation but whose potential has yet to be tested.

## ANTI-LEUKOTRIENES

Anti-leukotrienes can be divided into cysteinyl-leukotriene (cys-LT) receptor antagonists that antagonize the effects of cys-LTs, such as $LTD_4$, and leukotriene synthesis inhibitors that are inhibitors of 5′-lipoxygenase (5-LO) enzyme that generates cys-LTs and $LTB_4$ (Fig. 52.1). Anti-leukotrienes are mainly indicated for the treatment of asthma, and $LTB_4$ inhibitors, such

as $LTB_4$ receptor antagonists, have no effect in asthma and are being considered for the treatment of COPD.

## 5′-Lipoxygenase inhibitors

5-LO is a critical enzyme involved in the generation of leukotrienes. Inhibitors of 5-LO may be classified as direct inhibitors of the enzyme and indirect inhibitors that interfere with a nuclear membrane docking protein, 5-LO activating protein (FLAP), that is necessary for enzyme activation. Many hydroxamates and *N*-hydroxyureas are 5-LO inhibitors and act by interfering with the redox state of the active binding site. Zileuton is the most extensively investigated and is the only 5-LO inhibitor available for prescription in asthma (but only in the USA) [1]. The effect of zileuton is similar to that of leukotriene receptor antagonists, and zileuton inhibits allergen- and exercise-induced asthma, as well as aspirin-induced asthma. It decreases airway hyperresponsiveness and inflammatory cells in nocturnal exacerbations of asthma [2]. In addition, zileuton inhibits eosinophil influx induced by allergen challenge [3].

Zileuton has a short duration of action and has to be taken four times daily; a twice daily controlled-release preparation is also available [4]. Its side effects are mainly on the liver, with frequent abnormalities of liver function tests. Other redox 5-LO inhibitors have been developed but have not reached the market. Non-redox 5-LO inhibitors and inhibitors of FLAP (e.g. MK-886, MK-591, Bay-x1005) have been developed and are currently being developed further for clinical use in asthma and possibly COPD. One theoretical advantage of the 5-LO inhibitors on the receptor antagonists
**FIG. 52.1** Inhibition of effects of cysteinyl-leukotrienes (cys-LT) in asthma.

is that they inhibit the formation of $LTB_4$, and other 5-LO products such as eoxins, as well as cys-LTs. This may make the drugs more applicable to other airway diseases where $LTB_4$ may be involved, such as COPD and cystic fibrosis. There is anecdotal evidence that zileuton was more effective in controlling severe asthma than cys-$LT_1$ antagonists, supporting the view that other 5-LO products may be important, particularly in severe asthma.

## cys-LT antagonists

The pathophysiological role of cys-LTs is discussed in Chapter 24. Cys-LTs cause airway obstruction through the stimulation of specific receptors termed the cys-LT receptor type 1 (Cyst-$LT_1$) present on airway smooth muscle. This a seven-transmembrane spanning, G-protein-coupled receptor, where the gene is mapped to the X chromosome [5]. Signaling through cyst-$LT_1$ occurs through stimulation of phosphoinositide hydrolysis [6]. A second cys-LT receptor, cyst-$LT_2$, is also expressed on vascular endothelium, blood eosinophils, mast cells, and lung macrophages, and could mediate activation of these cells [7] Zafirlukast and montelukast are potent leukotriene receptor antagonists available in most countries, while pranlukast is currently available only in Japan and Korea. There is only one anti-leukotriene a 5-lipoxygenase inhibitor, zileuton, which is available in the USA.

## Clinical studies in asthma

Leukotriene receptor antagonists in clinical use inhibit the bronchoconstrictor effects of inhaled cys-LTs. For example,

a single 40 mg dose of zafirlukast produces a 100-fold shift of the $LTD_4$ dose–response curve, and significant protection is present for 24 h [8]. Oral administration of leukotriene receptor antagonist inhibits both the early and late responses to allergen, and exercise-induced asthma [9, 10]. Leukotriene receptor antagonists are able to cause bronchodilation, and their effect is additive to that of short-acting $\beta_2$-agonists [11, 12].

In many studies of anti-leukotrienes such as zileuton, zafirlukast, pranlukast, and montelukast, their effectiveness has been compared with that of placebo in short-term studies of 4–6 week duration [13–16]. A greater increase in $FEV_1$, a reduction in asthma medication use and in asthma symptoms, with an increase in morning peak flow has been demonstrated in mild-to-moderate severe asthma with some degree of airflow obstruction and usually in cohorts not on inhaled corticosteroid therapy. These findings have been confirmed and extended in longer studies in patients with mild-to-moderate chronic stable asthma with zileuton, zafirlukast, montelukast, all demonstrating clinical benefit [17–19]. Their additive effect to the bronchodilation achieved with high doses of inhaled β-agonist indicates that they may have a place in the treatment of acute severe asthma. Intravenous administration of montelukast in acute severe asthma provided additional benefit to the receevery when given together with standard therapy [20]. Clinical benefit has also been demonstrated with the addition of anti-leukotrienes to the patients with poor asthma control who are already taking high doses of inhaled corticosteroids [21]. Anti-leukotrienes may also reduce to a small extent the doses of inhaled corticosteroids required for asthma control [22]. Anti-leukotrienes may reduce the risk of acute severe asthma exacerbations [23, 24].

The effects of anti-leukotrienes have been compared with these inhaled corticosteroids [25]. In a recent meta-analysis, inhaled corticosteroids (250–400 μg beclomethasone dipropionate equivalent per day) was found to provide better improvements in lung function and quality of life, as well as reduction in symptoms, night awakenings, and need for rescue β-agonist. The rate of asthma exacerbations was similar when the anti-leukotrienes were compared with inhaled corticosteroids. The benefit of adding leukotriene-receptor antagonist with inhaled corticosteroids has been evaluated. Addition of pranlukast to half the usual dose of inhaled corticosteroids in patients with moderate-to-severe persistent asthma led to maintained control, while the placebo group demonstrated less improved asthma control [26]. Montelukast maintained control of asthma in patients in whom removal of inhaled corticosteroids caused worsening of asthma [26]. When compared to long-acting β-agonists, montelukast was less superior for preventing exacerbations and for improving lung function, symptoms, and the use of rescue β-agonists [27, 28]. Combination of a leukotriene receptor antagonists with long-acting β-agonists is not advisable for the treatment of moderate asthma [29].

Anti-leukotrienes are effective in blocking aspirin-induced asthmatic responses [30] and may be particularly indicated in patients with aspirin-sensitive asthma. In addition, anti-leukotrienes are particularly effective in inhibiting exercise-induced asthma, [10, 31, 32] without the loss of protection with prolonged usage. In addition, leukotriene inhibitors improve concomitant symptoms of allergic rhinitis [33, 34].

In United States, zileuton, zafirlukast, and montelukast have been approved as a first-line choice for the trteatment of asthma, while in Europe, montelukast and zafirlukast have been approved as an add-on therapy when treatment with inhaled corticosteroids has failed, and for the prophylaxis of exercise-induced asthma. In the GINA 2006 guidelines, anti-leukotrienes are listed as a less preferred initial treatment compared to inhaled corticosteroids and a less preferred option as an add-on therapy compared to long-acting β$_2$-agonists [35].

## Anti-inflammatory effects

Cys-LTs can induce airway eosinophilia in patients with asthma, and conversely, leukotriene-receptor antagonists or synthesis inhibitors reduce blood and airway eosinophilia associated with poorly controlled asthma, [23] and airway inflammation associated with allergen-induced airway responses [36]. Therefore, anti-leukotrienes can be considered as an anti-inflammatory therapy for asthma, but this remains to be confirmed in the clinical situation. In a study of the combination therapy of montelukast with inhaled corticosteroid, there was no effect of montelukast on sputum eosinophil counts [37]. Although there is cellular and animal data to support a role for cys-LTs in airway smooth muscle hyperplasia and airway fibrosis [38, 39], there is as yet no data of the effect of leukotriene inhibitors on these parameters in asthma.

## Safety

At the recommended doses, all leukotriene receptor antagonists have not resulted in nonrespiratory symptoms nor laboratory abnormalities when compared with placebo-treated groups. However, with zileuton, asymptomatic 3-fold or greater increases in serum alanine-aminotransferase levels were found in 4.6% of patients receiving zileuton at the standard dose of 600 mg four times per day, compared with 1% of patients receiving standard asthma treatment together with placebo. Controlled-release zileuton at a dose of 1200 mg twice daily was shown to have efficacy within the range of zileuton 600 mg four times daily, with similar side effect profile [40]. These elevations of liver enzymes usually occurred during the first 3 months of therapy, with sometimes normalization of the values despite continuation of treatment.

A rare syndrome of Churg–Strauss, marked by circulating eosinophilia and evidence of tissue or organ infiltration and vasculitis by eosinophils in association with heart failure, cutaneous or gastrointestinal involvement, and peripheral neuropathy, has been associated with treatment with zafirlukast and montelukast. Most patients developing Churg–Strauss syndrome have previously received oral glucocorticoid therapy or high-dose inhaled corticosteroid therapy to control their asthma. This may be due to unmasking of vasculitis of Churg–Strauss syndrome, as corticosteroids are tapered with the introduction of leukotriene receptor antagonist therapy [41].

## Role in COPD

Small bronchodilator effects of zafirlukast has been observed in some patients with COPD [42, 43] Because LTB$_4$ may play a role in the recruitment of neutrophils in COPD, the use of 5-LO inhibitors may bring some additional effects. In a small study of the leukotriene synthesis inhibitor, a 5-lipoxygenase activating protein inhibitor, BAYx1005, a small reduction in sputum LTB4 was observed with no clinical benefit [44]. No studies of zileuton in COPD have been reported yet.

## PROSTAGLANDIN AND CRTH2 INHIBITORS

Prostaglandin D$_2$ (PGD$_2$) is produced by activated mast cells and is a relatively selective marker for mast cells, and two G-protein-coupled receptors, DP$_1$ and DP$_2$ (also known as CRTH2), mediate many of its effects. However, it is quite likely that the PGD$_2$-bronchoconstrictor effect is mediated via the TP receptor, since the activation of DP$_1$ receptor in airway smooth muscle cells leads to bronchodilation. DP$_2$-receptors play an important role in Th2 lymphocyte recruitment and activation [45] (Fig. 52.2). Ramatroban is an effective TP antagonist which has been approved as a treatment for perennial rhinitis. It reduces bronchial hyperresponsiveness to methacholine in asthmatics [46]. Ramatroban also has a partial action as an

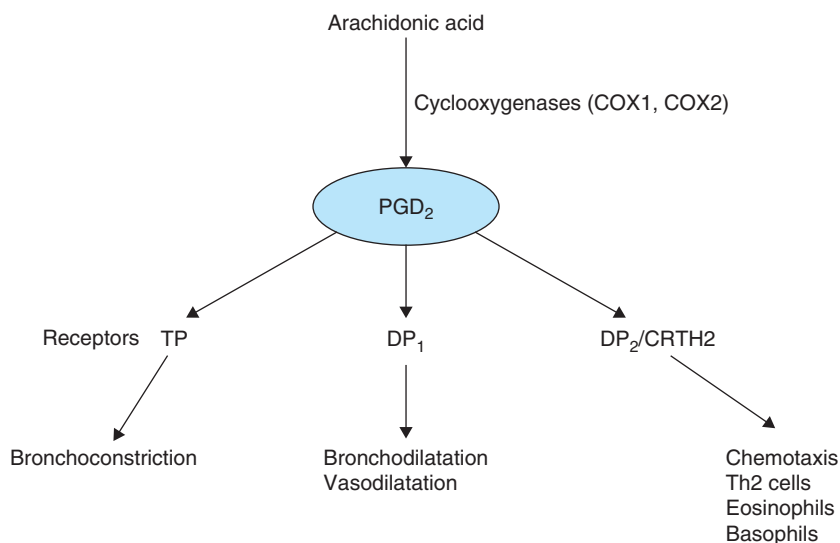
                       Vasodilatation              Th2 cells
                                                   Eosinophils
                                                   Basophils


**FIG. 52.2** Prostaglandin $D_2$ ($PGD_2$) effects. $PGD_2$ acts on three distinct prostanoid receptiors: the thromboxane receptor (TP) mediates bronchonstriction, $DP_1$-receptor mediates vasodilatation, and bronchodilatation and $DP_2$-receptor (also know as CRTH2) is chemotactic for Th2 cells, eosinophils, and basophils.

antagonist at the $DP_2$ receptor as shown by its inhibitory effect on $PGD_2$-stimulated eosinophil chemotaxis [47]. More selective and potent $DP_2$ antagonists have now been developed and are undergoing trials in asthma and allergic rhinitis [48].

## THROMBOXANE INHIBITORS

Although thromboxane production is increased in asthma and thromboxane analogs are potent bronchoconstrictors in asthmatic patients [49], there is no convincing evidence that thromboxane receptor (TP) antagonists or thromboxane synthase inhibitors are effective in asthma [50]. A selective TP antagonist, GR32191, caused a modest inhibition of early phase bronchoconstriction due to allergen but was not clinically effective in improving lung function or reducing symptoms in mild asthma [51]. However, a thromboxane synthase inhibitor (ozagrel) and a receptor antagonist (seratrodast) are used in the treatment of asthma in Japan, although their effects in asthma are small [52–54].

There is no evidence for a role for TP or DP receptors in COPD.

## ANTI-HISTAMINES

Histamine mediates most of its effects on airway function via $H_1$-receptors. Non-sedating potent $H_1$-receptor antagonists, such as terfenadine, fexafenadine, loratadine, desloratadine, ebastine, and astemizole, have useful clinical effects in allergic rhinitis, but they are far from effective in asthmatic patients [55]. The effects of anti-histamines are small and clinically insignificant. Terfenadine causes about 50% inhibition of the immediate response to allergen, but has no effect on the late response [56]. Anti-histamines cause

a small degree of bronchodilatation in asthmatic patients, indicating a certain degree of histamine "tone," presumably due to the basal release of histamine from activated mast cells [57]. Chronic administration of terfenadine has a small clinical effect in mild allergic asthmatic patients, [58] but is far less effective that other anti-asthma therapies. $H_1$-receptor antagonists have not been found to be useful in more severe asthmatic patients [48]. The new generation anti-histamines, cetirizine and astemizole, have some beneficial effects in asthma, [59, 60] that may be unrelated to their $H_1$-antagonist effects [61].

$H_2$-antagonists, such as cimetidine and ranitidine, may be contraindicated in asthma on theoretical grounds, if $H_2$-receptors are important in counteracting the bronchoconstrictor effect of histamine. In clinical practice, however, there is no evidence that $H_2$-antagonists have any deleterious effect in asthma. $H_3$-receptor agonists may have some theoretical benefit in asthma, since they may modulate cholinergic bronchoconstriction and inhibit neurogenic inflammation. Although (R)-$\alpha$-methylhistamine relaxes rodent peripheral airways *in vitro*, it has no effect when given by inhalation on airway caliber or metabisufite-induced bronchoconstriction in asthmatic patients, indicating that a useful clinical effect is unlikely [62].

Histamine $H_4$-receptors are expressed on eosinophils, T- cells, dendritic cells, basophils and mast cells, mediate mast cell, eosinophil and dendritic cell chemotaxis, and modulate cytokine production from dendritic cells and T-cells, indicating that blockade of histamine $H_4$-receptors may lead to anti-allergic and anti-inflammatory effects. Several histamine $H_4$-receptor antagonists are now available but remain to be tested in allergic asthma or rhinitis [63]. Antagonists that block both histamine $H_1$- and $H_4$-receptors may be an effective combination. Anti-histamines have a useful effect in the treatment of rhinitis, and particularly the rhinorrhea. As a large proportion of patients with asthma have concomitant rhinitis, an $H_1$-antagonist may help the overall management of asthma [64]. While $H_1$-receptor antagonists alone may be ineffective, some

studies suggest that they may have some efficacy in combination with other antagonists. Thus, an $H_1$-receptor antagonist when added to an anti-leukotriene was able to inhibit the early and late responses to allergen more effectively than the anti-leukotriene alone [65, 66], but as yet there has been no studies of combination mediator antagonists in asthma.

There is no evidence that anti-histamines have any role in the treatment of COPD.

## SEROTONIN ANTAGONISTS

The evidence for involvement of serotonin in asthma is weak. There is no evidence that serotonin is a direct constrictor in human airways, and it is not stored in and released from human mast cells, as in rodents. Serotonin receptor antagonists have been studied experimentally in asthmatic patients. Ketanserin, which antagonizes $5HT_2$ receptors and blocks the bronchoconstrictor effects of serotonin in animals, has no effect on airway function in asthmatic patients, but there is a small inhibitory effect on methacholine-induced bronchoconstriction [67]. Inhaled ketanserin has no effect on histamine-induced bronchoconstriction but has a small inhibitory effect on adenosine-induced bronchoconstriction, indicating a possible action on mast cells [68]. Tianeptine, which enhances serotonin uptake by platelets, lowers the elevated plasma serotonin levels reported in patients with asthma and is associated with a reduction in asthmatic symptoms [69].

## PAF ANTAGONISTS

Although PAF mimics many of the pathophysiological features of asthma including induction of airway hyperresponsiveness, PAF antagonists have proved to be very disappointing in asthma therapy.

Apafant (WEB 2086) potently inhibits the effects of inhaled PAF on airway function [70], but had no effect on the early or late responses to allergen or on airway hyperresponsiveness in patients with mild asthma [71]. A 3-month study of oral apafant in patients with symptomatic moderate asthma failed to show any effect on lung function, symptoms or on rescue $\beta_2$-agonist use [72]. Similarly, another PAF antagonist, modipafant (UK80067) had no beneficial effects in moderately severe asthmatics [73]. Another potent and long-acting PAF receptor antagonist, foropafant (SR27417A), was effective in inhibiting systemic, cellular, and pulmonary effects of PAF challenge in patients with mild bronchial asthma [74]. This antagonist produced a modest but significant reduction in the magnitude of the allergen-induced late response, but no effect on the early response, allergen-induced hyperresponsiveness, or on baseline lung function [75]. These clinical studies indicate that PAF plays little or no part in human allergic asthma, despite convincing data in animal models. There is no evidence that PAF is involved in COPD, and no studies with PAF antagonists in this disease have been reported.

## BRADYKININ ANTAGONISTS

There is evidence for the involvement of bradykinin in asthma, in particular a role in sensitizing and activating airway sensory nerves. However, a peptide bradykinin antagonist [D-Arg$^0$,Hyp$^3$,D-Phe$^7$]bradykinin (NPC567) was unable to inhibit the effect of bradykinin on nasal secretions, even when given at the same time as bradykinin, [76] presumably because of rapid local metabolism. There has been other more stable antagonists developed [77, 78]. Icatibant (HOE 140, D-Arg[Hyp$^3$,Thi$^6$,D-Tic$^7$,Oic$^8$] bradykinin is a potent selective $B_2$-receptor antagonist, [79] which has a long duration of action *in vivo* since it is resistant to enzymatic degradation. This antagonist is potent in inhibiting the bronchoconstrictor and microvascular leakage response to bradykinin [80] and the effect of bradykinin on airway sensory nerves [81]. Nasal application of icatibant reduces the nasal blockage induced by allergen in patients with allergic rhinitis [82]. In a clinical study of nebulized icatibant in asthma, there was a small improvement in airway function after 4 weeks without an improvement in asthma symptoms [83]. WIN 64338 is a nonpeptide $B_2$-receptor antagonist that blocked the bronchoconstrictor action of bradykinin in airway smooth muscle *in vitro* [84] and more potent nonpeptide antagonists, such as FR167344 have now been developed that have clinical potential [85].

## TACHYKININ ANTAGONISTS

Tachykinins interacts with the tachykinin $NK_1$-, $NK_2$-, and $NK_3$-receptors which exist in the airways, particularly on human bronchial glands, bronchial vessels, and bronchial smooth muscle. Inflammatory cells also express $NK_1$-receptors. $NK_1$- and $NK_2$-receptor antagonists have been shown to inhibit allergen-induced bronchial hyperresponsiveness and inflammation in various animal models. Potent $NK_1$- and $NK_2$-receptor antagonists have been recently available but have not shown any effects in asthma [86]. Thus, an $NK_2$-receptor antagonist, SR48968, that caused a significant inhibition of neurokinin-A bronchoconstriction by 3–5 fold shift did not affect baseline airway caliber or bronchial responsiveness to adenosine in asthma [87]. Dual NK1/NK2 and triple NK1/NK2/NK3 receptor antagonists are available with greater potencies, but it is unlikely that there will be trials in asthma. There has been no studies of tachykinin antagonists in COPD.

## ADENOSINE AGONISTS AND ANTAGONISTS

Adenosine is released following allergen exposure and exercise of sensitized asthmatics and is a bronchoconstrictor in asthmatics through the activation of mast cells. Adenosine may also be involved in allergic inflammation and remodeling. It interacts with G-protein-coupled receptors,

adenosine A$_1$-, A$_{2A}$-, A$_{2B}$- and A$_3$-receptors that are present on inflammatory and structural cells of the asthmatic airway. Various agonists and antagonists of these receptors have been developed as potential therapies for a variety of cardiac and pulmonary conditions, including asthma and COPD [88]. Activation of A$_{2A}$-receptors has been shown to have anti-inflammatory effects in animal models, and a selective A$_{2A}$- agonist has been shown to reduce the number of eosinophils and neutrophils in allergen-induced inflammation. However, two agonists of the A$_{2A}$-receptor, GW328267 and UK-432,097, have been tested in asthma. GW328267 had no effect on allergen-induced early or late phase response, and UK-432097 had no effect on lung function or bronchial hyperreactivity of mild asthma [89].

Adenosine has been shown to act through the A$_{2B}$-receptors to enhance various inflammatory responses seen in asthma. An antagonist of A$_{2B}$-receptors, CVT-6883, has been shown to inhibit the proinflammatory cytokines and profibrotic effects found in adenosine deaminase-deficient mice [90]. It is under development as an oral treatment for asthma.

## INTRODUCTION

Exacerbations of chronic obstructive pulmonary disease (COPD) are a frequent cause for office and emergency room visits as well as hospitalizations. Exacerbations are intermittent episodes of increased respiratory symptoms and worse pulmonary function that may be accompanied by fever and other constitutional symptoms. These episodes contribute significantly to the morbidity associated with COPD, and in advanced disease, they are also the most frequent cause of death [1–3]. The frequency of exacerbations varies widely between patients. Though severity of airflow obstruction is correlated with the frequency of exacerbations, other yet poorly understood factors predispose some patients to have more frequent exacerbations.

Several investigators have reported that exacerbations are important determinants of the decline in health-related quality of life in COPD [4, 5]. Following an exacerbation, acute symptoms usually subside over 2–3 weeks, however, quality of life indices takes several months to return to baseline. Furthermore, recurrent exacerbations are clearly associated with a more rapid decline in quality of life in COPD [6]. Based on studies performed by Fletcher and Peto in the 1960s it was widely believed that exacerbations do not contribute to the decline in lung function (measured as $FEV_1$). Recent data has disputed these results and shown that the frequency of exacerbations is associated with accelerated long-term decline in lung function, in both mild COPD and more advanced diseases [7, 8].

Undisputedly, exacerbations are a major contributor to the morbidity, costs, and mortality associated with COPD. Substantial progress has been made in understanding their etiology and pathogenesis of exacerbations. In contrast, such richness of data is unfortunately missing in the field of clinical management of exacerbations. Major modalities used to treat exacerbations include bronchodilators, systemic corticosteroids, and antibiotics. Only for systemic corticosteroid use in severe exacerbations requiring emergency room care or hospitalization is the adequate clinical trial data available. Adequately powered, well-designed clinical trials studies for the other modalities used to treat exacerbations are relatively few. Consequently, whether the use of antibiotics for exacerbations is appropriate is still debated and whether antibiotic choice makes a difference is even more controversial [9, 10].

Principles that should guide appropriate use of antibiotics in exacerbations are listed in Table 53.1. The comments in Table 53.1 illustrate the several barriers that currently exist in fully applying these principles in everyday practice. This chapter will describe the optimal approach to antibiotic treatment of exacerbations recognizing these limitations. Such an approach relies upon an accurate diagnosis of an exacerbation, including judicious application of diagnostic tests. This is followed by determining the severity of an exacerbation, the probability that it is bacterial and whether antibiotics are indicated. If antibiotics are indicated, then a risk stratification approach is described to choose an appropriate antibiotic.

## DIAGNOSIS OF ACUTE EXACERBATION

Clear, objective, universally accepted definition of a disease or syndrome is a pre-requisite for its accurate diagnosis. Unfortunately, for

**TABLE 53.1** Principles of appropriate antibiotic use in exacerbations of COPD.

| Principle | Comment |
| --- | --- |
| Bacteria cause significant proportion of exacerbations | 40–50% of exacerbations are of bacterial origin |
| Bacterial exacerbations can be reliably distinguished from nonbacterial episodes | Sputum purulence is a useful marker but not always easily assessed or reliable |
| Placebo-controlled antibiotic trials have shown benefit of antibiotics | This is true for moderate-to-severe exacerbations, but not mild episodes |
| Antibiotics used are appropriate for the causative pathogen | Sputum cultures are inaccurate and usually not performed, therefore therapy is usually empiric |
| Antibiotic dose and duration are appropriate | Shorter durations of 3–7 days appear to be as good as 10–14 days |
| Antibiotic choice makes a difference in outcome | Inadequate study methods have limited their ability to show differences among antibiotics |
| Risk stratification is useful in choosing antibiotics | Though not prospectively validated, it is widely advocated |

exacerbations of COPD, the current definitions are imprecise, variable, and lack objective measures [11]. There are two widely used definitions of exacerbation. In 1987, in a large placebo-controlled trial in exacerbations of COPD, Anthonisen and colleagues defined exacerbations based on the presence of one or more of the three cardinal symptoms, including an increase or new onset of dyspnea, sputum production, and sputum purulence [12]. When only one cardinal symptom is present, then one or more supporting symptoms or signs are required to make the diagnosis, including an upper respiratory tract infection in the past 5 days, wheezing, cough, fever without an obvious source, or a 20% increase in the respiratory rate or heart rate above baseline. Though simple and clinically useful, this definition does have several limitations. It is narrow in its scope, and several important symptoms of exacerbation such as cough, chest congestion, chest tightness, fatigue, and sleep disturbance are not included. It is subjective, however, that limitation applies to all definitions of exacerbations as reliable objective measures of exacerbations are currently unavailable.

A more recent and also commonly used definition came from a consensus panel that defined an exacerbation as an acute sustained worsening of the patients' condition from stable state, beyond day-to-day variability and which requires additional treatment [11]. This definition though more inclusive of symptoms of an exacerbation, is not specific with regard to the nature and duration of symptoms. It lacks objective measures. Longitudinal cohort studies with daily recording of symptoms have revealed that a significant proportion, up to 50%, of episodes of increased symptoms are not reported by patients to their health care providers and therefore are not associated with additional treatment. Such episodes, which likely represent mild exacerbations would not meet this definition of exacerbation.

Missing in both definitions is the clinical exclusion of entities that could lead to increased respiratory symptoms in a manner similar to exacerbation, such as pneumonia, congestive heart failure, upper respiratory infection, noncompliance with medications etc. These clinical entities have

distinct etiology, pathogenesis and treatment, and therefore should be in the differential diagnosis of an exacerbation rather than be included under the definition. In our clinical studies, we suspect an exacerbation when a patient with COPD reports a minor increase (or new onset) of two or a major increase (or new onset) of one of the following respiratory symptoms: dyspnea, cough, sputum production, sputum tenacity, sputum purulence [13]. The increase in symptoms should be of at least 24 h duration and should be of greater intensity than their normal day-to-day variability. Furthermore, as described above, clinical evaluation should exclude other clinical entities that could present in a similar manner.

## DETERMINATION OF SEVERITY

The decision to treat exacerbations is often based on severity, with antibiotic treatment recommended for moderate to severe exacerbations. However, currently our determination of severity of exacerbations is imprecise, and like the diagnosis, is determined in a variable manner among studies. The severity of an exacerbation is a complicated concept, determined by at least two factors, the severity of the underlying COPD and the acute change induced by the exacerbation. A severe exacerbation may therefore be assessed when a patient with very severe underlying COPD has a relatively small change from his baseline, or when a patient with mild COPD has much larger acute change in his symptoms and lung function. The exacerbation etiology and pathophysiology may differ considerably in these circumstances and may warrant distinct treatment approaches.

Exacerbation severity has been variously defined among studies. Ideally, changes in lung function should be used to define severity of exacerbations. However, spirometry and lung volumes are difficult to measure accurately during exacerbations, especially severe episodes. With simpler

**TABLE 53.2** Anthonisen classification of COPD exacerbations based on cardinal symptoms.

| Severity of exacerbation | Type of exacerbation | Characteristics |
|---|---|---|
| Severe | Type 1 | Increased dyspnea, sputum volume, and sputum purulence |
| Moderate | Type 2 | Any two of the above three cardinal symptoms |
| Mild | Type 3 | Any one of the above three cardinal symptoms and one or more of the following minor symptoms or signs<br><br>– Cough<br>– Wheezing<br>– Fever without an obvious source<br>– Upper respiratory tract infection in the past 5 days<br>– Respiratory rate increase >20% over baseline<br>– Heart rate increase >20% over baseline |

Based on data from Ref. [12].

measures, such as peak flow, often the change with an exacerbation is of the same magnitude as its day-to-day variability. Severity has been also measured by site of care, with hospitalized exacerbations regarded as severe, outpatient exacerbations regarded as moderate and self medicated exacerbations as mild [14]. Site of care is unreliable as a measure of exacerbation severity. Though the major factor determining site of care is undoubtedly illness severity, it is also dependent on differences in hospital admission practices among countries and health care systems, patient reporting of exacerbations, physician preferences, etc. The intensity of recommended treatment has also been used as a measure of severity of exacerbations, with treatment with bronchodilators only indicating mild exacerbations, while treatment with antibiotics and steroids in addition to bronchodilators regarded as indicating moderate or severe exacerbations. Such measurement of severity is beset with the same problems of preferences and practice approach as discussed above.

Another widely used determination of severity of exacerbations is the Anthonisen classification [12]. This classification relies on the number of cardinal symptoms and the presence of some supporting symptoms (Table 53.2). Though not developed as a severity classification, it has become so over time. Advantages of this determination of severity are its simplicity and that it correlates with benefit with antibiotics, with such benefit seen only in Type 1 and 2 exacerbations. Limitations include its lack of validation against objective measures of severity and that its ability to predict benefit with antibiotics has not been consistent in other studies. Another limitation is the lack of gradation of severity within each symptom, such that a Type 2 exacerbation with mild changes in two cardinal symptoms would be regarded as the same severity in this classification as an exacerbation with a marked increase in both symptoms.

It is evident that we need a better definition and objective measures of severity of exacerbations. Recent work in the development of patient reported outcomes to measure exacerbations has demonstrated that the experience of an exacerbation from the patient perspective includes not only respiratory symptoms but extra-respiratory manifestations including fatigue, anxiety, sleep disturbance etc. Future definitions of exacerbation should therefore include such symptoms. An expectation in the future is that a properly developed patient reported outcome measure would become universally applied to define exacerbations, where a certain change from baseline in this measure would constitute an exacerbation. Furthermore, the degree of change in such a measure from baseline would represent an objective measurement of severity.

Biomarkers in exacerbations are being vigorously explored, as they hold the promise of being objective measures to define an exacerbation and determine its severity. A recent study explored 36 plasma biomarkers in 90 patients with exacerbations and found that none of them alone or in combination were adequate to define an exacerbation [15]. In another study of multiple serum biomarkers in 20 hospitalized patients with exacerbation, reduction in interleukin-6 (IL-6) and interleukin-8 (IL-8) correlated with decrease in dyspnea during recovery from exacerbation, while decreases in IL-6 and tumor necrosis factor (TNF-$\alpha$) were proportional to recovery in $FEV_1$ [16]. Changes from baseline in sputum IL-8 and TNF-$\alpha$ as well as sputum neutrophil elastase (NE) and serum C-reactive protein (CRP) correlate with clinical severity of an exacerbation as assessed by a clinical score based on symptoms and signs [17, 18]. It appears unlikely that a single biomarker will be capable of defining an exacerbation, because of the heterogeneity of these episodes. However, biomarkers do hold promise in objectively determining severity of exacerbations and defining etiology to guide appropriate treatment.

## PATHOGENESIS OF EXACERBATIONS

An increase in airway inflammation from the baseline level in a patient appears central to the pathogenesis of most acute exacerbations [19, 20]. Airway inflammation measured in induced or expectorated sputum, bronchoalveolar lavage or bronchial biopsy has revealed that increased inflammation accompanies exacerbations and resolves with treatment [21–25]. Both neutrophilic and eosinophilic inflammations have been described. This acute increase in airway inflammation leads to increased bronchial tone, edema in the bronchial wall and mucus production. In a diseased lung, these processes worsen ventilation-perfusion mismatch and expiratory flow limitation. Clinically, these pathophysiologic changes present as an increase in or new onset of dyspnea, cough, sputum production, tenacity and purulence along with worsening gas exchange, which are the cardinal manifestations of an exacerbation. Inflammation in exacerbations extends beyond the lung, and increased plasma fibrinogen, interleukin 6 (IL-6) and CRP have been described during exacerbations [18, 26, 27]. These and other mediators likely

cause the systemic manifestations of exacerbations, including fatigue and in some instances fever.

The etiology of exacerbations appears to determine the nature and degree of inflammation in exacerbations. Neutrophilic inflammation is characteristic of bacterial exacerbations, while both neutrophilic and eosinophilic inflammations have been described with viral infection [28]. The intensity of neutrophilic inflammation, when measured as associated cytokines/chemokines (IL-8, TNF-$\alpha$) and products of neutrophil degranulation (NE and myeloperoxidase), is much greater in well-characterized bacterial exacerbations than exacerbations of nonbacterial etiology [18]. Systemic inflammation, measured as serum CRP is also more intense in bacterial exacerbations [18]. These findings have important implications. They can form the basis for biomarkers to distinguish etiology of exacerbations in a reliable and rapid manner, facilitating appropriate therapy. The heightened airway and systemic inflammation with bacterial exacerbations can be potentially damaging to the lungs. Effective antibiotic therapy to eradicate the bacteria responsible for exacerbations and reduce the inflammation to baseline levels becomes desirable and could have potential long-term benefits in COPD.

A variety of noninfectious and infectious stimuli can induce an acute increase in airway inflammation in COPD, thereby causing an exacerbation. Increased respiratory symptoms and respiratory mortality among patients with COPD during periods of increased air pollution have been described [29–31]. Environmental pollutants, both particulate matter, such as PM-10 and diesel exhaust particles, and nonparticulate gases, such as ozone, nitrogen dioxide, sulfur dioxide, are capable of inducing inflammation *in vitro* and *in vivo* [32–34]. Infectious agents, including bacteria, viruses, and atypical pathogens are implicated as causes of up to 80% of acute exacerbations [35].

## MICROBIAL PATHOGENS IN COPD EXACERBATIONS

Potential pathogens in COPD exacerbations includes typical respiratory bacterial pathogens, respiratory viruses, and atypical bacteria (Table 53.3). *Pneumocystis jiroveci*, a fungus, appears to cause chronic infection in COPD. Whether it induces exacerbations is being investigated. Among the typical bacteria, Nontypeable *Haemophilus influenzae* (NTHI) is the most common pathogen in COPD and is the best understood [36]. Among the viruses, *Rhinovirus* and *Respiratory syncytial virus* (RSV) have received considerable attention in recent years and their importance in COPD is now better appreciated [37, 38].

The predilection of these pathogens for causing infections in COPD may be related to certain shared characteristics. NTHI, *Streptococcus pneumoniae* and *Moraxella catarrhalis*

**TABLE 53.3** Microbial pathogens in exacerbations of COPD.

| Proportion of exacerbations (%) | Specific species | Proportion of class of pathogens (%) |
|---|---|---|
| Bacteria | | |
| 40–50 | Nontypeable *Haemophilus influenzae* | 30–50 |
| | *Streptococcus pneumoniae* | 15–20 |
| | *Moraxella catarrhalis* | 15–20 |
| | *Pseudomonas* spp. and *Enterobacteriaceae* | Isolated in very severe COPD, concomitant bronchiectasis, and recurrent exacerbations |
| | *Haemophilus parainfluenzae* | Isolated frequently, pathogenic significance undefined |
| | *Haemophilus hemolyticus* | Isolated frequently, pathogenic significance undefined |
| | *Staphylococcus aureus* | Isolated infrequently, pathogenic significance undefined |
| Viruses | | |
| 30–40 | *Rhinovirus* | 40–50 |
| | *Parainfluenzae* | 10–20 |
| | *Influenza* | 10–20 |
| | *RSV* | 10–20 |
| | *Coronavirus* | 10–20 |
| | *Adenovirus* | 5–10 |
| Atypical bacteria | | |
| 5–10 | *Chlamydia pneumoniae* | 90–95 |
| | *Mycoplasma pneumoniae* | 5–10 |

are the predominant bacterial causes of two other common respiratory mucosal infections, acute otitis media in children and acute sinusitis in children and adults. *Pseudomonas aeruginosa* is the dominant mucosal pathogen in cystic fibrosis and noncystic fibrosis bronchiectasis [39]. These mucosal infections have been related to anatomical abnormalities with impaired drainage of secretions, antecedent viral infections and defects in innate and adaptive immunity. All these predisposing factors likely exist in COPD. NTHI, *S. pneumoniae* and *M. catarrhalis* are exclusively human pathogens. Their usual environmental niche in healthy humans is confined to the upper airway which they usually colonize without any clinical manifestations. Acquisition of these pathogens in COPD, because of compromised lung defense, allows establishment of infection in the upper as well as the lower respiratory tract (below the vocal cords). Infection of the lower respiratory tract in COPD can be with or without overt clinical manifestations, the former being addressed as exacerbation while the latter as colonization.

Respiratory viruses implicated in COPD cause acute tracheobronchial infections in healthy hosts, clinically referred to as acute bronchitis. In the setting of COPD, with diminished respiratory reserve, this acute bronchitis has more profound manifestations and serious clinical consequences.

## PATHOGENESIS OF INFECTIOUS EXACERBATIONS

Significant progress has been made in our understanding of acute exacerbation pathogenesis, especially in relation to bacterial infection over the last few years. The current model of bacterial exacerbation pathogenesis involves both host and pathogen factors (Fig. 53.1). Acquisition of strains of bacterial pathogens that are new to the host from the environment is the primary event that puts the patient with COPD at risk for an exacerbation [13]. Variation among strains of a species in the surface antigenic structure, as is seen with NTHI, *S. pneumoniae*, *M. catarrhalis*, and *P. aeruginosa*, is crucial to the development of recurrent exacerbations with these pathogens. This variation allows these newly acquired strains to escape the pre-existing host immune response that had developed following prior exposure to other strains of the same species. These newly acquired strains can therefore proliferate in the lower airways and induce acute inflammation. The virulence of the strain and as yet unidentified host factors may determine if the acute inflammatory response to the pathogen reaches the threshold to cause symptoms that present as an exacerbation [40]. In the majority of instances, mucosal and systemic antibodies develop to the pathogen [41, 42]. This immune response, in combination with appropriate antibiotics, eliminates or controls proliferation of the infecting bacteria. However, because of antigenic variability among strains of these bacterial species, these antibodies directed at the infecting strain are usually strain-specific, and do not protect the host from antigenically distinct strains of the same species. This allows recurrent bacterial infection and exacerbations in these patients.

The pathogenesis of acute viral exacerbations is less well understood, but may be similar to bacterial infections. A common cause of exacerbations, the rhinovirus, demonstrates considerable antigenic variation among its more than 100 serotypes, allowing for recurrent infections. The influenza virus demonstrates drift in the antigenic make-up of its major surface proteins, thereby leading to recurrent

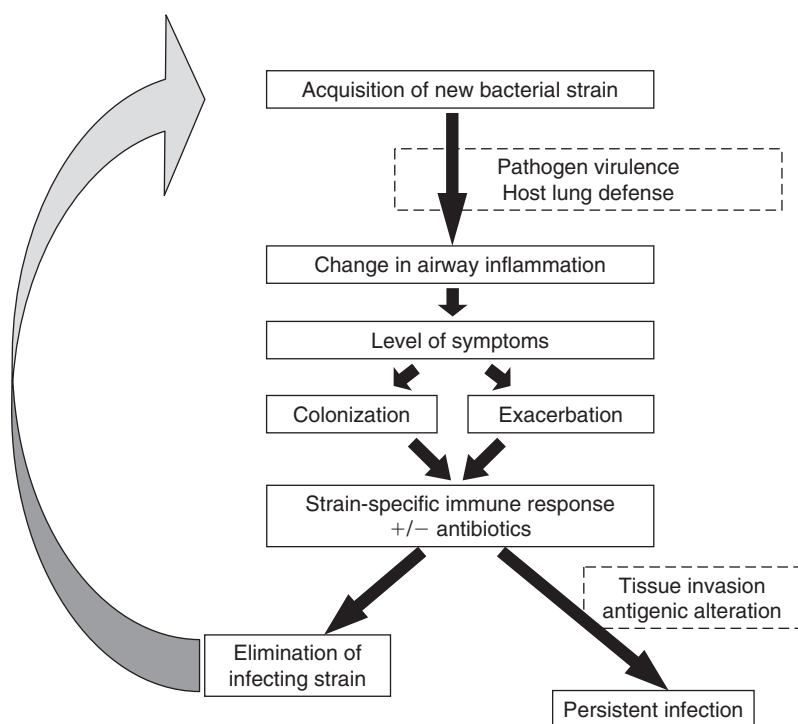

**FIG. 53.1** Proposed model of bacterial exacerbation pathogenesis in COPD. Reproduced with permission from Ref. [43].

infections. *In vitro*, viruses can damage airway epithelium, stimulate muscarinic receptors, and induce eosinophil and neutrophil influx [44]. Whether these pro-inflammatory actions are enhanced in epithelial cells from patients with COPD is not known. Bronchial epithelial cells obtained from patients with asthma have diminished production of interferons and increased ICAM-1 expression, changes which could result in increased inflammation, cell lysis, and viral replication on viral infection. Increased ICAM-1 expression in COPD bronchial epithelium has been seen, however the other changes have not been described.

## GOALS OF TREATMENT OF EXACERBATIONS

The traditional aims of treatment of an exacerbation are improvement in clinical status and the prevention of complications. Though undoubtedly important, several new observations question the adequacy of these goals. These include the importance of exacerbations in the course of COPD, the role of infection in exacerbations, the high rates of relapse with an adequate initial clinical response, and the potential damaging effects of chronic colonization in COPD. To draw an analogy, confining our goal in the treatment of COPD exacerbations to short-term resolution of symptoms would be the equivalent of treating acute myocardial infarction with the only aim being resolution of chest pain. Several other goals of treatment, both clinical and biological, should therefore be considered (Table 53.4).

A good example of an inadequate goal in the treatment of exacerbations is "clinical success," which is defined as resolution or improvement of symptoms to a degree that no further treatment is required in the opinion of the treating physician. Recent observations have shown that symptoms of an exacerbation are correlated with exaggerated airway and systemic inflammation. Hence, acceptance of clinical improvement as adequate rather than clinical resolution to baseline has important implications. Clinical improvement likely reflects inadequate treatment, permitting the inflammatory process accompanying the exacerbation to persist for prolonged periods of time, causing progressive airway damage [45]. Therefore, clinical resolution of symptoms to baseline is a more appropriate goal of treatment of exacerbations.

Additional important clinical goals of treatment include delaying the next exacerbation, prevention of early relapse and more rapid resolution of symptoms [46–48]. Lengthening the inter-exacerbation interval and prevention of early relapse ultimately translate to a decrease in the frequency of exacerbations, which is now a major focus of COPD treatment. Though most patients and physicians would accept faster recovery to baseline as a desirable goal of treatment, development of this parameter has been hampered by lack of well-validated instruments to reliably measure exacerbation resolution. Patient reported outcomes in development will address this need in the near future.

Biological goals of treatment are either still in their infancy or, in the case of bacteriologic eradication, inadequately assessed in clinical studies to satisfy regulatory requirements for approval of new antibiotics. Most exacerbations are inflammatory events, therefore it is logical that resolution of inflammation to baseline should be an important goal of treatment. Similarly, exacerbations are in many instances induced by infection, therefore eradication of the offending infectious pathogen should be a goal of treatment. Practical application of these biological goals of treatment of exacerbations awaits the development of biomarkers that provide simple, rapid and reliable measurements of inflammation and infection.

A multi-modality approach to treatment of exacerbations is common, that utilizes several modalities simultaneously, to relieve symptoms, to treat the underlying cause or to provide support till recovery occurs [14, 49]. These therapies include bronchodilators, corticosteroids, antimicrobials,

**TABLE 53.4** Goals of treatment of COPD exacerbation.

| Goals | Comments |
| --- | --- |
| *Clinical* | |
| Faster resolution of symptoms | Needs validated symptom assessment tools |
| Clinical resolution to baseline | Needs baseline assessment prior to exacerbation onset for comparison |
| Prevention of relapse | Relapse within 30 days is quite frequent |
| Increasing exacerbation-free interval | Needs long-term follow-up after treatment |
| Preservation of health-related quality of life | Sustained decrements seen after exacerbations |
| *Biological* | |
| Bacterial eradication | Often presumed in usual antibiotic comparison studies |
| Resolution of airway inflammation | Shown to be incomplete if bacteria persist |
| Resolution of systemic inflammation | Persistence of systemic inflammation predicts early relapse |
| Restoration of lung function to baseline | Incomplete recovery is seen in significant proportion |
| Preservation of lung function | Needs long-term studies |

mucolytics and expectorants and, in the more severe cases, oxygen supplementation and mechanical ventilation for acute respiratory failure.

## ANTIBIOTICS IN THE TREATMENT OF EXACERBATIONS

The role of antibiotics in the treatment of COPD exacerbations has been a matter of controversy. Even more contentious has been the issue whether antibiotic choice is relevant to clinical outcome of exacerbations. Recommendations for antibiotic use among published guidelines are inconsistent [14, 50–52]. There is a paucity of well-designed, large randomized controlled trials with adequate goals of treatment comparing antibiotics to placebo or among antibiotic classes. This paucity of evidence upon which to base solid recommendations has undoubtedly contributed to the controversy and inconsistency of recommendations regarding antibiotic use [53].

Recently, a few well-designed placebo controlled and antibiotic comparison trials have been reported. Furthermore, epidemiologic studies have consistently identified certain "clinical risk factors," which in the setting of an exacerbation are predictive for failure of treatment or early relapse. The clinical outcomes of exacerbation in observational real-life studies are clearly sub-optimal, with as many as 25–33% of patients experiencing treatment failure or early relapse. Considering the heterogeneity of COPD and of exacerbations, it is clear that the "one size fits all" approach of using the same antibiotic in all episodes is sub-optimal. It is likely that a proportion of treatment failures in exacerbations are related to ineffective antibiotics. Patients "at risk" for poor outcome are the logical candidates for aggressive initial antibiotic treatment, with the expectation that such an approach would improve overall exacerbation outcomes. This "risk stratification" approach has also been advocated for other community-acquired infections such as pneumonia and acute sinusitis [23, 54]. Though improved outcomes with such risk stratification has not yet been demonstrated in prospective controlled trials, this approach takes into account concerns of disease heterogeneity, antibiotic resistance and judicious antibiotic use.

### Placebo-controlled antibiotic trials

Exacerbations of COPD result in significant antibiotic consumption, however, there are only a handful of placebo controlled trials in this disease. Two meta-analyses of placebo controlled trials in exacerbations have been published. The first such analysis published in 1995 included nine trials and found a small but significant beneficial effect of antibiotics over placebo [55]. In the second analysis published in 2006, 11 trials were included, and a much larger beneficial effect on mortality and prevention of clinical failure was demonstrated, especially in moderate to severe exacerbations [56]. In this analysis, the number needed to treat in severe exacerbations in hospitalized patients to prevent one death was

only three patients and the number needed to treat to prevent one clinical failure was six patients. Diarrhea was the most frequently related adverse effect, with one episode per seven patients treated. Antibiotic treatment was also beneficial in resolving sputum purulence. A benefit on lung function and gas exchange was not observed, however, the data examining this end point was scanty.

The reason that the two meta-analyses came up with different results is in large part inclusion in the later analysis of a study performed by Nouira et al. published in 2003. In this randomized double blind study, 93 patients with exacerbations of severe underlying COPD requiring ventilator support in an intensive care unit were randomly assigned to receive a fluoroquinolone antibiotic, ofloxacin, or placebo [57]. No systemic corticosteroids were administered. Bacterial pathogens were isolated in tracheobronchial aspirates in 61% of patients. Ofloxacin administration was associated with dramatic benefits compared to placebo, reducing mortality (4% versus 22%) and the need for additional antibiotics (6% versus 35%) by 17.5-fold and 28.4-fold, respectively.

Another important study, which for some reason has not been included in either meta-analysis, was performed in Italy by Allegra et al. and published in 1991. In this double blind randomized trial, amoxicillin/clavulanate was compared with placebo in 414 exacerbations in 369 patients with varying severity of underlying COPD [58]. A unique feature of this study was the measurement of primary outcome at 5 days after the start of treatment, instead of the traditional 2–3 weeks. This earlier timing is clinically of greater relevance than the usual later one, as in clinical practice if patients are not improved within 3–5 days, they are reassessed and their therapy altered. Clinical success (including resolution and improvement) was significantly better with the antibiotic, seen in 86.4% of patients, compared with 50.6% in the placebo arm. In addition, with increasing severity of underlying COPD, the benefit with antibiotics as compared to placebo was larger.

Results of the meta-analyses, the Allegra study, and of the previous classic large placebo-controlled trial conducted by Anthonisen et al., clearly demonstrate that antibiotics are beneficial in the treatment of moderate to severe exacerbations [12, 56–58]. Furthermore, the benefit with antibiotics is more marked early in the course of the exacerbation, suggesting that antibiotics hasten resolution of symptoms [58, 59]. The benefit with antibiotics is also greater as the severity of underlying airflow obstruction increases. This could be related to more frequent bacterial infections and/or a decreased ability of the host in dealing with infections, therefore requiring "help" with antibiotics to resolve them.

Important questions regarding the role of antibiotics in exacerbations still remain. The benefit of antibiotics in mild exacerbations in the context of mild underlying COPD is unproven and warrants a placebo controlled trial. The effect of concomitant treatment with systemic corticosteroids on the benefits of antibiotic therapy in exacerbations is not known. Placebo controlled trials of antibiotics have not systematically regulated concomitant therapy, and all the placebo controlled trials of steroids had antibiotics administered to all patients. Because inflammation and infection are linked, it is likely that there would be additive

benefits when both treatments are used over either treatment alone [56, 60].

## Antibiotic comparison trials

Antibiotics are clearly useful in moderate to severe exacerbations of COPD. However, there remains considerable controversy as to antibiotic choice, especially for initial empiric therapy of exacerbations [14, 50–52, 61]. Most exacerbations nowadays are treated without obtaining sputum bacteriology and with the trend to short course antibiotic therapy, this initial empiric choice often becomes the only choice made of antibiotics in exacerbations. Results of antibiotic comparison trials should guide the recommendations for appropriate empiric antibiotics in exacerbations. However, though the literature is replete with such trials, in the vast majority, antibiotic choice does not apparently affect the clinical outcome. However, differences in bacteriological eradication rates among antibiotics are seen, with a dissociation between clinical and bacteriological outcomes [62]. These results are contrary to expectations that antibiotics with better *in vitro* and *in vivo* antimicrobial efficacy and better pharmacodynamic and pharmacokinetic characteristics should show superior clinical outcomes. A closer examination of the trial design of these studies reveals several shortcomings that offer potential explanations for this paradox (Table 53.5) [53]. Many of these deficiencies are related to the fact that these trials are performed for regulatory approval of the drugs, therefore are designed for demonstrating noninferiority rather than differences between the two antibiotics. In the face of this large body of data showing clinical equivalence, it is not surprising that several guidelines do not differentiate between antibiotics for therapy of exacerbations.

Most antibiotic comparison trials are underpowered to detect differences among antibiotics. However, because of regulatory requirements, these studies are conducted in a very similar manner and in similar patient populations. This makes these trials very amenable to a meta-analytic approach. Dimopoulos *et al.* used such an approach to determine whether there was any difference in clinical outcomes among first-line antibiotics (amoxicillin, ampicillin, pivampicillin, trimethoprim/sulfamethoxazole, and doxycycline) and second-line antibiotics (amoxicillin/clavulanate, macrolides, second-generation or third-generation cephalosporins, and fluoroquinolones) in the treatment of exacerbations of chronic bronchitis [63]. They identified 12 randomized controlled trials that had enrolled 2261 patients, 10 of these trials included the penicillins as the first-line antibiotic. Only a single trial each with trimethoprim/sulfamethoxazole and doxycycline was included. In the clinically evaluable patients, first-line antibiotics were only half as effective as second-line antibiotics with an odds ratio for clinical treatment success of 0.51 (95% CI, 0.34–0.75). This result was consistent in several sensitivity analyses, with the exception of trials published before 1991, where the difference between first line and second line antibiotics was not seen. There was no difference between the first-line and second-line antibiotics in adverse effects.

This meta-analysis provides additional evidence that antibiotic choice does make a difference in the treatment of exacerbations. Similar treatment success for first line and second line antibiotics in trials before 1991 but not after 1991, suggests that resistance emergence in causative bacterial pathogens (*H. influenzae, M. catarrhalis, S. pneumoniae*) is responsible for the findings of this meta-analysis. Because of the limited number of studies in which the first line antibiotics were not penicillins, the results of this meta-analysis mainly applies to the penicillins. Based on this meta-analysis, recommendations to use amoxicillin and ampicillin in the treatment of exacerbations cannot be supported.

These investigators also performed a similar meta-analysis where they compared second-line antibiotics,

**TABLE 53.5** Limitations of published placebo-controlled antibiotic trials in acute exacerbations of COPD.

| Limitation of study design | Potential consequences |
| --- | --- |
| Small number of subjects | Type 2 error |
| Subjects with mild or no underlying COPD included | Diminished overall perceived efficacy of antibiotics |
| Nonbacterial exacerbations included | Type 2 error |
| Endpoints compared at 3 weeks after onset | – Spontaneous resolution mitigates differences between arms<br>– Clinically irrelevant as most decisions about antibiotic efficacy are made earlier |
| Speed of resolution not measured | Clinically relevant endpoint not assessed |
| Lack of long-term follow-up | Time to next exacerbation not assessed |
| Antibiotic resistance to agents with limited *in vitro* antimicrobial efficacy | Diminished overall perceived efficacy of antibiotics |
| Poor penetration of antibiotics used in to respiratory tissues | Diminished overall perceived efficacy of antibiotics |
| Concurrent therapy not controlled | Undetected bias in use of concurrent therapy |

Reproduced with permission from Ref. [53].

the macrolides, the fluoroquinolones and amoxicillin/clavulanate in a similar manner [64]. In this analysis of 19 randomized controlled trials that had enrolled 7405 patients, no differences were found among these agents in clinical treatment success defined in the conventional manner.

In addition to these meta-analyses, welcome additions to the literature on antibiotic treatment of exacerbations are two recent antibiotic comparison trials that were designed as superiority studies. They also measured some unconventional but clinically relevant end-points. The GLOBE (Gemifloxacin and Long term Outcome of Bronchitis Exacerbations) trial, a double blind, randomized trial, compared a fluoroquinolone, gemifloxacin, with a macrolide, clarithromycin [65]. End of therapy and long-term outcome assessments were made at the conventional 10–14 day and 28-day time intervals. These assessments, in line with most antibiotic comparison trials, did not demonstrate statistically significant differences in the two arms, with clinical success rates of 85.4% and 84.6% for gemifloxacin and clarithromycin respectively. Also in line with similar studies, bacteriological success, measured as eradication and presumed eradication, was significantly higher with gemifloxacin (86.7%) compared to clarithromycin (73.1%).

Patients with a successful clinical outcome at 28 days were enrolled in a follow-up period for a total of 26 weeks of observation. In this time period, the primary outcomes were the rate of repeat exacerbations, hospitalizations for respiratory disease and health-related quality of life measures. A significantly lower rate of repeat exacerbations was observed with gemifloxacin, with 71% of the patients remaining exacerbation free at 26 weeks compared to 58.5% in the clarithromycin arm. The relative risk reduction for recurrence of exacerbation was 30%. The rate of hospitalization for respiratory tract illness in the 26 weeks was also lower in the gemifloxacin treated than in the clarithromycin treated patients (2.3% versus 6.3%, $p = 0.059$) [65]. Patients who remained free of recurrence in the 26-week period regained more of their health-related quality of life than those who had a recurrent exacerbation [6]. This trial clearly demonstrates that conventional medium-term clinical outcomes are unsuitable for measuring differences among antibiotics in exacerbations. If the 26-week follow-up period had not been included in the GLOBE study, significant differences in the two treatment arms in clinically relevant outcomes of recurrence of exacerbations and respiratory related hospitalization would have been missed.

The MOSAIC trial is another recent landmark antibiotic comparison trial in exacerbations of COPD. Patients in this study were randomized to a fluoroquinolone, moxifloxacin or to standard therapy (which could be one of the following: amoxicillin, cefuroxime or clarithromycin) [66]. Several unique design features of this trial are noteworthy, which relate to observations made in this study and set the standard for future antibiotic comparison trials in this disease. The number of patients enrolled was much larger than previous studies, in order to provide adequate power to demonstrate superiority. Patients were enrolled when stable to establish a baseline as a comparison to reliably distinguish between clinical improvement (enough improvement that no additional antibiotic treatment is required) from clinical cure (improvement of symptoms

to baseline) following treatment. A substantial proportion of the patients enrolled had one or more risk factors that would predispose to a poor outcome as discussed below. Patients were followed up to 9 months after randomization to provide an estimate of recurrence of exacerbation.

In line with usual antibiotic comparison trials, moxifloxacin and standard therapy were equivalent (88% versus 83%) for clinical success (resolution and improvement) at 7–10 days after the end of therapy. However, moxifloxacin therapy was associated with a superior clinical cure rate (defined as resolution of symptoms to baseline, rather than simply improvement) than standard therapy (71% versus 63%), as well as with superior bacteriologic response (91.5% versus 81%). Several other *a priori* unconventional end-points were examined. Moxifloxacin treatment resulted in significantly fewer courses of additional antibiotic therapy (8% versus 14%) and an extended time to the next exacerbation (131 versus 104 days) [66]. A composite end-point of clinical failure, requirement of additional antibiotics and recurrence of exacerbation demonstrated a clear difference between the two arms, with moxifloxacin being statistically superior to standard therapy for up to 5 months of follow-up. As with the GLOBE trial, if conventional clinical success would have been measured solely in this study, all the other significant differences in the two arms would have not been discovered.

The GLOBE and MOSAIC trials demonstrate that *in vitro* microbiological superiority as well as the enhanced pharmacokinetic/pharmacodynamic properties in the respiratory tract of the fluoroquinolones does translate to greater *in vivo* effectiveness in the treatment of exacerbation. Antibiotics for exacerbation have very similar results for the standard regulatory end-point of clinical success at 7–14 days after the end of therapy. This standard end-point not only lacks discriminatory power, it also has little clinical relevance. Most decisions about antibiotic benefit in the clinical setting are made within the 1st week of therapy. Differences among antibiotics are perceptible when clinically relevant end-points such as speed of resolution, clinical cure, need for additional antimicrobials and time to next exacerbation are considered [65, 66].

## RISK STRATIFICATION OF PATIENTS

Fluoroquinolones are excellent antimicrobials for exacerbations, and based on the MOSAIC and GLOBE studies, it is tempting to prescribe them for all moderate to severe exacerbations. Such a strategy, though likely to be successful in the short-term, would foster antimicrobial resistance to these valuable antibiotics in the long term. Therefore, it would be judicious to make an effort to identify those patients and exacerbations that are most likely to benefit from these antibiotics and use them in those circumstances.

Observational real life studies of the outcome of exacerbations in the community have clearly demonstrated that our current treatment approach is sub-optimal. In these studies, treatment failure rates, either defined as failure to improve or relapse within 30 days of 25–33% are seen

[67, 68]. These studies have also demonstrated that certain patient characteristics that antedate the onset of the exacerbation impact the outcome of the exacerbation [48, 67–71]. Interestingly, several of these characteristics, such as co-morbid cardiac disease and frequent exacerbations, were found to be relevant to outcome in more than one study. These risk factors for poor outcome should be considered in the decision regarding choice of empiric antibiotics when treating exacerbations. In theory, patients at risk for poor outcome would have the greatest benefit from early aggressive antibiotic therapy, such as with the fluoroquinolones. These are the patients in whom the consequences of treatment with an antibiotic ineffective against the pathogen causing the exacerbation are likely to be significant, with clinical failures, hospitalizations and early recurrences likely. These at risk patients contribute substantially to the overall poor clinical outcomes of exacerbations. Therefore, targeting these patients with potentially more effective treatment is likely to have a significant impact on the overall outcomes of exacerbations.

Risk factors for poor outcome identified in various studies are increasing age, severity of underlying airway obstruction, presence of co-morbid illnesses (especially cardiac disease), a history of recurrent exacerbations, use of home oxygen, use of chronic steroids, hypercapnia and acute bronchodilator use [48, 67–71]. It is likely that home oxygen use, hypercapnia and chronic steroid use mainly reflect increasing severity of underlying COPD. Acute bronchodilator use could either be related to the severity of underlying COPD or reflect the wheezy phenotype of exacerbation that would be less responsive to antibiotic treatment. Many of these risk factors are continuous in severity, however, certain thresholds have been defined in studies that are clinically useful and predictive of poor outcome and easier to use clinically. These include an age of more than 65 years, forced expiratory volume in 1 s ($FEV_1$) <50%, and >3 exacerbations in the previous 12 months.

Another important consideration in choosing antibiotics for exacerbation is recent antibiotic use, especially within the past 3 months. Because of the recurrent nature of exacerbation and the high prevalence of co-morbid conditions in COPD, such antibiotic exposure is likely to be prevalent in COPD patients. In other respiratory infections such as pneumonia, recent antibiotic use leads to increased risk for harboring antibiotic resistant pathogens and therefore having a poor outcome following treatment. This phenomenon has been best described for *S. pneumoniae* among patients with community acquired pneumococcal pneumonia and recently also described for this pathogen among patients with COPD [72, 73]. Whether such selection for antibiotic resistant strains occurs among NTHI and *M. catarrhalis* after antibiotic exposure is not known, but is possible.

## RISK STRATIFICATION APPROACH TO ANTIBIOTIC THERAPY IN ACUTE EXACERBATION

A risk stratification approach has been advocated by several experts for the initial empiric antibiotic treatment of exacerbations based on the risk factors discussed above as well as the *in vitro* and *in vivo* efficacy of antibiotics. Our current treatment algorithm is shown in Fig. 53.2 [14, 51, 61]. Once an exacerbation is diagnosed, the initial step in the algorithm is determination of the severity of the exacerbation. We use the Anthonisen criteria by defining single cardinal symptom exacerbations as mild, while the presence of two or all three of the cardinal symptoms defines moderate and severe exacerbations.

Mild exacerbations are initially managed with symptomatic treatment, including bronchodilators, antitussives and expectorants and antibiotics are with held. However, patients are counseled regarding the cardinal symptoms and if additional symptoms appear, then antibiotics are prescribed. If a moderate to severe exacerbation is diagnosed, the next important step is the differentiation of "uncomplicated" patients from the "complicated" patients. Uncomplicated patients do not have any of the risk factors for poor outcome. Complicated patients have one or more of the following risk factors for poor outcome: Age >65 years, $FEV_1$ < 50%, co-morbid cardiac disease and three or more exacerbations in the previous 12 months [14, 51, 61]. A threshold of four or more exacerbations in the previous 12 months has been used to define frequent exacerbations in previous studies and guidelines. However, current therapy of COPD with long acting bronchodilators and inhaled steroids has reduced overall frequency of exacerbations in this disease by about 25%. Therefore, we use a threshold of three or more exacerbations to define the complicated patient on contemporary COPD treatment.

In uncomplicated patients, antibiotic choices include an advanced macrolide (azithromycin, clarithromycin), a cephalosporin (cefuroxime, cefpodoxime, or cefdinir), doxycycline or trimethoprim/sulfamethoxazole. Amoxicillin (or ampicillin) is not an appropriate choice because of prevalent antibiotic resistance and the results of the meta-analysis discussed above. In complicated patients, our usual antibiotic choice is a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, levofloxacin) with amoxicillin/clavulanate as an alternative.

Other important considerations in choosing antibiotics include exposure to antibiotics within the past 3 months. This exposure history should be elicited not only for respiratory infections, but includes antibiotics prescribed for any indication. The antibiotic chosen to treat the exacerbation should be from a different class of agents from the one prescribed within the past 3 months. For example, exposure to a macrolide in the past 3 months should lead to use of a cephalosporin in an uncomplicated patient. Similarly, prior use of a fluoroquinolone in a complicated patient should lead to use of amoxicillin/clavulanate.

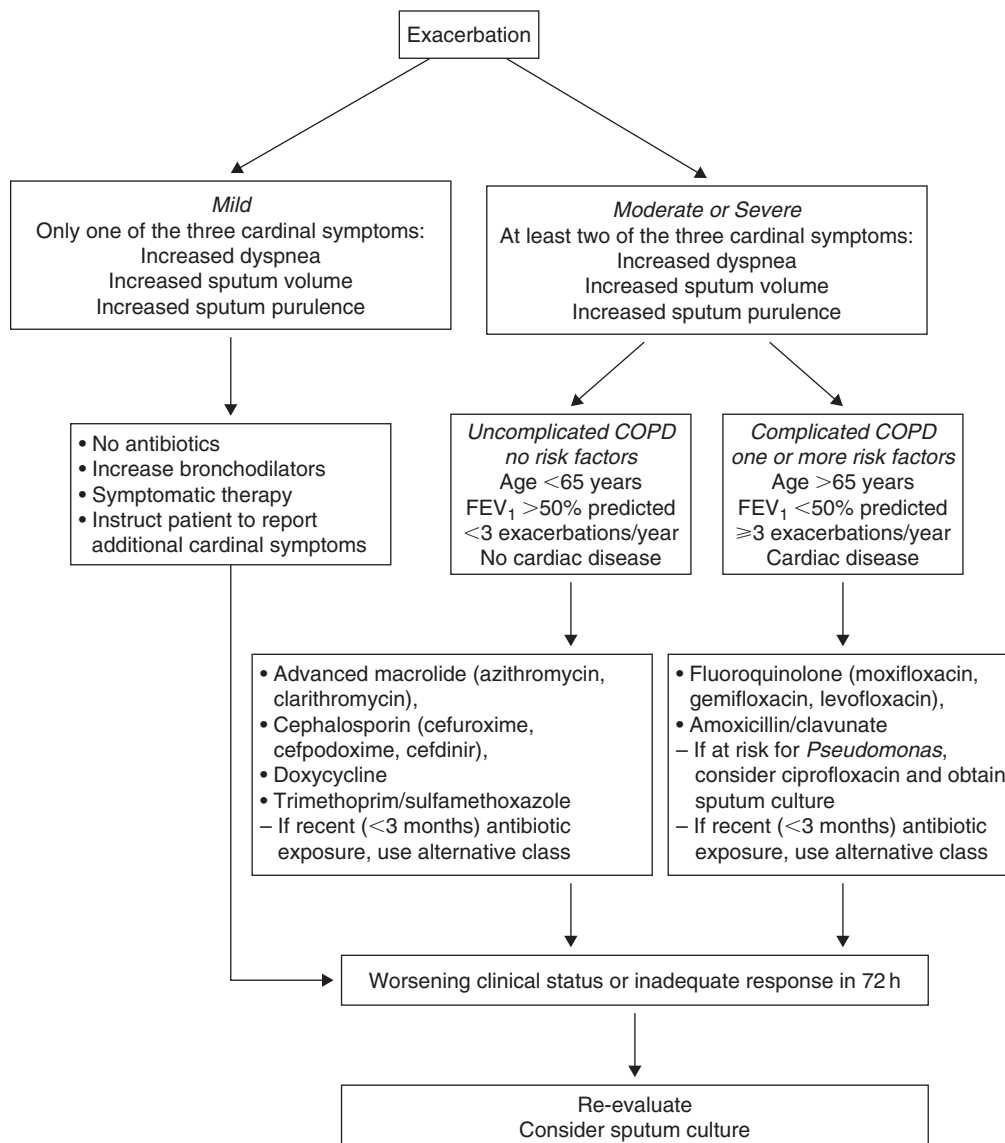
Another important consideration in the complicated patients is a sub-group of these patients who are at risk for infection by *P. aeruginosa* and *Enterobacteriaceae* or have a documented infection by these pathogens [74]. These patients usually have very severe underlying COPD ($FEV_1$ < 35%), have developed bronchiectasis, are hospitalized (often requiring intensive care), or have been recently hospitalized or have received multiple courses of antibiotics. In such patients, empiric treatment with ciprofloxacin is appropriate. However, resistance among *P. aeruginosa* and


FIG. 53.2 Algorithm for antibiotic treatment of acute exacerbations of COPD.

the *Enterobacteriaceae* to the fluoroquinolones may compromise their efficacy. Therefore, in this sub-group of patients, we obtain a sputum (or tracheobronchial aspirate if intubated) culture to allow adjustment of antibiotics based on the *in vitro* susceptibility of pathogens isolated. Unless dictated by poor clinical response and *in vitro* antimicrobial susceptibility, we do not use combination or parenteral antibiotic therapy for *P. aeruginosa* as this approach has never been systematically examined and is of unproven benefit in exacerbations.

We instruct our patients to report to us any deterioration or lack of improvement at 48–72 h, because in this time frame clinical improvement should be apparent. In these patients who are failing initial empiric antimicrobial therapy, we re-examine the patient to confirm the diagnosis, consider sputum studies to ascertain for resistant or difficult

to treat pathogens and treat with an alternative agent with better *in vitro* microbiological efficacy.

## ALTERNATIVE APPROACHES TO ANTIBIOTIC THERAPY IN ACUTE EXACERBATION

Patients with COPD exacerbation often experience a change in the color of sputum from white or gray (mucoid) to yellow, green or brown (purulent). Purulence of sputum is related to the presence of myeloperoxidase, a product of neutrophil degranulation. Neutrophil degranulation is associated with bacterial infection, therefore sputum purulence
**FIG. 53.3** Receiver operating characteristic (ROC) curve for distinguishing new bacterial strain exacerbations from exacerbations without new strains with levels of sputum TNF-α, sputum NE, and serum CRP at exacerbation included in the prediction model. The predictive values for each of the mediators in this model were sputum TNF-α: 0.32 ng/ml; sputum NE: 0.76nM; and serum CRP: 2.37 mg/l. AUC: Area under the ROC. Reproduced with permission from Ref. [18].

at exacerbation is a marker of bacterial infection, defined by quantitative cultures of sputum and bronchoscopic protected brush specimens [75, 76]. Presence of sputum purulence has been advocated as the sole determinant for antibiotic treatment of exacerbations. However, its accuracy and reproducibility as an indicator of bacterial infection is limited, and is likely to be even more so in clinical practice than in research studies [75, 76]. Often, patients have purulent sputum production even when stable, have intermittent purulent sputum production during exacerbation, or have not have observed the sputum color. Sputum purulence is one of the cardinal Anthonisen criteria, and we recommend it should be used in conjunction with other symptoms and other measures of risk stratification in antibiotic treatment of exacerbations (Fig 53.2).

Utilization of biomarkers to rapidly identify bacterial exacerbations and to guide antibiotic use is another potential approach in exacerbations. Several potential biomarkers have been identified in sputum and serum. The best studied biomarker of bacterial infection is serum procalcitonin level. In a recent study in patients hospitalized for exacerbations, antibiotic treatment was only recommended if the procalcitonin level was above a certain threshold. There was no difference in outcomes in spite of reduction in antibiotic use from 72% to 40% with procalcitonin guidance [77]. However, this approach needs to be validated in multi-center trials with varied populations before widespread application [78]. Furthermore, it needs to be tested in outpatients which represent the majority of exacerbations treated, where patients are not as closely supervised and other supportive care is less rigorous. Only a minority of patients received a fluoroquinolone in this study, which should have been the antibiotics of choice in these complicated patients. Therefore, the lack of effect of withholding antibiotics could have been related to their relative inefficacy in the first place. In this study, short-term goals as well

as biologic goals of bacterial eradication and inflammation reduction as discussed above were also not recorded.

Other biomarkers that have been explored in COPD exacerbations include sputum TNF-α and NE and CRP (Fig. 53.3). Though individually they do not appear to discriminate between exacerbations, a combination of these parameters reliably distinguishes well-characterized bacterial exacerbations from others [18]. Additional studies are required to confirm and extend these observations.

Other important considerations in antibiotic prescribing are safety and tolerability of the agent, drug interactions and cost of treatment. It is important that cost of the antibiotic not be considered in isolation. Miravittles *et al.* have shown that exacerbations in which initial empiric treatment fails cost 10 times more than clinical successes [79]. The investigators estimated that the overall cost of care could be reduced by half with reduction in clinical failure rates by a third. Though not shown as yet in properly designed studies, it is likely that an appropriate and logical approach to antibiotic choice, as discussed above, would reduce clinical failure rates in exacerbations.

# Long-Term Oxygen Therapy

**Bartolome R. Celli**

**Division of Pulmonary and Critical Care,
Caritas St. Elizabeth's Medical Center,
Tufts University, Boston, MA, USA**

The use of oxygen as a therapeutic agent is generally thought to have began in the 1920s [1]. Since then, much has been learned about the effects of oxygen and many methods of delivery have been developed. In this chapter, we will review the known effects of chronic oxygen therapy, its indications, and the various delivery systems now available.

## PATHOPHYSIOLOGY OF OXYGENATION

To understand the scientific rationale and guidelines concerning oxygen therapy, it is necessary to know about the physiology of gas exchange, transportation of oxygen to tissues, and the consequences of tissue hypoxia. Hypoxemia is defined as an abnormally low arterial oxygen tension $P_aO_2$. The physiologic causes of hypoxemia include a low inspired partial pressure of oxygen ($F_iO_2$), abnormal ventilation–perfusion relationship ($\dot{V}/\dot{Q}$ mismatch), decreased diffusion capacity, alveolar hypoventilation, and right to left shunt. Oxygen therapy increases the $F_iO_2$ and is the primary treatment for hypoxemia resulting from the first three causes. The hypoxemia of alveolar hypoventilation is best treated by increased ventilation while a true shunt is by definition unresponsive to hyperoxia.

Oxygen delivery ($DO_2$) to the tissues is dependent upon the arterial oxygen content ($C_aO_2$) and the cardiac output ($\dot{Q}_t$) as illustrated by the following equation:

$$DO_2 = C_aO_2 \times \dot{Q}_t \qquad (54.1)$$

Arterial oxygen content is further determined by

$$C_aO_2 = (\text{Hgb} \times 1.39 \times \%\,\text{sat}/100) + (0.003 \times P_aO_2)$$

where Hgb is blood hemoglobin concentration in g/100 ml, 1.39 is the maximum amount of oxygen (ml) that can combine with 1 g of hemoglobin, % sat is the amount of oxygen combined with hemoglobin divided by the maximal amount possible, 0.003 is the amount of oxygen (ml) soluble in 100 ml of blood per torr $P_aO_2$ in the absence of Hgb, and $P_aO_2$ is the partial pressure of oxygen in arterial blood. Tissue hypoxia occurs when the amount of oxygen present cannot meet the metabolic needs. Inadequate oxygen transport is dependent upon any of the above factors and is the most common cause of tissue hypoxia. However, decreased oxygen utilization is another possible cause of hypoxia. This is demonstrated by shunting at the capillary level in sepsis or more dramatically by mitochondrial poisoning secondary to certain substances such as cyanide.

The physiologic response to acute hypoxemia is to maintain oxygen transport (Fig. 54.1). At a $P_aO_2$ below 55, ventilatory drive increases rapidly leading to a higher arterial $P_aO_2$ and hypocapnia. Vascular beds supplying hypoxic tissue vasodilate, resulting in tachycardia, increased cardiac output, and oxygen delivery. The lung responds to hypoxemia by vasoconstriction to increase ventilation–perfusion matching and the $P_aO_2$. Subsequently, secretion of erythropoietin results in erythrocytosis and improved oxygen carrying capacity. These adaptations improve oxygen delivery. Unfortunately, the short-term benefit of these responses may have a detrimental long-term effect. Prolonged pulmonary

vasoconstriction and increased cardiac output can result in pulmonary hypertension (PH), right ventricular failure, and decreased survival [2–5]. In addition, the increased minute ventilation and increased oxygen cost of breathing ($O_2$ COB) may contribute to chronic malnutrition [6]. To interrupt this sequence of events, oxygen therapy has become important in hypoxemic patients [4, 5, 7, 8]. We shall review what is known about the long-term effects of oxygen therapy with particular attention to COPD because this is the only disease in which chronic oxygen therapy has been studied in detail (Table 54.1).

## Survival

Although the cause of death in patients with hypoxic cor pulmonale is uncertain, the factors predicting survival in patients on long-term oxygen have been investigated. In general, variables reflecting worse severity of COPD, such as reduction of $P_aO_2$ or increased $PCO_2$, [6–9] lower $FEV_1$ [6, 9], and elevated mean pulmonary artery pressure (PAP) [9], correlate with survival. On the other hand, the effect of transient hypoxemia measured by oxygen desaturation appears to have limited impact on survival [10]. In the most hypoxemic patients as determined by arterial hypoxemia, the most important evidence supporting the use of chronic oxygen has been derived from studies investigating its effect on survival [11].

In 1970, Neff and Petty [12] found a 30–40% decrease in mortality in their severely hypoxic patients on continuous oxygen when they were compared with those in the literature. Subsequently, two large controlled trials studied the effect of oxygen on survival in COPD [4, 5]. The British Medical Research Council Study randomized patients to 15 h of continuous oxygen each day compared with no oxygen. During the 5-year follow-up, 19 of 42 oxygen therapy patients compared with 30 of 45 controls died. The Nocturnal Oxygen Therapy Trial (NOTT) randomly assigned patients to either 12 or 24 h of oxygen per day. After 26 months, the mortality of the continuous group (mean 19 h/day) was one-half that of the 12-h group. Taken together, these studies found survival to improve proportionally to the number of hours of supplemental oxygen per day. As a result, the current recommendation for hypoxemic patients ($P_aO_2 < 55$ mm Hg or $S_aO_2 < 88\%$) is continuous 24 h/day oxygen therapy. In addition, patients with a $P_aO_2$ of 55–59 mm Hg or a $S_aO_2 < 89\%$ in the presence of cor pulmonale or polycythemia also qualify for long-term

continuous oxygen. The findings of these trials have been confirmed in the routine clinical setting [13].

Because of the lifestyle changes and economic implications of chronic oxygen therapy, patients must meet certain criteria for longer-term prescription. First, patients must be stable, on optimal medical therapy and not smoking. In addition, patients must be observed for at least 3 months to document persistent hypoxemia requiring long-term oxygen. During both the NOTT study [4] and a multicenter French study [14], approximately 40% of patients had improved enough after 1 month to no longer qualify for chronic oxygen. Consequently, patients should be reassessed 1–3 months after initiation of oxygen therapy to determine continued need for its use.

## Pulmonary hemodynamics

Although the reason for increased survival with oxygen is not clear, there is evidence that $O_2$ can improve pulmonary hemodynamics and lead to reduced cardiac work and greater oxygen delivery. Initially, uncontrolled studies in hypoxemic patients suggested that continuous oxygen for 6–8 weeks could reduce pulmonary artery hypertension (PAH) [15, 16]. Subsequently, however, the controlled NOTT and MRC studies revealed no definite hemodynamic improvement [4, 5]. In the MRC trial, the mean PAP remained stable in patients receiving oxygen 15 h/day, but increased significantly in the control group. In NOTT, there was only a slight decrease in pulmonary vascular resistance (PVR) after 6 months on continuous oxygen while the nocturnal oxygen group had a minimal increase in PVR. However, the results of both these studies may have been flawed by the fact that each was devoted mainly to prognosis, follow-up was short, and not all patients were evaluated.

Some studies have specifically examined the effect of oxygen therapy on PAH. Weitzenblum and colleagues [3] performed right heart catheterizations on an average of 41 months prior to oxygen, just before starting oxygen, and 31 months after oxygen in 16 severely hypoxemic COPD patients on oxygen therapy. Before oxygen therapy, there was a mean yearly increase in PAP of $1.47 \pm 2.3$ mm Hg. Following oxygen, PH improved in 12 of 16 patients as demonstrated by an annual decrease in PAP of $2.15 \pm 4.4$ mm Hg. Complete normalization of PAP rarely occurred, but the changes in PAP were related to differences in PVR.

Further analysis of the NOTT data showed that the continuous oxygen therapy group had significant improvements in resting and exercise mean PAP, PVR, and stroke volume index after 6 months [2]. In addition, the nocturnal oxygen therapy group showed stable hemodynamic variables. However, the absolute differences between the two groups were not significant. Despite this, the authors suggested that further follow-up may show hemodynamic improvement as a factor altering the longevity between the two groups. One investigator has suggested that the reason continuous oxygen therapy improves survival may be due to the detrimental effect of oxygen withdrawal from patients on long-term therapy [16]. Selinger and colleagues [17] showed that removal of oxygen caused a 31% increase in PVR index coupled with a decrease in stroke volume index

and oxygen delivery. They propose that the effect of recurrent oxygen withdrawal may be responsible for the worse prognosis of intermittent oxygen therapy.

In the longest of all the observational therapeutical oxygen trials, Zelinski and coworkers [7] evaluated pulmonary hemodynamics at 2-year intervals for 6 years in a group of 12 patients with hypoxemic COPD. The PAP which was $27 \pm 7$ torr at entry, decreased to $21 \pm 4$ at 2 years, to then return to stable values of $26 \pm 7$ and $26 \pm 6$ torr at 4 and 6 years, respectively. This was observed in spite of further deterioration of gas exchange with worsening of room air $P_aO_2$ and $P_aCO_2$. This study lends support to the concept that oxygen supplementation to hypoxemic patients halts progression of PAH.

Many patients continue to worsen despite long-term oxygen. Early identification of those patients who are unlikely to benefit from oxygen would avoid the cost and inconvenience of oxygen in these patients. As a result, various investigators have attempted to correlate an acute hemodynamic response to oxygen with long-term survival. In most studies, acute oxygen delivery (30 min to 24 h) decreases the PAP in a minority of patients [2, 18, 19]. Conversely, others have shown 28% oxygen to reduce PAP >5 mm Hg in greater than half of their patients [20, 21] and this acute response to oxygen predicted 2-year survival in patients with COPD and cor pulmonale [22]. However, Sliwinski *et al.* [19] have found little correlation between acute response to oxygen and long-term survival. They propose that the difference in results of these studies may be attributable to the lack of a pre-entry period in Ashutosh's study, which may have allowed inclusion of patients who were not stable. Consequently, these patients may have had acute hypoxic vasoconstriction superimposed upon the more irreversible anatomic changes. In their study, responders had lower mean PAP (26 mm Hg) after oxygen compared with the nonresponders (33 mm Hg) suggesting they could have had less severe baseline PH which might have accounted for their better prognosis.

Patients who have an acute hemodynamic response to oxygen may have structural differences in their pulmonary vasculature as compared with those who do not improve. However, an autopsy study examining the pulmonary arteries of patients who died during the NOTT study found no difference in the vascular structure of those who responded to oxygen and those who did not [23]. In addition, these authors found structural alterations of the muscular pulmonary arteries in patients with PAH secondary to COPD, but these changes did not correlate with the degree of PAH.

Because determination of PAP is invasive, noninvasive methods have been assessed to predict response to oxygen therapy. Ashutosh and Dunsky [21] studied exercise $\dot{V}O_2$ max and found a $\dot{V}O_2$ max >6.5 ml/min/kg to predict a fall in PAP >5 mm Hg and 3-year survival on oxygen. Attempts to show an acute or chronic benefit of oxygen on RVEF (right ventricular ejection fraction) [24, 25], and a change in RVEF on oxygen to predict a change in PAP [21, 25] or survival [21] have been disappointing. Therefore, the response of RVEF to oxygen does not appear to predict a beneficial effect of this therapy.

The possibility that long-term oxygen therapy could benefit patients with a lesser degree of resting hypoxemia

($P_aO_2$ between 56 and 69 torr) was explored by Gorecka *et al.* [26]. They prospectively evaluated patients with moderate hypoxemia and observed no difference in mortality between treated and untreated patients. This lack of beneficial effect is further highlighted by the multicenter trial reported by Chaouet and coworkers [27] who after 2 years of therapy observed no effect on survival or pulmonary artery hemodynamics in a cohort of moderate hypoxemic patients randomized to supplemental oxygen or routine therapy.

Most of the studies evaluating oxygenation and survival have centered on the actual value of $P_aO_2$ and to some degree on the oxygen saturation. Recent evidence shows that the level of hemoglobin may be as important in predicting outcome in patients with COPD. The long held belief that most patients with COPD develop compensatory polycythemia has proven to not be the case as those large series show that anemia is highly prevalent in those patients and is associated not only with decreased exercise capacity but also with impaired survival [28, 29].

In summary, long-term oxygen has beneficial effects on survival and PH in patients with COPD and significant hypoxemia. Currently, most studies do not support the ability of acute hemodynamic response to oxygen measured either invasively or noninvasively to predict improvements in PAP, pulmonary vascular changes, or survival. Therefore, long-term oxygen is currently administered to all significantly hypoxemic patients ($P_aO_2 \leq 55$ torr), since some benefit cannot be ruled out and other therapeutic options are limited. There is no evidence to support the administration of long-term oxygen therapy to patients with mild or transitory hypoxemia. The value of correcting the hemoglobin in patients with COPD and anemia has not been explored.

## Exercise

Ventilatory, rather than circulatory, factors limit maximum exercise performance in most patients with COPD. Performance is most closely related to airflow limitation [30]. Other investigators have suggested that the ventilatory muscles may contribute to exercise limitation in COPD [31, 32]. The process involves hyperinflation secondary to inability to exhale trapped air which in turn leads to more inspiratory muscle dysfunction at an unfavorable length. This muscles have to generate pressures, which are close to their maximum capacity and this may lead to fatigue as well as a lack of appropriate mechanical response to the increased central drive [33]. The resulting dyspnea leads to premature termination of exercise.

Oxygen therapy has been shown to improve exercise endurance in many studies. Various investigators have found oxygen to increase with distance walked [34, 35], time on a treadmill [36, 37], and time on a cycle ergometer [38, 39]. The precise mechanisms resulting in improvement are unknown [40], but a number have been suggested. In hypoxemic patients and those who desaturate with exercise, oxygen therapy results in greater oxygen delivery and utilization by exercising muscles [41–45]. However, increased oxygen saturation is not always predictive of improved exercise performance [37, 38] and other factors may contribute to this. Some studies have shown oxygen to reduce minute ventilation and respiratory rate for a given workload [35, 38]. Indeed, van Helvoort and colleagues have shown that administration of supplemental oxygen to patients with COPD even if the levels of oxygen are not critical may ameliorate the generation of oxidative stress and inflammatory burst observed during exercise in these patients [46].

Oxygen has been found to improve ventilatory muscle function during exercise, by postponing the onset of fatigue as demonstrated by a delay in the appearance of abdominal paradox and a slower fall in the high to low frequency of the diaphragm electromyogram power spectral density [38]. Criner and Celli [47] found that exercising COPD patients with oxygen resulted in the diaphragm performing more ventilatory work which may prevent overloading of the accessory muscles and contribute to the decrease in dyspnea. Finally, others have suggested that supplemental oxygen may decrease dyspnea and improve endurance by directly reducing chemoreceptor activity from the carotid body [39, 48]. Currently, qualification for oxygen during exercise requires documentation of a $P_aO_2$ less than or equal to 55 mm Hg or an $S_aO_2 < 88$ [49, 50]. A helpful clue to predicting which patients will desaturate with exercise is the diffusing capacity. Owens and colleagues [51] found a diffusing capacity above 55% predicted to be 100% specific in excluding desaturation.

## Oxygen cost of ventilation

Beyond the effect of oxygen on arterial $P_aO_2$, there is evidence that oxygen may improve dyspnea by decreasing airway resistance and work of breathing (WOB). Astin and Penman [52] studied 18 COPD patients and found a significant association between airway resistance and $P_aO_2$. Administration of 30% oxygen for 20 min to these patients resulted in an average reduction of airway resistance of 20%. Subsequently, it was also found that 30% oxygen improved flow rates in mildly hypoxemic patients (mean $P_aO_2 = 61$ torr) [53]. Furthermore, atropine caused a similar increase in flow rates that aborted the effect of oxygen. This led the authors to conclude that hypoxemia-related bronchoconstriction may be mediated by vagal tone as had been previously suggested [52, 54].

In addition to its effects on airways resistance, oxygen via a face mask or transtracheal flow in patients with COPD has also been found to decrease minute ventilation [55, 56]. As a consequence of these effects, oxygen may lead to a decrease in the WOB or the $O_2$ COB and thereby improve dyspnea. Astin [57] studied the effect of 30% oxygen on 15 patients with COPD and found a decrease in WOB in 10 patients and an increase in 5 patients. Mannix *et al.* [58] calculated the COB induced by breathing 7% carbon dioxide. They found 30% oxygen to decrease the $O_2$ COB by 42% in both COPD patients and controls. In the COPD patients, the decrease in $O_2$ COB was only due to a smaller increment in $VO_2$ for a given level of ventilation, while controls had both a lower $VO_2$ and a VE. They concluded that supplemental oxygen decreases the $O_2$ demand of the respiratory muscles. Benditt and coworkers [59] observed a decrease in the oxygen cost of breathing with both transtracheal air and oxygen, but the effect was greater

with oxygen. Because most patients receive long-term oxygen by a nasal cannula, the effect of nasal flow oxygen on the oxygen cost of breathing was recently assessed [60]. At high flows ($O_2$ 5 l/min), oxygen significantly decreased the $O_2$ COB while compressed air did not. These initial studies have been recently confirmed with a study that shows that in a dose-dependent ways, supplemental oxygen decreases breathing frequency and dynamic hyperinflation thereby decreasing WOB [61]. The same group has shown that the administration of oxygen may help better train patients undergoing pulmonary rehabilitation [62].

In summary, there is overwhelming evidence that supplemental oxygen increases exercise capacity in hypoxemic patients with COPD and the effect may occur even in patients with mild hypoxemia. The long-term impact of this effect is less clear.

## Neuropsychologic effects

Beginning in the 1930s and 1940s, aviation research demonstrated the acute effects of mild to severe hypoxia on healthy young men [63]. These studies found that even mild hypoxia ($P_aO_2$ 45–60) could impair judgment, learning, and short-term memory in normal subjects. To investigate the effects of chronic hypoxia, research has focused on the neurobehavioral effects of hypoxemia in patients with COPD.

Early work by Krop and colleagues [64] demonstrated poorer neuropsychologic performance in a group of COPD patients with a $P_aO_2$ < 55 mm Hg. Administration of continuous oxygen at 2 l/min by nasal cannula for 4 weeks resulted in significant improvement in 8 of 10 neuropsychologic tests. Because this study and another [65] only looked at a small group of patients without a stabilization period, two large multicenter studies in the United States and Canada examined the neuropsychologic consequences of hypoxemia [66, 67]. The US NOTT studied 203 patients with a mean age of 64 years and $P_aO_2$ of 51 torr and found that 42% of patients had moderate to severe impairment of cerebral function [66]. The Canadian IPPB Trial examined 100 patients with less hypoxia (mean $P_aO_2$ 66 torr) which resulted in more selective impairments [67]. The results of both these studies were combined, demonstrating an increase in the rate of deficits from 27% in mild hypoxemia ($P_aO_2$ > 60) to 61% in severe hypoxemia ($P_aO_2$ < 50) [68].

The NOTT study has evaluated the effect of continuous (19 h/day) and nocturnal oxygen on neuropsychologic functioning and life quality in 150 COPD patients. The results show an improvement after 6 months in both groups in general alertness, motor speed, and hand grip [69]. Despite these benefits, patients had no change in emotional status or quality of life. Although improvements after 6 months were no greater on continuous as compared with nocturnal oxygen, a subgroup of patients followed for 12 months showed significantly better neuropsychologic function on continuous oxygen.

The poor neuropsychologic performance in hypoxemic COPD patients has been explained by weakness, fatigue, and depression. However, there is increasing evidence that brain hypoxia itself is responsible for the impaired function. The conventional belief that mild cerebral hypoxia could impair ATP generation and neuron function has been disproved [70]. Some studies suggest that hypoxia can result in reduced synthesis of acetylcholine from labeled precursors [71], which is interesting, since there is growing evidence to support the role of acetylcholine in memory and learning [72].

## Sleep

In the original description of rapid eye movement (REM) sleep in 1953, it was observed that breathing became more variable during this stage of sleep [73]. Subsequently, it was found that decreased chest movement and oxygen saturation occurred in this sleep stage [74]. Other groups also demonstrated worsening hypoxemia and carbon dioxide retention during sleep [75, 76]. Koo and colleagues [77] correlated arterial blood gas tension with sleep stage in COPD patients and found that $P_aO_2$ decreased shortly after sleep from 64 to 58 mm Hg during non-REM sleep. Upon entering REM sleep, $P_aO_2$ fell further to 50 and the $P_aCO_2$ rose from 48 to 58 mm Hg. These findings were later confirmed by many others [78–82].

The mechanisms of hypoxemia during sleep in COPD include hypoventilation, a reduction in functional residual capacity (FRC), and alterations in ventilation perfusion matching [83] The major cause of hypoxemia during REM sleep is hypoventilation, which appears related to rapid shallow breathing [83, 84] and long episodes of hypopneas, but not actual apneas [81]. In addition, both the hypoxic [85, 86] and hypercapnic [87, 88] ventilatory responses are diminished. The cause of REM sleep hypoventilation has not been fully determined, but appears related to altered brain stem function during phasic neuronal activity [89]. During REM sleep, the ribcage contribution to ventilation decreases by 18–34% [90, 91], as a consequence of hypotonia of the intercostal muscles and decreased activity of accessory muscles [92]. This may be particularly important in patients with COPD who greatly depend on accessory muscles for breathing [93, 94]. Though it is generally believed that hypoventilation during REM sleep will result in ventilation–perfusion mismatch [83], its relative importance with regard to REM hypoxemia is unknown. Although some patients with COPD have sleep apnea, there is no evidence that this occurrence is more common than would be expected by chance alone [83].

A few studies have measured pulmonary hemodynamics during sleep in COPD and found an increase in PAP with acute desaturation [95–99]. In addition, some studies support an association between nocturnal desaturation and PH in COPD patients who have a daytime $P_aO_2$ > 60 mm Hg [98, 99]. Both studies found significantly higher PAP in the patients who desaturated as compared with the non-desaturators.

Patients with COPD have poor sleep quality as compared with age-matched controls [100–101] and arousals are frequent during periods of desaturation [102]. Whether oxygen therapy improves sleep quality in hypoxemic patients is debatable, since various studies have shown conflicting results [100, 103]. Some studies have found fewer hypoxemic episodes as well as increased total sleep and REM sleep with oxygen [100, 104].

Although mean nocturnal oxygen saturation ($S_aO_2$) and lowest nocturnal $S_aO_2$ have been found to correlate with survival, one study found these parameters to have no prognostic value over vital capacity or awake $S_aO_2$ [104, 105]. Furthermore, patients with greater nocturnal hypoxemia than would be predicted, had no difference in survival. In addition, the clinical characteristics of patients with COPD who had desaturation during 24 h monitoring were not different from that of patients who did not desaturate during the same period [106]. Fletcher's group retrospectively compared survival in COPD patients with a daytime $P_aO_2 > 60$ mm Hg with and without $O_2$ desaturation at night [107]. They found an improved survival in those patients without nocturnal desaturation. There was also a trend toward improved survival with nocturnal oxygen in those patients who did desaturate at night. These authors attribute the difference in survival in their study and one by Connaughton *et al.* [105] to the worse daytime $P_aO_2$ of the patients in that study (mean $P_aO_2$ 53 ± 10 mm Hg). They proposed that as the disease becomes more advanced, the daytime $S_aO_2$ may become a strong predictor, while sleep $S_aO_2$ correlates less well with survival. However, the recent report by Chaouet *et al.* [10] suggests that oxygen supplementation at night to mildly hypoxemic patients has a limited, if any, beneficial effect in pulmonary hemodynamics or survival.

Presently, patients who are hypoxemic while awake should also be prescribed oxygen during sleep. In addition, patients who are well saturated during wakefulness, but desaturate at night can qualify for oxygen if they have complications attributable to sleep hypoxemia, such as PH, daytime somnolence, or cardiac arrhythmias [50, 108].

Although it seems intuitive that patients who manifest oxygen desaturation during sleep should have a worse prognosis, this has not been confirmed in the few prospectives studies that have been conducted. However, it has been accepted that patients with prolonged destauration at night without sleep apnea as the cause, be provided with supplemental oxygen.

## OXYGEN PRESCRIPTION

Currently, there are strict guidelines for oxygen prescription based upon resting hypoxemia ($P_aO_2 < 55$ mm Hg or $S_aO_2 < 88$) and hypoxemia induced by sleep or exercise (Table 54.2).

Once a patient qualifies for long-term oxygen, prescription requires completion of the Certificate of Medical Necessity for Home Oxygen Therapy form in the United States. This form should be completed before a patient leaves the hospital to ensure inclusion of all information such as patient data, reason for oxygen, blood gases, type of system, and liter flow at rest, exercise, and sleep.

Long-term oxygen administration can be accomplished with:

- oxygen concentrator
- compressed gas
- liquid oxygen.

**TABLE 54.2** Indications for chronic oxygen therapy.

*Continuous oxygen*

Resting $P_aO_2 < 55$ mm Hg or $S_aO_2 \leq 88\%$

Resting $P_aO_2$ 56–59 mm Hg or $S_aO_2 \leq 89\%$ in the presence of the following:

  1 Dependent edema suggesting congestive heart failure

  2 "P" pulmonale on EKG (P wave greater than 3 mm in standard leads II, III, or AVF)

  3 Erythrocythemia (hematocrit ≥56%)

Resting $P_aO_2 \geq 59$ mm Hg or $S_aO_2 \geq 89\%$

  Only reimbursable with additional documentation justifying the oxygen prescription and a summary of more conservative therapy which has failed

*Noncontinuous oxygen*

Must specify the oxygen flow rate and the number of hours/day

  During exercise, $P_aO_2 \leq 55$ mm Hg or an $S_aO_2 \leq 88\%$ with low level exertion

  During sleep, $P_aO_2 \leq 55$ mm Hg or an $S_aO_2$ 88%, with associated complications such as pulmonary hypertension, daytime somnolence, and cardiac arrhythmias

**TABLE 54.3** Modes of oxygen delivery.

| System | Advantages | Disadvantages |
|---|---|---|
| Gas | Low cost | Heavy weight |
| | Wide availability | Difficult to refill |
| | Fair portability | Short supply time |
| Liquid | Light weight | High cost |
| | Very portable | Vendor incompatibility |
| | Easy refill | Pressure venting |
| Concentrator | Low cost | Heavy weight |
| | Good availability | Least portable |

Table 54.3 summarizes the advantages and disadvantages of each mode of therapy comparing weight, cost, portability, ease of refill, and availability. Because home oxygen is supplied under a fixed reimbursement policy regardless of the system used [104], oxygen vendors will attempt to provide the least expensive system.

## Oxygen concentrator

Most patients will require a stationary source of oxygen which is usually provided by an oxygen concentrator. Since concentrators are relatively inexpensive and require less frequent home visits than liquid oxygen, they have become the system of choice for suppliers. These electrically powered devices utilize a molecular sieve to separate oxygen from air resulting in delivery of oxygen to the patient, while nitrogen

is returned to the atmosphere. The typical sieve achieves oxygen purity of 97% at low flows and 94% at higher flows. However, due to their voltage requirement and their weight, they are primarily a fixed source of oxygen. Consequently, patients need either compressed gas or liquid oxygen as an ambulatory source of oxygen. New, more portable devices should improve availability of these units.

## Compressed gas oxygen

Compressed gas oxygen has been provided for many years in high pressure metal or aluminum cylinders. These containers vary in size weighing 90.8, 7.2, 4, and 1.8 kg and provide $O_2$ at 2 l/min flow for 2.4 days, 5.2 h, 2 h and 1.2 h, respectively. The smaller cylinders can be refilled but the process is inefficient and potentially hazardous. The major advantages of compressed gas are its low cost and wide availability. Its disadvantages are the weight of the cylinders, the difficulty in refilling and the short oxygen supply time.

## Liquid oxygen

Liquid oxygen is stored at very cold temperatures which reduces its volume to less than 1% of the volume of atmospheric oxygen. Stationary units weigh 140 lbs and can provide several days of continuous oxygen at 2 l/min flow. There are portable containers weighing as low as 4 lbs that will last for up to 12 h at 2 l/min flow. Compared with compressed gas, an equivalent weight container of liquid oxygen is more portable and easier to refill, its liabilities include a higher cost, manufacturer incompatibility, and the need for pressure relief venting which wastes unused oxygen.

Deciding on which portable system to prescribe depends upon the activity level of the patient. For patients who are more active, liquid oxygen is the ambulatory system of choice since the oxygen lasts longer and the canister is easier to refill and to carry. Lock *et al.* [109] compared liquid and gaseous oxygen and found patients would use liquid oxygen more hours per week (23.5 versus 10 h) and leave their house more hours per week (19.5 versus 15.5 h).

A recently conducted study to evaluate whether portable oxygen improves quality of life has been disappointing with no benefit shown in the largest of them [110].

## OXYGEN ADMINISTRATION DEVICES

## Nasal cannula

Patients with COPD and other chronic lung diseases usually receive continuous flow of oxygen via a nasal cannula. Delivery at a flow of 2 l/min increases the $F_iO_2$ to approximately 27%, which provides an adequate $O_2$ saturation in the majority of patients. Although this method is effective, it is quite inefficient. During the respiratory cycle, alveolar gas exchange is limited to early inhalation which accounts for only one-sixth of the cycle. Conversely, alveolar ventilation

does not occur during late or dead space inspiration and exhalation [111]. Consequently, only oxygen flowing during early inspiration is available to the patient, while the remainder is wasted into the environment. To improve efficiency and mobility, oxygen-conserving devices have been designed to deliver oxygen during early inhalation. These devices include reservoir nasal cannulas, transtracheal catheters, and electronic oxygen demand devices. In general, these three devices each result in oxygen savings of two to four times a conventional nasal cannula. For a more detailed review the reader may refer to Ref. [111].

## Reservoir cannula

The reservoir cannula was the first method of oxygen conservation to be used [111, 112]. This device stores 20 ml of oxygen in a reservoir during expiration and delivers an oxygen bolus at the onset of inspiration. The two available reservoirs are shaped as either a mustache attached to nasal prongs or a pendant placed over the anterior chest wall. The mustache reservoir was developed first, but because of dissatisfaction with its high visible location, the pendant was designed to be hidden by clothing [113]. Although this device has better cosmesis, it is still more noticeable than the standard nasal cannula.

## Electronic demand devices

Electronic demand devices sense the beginning of inspiration and deliver a pulse of oxygen during early inhalation [114, 115]. There are several units available with many similarities and differences. Most devices are relatively inexpensive and have built-in rechargeable batteries and alarms [116]. Some systems can be switched manually from demand to continuous flow [116], while others automatically change to continuous flow if an inspiratory signal is not sensed [117]. Another demand valve is able to maintain constant oxygen delivery by adjusting the pulse size depending on the respiratory rate. A recent comparison of standard nasal cannula, reservoir nasal cannula, and a demand flow device in 15 patients with COPD found no difference in exercise tolerance among the three systems. However, oxygen saturation tended to be lower during the exercise using the demand flow device [118].

## Transtracheal catheters

Transtracheal catheters improve oxygen delivery by bypassing anatomic dead space and utilizing the upper airways as a reservoir during end expiration [119]. Heimlich [120] developed the first catheter after experiments in dogs and demonstrated an increased $P_aO_2$ as a catheter was placed more distally. In addition to increased oxygen savings, other advantages of TTO include its relative inconspicuousness, the lack of nasal, auricular, or facial skin irritation, its infrequent displacement during exercise and sleep [120]. In addition, there are patients with refractory hypoxemia on a nasal cannula that have been successfully oxygenated on TTO [121–124]. Patient acceptance of transtracheal catheters has

been variable with rates ranging from 50% to 96% during 9- to 20-month periods [120–125].

## Complications

Complications of TTO vary depending on the system implemented and whether the acute or late phase of treatment is examined. The most common procedure-related problems include subcutaneous emphysema, bronchospasm, and paroxysmal coughing [123, 126]. Frequently encountered late complications and sequelae include dislodged catheters, stomal infections, and symptomatic mucous balls. Mucous balls result from oxygen drying the sputum and causing it to adhere to the catheter. The greater frequency of mucous balls seen in 10–25% patients with the Scoop catheter (Transtracheal Systems, Denver, CO, USA) appears to be the result of its larger surface area and the presence of side holes which allow accumulation of secretions. Some reports show life threatening [127, 128] and even fatal airway obstruction due to mucous balls [129]. Many other uncommon complications have been described including broken catheter tips, hemoptysis, keloid formation, hoarseness, and cardiac arrhythmias. After an initial burst of enthusiasm, the number of transtracheal earlier initiations has decreased primarily due to the need for continuous supervision and relatively poor long-term compliance.

## OXYGEN AND AIR TRAVEL

Commercial airline travel exposes passengers to hypobaric hypoxia since aircraft cabins are not routinely pressurized to sea level [130]. In patients who have compensated COPD at sea level, lowering the partial pressure of oxygen in the aircraft cabin can produce severe hypoxemia. Physical exertion during the flight can increase the risk of an exacerbation of symptoms. The proportion of patients suffering from complications during air travel is not well known.

Aircraft are usually pressurized to between 5000 and 7000 ft (1500–2100 m). For the preflight evaluation of most patients, clinicians should consider 8000 ft (2438 m) of altitude above sea levels as realistic "worse case scenario."

Preflight assessment can be accomplished with the following elements:

- Estimation of the expected degree of hypoxemia at altitude.
- Identification of comorbid disease conditions.
- Provision of an oxygen prescription if necessary.

Documentation of the recent clinical condition and laboratory tests, particularly if the patient is traveling abroad, and counseling are also desirable elements of the preflight patient care [50, 118].

The two means of estimating the degree of hypoxia at altitude are:

- Hypoxia inhalation test (HIT), which is not performed in many clinical laboratories in the United States and is not recommended for routine use.

- Use of regression formulae. Regression equations offer the opportunity to compare a patient with a group of patients with similar clinical characteristics who have been previously studied during exposure to hypoxia. While regression equations may provide a more physiological basis for the effects of high altitude than the HIT, the regression approach does not assess the individual's susceptibility to the development of symptoms or electrocardiographic changes during hypoxia.

The A-aO$_2$ gradient and the a-AO$_2$ ratio generally have no advantages over regression equations. It is currently recommended that the $P_a$O$_2$ during air travel should be maintained above 50 mm Hg [50]. While 2–31 of oxygen by nasal cannula will replace the inspired oxygen partial pressure lost at 8000 ft compared with sea level, lesser increments of oxygen will maintain the $P_a$O$_2$ above 50 mm Hg in many patients.

COPD patients receiving continuous oxygen at home will require supplementation during air flight. Such patients should receive greater oxygen supplementation during the flight than at sea level. Increments equivalent to 1–2 ls of oxygen by nasal cannula during flight should suffice for most patients. Patients will also require additional oxygen supplementation if the elevation at the destination is significantly greater than at home. The Federal Aviation Administration requires a physician's statement of oxygen need in order for a patient to receive continuous oxygen during flight. There is no uniform airline request form, so each airline must be contacted by the patient to determine what is required. As the airlines do not provide oxygen for ground use in the airline terminal, patients who require continuous oxygen should be advised to make plans for such locations. The American Lung Association provides patient education materials for individuals who travel with oxygen entitled "Airline Travel with Oxygen."

Many ambulatory COPD patients not receiving oxygen at home can tolerate $P$O$_2$ values below 50 mm Hg for brief periods of time without serious consequences. Stable COPD patients without comorbid disease who have previously traveled without incident and who are currently clinically stable compared with their previous air travel, may be advised to travel by air as there is little risk to them.

## SUMMARY

Oxygen therapy has become very important in the treatment of severe COPD. Because long-term oxygen improves survival in hypoxemic COPD, patients with a daytime $P_a$O$_2$ < 55 mm Hg or $S_a$O$_2$ < 88% qualify for continuous oxygen therapy. Other benefits of oxygen include better exercise tolerance, decreased dyspnea, and improvements in neuropsychological performance. In addition, there appear to be beneficial effects on pulmonary hemodynamics, sleep quality, reduced minute ventilation, and WOB. The consequences of exercise induced and nocturnal desaturation are not absolutely known. Clinicians should be aware of air travel-induced hypoxemia in COPD and be able to identify those

who need oxygen in flight. Once a patient meets the criteria for oxygen prescription, the physician must complete the certificate of Medical Necessity Form specifying the indication for oxygen, type of system and liter flow at rest, exercise and sleep. Patients should be reevaluated at 1 to 3 months to document a persistent need for oxygen therapy. Occasionally, patients should be considered for oxygen-conserving devices to decrease oxygen flow, cost and to improve mobility.

# Immunomodulators

**Christopher J. Corrigan**

**Department of Asthma , Allergy and Respiratory Science, Guy's Hospital, London, UK**
**MRC and Asthma UK Centre in Allergic Mechanisms of Asthma King's College London, UK**

## INTRODUCTION: THE CLINICAL NEED

Asthma affects 10% of children and 4% of adults, with an overall prevalence of 6% (3 million patients) in the United Kingdom. Mortality from asthma is relatively low (1680 deaths in the United Kingdom in 1994), but considerable morbidity arises from disease in that minority of patients whose symptoms are inadequately controlled by conventional therapy (inhaled corticosteroid, long-acting $\beta_2$-agonist, leukotriene receptor antagonist) even when optimal delivery has been assured, compliance has been verified and the effects of other exacerbating factors minimized. In these patients oral corticosteroid is often employed, but even then patients may remain symptomatic and become vulnerable to unwanted effects of the therapy. No existing therapy for asthma is preventative, curative, or clearly disease modifying. Estimates from studies of prescribing practice in the United Kingdom [1] suggest that approximately 6% of asthmatics are receiving therapy that would place them at steps 4 or 5 of the British Thoracic Society asthma treatment guidelines. Although in a minority, these patients account for the majority of the costs of asthma care because of their frequent need for physician consultations and emergency and inpatient care. For such patients, new approaches to therapy are urgently required.

In contrast with asthma, chronic obstructive pulmonary disease (COPD), a disease caused largely by cigarette smoking, has a lower prevalence (1% or 600,000 patients, usually 65 or more years of age in the United Kingdom), but a much higher mortality (23,550 deaths in 1994) and considerable morbidity. Once established, the clinical progression of airways obstruction and destruction is relentless. Yet, no existing therapy has been shown to be preventative, curative, or disease modifying.

## IMMUNOMODULATORY THERAPY IN ASTHMA

Asthma is associated with chronic, cell-mediated inflammation of the bronchial mucosa in which eosinophil-active cytokine products of activated T-cells play a prominent role (Fig. 55.1). Evidence suggests that glucocorticoids ameliorate asthma at least partly by inhibiting T-cell activation and cytokine production [2–4]. There has been a great deal of research directed at why T-cells in some asthmatics are relatively resistant to glucocorticoid inhibition, but it will be some time before this research evolves toward new approaches to therapy. In the meantime, other T-cell immunomodulatory agents have been investigated for their possible therapeutic effects in asthma. As many of these agents have potentially serious unwanted effects, attention has generally been focused on those asthmatics who continue to have severe disease despite maximal therapy (i.e., in those patients in whom the benefit/risk ratio of therapy is most likely to be acceptable).

### Gold salts

Evaluation of these drugs in asthma has been based on empirical observation of their "antiinflammatory" effects in diseases such as rheumatoid arthritis, rather than cogent hypothesis regarding their possible mechanisms of action. Actions of gold salts which may be relevant to a glucocorticoid-sparing effect in asthma are ill-defined, but may include inhibition of T-cell proliferation, IL-5-mediated prolongation of eosinophil survival [5], IgE-mediated degranulation of mast cells and basophils [6], and leukotriene production by granulocytes [7]. Some of these effects may be secondary to inhibition by gold salts of pro-inflammatory
**FIG. 55.1** Working hypothesis of asthma pathogenesis. Mast cells sensitized by surface, allergen-specific IgE release acute mediators of bronchoconstriction on allergen exposure, which may serve as a mechanism for acute exacerbation of asthma in atopic patients. Th2 T-cell differentiation in the airways is driven by dendritic cells (DC) which present allergens and possibly other antigens to T-cells in an MHC Class II restricted fashion, possibly under the influence of thymic stromal lymphopoietin (TSLP) produced by mast cells, epithelial cells and other cells. Th2 cytokines control IgE synthesis by B cells (IL-4, IL-13) and encourage recruitment and activation of eosinophils (IL-5) which may damage the mucosa through release of major basic protein, and are also a source of remodeling cytokines such as transforming growth factor-$\beta$ (TGF-$\beta$). Th2 cytokines such as IL-4 and IL-13 also induce release of growth factors by structural cells in the airways such as epithelial cells (Epi), myofibroblasts (Fib) and airways smooth muscle cells (ASM) causing remodeling changes (fibrous protein lay down, mucous hyperplasia, smooth muscle hypertrophy/hyperplasia). Mast cells are also a source of remodeling cytokines.

transcriptional regulatory proteins, in particular NF-$\kappa$B [8]. Two double-blind, placebo-controlled parallel group studies [9, 10] in which oral gold salts were administered for 6 months showed a modest but significant glucocorticoid-sparing effect of the therapy as compared with placebo. Lung function was not improved, and additional antiasthma therapy was not reduced. Not all of the patients showed a significant response. The unwanted effects of oral gold salts include dermatitis, hepatic dysfunction, proteinuria, interstitial pneumonitis, and, rarely, blood dyscrasias [11]. Nevertheless, it has been concluded in one study [12] comparing the glucocorticoid-sparing effects of gold salts, methotrexate, and cyclosporin A (CsA) in severe asthma that gold salts provide the optimal risk/benefit ratio in terms of efficacy and tolerability.

## Methotrexate

Methotrexate is a folic acid analog used at low dosage for its anti-inflammatory activity in an increasing variety of chronic diseases. It exerts a delayed but sustained therapeutic effect with weekly dosage regimens. This probably reflects its accumulation in cells as polyglutamate complexes, resulting in accumulation of S-adenosyl methionine and adenosine, both of which are inhibitory to T-cell function [13]. Methotrexate therapy also appears to increase T-cell sensitivity to glucocorticoid inhibition [14]. Meta-analysis of placebo-controlled trials of methotrexate therapy in oral glucocorticoid-dependent asthma [15, 16] suggest

that methotrexate therapy for a minimum of 3–6 months allows significant (overall 20%, but only in about 60% of responding patients) reduction in oral glucocorticoid requirements, with no significant improvement in lung function. In a more exacting analysis of these trials by the Cochrane reviewers [17], however, it was concluded that existing trial data do not justify the premise that methotrexate is glucocorticoid-sparing. The most serious potential unwanted effect of methotrexate therapy is cumulative hepatic toxicity and hepatic fibrosis, with isolated reports of deaths from opportunistic infections and pneumonitis.

## Cyclosporin A

CsA is a lipophilic, cyclic undecapeptide derived from the fungus *Tolypocladium inflatum*. In a complex with the cytoplasmic binding protein cyclophilin, it inhibits calcineurin-mediated dephosphorylation and nuclear translocation of the cytoplasmic subunit of the T-cell transcriptional activator NF-AT, thus inhibiting T-cell proliferation and cytokine production relatively specifically [18].

Two blinded, placebo-controlled trials in severe, glucocorticoid-dependent asthmatics [19, 20] together showed that concomitant CsA therapy improved lung function while reducing oral prednisolone requirements. As with methotrexate, not all patients showed a significant response. Unwanted effects of low-dosage CsA therapy include hypertension and renal impairment. Regular monitoring of renal function,

blood pressure, and whole blood trough concentrations of CsA is necessary. Lymphoproliferative disorders and serious opportunistic infections appear to be very uncommon.

## Intravenous immunoglobulin therapy

Therapy with pooled intravenous immunoglobulin (IVIG), originally designed to restore immune deficiency, also appears to have immunomodulatory effects in diseases involving immune-effector mechanisms. In a blinded, parallel group study of oral glucocorticoid-dependent asthmatics [21], patients were randomized to receive IVIG 2 g/kg, 1 g/kg, or albumin (placebo) 2 g intravenously monthly for a total of 6 months (7 infusions). During the therapy, oral prednisone requirements were reduced to an almost identical extent (33–39%) in all three groups, with no significant differences in changes in symptoms, lung function, and the frequency of disease exacerbations. In a second, similar blinded trial [22], treatment of patients with both IVIG and placebo allowed significant reduction in oral prednisone dosages, which was significantly greater in the IVIG-treated group when only those asthmatics on relatively high-initial dosages of oral prednisone were included in the analysis. Another double-blind, placebo-controlled study of IVIG therapy in severe childhood asthma [23] failed to show any benefit of IVIG over placebo in terms of changes in symptoms and lung function. The possible mechanisms by which IVIG therapy could exert a beneficial effect in asthma are not clear. Some of the benefits may result from immunoglobulin replacement itself, since a proportion of chronic asthmatics have depressed serum IgG concentrations, although there is little evidence that this results in defective humoral immunity [24]. Additionally, IVIG has been shown to increase T-cell susceptibility to glucocorticoid inhibition *in vitro* [25], to abrogate IgE synthesis by B-cells *in vitro* [26], and to contain other potential immunomodulatory products including soluble CD4, CD8, and HLA molecules and cytokines.

In summary, the evidence that IVIG is of any benefit in glucocorticoid-dependent asthma is at present equivocal. In addition, the therapy is very expensive and is associated with a high incidence of unpleasant urticarial and anaphylactic reactions, as well as fever and aseptic meningitis.

## Newer immunomodulatory drugs

Tacrolimus (FK506) is a macrolide derived from the soil organism *Streptomyces tsukudaiensis* which, despite having a different structure to CsA, similarly inhibits NF-AT activation. Its increased potency may be outweighed by similarly increased toxicity.

Sirolimus (rapamycin) is another macrolide derived from *Streptomyces hygroscopius*. It has a fundamentally different inhibitory action on T-cells [27], since it inhibits IL-2 signaling at least partly by inhibiting phosphorylation/activation of the kinase p70 S6 (p70$^{S6k}$), and by inhibiting the enzymatic activity of the cyclin-dependent kinase cdk2-cyclin E complex.

Other new immunomodulatory drugs, the inhibitory actions of which are relatively specific for T-cells continue to appear, including brequinar sodium and mycophenolate mofetil (inhibitors of *de novo* synthesis of pyrimidines and purines

respectively, particularly in T-cells), leflunomide and the napthopyrans. Whether or not these drugs will offer opportunities for the therapy of severe asthma with a more favorable benefit/risk ratio remains to be seen. One new immunosuppressive agent, suplatast tosilate, appears to inhibit the production of asthma-relevant cytokines relatively selectively, and early studies suggest clinical benefit in asthma.

## CYTOKINE-DIRECTED THERAPY IN ASTHMA

T helper 2 (Th2) lymphocytes are thought to play a key role in asthma pathogenesis as they are a principal source of asthma-relevant cytokines. Therapeutic strategies directed toward inhibition of Th2 cytokines would thus seem to offer an attractive immunomodulatory strategy for asthma (Table 55.1). Alternatively, because a range of Th1 cytokines are inhibitory to the development of Th2 T-cells, or antagonize the actions of Th2 cytokines on target pro-inflammatory leukocytes, therapy with key Th1 cytokines may also be effective in asthma (Table 55.1).

## Inhibition of Th2 and other cytokines

Of the Th2 cytokines, IL-5 has been regarded as of particular importance because its expression most closely correlates with asthma severity and local eosinophil infiltration (one of the most constant features of asthma). Humanized monoclonal antibodies against human IL-5 have been manufactured. A single intravenous infusion of one of these antibodies (mepolizumab) markedly reduced circulating blood eosinophils and greatly reduced eosinophil recruitment to the airways following allergen bronchial challenge of mild, atopic asthmatics [28]. Unfortunately, however, this had no effect on early or late-phase bronchoconstriction or associated changes in bronchial hyperresponsiveness. A more prolonged study [29] on patients with moderate to severe asthma was also disappointing in terms of improvements in asthma symptoms or lung function. A biopsy study [30] suggested that, while anti-IL-5 antibody profoundly reduced circulating eosinophils, it was less effective in removing eosinophils from the bronchial mucosa but

**TABLE 55.1**  Cytokine-directed therapeutic strategies in asthma.

| Inhibition of pro-inflammatory cytokines | Therapy with inhibitory cytokines |
| --- | --- |
| IL-5 | IL-10 |
| IL-4 | IL-12 |
| IL-13 | IFN-α/γ |
| IL-9 | IL-18 |
| IL-25 | IL-23 |
| TNF-α | |

IL: interleukin; IFN-α/γ: interferon-α/γ; TNF: tumor necrosis factor.

did reduce extracellular matrix deposition [31]. These studies have cast doubt upon the role of infiltrating cells such as eosinophils in the causation of the clinical abnormalities associated with asthma, although since current strategies have not been effective in removing eosinophils entirely from the bronchial mucosa, this conclusion must be guarded. Alternatively, cells such as eosinophils may participate in longer term remodeling changes associated with asthma. Whatever the case be, these observations have at least temporarily quenched enthusiasm for further evaluation of anti-IL-5 strategies.

IL-4, another Th2 cytokine, is one of the only two cytokines (the other being IL-13) which causes switching of B-lymphocytes to IgE synthesis and is therefore implicated in the pathogenesis of atopy. IL-4 is also involved in recruitment of eosinophils to the airways in asthma and acts in an autocrine fashion further to promote the differentiation of Th2 lymphocytes. Soluble, humanized IL-4 receptors (altrakincept), administered by nebulization, have been tested in clinical trials and have been shown to prevent deterioration in lung function induced by withdrawal of corticosteroids in patients with moderately severe asthma [32]. In addition, weekly nebulization of soluble IL-4 receptor improved asthma control over a 12-week period [33]. Further, more prolonged studies were more disappointing and this strategy also is currently not being pursued. IL-4 and the closely related IL-13 signal through the transcriptional activator STAT-6 and endogenous inhibitors of STAT-6 may prove to be useful therapeutic agents [34].

Further on the theme of cytokines causing airways changes in asthma independently of cellular infiltration, IL-13, which shares a surface receptor, IL-4Rα, with IL-4, when selectively over-expressed in the airways of mice causes many of the features associated with airways "remodeling" [35]. Deletion of the IL-13 gene in mice prevents development of airways hyperresponsiveness following allergen sensitization and challenge despite infiltration of eosinophils (another effect of IL-13 is to increase the production of eosinophil attracting chemokines such as eotaxin by airways epithelial cells) [36]. Apart from IL-4Rα, IL-13 has two other specific receptors named IL-13Rα1 and IL-13Rα2. The latter receptor also exists naturally in a soluble form and may act as a "decoy" receptor, scavenging and thus inhibiting the effects of free IL-13. Soluble IL-13Rα2 is currently in clinical development as a possible new therapeutic approach for asthma. In addition, a neutralizing, anti-IL-13 monoclonal antibody [37] and a soluble anti-IL-13 fusion protein [38] were shown to prevent airways hyperresponsiveness produced by allergen challenge in mice. Recently, a recombinant human IL-4 mutant protein called pitrakinra has been developed which competitively inhibits the IL-4Rα complex and thus blocks the actions of IL-4 and IL-13 simultaneously. When given by inhalation or subcutaneous injection it very convincingly reduced the late-phase response to allergen bronchial challenge of atopic asthmatics [39]. The mechanism of this effect is unknown but could reflect blockade of the actions of IL-4 and/or IL-13 signaling. In addition to possible anti-inflammatory actions of IL-4Rα blockade, pitrakinra also accelerated recovery from the acute-phase fall in $FEV_1$ immediately after allergen challenge, which may also suggest an effect of IL-4/13 blockade on acute mast-cell releasability [40].

Other cytokines are of similar interest as possible therapeutic targets in asthma. The cytokines IL-9 and IL-25 both amplify the production of Th2 cytokines. In addition, IL-9 promotes mast-cell differentiation and mediator release and augments IgE production, and also promotes some of the changes associated with asthmatic airways remodeling when over-expressed experimentally in animals. In an animal model, a blocking anti-IL-9 antibody inhibited airways inflammation [41]. Humanized, blocking anti-IL-9 antibodies are currently in development [42].

The cytokine tumor necrosis factor (TNF)-α is expressed in asthmatic airways and may play a pivotal role in amplifying a wide range of inflammatory responses. A blocking, humanized anti-TNF-α antibody (infliximab) and soluble TNF-α "decoy" receptors (etanercept) have shown remarkable (not to mention unprecedented and unexpected) clinical efficacy in treating other inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease, although there are concerns about the immunosuppressive actions of this therapy on resistance to microbial infections (recrudescence of tuberculosis, e.g., is a real problem) and possibly even tumor surveillance. In one study, treatment of moderate to severe asthmatics with etanercept 25 mg subcutaneously twice weekly for 12 weeks produced impressive improvements in symptoms and reductions in bronchial hyperresponsiveness [43] to a degree approaching that expected with systemic corticosteroid therapy. A further study [44] replicated these findings, while a third [45] preliminary study was negative, suggesting that the therapy might be effective only in a subgroup of asthmatics in whom TNF-α plays a relatively prominent role. Anti-TNF-α therapies thus seem to hold considerable promise, which may however be outweighed by their unwanted effects. Because these therapies have to be administered by injection, a search is on for small molecule TNF-α inhibitors. TNF-α-converting enzyme (TACE) is a matrix metalloproteinase-related enzyme required for the release of TNF-α from cell surfaces where it is stored in an extracellular matrix "reservoir." Small molecule oral TACE inhibitors are currently in development [46].

## Therapy with potential antiasthma cytokines

Some cytokines inhibit the Th2 cytokine responses of T-cells which characterize asthma with varying degrees of specificity. While it may not be possible to administer such cytokines to patients in the long term, it may be possible to develop strategies that increase their release or drugs which activate their particular signaling receptors and pathways.

IL-10 has a number of anti-inflammatory properties which may be relevant to asthma therapy. It is one of the few cytokines the expression of which is enhanced, rather than inhibited by corticosteroids. It inhibits the function of antigen-presenting cells (APC) and impairs their ability to prime T-cells for Th2 cytokine release. It also reduces Th2 cytokine production by differentiated Th2 T-cells and is thought to be one of the principal effector cytokines which mediate the activity of T regulatory cells. In addition, it exerts inhibitory actions on a range of inflammatory leukocytes such as mast cells and eosinophils. Recombinant human IL-10 has proven effective in controlling other inflammatory diseases

such as inflammatory bowel disease and psoriasis, where it is given as a weekly injection [47]. It is reasonably well tolerated, although hematological unwanted effects have been noted. With regard to asthma, peripheral blood T-cells from clinically corticosteroid resistant, as compared with sensitive severe asthmatics showed a marked defect in corticosteroid-induced IL-10 production [48]. There is also evidence that IL-10 production plays a role in the well-known synergistic clinical effects of inhaled glucocorticoids and long-acting β-agonists in asthma [49]. These data strongly support a role for IL-10 in regulating asthma severity. Recent studies suggest that the defect in IL-10 production observed in T-cells from corticosteroid resistant asthmatics may be overcome by other agents such as vitamin D3, which are known to increase IL-10 production, both *in vitro* and *ex vivo* [50]. Manipulation of IL-10 production by such relatively innocuous agents, as distinct from therapy with IL-10 itself, offers great promise for future asthma therapy.

IL-12 is a cytokine produced largely by APC which is a key regulator of Th1 T-cell development. Th1 cytokines, particularly interferon-γ strongly inhibit Th2 responses. Recombinant human IL-12 has been administered to humans but has a range of toxic effects which are somewhat minimized by slow escalation of the dosage. In a single study on atopic asthmatics [51], weekly infusions of IL-12 over 4 weeks at escalating dosage caused a progressive fall in circulating eosinophils and also reduced ingress of eosinophils into induced sputum following allergen bronchial challenge. Unfortunately, as with anti-IL-5, there was no evidence of reduction of the early or late-phase bronchoconstrictor responses to allergen challenge or alteration of the associated increased bronchial hyperresponsiveness. Most of the patients suffered with malaise and one with cardiac dysrhythmia. Consequently, IL-12 is not likely to be used alone as a therapeutic agent for asthma.

Cytokines such as IL-18, which synergizes with IL-12 to enhance the release of Th1 cytokines by T-cells, and IL-23, which is related to, and shares some of the effects of IL-12, are also potential therapeutic agents for asthma waiting to be explored, although problems with unwanted effects similar to those of IL-12 might be anticipated. Interferon-γ, a signature Th1 cytokine has been administered by nebulization to asthmatics [52]. It did not seem to reduce inflammation, at least as judged by eosinophil infiltration, although it is not certain whether sufficient concentrations reached the airways. Preliminary reports suggest that interferon-α may be useful for the treatment of severe, corticosteroid refractory asthmatics [53].

## Inhibition of chemokines

Chemokines are particularly involved in the regulation of transit of inflammatory cells out of the bone marrow and into target tissues. Over 50 different chemokines, acting on over 20 different surface receptors have been described, allowing for much possible redundancy of action. Chemokine receptors belong to the seven transmembrane receptor superfamily of G-protein-coupled receptors, for which it is possible to manufacture small molecule inhibitors. Many such inhibitors have been developed but only few, if any, have progressed into clinical trials in asthma.

Several chemokines, including eotaxin, eotaxin-2, eotaxin-3, regulated on activation, normal T-cell expressed and secreted (RANTES) and monocyte chemoattractant protein-4 (MCP-4) activate a common receptor on Th2 T-cells, mast cells and eosinophils called CCR3. All of these chemokines are over expressed in the asthmatic airways mucosa [54, 55]. Several small molecule inhibitors of CCR3 block eosinophil recruitment in animal models of asthma.

The chemokine receptor CCR4 is selectively expressed on Th2 T-cells, while CCR8 is expressed on a subset of these cells. Ligands for CCR4 include thymus and activation dependent cytokine (TARC) and monocyte-derived chemokine (MDC), while a ligand for CCR8 is I-309. In animal models of asthma, antibody blockade of all of these molecules attenuated eosinophil influx, although only MDC and TARC blockade attenuated bronchial hyperresponsiveness [56–58]. On the other hand, blockade of the CCR4 receptor [59] and gene deletion of the CCR8 receptor [60] in animal models of asthma failed to reduce cellular influx, perhaps reflecting the extreme redundancy of these pathways. The chemokine receptor CXCR4 is also selectively expressed on Th2 T-cells, and a small molecule inhibitor of this receptor inhibited allergen-induced airways inflammation in a murine model [61].

## THE WORTH OF CURRENT IMMUNOMODULATORY THERAPY IN ASTHMA

### Immunosuppressive therapy

In view of these clinical observations, it will be clear that many reservations remain about the use of currently available immunosuppressive therapy for the treatment of severe, corticosteroid-dependent asthma since:

- Not all patients respond, and the response cannot be predicted *a priori*;
- The high incidence of unwanted effects makes it difficult to assess overall benefit/risk ratios even in asthmatics who are able to reduce oral corticosteroids;
- There is a risk of opportunistic infection and (at least theoretically) neoplasia;
- There are many relative or absolute contraindications to therapy, such as pregnancy;
- There is lack of knowledge about the long-term effects, beneficial or otherwise, of therapy.

Consequently, it is clear that any further investigation of immunosuppressive therapy for asthma should be performed within the confines of a controlled trial. There is an urgent need to produce a global definition of precisely which patients are suitable for such trials, and what constitutes an appropriate trial of therapy. None of the immunosuppressive strategies discussed above has made a significant impact on the management of severe, oral corticosteroid-dependent asthma, although isolated patients do respond. A large gap in our knowledge is whether or not these drugs do what they are assumed to do in asthma, which is to reduce

T-cell activation and cytokine production. Few studies have addressed possible effects of immunosuppressive therapy on the cellular and molecular immunopathology of the disease.

## Cytokine-directed therapy

The similar general lack of success of cytokine-directed therapy so far in asthma has also been disappointing. The apparent failure of anti-IL-5 sent a wave of shock and controversy through the asthma research community, because the eosinophil/IL-5 axis was thought to be fundamental to asthma pathogenesis. These problems have, however, served little more than to highlight the chasm of ignorance about how the cellular, immunological and structural changes one can observe in asthma are related, if at all, to the clinical manifestations of disease. There is a pressing need to delineate the precise functions of cells and cytokines implicated in asthma pathogenesis, otherwise the success of cytokine-directed strategies (as with TNF-α, perhaps the least "asthma related" cytokine) will remain serendipitous. It is also essential to understand what mechanisms cause irreversible airways obstruction in asthma so that therapy can be directed to these.

## IMMUNOMODULATORY THERAPY FOR COPD

Key elements of the pathogenesis of COPD include the following:

- Chronic exposure to cigarette smoke (a causal factor in more than 90% of cases in the United Kingdom);
- Individual (possibly inherited) susceptibility, since only 10–20% of heavy smokers develop symptomatic disease.
- A smoking-induced inflammatory cellular infiltrate in the airways, more marked peripherally, comprising

of neutrophils, CD8 T-cells and variable numbers of eosinophils [62, 63]. The amount of this infiltrate is closely related to total smoke (pack years) exposure, but not so closely related to the presence/absence of COPD, although some studies [64]seem to demonstrate a COPD-specific, elevated influx of CD8 T–cells.

- Excessive production of proteinases, which digest the lung parenchyma, and overwhelm endogenous antiproteinases which normally protect against this. The principal proteinases are elastase and other serine proteinases from neutrophils, and matrix metalloproteinases (a group of over 20 related neutral endopeptidases) from macrophages and epithelial cells.

A working hypothesis for the pathogenesis of COPD is shown in Fig. 55.2. At present this remains largely theoretical; in particular, there is only circumstantial evidence for a role for T-cells, although in transgenic animal "models" of COPD where cytokines are artificially expressed in the respiratory mucosa, the cytokines TNF-α, IFN-γ, and IL-13 can produce changes reminiscent of emphysema and airways remodeling changes which characterize the human disease, probably through distinct mechanisms [65]. As with asthma (Fig. 55.1), the scheme takes no account of why the process persists in some individuals but not others. It may be inferred that therapeutic approaches to COPD may involve the use of inhibitors of macrophage and neutrophil function, leukotriene inhibitors, and inhibitors of cytokines or chemokines and/or their actions on target cells, and measures which increase proteinase inhibition. It should not be forgotten that, at present, the cheapest and only effective therapeutic maneuver is smoking cessation.

## Glucocorticoids as immunomodulators in COPD

In contrast with asthma, glucocorticoids have no significant effect on progressive loss of lung function which characterizes

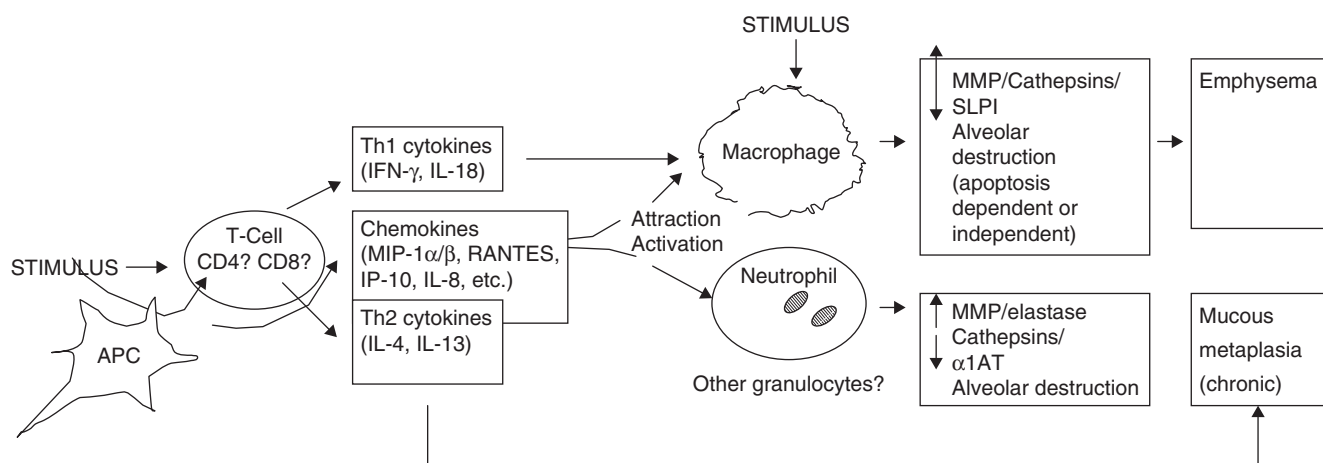

**FIG. 55.2** Theoretical scheme of COPD. Both Th1/Tc1 and Th2/Tc2 cytokines from CD4 or CD8 T-cells cause emphysema through secondary release of chemokines, which attract monocyte/macrophages and granulocytes which in turn are a source of proteases such as matrix metalloproteinase (MMP), and also by direct induction of apoptosis and down regulation of anti-proteases such as α1-anti-trypsin (α1AT) and SLPI. CD8+ cytotoxic T-cells may also attack alveolar epithelial cells directly. Although COPD is much more common in cigarette smokers, the precise stimulus to T-cell and monocyte/macrophage activation is unknown, as is whether T-cell activation is in any way antigen-specific involving antigen-presenting cells (APC) (which are also a potential source of chemokines).

COPD [66] and little effect in reducing inflammatory-cell infiltration into induced sputum [67] or the bronchial mucosa [68], although when administered systemically they reduce hospital stay and re-admission rates in patients with exacerbations [69, 70]. Inhaled glucocorticoids also reduce exacerbation rates in "stable" disease [71] and this is likely the principal (and possibly the only) action of glucocorticoids which accounts for their improvement in the quality of life of COPD sufferers.

It is not clear why this disparity exists in the anti-inflammatory action of glucocorticoids in asthma and COPD. It is possible to hypothesize that the environment of the mucosa of chronic smokers with COPD renders cells insensitive to glucocorticoid inhibition [72]. The possibility that T-cells, particularly of the CD8+ phenotype, produce cytokines which have been implicated in causing COPD in animal models provides the only precedent for the hypothesis that immunomodulatory therapy will ameliorate symptoms of COPD or alter the natural history of the disease. On the other hand, this approach might be particularly troublesome in view of the fact that these patients are much more susceptible to debilitating infection than asthmatics.

## Inhibition of cytokines

Concentrations of TNF-$\alpha$ and its soluble receptor are increased in the induced sputum of patients with COPD [73] and this mediator has been implicated in the pathogenesis of the weight loss sometimes associated with COPD [74]. A recent multi-center, placebo-controlled trial of therapy with the humanized antiTNF monoclonal antibody infliximab for 6 months (with evaluation for nearly 1 year) however showed no impact on quality of life, exercise tolerance, or disease exacerbations in patients with COPD [75].

Furthermore, more patients on active treatment developed more severe exacerbations and there was a trend toward more cases of cancer and pneumonia. It is not understood why antiTNF-$\alpha$ therapy is apparently more effective, at least in the short term, in asthma as compared with COPD, and again this reflects our ignorance of the true role of cytokines and indeed any mediators in disease causation. Longer term blockade might be more effective, but not without serious hazards. Other cytokines which have been implicated in COPD either from animal models (as discussed earlier) or circumstantially because their concentrations are elevated in the target organ include IFN-$\gamma$, IL-13, IL-1$\beta$, IL-6, IL-11, and IL-17 [76], but it is fair to say that in our current state of knowledge any further advances with cytokine blockade in COPD are most likely to be serendipitous.

## Inhibition of chemokines

The CXC chemokine IL-8 is increased in the sputum of COPD patients and may contribute to the bronchial mucosal and sputum neutrophil influx that characterizes COPD, although there is little direct evidence for its involvement in the causation of COPD. A humanized, monoclonal neutralizing antibody to IL-8 has been tested in COPD, and while it had a small effect in reducing dyspnea scores there was no other clinical improvement [77]. IL-8 interacts with the CXCR1 and CXCR2 chemokine receptors. Since other ligands for CXCR2 such as growth-related oncoprotein (GRO)-$\alpha$ are also circumstantially implicated in COPD [78], CXCR2 inhibitors may be more effective than blockade of single chemokines [79], although there have been no clinical trials of such agents as yet in COPD.

## PHOSPHODIESTERASE INHIBITORS IN ASTHMA AND COPD

Phosphodiesterase (PDE) inhibitors may be regarded as honorary immunomodulatory drugs since they modify the functions of a wide range of immune as well as structural cells. PDE hydrolyzes cyclic AMP, and inhibitors elevate intracellular cyclic AMP concentrations, which in turn inhibits the pro-inflammatory actions of many immune leukocytes including T-cells, macrophages, and neutrophils and relaxes airways smooth muscle cells. There are many sub-types of PDE and some of these sub-types also exist in multiple forms [80]. PDE4 is the predominant enzyme in immune cells. Two PDE4 inhibitors, cilomilast, and roflumilast have been evaluated for their possible therapeutic benefits in asthma and COPD. Roflumilast improved lung function in patients with mild/moderate asthma to a degree comparable to that achieved with inhaled glucocorticoid [81]. In a 6-month trial in patients with moderate COPD, treatment with roflumilast 0.5 mg daily resulted in a small but significant improvement in post-bronchodilator $FEV_1$ (0.097 l compared with placebo) and a reduction in the numbers of exacerbations (0.75/patient compared to 1.13/patient with placebo) [82]. Quality of life was also improved in the patients taking active drug ($-3.5$ points on the St. George's Hospital respiratory questionnaire). Cilomilast at a dose of 15 mg twice daily for 12 weeks reduced the numbers of T-cells, macrophages, and neutrophils in bronchial biopsies of patients with COPD [83]. Unfortunately, dose-limiting adverse events (nausea, vomiting, and mesenteric arteritis) are still a cause for concern with these drugs and neither has yet been licensed for the treatment of asthma or COPD [84].

## CONCLUDING REMARKS

New drugs for the prevention and treatment of asthma and COPD are still greatly needed. In order to develop them, it seems of paramount importance not just to describe the pathophysiological features of each disease but to understand exactly how these features cause clinical symptoms and compromise lung function. Despite three decades of research, evidence for a role for T-cells and cytokines in asthma and COPD, which would mandate continuing the development of drugs which block their production or actions, remains largely circumstantial, and the fundamental questions as to why asthma develops in some individuals but not others, and why COPD develops only in a minority of heavy smokers [85] remain unanswered. Most of our current information comes from static, cross-sectional

studies of diseased subjects and there is very little known about what role cytokines and other mediators play in acute, short-term exacerbations of disease or in progressive decline in lung function. Hence there is a need to develop novel short- and long-term outcome measures and surrogate biomarkers of disease in the short term, and better measures of lung functions decline in the longer term, such as computerized tomography [86]. Powerful new techniques such as positional genomics may in future allow analysis of heritable susceptibility factors in a manner unbiased by our limited understanding of disease pathophysiology, and allow new approaches to disease prevention which may not depend on the inhibition of immunological processes. This will be the future challenge to counter these common and significant diseases for which no effective, preventative therapies currently exist.

# Pulmonary Vasodilators in COPD

**Richard N. Channick and Lewis J. Rubin**

**Division of Pulmonary and Critical Care Medicine, University of California, San Diego School of Medicine, La Jolla, CA, USA**

## INTRODUCTION

Pulmonary hypertension is a common complication of severe chronic obstructive pulmonary disease (COPD) and contributes substantively to both its morbidity and mortality [1]. Although generally mild, pulmonary hypertension in the setting of COPD is a marker of poor prognosis. Furthermore, acute exacerbations of COPD which result in worsening gas exchange are likely to produce acute deteriorations in pulmonary hemodynamics, which further compromise oxygen transport to peripheral tissues. Accordingly, considerable effort has been given to understanding the pathogenesis of pulmonary hypertension in COPD and in attempting to develop strategies for its treatment.

## PATHOGENESIS OF PULMONARY HYPERTENSION IN COPD

Several factors contribute to the development of pulmonary hypertension in COPD.

### Loss of cross-sectional vascular surface area

As a result of the widespread destruction of airways and lung parenchyma typical of emphysema, there is also concomitant loss of vasculature, leading to an increase in perfusion pressure to accommodate pulmonary blood flow. In addition, increases in pulmonary blood flow, such as those that occur with physical activity, are associated with further increases in pulmonary arterial pressure owing to the loss of vascular distensibility and the inability to recruit unused vasculature. This process, by its very nature, is irreversible [2]. However, there has not been found a clear relationship between the severity of pulmonary parenchymal destruction and the presence or severity of pulmonary hypertension. Several recent investigations have found more "primary" vascular changes at the cellular and the molecular levels. In one study, Kasahara and coworkers found significant abnormalities in vascular endothelial growth factor expression in emphysema [3]. In addition, abnormalities in endothelial mediators, such as endothelin 1 [4], and increases in proinflammatory cytokines, such as IL-6 and C-reactive protein (CRP), have been found in COPD patients with pulmonary hypertension [5].

### Dynamic pulmonary vasoconstriction

The muscular pulmonary arteries respond with constriction to a variety of stimuli that are common in COPD. Of these, hypoxia is the most potent and the frequent stimulus for pulmonary vasoconstriction; hypoxic pulmonary vasoconstriction (HPV) is unique to pulmonary artery smooth muscle cells and is due to inhibition of an oxygen (or redox)-sensitive membrane-bound $K^+$ channel, leading to cell depolarization and increased intracellular $Ca^{++}$ concentrations [6]. Impaired endothelial function may also be present and further contributes to the vasoconstriction resulting from diminished production of endothelial-derived relaxing factors such as nitric oxide (NO) and prostacyclin ($PGI_2$).

As a result of vasoconstriction and altered endothelial function, severe COPD results in the elaboration of a variety of promoters of vascular

growth and remodeling. Among these, endothelin, platelet-derived growth factor, and transforming growth factor have been suggested to play major roles in the evolution of the chronically hypertensive pulmonary vascular bed. In concert, these and other mitogens promote endothelial and smooth muscle proliferation and extension of smooth muscle cells into the smaller, peripheral vessels [7]. Although this remodeling process may be modified by restoration of normoxic conditions, the amelioration is usually incomplete.

## PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION IN COPD

As a result of the aforementioned processes, the narrowing of the vascular lumen produces elevations in pulmonary arterial pressure and pulmonary vascular resistance. Furthermore, pressures increase further with exercise or with acute exacerbations associated with deteriorations in gas exchange. The increased right ventricular afterload may eventually lead to impaired right ventricular output and, if severe and progressive, right ventricular failure ensues. Although the term *cor pulmonale* is frequently used to describe right heart failure, it is more appropriately used to define pulmonary vascular disease in the setting of respiratory disease; right heart failure is a late and an unusual complication of *cor pulmonale*, particularly in the present era of widespread availability of supplemental oxygen therapy for chronic hypoxemia.

How severe is the PH caused by COPD? The answer to this question is both clinically relevant and debatable. What is known is that in several large series of COPD patients with varying severity of disease, the average level of resting pulmonary arterial pressure is either normal or mildly elevated. However, within these series, there are between 4% and 7% of patients who have what could be termed "disproportionate" pulmonary hypertension. Thabut and coworkers found 7.4% of patients in this subgroup, defined as a mean pulmonary arterial pressure of at least 40 mmHg with relatively modest severity of COPD (Fig. 56.1) [8]. Although the mechanistic reasons for this "disproportionate" PH are unclear, it seems plausible that
an excessive vascular response to a stimulus, such as alveolar hypoxia, leads to an exaggerated degree of pulmonary hypertension in these patients. Another possibility is that these patients, in fact, have idiopathic pulmonary arterial hypertension (PAH), completely distinct from the COPD.

In addition, it has been shown that some patients with COPD manifest an excessive rise in pulmonary arterial pressure during exercise. In one study, COPD patients with polymorphisms in the angiotensin converting enzyme (ACE) gene had greater exercise rises in pulmonary arterial pressure (Fig. 56.2) [9], again pointing to an intrinsic "susceptibility" to excessive pulmonary vascular disease in some COPD subjects.

Because it appears that some patients with COPD have more severe PH, it would seem likely that these patients would be limited, not by the underlying lung disease, but by the pulmonary vascular disease. It would then follow that benefit from therapy directed at the PH could be realized. What data exist to support this hypothesis?

## VASODILATOR THERAPY FOR PULMONARY HYPERTENSION IN COPD

### Rationale

As mentioned, the rationale for the use of PAH-directed therapy in COPD is based on the premise that pulmonary vasculopathy and, possibly pulmonary vasoconstriction, are key elements in its pathogenesis. In the older era, before the development of true PAH-targeted therapy, numerous systemic vasodilator agents were evaluated. Indeed, a variety of systemic antihypertensive agents have been shown to reduce pulmonary arterial pressure in experimental animals with pulmonary hypertension produced by acute hypoxic

**FIG. 56.1** Spectrum of pulmonary arterial pressures in patients with COPD (from Ref. [8]).

**FIG. 56.2** Deletion polymorphisms in the ACE gene are associated with greater rise in mean pulmonary arterial pressures during exercise (from Ref. [9]).

ventilation or the administration of pulmonary vasoconstrictor agents [10]. Unfortunately, as described above, the pulmonary hypertensive state in COPD is the result of more than simple vasoconstriction, with remodeling playing a pivotal role. Thus, it would be conceptually unlikely that simple vasodilators would achieve much efficacy.

## Oxygen

It is important to remember that supplemental oxygen, a selective pulmonary vasodilator, is the only pulmonary "vasodilator" which has been demonstrated to improve survival in COPD, although the hemodynamic effects are variable [11–13]. It is likely that the favorable impact of oxygen therapy on survival in COPD is due to a variety of effects, including optimizing myocardial and other peripheral tissue oxygen delivery.

## Older vasodilators

Several older studies have evaluated other vasodilators in patients with COPD. Studies, until recently focused on oral vasodilators, including hydralazine [14], oral nitrates, and calcium channel antagonists [15–22]. Several, small reports consistently demonstrate a small, but significant acute pulmonary vasodilating effect from the administration of calcium channel blockers, including nifedipine [15–18, 22], felodipine [19, 20], verapamil [21], and diltiazem [21]. The magnitude of this effect is quite variable, ranging from 10% to 30%, depending on the study. In addition, nifedipine has been shown to reduce $PaO_2$, presumably by inhibition of HPV and worsening V/Q matching, an effect which is magnified during exercise and with supplemental oxygen administration [15]. Possibly mitigating the worsening of arterial oxygenation by nifedipine, however, is data demonstrating improvement in cardiac output and oxygen delivery during nifedipine administration [15, 22].

Given the modest hemodynamic effects, at least at rest, of oral vasodilators, and the relatively mild nature of the pulmonary hypertension, at least at rest, observed in COPD, it reasonable to question whether oral vasodilators have any long-term clinical utility in these patients. To date, there have been no large placebo-controlled trials addressing this issue. There are several controlled studies, all yielding unimpressive results. Vestri and coworkers found that, compared to a well-matched control group, no significant objective improvement occurred with 1 year of nifedipine [23]. Interestingly, a significant improvement in dyspnea was seen in the nifedipine group. Similarly, Domenighetti et al. found that, even in a subgroup of COPD patients with marked acute pulmonary vasodilation in response to nifedipine (43% decrease in PAP mean), "typical" clinical deterioration over 12 months occurred [17].

Sajkov et al., in a 12-week study of another calcium channel antagonist, felodipine, found reductions in pulmonary arterial pressure and in pulmonary vascular resistance that were felt to be significant (22% and 30%, respectively) [19]. However, exercise capacity was not improved.

One theoretical limitation of pulmonary vasodilator therapy, in general, is that although the presence of pulmonary hypertension is an ominous prognostic sign in COPD,

it may, in the majority of patients, merely serve as a marker of disease severity and not contribute substantively, per se, to symptom limitation or survival. Unlike patients with other forms of pulmonary vascular disease, such as IPAH, CTEPH, and connective tissue disease, patients with COPD are primarily symptom-limited not by the cardiovascular process but by the airway and the parenchymal lung disease [24]. Right ventricular function is not normal, but is usually not severely depressed, although the compensatory mechanisms may fall short during acute exacerbations of airway disease. Accordingly, improving the pulmonary hemodynamic state may not result in improved activity tolerance or survival in this disease.

Another concern regarding vasodilator use is that COPD is typically a disease of older patients, a population that is also prone to have coexistent coronary artery disease. Vasodilators can increase cardiac work if tachycardia is produced, while at the same time they can also "steal" blood flow away from areas of anatomic obstruction, leading to worsening cardiac ischemia.

Finally, systemically administered agents exert nonselective cardiovascular effects, including systemic hypotension, tachycardia, and potentially negative inotropic myocardial effects. While these effects may be dose related, they can occur in patients even at low doses and can limit the utility of vasodilators.

In summary, presently available data suggest that oral calcium channel blockers do cause acute reductions in pulmonary arterial pressure and pulmonary vascular resistance, and modest increases in cardiac output in COPD patients. However, there is no convincing evidence of any improvement in exercise capacity or outcome in these patients.

## New vasodilators

Recently, interest has begun to be focused on the utility of the "modern" PAH therapies in COPD patients with, what is felt to be, more clinically significant pulmonary hypertension, the so-called "outliers." These modern therapies include prostacyclin analogs, endothelin receptor antagonists, and phosphodiesterase type 5 inhibitors (Table 56.1). Unique features of these newer agents that might make them beneficial in COPD patients with more advanced PH include their relative lack of systemic hemodynamic effects and their targeting of the pulmonary vasculopathy through direct effects on the endothelial dysfunction, which is a prominent feature of pulmonary hypertension.

Although the data on the efficacy and safety of these therapies for patients with IPAH and PAH associated with some other conditions, such as connective tissue disease, have been clearly proven in several randomized, placebo-controlled trials [25–30], there have been no such systematic trials in the COPD/PH subgroup. It should, however, be noted that patients with modest degrees of COPD ($FEV_1$ between 60% and 80% predicted) were not necessarily excluded from PAH trials, although the number of these patients was too small to allow subgroup analysis.

There are, on the other hand, uncontrolled reports and case series reporting the effects of various PAH therapies in COPD patients. Madden and coworkers treated 4 severe

COPD patients with sildenafil citrate for 8 weeks in an open label trial [31]. These authors reported consistent but non-statistically significant improvements in pulmonary vascular resistance and cardiac output as well as significant increase in 6 minute walk distance.

In a larger, uncontrolled study of 18 COPD patients (GOLD II–IV) with mild resting pulmonary hypertension or exercise-induced pulmonary hypertension, a single dose of 50 mg of sildenafil attenuated the rise in mean pulmonary arterial pressure during exercise [32]. However, this effect was not accompanied by an augmentation in cardiac output or an increase in maximal exercise capacity. In a recently published study by the same group, 15 stable COPD patients were treated with 3 months of sildenafil 50 mg three times daily [33] No improvement in stroke volume as assessed by cardiac MRI or exercise capacity were noted in this group. Although these small trials do not exclude an effect of sildenafil in COPD patients with PH, without a larger, controlled study, this agent should not be routinely used in this group.

Another group of drugs commonly used to treat PAH are the prostacyclin analogs, including epoprostenol, treprostinil, and iloprost. A rationale exists for use of these agents in COPD/PH patients, as one study has demonstrated reduction in prostacyclin synthase expression in the small pulmonary arteries of patients with emphysema [34]. However, to date no clinical data has been published on the effects of prostacyclin analogs in COPD patients. Moreover, it has been the authors' experience that intravenous epoprostenol may lead significant worsening of arterial hypoxemia, presumably due to increased intrapulmonary shunting in patients with underlying ventilation/perfusion inequality.

Endothelin receptor antagonists, such as bosentan, also have theoretical rationale in COPD/PH. Increase in endothelin expression has consistently been found in COPD patients with PH [4]. In addition, these levels have been found to correlate with exercise increases in pulmonary arterial pressures in COPD [35]. However, no clinical studies have yet been published examining the effects of endothelin receptor antagonists in COPD patients.

Inhaled pulmonary vasodilators, such as iloprost or nitric oxide, theoretically are attractive candidates for treating COPD-related PH, as these agents often improve shunt fraction and have minimal systemic hemodynamic effects. However, no data have yet been published on inhaled iloprost in this group. Inhaled nitric oxide, although not available

for chronic therapy has shown some promise in patients with underlying lung disease. Acutely, in ARDS [36], marked increases in $PaO_2$ occur in over two-third of patients given inhaled nitric oxide. The data in COPD, however, is conflicting. Both improvement [37–39] and deterioration [40, 41] in resting arterial oxygenation have been reported in COPD patients given inhaled NO, despite comparable degrees of pulmonary vasodilation. These "conflicting" results may, in fact, reflect the heterogeneity of the V/Q disturbances seen in COPD. For instance, if more low V/Q areas are present, inhaled NO may get into some of these lung units and actually worsen V/Q matching, a phenomenon reproduced in an animal study by Hopkins *et al.* [42]. On the other hand, if the predominant disturbance is shunt, inhaled NO would tend to improve oxygenation by shifting perfusion away from the shunt.

Additionally, the effects of inhaled NO on gas exchange during exercise may be even more important. Roger and colleagues found, in fact, that inhaled NO, despite worsening oxygenation at rest, actually prevented exercise-induced $O_2$ desaturation in patients with COPD, possibly due to preferential distribution of NO to well-ventilated regions during exercise [38].

However, despite potential beneficial effects of inhaled NO during exercise in COPD patients, exercise limitation is generally not due to either $O_2$ desaturation or pulmonary hypertension. Thus, it is uncertain whether or not chronic NO administration would benefit these patients. Again, no controlled trials have been done.

## SUGGESTED GUIDELINES FOR THE USE OF VASODILATORS IN COPD

Current experience does not support the widespread use of PAH therapy in COPD-related PH, owing to the hazards described above and the dearth of studies demonstrating sustained clinical benefit. Nevertheless, there are selected patients who appear to have alterations in pulmonary hemodynamics which are well out of proportion to the severity of chronic respiratory disease and in whom conventional approaches to therapy are only partially successful. These patients might be considered as having true PAH, idiopathic or associated, and might be candidates for PAH therapy. However if used, the effects of PAH therapy should be monitored using some clinically meaningful parameter, such as objective testing of cardiopulmonary exercise tolerance, noninvasive evaluation of right heart size and function using echocardiography, or invasive measurements of cardiopulmonary hemodynamics.

Theoretically, the use of pulmonary vasodilators in the setting of acute *cor pulmonale* may be more appealing than their use in the chronic state, owing to the acute and, therefore potentially reversible component and the impact of this alteration on morbidity and mortality. Unfortunately, no clinical trials have addressed the role of vasodilators in this population; furthermore, the deleterious effects of vasodilators may be particularly problematic in this setting. The use of more selective agents, such as nitric oxide by inhalation, would be preferred in the acutely decompensated patient. The impact of this therapy, however, remains unproven.

## SUMMARY AND CONCLUSIONS

While pulmonary hypertension remains a serious complication of COPD, effective therapy has been elusive. It is likely that pharmacological agents that exert both vasodilator and antiproliferative effects are most likely to produce sustained improvement in cardiopulmonary hemodynamics, although the impact of this therapy on symptoms and the survival in COPD remain unknown. In addition, delivery of these agents in a manner that facilitates selectivity of their effects to the pulmonary vasculature, such as by the inhaled route, would be preferable in order to minimize the adverse effects of systemic vasodilation. As our understanding of the molecular basis for the pulmonary vascular remodeling in COPD unfold, targeted therapy should be feasible and could be combined with other modalities in order to both prevent and treat the vascular complications of end-stage chronic obstructive pulmonary disease.

[2]Loyola University of Chicago, Stritch School of Medicine and Hines Veterans Administration Hospital, Maywood, IL, USA

In patients with obstructive lung disease, the development of acute respiratory failure is a common cause for admission to the intensive care unit (ICU) [1–8]. Between 2% and 61% of patients [1, 2, 4–9] require mechanical ventilation, with an associated mortality of 6–30% [6–12]. The high mortality may be a consequence of both disease severity and complications of mechanical ventilation.

## INDICATIONS FOR VENTILATOR SUPPORT

When severe hypoxemia develops in patients with asthma [13] and chronic obstructive pulmonary disease (COPD) [14], intubation and mechanical ventilation may be necessary to ensure the delivery of a sufficiently high fractional inspired oxygen concentration ($F_1O_2$). The development of an acute respiratory acidosis is another major indication for mechanical ventilation [15], although simpler measures can sometimes reverse the process [16]. An increase in work of breathing, secondary to an increase in airway resistance [17] or an inspiratory threshold load associated with auto-positive end-expiratory pressure or intrinsic positive end-expiratory pressure ($PEEP_i$), often requires mechanical ventilation to rest the respiratory muscles and decrease the oxygen cost of breathing.

## INVASIVE POSITIVE PRESSURE VENTILATION

### Modes of mechanical ventilation

The term *mode* refers to the relationship among various breath types (mandatory, assisted, supported, spontaneous), as well as inspiratory phase variables.

### Controlled ventilation

With controlled mechanical ventilation, the ventilator delivers all breaths at a preset rate and the patient cannot trigger the machine. With volume-controlled ventilation, breaths have a preset volume (volume targeted), whereas with pressure-controlled ventilation breaths are pressure limited and time cycled [18]. Use of volume-controlled ventilation is largely restricted to patients who are apneic as a result of brain damage, sedation, or paralysis.

### Assist-control ventilation

In the assist-control (AC) mode, the ventilator delivers a breath either when triggered by the patient's inspiratory effort or independently if such an effort does not occur within a preselected period. All breaths are delivered under positive pressure by the machine, but unlike controlled ventilation the patient's triggering efforts commonly exceed the preset rate. The amount of active work performed by a patient is critically dependent on the trigger sensitivity and inspiratory flow settings. Even when these settings are optimized, patients actively perform about one-third of the work performed by the ventilator during passive conditions [19, 20].

### Intermittent mandatory ventilation

With intermittent mandatory ventilation (IMV), the patient receives periodic positive-pressure breaths from the ventilator at a preset volume and rate, but the patient can also breathe spontaneously between these ventilator breaths [21]. With synchronized IMV, the ventilator waits until the patient begins to inhale and then synchronizes the machine breath with the patient's inspiratory effort. If a patient does not make an effort within a preset time, the ventilator delivers a positive-pressure breath.

With IMV, patients frequently have difficulty in adapting to the intermittent nature of assistance. It was previously assumed that respiratory muscle rest was proportional to the number of machine-assisted breaths. Recent studies, however, indicate that inspiratory effort is equivalent for spontaneous and assisted breaths [22–24]. At a moderate level of machine assistance, that is, where the ventilator accounted for 20–50% of the total ventilation, electromyographic activities of the diaphragm and sternomastoid muscles were equivalent for assisted and spontaneous breaths [23]. These findings suggest that respiratory center output is preprogrammed and is unable to adjust to breath-to-breath changes in unloading. As a result, IMV may contribute to the development of respiratory muscle fatigue or prevent its recovery.

### Pressure support ventilation

Pressure support (PS) ventilation is patient-triggered like AC and IMV, but differs in being pressure targeted and flow cycled [25]. The physician sets a level of pressure that augments every spontaneous effort, and the patient can alter respiratory frequency, inspiratory time, and tidal volume. A fall in airway pressure triggers the ventilator, which in turn increases pressure to a preset value. Accordingly, the pressure to inflate the lungs and chest wall is provided jointly by the ventilator and the patient. Unlike the guaranteed volume achieved by AC and IMV, tidal volume varies depending on the set pressure, patient effort, and pulmonary mechanics. The lack of guaranteed assistance in the absence of patient effort can cause apnea in patients with an unstable respiratory center output. Cycling to exhalation is triggered by a decrease in inspiratory flow to a preset level, such as 5 l/min or 25% of the peak inspiratory flow. Inspiratory assistance can also be terminated by a small increase in pressure (1–3 cm $H_2O$) above the preset level, resulting from expiratory effort [25].

PS is very effective in decreasing the work of inspiration. The degree of inspiratory muscle unloading, however, is variable, with a coefficient of variation of up to 96% among patients [26]. In patients with COPD, the variability in the work of breathing can be explained by the inspiratory resistance, minute ventilation, and degree of $PEEP_i$ [26]. It is noteworthy that, PS does not decrease $PEEP_i$ in patients with COPD [26, 27]. Instead, increasing levels of PS increase the contribution from $PEEP_i$ to the overall work of breathing, accounting for approximately two-thirds of the inspiratory effort [26]. The algorithm used to terminate inspiratory assistance during PS can also affect the work of breathing in patients with COPD. Patients with a prolonged time constant require more time for flow to fall to this threshold, and consequently, mechanical inflation may persist into neural expiration. To counteract such neural–mechanical dysynchrony, patients may activate their expiratory muscles at a time when the ventilator is still inflating the thorax, causing the patient to fight the ventilator.

There is no consensus for the appropriate level of PS for an individual patient. In one study, the level minimizing activity of the sternomastoid muscles also reversed electromyographic evidence of excessive diaphragmatic stress [25]. Commonly, PS is titrated to achieve a decrease in respiratory frequency and an increase in tidal volume. Considerable discrepancy exists among studies as to the preferred target or "optimal" level of PS. Achieving a decrease in respiratory rate

**FIG. 57.1** At proportional levels of ventilator assistance, work, as measured by the pressure–time product (PTP/min), was significantly lower for the combination of IMV and PS of 10 cm $H_2O$ than for either PS or IMV alone (from Ref. [20] with permission).

to ≤30/min was previously found to be a better predictor of a decrease in the work of breathing than achieving a tidal volume of >0.6 l [26]. Increasing PS to achieve a low respiratory frequency and inspiratory muscle unloading may be accompanied by an increase in expiratory muscle activity, causing the patient to fight the ventilator [26]. Thus, selecting the optimal level of PS can be quite complex.

## Comparison between modes of mechanical ventilation

A head-to-head comparison of the common modes of assisted ventilation was previously conducted, with most of the patients having COPD [24]. Compared with spontaneous breathing, AC achieved the largest decrease in the work of breathing. The decrease in the work was greater for PS than for IMV at lower levels of support. Addition of PS of 10 cm $H_2O$ to a given level of IMV caused a greater reduction in the work of breathing (Fig. 57.1), not only during the intervening PS breaths, but also during the mandatory IMV breaths. The decrease in work during the mandatory breaths was proportional to the decrease in respiratory drive during the intervening breaths.

## VENTILATOR SETTINGS

## Fractional inspired oxygen concentration

The lowest $F_IO_2$ that achieves satisfactory arterial oxygenation should be selected. With arterial blood samples, a $SaO_2$ target of 90% is appropriate, but with pulse oximetry the same target can be associated with $PaO_2$ values as low as 41 torr in black patients [28].

## Trigger sensitivity

Most ventilators employ pressure triggering, whereby a decrease in circuit pressure is required to initiate the ventilator. With flow triggering (sometimes termed "flow-by"), a base flow of gas (usually set at 5 to 20 l/min) is delivered during both the expiratory and the inspiratory phases of the respiratory cycle [29]. With patient effort, gas enters the patient's lungs and is diverted from the exhalation port. The difference between inspiratory and expiratory base flow is sensed, causing the ventilator to switch phase; sensitivity is usually set at 2 l/min. A decrease in breathing effort is noted with flow triggering in the PS, but not the AC, mode [30].

Triggering the ventilator is more difficult in patients with dynamic hyperinflation. In this situation, the patient must first generate sufficient pressure to offset the elastic recoil associated with hyperinflation, and thereafter overcome the sensitivity threshold. With all modes of ventilation, ineffective triggering increases in proportion to the level of assistance, secondary to a decrease in respiratory drive [24]. Breaths preceding the non-triggered effort have a higher volume, a shorter expiratory time, and a higher $PEEP_i$.

## Tidal volume

To prevent alveolar overdistension and lung injury, tidal volumes of 5–7 ml/kg (or less) have become increasingly popular [31]. This ventilator strategy is termed permissive hypercapnia or controlled hypoventilation [32], because it commonly produces an increase in $PaCO_2$. If pH falls below 7.20, some physicians administer intravenous bicarbonate, although its benefit is unproven [32]. In patients with severe asthma requiring mechanical ventilation, most studies suggest that permissive hypercapnia decreases mortality [33, 34]. In a controlled study [4] of patients with asthma and acute respiratory failure, pulmonary barotrauma and hypotension were significantly lower in patients who were electively hypoventilated.

## Respiratory rate

Setting the ventilator rate depends on the mode being employed. With AC ventilation, the ventilator supplies a breath in response to each patient effort; the backup rate should be set at approximately four breaths below the patient's spontaneous rate. With IMV, the mandatory rate is initially set high and then gradually decreased according to patient tolerance. As discussed above, this common approach does not ensure adequate rest. With pressure-support ventilation, the ventilator rate is not set.

## Inspiratory flow rate

In patients with COPD, increasing inspiratory flow to 100 l/min produces better gas exchange, probably because the resulting increase in expiratory time allows more complete emptying of gas-trapped regions [35]. Studies in healthy subjects [36], as well as in intubated patients [37], have demonstrated that increasing the inspiratory flow setting causes an immediate increase in respiratory frequency and respiratory drive. Yet, it has been demonstrated that imposed ventilator inspiratory time, independent of delivered inspiratory flow and tidal volume, can determine respiratory frequency [38]. More recently, in patients with COPD, it was demonstrated that the increase in respiratory rate noted as inspiratory flow was increased, was associated with an increase in expiratory time and a decrease in $PEEP_i$ [39] (Fig. 57.2). A shortened inspiratory time combined with time-constant inhomogeneity of COPD will cause overinflation of some lung units to persist into neural expiration. Continued inflation during neural expiration causes stimulation of the vagus, which prolongs expiratory time [40].

**FIG. 57.2** Continuous recordings of flow, esophageal pressure (Pes), and the sum of ribcage and abdominal motion, in a patient with COPD receiving AC ventilation at a constant tidal volume. As flow increased from 30 to 60 and 90 l/min (from right to left), frequency increased (from 18 to 23 and 26 breaths/min, respectively), $PEEP_i$ decreased (from 15.6 to 14.4 and 13.3 cm $H_2O$, respectively), and end-expiratory lung volume also fell. Increases in flow from 30 to 60 and 90 l/min also led to decreases in the swings in Pes from 21.5 to 19.5 and 16.8 cm $H_2O$, respectively (from Ref. [39] with permission).

## POSITIVE END-EXPIRATORY PRESSURE

In patients with COPD, dynamic hyperinflation results from dynamic airway collapse. The accompanying increase in alveolar pressure is termed $PEEP_i$. To trigger the ventilator in this situation, the patient must first generate a negative inspiratory pressure equal in magnitude to $PEEP_i$ and then overcome the trigger sensitivity setting. Provided the increase in $PEEP_i$ is secondary to increased elastic recoil, rather than expiratory effort, the addition of external PEEP can decrease the inspiratory threshold load [41,42].

Deciding the appropriate amount of external PEEP in patients with airflow limitation can be difficult because of regional inhomogeneities among lung units, each with its own critical closing pressure [43]. If application of external PEEP causes an increase in end-expiratory lung volume, decreases in cardiac output and blood pressure are likely to follow [44–47]. In general, a level of external PEEP, approximately 70% of the $PEEP_i$ value, is used in patients with COPD [44–47]. In contrast to patients with airflow limitation secondary to COPD, PEEP should be avoided in patients with asthma, because it is likely to increase lung volume and decrease cardiac output [48].

## ANCILLARY THERAPY

Studies have established that it is possible to achieve satisfactory bronchodilation using a metered-dose inhaler (MDI) despite the presence of an endotracheal tube in mechanically ventilated patients. It is essential to follow a specified protocol, use an inline chamber device [49], and actuate the MDI at the onset of inspiratory airflow. Maximal bronchodilation can be achieved in patients with COPD with as few as four puffs of a sympathomimetic aerosol (Fig. 57.3) [50].

Analgesic, anxiolytic, and neuromuscular blocking agents are frequently used in mechanically ventilated patients. When selecting an analgesic in a patient with asthma, use of morphine should be avoided because of the risk of histamine release and worsening bronchospasm [51]. Neuromuscular blocking agents can result in prolonged paralysis and the development of an acute myopathy [52, 53]. The concurrent use of corticosteroids appears to increase the risk. The inadvertent discontinuation of mechanical ventilation in patients receiving a neuromuscular blocking agent will cause complete apnea, leading to cardiopulmonary arrest. Train-of-four monitoring is recommended while patients receive neuromuscular blocking agents, although clinical assessment at the bedside is equally important [54].

Heliox is a mixture of either 70% or 80% helium with oxygen, that has a density one-third that of room air. It has been theorized that heliox may decrease the work of breathing and improve gas exchange during an acute exacerbation in patients with asthma and COPD. Controlled studies involving noninvasive ventilation or intubated patients have demonstrated mixed results [55–58]; with only small changes in $PaCO_2$ [56] and hemodynamics [55], and a slight decrease in the work of breathing and $PEEP_i$

**FIG. 57.3** In mechanically ventilated patients with COPD, four puffs of albuterol with an MDI resulted in a significant decrease in maximal inspiratory airway resistance ($Rrs_{max}$) within 5 min, with no further improvement after a total of 28 puffs (from Ref. [41] with permission).

[55, 57, 58]. In patients receiving noninvasive ventilation, heliox does not decrease the intubation rate or the length of stay in the ICU [59].

While previously investigated in patients with acute lung injury [60], prone positioning has more recently been examined in intubated patients with COPD during an acute exacerbation. While improvements in oxygenation [61, 62], as well as chest wall and lung mechanics [62] have been reported, these studies were uncontrolled and involved small numbers of patients.

## COMPLICATIONS

Patients receiving mechanical ventilation are at risk of numerous complications, including oxygen toxicity, air leaks, infection, endotracheal tube complications, and decreased cardiac output. These problems occur frequently and they can be life threatening if not promptly detected and treated.

### Barotrauma

The development of extraalveolar air, in the form of pneumomediastinum, subpleural air cysts, subcutaneous emphysema, pneumothorax, or pneumoperitoneum is termed pulmonary barotrauma. These findings have been found in 14–27% of patients with obstructive lung disease receiving mechanical ventilation [4, 11, 12].

### Infection

Pneumonia develops in 21% of patients receiving mechanical ventilation for over 48 h [63]. In mechanically ventilated

patients with COPD, more than 40% of the patients have potentially pathogenic microorganisms present in their upper and lower airways, and have an increased risk of life-threatening pneumonia [64]. The diagnosis of pneumonia is often difficult in patients receiving mechanical ventilation, because clinical criteria are unreliable and airway colonization confounds the identification of causative organisms. Studies comparing the use of quantitative cultures of specimens obtained by bronchoalveolar lavage or with a protected specimen brush passed through the bronchoscope to nonquantitative culture of endotracheal aspirates have demonstrated conflicting results [65–67]. Therefore, the optimal approach to diagnosis ventilator-associated pneumonia is yet to be determined.

## Effects on cardiac output

Both PEEP and $PEEP_i$ can cause similar decreases in cardiac output, primarily by decreasing venous return. In addition, increases in pulmonary vascular resistance, secondary to alveolar distension and stretching of adjacent vessels, increases right ventricular afterload. As a result, the interventricular septum may shift to the left and decrease left ventricular compliance. Distended lung parenchyma may also increase juxtacardiac pressure and decrease left ventricular compliance. $PEEP_i$ has been noted in patients with COPD experiencing hemodynamic embarrassment [68]. On discontinuation of mechanical ventilation, hemodynamics improved as the amount of $PEEP_i$ decreased.

## WEANING

About 70% of patients tolerate the first attempt to discontinue mechanical ventilation [69, 70]. Nevertheless, about 40–60% of total ventilator time is devoted to the process of weaning.

## Pathophysiology of weaning failure

In patients with COPD, a decrease in respiratory motor output appears to be a rare cause for failure to wean [17]. The major reason that patients with COPD fail weaning trials is because of a progressive increase in work of breathing secondary to increases in resistance, elastance, and $PEEP_i$. In contrast, pulmonary mechanics during passive ventilation are virtually indistinguishable in weaning success and weaning failure patients before a weaning trial [71]. Respiratory muscle weakness is commonly seen in patients that fail a weaning trial [72]. However, the development of respiratory muscle fatigue does not appear to be responsible for weaning failure [72]. One reason may be that failure patients become progressively distressed during a weaning trial, leading clinicians to reinstate ventilator support before patients have breathed long enough to develop fatigue [72, 73]. That is, monitoring clinical signs of distress provides sufficient warning to avoid respiratory muscle fatigue. Only a fraction of patients develop abnormal gas exchange, with

the development of hypercapnia and/or hypoxemia [74]. An increase in right and left ventricular afterload during a weaning trial may affect how the cardiovascular system meets oxygen demand in weaning failure patients, and contributes to the development of hypoxemia [75]. Rigorous studies of the pathophysiology of weaning failure in patients with asthma have not been conducted.

## Timing of weaning process

Previous studies emphasize that clinical bedside assessment and physician judgment are insufficient in determining the appropriate time to initiate weaning [76]. Weaning involves the use of three diagnostic tests in sequence: measurement of predictors, a weaning trial, and a trial of extubation. The fundamental job of a weaning-predictor test is screening; with an ideal screening test having a very high sensitivity [77]. The best predictor of weaning outcome is the measurement of the frequency-to-tidal volume ratio, a measure of rapid shallow breathing. A frequency-to-tidal volume ratio above 100 breaths/min/l suggests that weaning is not likely to be successful [78].

## Weaning techniques

When a screening test is positive, the clinician proceeds to a confirmatory test; an ideal confirmatory test has a very low rate of false-positive results. That is, a high specificity. Four weaning techniques are generally used. With IMV and PS, the level of ventilator assistance is gradually reduced. PS became popular as a means of overcoming the resistance of the endotracheal tube. This line of thinking, however, ignored the fact that the upper airway becomes swollen when an endotracheal tube has been in place, and after extubation patients will experience increased upper airway resistance. Indeed, the work of breathing following extubation is similar to that while breathing on a T-piece [79]. With IMV, at respiratory rates of 14 breaths/min or less, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue [22, 23].

Several randomized trials have been performed comparing weaning techniques [69, 80]. IMV has been shown to delay the weaning process. A once-a-day trial of spontaneous breathing resulted in a threefold increase in the rate of successful weaning compared with IMV, and a twofold increase in successful weaning compared with PS. Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day [69], but much simpler. In patients not expecting to pose any particular difficulty with weaning, a half-hour trial of spontaneous breathing is as effective as a 2-h trial [70]. The use of protocol-driven algorithms for weaning has not shown superiority in shortening the time to successful extubation [81–86].

Before removing the endotracheal tube, the clinician must judge whether or not the patient will be able to maintain a patent upper airway after extubation. Mortality among patients that require reintubation is more than six times as high as mortality among patents who can tolerate extubation [70]. The reason is unknown, but may reflect a greater severity of the underlying illness [87].

## NONINVASIVE POSITIVE PRESSURE VENTILATION

In patients with COPD and acute respiratory failure, the use of noninvasive positive pressure ventilation results in less frequent intubation, decreased complications, and a shorter hospital stay. More recently, noninvasive positive pressure ventilation was shown to be equally effective in those with more severe as compared to mild acute respiratory acidosis, both in regards to normalization of pH and $PaCO_2$, as well as duration of use and hospital length of stay [88]. In two of these studies, noninvasive positive pressure ventilation caused a decrease in mortality [89–91].

## CONCLUSION

Patients with obstructive lung disease commonly develop acute respiratory failure, requiring the institution of mechanical ventilation. Abnormalities in pulmonary gas exchange, lung mechanics, and respiratory muscle function contribute to the development of respiratory failure. Adapting ventilator strategies that account for these abnormalities, such as controlled hypoventilation in acute asthma or the application of external PEEP in patients with COPD, may decrease morbidity and possibly improve patient outcome.

# Pulmonary Rehabilitation

**Thierry Troosters[1,2], Wim Janssens[1] and Marc Decramer[1,2]**

[1]Respiratory Rehabilitation and Respiratory Division, University Hospital, Leuven, Belgium
[2]Faculty of Kinesiology and Rehabilitation Sciences, Department of Rehabilitation Sciences, Katholieke Universiteit Leuven, Leuven, Belgium

## INTRODUCTION

Pulmonary rehabilitation is nowadays a recognized evidence-based therapy which can be applied to patients with lung diseases who are symptomatic and have reduced activities of daily living, despite optimal medical therapy [1, 2]. Unlike most drugs, pulmonary rehabilitation does not target the lungs directly, but aims at reversing or stabilizing the extra-pulmonary effects of lung diseases [1].

Lung disease, especially chronic obstructive pulmonary disease (COPD), is a poorly diagnosed, but a very prevalent problem in our society. More than half the patients with mild to moderate COPD remain undiagnosed until late in the disease [3]. Physical inactivity is a natural defense strategy to avoid the distressing symptom of exercise induced dyspnea. Unfortunately, inactivity inevitably leads to many of the systemic

consequences associated with COPD, such as skeletal muscle weakness, osteoporosis, reduced insulin sensitivity, cardiovascular morbidity, and mood disturbance. Further catalyzed by smoking and perhaps systemic inflammation, oxidative stress, and exacerbations, these systemic consequences may develop along with the progressing airflow obstruction. In fact, particularly patients with comorbidity or systemic consequences were characterized by an inactive lifestyle even in milder stages of COPD [4]. Figure 58.1 shows that the vast majority of patients referred to our rehabilitation program had developed skeletal muscle weakness to some degree, independently of the lung function impairment. Undoubtedly, skeletal muscle dysfunction is an important extra-pulmonary consequence. In COPD, skeletal muscle weakness has been shown to be related to impaired survival [5, 6]. In addition, skeletal muscle weakness is an important driver of utilization of health-care recourses [7]. In the context

**FIG. 58.1** Relation between lung function impairment ($FEV_1$, expressed as a percentage of the predicted normal value) and Quadriceps force (QF, expressed as a percentage of the predicted value) in 380 consecutive patients with COPD (age $65 \pm 8$ years, $FEV_1$ $42 \pm 16$), referred to the authors' outpatient rehabilitation program. Pearsons correlation coefficient was 0.094, *p*-value 0.07.

**TABLE 58.1** An overview of the effects of pulmonary rehabilitation as reported in evidence-based practice guidelines [11], a state of the art review [12] and a Cochrane meta-analysis [13].

| Effect | Evidence grade [11] | Size of effect |
|---|---|---|
| Improvement of dyspnea | 1A | CRDQ-Dys: 1.06 (0.85 to 1.26) points [13] |
| Improvement of HRQoL | 1A | SGRQ total: −6.11 (−8.98 to 3.24)% [13] |
| Reduction in hospital days and utilization of health care recourses | 2B | |
| Survival | None provided | |
| Psychosocial benefits (self-efficacy with exercise, cognitive function, anxiety, depression) | 2B | |
| *Exercise tolerance* | | |
| Peak work rate | | 8W (3–13W) [13] + 18 (IQR 13–24) % baseline [12] |
| 6MWD | | 48 min (32–65 min) [13] + 34 min if <28 s, 50 min if >28 s [12] |
| Whole body endurance | | + 87% of baseline [12] |

Evidence grading 1A: Strong recommendation; 2B: Weak recommendation; CRDQ-Dys: Dyspnea subscale of the chronic respiratory disease questionnaire; SGRQ: saint Georges Respiratory Questionnaire; 6MWD: six minute walking distance.

of pulmonary rehabilitation, it is also important to recognize the non-physiological extra-pulmonary consequences of chronic lung disease. Depression, for example, is very prevalent in stable patients [8], and is significantly related to the adverse outcome of COPD, particularly after acute exacerbations [9]. In the recent Global Initiative for Obstructive Lung Disease (GOLD), the systemic consequences of COPD were specifically noted as an important marker of morbidity, complicating the management of obstructive lung disease [10].

As mentioned above, pulmonary rehabilitation targets the systemic consequences of lung diseases. It is now generally recognized as an evidence-based and effective therapy for patients with lung diseases, who are symptomatic and have reduced participation the in activities of daily life. The evidence on the effectiveness of pulmonary rehabilitation is impressive, and has been reviewed in several recent documents. Table 58.1 summarizes the most important effects of rehabilitation and where applicable the strength of the evidence, as provided in the different evidence-based reviews. To be successful, pulmonary rehabilitation is typically designed as a comprehensive intervention offered by a team of health-care providers over a substantial period of time. Typically, rehabilitation programs are carried out for 6 weeks to 6 months, with longer programs yielding more substantial effects [14]. Patients participate in an individualized tailored program which takes into account the complexity of the presenting patient. Exercise training is the cornerstone of such a program. Several other interventions may complement the program to maximize its effectiveness. Pulmonary rehabilitation may serve many goals, which depend on the perspective one takes. Examples of the goals from the different perspectives are as follows:

Patient's perspective:

- Reduced symptoms of breathlessness or fatigue
- Enhanced exercise tolerance and skeletal muscle strength

- Improved physiological and emotional function
- Increased health-related quality of life.

The health-care provider's perspective:

- Optimal self-management by the patient
- Optimal utilization of available recourses.

The societal perspective:

- Increased productivity and active participation of patients in society
- Reduction of cost associated with the management of the disease
- Enhanced coping of the family when a family member is suffering from COPD.

It is important to realize that patients suffering from other respiratory diseases, such as pulmonary sarcoidosis [15], cystic fibrosis [16], or after lung transplantation [17], equally present systemic consequences of their disease. Consequently, pulmonary rehabilitation programs should not be restricted to patients with COPD, but should be open to any patient suffering from extra-pulmonary consequences of lung diseases in general.

## THE INDICATION FOR REHABILITATION AND SETTING

According to the definition of the American Thoracic Society and the European Respiratory Society, pulmonary

rehabilitation is aiming at reducing symptoms, optimizing function, increasing participation, and reducing health-care cost through stabilizing or reversing the systemic consequences of the disease [1]. Hence, theoretically, patients with an indication for the need of rehabilitation are those suffering from extra-pulmonary consequences. This definition is, however, not very practical as the systemic consequences that can be targeted by pulmonary rehabilitation are not defined. Clearly, not all "systemic consequences" of the disease are amendable to pulmonary rehabilitation. For example, osteoporosis and anemia are the recognized systemic consequences of COPD [18], but it is unlikely that pulmonary rehabilitation would have a significant impact on these outcomes. In addition, the spin-off of pulmonary rehabilitation may well be an enhanced self-management, which leads to more efficient utilization of health care recourses and cost savings [19], without altering the "systemic consequences of the disease."

A more practical approach to identifying candidates for rehabilitation and guide the assessment of patients before enrollment in rehabilitation could be to select patients who are optimally pharmacologically treated, but still present with one of the following:

- Disabling symptoms due to deconditioning
- Skeletal or respiratory muscle weakness
- Poor health-related quality of life
- Repeated exacerbations or inefficient use of available recourses
- Depressed mood status
- Malnutrition (obesity of cachexia)
- Poor coping with the symptoms of their disease.

This allows to set up active screening for rehabilitation programs, which typically includes assessment of exercise tolerance, skeletal and respiratory muscle force, nutritional status, symptoms, health-related quality of life, and capability of self-management.

Depending on the complexity of the individual problem, the program can be designed across a range of complexities. Programs can be as simple as an intervention consisting of exercise training in the home setting of patients with uncomplicated COPD [20] or as complex as an in-patient program in a mechanically ventilated patient [21]. On the basis of proper assessment the individual program, its setting and components can be designed, taking into account the available recourses in a given region, current best practice, and evidence. Several guidelines may help those setting up pulmonary rehabilitation facilities to structure their program [1, 11, 22, 23].

Exercise training has now the status of the cornerstone of each program, and will be dealt with below. Exercise training has a strong evidence base. A program of exercise training of the muscles of ambulation is recommended and is a mandatory component of any pulmonary rehabilitation program [11]. For several other components of a rehabilitation program, however, evidence is also building up, particularly for specific subgroups of patients.

In depressed patients (some 40% (95% CI: 36–44%) of patients with COPD [24]), for example, *psychological counseling* may be of benefit in order to help reducing symptoms of depression or anxiety. Admittedly, a large trial to confirm the point is currently still missing [25, 26], but since depressive symptoms do significantly impact on health-related quality of life [27] and even impact readmission [9] in these patients, psychological counseling may well be worth the effort in patients who suffer from symptoms of depression, anxiety, or poor coping. It should be stressed, however, that exposure to exercise therapy may in itself have an anti-depressant effect [28]. *Nutritional interventions* have been shown to be unsuccessful in poorly selected COPD patients [29]. However, when nutritional interventions are successful in improving body mass in cachectic patients, they do spin-off in an important survival benefit [30]. Besides patients suffering from pulmonary cachectia, a less recognized role, but likely of equal importance, is the care for obese COPD patients. Clearly obesity is linked to increased pulmonary ventilation to carry out activities of daily living. Consequently, weight loss in obese patients might yield important functional benefits in activities carried out against gravity (e.g. stair climbing, walking). The authors believe that weight loss, particularly loss of fat mass, might be an important target in overweight COPD patients referred to pulmonary rehabilitation programs. *Occupational therapists* may be consulted within the context of a rehabilitation program [31]. Occupational therapists may advise patients on the mode and pace of carrying out activities of daily life. Oftentimes occupational therapists might advise on the use of wheeled walking aids (rollators). Although many patients show poor compliance with the daily use of a rollator [32], those who use it may substantially and suddenly improve their exercise tolerance [33, 34]. Other potentially cost-effective components of a rehabilitation program are interventions aiming at enhancing self-management. Generally, these interventions are supervised by *specially trained advanced practice nurses*, who work integrated in the rehabilitation team. Interventions aiming at enhancing self-management have shown variable success [35]. Studies showing cost-effectiveness of these interventions focused at a subgroup of patients with at least one hospital admission [19]. Hence it seems reasonable to direct efforts specifically to this subgroup of patients.

Another point to consider when a patient is referred to a pulmonary rehabilitation program is the setting of such a program. Programs have been successfully set up in a primary care (home) setting [20, 36] as an outpatient program in a rehabilitation center [37] or in the community [38, 38], or as an in-patient program [39, 40]. Clearly each of these programs has advantages and disadvantages. One of the most important problems of home-based programs is the limited staff and equipment, which makes it difficult to deal with more severe patients [41]. The most important problem of outpatient programs is the transportation to the center [42]. In-patient programs are costly and should be restricted to those patients with very limited mobility. Ideally, a reference rehabilitation center should have access to all modalities of rehabilitation. This can be done by establishing strong links between the different lines of health care.

## Screening of patients for rehabilitation

From the above it is clear that proper design of a rehabilitation program depends on a thorough screening of patients. This screening should answer the following questions:

1  Is there an indication for pulmonary rehabilitation in a given patient and what results can be expected?
2  Which components should be included in the program for a given patient and what will be the optimal setting of the program?

An example of the intake procedure in the authors' institute is given in Table 58.2.

## Indication and expected results

To establish the indication for a rehabilitation program, a formal exercise test should be carried out. Exercise intolerance is indeed an important reason to refer a patient for rehabilitation. We found that patients with skeletal and respiratory muscle weakness were most responsive to exercise training [43], justifying the assessment of peripheral and respiratory muscle strength. Rehabilitation programs are oriented toward patients who are symptomatic and have reduced activities of daily life, encouraging to assess symptoms and health-related quality of life, and physical activity. With evolving technology it becomes possible to assess the latter, rather than estimate physical activity levels with questionnaires [44, 45]. In patients admitted to the hospital with a severe exacerbation of COPD, pulmonary rehabilitation

**TABLE 58.2**  An example of the intake procedure for pulmonary rehabilitation at the authors' center.

| Test | Reason or consequence |
|---|---|
| Lung function assessment | Disease severity |
| *Exercise test* | |
| Incremental cycle ergometry | Exercise intolerance/factors limiting exercise |
| 6MWD | Exercise intolerance, treatment effect |
| Constant work rate test | Treatment effect |
| *Muscle function* | |
| Quadriceps force, biceps, triceps | Muscle weakness? Need for resistance training |
| Respiratory muscle force | Need for inspiratory muscle training |
| *Symptoms, Function* | |
| MRC | Severity of impairement in daily life |
| PFSDQ | Symptoms in daily life (occupational therapists) |
| *HRQoL* | |
| CRDQ | Indication for rehabilitation, identification of problems in four domains |
| *Activity monitoring* | |
| 1 week of monitoring | Actual physical activity level |
| *Interview psychologist* | |
| HADS | Psychological burden |
| Social anamnesis | Social support |
| Nutritional anamnesis | Calorie intake and nutritional + protein balance |
| Bioelectrical impedance | Assessment of body composition |

6MWD: six minute walking distance; MRC: medical council dyspnea scale; PFSDQ: Pulmonary functional status and dyspnea scale;
HRQoL: Health related quality of life with the Chronic Respiratory Disease Questionnaire (CRDQ); HADS: Hospital anxiety and depression scale.

should be part of the proper after care. In these patients rehabilitation does reduce readmission rate by 75% and may even enhance survival [46]. In addition substantial and clinically relevant improvements in exercise tolerance and health-related quality of life were reported [47].

## Components of the rehabilitation program

To establish the components of the rehabilitation program and its optimal setting, a multidisciplinary assessment is needed. This consists of a nutritional assessment, including analysis of the fat free mass and a nutritional interview to estimate the caloric balance [48]. A thorough social interview to gain insight in the social network and available social support is helpful since patients lacking social support are at risk to drop out from a program [49]. An intake by a psychologist may allow to identify the large proportion of patients suffering from significant depressive symptoms or other psychiatric morbidity [50]. An important and often forgotten aspect may be the burden on the partner of the patient [51]. A first screening for psychological morbidity can be done using questionnaires such as the Beck depression inventory or the Hospital Anxiety and Depression Scale. Lastly physical activity levels of patients and symptoms during specific activities of daily living can be assessed using questionnaires such as the Pulmonary Functional Status and Dyspnea Questionnaire (PFSDQ) [52, 53].

Depending on the complexity of the individual case one or more disciplines can be engaged in the rehabilitation process of the individual patient. Ideally the patient is referred to a program which optimally meets his needs and takes into account the motivation and social circumstances. Needless to say that a program should also be moduled along the possibilities of the health-care system in a given region.

## Exercise training

Exercise training is undoubtedly the cornerstone of a pulmonary rehabilitation program. Programs aim at enhancing exercise tolerance and skeletal muscle force. Skeletal muscle force can be enhanced by specific resistance training (weightlifting) exercise [54–56]. Improvement in exercise tolerance is essentially obtained through two main pathways. First, the oxidative capacity of the skeletal muscle is enhanced [57], leading to reductions in lactate production at identical work [58]. A second pathway involves an improvement in movement efficiency, yielding less oxygen consumption to cover identical work rate. Both pathways are not mutually exclusive, and both lead to reductions in pulmonary ventilation, and dynamic hyperinflation during exercise. The reduction in pulmonary ventilation, the improved dynamic hyperinflation, and the desensitization (better tolerance to high ventilatory levels) are crucial to the improved exertional dyspnea, which is seen after exercise training [13]. To enhance the oxidative capacity of the skeletal muscle, exercise training should be conducted at relatively high training intensity [58] (see below). Improvement in movement efficiency is obtained by practicing specific exercises (e.g. walking training will only improve walking efficiency). For this pathway, the modality of the exercise is more crucial than the intensity at which the exercise is carried out.

In general, exercise training in patients with COPD follows the principles of exercise training in the healthy elderly [59]. Programs generally consist of a brief warm-up, a core program lasting at least 30 min of exercise and a cooling down. An example of an exercise training program is given in Table 58.3. Close supervision and proper monitoring of the patients ensure the safety during the program [12]. In fact, very few exercise-related events and, as far as the authors are aware, no fatal events have been reported after pulmonary rehabilitation in the published literature.

**TABLE 58.3** An overview of an outpatient rehabilitation session in the rehabilitation center of the authors.

| Time | Duration (min) | Item | Intensity |
|------|----------------|------|-----------|
| 13:00 | 5 | Brief contact with health care provider to check the health status. Resting saturation, peak flow, and heart rate are recorded | |
| 13:05 | 10 | Low intensity warm-up exercise on bicycle | 20–30 W |
| 13:15 | 32 | Cycling exercises e.g. 8 blocks of 2 min interval training with 2 min of rest between the intervals | 75% Wmax |
| 13:47 | 15 | Resistance training exercises for the upper and lower limb. Typical muscle groups are quadriceps, triceps, biceps and pectoral muscle | 3 series of 8 repetitions |
| 14:02 | 6 | 2 blocks of 2 min stair climbing separated by 2 min of rest | Dyspnea 4–6/10 |
| 14:08 | 6 | 2 blocks of 2 min of arm ergometry separated by 2 min of rest | Dyspnea 4–6/10 |
| 14:14 | 20 | 2 blocks of 8 min of treadmill walking | 80% 6 MWs |
| 14:34 | 30 | Individual contact with another health care worker (psychologist, social worker, dietician) | |
| 15:04 | | End of session | |

## Whole body exercise

Exercise training has been included in virtually all studies investigating the benefits of pulmonary rehabilitation. To successfully increase skeletal muscle properties and render measurable physiological benefits, it is important that patients do exercise at relative high work loads. To do so, the exercise training intervention can be adapted to the individual exercise limitations of the patient. The conventionally used form to deliver exercise training to COPD patients is endurance training. In COPD patients with primarily moderate disease, exercise training conducted at approximately 75% of the peak work rate (60% of the difference between the lactate threshold and peak oxygen uptake) resulted in significant physiological effects [58]. A similar training strategy was shown to be effective in patients with severe disease [60]. Others have confirmed that high training intensity is required to elicit physiologic training effects [61, 62].

It is important to adjust and increase the training load in every training session. Trained personnel should be available to ensure close supervision on the training intensity. Training intensity can be monitored using 10-point Borg symptom scales. A score around 4–6 is generally advised as an appropriate training intensity, provided the patients are familiar with the scale. Interestingly, a given Borg symptom score is generally chosen by a patient at an identical relative work rate. Hence as patients improve during training, the same Borg rating will be achieved at higher absolute work rates [63]. Since most patients are not limited by the cardiovascular system, using heart frequency to guide exercise training is not to be advised.

In patients who reach a ventilatory limitation during exercise, it is difficult to obtain a high training intensity for sustained periods of time. Several strategies may help clinicians to ensure high intensity training in more severe COPD. Interval exercise training has been used and showed to result in physiological benefits, comparable to those of endurance training [64–67]. The advantage of interval training is that the ventilatory requirements remain relatively limited [68]. Interval training is achieved by breaking down the long exercise bouts into smaller bouts of exercise separated by periods of active recovery (low work rate) or rest.

An intervention that minimizes the ventilatory burden during exercise training is the use of supplemental oxygen. Oxygen, dose dependently, reduces the ventilation for a given exercise intensity [69, 70]. The application of oxygen supplements hence allows training at higher training intensity [71]. Non-invasive mechanical ventilation reduces the work of breathing and has been used successfully in severe COPD as an adjunct to exercise training [72–74]. In less severe COPD the impact of using non-invasive mechanical ventilation was not significant [75]. Lastly, the required ventilation can be reduced simply by reducing the amount of muscles set at work. If exercise is confined to one leg, ventilation is considerably reduced, allowing a significant increase in training load [76]. A recent trial confirmed that in severe patients, single leg exercise training resulted in 20% more increase in peak oxygen consumption and peak work rate compared to conventional cycling training (two legs) [77]. In the latter study, however, no patient centered outcomes were assessed. Hence, although interesting from a physiological perspective, it is too early to judge whether single leg exercise training is

ready for wide clinical use [78]. Similarly, during cycling less muscles are recruited compared to walking exercises; hence it is not surprising that for a given oxygen consumption, cycling is more fatiguing for the quadriceps muscle [79]. It would be interesting to conduct a head-to-head comparison study on the physiological effects of cycling versus walking exercises. On the basis of the larger potential to elicit muscle fatigue, cycling would be a form of exercise training that may result in larger physiological effects, compared to walking. However, such a study is currently unavailable.

All the above techniques reduce the ventilatory burden. Another complementary option is to enhance the ventilatory capacity. Obviously optimal bronchodilator therapy does also allow for larger pulmonary ventilation and less dynamic hyperinflation during exercise. In one study, a potent long-term anti-cholinergic drug showed to enhance exercise training effects compared to the use of short acting bronchodilators only [80]. Breathing gases with light density (e.g. helium and oxygen, HELIOX) also enhance the ventilatory capacity. One study suggests that maximal ventilation is enhanced by 16% when breathing 21% oxygen and 79% helium [81]. Although this would technically allow training at higher intensity, it is doubtful whether this intervention is currently ready for clinical routine. A last intervention which enhances peak ventilatory capacity is bracing the arms. During walking, this can be applied using a wheeled walking aid (rollator). Our group showed that bracing the arms on a rollator enhanced maximal voluntary ventilation by 8 l/min, which partly explained the acute beneficial effect of a rollator [82]. During treadmill walking, bracing of the arms can also easily be achieved.

## Resistance training

Another form of conventional training is resistance training. This form of exercise, generally consisting of weight lifting, can be used as the only form of training [55, 56, 83], or in combination with whole body exercises [54, 55, 84]. In all the latter studies, muscle strength was significantly more increased when resistance training was added to the exercise regimen. Increased muscle strength is an important treatment objective in patients with COPD suffering from muscle weakness, as activities of daily life do require strength apart from muscle endurance. As mentioned above, muscle weakness is an important factor related to morbidity and even mortality in COPD. It follows that patients suffering from muscle weakness may be particularly good candidates to a resistance training program.

Resistance training is easy to apply in clinical practice. Patients are instructed to lift weights (generally on a multi-gym device). The weight imposed and the number of repetitions ensure overload of the skeletal muscle. In patients with COPD and several other chronic diseases, resistance training is started at approximately 70% of the weight a patient can lift once (i.e. the one repetition maximum). The effects of resistance training programs may be enhanced in male hypogonadal patients by testosterone replacement therapy. In one study, [85] weekly intramuscular injections with testosterone, aiming at restoring testosterone levels to normal values in initially hypogonadal men, did enhance skeletal muscle force more than either of the interventions

alone. Further studies are required to investigate the long-term safety of this intervention. However, since skeletal muscle dysfunction is in itself a negative prognostic factor, a short-term use of testosterone may be beneficial to result in a rapid restoration of this potentially harmful situation.

## Neuromuscular electrical stimulation

Another intervention used to specifically stimulate the peripheral muscles is medium to high-frequency neuromuscular electrical stimulation (NMES). Four studies have investigated successfully the effects of this intervention [86–89]. All studies in COPD used transcutaneous electrical stimulation with stimulation frequencies of 35 [89] to 50 Hz [86, 87, 90]. In patients with congestive heart failure, low-frequency (10–15 Hz) transcutaneous electrical stimulation was successfully applied [91, 92]. Studies showed that there was more strength gain in the skeletal muscles treated with electrical stimulation, either as mono-therapy or in combination with general exercise training [89]. This intervention may prove to be attractive in patients who have difficulties to take part in regular rehabilitation, such as patients admitted to hospital with acute exacerbations.

## Enhancing physical activity

In the last few years, more attention has been given to the effect of pulmonary rehabilitation on physical activity levels. A minimum of 30 min of physical activity of moderate intensity is critical to maintain health [93]. A recent study also showed the importance of maintaining a healthy and physically active lifestyle, which has been shown to be crucial for survival in COPD [94]. Only a handful of studies have investigated the effect of pulmonary rehabilitation on physical activity [95–100]. The results of these studies are summarized in Fig. 58.2. None of these studies were randomized controlled trials, so the differences presented represent pre- to post-program differences. Interestingly not all of them showed significant improvements of the amount and intensity of physical activities in daily life after pulmonary rehabilitation. One trial [95] suggests that the effect of rehabilitation on physical activity is larger after longer programs. However, the relation between the length of the programs and their effectiveness on physical activity can surely not be seen across the different published trials. From the available evidence, it can be appreciated that the transfer of improvements in exercise tolerance toward enhanced activities of daily living should not be taken for granted. Indeed, physical activity is a behavior. The amount and intensity of activities in which patients engage depends, besides their exercise capacity, on intrinsic factors such as motivation, perceived self-efficacy, mood status, and health beliefs. Other factors related to physical activity are extrinsic factors such as social and cultural role, external barriers (e.g. environmental), and climate. Clearly more research is needed to enhance the impact of pulmonary rehabilitation beyond the immediate effects on health-related quality of life, symptoms, exercise tolerance and utilization of health care recourses and also enhance activities of daily living. The missing link toward more endurable effects of pulmonary

**FIG. 58.2** The effect of different pulmonary rehabilitation on assessed activities of daily living. Different activity monitors were used, hence data are expressed as a % of the baseline measure. Open symbols represent studies in which the effect was reported as non-significant, closed symbols are studies that reported a statistically significant effect. ◆ Sewell, *Chest* 2006; ○ Pitta, *Chest* 2008 (after 3 months); ● Pitta, *Chest* 2008 (after 6 months); △ Corronado, *J Cardiopulm Rehabil* 2003; ▼ Mercken, *Am J Respir Crit Care Med* 2005; □ Steele, *Arch Phys Med Rehabil* 2008; ◇ Steele, *J Rehabil Res Dev* 2003.

rehabilitation may very well be the failure to successfully enhance daily physical activity levels of patients toward levels of moderate intense physical activity, sufficient to maintain health, and perhaps, the achieved benefits of the previous rehabilitation program.

## INTRODUCTION

Although drugs, together with pulmonary rehabilitation, will form the mainstay of treatment for most patients with chronic obstructive pulmonary disease (COPD) as the lung destruction progresses, these therapies become insufficiently effective for a minority of patients who may then be prepared to consider a surgical treatment. As a general rule, these therapies should not be offered to patients who have not completed pulmonary rehabilitation and should not be offered outside specialist centers where a truly multidisciplinary approach is available. Asthma, being a condition characterized by variable airflow obstruction, is seldom suitable to a surgical approach although the experimental approach of thermoplasty will be briefly discussed.

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE

### Surgical procedures

In the 1950s Owen Brantigan formed the concept that a surgical treatment of emphysema would be to "reduce lung volume to fit the expiratory phase of the respiratory cavity [by] removing lung tissue that has no respiratory function" [1]. In fact, perhaps due to difficulty with patient selection and the poorer standard of anesthetic and postoperative care at the time the technique was never widespread and except for occasional patients who could benefit from a bullectomy [2, 3] or a Monaldi procedure [4], the only surgical therapy available until recently was single or double lung transplantation. Transplantation remains a moderately dangerous procedure with a mortality in the first year of approximately 15%. More importantly there are insufficient donor organs for the number of patients willing to undergo the procedure.

For this reason surgical lung volume reduction was revived in the 1990s by Joel Cooper and colleagues [5]; their original data was confined to patients with marked hyperinflation and contained no control group but showed, at 6 months, a 51% improvement in $FEV_1$ and a reduction in oxygen usage such that 70% of patients were able to discontinue domiciliary oxygen therapy.

The technique was later submitted to randomized controlled trials of which the most important was the National Emphysema Treatment Trial (NETT) study [6] (*vide infra*) which accounted for 73% of all presently randomized patients. The results of the smaller studies are summarized in the table and have been usefully summarized in a Cochrane review [7] (Table 59.1). Broadly speaking, the review found that at 90 days there were significant benefits conferred by surgery with regard to quality of life whether measured with generic- or disease-specific instruments but it must be borne in mind that surgery itself has a significant placebo benefit. Other benefits from surgery included improved

**TABLE 59.1** Results of lung volume reduction surgery.

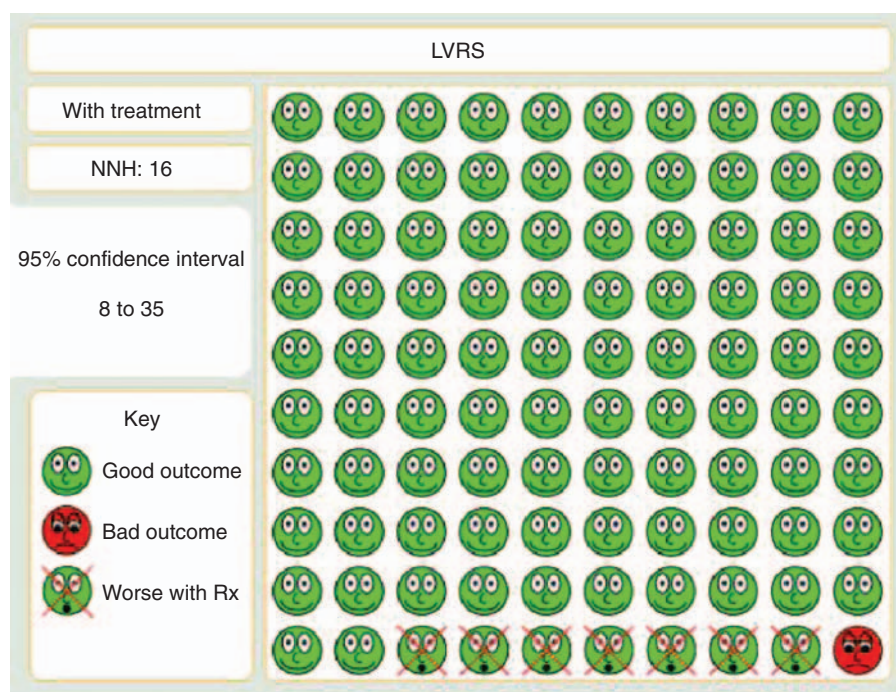

**FIG. 59.1** Ninety-day outcome of LVRS reproduced from the meta-analysis by Tiong *et al.* [7]. A second figure may be found in the paper showing the results when the high risk patients from NETT were excluded [13]. Interestingly although this exclusion reduces the number of patients who are worse after surgery but not the mortality; however the number needed to treat rises.

exercise performance, reduced emergency room attendance in postoperative year 2 (but not 1).

The NETT study is by far the biggest study to assess lung volume reduction surgery (LVRS) [6]; briefly after pulmonary rehabilitation 1218 were randomized to receive either LVRS or continued medical care (Fig. 59.1). An early analysis showed that patients with a homogenous distribution of disease and either a FEV$_1$ < 20% predicted or a carbon monoxide gas transfer (TL$_{CO}$) < 20% predicted had a poor outcome and were excluded from the remainder of the study [13]. The study showed that in the surgical group (compared with medical therapy) the exercise capacity improved on an incremental test by more than 10W in 28% and 15% of operated patients but only 4% and 3% of controls at 6 and 24 months respectively ($p$ < 0.001). Surgical patients were more likely to achieve an improved 6-min walk distance and exhibited an approximately 30% reduction in exacerbations [14]. An accompanying paper [15] found the difference in total cost at 3 years between the two groups was $36,392.

Long-term follow up of the randomized controlled trials conducted is confined to data from the Brompton study [9]; Lim and colleagues [16] found that improvement in residual volume (RV)/total lung capacity (TLC) ratio

and gas transfer tended to be more sustained than those in FEV$_1$. Overall the data showed that the surgical group was better than the control group for at least 3 years.

The current position for surgical LVRS is that it may best be described as useful only in patients with the most favorable radiological appearances (heterogenous upper zone disease), who are a minority of emphysema patients. Even so the operation is confined to those patients willing to accept the perioperative mortality (typically 5%) but who meet the safety criteria. These will vary slightly from institution to institution but, for example, we require an FEV$_1$ > 20%, a TL$_{CO}$ > 30%, and a shuttle walk distance (after rehabilitation) of >150 m. A further problem is that a minority of patients experience no benefit but these patients cannot be reliably predicted prior to surgery. As a result the number of procedures presently performed is small.

## Minimally invasive surgical therapies

Since LVRS was demonstrated to work in carefully selected patients the question arose as to whether lung volume reduction could be achieved more safely and cheaply using

a nonsurgical mechanical result. In principle, lung volume reduction could be achieved by the introduction of a blocker (subsequently modified to a one-way valve) into the airway. Sabaratnam Sabanathan, an English surgeon, first suggested endobronchial blockade as an alternative approach. Sadly he died whilst developing the concept but his preliminary data, from procedures performed between November 1996 and April 1997, [17] were published posthumously and showed that significant improvement was possible using this approach. However, the blockers initially used were not designed for endobronchial occlusion and later patients in the series had devices inserted that were custom built in Sabanathan's hospital. Significant problems were observed with migration of the first type of blockers and in the case of the custom built devices one episode of blocker disintegration occurred.

Biotechnology companies subsequently took up the challenge and two devices are commercially available. The Emphasys system (Emphasys Medical, Inc; Redwood City, CA) uses a one-way duckbill valve that is inserted in such a way that air is permitted to leave the subtended segment but not enter it. The valve is secured and supported by a collapsible metal framework. The initial valves (Fig. 59.2A) were inserted over a guide wire but later models (Fig. 59.2B) can be inserted through the working channel of a flexible bronchoscope. Five human studies have been reported with the valve [18–22], and the company has recently reported the combined data [23].

The Spiration (Spiration, Inc; Redmond, WA) device is an umbrella arrangement (Fig. 59.2C) arranged so that the convex surface is positioned distally with the aim again of allowing expiratory but not inspiratory flow; so far human data are reported from an uncontrolled study of 30 patients [24]. These patients were subjected to bilateral upper lobe placement. The reported safety data were satisfactory but less than a third of patients showed improvements in $FEV_1$ or 6 min walking test greater than 15%.

Similarly, although animal data exist for the tissue engineering approach [25]; human data so far are confined to subsegments of a single lung in six subjects [26]. Again the safety profile was satisfactory.

## Experience with endobronchial therapy

Snell et al. [18] used an early version of the valve and aimed for bilateral lung volume reduction. No improvement was observed in any parameter except $TL_{CO}$, although they also found valve insertion to be safe and well tolerated. Toma et al. reported the use of the Emphasys valve for bronchoscopic lung volume reduction [22]. Data from eight patients was presented; despite the small sample size a statistically significant improvement in $FEV_1$ was observed with an increase from 0.791 (range 0.61–1.07) to 1.061 [0.75–1.22] (difference 34%, $p = 0.028$). Other investigators in uncontrolled series found improvements in $FEV_1$ either alone [19] or with significant improvements in plethysmographic lung volumes and mean $TL_{CO}$ [20].

Hopkinson et al. reported the only study of BLVR in which dynamic hyperinflation was directly measured [21]. We studied 19 patients treated with unilateral endobronchial

FIG. 59.2 Endobronchial valves (A) Initial Emphasys endobronchial valve. (B) Modified Emphasys endobronchial valve, suitable for transcopic insertion. (C) Intrabronchial valve (Spiration Inc).

valve insertion and made key measurements 4 weeks after the procedure. As in previous studies, we observed a statistically significant improvement in mean $FEV_1$ (28–31% predicted, $p < 0.05$) and in mean $TL_{CO}$ (36–41% predicted, $p = 0.016$). A statistically significant improvement in TLC and functional residual capacity (FRC) was observed though this failed to reach significance in the case of RV.

*A priori* we divided patients into improvers and nonimprovers. Improvers were defined as patients who were able to show an increase of both 60 s and 30% in endurance time on the constant rate cycle endurance test. Nine of nineteen patients (47%) met this criterion. In stepwise regression analysis only change in resting inspiratory capacity and $\Delta TL_{CO}$ were retained as independent predictors, producing an equation that explained 81% of the variation in endurance time ($p < 0.0001$). If patients with atelectasis were excluded, again, only the same two variables were retained in the model ($r^2 = 0.61$; $p = 0.002$).

The combined Emphasys data set was recently reported [23]: 98 patients were studied with an average number of 4 valves per patient, the majority had complete unilateral (48%) or bilateral (21%) lobar occlusion. On average significant improvements were observed in $FEV_1$ (mean 60 ml, 10%) and in walking distance (37 m, 23%). Clinically the mean improvements are at the lower range of what might be considered worthwhile. The safety profile compared favorably to surgical LVRS. *Post hoc* subset analysis showed that the biggest improvements were seen in those patients submitted to complete lobar occlusion, the lowest $FEV_1$ and the greatest hyperinflation.

Emphasys have recently concluded a multicenter randomized controlled study (for design see Ref. [27]). The results were presented orally at the Annual Congress of the European Respiratory Society in September 2007 but are not yet available in print form.

## Extrapulmonary bypass

An alternative approach to emphysema was proposed by Macklem in 1978 [28]. Based on the observation that emphysematous lungs, unlike normal lungs, demonstrated significant collateral ventilation he proposed that a physical connection between the lung parenchyma and the atmosphere could reduce hyperinflation.

So far, one biotechnology company has created a product which attempts to exploit this property. Broncus Inc (Mountain View CA 94043) has developed a stent which is placed in a bronchial segment to permit exhaled air to bypass the point of flow limitation. So far the device has been demonstrated to be feasible in dogs with patency enhanced by the use of drug eluting stents [29]. The stents increase expiratory flow in explanted human lungs [30, 31]. An uncontrolled study has been reported in 35 patients with emphysema [32]: for the group as a whole a 7.3% reduction in $FEV_1$ and a 37% increase in 6-min walk were observed. However *post hoc* analysis showed that the greatest benefit was observed in patients with the most preprocedure hyperinflation as one might expect. 69% of stents examined bronchscopically were patent at 6 months after the procedure. An ongoing randomized controlled trial (RCT) is presently underway which is expected to report in 2009.

## Overview of options for emphysema

At present the only evidence-based therapy is LVRS but this is unattractive to purchasers, patients, and surgeons because of the cost, risk, and the relatively high safety criteria which are necessary to avoid an unacceptable mortality. Two main noninvasive approaches are feasible. Endobronchial blockade is likely to be the most suitable for the minority of patients with no collateral ventilation and heterogenous upper zone disease. Extrapulmonary bypass is likely to be most suitable for the majority of patients with homogenous disease, resting hyperventilation, and collateral ventilation. In both cases pivotal studies have yet to be reported and neither treatment can be recommended (except on a compassionate basis) until they are shown to be both safe and effective. Collateral ventilation is frequently but not universally present in patients with COPD [33] and can be measured in man [34, 35] and we speculate that these techniques may become part of the work up when assessing patients for these therapies.

## ASTHMA

Bronchial thermoplasty is a novel approach in the treatment of asthma, which targets smooth muscle within the airways. In asthma there is frequently an increase in the number and the size of smooth muscle within the airway and this in turn causes bronchoconstriction, hyperresponsiveness and inflammation. Bronchial thermoplasty uses low energy radio frequency to ablate the smooth muscle. The epithelium, mucous glands, and nerves appear to regenerate but there is permanent reduction in the smooth muscle bulk.

A feasibility study was performed in patients with lung cancer who were due to undergo surgical resection. Bronchial thermoplasty was performed in these individuals up to 3 weeks prior to their surgery and segmental bronchi within the lobe that was to be resected were treated with bronchial thermoplasty. This study demonstrated that bronchial thermoplasty was well tolerated and resulted in a significant reduction in smooth muscle mass in the treated airways [36].

A safety study in 16 subjects with mild to moderate asthma was subsequently performed [37]. The patients underwent bronchial thermoplasty in three separate treatments, initially one of the lower lobes was treated, followed by the contralateral lower lobe 3 weeks later, and finally both upper lobes were treated on the last treatment setting a further 3 weeks later. The patients all underwent detailed monitoring with lung function tests, methacholine challenge, and an assessment of their symptom-free days was made. The study demonstrated a significant improvement in morning and evening peak flows and also an increase in symptom-free days following treatment with bronchial thermoplasty. There was a reduction in bronchial hyperresponsiveness in the patients treated, which was maintained at 1 and 2 years following treatment with bronchial thermoplasty.

A further randomized study in 112 subjects with moderate or severe persistent asthma has also shown significant improvements in quality of life, symptom scores, a significant increase in symptom-free days, and morning peak expiratory flow measurements [38]. An increase in adverse events immediately following bronchial thermoplasty was observed. These events were usually mild and well tolerated. They comprised of an increase in breathlessness, cough, wheezing, and chest discomfort. The majority of these events occurred within 1 day of the procedure and resolved within 7 days of

onset. There was no increase in adverse events 6 weeks after the last treatment and following this period the adverse event rates were similar in both treatment and controlled groups.

In this study baseline measurements were conducted during a 2-week period when the patients were withdrawn from their long active bronchodilators and similar analyses were performed on bronchodilators at 3, 6, and 12 months. Measurements at this time point demonstrated significant improvement in the number of symptom-free days and on average treatment subjects had 86 additional symptom-free days per year compared to the control group. There was also an improvement in symptom scores, asthma quality of life questionnaire (AQLQ), and asthma control questionnaire (ACQ) scores. There was a significant reduction in $\beta_2$-agonists used that would equate to approximately 2 inhalers per patient over the 1-year treatment period. Finally, there was a reduction in mild and severe exacerbations and in the treatment group there were approximately 10 fewer mild exacerbations than in the control group. The main limitation of this large study was that it was an open-label design and hence, subject to bias.

A small study was performed in patients with severe refractory asthma who were on more than 750μg fluticasone propionate per day in addition to long-acting bronchodilators [39]. A significant proportion of patients were also on maintenance of oral steroids. In this study, 15 patients were randomized to bronchial thermoplasty and there were 17 controlled subjects. The study design was to randomize the patients to treatment or control followed by a 6-week stabilization period. The patients were maintained on their regular treatment for the following 14 weeks, and then the patients entered a steroid weaning phase where the dose of oral steroids or inhaled steroids was reduced by 20–25% in 2-week steps. Following the 14-week steroid-wean phase, patients were maintained on a reduced dose for a further 16 weeks and assessments performed over the two study periods. Overall, bronchial thermoplasty was well tolerated although there was an increase in adverse events over the treatment period. During this treatment period there were seven hospitalizations for adverse events in four subjects in the bronchial thermoplasty group and none in the control group. In the posttreatment period the number of hospitalizations and adverse events were similar in both treatment groups. There were significant improvements in a number of parameters including lung function and quality of life scores in the treatment group compared to the control group both prior to reduction in steroids and also following the steroid-wean phase. Four of the eight patients in the bronchial thermoplasty group were completely weaned off their oral steroids in contrast to only one of the seven patients in the control group who was weaned off oral steroids. Prebronchodilator $FEV_1$ was improved by around 15% in the treatment group compared to the control group, and there was an over 26% reduction in rescue medication use in the treatment group. There were significant improvements in asthma control scores and quality of life both during the steroid weaning phase and following steroid reduction in the bronchial thermoplasty group compared to the control group.

The clinical studies thus far have demonstrated that bronchial thermoplasty is safe and appears to have significant improvements in quality of life, peak flow measurements, and the number of symptom-free days in asthma patients. $FEV_1$ only appears to improve in the severe refractory group. The clinical studies that have thus far been published are open-label randomized studies but a pivotal double-blind sham controlled study is nearing completion with the results due in late 2008. This is a uniquely designed interventional study which attempts to reduce the obvious biases of an open-label study and will more critically evaluate the safety and efficacy of bronchial thermoplasty in moderate and severe asthma patients; until this study is formally reported it seems appropriate to reserve thermoplasty for a research setting.

## VACCINES AND ANTIVIRAL AGENTS

### Influenza vaccines

#### Efficacy

A recent systematic review of trials undertaken to assess the efficacy of influenza vaccination in chronic obstructive pulmonary disease (COPD) patients concluded that inactivated vaccine reduces the rate of exacerbations [1]. In asthma the benefits of inactivated vaccination has not been proven [2]. Administration of live-attenuated influenza vaccine by intranasal spray is effective and safe in both healthy adults and in children with asthma. The cold adapted live vaccine produces superior protection compared to the inactive vaccine in children with asthma [3, 4]. The addition of the live-attenuated vaccine to inactivated vaccine offers no additional protection in COPD [1].

#### Adverse effects

Vaccination is contraindicated in those individuals hypersensitive to eggs, although the risk of reactions is low. The inactivated influenza vaccines can be safely administered to adults and children with asthma and to patients with COPD without any increase in exacerbation rates in either condition [2, 4, 5]. The live-attenuated influenza vaccine can be safely used in children with asthma [4].

#### Recommendations

Health authorities in the United States and in many European countries recommend annual inactivated influenza vaccination for adults and children with chronic pulmonary disease including asthma [6]. The Global Initiative for Asthma (GINA) guidelines recommend that patients with moderate to severe asthma should receive influenza vaccination every year [7]. The Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines emphasize the importance of targeting elderly individuals with COPD [8]. The live-attenuated influenza vaccine has been licensed recently in the United States for use in healthy persons aged 5–49 years and it has been advocated as the preferred vaccine for use in children with asthma [4].

### Antiviral agents against influenza

Neuraminidase inhibitors are a class of antiviral agents that are active against both influenza A and influenza B. The neuraminidase inhibitors, inhaled zanamivir (Relenza) and oral oseltamivir (Tamiflu) have received regulatory approval in some countries for the treatment of acute influenza and for chemoprophylaxis [6]. If these agents are started within the first 2 days after the onset of illness, then treatment will shorten the duration of symptoms by 1 to 1 1/2 days and in some studies the need for antibiotics is reduced. Oseltamivir administered to influenza-infected children with asthma aged 6–12 years is well tolerated and produces improvements in pulmonary function and fewer exacerbation of asthma up to day 7 [9]. Antiviral drugs amantadine and rimantadine are not now recommended for treating the influenza A because of concerns about drug resistance [6]. Antiviral drugs should be considered for patients with asthma and COPD, if started within 2 days of infection, particularly in those who have not been vaccinated. It has also been recommended that chemoprophylaxis should be considered in vaccinated members of high-risk groups, including patients with asthma and COPD, because the combination of vaccination and antiviral drug increases protection against influenza.

## Pneumococcal vaccines

### Efficacy

In elderly individuals with chronic lung disease including COPD, pneumococcal vaccination has been reported to result in fewer outpatient visits, fewer hospitalizations, and fewer deaths [10]. A Cochrane review of four studies of patients with COPD, however, found no evidence for a reduction in exacerbation rates, morbidity, or mortality following pneumococcal vaccination [11]. Routine revaccination is not generally recommended because of the increased incidence of adverse reactions. A Cochrane review found limited evidence of effectiveness in children and adults with asthma [12].

### Adverse effects

Transient erythema at the site of injection is common. Hypersensitivity reactions may occur.

### Recommendations

Health authorities in some European countries and the United States recommend polyvalent pneumococcal vaccination for all patients with chronic lung disease [13]. The GOLD guidelines recommend vaccination for patients aged 65 years and older with COPD [8].

## *Haemophilus influenza* vaccine

A systematic review of six small studies of oral immunization with monobacterial whole-cell, killed, nontypeable *H. infuenzae* vaccine in patients with recurrent acute exacerbations of chronic bronchitis in the autumn found that vaccination reduced the number and severity of exacerbations over the following winter [14]. The authors suggested that one episode of bronchitis may be prevented for every five individuals vaccinated. The review concluded however that a large clinical trial into the long-term effects of *H. infuenzae* vaccine was needed. Its routine use is not recommended in the management of asthma or COPD.

## Multi-component oral bacterial vaccines

OM-85 BV (Broncho–Vaxom) is a mixture of eight bacterial products thought to be important in respiratory infections. It is administered orally and is thought to act as a nonspecific immunostimulant. A randomized controlled study in 381 patients with COPD treated with OM-85 BV did not reduce the risk of having at least one episode of an acute exacerbation (primary outcome) over a 6-month period compared with placebo. Treatment with OM-85, however, reduced the risk and total number of days of hospitalization for a respiratory problem by 30% and 55% respectively [15]. A systematic review of 13 studies, most of which were assessed to be of low quality, found that oral purified bacterial extracts improve symptoms in patients with chronic bronchitis and COPD, but that there was insufficient evidence to suggest that they prevent exacerbations [16]. Skin and urological adverse effects were commonly reported. Further studies are required before oral vaccines are considered for use in COPD.

## ANTIOXIDANTS

Antioxidant enzymes form the first line of defense in the lungs. Antioxidants may reduce chronic airway inflammation by neutralizing the damage produced by reactive oxygen species and also possibly by preserving the inhibitory action of antiproteases. Antioxidant genes, however, may be upregulated by oxidative stress [17] and the dose of administered exogenous antioxidant may need to be titrated to avoid suppression of endogenous antioxidant activity.

## Asthma

### Dietary antioxidants

Dietary antioxidants such as vitamin C, vitamin E, caratenoids, and selenium are derived mainly from fruit and vegetables. Reduced circulating levels of dietary antioxidants have been found in asthma [18, 19] raising the hope that clinical benefits would result from dietary supplementation with these compounds. However, clinical trials of dietary supplementation with vitamin C, vitamin E, or selenium have shown no benefit in adults with mild-to-moderate asthma [20–22].

### Inhaled glutathione

The antioxidant glutathione administered to adults with mild asthma-induced bronchoconstriction [23].

## COPD

Oxidative stress is increased in smokers and reactive oxygen species may be involved in the pathogenesis of COPD [24]. There is evidence that endogenous antioxidant capacity is reduced in COPD and so antioxidants may be useful in the treatment of COPD.

### Dietary antioxidants

There is some evidence linking dietary deficiency of antioxidants and COPD. There are no controlled studies of vitamins C or E supplementation in COPD. β-Carotene and α-tocopherol supplements had no benefit on the symptoms of COPD [25].

### *N*-Acetylcysteine

*N*-Acetylcysteine, which is a mucolytic, may also act as an antioxidant by providing cysteine intracellularly for increased production of glutathione [26]. *In vitro N*-acetylcysteine reduces neutrophil chemotaxis and in smokers it reduces the number and activity of bronchoalveolar neutrophils and alveolar macrophages. *N*-acetylcysteine preserves the inhibitory action of antiproteases from oxidative inactivation. It has not been established, however, whether any clinical benefits of *N*-acetylcysteine and other mucolytics can be attributed to the antioxidant properties of these drugs (see "Mucolytic Drugs").

## MUCOLYTIC DRUGS

Mucolytic drugs such as *N*-acetylcysteine, ambroxol, erdosteine, iodinated glycerol, methylcysteine, and carbocysteine reduce the viscosity of mucous *in vitro* and have been assessed in several clinical trials in COPD. These drugs have not been tested in asthma.

## COPD

### Efficacy

A Cochrane systematic review of 26 randomized controlled trials of mucolytic drugs including *N*-acetylcysteine in the treatment of chronic bronchitis or COPD found that these drugs produced a small reduction in the frequency of acute exacerbations and the total days of disability compared with placebo [27]. The efficacy and side-effect profile was similar between *N*-acetylcysteine and the other mucolytic drugs.

A further systematic review of 11 randomized trials comparing oral *N*-acetylcysteine with placebo administered from 12 to 24 weeks in patients with chronic bronchitis concluded that active treatment reduced the risk of exacerbations and improved symptoms without an increased risk of side effects [28]. Stey and colleagues [28] estimated that of 100 patients with chronic bronchitis taking *N*-acetylcysteine for 12–24 weeks, 17 would be prevented from having an exacerbation and 26 would note an improvement in symptoms compared with placebo. However, a recent large multicentre Bronchitis Randomized on NAC Cost-Utility Study (BRONCUS) in which patients with COPD were followed for 3 years found that *N*-acetylcysteine 600 mg daily was ineffective at preventing exacerbations and rate of decline in lung function [29]. Subgroup analysis suggested that exacerbation rates were reduced in patients not treated with inhaled corticosteroids.

### Adverse effects

The main side effects of mucolytic drugs are gastrointestinal in nature.

### Recommendations

The GOLD guidelines do not recommend the use of mucolytic drugs in the management of COPD [8].

## CROMONES

### Mechanism of action

The cromones, sodium cromoglycate and nedocromil sodium, were first introduced as prophylactic drugs for asthma over 40 and 25 years ago respectively. The mechanism of action of the cromones has not been clearly established. Both drugs act as nonspecific chloride channel blockers in a large range of cell types and through this action, these compounds may reduce alterations in cell volume and function [30]. *In vitro* studies of human inflammatory cells and *in vivo* studies in experimental animals have shown that both drugs inhibit functions of a variety of inflammatory cells including mast cells, eosinophils, neutrophils, platelets, and alveolar macrophages [30–32]. Nedocromil sodium has either similar or slightly greater potency to that of sodium cromoglycate. Both sodium cromoglycate and nedocromil sodium may also have inhibitory effects on sensory nerve endings in the lung, thus preventing the release of tachykinins.

## Asthma

### Anti-inflammatory effects

There is limited and conflicting evidence for an anti-inflammatory effect of cromones in asthma [33–35].

### Clinical studies

#### Bronchial challenge

Sodium cromoglycate and nedocromil sodium are equally effective in attenuating exercise-induced asthma [36]. The early and late response to allergen and the allergen-induced seasonal increase in nonallergic bronchial reactivity can be prevented by both drugs [31]. Nedocromil sodium can also produce small reductions in nonseasonal bronchial reactivity.

#### Clinical asthma

*Comparison with placebo*: In both pediatric and adult asthma, treatment with inhaled sodium cromoglycate has been reported to improve asthma control. A systematic review of 24 randomized controlled trials, however, questioned the efficacy of sodium cromoglycate in children with asthma and concluded that it was no longer justified to recommend sodium cromoglycate as a first-line prophylactic agent in chronic childhood asthma [37]. Some studies comparing nedocromil sodium with placebo have demonstrated benefit in both children and adults with asthma. However, efficacy was not confirmed in a large randomized controlled trial of 1041 children with mild-to-moderate asthma [38]. A small number of clinical trials have compared the two cromones in adults with asthma and in most studies the therapeutic effects were found to be comparable.

*Comparison with inhaled steroids*: The results of most short-to-medium term studies suggest that the improvement in asthma control produced by the cromones is commonly slightly less than that produced by 400 µg of inhaled beclomethasone daily. A large long-term randomized controlled trial in children aged 5–12 years with mild-to-moderate asthma found that inhaled budesonide 200 µg daily provided better control of asthma and improved airway responsiveness when compared with placebo or nedocromil 8 mg daily [38]. Neither drug was better than placebo in terms of improvements in lung function.

*Add-on therapy*: The addition of inhaled nedocromil sodium to asthmatic patients with symptoms poorly controlled by high-dose (>1000 µg daily) inhaled corticosteroids produces small improvements in symptoms, peak flow readings, and bronchodilator use [39]. Nedocromil sodium does not have a clinically relevant oral corticosteroids sparing effect [40].

*Adverse effects*: Sodium cromoglycate and nedocromil sodium are safe drugs and uncommonly cause adverse effects. The main side effects reported include a distinctive bitter taste, headache, and nausea.

### Place in management

The cromones have a very limited role in the management of adults and children with chronic asthma. The GINA guidelines recommend that the cromones should be considered as an alternative to an inhaled short acting $\beta_2$-agonists to prevent exercise-induced asthma but should not be normally used as controller therapies at step 2 because of their poor efficacy, but should be considered as third-line alternative options to inhaled corticosteroids, leukotriene modifiers, or oral sustained release theophylline [7]. There is no role for the use of the cromones as additional therapy for patients already receiving inhaled or systemic corticosteroids.

## COPD

A randomized controlled study in patients with COPD reported that nedocromil sodium treatment for 10 weeks reduced the number of dropouts because of exacerbations but had no effect on symptoms, lung function, or airway responsiveness to histamine and adenosine [41]. A further clinical trial of 12-weeks duration noted limited clinical efficacy of nedocromil sodium in patients with obstructive airways disease and sputum production. Nedocromil sodium treatment was associated with a reduction of plasma protein exudation as measured in sputum sol phase suggesting some anti-inflammatory properties in COPD [42]. The GOLD guidelines do not recommend either sodium cromoglycate or nedocromil sodium for the treatment of COPD due to inadequate data [8].

## BRONCHIAL THERMOPLASTY

Bronchial thermoplasty to the airways is a new treatment technique that involves the delivery of radio frequency energy to the airways with the aim of reducing airway responsiveness in asthma. Pre-clinical studies showed that bronchial thermoplasty reduces airway smooth muscle, increases airway size, and produces a long-lasting decrease in airway responsiveness to methacholine [43–46]. In the canine model the reduction in airway smooth muscle is directly related to the decrease in airway responsiveness suggesting that the benificial effects of bronchial thermoplasty may be due to a decrease in airway smooth muscle although other mechanisms may be involved, for example altered contractility of airway smooth muscle or stiffening of the airway wall [43]. In an observational study to determine the safety of bronchial thermoplasty in subjects with mild-to-moderate asthma ($n = 16$), there were no severe adverse events in the 2-year-study period [47]. Although the study was not powered to evaluate efficacy, bronchial thermoplasty resulted in improvements in symptom-free days, morning peak expiratory flow (PEF) at 3 months, and a reduction in airway hyperresponsiveness to methacholine that lasted for at least 2 years [47]. In randomized controlled study, the Asthma Intervention Research (AIR) Trial, the effects of bronchial thermoplasty were evaluated in subjects with moderate or severe asthma ($n = 112$) over12 months [48]. Treatment significantly reduced the mean rate of mild exacerbations and use of rescue medication [48] (Fig. 60.1). Bronchial thermoplasty also improved morning PEF, Asthma Quality of Life Questionnaire (AQLQ) scores, Asthma Control Questionnaire (ACQ) scores, and symptom scores compared with the control group. A *post hoc* analysis suggested that the benefits of treatment were particularly marked in subjects requiring high-maintenance doses of inhaled corticosteroids ($>1000\mu$g of beclomethasone

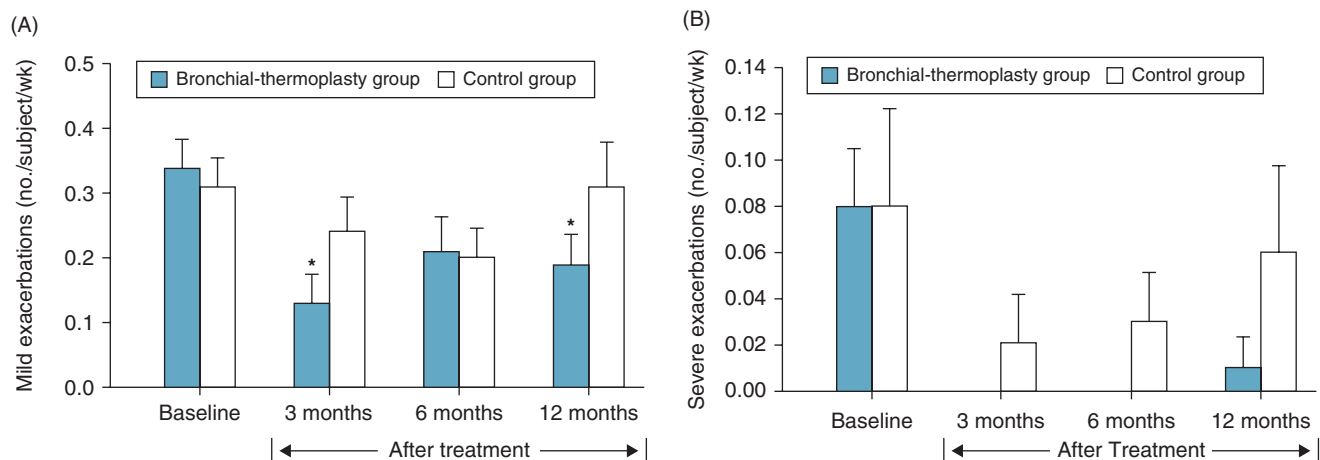

**FIG. 60.1** Rates of mild and severe exacerbations per subject per week. Mean values are shown for all subjects receiving inhaled corticosteroids alone for whom data were available at the given time points. Asterisks indicate a statistically significant difference in the mean change from baseline between the two groups, and I bars represent the standard errors. $p = 0.03$ for the comparison between subjects in the two groups treated with inhaled corticosteroids alone at 3 months and at 12 months. Reproduced with permission from Ref. [48].

equivalent daily) [48]. The Research in Severe Asthma (RISA) Trial was designed to determine the safety and efficacy of bronchial thermoplasty in subjects with symptomatic, severe asthma ($n = 32$) [49]. Bronchial thermoplasty was associated with a short-term increase in asthma-related morbidity including increased hospitalizations for asthma. At 22 weeks, bronchial thermoplasty subjects had significant improvements compared to control subjects in rescue medication use, pre-bronchodilator $FEV_1$% predicted and ACQ scores. Improvements in rescue medication use and ACQ scores remained significantly improved compared to the control group at 52 weeks. The efficacy and safety of bronchial thermoplasty is currently being assessed in a placebo-controlled trial involving the use of sham bronchial thermoplasty.

Taken together, these finding suggest the potential clinical benefits of targeting airway smooth muscle in the treatment of asthma [50]. Future studies need to determine the risk benefit ratio of bronchial thermoplasty in different severities of asthma, to identify factors that predict a beneficial clinical response to bronchial thermoplasty and to investigate whether other less invasive techniques can be used to target airway smooth muscle.

## MANAGEMENT OF MALNUTRITION

### COPD

Malnutrition (defined as <90% of ideal body weight) is found in 25% of outpatients with COPD and in over 50% of patients admitted to hospital because of COPD. The mechanisms of weight loss are unclear, although changes in energy balance and systemic inflammation are likely to play a part. The mortality rate is increased in malnourished patients with COPD [51]. Malnourished patients with COPD exhibit reduced exercise capacity and respiratory muscle function. No simple recommendation can be given regarding the "best" test for nutritional assessment.

These patients are often unable to regain weight despite receiving nutritional support. High-carbohydrate diets should be avoided to prevent excess carbon dioxide production. A Cochrane review of fourteen nine randomized controlled trials, of which two were double blind, concluded that nutritional support (caloric supplementation for at least 2 weeks) had no effect on improving anthropometric measures, lung function, or exercise capacity among patients with stable COPD [52]. The GOLD guidelines recommend that increased calorie intake is best undertaken with an exercise program [8].

## MANAGEMENT OF OBESITY

### Asthma

An elevated body mass index has been associated with several features of asthma including an increased prevalence and severity as well as an enhance airway inflammatory response

[53–56]. Weight reduction has been shown to improve lung function, symptoms, and health status in obese people with asthma [57, 58] (Fig. 60.2).

## COPD

Obesity is also a common feature of COPD and is associated with a poor prognosis, independent of $FEV_1$. The influence of weight reduction on the morbidity and mortality from COPD has not been systematically studied.

## COMPLEMENTARY THERAPIES

Complementary and alternative medicines are frequently used by adults and children with asthma [59, 60]. The

FIG. 60.2 Obesity, weight reduction and asthma: mean morning premedication values for PEF, $FEV_1$, and FVC (% predicted) at different stages during study. Vertical bars show standard errors of the mean. Changes from baseline show significant ($p < 0.05$) difference between groups. Reproduced with permission from Ref. [57].

therapies most frequently used are breathing techniques, homeopathy, herbal medicines, and acupuncture [59, 60]. Complementary therapy use often reflects patients and parents wish to achieve greater self management of their condition [61]. Thirty percent of the general populations in the United States currently use complementary medicine and two-thirds had used at least one complementary and alternative therapy during their lifetime [62].

## Asthma

### Breathing techniques and inspiratory muscle training

Breathing techniques and inspiratory muscle training have been used to treat asthma. The Buteyko breathing technique is based on the hypothesis that all patients with asthma hyperventilate at rest and that rectifies this problem, by reducing the rate of breathing, results in an improvement in asthma control. The Buteyko breathing technique was compared with a placebo breathing technique in 39 adult asthmatic patients over a 3-month period [63]. At the end of the trial the Buteyko breathing technique group compared with the placebo breathing technique showed reduction in median β-agonist usage. Unfortunately the follow-up arrangements were not identical between the two groups and there was the possibility of greater patient contact in the Buteyko-treated group. Measurements of lung function and quality of life were unaltered in both groups. A larger randomized clinical trial of the Buteyko technique for 6 months reported improved symptoms and reduced bronchodilator use, but no change in bronchial responsiveness or lung function in patients with asthma [64]. A systematic review of breathing exercises for asthma found that although there were trends of improvement in a number of outcomes no firm conclusion can be drawn concerning the use of breathing exercises for asthma in clinical practice [65]. A Cochrane review concluded that there was insufficient evidence to suggest that inspiratory muscle training provides any clinical benefit to patients with asthma [66]. A recent clinical study reported that an integrated breathing and relaxation technique known as the Papworth Method reduced respiratory symptoms, dysfunctional breathing, and adverse mood compared with usual care [67].

### Manual therapies

Manual therapies such as massage, chiropractic, and osteopathic techniques are used to treat asthma, but there is insufficient evidence of efficacy [68].

### Homeopathy

Homeopathy involves identifying factors that precipitate asthma in an individual and then prescribing a specific homeopathic remedy for that person. In some cases, the remedy may include very small quantities of the allergen to which the patient is allergic, for example. house dust mite. A small randomized controlled parallel group study in 28 patients with allergic asthma compared oral homeopathic immunotherapy to their principal allergen or identical placebo for a 4-week period [69]. All patients continued their unaltered conventional therapy. A daily visual analog scale of overall symptom intensity showed improvements in favor of homeopathic immunotherapy within 1 week of starting treatment which persisted through the treatment period. There were no significant changes in measurement of baseline lung function and bronchial reactivity. A systematic review of placebo-controlled trials of homeopathy have concluded that there is insufficient evidence of efficacy [70].

### Acupuncture

Acupuncture involves the insertion of needles at specific points of the body. The technique is based on Chinese theories of the bodies' balance of energies. The effects of acupuncture were assessed in a randomized, double-blind controlled, cross-over study in 22 patients with asthma [71]. There was a statistically significant improvement in assessments of quality of life and reductions in β-agonist use after both the active and sham interventions, but no change in PEF recordings. A Cochrane review of acupuncture for asthma concluded that there was insufficient evidence to make any recommendations about its use, but highlighted the need for well-controlled studies to assess its effectiveness in asthma [72].

### Herbal medicines

A large range of herbal medicines including traditional Chinese medicine are used for the treatment of asthma. The efficacy and safety of some of these remedies are now being assessed in controlled trials [73].

### Yoga

Yoga is an ancient Hindu discipline that promotes increased mental and physical control of the body. One of the eight steps of yoga, pranayama, deals with control of breathing to promote relaxation and improve fitness. The effects of two pranayama yoga breathing exercises were assessed in a randomized, controlled, cross-over trial in 18 patients with mild asthma [74]. There was a statistically significant reduction in bronchial reactivity to histamine after the active intervention compared with placebo, but no change in baseline lung function tests, symptom scores, or β-agonist use.

## Safety of complementary medicine

The safety of complementary therapies is rarely assessed. Although patients often consider these treatments as harmless, this may not always be the case. The health of a patient starting a complementary therapy may be put at risk for several reasons. The patient may abruptly stop their conventional medicines for asthma. Some herbal remedies can cause severe toxic effects due to hepatotoxicity, heavy metal poisoning, or to microorganisms. Herbal medicines may contain conventional pharmaceutical drugs, for example, corticosteroids or nonsteroidal anti-inflammatory drugs. Finally, it is known that acupuncture can cause pneumothoraces and transmit hepatitis.

# Future Therapies

**Peter J. Barnes**

**National Heart and Lung Institute (NHLI), Clinical Studies Unit, Imperial College, London, UK**

## INTRODUCTION

As indicated in previous chapters, asthma and chronic obstructive pulmonary disease (COPD) are different diseases that involve different cells, mediators and inflammatory effects so that different treatments are needed. However, it is increasingly recognized that there are any similarities in the inflammatory process between severe asthma and COPD [1]. Many new classes of drugs are now in development for asthma and COPD and there are several new drugs that are being developed for both diseases [2–4].

## THE NEED FOR NEW TREATMENTS

### Asthma

Current asthma therapy is highly effective and majority of patients can be well controlled with inhaled corticosteroids and short- and long-acting $\beta_2$-agonists. These treatments are not only effective, but safe and relatively inexpensive. This poses a challenge for the development of new treatments, since they will need to be safer or more effective than existing treatments, or offer some other advantage in long-term disease management. However, there are several problems with existing therapies.

- Existing therapies have side effects as they are non-specific. Inhaled $\beta_2$-agonists may have side effects and there is some evidence for the development of tolerance, especially to their bronchoprotective effects. Inhaled corticosteroids may also have local and systemic side effect at high doses and there is still a fear of using long-term steroid

treatment in many patients. Other treatments, such as theophylline, anticholinergics and anti-leukotrienes are less effective and are largely used as add-on therapies.

- There is still a major problem with poor compliance in the long-term management of asthma, particularly as symptoms come under control with effective therapies [5]. It is likely that a once daily tablet or even an infrequent injection may give improved compliance. However, oral therapy is associated with a much greater risk of systemic side effects and therefore needs to be specific for the abnormality in asthma or COPD.

- Patients with severe asthma are often not controlled on maximal doses of inhaled therapies or may have serious side effects from therapy, especially oral corticosteroids. These patients are relatively resistant to the anti-inflammatory actions of corticosteroids and require some other class of therapy to control the asthmatic process. Corticosteroid resistance is also a major barrier to effective therapy in COPD.

- None of the existing treatments for asthma is disease modifying, which means that the disease recurs as soon as treatment is discontinued.

- None of the existing treatments is curative, although it is possible that therapies which prevent the immune aberration of allergy may have the prospects for a cure in the future.

### COPD

In sharp contrast to asthma there are few effective therapies in COPD, despite the fact that it is a common disease that is increasing worldwide [6].

The relative neglect of COPD by pharmaceutical companies is probably as a result of several factors:

- COPD is regarded as largely irreversible and is treated as poorly responsive asthma.
- COPD is self-inflicted and therefore does not deserve substantial investment.
- Animal models do not mimic many of the key aspects of the disease, such as small airway disease and exacerbations.
- Relatively little is understood about the cell and molecular biology of this disease or even about the relative role of small airways disease and parenchymal destruction.

None of the treatments currently available prevents the progression of the disease, and yet the disease is associated with an active inflammatory process that results in progressive obstruction of small airways and destruction of lung parenchyma. Increased understanding of COPD will identify novel targets for future therapy (Fig. 61.1) [7].

There are also uncertainties about how to test drugs for COPD, which may require long-term studies (3 years) in relatively large numbers of patients at an enormous cost. For example, a recent study looking at the effects of drug intervention on mortality costs several hundred million dollars [8]. Many patients with COPD may have co-morbidities, such as ischaemic heart disease and diabetes, which may exclude them from clinical trials of new therapies. There is little information about surrogate markers, for example biomarkers in blood, sputum or breath, to monitor the short-term efficacy and predict the long-term potential of new treatments [9]. Finally, it is difficult to accurately measure small airway function in patients with COPD so there is a need to develop better tests of small airway function that are not affected by emphysema or abnormalities of large airway function [10].

Although asthma and COPD involve different patterns of inflammation, there is increasing evidence that patients with severe asthma have inflammatory features that are very similar to those seen in COPD [1]. This suggests that drugs that are effective in suppressing the inflammation of COPD might also be effective in treating severe asthma.

## DEVELOPMENT OF NEW THERAPIES

Several strategies have been adopted in the search for new therapies:

- *Improvement of an existing class of drug*: This is well exemplified by the increased duration of $\beta_2$-agonists with salmeterol and formoterol and of anticholinergics with tiotropium bromide, and with the improved

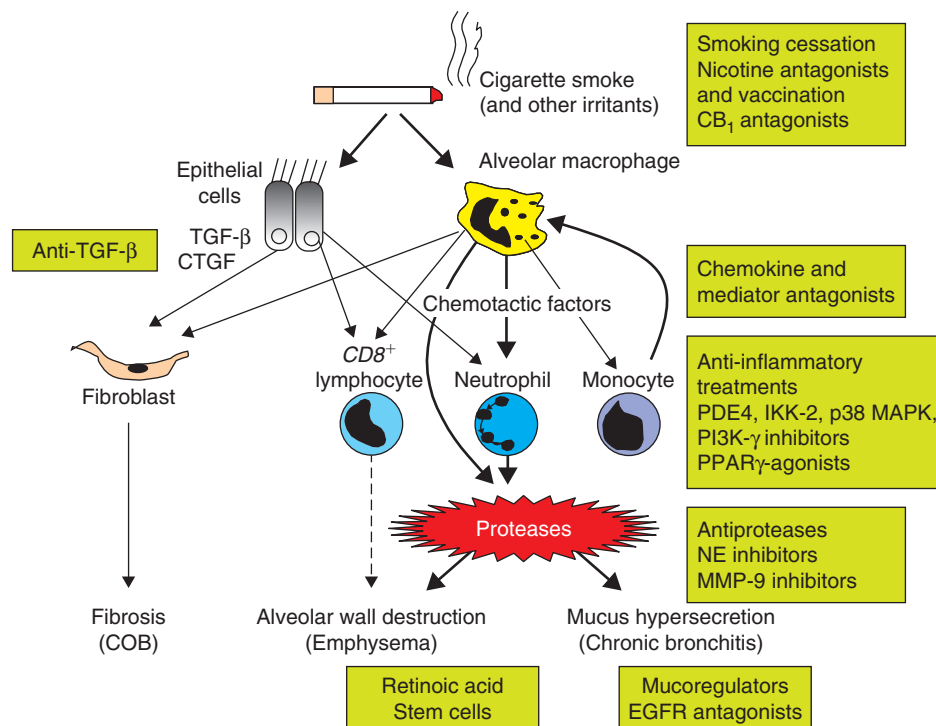

**FIG. 61.1** Targets for COPD therapy based on current understanding of the inflammatory mechanisms. Cigarette smoke (and other irritants) activate macrophages in the respiratory tract that release multiple chemotactic factors that attract neutrophils, monocytes, and T-lymphocytes (particularly CD8+ cells). Several cells also release proteases, such as neutrophil elastase (NE) and matrix metalloproteinase-9 (MMP-9) which the break down connective tissue in the lung parenchyma (emphysema) and also stimulate mucus hypersecretion (chronic bronchitis). CD8+ may also be involved in alveolar wall destruction. This inflammatory process may be inhibited at several stages (shown in the boxes). PDE: phosphodiesterase; IKK: inhibitor of nuclear factor-κB kinase; MAPK: mitogen-activated protein kinase; PI3K: phosphoinositide-3-kinase; PPAR: peroxisome proliferator activated receptor; COB: chronic obstructive bronchitis; TGF: transforming growth factor; CB: cannabinoid; EGFR: epithelial growth factor receptor.

pharmacokinetic of the inhaled corticosteroids fluticasone propionate, mometasone, ciclesonide and budesonide, with increased first-pass (hepatic) metabolism and therefore reduced systemic absorption.

- *Development of novel therapies through better understanding of the disease process*: Examples are anti-interleukin(IL)-5 as a potential treatment of asthma and phosphodiesterase (PDE)-4 inhibitors as an anti-inflammatory therapy for COPD.

- *Serendipitous observations, often made in other therapeutic areas*: Examples are tumor necrosis factor-$\alpha$ (TNF-$\alpha$) antagonists for airway diseases, derived from observations in other chronic inflammatory diseases.

- *Identification of novel targets through gene and protein profiling*: This approach will be increasingly used to identify the abnormal expression of genes (molecular genomics) and proteins (proteomics) from diseased cells, and through identification of single nucleotide polymorphisms (SNPs) that contribute to the disease process [11]. So far there have been no new drugs developed from this approach in any area of medicine.

## NEW BRONCHODILATORS

Bronchodilators act predominantly by relaxation of airway smooth muscle cells, although additional effects, such as inhibition of bronchoconstrictor mediator and neurotransmitter release may contribute. $\beta_2$-Agonists are by far the most effective bronchodilators in asthma and act as functional antagonists, blocking the effect of all bronchoconstrictors. The increased bronchodilator duration of long-acting inhaled $\beta_2$-agonists have been an important advance and there are now several once daily inhaled $\beta_2$-agonists in development. By contrast, in COPD anticholinergics appear to be the most effective bronchodilators and there has been a search for selective anticholinergics and drugs with a longer duration. Novel classes of bronchodilator have also been developed (Table 61.1.)

### Ultra-LABAs

Several once daily inhaled $\beta_2$-agonists, such as indacaterol and carmoterol, are now in clinical development [12].

**TABLE 61.1** New bronchodilators.

| Drug class | Examples |
| --- | --- |
| Ultra-long acting $\beta_2$-agonists | Indacaterol, carmoterol |
| Long-acting muscarinic antagonists | Glycopyrrolate, aclidinium |
| Combination inhalers | LABA + LAMA, MABA |
| Rho kinase inhibitors | In development |
| Myosin light chain kinase inhibitors | In development |

Indacaterol is an effective once daily bronchodilator in asthma and appears to be well tolerated with no evidence for the development of tolerance [13]. Indacaterol is a very effective dilator of small human airways measured by videomicroscopy in a precision-cut lung slice preparation, indicating that it will be useful in severe asthma and COPD where small airway obstruction is a problem [14].

## New anticholinergics

The once daily inhaled anticholinergic tiotropium bromide has been an important advancement in therapy of COPD and several other long-acting inhaled muscarinic antagonists (LAMA), such as aclidinium bromide and glycopyrrolate are now in development [15, 16]. Combination inhalers with a long-acting $\beta_2$-agonist (LABA) with a LAMA are also in development as there is an additive effect between these two bronchodilator classes [17]. Single molecules that link a muscarinic antagonist to a $\beta_2$-agonist (MABA) are also in development.

### New classes of bronchodilator

It has proved difficult to discover novel classes of bronchodilator drug. Potassium channel openers, while effective in human airways *in vitro*, were not effective in asthma as they were more potent as vasodilators and this limited the dose that could be administered. There has been interest in developing drugs that inhibit the contractile machinery in airway smooth muscle, including Rho kinase inhibitors, inhibitors of myosin light chain kinase and direct smooth muscle myosin inhibitors. As these agents also cause vasodilatation it will be necessary to administer them by inhalation.

## MEDIATOR ANTAGONISTS

Blocking the receptors or synthesis of inflammatory mediators is a logical approach to the development of new treatments for asthma and COPD. Several mediator antagonists have now been tested in asthma and COPD (see Chapter 52). However, in both diseases many different mediators are involved and therefore blocking a single mediator may not be very effective, unless it plays a key role in the disease process [18, 19]. Several specific mediator antagonists have been found to be ineffective in asthma, including antagonists/inhibitors of histamine, thromboxane, platelet-activating factor, bradykinin and tachykinins. There is now increasing evidence that this approach is equally ineffective in COPD, with no clinical evidence of benefit for inhibitors of TNF-$\alpha$, IL-8 or leukotriene B$_4$. However, it is possible that there may be an upstream mediator that is playing a disproportionate role in the pathogenesis of asthma and COPD so that targeting this mediator may give greater than expected clinical benefits, as is the case for antihistamines in rhinitis and TNF-$\alpha$ inhibitors in rheumatoid

arthritis. In asthma there is hope for blocking IL-13 as this cytokine appears to mimic many of the pathophysiological features of asthma. A mutated protein that blocks the common receptor for IL-4 and IL-13 pitrakinra has shown some inhibitory effects on the late response to allergen challenge in patients with mild asthma [20]. The cytokine thymic stomal lymphoietin (TSLP), which is secreted by epithelial cells and mast cells in asthmatic patients, appears to play a critical role in the programing of dendritic cells to orchestrate Th2 cells and allergic inflammation and appears to be a promising target for inhibition in asthma [21].

Chemokines play a key role in attracting inflammatory cells into the lung and act on G-protein-coupled receptors expressed on these cells. Small molecule inhibitors of chemokines receptors are a promising approach in asthma and COPD [22, 23]. Front-runners for asthma are CCR3 expressed predominantly on eosinophils and CCR4 expressed on Th2 cells and for COPD are CXCR2 expressed on neutrophils and monocytes and CXCR3 expressed on T-lymphocytes. Chemokine antagonists have the advantage of oral administration but so far there have been unexpected toxicological problems with many of the small molecule antagonists developed. A dual CXCR1/2 antagonist given orally has been shown to reduce neutrophil and macrophage influx into sputum after endotoxin challenge in normal patients after oral administration [24]. A CCR5 antagonist maraviroc has been approved for use in HIV/AIDS but may also be useful in COPD and these receptors are expressed in T-cells and their agonist CCL5 (RANTES) is increased in COPD sputum [25] (Fig. 61.2).

## Anti-oxidants

Oxidative stress is important in severe asthma and COPD, particularly during exacerbations [26]. Oxidative stress activates the proinflammatory transcription factors NF-κB and activator protein-1 (AP-1), resulting in enhanced inflammation. Oxidative stress is increased in patients with COPD, particularly during exacerbations, and reactive oxygen species contribute to its pathophysiology. Oxidative stress reduces steroid responsiveness via a reduction in histone deacetylase-2 (HDAC2) activity and expression [27]. This suggests that antioxidants may reverse

corticosteroid resistance and also reduce inflammation. Unfortunately currently available antioxidants based on glutathione are relatively weak and are inactivated by oxidative stress, so new more potent and stable antioxidants are needed, such as superoxide dismutase mimics and NADPH oxidase inhibitors [28].

## PROTEASE INHIBITORS

Proteases are involved in the pathophysiology of asthma and COPD and are therefore a logical target for inhibition. However, it has proved very difficult to find drugs that effectively block specific proteases without side effects.

## Tryptase inhibitors

Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation [29]. Some of these effects are mediated by activation of the proteinase-activated receptor PAR2. A tryptase inhibitor APC366 was effective in a sheep model of allergen-induced asthma [30], but was only poorly effective in asthmatic patients in a preliminary study [31] and ineffective in allergic inflammation [32]. More potent tryptase inhibitors and PAR2 antagonists are in development.

## Neutrophil elastase inhibitors

Neutrophil elastase (NE), a neutral serine protease, is a major constituent of lung elastolytic activity. In addition it potently stimulates mucus secretion and induces CXCL8 release from epithelial cells and may therefore perpetuate the inflammatory state. This has lead to a search for NE inhibitors. Peptide NE inhibitors, such as ICI 200355, and non-peptide inhibitors, such as ONO-5046, have been developed for use in COPD, but so far all of these drugs have been withdrawn due to toxicological problems or side effects. The NE inhibitor MR889 administered for 4 weeks

| CXCL1, CXCL5, CXCL8 | CCL2 | CXCL9, CXCL10, CXCL11 | CCL3, CCL5 |

CXCR2 — Neutrophil, Monocyte
CCR2 — Monocyte, T-cell
CXCR3 — Tc1, Th1 cells
CCR5 — Tc1, Th1 cells

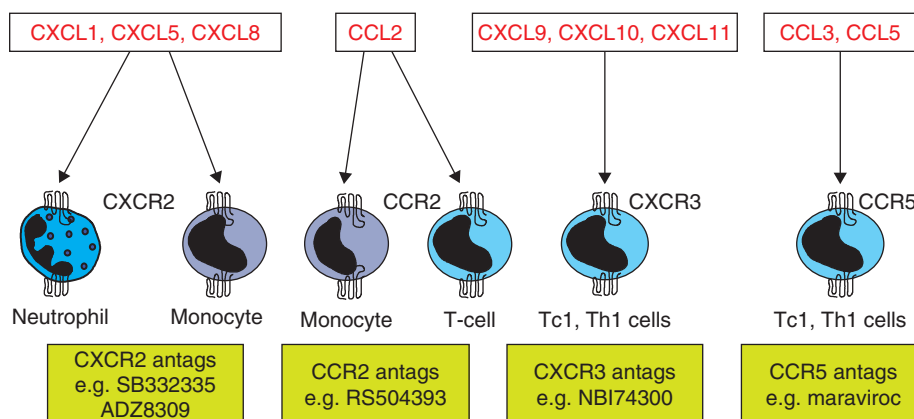
| CXCR2 antags e.g. SB332335 ADZ8309 | CCR2 antags e.g. RS504393 | CXCR3 antags e.g. NBI74300 | CCR5 antags e.g. maraviroc |


**FIG. 61.2** Several chemokines and chemokine receptors are involved in the inflammation of COPD. Chemokines released from epithelial cells and macrophages in the lung recruit inflammatory cells (Tc1 CD8+ T-lymphocytes, neutrophils, and monocytes) from the circulation. Small molecule chemokine receptor antagonists are now in development (shown in boxes).

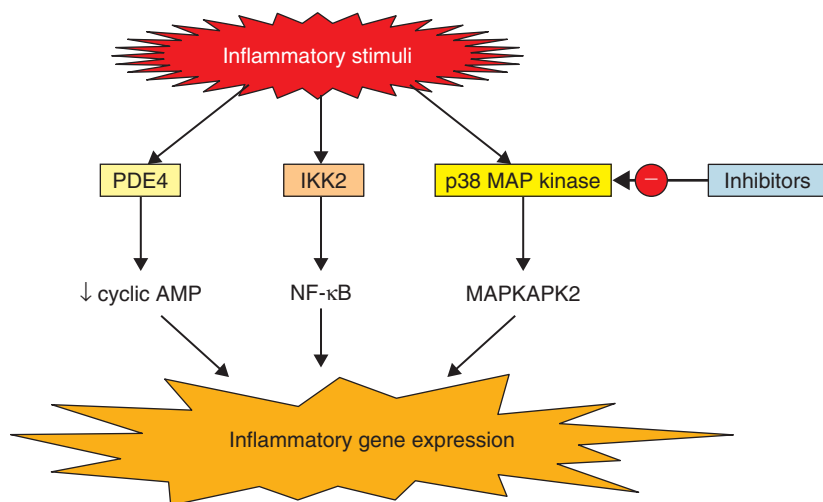
showed no overall effect on plasma elastic-derived peptides or urinary desmosine (markers of elastolytic activity) [33]. Although NE is likely to be the major mechanism mediating elastolysis in patients with $\alpha_1$-antitrypsin ($\alpha_1$-AT) deficiency, it may well not be the major elastolytic enzyme in smoking-related COPD, and it is important to consider other enzymes as targets for inhibition.

## Matrix metalloproteinase inhibitors

Matrix metalloproteinases (MMPs) with elastolytic activity appear to play a more important role in the pathogenesis of emphysema than NE so has become a target for drug development. MMP-9 appears to be the predominant enzyme, which is released from macrophages, neutrophils and epithelial cells. Non-selective MMP inhibitors, such as marimastat, appear to have major side effects [34], suggesting that isoenzyme-selective inhibitors or inhaled delivery may be needed. A dual MMP9/MMP12 inhibitor, AZ11557272, has been shown to prevent emphysema and small airway thickening in guinea pigs exposed to cigarette smoke over 6 months, but the clinical development of this inhibitor has been stopped for toxicological reasons [35]. Several other selective MMP inhibitors are now in development [34].

## NEW ANTI-INFLAMMATORY DRUGS

Inhaled corticosteroids are by far the most effective therapy for asthma, yet are ineffective in COPD. Thus for asthma, one strategy has been to develop safer inhaled corticosteroids or drugs that mimic their effects, whereas in COPD new non-steroidal anti-inflammatory treatments are needed (Table 61.2). Several novel anti-inflammatory treatments inhibit enzymes that are involved in the signal transduction pathways involved in transcription of multiple inflammatory genes and therefore may act in a similar way to corticosteroids (Fig. 61.3).


## New corticosteroids

Inhaled corticosteroids are by far the most effective anti-inflammatory therapy for asthma and work in almost every patient [36]. However, all currently available inhaled corticosteroids are absorbed from the lungs and therefore have the potential for systemic effects. This has led to a concerted effort to find safer corticosteroids, with reduced oral bioavailability, reduced absorption from the lungs or inactivation in the circulation. Ciclesonide, a newly introduced steroid, is a prodrug that becomes activated to the active des-ciclesonide by esterases in the lung. This corticosteroid appears to have less systemic effects than currently available corticosteroids and this may be due to long-term retention in the lung, no oral bioavailability, and a high degree of binding to circulating proteins [37]. Another approach is to develop dissociated steroids that separate the side effect mechanisms from the anti-inflammatory mechanisms. This is theoretically possible as side effects are largely mediated via genomic effects and the binding of glucocorticoid receptors to DNA, whereas anti-inflammatory effects are largely

**TABLE 61.2** New anti-inflammatory drugs for asthma and COPD.

| Drug class | Example |
|---|---|
| Phosphodiesterase-4 inhibitors | Roflumilast |
| NF-κB inhibitors | PS1145 |
| p38 MAP kinase inhibitors | SB203580, SD-208 |
| Phosphoinositide 3-kinase-γ/-δ inhibitors | In development |
| PPAR-γ agonists | Rosiglitazone, pioglitazone |
| *Syk* kinase inhibitors | R112 |
| Adhesion molecule inhibitors | anti-ICAM-1, E-selectin inhibitors, VLA-4 inhibitors |

**FIG. 61.3** Inhibition of signal transduction pathways. Selective inhibitors have been developed for phosphodieatease-4 (PDE4), which degrades cyclic adenosine monophosphate (AMP), inhibitor of inhibitor of NF-κB kinase (IKK2), which activates NF-κB, and p39 mitogen-activated protein (MAP) kinase, which activates MAP kinase activated protein kinase 2 (MAPKAPK2). Selective inhibitors have now been developed for these enzyme targets.

mediated via inhibition of transcription factors through a non-genomic effect [38]. Some novel corticosteroids have a greater effect on the non-genomic than genomic effect (dissociated steroids) and thus may have a better therapeutic ratio and might even be suitable for oral administration [39]. Non-steroidal glucocorticoid receptor activators, such as AL-438, have now been discovered and are in clinical development [40]. Corticosteroids switch off inflammatory genes by recruiting the nuclear enzyme HDAC2 to the activated inflammatory gene initiation site so that activators of this enzyme may also have anti-inflammatory effects or may enhance the anti-inflammatory effects of corticosteroids [38]. There may be additional mechanisms for the anti-inflammatory effects of corticosteroids which may also be targeted in the future.

## Phosphodiesterase inhibitors

The most advanced of the new anti-inflammatory therapies are phosphodiesterase(PDE)-4 inhibitors which have been in development for asthma and COPD as they have a broad spectrum of anti-inflammatory effects. PDE4 inhibitors inhibit T-lymphocytes (CD4$^+$ and CD8$^+$ cells), neutrophils, eosinophils, mast cells, airway smooth muscle, epithelial cells and airway nerves and have been shown to be highly effective in animal models of asthma and COPD [41, 42]. An oral PDE4 inhibitor, roflumilast, has an inhibitory effect on allergen-induced responses in asthma and also reduces symptoms and lung function in a comparable way to low doses of inhaled steroids [43]. In COPD patients oral roflumilast given over 4 weeks significantly reduces the numbers of neutrophils (by 36%) and CXCL8 concentrations in sputum [44]. In clinical trials roflumilast given over 6 months or 12 months improves lung function in COPD patients to a small extent but has no significant effect in reducing exacerbations or improving quality of life [45]. These disappointing results are likely to reflect the fact that side effects, particularly nausea, diarrhea and headaches, limit the dose that can be tolerated. This indicates that it may not be possible to reach an oral dose that is effective and acceptable to patients.

This could be overcome by inhaled delivery, but to date two inhaled PDE4 inhibitors have been found to be ineffective, although well tolerated. Another approach is to develop isoenzyme-selective inhibitors. PDE4D inhibition appears to account for nausea and vomiting, whereas PDE4B inhibition may account for the anti-inflammatory effects, so that PDE4B selective inhibitors may be better tolerated. However, PDE4D inhibition may also have some anti-inflammatory effects, for example in T-lymphocytes, so that PDE4B selective inhibitors may not be as effective as pan-PDE4 inhibitors [46]. PDE7A is also expressed in the same inflammatory cells as PDE4 so inhibition of PDE7 may be beneficial. However, a selective PDE7 inhibitor had only a small anti-inflammatory effect, but potentiated anti-inflammatory effects of a PDE4 inhibitor, suggesting that a combined inhibitor may be useful as it should not increase side effects [47].

## NF-κB inhibitors

NF-κB regulates the expression of CXCL8 and other chemokines, TNF-α and other inflammatory cytokines, as well as MMP9. NF-κB is activated in macrophages and epithelial cells of asthma and COPD patients, particularly during exacerbations. Although there are several possible approaches to inhibition of NF-κB, small molecule inhibitors of NF-κB kinase (IKK)2 are the most promising approach. An IKK2 inhibitor is effective in some animal models of COPD (LPS exposure) but not in others (neutrophil elastase instillation), indicating that the effects may be complex [48]. Although several IKK2 inhibitors are now in development, so far none have been tested in asthma or COPD patients. IKK2 inhibitors not only block the activation of NF-κB-activated genes, but also have some unexpected beneficial effects such as inhibition of CXCR3 chemokines, indicating complex interactions between signal transduction pathways [49]. The hope is that IKK2 inhibitors will be effective in suppressing the corticosteroid-resistance inflammation of COPD and severe asthma. One concern about long-term inhibition of NF-κB is that effective inhibitors may result in immune suppression and impair host defenses, since mice which lack NF-κB genes succumb to septicemia. As it is highly likely that there will be systemic toxicity inhaled delivery is likely to be necessary.

## MAPK inhibitors

Mitogen-activated protein kinases (MAPK) play a key role in chronic inflammation and several complex enzyme cascades have now been defined. One of these, the p38 MAPK pathway, is activated by cellular stress and regulates the expression of inflammatory cytokines, including CXCL8, TNF-α and MMPs. p38 MAPK (measured by phosphorylated p38 MAPK) is activated in alveolar macrophages of COPD lungs indicating the activation of this pathway in COPD [50]. There is also evidence that this pathway is also activated in severe asthma. p38 MAPK is involved in the activation of GATA3 and allergic inflammation [51]. Furthermore, p38 MAPK inhibitors have also been shown to decrease eosinophil survival by activating apoptotic pathways [52] and an antisense oligonucleotide that blocks p38 MAP kinase demonstrated marked efficacy in inhibiting eosinophilic inflammation in mice [53]. p38 MAPK is also involved in corticosteroid-resistance through phosphorylation of the glucocorticoid receptor in response to lymphokines [54]. Several small molecule inhibitors of the α- and β-isoforms of p38 MAPK (but not the γ- and δ-isoforms) have now been developed. A potent inhibitor of p38-α isoform, SD-282, is effective in inhibiting TNF-α release from human lung macrophages in vitro [55] and the same inhibitor is also effective in suppressing inflammation in a smoking model of COPD in mice in which corticosteroids are ineffective [56]. Several p38 MAPK inhibitors have now entered clinical trials, but there have been major problems of side effects and toxicity, indicating that it will probably be necessary to deliver these drugs by inhalation

to reduce systemic exposure. All of these p38 MAPK inhibitors target p38-α and/or -β isoforms of the enzyme. Little is known about the function of the -γ and δ isoforms of the enzymes as there are no selective inhibitors currently available. In human alveolar macrophages there is a high level of expression of the p38-δ isoform, but its function is currently unknown [55].

Recent studies indicate that other MAPK pathways, particularly extracellular signal-regulated kinase (ERK1/2) may also play an important role in regulating the expression of proinflammatory cytokines in alveolar macrophages, in contrast to its lack of effect in blood monocytes [57].

## Phosphoinositide 3-kinase inhibitors

PI3Ks are a family of enzymes that lead to the generation of lipid second messengers that regulate a number of cellular events, including innate and adaptive immune responses. A particular isoform, PI3K-γ, is involved in neutrophil recruitment and activation [58]. Knock-out of the PI-3K-γ gene results in inhibition of neutrophil migration and activation, as well as impaired T-lymphocyte and macrophage function, so PI3K-γ inhibitors may be potential anti-inflammatory therapy for COPD [59]. PI3K-δ is also involved in expression of inflammatory genes and several PI3K-δ or mixed PI3K-γ/-δ inhibitors are now in development [60]. Pan-isoform inhibitors of PI3K are likely to be associated with side effects as these enzymes appear to serve a number of key cell function, but the -γ and -δ isoforms have a more restricted distribution of leukocytes and may therefore be better tolerated, especially if delivered by inhalation.

## PPAR activators

Peroxisome proliferator-activated receptors (PPARs) are a family of ligand-activated nuclear hormone receptors belonging to the steroid receptor superfamily, and the three recognized subtypes PPAR-α, -γ, and -δ are widely expressed. There is evidence that activation of PPAR-α and PPAR-δ may have anti-inflammatory and immunomodulatory effects [61]. For example PPAR-γ agonists, such as troglitazone and rosiglitazone, inhibit the release of inflammatory cytokines from monocytes and induce apoptosis of T-lymphocytes, suggesting that they may have anti-inflammatory effects in COPD and severe asthma [62]. There is a reduction in PPAR-α expression in skeletal muscle of COPD patients that correlates with muscular weakness, indicating that PPAR-α agonists, such as clofibrate, may be useful in treating muscle weakness in severe disease [63].

## Tyrosine kinase inhibitors

*Syk* kinase (spleen tyrosine kinase) is a protein tyrosine kinase that plays a pivotal role in signaling of the high affinity IgE receptor (FcεRI) in mast cells and in *syk*-deficient mice mast cell degranulation is inhibited, suggesting that

this might be an important potential target for the development of mast cell stabilizing drugs [64]. *Syk* is also involved in antigen receptor signaling of B- and T-lymphocytes and in eosinophil survival in response to IL-5 and GM-CSF [65], so that *Syk* inhibitors might have several useful beneficial effects in atopic diseases. Inhibitors of the enzyme *Syk* kinase are currently in development for asthma [66]. An antisense inhibitor of *Syk* kinase is effective in an animal model of asthma [67] and a *Syk* inhibitor reduces mast cell activation and airway hyperresponsiveness in an allergic murine model [68]. The small molecule inhibitor R112 given nasally reduces nasal symptoms in hay fever patients [69]. As with other kinase inhibitors there may be side effects with systemic administration so that inhalation may be the preferred route of delivery. Another tyrosine kinase *Lyn* is upstream of *Syk* and an inhibitor of *lyn* kinase, PP1, has an inhibitory effect on inflammatory and mast cell activation [70].

## Cell adhesion blockers

Infiltration of inflammatory cells into pulmonary tissues is dependent on adhesion of blood borne inflammatory cells to endothelial cells prior to migration to the inflammatory site [71]. This depends upon specific glycoprotein adhesion molecules, including integrins and selectins, on both leukocytes and on endothelial cells, which may be up-regulated or show increased binding affinity in response to various inflammatory stimuli, such as cytokines or lipid mediators. Drugs which inhibit these adhesion molecules therefore may prevent inflammatory cell infiltration. Thus a monoclonal antibody to ICAM-1 on endothelial cells prevents the eosinophil infiltration into airways and the increase in bronchial reactivity after allergen exposure in sensitized primates [72]. The interaction between VLA-4 and VCAM-1 is important for eosinophil inflammation and humanized antibodies to VLA-4 ($\alpha_4\beta_1$) have been developed [73]. Small molecule peptide inhibitors of VLA-4 have subsequently been developed which are effective in inhibiting allergen-induced responses in sensitized sheep and in various models of eosinophilic inflammation [74, 75]. Several orally active VLA-4 inhibitors have now been tested in asthma without any clear clinical benefit, although these negative studies so far remain unpublished.

Inhibitors of selectins, particularly L-selectin and E-selectin, based on the structure of sialyl-Lewis[x] inhibit the influx of inflammatory cells in response to inhaled allergen in sensitized sheep [76]. These glycoprotein inhibitors, which may inhibit neutrophilic and eosinophilic inflammation, are now under investigation for asthma and COPD [77].

## IMMUNOSUPPRESSANTS

T-lymphocytes may play a critical role in initiating and maintaining the inflammatory process in asthma via the

release of cytokines that result in eosinophilic inflammation, suggesting that T-cell inhibitors may be useful in controlling asthmatic inflammation. The non-specific calcineurin inhibitor cyclosporin A reduces the dose of oral steroids needed to control asthma in patients with severe asthma [78], but its efficacy is limited. Side effects, particularly nephrotoxicity, also limit its clinical use. The possibility of using inhaled cyclosporin A has been explored, since in animal studies the inhaled drug is effective in inhibiting the inflammatory response in experimental asthma [79]. Immunomodulators, such as tacrolimus (FK506) and rapamycin, appear to be more potent but are also toxic and may offer no real advantage. Aerosolized tacrolimus is effective against allergen challenge in guinea pigs [80] and topical tacrolimus is effective against atopic dermatitis, but the effects of inhaled tacrolimus have not been reported in asthmatic patients. Novel immunomodulators that inhibit purine or pyrimidine pathways, such as mycophenolate mofetil, leflunomide and brequinar sodium, may be less toxic and therefore of greater potential value in asthma therapy. One problem with these non-specific immunomodulators is that they inhibit both Th1 and Th2 cells, and therefore do not restore the imbalance between these Th1 and Th2 cells in atopy. They also inhibit suppresser T-cells (Tc) that may modulate the inflammatory response. Selective inhibition of Th2 cells may be more effective and better tolerated and there is now a search for such drugs.

The role of immunomodulators in COPD is even less certain. There is an increase in Tc1 and Th1 cells in patients with COPD [81], but the role of these cells is uncertain and the usefulness of immunomodulators in COPD has not yet been assessed.

## JAK-3 inhibitors

The Janus-kinase (JAK)-3 appears to be important in signal transduction pathways in T-cells and mediates the secretion of IL-2, IL-4 and IL-9, all of which have been implicated in allergic inflammation. A small molecule inhibitor of JAK-3 CP-690550 is effective in inhibiting eosinophilic inflammation in a murine model [82].

## Costimulatory receptor inhibitors

Costimulatory molecules may play a critical role in augmenting the interaction between antigen presenting cells and CD4+ T-lymphocytes. The interaction between B7 and CD28 may determine whether a Th2 type cell response develops, and there is some evidence that B7-2 (CD86) skews towards a Th2 response. Blocking antibodies to B7-2 inhibit the development of specific IgE, pulmonary eosinophilia, and AHR in mice, whereas antibodies to B7-1 (CD80) are ineffective [83]. A molecule on activated T-cells CTL4 appears to act as an endogenous inhibitor of T-cell activation and a soluble fusion protein construct CTLA4-Ig is also effective in blocking AHR in a murine model of asthma [84]. Anti-CD28, anti-B7-2 and CTLA4-Ig also block the proliferative response of T-cells to allergen [85], indicating that these are potential targets for novel therapies that should be effective in all atopic diseases.

## Th2 cell inhibitors

Non-selective T-cell suppressants, such as cyclosporin A and tacrolimus, may be relatively ineffective in asthma as they inhibit all types of T-cell. CD4+ T-cells have been implicated in asthma and a chimeric antibody directed against CD4+ (keliximab) which reduces circulating CD4+ cells appears to have some beneficial effect in asthma [86], although long term safety of such a treatment might be a problem. Furthermore, there is increasing evidence that CD8+ cells (Tc2 cells), through release of IL-5 and other cytokines, might also be involved in atopic diseases, particularly in response to infections with certain viruses [87]. There has been a search for selective inhibitors of Th2 cells by identifying features that differentiate Th1 and Th2 cells. It is claimed that suplatast tosylate selectively inhibits Th2 cells and is in clinical use in the treatment of asthma in Japan [88]. However, its mechanism of action is uncertain and it does not appear to be very effective in controlling asthma. The transcription factor GATA-3, which regulates Th2 cell differentiation and the expression of Th2 specific cytokines, may be targeted by antisense oligonuleotides, but more easily by p38 MAPK inhibitors, as discussed earlier [51]. The calcium antagonist nicardipine appears to selectively inhibit Th2 cells in mice suggesting that dihydropyrridines may act as immunomodulators in asthma but this has not yet been demonstrated in humans [89]. Indoleamine-2,3-dioxygenase (IDO), a tryptophan-degrading enzyme, plays a key role in the regulation of T-lymphocyte function. IDO inhibits eosinophilic inflammation in a murine asthma model, and concentrations of IDO are reduced in asthmatic patients and restored by corticosteroids [90]. Other drugs which restore IDO activity may therefore be of value in suppressing eosinophilic inflammation in asthma.

## Regulatory T-cell activators

Regulatory T-cells (Tregs) play a key role in orchestrating immunity and there is evidence for a defect in Treg function in patients with asthma and COPD that may be linked to increased numbers of T-cells [91, 92]. There is convincing evidence that specific immunotherapy increased IL-10 production from Tregs (Tr-1 cells) [93]. Vaccines which enhance Tr-1 cell function and increase IL-10 release are now in development for asthma. T-cell peptides are also in development as a safer form of immunotherapy [94].

## B-lymphocyte depletion

An anti-CD20 blocking monoclonal antibody (rituximab) selectively depletes B-cells and has been found to be very effective in controlling resistant rheumatoid arthritis and other autoimmune diseases [95]. As there is an increase in B-cells in COPD and as B-cells produce IgE in asthma, this approach may also be useful in severe asthma and COPD. However, the potential disadvantages are an increased risk of pulmonary infections, particularly in patients with COPD.

## Anti-IgE

Blocking IgE with a chimeric antibody omalizumab is useful in controlling asthma in some patients with severe asthma, although there are no clinical indicators to show how responders can be predicted, so a prolonged trial of therapy is needed [96]. Omalizumab is very expensive as a maintenance therapy, especially in patients with high titers of IgE who require high doses. There is a quest for antibodies with higher affinity, so that patients with high IgE can also be treated. There is also a search for small molecule inhibitors of the IgE response through targeting the signal transduction pathways initiated by IgE interaction with its receptors.

Allergens bind to a low-affinity IgE receptor (FcεRII or CD23) as well as the high affinity receptor FcεRI on several immune cells, including T- and B-lymphocytes [97]. An anti-CD23 antibody (lumiliximab) was well tolerated and reduced IgE concentrations in patients with mild asthma, but did not appear to have clinical efficacy [97].

## PREVENTIVE STRATEGIES

The obvious preventive strategy for preventing COPD is stopping smoking, which is covered in Chapter 47. Preventive strategies for asthma are targeted to preventing the Th2 cell preponderance in atopy.

## Vaccination

None of the currently available treatments for asthma have long-term effects on airway inflammation or remodeling and therefore are not disease-modifying or curative. Inhaled corticosteroids are usually very effective in controlling asthma, but symptoms usually rapidly return when they are discontinued. The prospects for a cure are remote until the molecular and genetic causes of asthma are better understood, but there is a possibility that vaccination approaches may reverse the abnormal immune regulation found in asthma, restoring Th1 predominance or restoring Treg function [93, 98]. Various approaches, including non-pathogenic bacterial products, such as CpG oligodeoxynucleotides, which target toll-like receptor (TLR)-9, are currently being explored as potential therapies for asthma [99]. A CpG vaccine has been tested in asthma, and despite evidence for an increase in interferons, there was no effect on the response to allergen, in contrast to several positive studies in rodent models [100]. However, the long-term consequences of these approaches need to be carefully evaluated, particularly as they would probably need to be applied in children at the onset of disease. The role of other TLRs in asthma is uncertain, with beneficial and detrimental effects reported in different animal models [101].

## REVERSAL OF CORTICOSTEROID RESISTANCE

Even high doses of corticosteroids have minimal effects on the progression of COPD and no effects on mortality [102]

and are poorly effective in severe asthma. This may reflect the resistance of inflammation in severe asthma and COPD to the anti-inflammatory effects of corticosteroids. There is increasing evidence that this may be due to a reduction in HDAC2 as a result of oxidative and nitrative stress [27, 103]. This results in increased acetylation of the glucocorticoid receptor which prevents it inhibiting NF-κB driven inflammation [104]. A novel therapeutic strategy is therefore reversal of this corticosteroid resistance by increasing the expression and activity of HDAC2 and this may be achieved in several ways.

## Theophylline-like drugs

Low doses of oral theophylline increase HDAC2 expression in alveolar macrophages from COPD patients and thereby restore steroid responsiveness [105, 106]. This has also been demonstrated in mice exposed to cigarette smoke, which develop a steroid-resistant inflammation in the lungs with increased neutrophils and macrophages. This inflammation is not reversed by high doses of corticosteroids or by theophylline alone but is reversed by low dose oral or inhaled theophylline combined with a corticosteroid via an increase in HDAC2 activity [107]. Understanding the molecular mechanisms of action of theophylline, which appear to be independent of PDE inhibition, may lead to novel therapeutic approaches to restoration of corticosteroid responsiveness which avoid the side effects and drug interaction problems of theophylline itself.

## Antioxidants

As discussed above, antioxidants may be valuable in reversing corticosteroid resistance since increased oxidative stress appears to be the mechanisms by which severe inflammation and cigarette smoke lead to reduced HDAC2 activity and corticosteroid resistance. Several more potent and stable antioxidants are needed, such as superoxide dismutase mimics and NADPH oxidase inhibitors [28].

## Macrolides

It has long been recognised that macrolides have anti-inflammatory effects that may be independent of their antibiotic effects [108]. Macrolides appear to inhibit inflammation by inhibiting NF-κB and other transcription factors. Recently it has been shown that a non-antibiotic macrolide (EM-703) reverses corticosteroid resistance due to oxidative stress by increasing HDAC2 activity [109]. Several non-antibiotic macrolides are now in development as anti-inflammatory therapies.

## REVERSAL OF STRUCTURAL CHANGES

In both asthma and COPD structural changes in the airways may lead to reversible narrowing as a result of

structural changes. These may be a consequence of persistent inflammation and the generation of growth factors that cause cell proliferation and fibrosis. However, it is possible that the structural changes may become independent of inflammation and may progress in the absence of inflammation. Therapeutic strategies to prevent these structural changes or ideally to reverse them in order to restore lung function are therefore of future interest. In COPR there is also destruction of connective tissue as a result of elastolysis and apoptosis of alveolar epithelial and endothelial cells.

## Fibrosis inhibitors

Transforming growth factor-β (TGF-β) appears to play a key role in the fibrosis of asthma and COPD and small molecule inhibitors of TGF-β tyrosine kinase have been developed [110]. However, TGF-β plays a critical role in wound healing and in Treg function, so its inhibition may have deleterious effects. It may be safer to inhibit a downstream cytokine connective tissue growth factor (CTGF), which appears to mediate many of the fibrotic responses to TGF-β.

## Reversal of emphysema

Retinoic acid increases alveolar septation during lung development and in adult rats and mice reverses the histological and physiological changes induced by elastase treatment [111]. This has not been seen in several other species and there are doubts whether emphysema is reversible in humans as alveolar formation ceases about the age of 6 years. A clinical trial of all-*trans*-retinoic and 9-*cis*-retinoic acid in patients with emphysema failed to show any improvement in clinical parameters, health status or CT density after 6 months of therapy [112].

Another possible approach to repairing damaged lung in emphysema is the use of stem cells to seed the lung combined with drugs that stimulate their homing and proliferation in the lung. Human embryonic stem cells have been transformed into alveolar type II pneumocytes which have the capacity to repair alveolar damage [113]. Adult bone marrow-derived stem cells may also be suitable for populating the lung, particularly if enhanced by retinoic acid or granulocyte-macrophage colony stimulating factor. However, there are several concerns about the use of stem cells for lung repair as there may be a problem engrafting these cells in the alveoli and there is always a risk of cancer or teratoma development [114]. The lung is a complex organ and it would probably be necessary to grow both endothelial and alveolar cells to repair emphysema.

## GENE THERAPY

Since asthma and COPD are polygenic, it is unlikely that gene therapy will be of value in long-term therapy. However, understanding the genes involved in asthma and COPD

and in disease severity may identify new molecular targets [115] and may also predict the response to different therapies [116]. Transfer of anti-inflammatory genes may provide specific anti-inflammatory or inhibitory proteins in a convenient manner and gene transfer has been shown to be feasible in animals using viral vectors [117]. Anti-inflammatory proteins relevant to asthma and COPD include IL-10 and IκB. Anti-sense oligonucleotides may switch off specific genes, but there are considerable problems in getting these molecules into cells. An inhaled antisense oligonucleotide directed against the adenosine A$_1$-receptor has been shown to reduce AHR in a rabbit model of asthma, demonstrating the potential of this approach in treating asthma [118]. Suitable target genes may be IL-4 or IL-5 in asthma and MMP-9 in COPD. Considering the practical problems encountered by gene therapy this approach is unlikely in the foreseeable future, other than for proof of concept studies.

## FUTURE DIRECTIONS

New drugs for the treatment of severe asthma and COPD are greatly needed and there has been an enormous effort now invested by the pharmaceutical industry to find such treatments. Both diseases are highly complex so it is unlikely that therapies that target a single cell or mediator will be very effective. While preventing and quitting smoking is the obvious preferred approach, this has proved to be very difficult in the majority of patients. It may be important to more carefully phenotype patients with asthma and COPD in clinical trials. For example, it may also be important to more accurately define the presence of emphysema versus small airway obstruction in COPD patients by using CT scans, as some drugs may be more useful for preventing emphysema, whereas others may be more effective against the small airway inflammatory-fibrotic process. More research on the basic cellular and molecular mechanisms of severe asthma and COPD and on more useful animal models is urgently needed to aid the logical development of new therapies these important diseases, for which no effective preventative drugs currently exist.

Of the drugs currently in development PDE4 inhibitors, p38 MAP kinase inhibitors, and IKK-2 inhibitors appear to be promising for severe asthma and COPD, but there are concerns about side effects so that inhaled administration is likely to be needed. There are also concerns about their long-term safety in increasing lung infection and cancer, particularly in COPD patients. For these reasons alternative strategies, such as reversal of corticosteroid-resistance may be more successful and there have been important advances in understanding the molecular mechanisms of corticosteroid resistance that will identify novel targets for therapy.

Drug delivery is an important issue. Most of the effective therapies used now are given by inhalation in both diseases, but inhaled therapies are more difficult to develop as there is only a poor understanding of inhalation

pharmacokinetics and toxicology studies are more difficult to conduct. In addition, the inhaled route may not deliver sufficient drug to peripheral airways, particularly in COPD and severe asthma. Oral administration has the advantage of easier drug development and the treatment of concomitant allergic diseases in the case of asthma and treating systemic complications in the case of COPD. However, oral administration has a high risk of side effects which may outweigh these advantages. Another approach is targeting of drugs to specific cell types, for example to macrophages which take up particles, as this may allow an enhanced therapeutic ratio.

# Health Economics in Asthma and COPD

**Andrew Briggs, Helen Starkie and Olivia Wu**

Section of Public Health and Health Policy, University of Glasgow, Glasgow, Scotland, UK

## INTRODUCTION

The aim of this chapter is to introduce the fundamental concepts underlying the use of health economic evaluation methods, with particular reference to treatments for asthma and COPD. The chapter begins with a section that introduces the general framework of cost-effectiveness and cost-utility analyses, the predominant forms of health economic evaluation that have been used to assess value for money in the respiratory field, and indeed in health care evaluation more generally. As part of this background, a distinction is drawn between cost-of-illness studies, which examine only the financial burden that a disease places a health system or society, and full economic evaluations that assess the change in both financial burden and health outcomes that can be expected from implementing a treatment intervention. The following two sections then review the published literature on cost-of-illness studies and health economic evaluations for asthma and COPD treatments separately. A final section summarizes the chapter.

## HEALTH ECONOMIC EVALUATION

Health economic evaluations are used to assist decision-makers in allocating scarce resources. Twenty three countries around the world currently have some form of guidelines on pharmacoeconomics, primarily European countries but there are also others, including Australia, Canada, and the United States [1].

In England and Wales, the relevant decision-making agency is the National Institute for Health and Clinical Excellence (NICE), an organization who are independent from Government and responsible for providing guidance on the use of health technologies and the implementation of public health programs. In the process of developing guidance on use of technologies, NICE brings together all available clinical and economic evidence in order to decide whether the adoption of the technology (drug, device or treatment) represents good value for the NHS (National Institute of Health and Clinical Excellence. A guide to NICE. London: National Institute of Health and Clinical Excellence, 2005). The National Institute for Health and Clinical Excellence (NICE) also produces clinical guidelines and published their own guidelines for the management of COPD in 2004 [2].

Within this chapter, two different types of economic evaluations are presented. The first is cost-effectiveness analysis and the second, cost-utility analysis. The main difference between the two relates to how health outcomes are measured. Cost-effectiveness studies present results in terms of natural units such as the cost per exacerbation avoided and improvement in health status [3], whereas a cost-utility evaluation identifies the cost per unit of utility (usually the Quality Adjusted Life Year, QALY). Utilities and the QALY concept are described in detail below.

The outcome measure(s) used should be based upon the aim and intended use of the evaluation. The use of natural units as outcome measures used within a cost-effectiveness analysis, constrains the end use of such a study. For example a study that investigates and reports the cost of an improvement in lung function can only be logically compared with another study where same outcome is also reported.
**FIG. 62.1** Quality Adjusted Life-Year profiles for a hypothetical patient with and without a treatment intervention. Profiles weight length of life by quality of life on a zero-one scale where one represents perfect health and zero death. In a chronic disease such as COPD, exacerbations might result in reduced quality of life for a period of time with incomplete recovery.

One of the problems found in both asthma and COPD is that there are a number of different outcome measures that could easily be chosen to investigate, for example, cost per exacerbation avoided or cost per symptom-free day. As a result there are few studies that report the same outcome measure and so comparison is difficult. Even if cost per exacerbation avoided was reported in every study, cost-effectiveness studies can only inform the efficient use of resources within the disease itself (or closely linked conditions). It is not possible to directly compare an exacerbation avoided in COPD to an increase in survival time for cancer patients.

A more useful approach for the decision-maker is to use a generic measure that captures the effect of a disease and its treatment on both quantity and quality of life, and which can be compared across disease areas. NICE recommends these cost-utility analyses as the appropriate way to make comparative assessments of value for money within a health system [4]. Although not universally accepted, the QALY is nevertheless acknowledged as the most popular measure of utilities for making comparative assessment of the value for money of alternative treatment choices. The QALY is by far the most accepted health-related utility measure and is the preferred outcome measure in many countries including Canada, New Zealand, Sweden, England and Wales, the Netherlands, and the United States [1].

The QALY quantifies changes in utility over the life of the patient and has two components, quality and quantity of life. This concept can be visualized as shown in Fig. 62.1.

As has previously been described, the use of the QALY within an economic evaluation enables treatments to be compared to one another both across and within disease areas using a cost per QALY ratio. This ratio represses the incremental costs ($C$) and incremental benefits ($B$) of a new therapy ($x$) are compared to the main comparator ($y$). The ICER is worked out using the simple formula:

$$\text{ICER} = \frac{Cx - Cy}{Bx - By}$$

The reimbursement of one treatment will displace health care resources spent on other treatments within the health system (so called opportunity cost). It is therefore important to ensure that the treatment reimbursed provides sufficient value for money. For this a "guide price" or a threshold from which it can be decided whether or not any one treatment should be reimbursed by the health care system is necessary. In the United Kingdom, NICE's documented threshold is said to be between £20,000 and £30,000 per QALY [5], such that below £20,000 per QALY there is a high probability of the technology being accepted and that above £30,000 per QALY there is less chance of the technology being accepted. In theory, this threshold should reflect the value of those treatments displaced at the margin of the health care budget [6].

Two main designs of economic evaluation exist: either based upon individual patient data from a clinical trial or observational study data, or aggregated using a decision analytic model. Model-based evaluations typically incorporate data from a wider range of sources than clinical trial based studies and can include data from: clinical and observational trials, burden of disease studies, epidemiology, and natural history studies.

The perspective that is adopted by the authors of the study depends upon the target audience [7] and can either be a specific provider/provider institution (i.e. the National Health Service, NHS), the patient/patient group, a third party payer (i.e. an insurer), or the perspective of society [8]. The perspective used will determine the costs employed. For example, a health perspective will only include costs that fall directly within the health care budget, but a broader societal perspective can include cost to individual patients and carers as well as other sectors, such as public sector services or employers.

Particularly important is the choice of comparator used. The use of an inappropriate comparator can bias an analysis and render little value for decision-making. Most published guidelines for economic evaluations assert that the comparator of interest is current treatment [9].

A potentially fundamental problem of conducting economic analyses alongside clinical trials, [10] is that many trials often only assess effectiveness relative to placebo.

Methods of handling uncertainty need to be explored, particularly if the study uses a decision analytical modeling framework. Sensitivity analysis, preferably probabilistic should be employed [11]; as this allows the combined uncertainty of all the parameters in the model to be included [12], by using the full probability distributions of each input into the model, rather than just the point estimates.

An important distinction exists between "full health economic evaluations" that involve a comparison of the resource use costs and health outcome consequences of two or more alternative treatment interventions [8] and so called cost-of-illness studies. Cost-of-illness studies are descriptive, providing information about the financial burden of disease on the health service and on patients and society more broadly. However, while a high financial burden of disease may imply the *potential* for a given treatment to offer value for money (by reducing that burden and thereby offsetting disease costs), value for money can only be proven in a full *incremental* cost-effectiveness analysis that compares the cost and health outcomes of the new treatment with the existing pattern of care. Therefore, in the two sections that follow, the literature on cost-of-illness and cost-effectiveness of treatments in asthma and COPD are presented in separate sections. More space is given to the cost-effectiveness of treatments, since this represents the ability of the health system to positively affect the burden of disease.

## COST-OF-ILLNESS STUDIES

### Asthma

The costs associated with the management of asthma in adults and in children, from both the health care payer and the societal perspective, are substantial worldwide. A number of cost-of-illness studies have attempted to estimate the annual cost of asthma and had reported a wide range of estimates. This is, in part, due to the variations in study design (e.g. the individual cost components that were included), perspective, and population of interest.

In the United States, the total annual costs for pediatric patients with mild to moderate persistent disease has been estimated to be US$564 [13], while the costs for adult patients ranged from US$1250 [14] to US$7106 [15]. In particular, one study estimated the total annual direct cost of asthma in the United States to be $1.48 billion [16], representing the most costly occupational illness in the United States. In Europe, the estimated average cost for a child with asthma ranged from €883 [17] to €2202 [18] per year, and the estimated average cost for an adult with asthma ranged from €632 [17] to €2745 [18] per year. In Asia, despite a lower prevalence of asthma than in the West, the cost of disease management is a significant and an increasing economic burden. In Japan, the annual direct medical cost associated with managing asthma has been estimated

to be US$8.2 billion. This accounted for 1.9% [19] of the annual cost of medical care and 18.9% of the annual cost of medical care for respiratory diseases.

Pharmaceutical expenditures represent an increasing share of total direct medical costs. In the United Kingdom, the estimated annual cost of asthma was £752.6 million, of which, 8% was hospital admissions, 13% general practice consultations, and 79% community prescriptions [20]. Indirect costs represent 40–50% of total societal burden of asthma. Loss of school and working days for children with asthma and their parents are the largest component of indirect costs. The overall cost to the family, health service, and society associated with caring for children aged 1–5 years in the United Kingdom in the 12 months following hospitalization for wheeze or asthma has been estimated to be £14.53 million [21].

Studies that assessed the relationship between costs and disease severity have all showed that costs significantly increase with increasing asthma severity. In particular, one Italian study showed that when stratified by disease severity, the total annual cost-per-patient according to increasing severity of asthma was €720, €1046, €1535, and €3328 for patients with intermittent, mild persistent, moderate persistent, and severe persistent asthma, respectively [22]. Similarly, based on the data from the TENOR database, the health care expenditures for an average uncontrolled patient in the United States, has been shown to be more than double that of an average control patient [15].

### COPD

The World Health Organisation (2000) reported that deaths attributable to COPD are the fifth largest killer globally; accounting for 4.5% of deaths worldwide [23]. The proportion of deaths for COPD varies significantly between regions of the world. Of particular concern is the Western Pacific region where COPD accounts for 13.8% of all deaths and where COPD is ranked as the second leading cause of death.

Data from both the United States and the United Kingdom show that the prevalence of COPD is comparatively small among the under 45s but increases markedly throughout later years [24]: approximately 1% of the UK general population and increasing with age to around 5% of men between 65 and 74, rising to 10% in men over 75 [25].

The true rate of COPD within the general population is likely to be greater than that recorded. There is much evidence that suggests COPD is heavily under diagnosed worldwide [25–27], and this is likely to be the situation, particularly among mild cases of COPD.

Total costs to the UK NHS for COPD have been estimated somewhere between £486 million [28, 29] and £848 million [30, 31] per year. The major drivers of this cost are disease severity and exacerbations.

Costs increase most as disease severity moves from moderate to severe (with a much smaller increase between mild and moderate) [32–38]. As $FEV_1$ deteriorates, a general shift from outpatient care to hospitalization, an increase in the use of oxygen therapy and a subsequent increase in total costs occurs, especially in the most advanced stages of the disease [39].

Exacerbations are the leading drivers of cost in COPD. A serious exacerbation will lead to hospitalization; indeed an exacerbation is the main reason why a COPD patient would attend hospital. COPD patients take up around 1 million bed days per year in the United Kingdom alone.

Reducing or preventing disease progression and/or an exacerbation, (particularly severe exacerbations), will have a direct effect on the total cost of COPD. In England and Wales, McGuire calculated that for every exacerbation-related hospital admission avoided, a total saving of approximately £1200 would be made [40].

## REVIEW OF ECONOMIC EVALUATIONS

### Asthma

Several cost-effectiveness analyses have been undertaken, alongside small and short-term clinical trials. These studies evaluated the cost-effectiveness of fluticasone propionate–salmeterol compared with fluticasone propionate alone, montelukast, or a combination of the two. In two of these studies FSC was found to dominate its comparators. One study evaluated the cost-effectiveness between three treatments: fluticasone propionate–salmeterol 100/50 μg BID, fluticasone propionate 100 μg BID, and montelukast 10 mg QID [41]. Based on data from four clinical trials assessing patients with symptomatic asthma previously treated with inhaled SABA, FSC showed significantly greater increase in $FEV_1$ and proportion of symptom-free days and reduced the number of exacerbations. Although daily drug costs were higher for FSC, daily mean exacerbation costs were much lower, making it more effective and less costly. The mean daily costs per patient exacerbation for fluticasone propionate–salmeterol, fluticasone propionate and montelukast were $29, $128, and $154, respectively.

In another study, the cost-effectiveness of fluticasone propionate-salmeterol 100/50 μg was compared to montelukast as initial maintenance therapy in patients with persistent asthma uncontrolled with a SABA alone [42]. The economic analysis used symptom-free days and 12% or greater improvement in $FEV_1$ from a 12-week randomized control trial along with direct medical costs to determine the incremental cost-effectiveness ratio. Considering the SFD endpoint the ICER for FSC versus montelukast was $2.87 indicating that it cost on average an extra $2.87 per day for an additional SFD when FSC is used instead of montelukast. The ICER for $FEV_1$ was $1.79, indicating that it costs on average an extra $1.79 per day for an additional patient to achieve a lung function improvement of 12% or greater.

The cost-effectiveness of fluticasone propionate–salmeterol 100/50 μg BID was compared to fluticasone propionate 100 μg BID plus montelukast 10 mg QID, based on data from a 12-week randomized control trial [41, 43]. FP/salmeterol was associated with a higher proportion of patients with a 12% improvement in $FEV_1$ and similar efficacy in terms of symptom-free days at a lower cost than FP plus montelukast. The mean daily cost per successfully

treated patient was significantly lower with FP/salmeterol ($6.77) than with FP + montelukast ($14.59). The cost per symptom-free day for FP/salmeterol was $11.96 and $17.10 for FP plus montelukast.

Retrospective database analyses have increased in the past few years. Single treatment regimes (fluticasone propionate, montelukast, and salmeterol) have been shown to incur similar total costs over 1 year [44]. Based on retrospective data from the North Carolina Medicaid program, asthmatic patients starting either fluticasone propionate 44 μg were compared with those using montelukast 5 and 10 mg in a cost-minimization study. No significant differences were found in the adjusted asthma-related health care costs following 1 year. A secondary analysis comparing montelukast to salmeterol also showed no difference between health care service use and costs.

Brüggenjürgen *et al.*[45] evaluated the cost-effectiveness of adjustable maintenance dosing with budesonide 160 μg/formoterol 4.5 μg twice daily in a single inhaler (*n* = 1679) compared with fixed dosing (*n* = 1618) alongside a 12-week randomized-controlled trial [46]. In general the results of the trial showed no significant differences in the primary efficacy outcome – health-related quality of life between the two groups. Despite the differences in fewer daily study drug inhalations (mean inhalations: 2.63 adjustable dosing versus 3.82 fixed dosing; $p < 0.001$) a cost-minimization analysis was conducted. The direct asthma-related cost associated with adjustable dosing was significantly lower than that with fixed dosing (mean costs: €221 versus €292; $p < 0.001$).

Pieters et al [47] suggested greater cost effectiveness when adding salmeterol to fluticasone propionate compared with montelukast/fluticasone in patients with asthma uncontrolled with inhaled corticosteroid alone. In the Netherlands salmeterol 50 μg/fluticasone 100 μg twice daily (*n* = 356) was compared with fluticasone 100 μg twice daily plus oral montelukast 10 mg daily (*n* = 369) in a 12-week randomized-controlled trial [48] that measured the proportion of successfully treated weeks (based on mean morning PEF); in addition, episode-free days and symptom-free days and nights were also recorded. Incremental cost-effectiveness ratios were calculated and sensitivity analysis was carried out. Salmeterol/fluticasone combination was associated with significantly better outcomes compared with fluticasone plus montelukast (median difference 25%; $p < 0.001$). The mean total direct health service costs per patient in the fluticasone plus montelukast group was 16% greater than that in the salmeterol/fluticasone group (€1.98 versus €2.25). Salmeterol/fluticasone showed dominance – clinically more effective in all outcome measures and less costly than fluticasone plus montelukast.

Jönsson *et al.* [49] assessed the cost-effectiveness of increasing the dose of inhaled corticosteroid, the addition of a long-acting $\beta_2$-agonist, and both strategies in combination, in patients with mild to moderate persistent asthma. In Sweden four treatment scenarios were compared in a randomized-controlled trial: budesonide 100 μg (*n* = 313); budesonide 200 μg (*n* = 302); budesonide 100 μg plus formoterol 4.5 μg (*n* = 310); and budesonide 200 μg plus formoterol 4.5 μg (*n* = 308) [50]. The primary clinical outcome evaluated was the number of symptom-free days per year. In addition, the number of severe exacerbations per patient per year was also recorded. Health care resource data and

medication use were recorded during the trial. Sensitivity analysis was carried out by applying UK and Spanish costs to the analysis. Budesonide 100 μg plus formoterol 4.5 μg was shown to be dominated. The incremental cost-effectiveness ratio for budesonide 200 μg plus formoterol 4.5 μg compared with budesonide 200 μg alone was SEK 21 per symptom-free day gained.

Lindgren *et al.* [51] evaluated the cost-effectiveness for formoterol 4.5 μg ($n = 57$) and salbutamol 200 μg ($n = 58$) as reliever medication in Sweden and Spain, based on data from a 6-month trial. Resource use was recorded in the trial. Costs associated with resource use were calculated and effectiveness was expressed as exacerbations rate per year; the percentage of symptom-free days was also recorded. For Sweden, the total health care cost per severe exacerbation avoided was €504 per year (95%CI 95–2239) and the health care cost per any exacerbation avoided was €140 per year (95%CI 40–573). For Spain, the total health care cost per severe exacerbation avoided was €1088 per year (95%CI 537–3559) and the health care cost per any exacerbation avoided was €489 per year (95%CI 281–924).

Price *et al.* [52] compared the cost-effectiveness of adjustable dosing of budesonide 80–160 μg/formoterol 4.5 μg ($n = 782$) with fixed maintenance dosing ($n = 771$), alongside a pragmatic randomized-controlled trial [53]. From the UK perspective the primary outcome measure was the net proportion of patients experiencing clinically significant improvement in quality of life, assessed by the mini-Asthma Quality of Life Questionnaire (AQLQ); symptom-free days without the use of rescue medication was used as a secondary outcome measure. Data on resource use were collected prospectively during the trial. The trial reported no significant difference in effectiveness between the two groups; therefore, a cost-minimization analysis was carried out. The total per patient daily cost was £1.13 (95%CI £1.08–£1.18) in the adjustable dosing group compared with £1.31 (95%CI £1.27–£1.34) in the fixed dosing group ($p < 0.001$).

## COPD

The aim of current treatment for COPD, in the absence of a disease cure, is to prevent and control symptoms, reduce the frequency and severity of exacerbations, improve health status, and improve exercise tolerance [54].

"Smoking cessation is the single most … cost effective way to reduce exposure to COPD risk factors" [54].

Smoking cessation is recommended at all stages of the disease. Interventions to assist individuals in quitting smoking include: counseling; nicotine replacement products: gum, patches, spray, lozenges; and the drug therapies: Bupropion, Nortriptyline and Varenicline.

A review of smoking cessation on interventions (e.g. advice and nicotine gum) for different subgroups of the US population [55] found that societal cost per life year ranged from $0 to $13,000 (1993 prices) (€0–8944). A more recent review of the literature [56], carried out from a UK societal perspective, found cost-effectiveness estimates of between £212 (€304) for advice and £873 (€1253) for advice, self help, nicotine replacement therapy, and a specialist cessation service, per life year saved. Given this evidence, smoking cessation interventions seems to represent good value for money.

There are numerous options available for treating COPD. These are set out in Table 62.1, along with the most

TABLE 62.1 Treatment guidelines for COPD by disease severity [47].

| Disease stage | Mild | Moderate | Severe | Very severe |
|---|---|---|---|---|
| Classification | $FEV_1/FVC < 0.70$ <br> $FEV_1 \geq 80\%$ predicted | $FEV_1/FVC < 0.70$ <br> $50\% \leq FEV_1 < 80\%$ predicted | $FEV_1/FVC < 0.70$ <br> $30\% \leq FEV_1 < 50\%$ predicted | $FEV_1/FVC < 0.70$ <br> $FEV_1 < 30\%$ predicted or <br> $FEV_1 < 50\%$ predicted plus chronic respiratory failure |
| Treatment | Influenza vaccination <br> Short-acting broncholdilator added when necessary: short-acting β2-agonists/short acting anticholinergic | Add rehabilitation <br> Add regular treatment with one or more long-acting broncholdilators if needed: long-acting β2-agonists/long acting anticholinergic | Add inhaled corticosteroids if exacerbations are repeated | Add long-term oxygen if chronic respiratory failure. Consider surgical treatments. |

established and up to date treatment guidelines for the management of the disease. Treatment is dependent upon disease severity; classified here in terms of the GOLD guidelines, with four states from mild through to very severe.

Disease management is additive; as the disease progresses through the four stages, more treatments are added. In respect of this, this section has four parts: mild, moderate, severe, and very severe. Under each and where available, the economic evidence for each treatment is presented at the stage where this treatment is first recommended.

## Mild COPD

### Influenza vaccination

Influenza vaccines are recommended to treat all COPD patients, regardless of severity. The cost for the vaccine for high risk people was found to be $570 (€392) per life year saved. The Pnuemococcol vaccine is recommended for patients aged 65 years or over. For this subgroup, the cost-effectiveness ratio has been found to be between $1800 to $2200 (€1238–1513) per life year [55]. Both vaccines represent good value for money.

### Use a short-acting bronchodilator, short-acting anticholinergic when necessary

One study modeled the costs and cost-effectiveness of theophylline compared to ipratropium in moderate to severe COPD. In this case no Incremental Cost-Effectiveness Ratio (ICER) was calculated since ipratropium was found to be both less costly and more cost-effective than theophylline [57].

Sometimes these products are combined and evidence exists to support one such combination. One study examined the efficacy of ipratropium combined with albuterol, compared to each monocomponent in moderate to severe COPD patients. The ICER for the combination product was not calculated: combining ipratropium with albuterol compared to albuterol alone was found to strictly dominate [58].

## Moderate COPD

### Add rehabilitation

Rehabilitation is a multifaceted approach which incorporates a wide range of programs to improve quality of life and functional independence and to reduce symptoms and disability for the patient. Areas within the rehabilitation program can include exercise and physical training, psychological, social interactions, education around the disease, and about nutrition [59].

A recent US study found a marked reduction in cost following a rehabilitation program in terms of a reduction in health care utilization after 1 year of treatment compared to the previous year of no treatment [60]. A 2001 UK paper reports that the cost-effectiveness of a rehabilitation program leads to overall gains in utility in the patients receiving rehabilitation and also a drop in total costs, compared to the control group [61]. The probability that rehabilitation was cost-effective was 90% at £10,000 and 95% at £17,000 (€ = 24,405) [62]. Given the data, rehabilitation seems to represent a cost-effective treatment.

### Add regular treatment with one or more long-acting bronchodilators/anticholinergic

One clinical trial based study compared formoterol to the short-acting anticholinergic, ipratropium and also to placebo in moderate to severe patients. In terms of the ICER for HRQoL, formoterol dominated ipratropium. The ICER for formoterol compared to placebo was found to be $25.20 over the 12 weeks [63].

A UK study that examined salmeterol compared to placebo in moderate patients found that hospital costs and costs for GP contracts and COPD-related medications were lower in the salmeterol arm of the trial compared to placebo. In addition significant benefits were observed in the measures of health outcome that were used, including improved health status (as measured by the St George's Respiratory Questionnaire, SGRQ). These improvements were found to be made at a moderate cost that is for a four point increase in SGRQ score, was found to have an ICER of £4.44 per patient per day (£1622 per year) [64].

In 2002, the long-acting anticholinergic, tiotropium was launched onto the UK market and later, in 2004 to the United States. Several related economic evaluations have centered on tiotropium.

The earliest cost-effectiveness analysis for tiotropium was carried out for the Netherlands and Belgium and compared tiotropium to ipratropium. The study found that tiotropium led to improved health outcomes, including an improvement in SGRQ score and an improvement in $FEV_1$ at a small additional cost [65].

Oostenbrink *et al*. then designed a 1-year Markov model around disease severity states (moderate, severe and very severe) and exacerbations (severe) in order to examine the cost-effectiveness of ipratropium, salmeterol, and tiotropium in the Netherlands and in Canada. In the Netherlands and in Canada, tiotropium was found to be associated with maximum expected net benefit for plausible values of the ceiling ratio [66].

Two additional models, adapted from Ref. [66], and applied to different countries have recently been published. The first, to a Greek setting, examined the cost-effectiveness of tiotropium compared to salmeterol, from the perspective of the Greek NHS [67]. Tiotropium was concluded to be cost-effective, but there was no statistically significant difference found between the treatments.

The second study applied the original model to a Spanish setting and sought to compare the cost-effectiveness of tiotropium, salmeterol, ipratropium, and placebo. The ICER per QALY for tiotropium compared to salmeterol was found to be €4118 and for salmeterol compared to ipratropium, €38,931. At low values of the ceiling ratio (below €11,000 per QALY) ipratropium was found to have the highest probability of being cost-effective. Above €11,000, tiotropium had the highest probability of being cost-effective [68].

## Severe COPD

### Add inhaled corticosteroids if exacerbations are repeated

An economic model examined the effects of adding inhaled corticosteroids to treatment for three groups; all COPD patients, patients with stage 2 or 3 disease, and stage 3 disease.

The model was 3 years in duration with 12 cycles; each cycle being 3 months in length. The model was split into three states according to disease severity, one being least severe and three most severe. Treatment was found to be cost-effective when given to patients with stage 2 or 3 disease [69].

Three clinical trial based studies have compared fluticasone to placebo in COPD patients. The first was by van den Boom *et al.* in a group of patients who, prior to the study, were undiagnosed but had signs of obstructive airway disease. The incremental cost-effectiveness for early treatment was found to be $13,016 per QALY [70].

The second study looked at moderate to severe COPD patients and found that fluticasone produced significant improvements in a range of clinical outcomes including improvement in $FEV_1$ and in the proportion of patients remaining exacerbation free compared to placebo. Fluticasone was found to be cost-effective in the study population [71].

The third study investigated QALY's over 3 years and also life expectancy between the treatment arms in moderate and severe COPD patients. Cost per QALY was found to be £9500 for treatment with fluticasone compared to placebo and a life expectancy increase was found of 23 days [72].

The combination product Salmeterol and Fluticasone (Seretide) was introduced into the EU market in 2000. Since then it has experienced substantial growth in patient market share. Spencer and colleagues' model [73] employ a Markov model in order to compare the cost-effectiveness of this combination product in relation to usual care. The model has four mutually exclusive states: mild, moderate, severe, and death. Each cycle of the model was 3 months in duration over a time horizon of 25 years. Baseline values for the model were sourced from GSK clinical trial data (TRISTAN), published medical literature, and from expert opinion. The paper concludes that adding a long-acting $\beta_2$-agonist to an inhaled corticosteroid may represent a cost-effective treatment in those patients who have a history of frequent exacerbations and poorly reversible COPD.

The combination drug, Budesonide and Formoterol (Symbicort) was introduced into the EU market in 2001. This product has also obtained a significant foothold in the market. Lofdahl *et al.* investigated the cost-effectiveness of combining budesonide with formoterol compared to either monocomponent alone or placebo in severe and very severe patients. Improvements were observed in the combination arm compared to the other arms in terms of fewer accident and emergency admissions, hospitalizations, and specialist visits. The combination was found to be cost-effective if the decision-maker is willing to pay about €2 per day per avoided exacerbation [74].

Two studies have investigated the cost-effectiveness of combining a $\beta_2$-agonist with an inhaled corticosteroid. The first examines three treatments arms to one another. The first arm was a combined $\beta_2$-agonist and corticosteroid, the second, a $\beta_2$-agonist with an anticholinergic, and the third, a $\beta_2$-agonist with a placebo. The study was conducted along the side of a two and a half year clinical trial of moderate and severe patients. The addition of an inhaled corticosteroid to a β2 agonist led to significant benefits in respiratory function and reduced the number of restricted activity days. On the other hand, the addition of an anticholinergic was found to be both expensive and of no long-term value. The

ICER of the corticosteroid versus the placebo was found to be $200 per 10% improvement in $FEV_1$ and $5.35 per symptom-free day gained [75].

The second study by Gagnon *et al.* was an observational study and compared four treatment arms. The first, a combination of a long-acting $\beta_2$-agonist and an inhaled corticosteroid, the second, just the inhaled corticosteroid, the third, just the long-acting $\beta_2$-agonist, and the fourth, placebo. Both the placebo and the inhaled corticosteroid arms were dominated by the long-acting $\beta_2$-agonist and the combination. The ICER between the inhaled corticosteroid/long-acting $\beta_2$-agonist and the long-acting $\beta_2$-agonist was found to be $91,430 [76].

## Very severe COPD

### Add long-term oxygen if chronic respiratory failure

Oxygen therapy is recommended for use in some very severe patients in order to increase the partial pressure of oxygen in the arterial blood ($PaO_2$) and has three different uses: to relieve dyspnea, to aid oxygen intake during exercise and for long term, continuous treatment [54]. Whilst it is clear that oxygen therapy forms a high proportion of outpatient costs for COPD patients [77], little is known about the cost-effectiveness of this treatment, outside of findings that concentrators for the delivery of oxygen therapy may be more cost-effective than cylinders [78, 79].

### Consider surgical treatments

Lung volume reduction surgery (LVRS) involves cutting away around 30% of the diseased lung tissue in order to increase the effectiveness and efficiency of the remaining lung and surrounding muscle. It is only suitable for some patients with very severe COPD.

Estimates of cost-effectiveness ratios for LVRS, from a societal perspective, compared to medical therapy were found to be $190,000 (€ = 1386) per QALY for 3 years and $53,000 (€ = 36,459) per QALY for 10 years [80]. Because this procedure is very expensive, patients undergoing LVRS must be carefully selected [54] in order to select those patients who are most likely to benefit and least likely to have associated complications. The National Emphysema treatment trial identified the profile of this subset of patients: those with an upper lobe emphysema and a low exercise capacity. The cost-effectiveness ratio for this subgroup, showed a more favorable ICER than for the study average at $98,000 (€ = 67,414) per QALY for 3 years and $21,000 (€ = 14,446) per QALY for 10 years [80].

The cost of surgery, coupled with lifetime follow-up costs, makes lung transplantation very expensive. In addition the supply of suitable organs is very limited. Like with LVRS, lung transplantation is a viable option for some patients who are in the most severe COPD stratification, however it is important to identify those patients who are most likely to benefit and least likely to have adverse reactions to the surgery.

A small observational study yielded a lifetime incremental cost of $176,817 (€ = 121,635) per QALY compared to those not receiving surgery [81]. A larger study which used a simulation model to calculate a cost-effectiveness ratio over 40 years yielded a cost of 167,000 Netherlands Guilders

per QALY (€ = 75,781) compared to non surgery [82]. A UK study, extrapolated to 15 years found that the costs per QALY gained were $48,241 (€ = 33,186) for single lung transplantation and $32,803 (€ = 22,566) for double lung transplantation [83]. All three of these studies found substantial gains in quality of life following lung transplantation; however evidence of an effect on survival was mixed.

Bullectomy may be an option when a large air filled bulla exists that fills half of the thoracic volume and compresses the relatively normal adjacent parenchyma [84]. There is no cost-effectiveness information on this surgery option.

## SUMMARY

Treatment patterns have changed remarkably in both asthma and COPD in recent years. In both disease areas, the use of pharmacotherapy as part of the armamentarium of treatment options for patient management has increased, with a trend toward using alternative products in combination, especially for the most severe patients. In general terms, the value for money of treatments, including pharmacotherapies, in both disease areas has been demonstrated. Nevertheless, in looking to the future, the challenges of demonstrating value for money of increasingly novel approaches to patient treatment and management in both disease areas are likely to increase. In asthma, the potential for biologic treatments, at high levels of cost-per-patient year, are likely to bring issues of cost-effectiveness to the fore in any regions of the world. Similarly, in COPD, the increasing use of combination therapy (inhaled corticosteroid and long-acting β-agonist) and triple therapy (ICS/LABA combination plus anticholinergic) are likely to put pressure on pharmaceutical budgets in this patient group. Consequently, issues of cost-effectiveness and value for money are likely to become ever more important as all health systems grapple with providing the maximum health gain possible for their population from limited resources.

# Clinical Management of Asthma and COPD

# Management of Chronic Asthma: In Adults

**Rodolfo M. Pascual and Stephen P. Peters**

Section on Pulmonary, Critical Care, Allergy and Immunologic Diseases, Department of Internal Medicine, Wake Forest University School of Medicine, Medical Center Boulevard, Winston-Salem, NC, USA
## INTRODUCTION

Knowledge gained from research into the pathogenesis of asthma combined with numerous randomized clinical trials (RCTs) has revolutionized our understanding of this prevalent disease and its treatment. However, although mortality from asthma appears to be declining in developed nations, the World Health Organization estimates that asthma mortality worldwide will increase in the next 10 years. The reduction in asthma mortality in developed nations appears to coincide with the development of management guidelines [1, 2] that emphasize disease control using anti-inflammatory medications. Unfortunately, asthma morbidity in developed nations remains a significant problem. A recent survey assessing asthma control in the United States demonstrated that the majority of patients surveyed (55%) characterized their asthma as being "uncontrolled." This was despite the fact that for the most part these patients were receiving care in accordance with widely accepted asthma guidelines. These authors also found that most patients do not utilize asthma action plans [3]. Additionally, patients with poorly controlled asthma use a disproportionate amount of healthcare resources. Despite the recognition that patient education strategies and the use of management guidelines improve asthma outcomes, these tools remain underutilized by practitioners, patients often remain ignorant about their asthma and outcomes achieved in the real world fall short of what can be achieved in clinical studies.

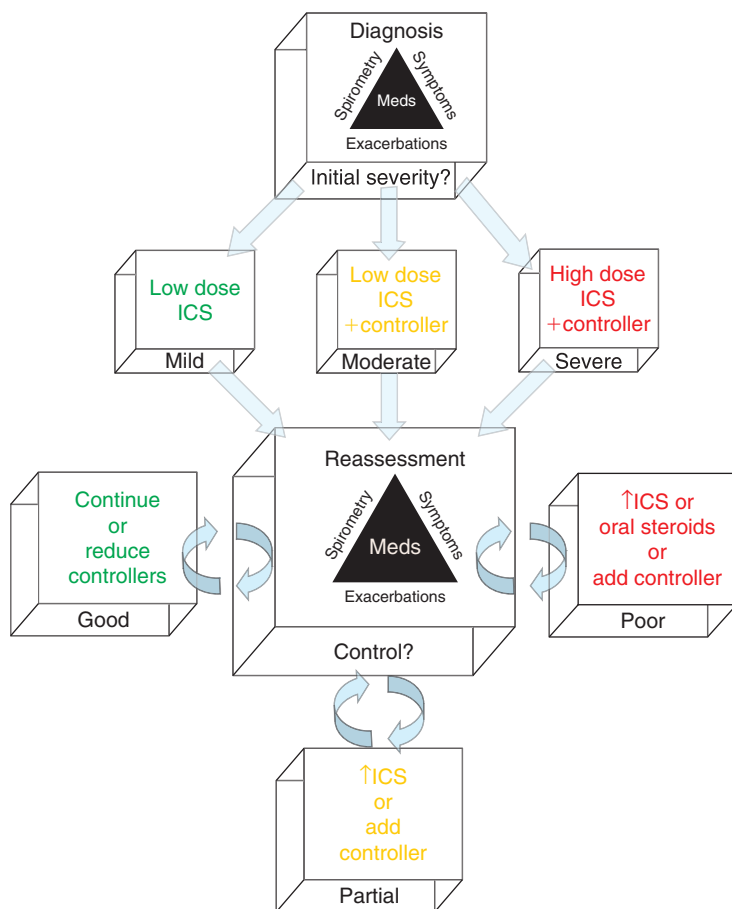
Thus, one key overarching theme is that to improve outcomes for individual patients one must improve the process of care. Even though, where guidelines are rigorously implemented, in some patients asthma continues to remain poorly controlled, it has been shown that control can be achieved in a majority of patients [4]. Asthma management is a complex process for a number of reasons. First, asthma is best characterized as a syndrome that exhibits heterogeneity with respect to its etiology, clinical presentation, severity, natural history, and response to therapy. As such, asthma has been termed a complex genetic disorder in that multiple genes and gene–environment interactions lead to the characteristic symptoms and signs in a given patient. One might say that there are many asthma phenotypes so that a single-management approach will not work for all patients, and therapy must be tailored to the individual patient. Second, within each patient, the severity of symptoms and lung function varies over time. Some patients experience prolonged remissions of symptoms whereas others rarely achieve adequate symptom relief. Asthma is also characterized by the occurrence of exacerbations, events where an environmental factor triggers increased airway inflammation, bronchial hyperresponsiveness, and resultant increased symptoms. Such exacerbations may be brief, lasting for minutes and readily ablated by bronchodilators or prolonged lasting days-to-weeks and requiring intensive pharmacotherapy. In earlier studies assessing the efficacy of drugs used to treat asthma changes in lung function is the major outcome of interest; however, more recent studies assess for more patient-centric outcomes like reductions in exacerbations or symptoms and improvements in quality of life. Third, unlike many other diseases where treatment decisions are made predominantly by the healthcare provider during a scheduled encounter, the minute-to-minute variability of asthma requires that the patient frequently makes


**FIG. 63.1** Managing asthma. Once the diagnosis is established, symptoms, medication use, exacerbation history, and spirometry are used to assess initial asthma severity. After treatment is initiated, the patient then undergoes reassessment at an appropriate interval based on severity. From that point on, the emphasis is placed on disease control and control is constantly reassessed at an interval dictated by the degree of recent asthma control. Importantly, the same set of disease measurement tools such as symptoms, medication use, recent exacerbation history, and spirometry are also used to subsequently assess asthma control.

treatment decisions. The quality of this decision-making is dependent on the patient's understanding of their disease and the tools provided to the patient for their disease assessment.

## MANAGING ASTHMA NOT IN EXACERBATION

Once the diagnosis of asthma has been established and co-morbidities identified, a management process should be implemented (Fig. 63.1). Though as stated previously the management of asthma should be individualized, guidelines are quite useful in that they outline a process of care. First, the initial severity should be determined; it is especially important to identify those subjects with severe disease. Because patients with severe asthma have a disproportionate morbidity, mortality, and healthcare utilization compared to nonsevere patients, hence facing a higher risk from their disease, it is important to target them for intensive treatment and frequent follow-up. Previous intubation for asthma, ICU care for asthma, hospitalization for asthma, excessive use of asthma medications, psychiatric disease, and low lung function are risk factors for future life-threatening episodes of asthma.

Another variable that is not accounted for by merely assessing medication use, symptoms, and lung function is the exacerbation history. Recent severe asthma exacerbations (in the prior 3 months) or the recent use of a steroid burst appear to be powerful indicators of future severe asthma exacerbations [5]. Thus, we recommend that the recent exacerbation history and history of life-threatening episodes be included as part of the assessment of initial asthma severity and subsequently as a measure of asthma control on reassessment. It is our opinion that this initial step of determining severity be performed in any patient with asthma who is new to a practitioner even if the diagnosis had been previously established by another healthcare provider, because asthma frequently is not appropriately treated or misdiagnosed. As shown in Fig. 63.1 and Table 63.1 and consistent with the latest guidelines [1, 2], the assessment of severity integrates the impairment domain that includes frequency of daytime and nocturnal symptoms, the amount of medication used, and lung function with the risk domain that accounts for exacerbation history, medication side effects, and potential loss of lung function. Impairment as it applies to daily activities, exercise, and the performance of job-specific tasks should also be determined. Second, initial therapy should be selected based on severity using increasingly intensive anti-inflammatory regimens for increasingly severe disease as

**TABLE 63.1** Initial asthma severity* and treatment steps in adults.*

| Components of severity | | Intermittent | Persistent | | |
| --- | --- | --- | --- | --- | --- |
| | | | Mild | Moderate | Severe |
| Impairment domain | Symptoms | ≤2 days/week | >2 days/week, but not daily | Daily | Throughout the day |
| | Nocturnal symptoms | ≤2 ×/month | 3–4 ×/month | >1 ×/week but not every night | Often every night |
| | Short-acting β-agonist use for rescue | ≤2 days/week | >2 days/week, but less than daily | Daily | Several times per day |
| | Interference with normal activity | None | Minor | Some | Extreme |
| | Lung function when not in exacerbation | $FEV_1 > 80\%$ predicted | $FEV_1 \geq 80\%$ predicted | $FEV_1$ 60–79% predicted | $FEV_1 < 60\%$ predicted |
| Risk domain | Exacerbations requiring systemic corticosteroids | 0–1/year | | ≥2/year | |
| | Treatment step | Step 1 | Step 2 | Step 3 or 4 | Step 5 or 6 |

Adapted from Figures 3–4c in Ref. [1].

*Severity is determined by the most severe component of each domain.

shown in Table 63.2. Third, reassessment should be performed at return visits scheduled at an interval commensurate with either initial asthma severity or later, current asthma control. As shown in Table 63.3, medications are then adjusted in a stepwise manner based on current control and drug-related side effects. When control is achieved for a reasonable period of time, consideration is given to stepping down therapy but if the patient remains uncontrolled, therapy is intensified. In a new patient, a less adherent patient, or in a patient with recent poor asthma control, more frequent reassessment is indicated. Asthma management is thus a dynamic process requiring flexibility from both the patient and the healthcare provider.

## Implementing initial therapy

As noted in Table 63.2, inhaled corticosteroids (ICSs) should be used as the initial controller in all patients with persistent asthma of any severity. Of all pharmacological agents ICS have most consistently been shown to improve lung function, quality of life and prevent exacerbations while having a good side effect profile. For *initial* therapy in severe asthma we additionally recommend a short course of oral corticosteroids (0.25–0.5 mg/kg daily). Lung function and asthma control should then be reassessed after 2–4 weeks. Systemic steroid therapy serves two purposes as it improves the chances of quickly achieving asthma control in those patients who will be responsive while at the same time identifying those patients who may be steroid-resistant. In the steroid-phobic

patient with mild persistent asthma (Step 2), a leukotriene receptor antagonist (LTRA) can be used as an alternative to ICS, however, it should be understood that for a significant majority of patients, ICS are superior to LTRAs for all relevant asthma treatment outcomes [6, 7]. The benefits of ICS have been known for over two decades [8, 9], and the regular daily use of ICS for asthma control has been the standard of care for persistent asthma. However, it is known that many patients do not use these agents on a regular basis, some studies suggesting that patients refill medications less than half of the time that they are prescribed. Importantly, the use of combination inhalers improves adherence when compared to the use of multiple single-drug devices [10, 11]. Patients with only occasional symptoms (cough, wheezing, dyspnea), no more than one nocturnal awakening/month and normal lung function (Step 1), do not need controller therapy and may be given a reliever to be used as needed. Additionally, such patients that do not need a controller and suffer from exercise-induced bronchospasm can be advised to take a β-agonist with a rapid onset of action whether it be short- or long-acting in duration [12], or an inhaled cromone [13], about 30 min prior to exercise, or a daily LTRA in a prophylactic manner [14]. Patients already taking controller therapy with otherwise well-controlled asthma may also utilize an additional agent (β-agonist, inhaled cromone) which they are not using as a controller, as an add-on for exercise prophylaxis if they experience bothersome symptoms with exercise.

Interestingly, several recent studies of novel treatment protocols using ICS have perhaps emulated the

**TABLE 63.2** Treatment for asthma in adults.

| Treatment step | Intermittent | Mild | Moderate | | Severe | |
| | Step 1 | Step 2 | Step 3 | Step 4 | Step 5 | Step 6 |
| --- | --- | --- | --- | --- | --- | --- |
| Preferred controller | SABA prn | Low-dose ICS | Low-dose ICS + LABA or Medium dose ICS | Medium-dose ICS + LABA | High-dose ICS + LABA and Consider Omalizumab | High-dose ICS + LABA + low-dose oral corticosteroids and Consider Omalizumab |
| Alternative controller | | Cromolyn, LTRA, Nedocromil, or Theophylline | Low-dose ICS + LTRA, Theophylline, or Zileuton | Medium-dose ICS + LTRA, Theophylline, or Zileuton | Consider other additional controllers | Consider other additional controllers |
| Allergen immunotherapy | | Consider | Consider | Consider | No | No |
| Written action plan and self-monitoring | | Consider | Yes | Yes | Yes | Yes |
| Return visit | Annual | 6 months | 3–4 months | 3–4 months | 1–2 months | 2–4 weeks |

Partially adapted from Figures 4–5 in Ref. [1].

For treatment step see Table 63.1 (initial severity) or Table 63.3 (current control).

ICS, inhaled corticosteroid; SABA, short-acting β₂-agonist; LTRA, leukotriene receptor antagonist; sustained-release theophylline is preferred.

*de facto* use of these agents by many patients. Since ICS have side effects and as discussed previously adherence to daily use appears to be poor, one obvious question is whether controller agents can be used as needed rather than a regular basis. In one such study, the level of asthma control was examined in patients with mild asthma randomized to an intermittent treatment plan, which instituted the use of ICS or oral steroids only when indicated using a protocol similar to many asthma action plans, or randomized to regular use of ICS, or randomized to regular use of a leukotriene-receptor antagonist. Intermittent treatment appeared to be equivalent to regular use of controllers for rates of asthma exacerbation, even though the overall steroid consumption by the intermittent group was quite low [15]. In another study with a different design, symptom-driven use of an inhaler continuing both an ICS and a short-acting β-agonist was as effective as regular use of ICS and as-needed use of the short-acting β-agonist; steroid consumption again was lower in the group using the controller agent as needed [16]. In yet another trial with a similar theme a long-acting bronchodilator that happens to have an onset of action similar to many relief inhalers was combined with ICS and used as both a regularly taken controller and an as-needed relief inhaler. This strategy proved to be superior in terms of preventing asthma exacerbations when compared to regular use of the ICS/long-acting β-agonist (LABA) combination inhaler as a controller with a short-acting β-agonist used as-needed as a reliever. Total steroid use was actually reduced when the ICS/LABA was used as both a controller and a reliever [17].

All patients should be provided with and instructed on the proper usage of a quick relief medication, preferably a short-acting inhaled β-agonist. Regular use of short-acting bronchodilators is clinically not better than as-needed use, and regular use leads to more medication use and side effects, so short-acting bronchodilators should only be used as-needed for relief of symptoms.

Unfortunately, the proper use of inhaled medication is often not straightforward. The patient should be showed the proper technique for using a device when it is prescribed, and this technique should be reinforced frequently especially if there are excessive side effects or a poor therapeutic response. Quick relief medications should be used as-needed whereas controller medications should be used on a scheduled basis, and this concept should be reinforced frequently with the patient.

### Asthma self-management education

Studies suggest that patient education and environmental control programs are effective in reducing asthma morbidity. Asthma self-management education reduces hospitalizations, emergency room visits, unscheduled physician visits, days-off from work or school, and nocturnal asthma symptoms and improves quality of life [18–21]. The goals of asthma education are to improve patient understanding of their disease, medication adherence, self-management and efficiency of healthcare utilization. Educated patients are more likely to recognize and modify environmental factors and avoid triggers that worsen asthma control. In many patients as a prolonged exacerbation is developing, peak

**TABLE 63.3** Assessing asthma control in adults.

[b]Treatment-related adverse effects should be considered when assessing risk and making changes in therapy.

expiratory flow (PEF) will begin to deteriorate prior to symptom worsening. Moreover, there appears to be a subset of asthma patients that do not sense worsening airflow obstruction. So we recommend that the action plan include elements of symptom monitoring and PEF measurements and that it be introduced to the patient at the earliest opportunity. An example of an asthma action plan is provided in Fig. 63.2.

Environmental control is an important, often overlooked part of the management plan for all asthmatics, especially those with severe asthma and it consists of measures to control environmental triggers. Avoidance of aeroallergens, viral respiratory pathogens, air pollution, and certain drugs can prevent exacerbations, reduce the need for drug treatment, and decrease utilization of emergency facilities. The relative importance of different indoor allergens may vary among populations, and there is substantial variability among patients. For moderate-to-severe asthma, we recommend an assessment for allergy performed by a subspecialty

trained allergist. For mild disease a simpler assessment for other atopic disease (rhinitis, eczema), triggers, seasonal patterns, and home and work environment is often sufficient. The possibility of occupational asthma should be determined during the initial assessment and is discussed in Chapter 36. Most patients with chronic asthma have numerous triggers, and avoidance strategies should be discussed at every opportunity. Allergen immunotherapy can benefit highly selected patients with defined allergic triggers [22]. Though serious complications from immunotherapy are rare they occur more frequently in patients with asthma [23], so immunotherapy should not be used in patients with severe asthma and should only be administered by physicians specifically trained in it use.

Strategies to avoid respiratory infections particularly viral upper respiratory tract infections should be discussed. Inactivated influenza vaccine may be safely administered to patients with asthma [24]. Though it has not conclusively been shown that influenza vaccination decreases the incidence

Asthma Action Plan for _____ Last Reviewed:_____

Instructions:

1. Measure your PEF both upon awakening and at 4 PM each day.
2. Each morning answer the following questions: Did you wake up last night? How many times did you use albuterol in the last 24 hours? Did you have any trouble with exercise or any activities?
3. Based on both items #1 and #2 above find your asthma zone.
4. Follow the instructions in the action box for your current asthma zone
5. If you experience severe or frightening symptoms call EMS (dial 911)
6. If you do not need immediate care but have concerns call our office at_____, if you do not get through proceed to the nearest emergency room.

| Green Zone | Action |
|---|---|
| Your PEF is >_____ (80% personal best) | Continue to monitor PEF twice daily |
| You are not waking up at night because of your asthma | Continue usual asthma medications |
| You use your albuterol inhaler less than once daily | ICS_____ _____µg two puffs twice a day<br>Albuterol MDI 2 puffs every six hours as needed |

| Yellow Zone | Action |
|---|---|
| Your PEF <_____ but >_____ for more than 12 hours (50−80% of personal best)<br>OR<br>You woke up last night because of your asthma<br>OR<br>You are using your albuterol inhaler more than twice a day<br>OR<br>You are more short of breath with exertion or exercise | Increase _____ to 4 puffs twice a day<br>AND<br>Monitor your PEF, and if it does not improve to greater than _____within 24 hours take Prednisone 30 mg daily for 4 days<br>AND USE<br>Albuterol MDI 2 puffs every four hours as needed<br>AND<br>*Contact your physician at _____* |

| Red Zone | Action |
|---|---|
| Your PEF is <_____ (50% of personal best) at any time<br>OR<br>You are using your albuterol inhaler more than 4 times a day<br>OR<br>Relief from albuterol lasts less than 4 hours<br>OR<br>You are so short of breath that daily activities are difficult | Immediately go to the emergency room or call EMS (dial 911)<br>AND<br>Take prednisone 60 mg once<br>AND USE<br>Albuterol MDI 4 puffs up to every twenty minutes until you obtain medical attention |

**FIG. 63.2** Asthma action plan. Action plans should be simple, empowering the patient to self-monitor their asthma while providing clear, specific instructions to deal with exacerbations. A combination of symptoms, medication use, and lung function is used by the patient to assess the current control of their asthma. It is important to emphasize that patients should not attempt to manage severe exacerbations without medical assistance.

of exacerbations of asthma [25], patients with asthma should receive inactivated influenza vaccine if there are no other contraindications and especially if they have other conditions that increase the risk of death from influenza infection [26].

## Pharmacologic therapy

The categorization of asthma by clinical severity is a key tenet of the major clinical guidelines. The severity indices use symptoms, lung function, and rescue medication use as variables [27, 2]. Asthma drugs currently available are classified as long-term control medications or "controllers" or quick-relief medications or "relievers" based on their principle pharmacodynamic and clinical effects. Short-acting agents that primarily work by inducing rapid bronchodilation such as inhaled β-agonists or anticholinergics are considered quick-relief medications; they should be taken on an as-needed basis. Corticosteroids, long-acting β-agonists, leukotriene pathway inhibitors, cromolyn sodium, nedocromil sodium, sustained-release theophylline, and omalizumab act by promoting sustained bronchodilation, have anti-inflammatory effects or both and are considered as long-term control medications; they should be taken on a scheduled

basis. Though the controller versus reliever concept is straightforward to the healthcare provider, it is often not grasped by patients who sometimes will not take controllers when they are symptom-free or may take relief medications on a regular basis. It is important to provide patients with clear instructions regarding the proper use of all of their asthma medications.

Inhaled $\beta_2$-adrenergic agonists are the drugs of choice for relief of symptoms due to acute airway obstruction. Short-acting $\beta$-agonists have a rapid onset of action and 3–6 h duration of activity. At recommended doses, inhaled $\beta$-agonists have few adverse effects. Since regular use of short-acting $\beta$-agonists has not been shown to be superior to as needed use of these agents and several studies have associated excessive use of short-acting $\beta$-agonists with asthma-related morbidity and mortality, we recommend that these agents be used only as needed. Inhaled anticholinergic drugs that are also effective bronchodilators, though generally less so than $\beta$-agonists in asthma, are also indicated for the relief of acute bronchospasm.

Glucocorticoid steroids are the most effective controller agents for treating asthma. Inhaled steroids improve lung function when compared to placebo and reduce exacerbation rates. Patients with asthma stabilized on inhaled steroids experience more exacerbations when the steroids are withdrawn [28]. Unique to this drug class, retrospective data suggests that the consistent use of inhaled steroids reduces asthma mortality [29, 30]. However, as a drug class, the inhaled glucocorticoids suffer from important limitations. First, the dose–response curve of inhaled steroids is relatively flat-higher doses are only incrementally better than low-medium doses. Second, there appears to be substantial variability in both acute [31], and chronic efficacy of glucocorticoids particularly with respect to improvements in bronchial hyperresponsiveness and $FEV_1$. Finally, some patients appear to be relatively insensitive to the effects of glucocorticoids, some being so insensitive that their asthma may be termed steroid-resistant. The steroid-insensitive phenotype is associated with severe asthma, persistent symptoms, frequent nocturnal symptoms, low and partially irreversible lung function, need for systemic steroids at a young age, higher maintenance doses of oral steroids and African-American race [32]. Fortunately, additional efficacy can often be obtained, using combinations of steroids and other controllers rather than just increasing the inhaled steroid dose. Combinations of ICS with long-acting $\beta$-agonists [4, 33–35], LTRAs [36], or theophylline [37], have been shown to provide superior bronchodilation and improve other outcomes when compared to single controller agents alone.

LABAs have at least 12-h duration of action and are not currently recommended for the short-term relief of acute symptoms. When used alone LABAs are clearly inferior to ICS with regards to exacerbations and *there is current consensus that LABAs should not be used as monotherapy for the control of asthma of any severity*. As discussed previously LABA and ICS combinations provide clinical synergy and promote better adherence; the combination of formoterol and budesonide was shown to be effective when used as both a controller, and relief agent and thus provides the advantage of a single device used for both purposes [17].

Theophylline now is primarily used as an adjunct and has steroid sparing effects. Theophylline has a narrow therapeutic index, interacts with many drugs and its use requires monitoring of serum drug levels. The steroid sparing effects of theophylline seem to occur at levels below the traditional therapeutic range of 10-20 mg/l [37]. We recommend that sustained release preparations of theophylline be used and titrated to steady state serum concentrations of 5–10 mg/l or peak concentrations of no higher than 15 mg/l.

Anticholinergic agents by blocking muscarinic receptors induce airway smooth-muscle relaxation. In general, the short-acting anticholinergic agent ipratropium is not so effective as $\beta$-agonists as a bronchodilator in asthma. The use of anticholinergic agents in asthma has been reviewed [38]. Inhaled ipratropium can be used as a reliever in chronic asthma; the utility of ipratropium in an individual patient should be determined empirically. Ipratropium, when combined with $\beta$-agonists appears to provide faster and greater bronchodilation in acute severe asthma when compared to $\beta$-agonists alone and can be added to $\beta$-agonists for this purpose when the response to $\beta$-agonists is insufficient [2]. One small study showed that the long-acting, inhaled anticholinergic drug tiotropium can provide modest bronchodilation and as would be expected provided prolonged protection against methacholine-induced bronchoconstriction in subjects with asthma [39]. Clinical trials are underway to determine the utility of tiotropium in asthma.

Cromolyn sodium and nedocromil sodium (cromones) are classified as controller agents, and inhibit both antigen-mediated and nonimmunologically (i.e. exercise)-mediated bronchoconstriction in asthmatics. Nedocromil generally has displayed greater potency in protecting patients against exercise-induced bronchospasm [40]. These agents are safe, are considered first-line agents in the treatment of children with asthma but are inferior to inhaled steroids with respect to most relevant asthma outcomes [41, 42].

Leukotriene pathway inhibitors are a group of drugs that mitigate the effects of leukotrienes derived from the 5-lipoxygenation of arachidonic acid. There are two classes of agents: 5-lipoxygenase (5-LO) enzyme inhibitors and cysteinyl-leukotriene receptor type 1 antagonists. When compared head-to-head corticosteroids are superior asthma controllers. [6, 7, 43] Leukotriene pathway inhibitors may be substituted for ICS in selected patients with mild disease and are especially useful when steroids are poorly tolerated, when steroid use is not desired by the patient, or when there is significant, concomitant rhinosinusitis. LTRAs have been shown to prevent exercise-induced bronchospasm [44] and can be used as monotherapy for this indication in selected patients with mild asthma. Finally, leukotriene pathway inhibitors are quite useful as add-on therapy to inhaled steroids in moderate-to-severe asthma and have steroid sparing effects [36, 41, 45–47].

## Reassessment

Since asthma is characterized by substantial variability in disease severity over time and response to therapy, reassessment and adjustment of therapy is the cornerstone of management. More severe disease is associated with more

frequent exacerbations, more risk of severe events like hospitalization and death and probably with more rapid loss of lung function over time, hence, more severe disease requires frequent reassessment (every few weeks to every few months). On the other hand some patients with mild asthma may be stable clinically for long periods of time and annual reassessment can be appropriate.

## Disease monitoring tools

When one is reassessing asthma the key parameter to be ascertained is disease control. When asthma is well controlled, lung function is stable or not declining faster than usual, there is minimal rescue medication use, sleep is not disturbed by asthma symptoms, daytime symptoms are absent or minimal, and there is no limitation to activity. Moreover, there is little day-to-day variability in these clinical parameters; well-controlled asthma has little to no impact on quality of life. In contrast, poorly controlled disease is characterized by frequent symptoms, exacerbations, rescue medication usage and accelerated loss of lung function over time; these patients suffer significant disability. Though well-controlled asthma can be achieved in a majority of patients at least over short periods of time, unfortunately, a significant minority of patients do not achieve good control [4]. If symptoms are not adequately addressed, quality of life is not improved and patient satisfaction is likely to be poor. Additionally, a subset of patients may have few symptoms but poor lung function. Still other patients have controlled symptoms and good lung function but at the cost of heavy medication usage. Generally, such patients are considered to have more severe disease than those otherwise clinically similar patients, but maintained on less medication. For this reason many validated instruments like the Asthma Control Test™ (ACT) (www.asthmacontrol.com) integrate an assessment of symptoms and medication use. We encourage the use of this and similar instruments along with the use of office spirometry to assess for asthma control. These instruments often have important limitations, for example the ACT™ only assesses short-term control using a 1-month recall; though this is valid given the fact that longer periods of recall are associated with diminished accuracy. We suggest that one ask additional questions especially probing for exacerbations that have occurred since the last assessment like asthma-related unscheduled physician visits, emergency department visits, or the use of systemic glucocorticoids. Medication side effects should be noted and when therapy has changed spirometry should be measured. Thus, we recommend the use of a combination of objective tools and subjective assessment to reach an integrated determination as to whether asthma is well controlled, partially controlled, or poorly controlled.

As shown in Fig. 63.1 asthma control can be put into one of three categories: poorly controlled, partially (not well) controlled, or well controlled. Well-controlled asthma is straightforward and one can either keep the medication regimen the same or consider a step down in intensity. In any case the patient should be reminded that control can be lost if adherence to medications or environmental control lapses as many studies have shown that withdrawal of controllers leads to increased rates of exacerbation [28, 34]. Before one considers removing a medication it is important to consider if current control will be lost, that is if that medication was the one that helped to achieve control. When there is only partial control or poor control, generally another agent needs to be added or substituted for one currently in use but that is not working. Unfortunately, there is a tendency to add medications sequentially until control is achieved rather than assessing if an added medication had been helpful. The heterogeneity of response to a given medication is likely due to a combination of genetic and environmental factors. Pharmacogenomics is a growing field investigating the genetic factors responsible for the between-patient variability of response to medications. Unfortunately, we do not currently have the tools to identify ahead of time which drug is most likely to yield a good response in a given patient, so therapeutic challenge is needed. For example, a newly diagnosed moderate asthmatic is started on a low-dose ICS/LABA combination inhaler and asthma is then reassessed and felt to be only partially controlled so a LTRA is added and the patient is then reassessed after a short interval. The LTRA has no effect on control, so SR theophylline is added and then control is achieved. The common error at this point would be to continue the patient on three medications rather than stopping the add-on controller that had no effect.

If asthma is not well controlled, environmental control needs to be reassessed. The patient should be reminded to control those factors known to worsen their asthma and questioned about potential new exacerbating factors or triggers. At this point one also needs to evaluate for co-morbid conditions like sinusitis, gastroesophageal reflux disease (GERD), or other cardiopulmonary disease. If identified and felt to be contributing to poor control these should be treated but this should be done in concert with asthma medication escalation, because one cannot know with certainty if modifying a suspected environmental factor or condition by itself will yield a good therapeutic response. Depending on the disease severity and prior history of severe exacerbations, one should consider using systemic glucocorticoids judiciously to achieve control. Despite the side effects, there should be a low threshold to use systemic steroids in a poorly controlled patient with severe disease especially if there have been previous life-threatening exacerbations. The poorly controlled patient should be reassessed frequently until control improves.

## Treatment of Associated Conditions

A clinical assessment for these conditions consisting of focused questions and physical examination should be performed as part of the initial assessment. If treatment for asthma does not easily yield good control a more careful search for these conditions may be indicated.

Cough, breathlessness, and wheeze, also classic asthma symptoms, have been associated with GERD for more than 40 years [48]. Until recently, evidence that GERD can aggravate asthma had been largely based on empiric observations that anti-reflux therapy sometimes improves asthma control. Moreover, GERD has been identified as

a risk factor in patients with frequent exacerbations [49], and in asthma patients, esophageal acid perfusion increases bronchial hyperresponsiveness [50]. Interestingly, oral steroids, often used in severe asthma increase esophageal acid contact time in patients with asthma [51]. Studies examining the effect of medical or surgical therapy for GERD on asthma-related outcomes typically have been small and have suffered from poor study design. A recent study [52] showing that surgical anti-reflux therapy but not intensive medical therapy using an $H_2$-antagonist improved asthma outcomes provides further evidence that treating reflux may be helpful, but this result is tempered by the fact that anti-reflux surgery has been associated with increased mortality when compared to medical therapy for GERD [53]. In a recent RCT in which a high dose proton-pump inhibitor was compared to placebo in moderate-to-severe asthma, efficacy was not universal, patients with nocturnal asthma symptoms and GERD seemed to benefit whereas patients without nocturnal symptoms did not benefit. Moreover, the primary outcome was only a modest improvement in morning peak flow, and there was no effect on symptoms or quality of life making the results of doubtful clinical relevance [54]. If GERD-specific symptoms or nocturnal asthma symptoms are prominent, we recommend ambulatory intraesophageal pH monitoring as a sensitive and specific diagnostic test to verify the diagnosis of GERD. A negative study is valuable in excluding GERD as a cause of asthma symptoms, but a positive study does not prove that GERD is the cause of asthma symptoms; a symptom diary should be used with the study. Empiric treatment without objective confirmation should especially be avoided when patients do not have classic reflux complaints and because chronic GERD may have serious consequences, we suggest specialty consultation. If the study supports a role for GERD in asthma in a patient, we suggest an empiric course of high dose proton-pump inhibitor treatment that should only be continued if it significantly relieves asthma symptoms or is otherwise indicated for GERD itself. We also find that weight loss when appropriate, elevation of the head of the bed, and avoidance of large meals can be helpful.

The relationship between asthma and chronic sinusitis is well established [55], although the underlying mechanisms are not clear. In general, there is a better association between asthma and chronic sinusitis when there is extensive sinus disease. There is little published supportive evidence to support the assertion that aggressive treatment of chronic sinusitis improves asthma control. Therapy for sinusitis includes antibiotics, decongestants, and intranasal topical glucocorticoids. Patients who fail to respond to medical therapy may benefit from endoscopic sphenoethmoidectomy, but the results of endoscopic sinus surgery tend to be poorest in patients with asthma, especially those with aspirin sensitivity and polyposis. Specific allergen immunotherapy is particularly useful in asthmatics with concomitant allergic rhinitis and sinusitis [22].

There is epidemiological evidence that obesity is associated with asthma [56]. Prospective studies showing an association between the body mass index (BMI) and the subsequent development of asthma are generally limited by the fact that they rely on patient-reported asthma. For example, in NHANES III, obese patients reported more asthma, wheezing, and bronchodilator use but were less likely to demonstrate airflow obstruction than non-obese patients [57]. Hence, though obesity may be associated with asthma, obese patients are more likely to be misdiagnosed with asthma and to be incorrectly treated. In one prospective study of physician-diagnosed asthma, a BMI $\geq 28$ was associated with asthma largely driven by obese female subjects [58]. Finally, intervention studies have shown that weight loss can favorably affect asthma outcomes [59, 60], so it is prudent to aggressively treat obesity in the asthmatic patient.

## Add-on pharmacological therapy

A monoclonal antibody to IgE (omalizumab) reduces serum IgE and should be considered as a controller for atopic asthmatic patients dependent on oral corticosteroids or for use in patients with poorly controlled disease despite high dose ICS also using multiple controllers. Studies in patients with moderate-to-severe corticosteroid-dependent asthma have shown a significant steroid-sparing effect of omalizumab and a reduction in exacerbation frequency [61–64]. Omalizumab is most useful when patients require $>800\,\mu g$ (medium doses) of inhaled steroids daily, take daily oral steroids, have an $FEV_1$; $< 65\%$ predicted, or have required emergency room treatment within the prior year [65]. Post-marketing data reported to the Food and Drug Administration suggests that omalizumab may cause anaphylaxis with an estimated incidence $>0.1\%$; anaphylaxis after omalizumab administration usually occurs within 2 h but can occur even after 24 h, and omalizumab-associated anaphylaxis can occur even after several treatments (www.fda.gov). The Providers administering this agent should be prepared to deal promptly with this infrequent but important complication.

If the patient remains poorly controlled despite trials of the first-line agents, ICS, LABAs, LTRA, SR theophylline, and omalizumab, there are few therapeutic options besides for further escalation of oral steroids. Studies using macrolide antibiotics in asthma have yielded discordant results [66]. In one clinical trial, the administration of clarithromycin to subjects with asthma resulted in improvements in lung function but *post hoc* analysis showed that improvement only occurred in patients with demonstrable evidence of *mycoplasma* or *chlamydia* infection [67]. Why macrolides may be effective remains under study; macrolides may treat chronic, subclinical airway infection from *mycoplasma* and *chlamydia* bacteria or may have other anti-inflammatory effects [68]. More studies of the utility of macrolide antibiotics in asthma are currently underway.

Several other targeted and nontargeted drugs have been tested in clinical trials and others are under development. Non-targeted drugs useful in other conditions such as gold salts, methotrexate, colchicine, and cyclosporine have been studied in asthma with disappointing results [69–73]. Targeted agents like those designed to inhibit the effects of cytokine products, such as IL-4, and IL-5 [74] and TNF-$\alpha$ [75–77], have been studied in clinical trials with disappointing results to date. Because of the specificity of newer agents, it is likely that some agents will prove more effective

in certain patients than others, and this will be likely related to pharmacogenomic and environmental factors.

## MANAGING ASTHMA IN EXACERBATION

Asthma is characterized by disease exacerbations that result in substantial morbidity, occasional mortality and considerable medical and economic costs. Most asthma exacerbations occur in a minority of asthma patients. When deaths from asthma have been analyzed, most decedents had experienced worsening symptoms over a period of several hours to several days highlighting the importance of identifying and educating the at-risk patient. Life-threatening episodes can develop in patients whose asthma appears to be mild at baseline, but patients who have at baseline, severe or poorly controlled disease, are those who frequently access the ER, are frequently hospitalized, and are at the highest risk [78]. These patients should be identified and targeted for intensive disease management. There is a spectrum of exacerbation severity, and it is important that a proper action plan based on severity be in place to be rapidly utilized. Patients need to be instructed to promptly seek medical attention for serious symptoms. Less serious exacerbations can be managed in the outpatient setting and are discussed later.

The management of acute severe asthma that requires hospitalization is discussed in Chapter 64.

The cornerstone of therapy for an exacerbation of asthma involves the escalation of both glucocorticoids and quick-relief medications, usually inhaled $\beta_2$-adrenergic agonists, with frequent reassessment of symptoms and the degree of airflow obstruction. Initial management in the emergency department or in an urgent care setting involves assessment for hypoxia, severity of symptoms, severity of airflow obstruction, and rapid triage coupled with the administration of intensive glucocorticoid therapy and bronchodilators. Patients who do not immediately need critical care or hospital admission are reassessed after intensive therapy. Those with a good response to treatment are candidates for discharge and continuing outpatient treatment.

Surprising little is known about the optimal dosing of systemic glucocorticoids in acute asthma. It is generally held that inflammation in acute asthma is relatively resistant to glucocorticoids, so relatively high doses of daily oral steroids (0.25–1 mg/kg) are initially used and the steroids tapered at a rate determined by the patient's response. Sometimes a few days of therapy are required before a noticeable improvement in lung function occurs. Steroids may be tapered once there is a response but it is the authors' opinion that systemic steroids should be tapered over a 7–14 day period in cases of severe asthma exacerbation. The patient's prior history of response to steroids often informs that decision. Mild exacerbations in asthmatics with mild persistent disease may be managed in some cases by escalating the dose of or initiating inhaled steroids in cases where patients are taking low dose steroids or no steroids respectively.

More than the usual dose of bronchodilators is often needed to relieve symptoms during an exacerbation: *Exacerbations of asthma should never be treated by escalating bronchodilators alone.* Fatalities from asthma typically occur when patients fail to promptly seek medical attention; instead self-medicating with escalating doses of quick-relief medications or long-acting bronchodilators. Inhaled $\beta_2$-adrenergic agonists are safer and equally efficacious to oral preparations. Inhaled $\beta_2$-adrenergic agonists may be used safely in quite high doses with close monitoring. Inhaled ipratropium appears to provide further bronchodilation in acute severe asthma. [79, 80] Patients suffering from an exacerbation that do not get relief from reasonable doses of bronchodilators for example 4 puffs from an MDI or one wet nebulizer treatment every 3 h should be hospitalized. Antibiotics are not indicated for acute asthma exacerbations unless there is objective evidence of bacterial pneumonia or co-existing bacterial sinusitis.

## INTRODUCTION

Asthma is a global health problem of particular importance in developed nations. In the United States, for example, approximately 32 million people have been told by a health professional that they have asthma, while approximately 22 million *currently* have asthma [1]. Children ages 5–17 years have the highest prevalence rates for ever asthma and current asthma, with both rates decreasing with age. Asthma currently affects approximately 8.9% of US children and 7.2% of US adults.

A defining characteristic of asthma is the episodic worsening of the disease, with a more severe episode described as an "asthma attack" or "asthma exacerbation". These episodes also are referred to as "acute asthma", a term that emphasizes the distinction between an acute flare-up of asthma and the day-to-day fluctuations of this chronic, inflammatory disease. In the United States, approximately 12 million Americans have an asthma attack each year [1]. This represents just over half of the 22 million individual with current asthma. As with the prevalence of current (or lifetime) asthma, the highest attack prevalence is among children ages 5–17 years.

Although most exacerbations are mild and can be managed without difficulty outside the acute health care system, or through an urgent (unscheduled) office visit, more severe exacerbations prompt emergency department (ED) visits, and overnight hospital stays. ED visits and hospitalizations together account for approximately 25–50% of the US $14.7 billion in direct asthma-related health care costs [1, 2]. Indirect costs (lost productivity) add another $5 billion for a grand total of $19.7 billion. Asthma exacerbations obviously contribute to these indirect costs as

well. For example, fatal exacerbations accounts for $1.9 billion of the $5 billion of indirect costs.

As suggested by these financial data, presentations with acute asthma to the ED or other acute care settings are common. In the United States, acute asthma accounts for approximately 1.8 million ED visits each year and approximately 488,000 hospitalizations [1]. These acute presentations are precipitated by many possible factors, but the most common are an associated upper respiratory tract infection or environmental allergies. For individuals without regular asthma care, an undefined portion of ED visits is likely due to poor control of chronic asthma with or without associated common asthma triggers such as upper respiratory tract infection.

ED visits are important events for asthmatic individuals and their families, as they represent a vulnerable point in the illness and are associated with significant morbidity and occasional mortality. Moreover, in spite of adequate care, patients who experience an exacerbation may suffer from that episode for many days and they remain at risk of subsequent relapses for weeks after the initial ED visit [3, 4].

For all of these reasons, the management of acute asthma has been the focus of an increasing number of studies worldwide. The Cochrane Collaboration has played a vital role in organizing the results of published and non-published randomized trials, and this chapter is based heavily (and appropriately) on these systematic reviews. Moreover, this growing evidence base has led to much greater focus on the management of acute asthma in clinical practice guidelines, such as the recently released US guidelines, *Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma* of the National Asthma Education and Prevention

Program (NAEPP) [5]. The new EPR3 guidelines provide an excellent foundation for this chapter.

Despite this growing evidence base, and the increasing attempts to standardize and improve acute asthma care, there remain important gaps in diagnostic and therapeutic knowledge. We will address several of these controversial areas in this chapter. There also remain wide gaps between what is known and what is practiced. Although data are lacking, we believe that most of the latter gap is related to physician variation in the emergency treatment and approach to the patient with acute asthma. There are, however, encouraging signs that this asthma management gap is narrowing in emergency medicine [6].

## EVALUATION

The emergency management of acute asthma requires the health care provider to perform a brief history and physical examination [5]. Key elements in the history include the details of the current exacerbation (e.g. time of onset and any potential causes); severity of symptoms (especially compared to previous exacerbations) and response to any treatment given before presentation; all current medications and time of last dose (especially of asthma medications); the patient's previous asthma history (e.g. number of previous unscheduled office visits, ED visits, and hospitalizations for asthma, particularly within the past year; history of intubation for asthma); and other co-morbid conditions (e.g. other pulmonary or cardiac diseases or disease that may be aggravated by systemic corticosteroid therapy).

The key elements of the initial brief physical examination are the assessment of overall patient status (e.g. alertness, fluid status, respiratory distress); vital signs (including pulse oximetry); and chest findings (e.g. use of accessory muscles, wheezing). The examination also should focus on the identification of possible complications (e.g. pneumonia, pneumothorax, or pneumomediastinum); although rare, these complications have the potential to affect patient management. Particularly in children, the examination also should try to rule out upper airway obstruction (e.g. upper airway foreign bodies).

As noted in the EPR3 guidelines, "Most patients who have an asthma exacerbation do not require any initial studies. If laboratory studies are ordered, they must not delay initiation of asthma treatment" [5]. The most important objective of laboratory studies, such as arterial blood gas testing, is the detection of actual or impending respiratory failure. Another objective is to detect conditions that potentially complicate emergency asthma management (e.g. performing an EKG to rule out cardiac ischemia, or performing a chest film to rule out pneumonia). As noted earlier, since most patients have an uncomplicated, single-system disease presentation, they do not require *any* initial studies. Thus, low-yield tests should not be part of routine assessment; they should be reserved for patients that the health care provider believes are at increased risk of a specific complication or co-morbid disease.

By contrast, an important part of the initial assessment of most ED patients with acute asthma is an objective measure of pulmonary function. Although forced expiratory volume in one second ($FEV_1$) is preferred, serial peak expiratory flow (PEF) measurement can provide a rough, but still helpful, estimate of severity level and be used successfully to guide emergency management. All three editions of the NAEPP guidelines [5, 7, 8] have recommended that emergency management of acute asthma should be based on the $FEV_1$ or PEF severity level. The 2007 EPR3 guidelines [5] clarify that pulmonary function testing is not necessary in patients in extreme respiratory distress where the severity level is obvious. Thus, one should not use 100% initial PEF testing as a quality measure in the ED; for some patients, it would be highly inappropriate to perform such respiratory maneuvers at presentation or even in the first hour of their ED treatment. Nevertheless, when feeling better, physicians treating these same patients would likely benefit from reviewing objective measurements to assess lung function and monitor improvement.

The severity of asthma exacerbation drives treatment, as outlined in the 2007 EPR3 algorithms for management at home (Fig. 64.1) and in the ED/hospital setting (Fig. 64.2) [5]. An important change in the 2007 EPR3 guidelines, as compared to the 1997 EPR2 guideline [7] or 2002 update [9], is that the 2007 guidelines have reinstated the $FEV_1$ or PEF cutoffs used in the original 1991 guidelines [8]. Briefly, the 1991 and 2007 percent predicted $FEV_1$ or PEF cutoffs for asthma exacerbation severity are 40% for severe and 70% for mild. The "new" cutoff for severe exacerbations (<40% predicted $FEV_1$ or PEF) is useful because, as discussed later in this chapter, it is only at that severity level that several adjunct therapies have likely benefit (e.g. continuous nebulization of a $\beta_2$- agonist, intravenous (IV) magnesium sulfate, heliox). The "new" cutoff for mild exacerbations (≥70% predicted $FEV_1$ or PEF) represents the goal for discharge from the urgent/emergent care setting. Although it is certainly possible (indeed common) to discharge ED patients with lower PEF values [10], the 70% cutoff provides an ideal to guide ED and inpatient care. These cutoffs differ from those used to determine long-term asthma control and treatments (50% and 80% predicted FEV1 or PEF), thus underscoring the distinction between acute and chronic asthma. These revised cutoffs will likely be of greater use to ED clinicians than the 1997–2002 cutoff for "severe" exacerbations (i.e. <50% predicted $FEV_1$ or PEF), or the even higher cutoffs used in other asthma guidelines (e.g. <60% predicted PEF [11]).

## TREATMENT

Although currently available medications for acute asthma are not *always* effective, they have an impressive beneficial impact in most patients. For example, in North American EDs, approximately 80–90% of acute asthma patients will improve enough to be discharged to home [12]. The major therapeutic options are inhaled short-acting $\beta_2$-agonists (SABA), systemic (injected) $\beta_2$-agonists, anticholinergics, and systemic

**Assess severity**

+ **Patients at high risk for a fatal attack require immediate medical attention after initial treatment.**

+ Symptoms and signs suggestive of a more serious exacerbation such as marked breathlessness, inability to speak more than short phrases, use of accessory muscles, or drowsiness should result in initial treatment while immediately consulting with a clinician.

+ Less severe signs and symptoms can be treated initially with assessment of response to therapy and further steps as listed below.

+ If available, measure PEF—values of 50–79% predicted or personal best indicate the need for quick-relief mediation. Depending on the response to treatment, contact with a clinician may also be indicated. Values below 50% indicate the need for immediate medical care.

**Initial treatment**

■ Inhaled SABA: Up to two treatments 20 min apart of 2–6 puffs by metered dose inhaler (MDI) or nebulizer treatments.

■ Note: Medication delivery is highly variable. Children and individuals who have exacerbations of lesser severity may need fewer puffs than suggested above.

**Good response**

No wheezing or dyspnea (assess tachypnea in young children).

PEF ≥80% predicted or personal best.

■ Contact clinician for follow-up instructions and further management.

■ May continue inhaled SABA every 3–4 h for 24–48 h.

■ Consider short course of oral systemic corticosteroids.

**Incomplete response**

Persistent wheezing and dyspnea (tachypnea).

PEF 50–79% predicted or personal best.

■ Add oral systemic corticosteroid.

■ Continue inhaled SABA.

■ Contact clinician urgently (this day) for further instruction.

**Poor response**

Marked wheezing and dyspnea.

PEF <50% predicted or personal best.

■ Add oral systemic corticosteroid.

■ Repeat inhaled SABA immediately.

■ If distress is severe and non-responsive to initial treatment:
  – Call your doctor and
  – proceed to ED;
  – Consider calling 9–1–1 (ambulance transport).

■ To ED.

Key: ED: emergency department; MDI: metered dose inhaler; PEF: peak expiratory flow; SABA: short-acting $\beta_2$-agonist (quick-relief inhaler).

**FIG. 64.1** Management of asthma exacerbations: Home treatment [5].

corticosteroids. Although we provide some information about these key "rescue" medications, we devote disproportionate space to more controversial aspects of emergency asthma management. This includes both pharmacological and non-pharmacological approaches. In doing so, we rely heavily on systematic review evidence from the Cochrane Collaboration [13], and the 2007 EPR3 guidelines [5]. As noted earlier, the Cochrane reviews use standardized and rigorous methods to summarize and combine the best evidence from individual randomized controlled trials on a specific topic area, and they were used in the development of the 2007 EPR3 guidelines.

## In-ED care

The goals of in-ED are to assure adequate oxygenation, to safely and effectively reverse the acute obstruction to airflow that led to the presentation to the ED, and to initiate

**Initial assessment**
Brief history, physical examination (auscultation, use of accessory muscles, heart rate, respiratory rate), PEF or FEV$_1$, oxygen saturation, and other tests as indicated.

**FEV$_1$ or PEF ≥40% (Mild-to-moderate)**
+ Oxygen to achieve SaO$_2$ ≥90%.
+ Inhaled SABA by nebulizer or MDI with valved holding chamber, up to 3 doses in first hour.
+ Oral systemic corticosteroids if no immediate response or if patient recently took oral systemic corticosteroids.

**FEV$_1$ or PEF <40% (Severe)**
+ Oxygen to achieve SaO$_2$ ≥90%.
+ High-dose inhaled SABA plus ipratropium by nebulizer or MDI plus valved holding chamber, every 20 min or continuously for 1 h.
+ Oral systemic corticosteroids.

**Impending or actual respiratory arrest**
+ Intubation and mechanical ventilation with 100% oxygen.
+ Nebulized SABA and ipratropium.
+ Intravenous corticosteroids.
+ Consider adjunct therapies.

**Repeat assessment**
Symptoms, physical examination, PEF, O$_2$ saturation, other tests as needed

**Admit to hospital intensive care (see box below)**

**Moderate exacerbation**
FEV$_1$ or PEF 40–69% predicted/personal best
Physical examination: moderate symptoms
+ Inhaled SABA every 60 min
+ Oral systemic corticosteroid
+ Continue treatment 1–3 h, provided there is improvement; make admit decision in <4 h.

**Severe exacerbation**
FEV$_1$ or PEF <40% predicted/personal best
Physical examination: severe symptoms at rest, accessory muscle use, chest retraction
History: high-risk patient
No improvement after initial treatment
+ Oxygen
+ Nebulized SABA + ipratropium, hourly or continuous
+ Oral systemic corticosteroids
+ Consider adjunct therapies.

**Good response**
+ FEV$_1$ or PEF ≥70%
+ Response sustained 60 min after last treatment
+ No distress
+ Physical examination: normal

**Incomplete response**
+ FEV$_1$ or PEF 40–69%
+ Mild-to-moderate symptoms

**Poor response**
+ FEV$_1$ or PEF <40%
+ PCO$_2$ ≥42 mmHg
+ Physical examination: symptoms severe, drowsiness, confusion.

**Individualized decision re-hospitalization (see text)**

**Discharge home**
+ Continue treatment with inhaled SABA.
+ Continue course of oral systemic corticosteroid.
+ Consider initiation of an ICS.
+ Patient education
  − Review medications, including inhaler technique.
  − Review/initiate action plan.
  − Recommend close medical follow-up.

**Admit to hospital ward**
+ Oxygen
+ Inhaled SABA
+ Systemic (oral or intravenous) corticosteroid
+ Consider adjunct therapies
+ Monitor vital signs, FEV$_1$ or PEF, SaO$_2$.

**Admit to hospital intensive care**
+ Oxygen
+ Inhaled SABA hourly or continuously
+ Intravenous corticosteroid
+ Consider adjunct therapies
+ Possible intubation and mechanical ventilation.

**Improve**

**Improve**

**Discharge home**
+ Continue treatment with inhaled SABAs.
+ Continue course of oral systemic corticosteroid.
+ Continue on ICS. For those not on long-term control therapy, consider initiation of an ICS.
+ Patient education (e.g. review medications, including inhaler technique and, whenever possible, environmental control measures; review/initiate action plan; recommend close medical follow-up).
+ Before discharge, schedule follow-up appointment with primary care provider and/or asthma specialist in 1–4 weeks.

Key : FEV$_1$: forced expiratory volume in 1 s; ICS: inhaled corticosteroid; MDI: metered dose inhaler; PCO$_2$: partial pressure carbon dioxide; PEF: peak expiratory flow; SABA: short-acting β$_2$-agonist; SaO$_2$: oxygen saturation.

**FIG. 64.2** Management of asthma exacerbations: ED and hospital-based care [5].

anti-inflammatory therapy to control the exacerbation and reduce the likelihood of subsequent relapse. The approaches used should reduce the need for hospitalization, and ensure that patients receive the appropriate therapy required to prevent or reduce the potential of an adverse outcome (e.g. intubation, death).

## Oxygen

Supplemental oxygen is recommended for the initial treatment of most patients with acute asthma in the ED or inpatient setting [5]. The oxygen can be administered by nasal cannulae or mask, whichever is better tolerated, to maintain an $SaO_2 \geq 90\%$ (or $\geq 95\%$ in pregnant women or in patients with cardiac disease). $SaO_2$ should be monitored until the patient demonstrates a clear response to bronchodilator therapy. Although the evidence for this recommendation is weak, the risks of oxygen treatment are minimal.

## Inhaled short-acting $\beta_2$-agonists

In addition to oxygen, early treatment of patients with acute asthma has generally focused on the use of inhaled SABAs because of their undisputed, generally rapid, effect on relieving bronchospasm, and associated breathlessness. Because of the risk of cardiotoxicity, especially in older asthmatic patients, EPR3 guidelines recommend that only selective SABAs (i.e. albuterol (salbutamol), levalbuterol, pirbuterol) be used in high doses [5]. Whether the drug is most effective when delivered via a nebulizer or a metered dose inhaler (MDI) with holding/spacer device has been an area of intense research. A systematic review in the Cochrane Library by Cates *et al.* [14] examined 25 trials from ED and community settings, with participation of 2,066 children and 614 adults. The authors found that the use of either delivery method for inhaled SABAs produces similar outcomes [14]. For example, the use of an MDI was associated with identical admission rates among adults (odds ratio (OR) 0.97; 95% confidence interval (CI), 0.63 to 1.49) and a non-significant difference among children (OR 0.65; 95%CI, 0.4 to 1.06). There were no important differences in $FEV_1$ or PEF. In children, but not adults, MDI with holding chamber/spacer appeared to offer advantages in terms of ED length-of-stay and fewer adverse effects (e.g. tachycardia). Although economic evaluations of these approaches also tend to favor the use of MDI with spacer over nebulized treatments, these analyses are problematic [15].

Nebulizer therapy may still be preferred, however, for patients who are unable to cooperate effectively in using an MDI because of their age, agitation, or severity of acute asthma. Indeed, the clinical trial data have rarely included patients with severe asthma exacerbations, let alone those with the subset of life-threatening exacerbations. Accordingly, SABA delivery via MDI-spacer may be best confined to patients with mild to moderate asthma exacerbations, which includes many patients in the ED setting (particularly now that severe is defined as <40% predicted). For patients with truly severe asthma exacerbations, the documented benefits of continuous nebulization (reduced admissions, improved pulmonary function) [16] make nebulization a more attractive alternative. Future research will need to resolve the advantages and disadvantages of MDI-spacer versus nebulizer for SABA delivery in severe acute asthma.

Numerous attempts to identify optimal doses or treatment intervals to achieve maximal bronchodilation or symptom relief have not identified a single "best" regimen. For example, several studies have found that higher doses appear to be equivalent to lower doses with regard to affecting bronchodilation or clinical outcome [17–20]. There are a substantial number of patients who achieve a bronchodilation "plateau" and additional $\beta_2$-agonist therapy only seems to cause more side effects. For that reason, some guidelines have recommended that $\beta$-agonists be titrated to plateau using objective assessment of airway obstruction with pulmonary function measures [20]. The EPR3 recommendations are summarized in Figs 64.1 and 64.2.

## Inhaled anticholinergic agents

There is increasing support, particularly in children, for *adding* the anticholinergic agent ipratropium bromide (IB) to $\beta_2$-agonist therapy in more severe asthma exacerbations [21, 22]. A systematic review involving children compared IB plus $\beta_2$-agonists to $\beta_2$-agonists alone [22]. Although a single does of IB was not effective for the treatment of mild and moderate exacerbations, summary statistics indicate that *multiple* doses of IB result in a clinically significant improvement in $FEV_1$ at 60 (16%; 95%CI, 6 to 27%) and 120 (18%; 95%CI, 4% to 31%) minutes. Combined therapy, with multiple doses, reduced the risk of hospital admission by 25% (relative risk (RR) 0.75; 95%CI, 0.62 to 0.89) in children with moderate and severe exacerbations. The number needed to treat (NNT) to prevent one admission was 12 (95%CI, 8 to 32); the NNT decreased to 7 in severe cases. Neither therapy group was associated with significant adverse effects.

A similar meta-analysis in adults also demonstrated a modest beneficial effect of adding IB to inhaled $\beta_2$-agonists [21]. The absolute increase in $FEV_1$ and PEF, respectively, was 7% (95%CI, 4 to 11%) and 22% (95%CI, 11 to 33%) over 45 to 90 min, respectively. The risk of admission was decreased by 27% (RR 0.73; 95%CI, 0.53 to 0.99). After publication of this systematic review, a large randomized controlled trial confirmed these findings [23]. The trial observed a 21% (95%CI, 3 to 38%) improvement in PEF and a 48% (95%CI, 20 to 76%) improvement in $FEV_1$ over the control group. High doses of IB reduced the risk of hospital admission by 49% (RR 0.51; 95%CI, 0.31 to 0.83); the NNT to prevent a single admission was 5 (95%CI, 3 to 17). Although questions still need to be resolved regarding IB therapy in the ED setting (such as the dose–response relationship), it seems prudent to use this agent with inhaled $\beta_2$-agonists for patients with severe exacerbations [5].

## Systemic corticosteroids

The airway edema and secretions associated with acute asthma are most effectively treated with anti-inflammatory agents such as corticosteroids. The early use of systemic corticosteroids (i.e. within 1 h of ED presentation) delivered by oral or intravenous (IV) routes continues to be a principal treatment choice in all evidence-based asthma guidelines [5, 11]. A Cochrane systematic review of this topic identified 12 trials, involving 863 patients [24]. In brief, the early use

Favors MgSO$_4$        Favors placebo

**FIG. 64.3** Cochrane review on the effect of IV magnesium sulfate versus placebo on risk of hospital admission in acute asthma [28].

of corticosteroids for acute asthma in the ED significantly reduced admission rates (OR 0.40; 95%CI, 0.21 to 0.78), with an NNT of 8 (95%CI, 5 to 21). This benefit was more pronounced for those not already receiving systemic corticosteroids (OR 0.37; 95%CI, 0.19 to 0.70) and for those experiencing a severe exacerbation (OR 0.35; 95%CI, 0.21 to 0.59). Adverse effect profiles were similar between all systemic corticosteroids treatment routes (e.g. by mouth, IV) and placebo.

The debate about the use of IV versus oral corticosteroids in the ED is one that may never end; however, it now seems to be focused on identifying which patients require the IV route as opposed to the oral route. There is no clear evidence from controlled trials or meta-analyses that suggest the advantage offered by corticosteroids in acute asthma is related to the route of administration. Further, systematic evidence on dosing suggests that high-dose corticosteroids, at least in hospitalized patients, are no more effective than moderate doses in the acute setting [25].

Applying this information to practice requires a clear understanding that not all levels of severity have been assessed with sufficient rigor to confirm equivalency of systemic routes in all situations. For this reason, IV corticosteroids should be reserved for those who are too dyspneic to swallow, obtunded or intubated, or unable to tolerate oral medications (e.g. vomiting). Until further evidence is available, it seems reasonable to select oral agents as the first-line choice unless circumstances suggest otherwise.

## Magnesium sulfate

The use of magnesium sulfate (MgSO$_4$) in unresponsive acute asthma has gained support recently. This agent has both immediate bronchodilator effects, as well as mild anti-inflammatory effects. Several systematic reviews have concluded that IV magnesium is not only safe but effective in patients with severe exacerbations [26, 27]. In the original Cochrane review, the *addition* of IV MgSO$_4$ to β-agonist and IV systemic corticosteroid treatment among individuals with severe exacerbations reduced hospitalizations (OR 0.1; 95%CI, 0.04 to 0.27) and improved pulmonary function (mean increase in PEF: 52 l/min; 95%CI, 27 to 77) [27]. Overall, there were no changes in the systolic blood pressure with this treatment and adverse effects were rare or minor. It is important to note that the *routine* use of MgSO$_4$ in all patients with asthma did not produce a statistically significant benefit (OR for admission: 0.31; 95%CI, 0.09 to 1.04). A recently updated analysis (Fig. 64.3) yielded very similar results [28].

Although uncertainties remain, the 2007 EPR3 guidelines recommend consideration of IV MgSO$_4$ in patients who have life-threatening exacerbations and in those whose exacerbations remains in the severe category after 1 h of intensive conventional therapy [5]. Since this agent has been shown to be easy to use, extremely safe and inexpensive, we strongly support consideration of its early use in severe acute asthma. Currently, the recommended dose is 2 g IV over 20 min in adults and 25–100 mg/kg in children (total maximum dose of 2 g).

Given the evidence supporting the use of IV MgSO$_4$ in severe exacerbations, and the rapid uptake of this treatment into emergency asthma management [6], it was not surprising that clinical researchers have tried to treat acute asthma with inhaled magnesium. A 2005 Cochrane review identified six trials involving only 296 patients [29]; four of the trials

compared nebulized $MgSO_4$ with $\beta_2$-agonist to $\beta_2$-agonist alone, and two studies compared $MgSO_4$ alone to $\beta_2$-agonist alone. Overall, there was a lack of benefit across studies; however, the heterogeneity of the trials precluded definitive conclusions. For example, in subjects with severe exacerbations, the lung function differences were significant. The area remains controversial [30, 31] and will require further investigation. Currently, there is no evidence to suggest *replacing* inhaled SABAs with magnesium and insufficient evidence to support *combining* inhaled SABAs with magnesium.

## Heliox

Another controversial area in acute asthma is the role of heliox. Although this helium–oxygen mixture has been used sporadically since 1930s, there are relatively sparse data supporting its use. A recent Cochrane review identified 10 trials involving 544 patients [30, 31]. Pooling of the eight trials with pulmonary function data yielded a borderline significant group difference (Fig. 64.4). The authors note that there was significant heterogeneity among the studies but that heliox use did improve pulmonary function in the subgroup of patients with the most severe baseline pulmonary function impairment. The heterogeneity may result from small sample sizes and distinct patient populations. More importantly, however, some studies have neglected to account for the different effect of heliox versus oxygen (or room air) on the respirable mass of nebulized albuterol [32]. The technical differences among studies greatly complicate interpretation and synthesis of the literature. A large multicenter trial with optimal heliox delivery would help to resolve lingering concerns. Although uncertainties remain, the 2007 EPR3 guidelines recommend consideration of heliox in patients who have life-threatening exacerbations and in those whose exacerbations remains in the severe category after 1 h of intensive conventional therapy [5].

## Inhaled corticosteroids in the ED

Inhaled corticosteroids (ICS) are preferred therapy for chronic asthma, where beneficial effects are seen over a prolonged period of use. In addition, there is now emerging evidence supporting their use in the ED setting for acute asthma. A Cochrane systematic review suggests that ICS may reduce admissions to hospital and improve pulmonary function when administered early in the ED protocol [33]. In acute asthma, ICS reduced admissions (Fig. 64.5; OR 0.33; 95%CI, 0.17 to 0.64) and improved pulmonary function (mean difference PEF 8.0%; 95%CI, 3 to 13) compared to placebo. However, several of the studies included in this review did not administer systemic corticosteroids to either the treatment or control group, which limits the power of the review to determine the *additive* benefit of ICS when systemic corticosteroids are being used.

A large study demonstrated that there may be drawbacks to *replacing* oral corticosteroids with ICS in the treatment of acute asthma [37]. In this randomized double-blind study, patients received ICS versus oral corticosteroids in addition to standard $\beta_2$-agonist therapy. The oral corticosteroid-treated subjects performed better and were admitted less frequently than the ICS-treated subjects. Combined with the previous meta-analysis data, these results suggest that ICS may be useful as an adjunct to systemic corticosteroids, but not as a replacement choice [33, 35]. Additional research is needed in this area to determine the optimal dose, frequency, and drug to be used, and to clarify the magnitude of the additional benefit when oral corticosteroids are being administered concurrent with ICS. Until such time, the role of ICS in the treatment of acute asthma is not clear, but we support consideration of its early use in severe acute asthma.

## Leukotriene modifiers

Leukotriene modifiers may provide another approach to the management of acute asthma. For example, a randomized trial of IV montelukast in moderate–severe exacerbations demonstrated significant improvement in $FEV_1$ within 10 min of administration [36]. For rapid bronchodilation, the IV route is required since an oral formulation of montelukast would not begin to provide benefit until approximately

**FIG. 64.5** Cochrane review on the effect of inhaled corticosteroids in the ED on risk of hospital admission in acute asthma [33].

90 min after administration [37]. Nonetheless, the observed bronchodilation suggests another novel approach: to give an oral formulation to all patients with moderate-to-severe exacerbations at the time of ED presentation (e.g. as an adjunct to primary therapy with $\beta_2$-agonists, anticholinergic agents, and systemic corticosteroids). Early studies on the role of oral leukotriene modifiers in the ED suggest likely benefits [38, 39] but this concept requires further study.

## Other therapies

The therapeutic benefits of other agents, such as IV SABAs [40] and aminophylline [41] are limited. The cited Cochrane systematic reviews provide little, if any, support for their use in emergency asthma care; for both agents, the side effects clearly outweigh the benefits. It is important to note, however, that the SABA trials addressed a different question than the one that we would raise today. For example, even if IV SABA provides no benefit over inhaled SABAs in head-to-head comparisons, what is the role of IV SABA in addition to inhaled SABA for severe exacerbations? Few studies have directly examined this more relevant question to practitioners today; the few small trials that have examined this issue provide contradictory results [42–44]. Future, and much larger, trials will need to resolve this important issue. In the meantime, we encourage the use of other, more established therapies in the emergency management of acute asthma.

Likewise, systematic reviews have repeatedly shown that antibiotics should not be used routinely for acute asthma [9, 45]. Antibiotics should be limited to the treatment of co-morbid bacterial infections, such as community-acquired pneumonia or bacterial sinusitis. Despite this evidence-based recommendation, many clinicians continue to prescribe antibiotics for the viral upper respiratory tract infections that trigger acute asthma. For example, national data suggest that 22% of ED patients with acute asthma receive antibiotics as part of their asthma care. (Carlos Camargo MD, unpublished data). The continued prescription of antibiotics for acute asthma represents a potential focus of future quality improvement efforts to decrease in appropriate antibiotic use.

Non-invasive ventilation is another experimental approach for the treatment of respiratory failure due to severe asthma exacerbation, but data are sparse. The Cochrane review on this topic identified only one trial involving 30 patients [46]. Although this small trial [47] showed benefit with non-invasive positive pressure ventilation when compared to usual medical care alone, with significant improvements in hospitalization rate and pulmonary function, there are inadequate data to draw firm conclusions. Future multicenter studies should examine the role of heliox, non-invasive ventilation, or both in patients with severe exacerbations. Until that time, there is insufficient evidence to support use of NIV in the management of acute asthma.

## Post-ED care

The goal of post-ED care is to safely return each patient to a level of functioning commensurate with good asthma "control". Per EPR3, this includes reductions in both impairment and risk [5]. With regard to risk, this includes

a reduction in asthma exacerbation recurrences, with good control defined as at most one corticosteroid-requiring exacerbation in a year.

The more immediate concern, however, is to successfully treat the current exacerbation and prevent an acute asthma relapse. Please note that the term "relapse" differs from "recurrence", with relapse referring to the acute deterioration of a patient during an exacerbation despite increased medical care (e.g. over a shorter period of time of 1–4 weeks) whereas recurrence refers to repeated exacerbations over longer periods of time (e.g. 6–12 months).

## Oral corticosteroids

Approximately 10–20% of ED patients treated for acute asthma and sent home will relapse within 2 weeks of discharge [3, 4], many because of unresolved inflammation that leaves the airways sensitive to inhaled irritants. Guidelines strongly encourage treatment with systemic corticosteroids following ED discharge for an acute exacerbation [5, 11]. Compelling evidence for this approach is found in a recently updated Cochrane systematic review comparing post-ED corticosteroid therapy to placebo [48]. The review identified 6 trials involving 374 people. Surprisingly, despite the small number of total patients involved in this review, it showed that significantly fewer patients in the corticosteroids group relapsed in the first week (OR 0.38; 95%CI, 0.2 to 0.74). This reduced risk was maintained over the first 21 days (OR 0.47; 95%CI, 0.25 to 0.89). The corticosteroid group had less need for $\beta_2$-agonists (mean difference: −3 activations/day; 95%CI, −5.6 to −1.0). Changes in pulmonary function tests and adverse effects, while rarely reported, showed no differences between the treatment groups. A subgroup analysis indicated that intra-muscular (IM) corticosteroids and a 7- to 10-day tapering course of corticosteroids were similarly efficacious. IM therapy should be reserved for those patients with questionable compliance, inability to pay for an oral prescription, or those who are otherwise unreliable (cognitive impairment, intoxication, etc.). From these results, the authors conclude that as few as 10 patients need to be treated to prevent one relapse to additional care.

Small sample sizes in the randomized clinical trials (RCTs) performed to date did not permit an examination of the relative effectiveness of various regimens and definitive recommendation concerning dose or dosing protocol(s) cannot be provided. However, given the enhanced compliance associated with once daily dosing and the availability of 40 or 50 mg tablets in North America, the use of oral corticosteroids for a short period (e.g. 5–7 days) seems appropriate for most patients discharged with an acute asthma episode. The need to "taper" these oral corticosteroids over that period appears unwarranted [49, 50], especially when ICS are being employed concurrently [51].

## Inhaled corticosteroids

In North America, the majority of patients with acute asthma treated in an emergency setting are discharged and prescribed a short course (5–7 days) of oral corticosteroids. Less information exists regarding the use of ICS; however, the data that exist indicate impressive practice variation with respect to this treatment. For example, in US sites associated with a large North American emergency medicine research network (www.emnet-usa.org), only 11% of discharged patients were prescribed an ICS if they were not regularly taking one, whereas in Canadian sites, 63% of similar patients were treated with an ICS at discharge [12, 48, 52].

There is evidence to support using a combination of inhaled and oral corticosteroids after discharge from the ED [51]. There are three randomized controlled trials [51, 53, 54] which provide somewhat conflicting evidence for the addition of ICS to prevent relapse, but when combined in a systematic review the introduction of ICS appears to be worthwhile [55]. The pooled effect demonstrates a trend in favor of the ICS plus oral corticosteroid group which had fewer relapses after discharge than the group administered oral corticosteroids alone (OR 0.68; 95%CI, 0.46 to 1.02) [55].

The results of this review indicate that patients already taking ICS should be counseled by the ED staff about compliance-enhancing interventions [56–58]. It is important to remember that many of the patients with acute asthma who present to the ED exhibit features associated with poorly controlled chronic asthma [58]. They represent vulnerable patients who are the ideal candidates for ICS. Consequently, it seems prudent to recommend those patients not on ICS agents should be considered for short- or long-term ICS therapy in conjunction with oral prednisone after discharge. The dose and duration of inhaled and oral corticosteroids should be based on recent history of symptom control, health care utilization, and quality of life indicators. For those patients with more severe illness, this clearly would be the optimal treatment strategy. The 2007 EPR3 guidelines encourage clinicians to consider initiation of ICS given the potential for ICS to reduce subsequent ED visits, strong evidence that long-term control ICS therapy reduces exacerbations in patients with persistent asthma, and the opinion of the entire Expert Panel that the initiation (and continuation) of ICS therapy at ED discharge can be an important effort to bridge the gap between emergency and primary care for asthma [5].

There are several recent publications examining the effect of *replacing* oral corticosteroids with a high-dose ICS These generally compare oral prednisone to very high doses of ICS in mild exacerbations after discharge. While the systematic review failed to demonstrate a significant difference in asthma relapse between the two treatments (OR 1.0; 95%CI, 0.48 to 1.42), these results need to be interpreted cautiously [55]. Although the evidence implies equivalence, these results are not conclusive due to the width of the confidence intervals and the inclusion of only patients with mild asthma exacerbations. Given the limited data on this issue to date, use of ICS alone should be reserved for those patients with very mild asthma and those who refuse or cannot take oral corticosteroids (e.g. brittle diabetes, steroid psychosis). Compared to the traditional short course of prednisone, ICS are expensive and more difficult for patients and families to use.

If ICS are used in place of systemic corticosteroids in these subgroups, it is important to not just double the maintenance dose, as recommended in past guidelines, because several recent trials have not found that this approach is not effective [58–62]. In this exceptional situation, and on the basis of admittedly sparse data [63], the current recommendation is to quadruple the ICS dose.

## Other therapies

Over the past decade, there have been many exciting advances in chronic asthma care and some of these new approaches are now being tried in patients with acute asthma. A surprisingly under-studied area is the potential use of combination therapies at the time of ED discharge. Recently, Rowe and colleagues reported a small randomized, controlled, double-blind trial of fluticasone/salmeterol versus fluticasone alone at discharge from the ED; all patients were discharged on 7 days of prednisone [52]. Although relapse rates were numerically lower in the combination group, the difference was not statistically significant. Likewise, quality of life measures did not differ between groups but the authors noted that in the subset of patients who already were on ICS at the time of ED presentation, the fluticasone/salmeterol group had significantly improved quality of life ($p < 0.05$). Larger studies are needed to determine the role of inhaled combination therapies, especially those with formoterol, in the post-ED management of acute asthma. This question will become increasingly important as treatment of chronic asthma improves. For example, in the past, emergency clinicians were faced with many asthma patients who were not taking anti-inflammatory medications, such as ICS. In recent years, more patients presenting to the ED are already taking ICS and, increasingly, the combination agents (fluticasone/salmeterol or budesonide/formoterol). Understanding the relapse risks and the best management for patients already receiving anti-inflammatory agents will be an important contribution to evidence-based acute asthma care in the future.

## Non-pharmacological approaches

### Asthma education

Education is a key recommendation in all asthma guidelines [5, 11]. Emergency physicians, when surveyed, also felt it was an important component of asthma care and rated many educational items as necessary [58]. Despite widespread enthusiasm for asthma education, the overall results of individual trials and systematic reviews have been somewhat disappointing; this is especially true for the acute setting.

A systematic review of RCTs in children who attended the ED was conducted to identify whether asthma education leads to improved health outcomes [64]. The analyses found that structured education, as compared to usual care or lower-intensity education, did not reduce subsequent ED visits (RR 0.87; 95%CI, 0.37 to 2.08), hospital admissions (RR 0.74; 95%CI, 0.38 to 1.46), or unscheduled doctor visits (RR 0.74; 95%CI, 0.49 to 1.12). However, there was a significant heterogeneity among these pooled results ($p < 0.01$) with potential for uncontrolled confounding factors. The authors concluded that there was no firm evidence to support asthma education for children to improve asthma control and that more rigorous research was necessary.

Another Cochrane review examined the impact of limited asthma education programs (information only) for adults with asthma [65]. There was no effect on hospital admissions, doctor visits, lung function, medication use, or normal activity days lost. However, perceived asthma symptoms did improve in the education group (OR 0.40;

95%CI, 0.18 to 0.86). One study found that limited asthma education programs were associated with reduced ED visits (mean decrease visits/person/year: 2.8 visits; 95%CI, −4.3 to 1.2). The reviewers concluded that use of limited asthma education, as it has been practiced, does not appear to improve health outcomes in adults. The usefulness of education in the ED setting is encouraging, but further research is required to confirm these findings.

A second review by the same group assessed the effects of adult asthma self-management programs coupled with regular medical review [66]. Self-management education reduced hospitalizations (OR 0.57; 95%CI, 0.38 to 0.88), ED visits (OR 0.71; 95%CI, 0.57 to 0.90), unscheduled doctor visits (OR 0.57; 95%CI, 0.40 to 0.82), missed work/school days (OR 0.55; 95%CI, 0.38 to 0.79), and nocturnal asthma (OR 0.53; 95%CI, 0.39 to 0.72). Pulmonary function measures were minimally affected by these combined interventions. If a written action plan was added, there was an even greater reduction in hospitalization (OR 0.35; 95%CI, 0.18 to 0.68). Patients who could self-adjust their medications using an individualized written plan had better lung function than those whose medications were adjusted by a doctor.

In the latest Cochrane review [67], the authors examined the effectiveness of educational interventions administered following an ED visit for acute asthma. The review included 12 studies involving 1954 adults. Although education significantly reduced subsequent admission to hospital (Fig. 64.6; RR 0.50; 95%CI, 0.27 to 0.91), it did not significantly reduce the risk of re-presentation at ED during follow-up (RR 0.69; 95%CI, 0.40 to 1.21). The authors identified priority areas for further research but were reluctant to draw further conclusions from these data.

The clinical implications of these reviews are that isolated asthma education provides limited benefit. However, self-management programs associated with regular review by a health care provider and the addition of a written action plans appear to be effective in reducing asthma symptoms, health care use, and improving asthma quality of life. Moreover, educational interventions administered after an ED visit for acute asthma also appear to have tangible benefits (decreased risk of subsequent admission to the hospital). This conclusion receives strong support from a recent single-center randomized trial by Teach and colleagues [68], where the investigators describe striking benefits for children enrolled in an ED-based education program that emphasized patient self-monitoring and management, environmental modification and trigger control, and linkages and referrals to ongoing care.

In light of these findings, clinicians might be well advised to consider training staff, patients, and families in asthma self-management that involves monitoring of asthma (by either PEF or symptoms), regular medical review, and provision of a simple written action plan. Programs that enable people to adjust their medication using a written action plan appear to be more effective than other forms of asthma self-management and should be encouraged. To that end, Camargo and colleagues developed a simple "asthma discharge plan" for use in ED patients with acute asthma (Fig. 64.7) [69].

A conclusion that we draw from the reviewed evidence is the importance of seeing the ED as part of the continuum of asthma care. Given the chronicity of this

disease – and notwithstanding the fact that these exacerbations represent teachable moments – it is likely that the main role of the ED will continue to be *reinforcement* of other educational efforts and *facilitation* of follow-up with the primary care provider (assuming one exists). Evidence suggests that only 25–50% of patients see a primary care provider for a routine asthma reassessment within *1 month* of the ED visit [70, 71]. Despite this recognition, efforts to increase this primary care follow-up following an exacerbation have been surprisingly difficult. In one RCT, investigators used increasingly costly and complicated efforts to increase PCP follow-up following an exacerbation of asthma, only to find no impact on any clinically meaningful outcome [71]. The role of facilitated referral of ED patients to asthma specialists is not yet clear and merits rigorous investigation.

---

### EMERGENCY DEPARTMENT – ASTHMA DISCHARGE PLAN

**Name:** _____ was seen by **Dr.** _____ on ___/___/___

- Take your prescribed medications as directed—do not delay!
- Asthma attacks like this one can be prevented with a long-term treatment plan.
- Even when you feel well, you may need daily medicine to keep your asthma in good control and prevent attacks.
- Visit your doctor or other health care provider as soon as you can to discuss how to control your asthma and to develop *your own* action plan.

**Your follow-up appointment** with _____ is on:  ___/___/___  **Tel:** _____

**YOUR MEDICINE FOR THIS ASTHMA ATTACK IS:**

| Medication | Amount | Doses per day, for # days |
|---|---|---|
| Prednisone/prednisolone (oral corticosteroid) | | _____ a day for _____ days. Take the entire prescription, even when you start to feel better. |
| Inhaled albuterol | | _____ puffs every 4–6 h if you have symptoms, for _____ days |

**YOUR DAILY MEDICINE FOR LONG-TERM CONTROL AND PREVENTING ATTACKS IS:**

| Medication | Amount | Doses per day |
|---|---|---|
| Inhaled corticosteroids | | |

**YOUR QUICK-RELIEF MEDICINE WHEN YOU HAVE SYMPTOMS IS:**

| Medication | Amount | Number of doses/day |
|---|---|---|
| Inhaled albuterol | | |

**ASK YOURSELF 2 TO 3 TIMES PER DAY, EVERY DAY, FOR AT LEAST 1 WEEK:**

**"How good is my asthma compared to when I left the hospital?"**

| If you feel much better | If you feel better, but still need your quick-relief inhaler often: | If you feel about the same: | If you feel worse: |
|---|---|---|---|
| • Take your daily long-term control medicine. | • Take your daily long-term control medicine. • See your doctor as soon as possible. | • Use your quick-relief inhaler. • Take your daily long-term control medicine. • See your doctor as soon as possible – don't delay. | • Use your quick-relief inhaler. • Take your daily long-term control medicine. • Immediately go to ED or call 9–1–1. |

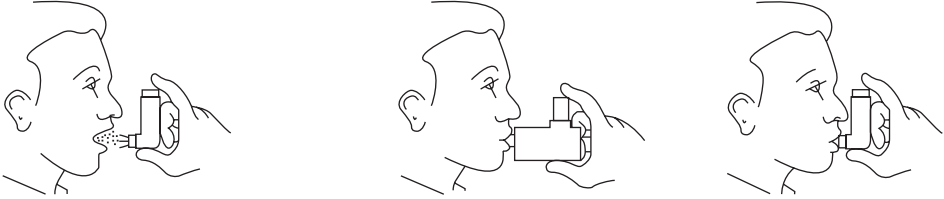
**YOUR ASTHMA IS UNDER CONTROL WHEN YOU:**

| ① Can be active daily and sleep through the night. | ② Need fewer than 4 doses of quick-relief medicine in a week. | ③ Are free of shortness of breath, wheeze, and cough. | ④ Achieve an acceptable "peak flow" (discuss with your health care provider). |
|---|---|---|---|

**FIG. 64.6** ED – Asthma discharge plan [69]. Reprinted by permission from Carlos Camargo, M.D., Principal Investigator of Agency for Health Care Research and Quality. Grant No. R13H31094.

Using an inhaler seems simple, but most patients do not use it the right way. When you use your inhaler the wrong way, less medicine gets to your lungs.

For the next few days, read these steps aloud as you do them or ask someone to read them to you. Ask your doctor, nurse, other health care provider, or pharmacist to check how well you are using your inhaler.

Use your inhaler in one of the three ways pictured below. A or B are best, but C can be used if you have trouble with A and B. Your doctor may give you other types of inhalers.


**Steps for using your inhaler**

| | |
|---|---|
| Getting ready | 1. Take off the cap and shake the inhaler.<br>2. Breathe out all the way.<br>3. Hold your inhaler the way your doctor said (A, B, or C below). |
| Breathe in slowly | 4. As you start breathing in slowly through your mouth, press down on the inhaler one time. (If you use a holding chamber, first press down on the inhaler. Within 5 s, begin to breathe in slowly.)<br>5. Keep breathing in slowly, as deeply as you can. |
| Hold your breath | 6. Hold your breath as you count to 10 slowly, if you can.<br>7. For inhaled quick-relief medicine (short-acting $\beta_2$-agonists), wait about 15–30 s between puffs. There is no need to wait between puffs for other medicines. |

(A) Hold inhaler 1–2 in. in front of your mouth (about the width of two fingers).

(B) Use a spacer/holding chamber. These come in many shapes and can be useful to any patient.

(C) Put the inhaler in your mouth. Do not use for steroids.

Clean your inhaler as needed, and know when to replace your inhaler. For instructions, read the package insert or talk to your doctor, other health care provider, or pharmacist.

### Other issues

Studies have documented a large percentage of patients who are repeatedly exposed to environmental irritants. A significant number of asthma patients are either exposed to cigarette smoke or persist with this habit despite the presence of asthma [72]. Smoking cessation counseling and avoidance strategies should be provided to these patients along with their families with every exacerbation in an attempt to motivate smokers to overcome this addiction. Although it is unlikely that a detailed intervention can be undertaken in a busy ED setting, simple approaches are possible and under investigation [73, 74]. At a minimum, ED staff are strongly encouraged to learn about referral options in their hospital (e.g. to refer ED patients to smoking cessation programs).
Acute exacerbations also represent an opportunity for ED physicians and staff to review pharmacological and non-pharmacological management of asthma. Adhering to a long-term plan to keep asthma under control is often problematic, especially in the areas of regular medication use and avoiding environmental triggers. The opportunity to introduce or reinforce helpful behaviors should not be lost, particularly during the inpatient stay.

Other interventions during the inpatient stay could include immunizations against influenza [75], and less orthodox interventions such as the use of acupuncture [76], homeopathy [77], and dietary changes (such as increased fatty acid intake [78]; all of these interventions have been promoted in the past. Despite this, there is little (if any) evidence of benefit from these interventions in the literature and one should be cautious about recommending these approaches – particularly at the expense of other better-established interventions.

All that being said, one unorthodox intervention probably merits further consideration. Almost a decade ago, Camargo and colleagues reported the first prospective data linking obesity and risk of asthma [79]. During the interim, a large number of studies have confirmed this association and linked obesity with poor asthma control, including an increased risk of exacerbations [80]. Although high-quality data are sparse, a recent systematic review suggests that weight loss among obese asthmatics probably leads to improved asthma control [81]. Indeed, the EPR3 guidelines encourage clinicians to start their obese asthmatic patients on a regular exercise program, and to make weight control a part of any long-term asthma management plan [5]. Although this is, of course, a difficult intervention to implement in a busy ED, it is a program that could be started in the inpatient setting – a time of heightened awareness and interest in health matters. Such an approach has been used for cardiovascular disease prevention for decades and we encourage asthma specialists to learn from this example and consider such initiating interventions during asthma hospitalizations.

### SUMMARY

Asthma is a common, chronic, and often debilitating disease. The treatment approaches summarized in this chapter provide hope for reduced symptoms, an early return to activities, and improved quality of life in the sub-acute period after an exacerbation. In addition, combining medication and education interventions provides an opportunity for prevention of future exacerbations. Thus, proper asthma management in all clinical settings, including the ED and inpatient ward, emphasizes the reduction of both impairment and risk [5]. After successful treatment of an acutely ill patient, emergency care should increasingly transition toward the optimization of sub-acute and sometimes chronic asthma care issues. Close collaboration between emergency specialists and chronic care specialists will ensure that asthmatic patients receive the best care possible.

# Pediatric Asthma: How Early Life Events Cause Lifelong Respiratory Disease

**Andrew Bush**

Imperial College of Science, Technology
and Medicine, Royal Brompton Hospital
and National Heart and Lung Institute,
London, UK

## INTRODUCTION

Asthma in childhood is a huge subject, and this chapter is therefore perforce selective in the coverage of the subject. It is assumed that all readers of this book are familiar with the British Thoracic Society (BTS): SIGN guidelines [1], and that most will be in adult respiratory practice, so there will be particular emphasis placed on pediatric issues relevant to adult physicians. The most important precept is not to be tempted to extrapolate from adult studies (which are admittedly often very large, very well conducted, and conclusive *for the relevant population*) into childhood, and still less into the preschool years. An obvious example is long-acting $\beta_2$-agonists (LABAs), dramatically effective in adults [2–4], but the evidence is much less convincing in children [5–7]. It is increasingly recognized that medicines used in children must be tested in children [8]; the disease may be different, pharmacokinetics may be different, and the risk profile is different (e.g. interference with linear growth).

If therapeutic studies in adults may be poorly relevant to children, are pediatric insights of any relevance to adults and their physicians? We are not born into the world as fully formed adults, from the head of our father, as was the Greek Goddess Pallas Athene, but in fact events prior to birth and during infancy are pivotal in determining long-term lung health, a fact under-recognized in many adult respiratory text books. This chapter will attempt to correct this perspective, as well as covering the basics of pediatric practice. More comprehensive accounts of developmental issues, and the management of childhood asthma, have been published elsewhere [1, 9–11].

## DEFINITION OF ASTHMA

It is clear that, in children, asthma is not one disease with a discrete pathology, but many. The best definition, modified from Pediatric Consensus statements [12, 13], is therefore "asthma is most often a diagnosis of exclusion, particularly in preschool children, comprising wheeze and/or excessive cough, accompanied by breathlessness and respiratory distress, which is usually intermittent with periods of remission; other respiratory conditions have to be excluded by clinical history, physical examination, and any indicated special tests." In older children, evidence in support of the diagnosis will be expected to come from demonstration of variable airflow obstruction over time, with treatment, or with a bronchial challenge test; and sometimes with the demonstration of an appropriate phenotype of airway inflammation.

The inclusion of respiratory distress and dyspnea is new to the definition and would preclude the diagnosis of asthma being applied to chronic dry nocturnal cough. Although rarely this can be due to asthma, in most cases it is not (below). Furthermore, since we have no disease-modifying therapies at least in pediatrics (below), there is nothing to be gained by diagnosing asthma at a very early, pre-symptomatic stage, when hypothetically cough might be the first sign of airway inflammation (and in pediatric asthma, but never shown in the general population, there is a relationship between airway inflammation as measured by exhaled nitric oxide [$FE_{NO50}$] [14]), but we cannot modify the progression of the disease.

If it is accepted that asthma is not one disease but many, then it follows that there are different syndromes or phenotypes. This is

particularly important in preschool wheeze. A phenotype may be considered as a cluster of either clinical features or pathological features, resulting from interactions between genes and the environment, which tend to be associated, and which are useful in some way, such as in managing the child or in understanding the mechanisms of disease [15]. There may be overlap between phenotypes, and they may change over time. It may be helpful to consider components of the asthma syndromes or phenotypes to be following [16, 17]:

- Extent and nature of any airway inflammation
- Degree of bronchial hyperreactivity (BHR)
- Extent of persistent, apparently irreversible, airflow obstruction (PAL)

Attempting to dissect out these components may allow a rational treatment plan to be achieved in those children particularly with therapy unresponsive asthma at any age, but also in the preschool years. In the future, more sophisticated factorial analyses [18, 19] may refine these relatively crude phenotypes.

## Airway inflammation

Traditionally, asthma, at least in older children, has been considered as a T-helper $(TH)_2$-lymphocyte mediated, eosinophil driven disease of airway inflammation [20, 21]. However, although undoubtedly well founded in many asthmatic children, the concept that this is the sole inflammatory mechanism has been challenged. Studies in particular utilizing bronchoalveolar lavage (BAL) and bronchial biopsy, and induced sputum, have characterized neutrophilic, mixed cellularity, and paucicellular forms of asthma [22–25].

Recent work in children with severe asthma has shown that, unlike in adult asthma, these cellular inflammatory phenotypes are not stable over time, and, over a 1-year period, fewer than 60% retain the same phenotype [26]. Other unexplored issues in pediatric airway inflammation include the relative importance of luminal and intramural inflammation [27], which correlate poorly, and, completely unexplored, the relationship between proximal inflammation and distal (alveolar) inflammation [28–30]. This last currently requires a transbronchial biopsy; the complication rate of this procedure would make it unacceptable for research in children [31].

## Extent and nature of BHR

This has traditionally been considered as one of the hallmarks of asthma, and the concepts of direct and indirect airway are well established [32]. The traditional model has been that inflammation causes BHR, and that BHR causes symptoms of asthma. This paradigm has been challenged. First, although there is a good correlation between BHR and severity of asthma for groups, there is much overlap between individuals within the groups, and thus for an individual, only the poorest correlation between level of BHR

and asthma severity [33]. There is a very poor correlation between eosinophilic airway inflammation and BHR [34]. Furthermore, therapies can improve inflammation without changing BHR (e.g. anti-IgE monoclonal antibody) [35] and improve BHR without changing airway inflammation (etanercept, the anti-TNF-α monoclonal) [36]. The significance of BHR in infants is discussed later.

## Extent of PAL

This is an important practical consideration; there is no point in escalating treatment if there is no further capacity to dilate the airway. PAL is defined pragmatically as a first second forced expired volume ($FEV_1$) which remains more than two Z- (standard deviation, SD) scores less than normal despite a trial of intramuscular triamcinolone (below) and high-dose bronchodilators; not necessary for the diagnosis, but likely to be a feature, is the absence of any airway inflammation which may be reversible. PAL may be due to anatomical reduction in airway caliber, either antenatal or postnatal; and alteration in airway wall compliance, either as a primary effect on wall structure or due to loss of the alveolar tethering effect (below).

## IMPORTANT METHODOLOGICAL ISSUES IN PEDIATRICS

### Pediatric lung function tests

The study of infant and preschool lung function is a whole chapter in itself, and will not be reviewed here. The numerous techniques available (including rapid thoraco-abdominal compression, the more sensitive raised volume rapid thoraco-abdominal compression, lung clearance index, plethysmography, the interrupter technique, tidal breathing indices and forced oscillation) all have their proponents. They measure different aspects of airway function, with differing sensitivity to abnormality, and it is important to be clear what the chosen technique is actually measuring, and to ensure appropriate normal ranges are used. The developmental perspective is important; $FEV_t$, for example, may not represent the same airway generations at age 15 as it does at age 2 [37, 38]. Conventionally, lung function is expressed as percent predicted. In pediatric practice at least, this should be replaced by Z (SD) scores, so that mean Z score at any age for any parameter is 0, with a range of $\pm 1.96$. This is more informative than percent predicted; 80% predicted may be in the normal range, depending on the spread of the data, but $-2.5$ Z scores is always abnormal.

### Significance of BHR

BHR can be measured in small infants, but this is technically very difficult, and data are far scantier than for conventional lung function. Furthermore, just as $FEV_t$ may

mean different things at different ages, so does BHR. In older children, BHR probably has the same significance as in adults. However, it is likely but unproven that BHR in babies may predominantly be determined by distal airway caliber rather than inflammation, in other words, "reactive" airways are in fact smaller ones, the same degree of constriction causing a bigger signal in terms of airflow obstruction in an airway that started smaller than one of normal starting caliber. Unlike in asthmatic adults, BHR is not necessarily a feature of wheezy infants [39], underscoring that BHR has different meanings at different ages. Supportive of the "anatomical" view of BHR in the newborn period is that neonatal bronchial responsiveness predicted $FEV_1$ at age 10 years (p = 0.03) but had no relationship with wheeze or diagnosed asthma at this age [40].

## The nomenclature of preschool wheeze

The epidemiological phenotypes most commonly used are described below and in Table 65.1. There is a common confusion in nomenclature and thinking between temporal pattern and epidemiological time course of symptoms. Temporal pattern should be described as intermittent (viral) wheeze and multi-trigger wheeze. Either pattern may be transient (disappears by third birthday) or persistent (still present at age 6 years). It must not be assumed that all episodic (viral) wheeze is transient, nor that all multi-trigger wheeze in the first 3 years of life will be persistent. It is likely that these phenotypes, although they have lead to new insights, will prove in the future to be an oversimplification.

## Gene: Environment interactions

Genes do not exist in isolation, but within their environment, which may influence gene expression. There are important gene–environment interactions in the pathogenesis of early onset wheeze, which illustrate an important principle. CD14 is involved in the responses to lipopolysaccharide, and as such, a likely candidate "asthma gene." Previous studies have implicated CD14 in the process of immune switching from $T_H1$ to $T_H2$, and in responses to viral infections [41, 42]. However, results from other previous epidemiological studies were inconclusive, as was

a meta-analysis [43]. However, the CD14/ − 260 C→T polymorphism in the CD14 promoter showed no association with any manifestation of atopic sensitization in the total population, but this masked significant findings in a hypothesis driven subgroup analysis. The promotor polymorphism was associated with higher levels of both total IgE and specific IgE to aeroallergens in children in regular contact with domestic pets, but the opposite relationship, not explained by endotoxin levels, in children in contact with stable animals [44]. Hence, a gene could produce exactly opposite effects depending on the environment, so-called phenotypic plasticity, well described in lower organisms. Thus, it is essential to embark on studies with focused hypotheses involving genes and the environment, if important observations are not to be missed.

## The role of parental genotype

Maternal smoking illustrates another important principle of gene:environment interactions. The glutathione-S-transferase gene is one of those responsible for protecting the organism against oxidative damage. Polymorphisms of this gene in the mother, but not the father, are important determinant of the effects of maternal smoking during pregnancy on fetal airway development [45, 46]; the null polymorphism exposes the fetus to the threat of oxidant damage, and is associated with airflow obstruction in the newborn period. Maternal smoking negatively affects neonatal birth weight and lung function, but the adverse effect of maternal exposure on neonatal birth weight could be modified by the maternal metabolic genotypes, GSTM1 and GSTT1 [47]. Maternal smoke exposure also resulted in reduced birth weight in the offspring of mothers who had any of the aryl hydrocarbon receptor wild-type genotype, the CYP1A1 variant genotype or the GSTM1 null genotype [48].

Thus if as is explained below, lung function at birth is an important determinant of adult lung function and chronic obstructive pulmonary disease (COPD) risk, at least some of the roots of COPD may lie in the proband's mother's genotype, including genes determining fetal susceptibility to the effects of maternal smoking in pregnancy. This area is fraught with difficulty, and at the moment much remains conjectural, but the collection of DNA from the mothers of COPD sufferers, in particular if the proband has

**TABLE 65.1** Wheezing phenotypes in the Tucson study [69, 70].

| | Number (%) | Findings at birth | Findings at age 3 | | Findings at age 6 | |
| | | Lung function | Wheeze | Lung function | Wheeze | Lung function |
| --- | --- | --- | --- | --- | --- | --- |
| Normals | 425 (51) | Normal | − | Not done | − | Normal |
| Transient wheeze | 164 (20) | Reduced | + | Not done | − | Normal |
| Persistent wheeze | 124 (15) | Normal | + | Not done | + | Reduced |
| Late onset wheeze | 113 (14) | Normal | − | Not done | + | Reduced |

+ = Present; − = Absent.

only a relatively minor smoking history, could be a fruitful avenue for future research [49].

<div style="background:#c6d34f;padding:4px;color:white;">

## NORMAL AND ABNORMAL LUNG GROWTH AND DEVELOPMENT IN UTERO

</div>

### Normal lung growth

This large topic has been reviewed in detail elsewhere [50–52]. Of relevance to the present subject is that the airway branching pattern and all airway generations are determined by 16 weeks of gestation, and it is in the second half of pregnancy that neonatal airway caliber is determined. Alveolar development is largely a postnatal phenomenon; there is a rapid growth phase in the first 6 months of life, probably a slower phase for the next 18 months, and thereafter alveoli increase in size, rather than number. However, since alveolar tethering to the airway is an important mechanism for the maintenance of normal airway caliber, failure of normal alveolarisation may also cause airflow obstruction [53]. The formation of the airway vasculature follows that of the airways and acinar vessels that of the alveoli. Thus efforts at improving long-term airway caliber, for example smoking cessation, are still relevant in the second half of pregnancy, and preservation of alveolar numbers in the first 2 years of life is also of particular relevance, in particular in the context of preterm delivery.

### Antenatal adverse influences on lung growth

The major issues are the effects of maternal smoking; maternal atopy; increasingly recognized, the effects of environmental pollution; and obstetric factors which lead to being small for gestational age (SGA), including maternal hypertension of pregnancy. Some, but not all, are amenable to intervention. In considering studies on both ante- and postnatal effects, it is important to consider whether the magnitude is very small, but of interest in generating hypotheses as to mechanisms, or large enough to be the focus of a public health intervention that will be clinically useful in that context.

#### Maternal smoking

Many studies have demonstrated the adverse effects of smoking during pregnancy. The Boston cohort [54] showed that there was early airflow obstruction in the offspring of smoking mothers, more marked in girls rather than boys, and with diminishing effect over the next 18 months. Other studies have also confirmed an adverse effect of maternal smoking [55–57]. Maternal smoking may cause BHR in the newborn [58], especially in those with a maternal history of asthma. It is important to note that smoking cessation in the second half of pregnancy may improve the outcome for the fetus [59].

There are some pathological correlates of the effects of cigarette smoke on the developing lungs. The offspring of smoke exposed guinea pigs have reduced numbers of alveolar attachment points to the airway [60]. This is likely to result in a reduction in airway stability, and increased collapsibility. A study of the lungs of sudden infant death syndrome victims, whose mothers smoked in pregnancy, revealed increased inner airway wall thickness and increased airway smooth muscle [61, 62]. Whether this is a direct effect of smoke, or related to another factor which caused the sudden death, is still conjectural.

Nicotine has been shown to exert antenatal effects on airway wall structure. Nicotine given by subcutaneous infusion to pregnant baboons caused airway remodeling in the pups [63]. There was increased airway wall area per millimeter of epithelium, and upregulation of mRNA for Types 1 and 111 collagen, confirmed by immunostaining, in the airway and alveolar walls. There were also increases in elastin mRNA, but if anything, elastin protein was decreased, but not increased; this counter-intuitive result did not reach statistical significance. The mechanism is probably via the reaction of nicotine with the $\alpha 7$ nicotinic acetylcholine receptor.

Maternal smoking may have immunological as well as physiological and structural effects. There are data showing that maternal smoking leads to lower cord blood IL-4 and IFN-$\gamma$ [64], and increased cord mononuclear cell proliferation to house dust mite [65]. Other cord blood studies showed that maternal smoking was associated with increased IL-13, and reduced IFN-$\gamma$ mRNA responses by stimulated cord blood cells [66]. The Perth group [67] has investigated the effects of maternal smoking on fetal Toll-like receptors (TLRs) and their signaling. Smoking during pregnancy was associated with reduced TLR2 mediated IL-6, IL-10, and TNF-$\alpha$ production. TLR3 and TLR4 mediated signaling of TNF-$\alpha$, but not IL-6, IL-10, and IL-12 was reduced in the infants of mothers who smoked. In terms of TLR9 responses, there were attenuated IL-6 and increased IFN-$\gamma$ responses in the infants of smoking mothers. Thus, smoking may be the link between (a) reduced airway caliber; (b) reduced alveolar tethering of airways; and (c) altered cord blood immune function, which subsequently interacts with effects of respiratory viral infections in infancy. Interestingly, birth order has an effect on cord blood immune responses. The $T_H2$ driven cord blood proliferative response of mononuclear cells to timothy grass, PPD, Concanavalin A and house dust mite was lower with successive pregnancies (including miscarriages, placing the effect likely with events in the first trimester of pregnancy) [65]. In other words, immunologically, the effects of a first pregnancy are more like that of pregnancy in a smoker, rather than a fourth pregnancy. This may be an alternative explanation (rather than the occurrence of multiple viral infections) for the occurrence of less atopy if the child has older siblings, the hygiene hypothesis.

#### Maternal atopy

Infants of asthmatic mothers also have airflow obstruction [56, 57, 68]. Other studies have confirmed an adverse effect of maternal atopy. These findings are difficult to reconcile with the reports of normal lung function at birth in those

babies who will become persistent wheezers, as reported from Tucson [69, 70], many of whom would be expected to have an atopic mother. Whether the differences between the studies are real or a manifestation of population or methodological differences is unknown. However, it is clearly not possible to prevent atopic mothers having babies!

### SGA effects

Two factors complicate the assessment of being SGA *per se* on lung function. The first is the choice of an appropriate control group, since forced expired flows (FEF) are usually normalized to body length. The second is the confounding effects of smoking, probably one of the commonest causes of SGA delivery. Impaired lung function soon after birth has been reported in SGA infants [71], but it seemed that in the subgroup of non-smoking mothers, the changes related only to reduce body length. The subsequent evolution of lung function changes suggested that they were independent of somatic growth [72]. A follow-up study in SGA infants born to non-smoking mothers showed that there was a consistent 9% reduction in FEFs and forced vital capacity (FVC), with no evidence of "catch-up" growth. Although no longitudinal study has followed these infants into adult life, cross-sectional studies have reported reduced lung function in adults and children who were born SGA, suggestive that the effect of SGA delivery, independent of smoking, persists long term [73–75].

### Effects of environmental pollution on the fetus

This is an area of recent and increasing interest. Proof of concept, that environmental pollutants could affect the fetus came with the demonstration that umbilical cord carbon monoxide (CO) correlated with environmental levels [76]. The readout from antenatal pollution studies has been birth weight, not lung function, but as discussed, the two are related. Maternal exposure to particulates ($PM_{2.5}$ and $PM_{10}$), CO, sulfur dioxide ($SO_2$), and nitrogen dioxide ($NO_2$) have all been implicated in reduced birth weight [77, 78]. The insectiside dichlorodiphenyldichloroethylene (DDE) was detectable in cord blood and high levels associated with a later asthma diagnosis [79]. This is an obvious focus for preventive strategies

### Other possible antenatal adverse effects

First trimester invasive procedures (chorionic villus sampling, amniocentesis) may be associated with hyperinflation suggestive of airflow obstruction in the infant [80], although another study suggested no influence of these procedures on wheeze [81]. Maternal hypertension of pregnancy is a risk factor for airflow obstruction [57, 81]. Maternal diabetes is a risk factor for persistent wheeze, antibiotics in pregnancy for maternal urinary infection is associated with transient early wheeze, and antibiotics at delivery for both phenotypes [81] (see Table 65.1 for the definition of these phenotypes). It should be noted that antibiotic administration around delivery might be a marker of maternal chorioamnionitis, which accelerates lung maturation and may thus have long-term consequences on lung function independent of antibiotic use [82]. Another maternal medication effect is that

paracetamol, but not aspirin, intake during pregnancy is associated with asthma, wheezing, and elevated IgE in school age children [83]. The role of diet is unclear; early work has surprisingly suggested that high maternal vitamin C intake in pregnancy may actually increase the prevalence of wheeze in the second year, but not the first year of life. High vitamin E intake [84], and eating apples and fish, in pregnancy may protect against allergic asthma and atopic disease [85], although since no neonatal lung function data were recorded, it is not possible to determine if this is structurally mediated, or by an effect on neonatal immune responses. No intervention study has determined that adjusting maternal diet affects outcomes in the baby.

### Summary: Maternal adverse effects

Maternal smoking is the most important and obvious effect amenable to intervention, followed by air pollution. Paracetamol and antibiotics should be discouraged in pregnancy. Whether dietary manipulation in pregnancy will be beneficial is contentious.

## NORMAL AND ABNORMAL LUNG GROWTH AND DEVELOPMENT EX UTERO

### Epidemiological studies

The Tucson group [69, 70] recruited over 1200 babies and divided wheezing phenotypes in the first 6 years of life into three categories (Table 65.1). They found that transient wheezers had reduced lung function at birth, and although there was catch-up, they still had evidence of airflow obstruction age 6 years. The persistent wheezers had normal lung function at birth, and by age 6 had evidence of airflow obstruction. The late onset wheeze group had no impairment of lung function. These lung function patterns established at age 6 track to age 16 at least [70]. Recently, they have shown that poor lung function at birth tracks into the early twenties irrespective of confounding factors such as wheeze, smoke exposure, or atopy [86], confirming that the first 6 years of life, and especially antenatally, are a pivotal time for the prevention of COPD.

The Perth birth cohort was smaller than Tucson (n = 243 versus 1246), but more detailed physiological measurements were made, including BHR in the newborn period [87]. Their detailed conclusions, based on smaller numbers, were different, but the importance of early life events again emerges. The discrepancies between the two cohorts have yet to be resolved. The Perth group found that the group wheezing between one year and 3 years of life (n = 17, transient wheeze, in the Tucson nomenclature; compared with more than 100 transient wheezers in the Tucson cohort) had *normal* lung function at birth (mainly using a tidal breathing, indirect measure of airway obstruction), but $FEF_{25-75}$ was reduced at age 11. The persistent wheezers (n = 12) had abnormal lung function shortly after birth, and it remained persistently lower than the never wheeze group. Both studies showed that children who

wheezed after age three had no impairment of lung function. In a study of more than 11,000 Sydney schoolchildren, those with a history of wheeze before 2 years of age had small decrements in lung function, supportive of the Tucson findings [88]. Children who were flow limited in the neonatal period (parts of the tidal breathing expiratory flow curve approximated to the forced flow-volume curve) had a trend toward a reduced $FEF_{25-75}$ at age 11 years, again supporting the concept of the tracking of lung function [68, 89].

The Manchester Birth Cohort [90] used the same subdivisions of wheezing phenotypes as Tucson, and measured airway resistance (sRAW) at age 3 and 5. By age 3, persistent wheezers had reduced lung function, and this tracked to age 5. Transient wheezers had normal lung function. sRAW at age 3 could not predict which infants would develop new wheeze in the next 2 years of life. The conclusions were the same irrespective of whether pre- or post-bronchodilator sRAW was studied. It should be noted that sRAW is not a particularly sensitive test to minor degrees of obstruction [91, 92]. These findings have been confirmed in a Dutch cohort, where airway resistance measured by the interrupter technique was higher in persistent wheezers than in normals [93]. They found no effect of transient wheeze on lung function; again, this may reflect the relative insensitivity of the interrupter technique.

Most studies have focused on airway obstruction, with the implication that this is due to airway maldevelopment. However, alternative mechanisms may also be relevant. It is well known that there is interdependence between the airways and the lung parenchyma, with alveolar tethering to the airways being responsible in part for maintaining airway caliber. Alveolar attachment points have been shown to be reduced in number by maternal smoking [60]. This could lead to airflow obstruction without there being a direct effect on the airway itself. Another group, using measurements of input impedance, have suggested that airway wall compliance may be abnormal in wheezing infants. They suggested that compliance, rather than actual caliber, may be the reason for the described lung function abnormalities [94].

Birth weight is an important determinant of lung function [95]. A Norwegian cohort study showed that babies with early tidal breathing lung function below the median were more likely to have a history of asthma and severe airway hyperresponsiveness (AHR) at age 10. There was some evidence of tracking, with early tidal volume indices weakly predicting mid-expiratory flows at age 10. The PIAMA birth cohort study [96] reported on the interactions between birth weight and respiratory symptoms in the first 7 years of life. In accordance with other studies [97–99], they found an increasing risk of wheeze in the first 5 years of life, which declined thereafter, being no longer significant at age 7 years. The novel finding was that smoking in the infant's home increased the effect of low birth weight, such that a 2.5 kg birth weight child had a nearly twofold risk of symptoms compared to a 4.5 kg birth weight child, and in the former, smoke exposure leads to a 12% increase in the prevalence of symptoms.

Studies in adults have extended these observations. A longitudinal birth cohort study of more than 5000 adults has shown that at age 31, each 500 gm increment of birth weight resulted in a 53.1 ml increase in $FEV_1$ and a 52.5 ml increment in FVC [100]. Another study showed a relationship between lung function age 45–50 years and birth weight [73].

There have been two major studies in which BHR was measured in the neonatal period. The Perth cohort of babies had BHR to histamine measured shortly after birth, and increased responsiveness was associated with reduced spirometry, a physician diagnosis of asthma, and increased respiratory symptoms at age 6 [101]. In the second (United Kingdom) study [39, 40], wheezing was categorized as occurring (1) only before the fourth birthday, (2) after the fourth birthday, or (3) never. No relation was seen between neonatal lung function and later lung function, but neonatal bronchial responsiveness predicted subsequent $FEV_1$. Increased neonatal BHR was associated with transient wheeze <4 years, but not with later wheeze. Wheeze after 4 years of age was typical of classical asthma, as it was strongly related to atopy and BHR at age 10.

The Groningen [102, 103] group studied 119 allergic asthmatics for the first time between ages 5 and 19, and followed them up into their 40s. They showed that, at the first visit, low $FEV_1$ and BHR were independent risk factors for low lung function in early adult life. Lower lung function in childhood, and less good evolution of lung function over time, was associated with worse BHR in adult life. Unsurprisingly, young adult asthmatics who smoked had a higher rate of decline in lung function.

The early childhood cohorts overlap a number of others spanning childhood and early adult life. The Dunedin cohort [104] followed over 600 people between the ages of 9 and 26. Their data clearly showed that lung function continued to track over this period, perhaps more in males than females. Pulmonary function was consistently lower in those who wheezed compared with those who did not, and the level of function was clearly set by events prior to recruitment, as the authors themselves recognized. The primary purpose of the Childhood Asthma Management Program (CAMP) study was the treatment of childhood asthma, not lung function tracking, but nonetheless, their data is supportive of this concept [105]. The Melbourne group recruited children age 7 who had either no wheeze, "wheezy bronchitis" (WB; what we would now call episodic (viral) wheeze), or persistent asthma. At age 10, the cohort was enriched by a group of really severe asthmatics. They showed that from recruitment until just below 50 years of age, lung function tracked in all groups, and that the level of lung function was set by early life events prior to recruitment [106]

The next consideration is the rate of lung aging. It has long been known that in the mid-40s, lung function starts to decline from a plateau. The plateau (highest lung function ever) is lower in asthmatics, and the slope of rate of decline is greater in smokers [107]. Recently, patients from the Aberdeen cohort, recruited in 1964 were restudied [108]. They were divided into normals, asthmatics and "wheezy bronchitics," who would now more likely be described as episodic (viral) wheezers. In middle age, the plateau $FEV_1$ is the same in normals and WB, and lower in asthmatics, as expected. However, when rate of decline of $FEV_1$ was studied, both the asthmatics and WB groups were declining at

the same accelerated rate. This finding persisted after controlling for smoking habit and socioeconomic class.

By contrast, another group found that childhood chest illness (pneumonia, pertussis, wheeze by age 7) did not appear to affect rate of lung function decline between age 35 and 45 [109]. Crucially, the earliest age of study was 7 years, and by the time of this study, perhaps unsurprisingly, >90% of participants had dropped out, leaving data on 1156. Their findings are supported by other groups [106, 110], but crucial methodological factors are the drop out rate and likely recall bias at the first interview, when many will have become symptom free (see e.g. [96]). They had previously showed that [111] parents who gave a history of previous pertussis in their child had forgotten the entire episode at the time of the next questionnaire, emphasizing the importance of recall bias.

The most long-term study relied on indirect measurements but is still enormously informative and challenging. Barker's group [112], in a series of seminal observations, analyzed death certificate data in a large number of individuals in widely differing communities, which were classified as county or London boroughs, or urban and rural areas. We know that death certificate data are often unreliable, but if a parameter of poor individual accuracy is measured thousands of times, inaccuracies will cancel out and important correlations which are robust, may emerge, as here. Barker's group found that, across all these communities, there was an extraordinarily close correlation between infant mortality from pneumonia and other respiratory disease, and standardized mortality rate (SMR) for COPD 50 years later. An area with high infant mortality rate would also have a high SMR for COPD 50 years later. Thus, *any* hypothesis about COPD has to take in the importance of early life events if it is to hold up.

## Postnatal adverse influences on lung growth

### Postnatal smoke exposure

The adverse effects of tobacco smoke continue postnatally. The adverse effects have been well previously summarized [113]. Environmental smoke exposure in childhood has effects extending well into adulthood [114]. Living with a smoker before the age of 18 increased the odds of chronic dry cough and, to a lesser extent, phlegm, after the age of 18. The associations were strengthened with higher numbers of smokers in childhood.

There are important gene–environment interactions with regard to smoking, which are still incompletely understood. The postnatal interactions between environmental smoke exposure and GSTM1 and GSTT1 polymorphisms are controversial. In a German cohort [115], only the combination of null polymorphisms in one of these genes, and postnatal exposure to environmental tobacco smoke, resulted in evidence of airway obstruction, whereas in a study from the United States [46], antenatal smoke exposure was thought to be more important. Tumor necrosis factor (TNF) polymorphisms are important; exposure to second hand smoke doubled the risk of respiratory related school absences in children with the TNF-308A compared with the G variant, leading to a fourfold increased risk of lower respiratory tract infections causing school absence [116].

## Respiratory viral infections

The observation upon which the "Hygeine hypothesis" is based incontestable, namely that higher birth order is associated with less atopic disease [117]. The interpretation that this relates to early viral infection is controversial. Evidence of the importance of early viral infections comes from studies in which infants were placed in childcare facilities at an early age. Firstborn infants in this environment wheeze more in the first year of life, but less at 6 years of age and older [118]. There is an important gene–environmental interaction, in that the infants of mothers with asthma do not show a subsequent decline in the prevalence of wheeze [119]. Whether viruses mediate all these effects or there are other factors in the environment of the crèche is not clear.

An important question is whether severe viral or other respiratory infections cause airway obstruction or are a manifestation of it. This is best resolved by the antenatal recruitment of babies into prospective, longitudinal studies. The Perth study showed that decrements in lung function preceded bronchiolitis [120]. A study from Tucson also showed impaired lung function preceded pneumonia [121]. However, there is no doubt that, for example, adenovirus infection leads to chronic severe airway obstruction due to obliterative bronchiolitis in putatively previously normal babies or at least babies with at worst only mild airflow obstruction [122]. The ill-studied nonatopic late onset wheeze phenotype may be related to viral bronchiolitis [123], but in this chapter, there were no premorbid data, and it is not possible to determine whether the severe early infections reported were a marker of preprogramming of airway or immune function, or causative of later problems. Furthermore, the diagnosis of "bronchiolitis" was very loosely based.

Much early work has been on respiratory syncytial virus (RSV) bronchiolitis. One study, with no premorbid measurements, but excellent retention during prolonged follow-up, suggested that RSV bronchiolitis causes asthma and atopic sensitization [124–126]. The conclusions have been criticized, partly on the grounds of choice of control group [127], and other work suggested that post-RSV symptoms in fact gradually improve with time [128]. The COAST study has highlighted that rhinovirus (RV) infection may be more strongly associated with wheeze outcomes in later childhood than RV [129]. The authors rightly point out, though, that they cannot distinguish between at least two important mechanisms (1) recurrent infections lead to airway damage and thus to asthma and (2) infants were already predisposed to asthma because of abnormal cord blood IFN-$\gamma$ or other cytokine responses, and RV infection is just a marker of this preprogramming.

It is obvious that severe viral (particularly adenoviral) infection may cause *de novo* airflow obstruction, but it would be a mistake to forget the antecedent insults which may increase the child's susceptibility to respiratory infection.

Overall, the best evidence is that much of the morbidity of early childhood viral infection is determined antenatally.

## Diet

If oxidative stress is important in lung growth and development, then it might be predicted that increasing dietary antioxidants might be beneficial. In one study, vitamin C, fruit, and magnesium intake was associated with better lung function in mid-childhood [130]. The traditional Mediterranean diet consists of a high intake of fruits and vegetables, predominantly whole grain bread and cereals, legumes and nuts, and olive oil as the main source of fats. In those consuming such a diet, atopy is not uncommon, but wheeze and rhinitis are rare [131]. A cross-sectional study showed that high adherence to this diet had a beneficial effect on the symptoms of asthma and rhinitis. Another group [132] confirmed a protective effect of the Mediterranean diet on chronic severe asthma in girls, and that exercise showed a dose response protection against occasional asthma and rhinoconjunctivitis in both sexes. Another group showed that eating bananas and drinking apple juice from concentrate, but not eating apples, may protect against wheezing [133]. The whole subject of dietary manipulation in the ante- and postnatal periods has recently been reviewed [134]. However, whether intervening to alter diet would benefit lung function has not been shown. A healthy diet is desirable in itself but is perhaps not likely to be hugely beneficial to lung development.

## Medication administration

This is still controversial. One study showed that frequent paracetamol [135] administration to children lead to increased wheezing, and possibly rhinitis and eczema. Studies of the effects of antibiotic administration for respiratory infection are dogged by reverse causation, that is, the antibiotics may have been erroneously given for asthmatic symptoms. Studies of antibiotics for non-respiratory infections are inconclusive, but recent evidence suggests that any association between antibiotic use and subsequent wheeze is weak at best [136]. On general principles, antibiotics should be avoided in childhood unless really necessary, but I doubt that such a policy will have much effect on population lung health.

## Outdoor air pollution

There are adverse effects of outdoor pollution on lung growth in children. $NO_2$, $PM_{2.5}$, acid vapor, and elemental carbon exposure all caused clinically significant decrements in $FEV_1$ at age 18 [137]. This group also showed that regional air pollution, and exposure to traffic fumes, had independent and detrimental effects on lung growth [138]. The adverse effects of ozone, $NO_2$, and particulates on lung growth have been reported from Mexico City. In a study from Leicester, United Kindom, there was a tight relationship between environmental $PM_{10}$, carbon content of alveolar macrophages, and spirometry [139]. However, the evidence that changing the flow of traffic can improve outcomes for childhood respiratory health is at best contentious [140, 141].

## Indoor air pollution: Allergens

There is challenging evidence for the role of allergens in airway development. The Manchester group showed that high house dust mite exposure was associated with airflow obstruction in infancy and stringent mite avoidance was beneficial [142]. The same group showed in adults that house dust mite and dog, but not cat, allergen levels, if high, had adverse effects on airway function and inflammation even if the patient is not sensitized to the allergen, as least on IgE mediated criteria [143]. The implication is that allergens have effects other than by stimulating an allergic response, and there is increasing epidemiological evidence for this [144]. Atopic patients, non-sensitized to cat allergen, still exhibited a dose response worsening BHR with increasing cat allergen levels. One possible mechanism is that allergens cause proteolytic damage to the airway epithelium; and indeed, many allergens are proteolytic enzymes [145]. The effects of allergen reduction are sometimes unpredictable, and high levels may be protective in some circumstances. A detailed description of the important interactions between aeroallergens and environmental endotoxin levels is beyond the scope of this chapter. However, it should be noted that sensitization to allergens in the first 3 years of life is an important marker of wheeze persistence [146]. It is not clear from the literature whether allergic sensitization is best prevented by removing furry pets from the baby's environment, or buying many more. The different effects of pets and farm animals on outlook have been briefly discussed above [44], and the details are beyond the scope of this chapter.

## Indoor air pollution: Others

A study from Poland [147] of indoor air quality based on reported environmental tobacco smoke and type of household heating, and the number of winter months that occurred during the first 6 months of life suggested that a lower level of lung function in preadolescent children can be related to postnatal exposure to indoor emissions in the winter. The findings must be extrapolated cautiously to communities with different indoor heating exposures. Multiple indoor factors, including mode of heating and cooking, may adversely affect the developing lung [148]. Housing issues may be important – moisture damage and mold growth in the living quarters were associated with recent onset asthma in a recent study [149]; however, the role of household molds in the initiation or exacerbation of asthma is still controversial [150, 151].

# The aging lung

It could be argued that the antenatal adverse effects described above are clinically trivial. However, their effects are magnified when lung aging commences. The effects may be twofold. First, the plateau of lung function reached at the end of development may be lower than normal; second, there may be an accelerated rate of decline in lung function. Both may coexist. The effects of childhood events on lung aging have been little studied, but there is sufficient evidence that aging superposed on an abnormal developmental

phenotype or early postnatal wheeze may cause accelerated decline, which presumably will predispose to COPD.

## CLINICAL IMPLICATIONS OF THE PHENOTYPES OF PRESCHOOL WHEEZE

The nature of wheezing phenotypes has been discussed above and in Table 65.1. The obvious clinical implication is that these phenotypes, although useful epidemiologically to determine mechanisms, are of no use to the clinician in practice; only time, not clinical acumen, will determine whether an infant wheezing at 2 years of age will have persistent symptoms. A number of predictive indices have been developed, based on severity of symptoms, and atopic manifestations [152–154]. In general, they are good at ruling out persistent symptoms, but less good at predicting those who will have ongoing problems (in fact hardly better than tossing a coin). In general, severe symptoms by age two, but not one, were the best predictor of asthma at age 10 [154], and were superior to stringent and loose indices based on severity but also atopic manifestations in infancy [152, 153]. At this stage, we do not have disease-modifying interventions, and these indices are of most use for giving prognostic advice to parents.

## ASTHMA AND COPD FROM ANTENATALLY TO OLD AGE

### Introduction

The ideal method of sorting out the effects of early influences on adult disease would be to recruit a large cohort of babies antenatally, preferably preconception, and follow them through until death, making measurements of lung function, airway pathology, infective agents and environmental exposures, both indoor and outdoor. Obviously, no such study exists. The epidemiological data have been summarized previously; this section reviews important pathological and genetic studies.

### Pathological studies

Ethical and practical constraints have limited the number of airway biopsy studies, which can be performed in young children. However, recent pathological data have confirmed the importance of the first 3 years of life. We and others have confirmed the safety of endobronchial biopsy in infants and children [155–158], so if a clinically indicated bronchoscopy is being formed, an airway biopsy for research is legitimate, subject to the approval of the institutional review board, and the agreement of the family [159]. What is not legitimate is the performance of a bronchoscopy just for research purposes [160]. Reticular basement membrane (rbm) thickening is one of the pathological hallmarks of asthma. We have shown that in children with severe asthma, rbm thickening is greater than adult and child controls, and equal to that seen in adults with both mild and severe asthma [161]. Until recently, it was not known at what age the changes developed. We have recently shown in a cross-sectional study that even infants (median age 1 year) who are atopic and have bronchodilator responsiveness have no evidence of eosinophilic inflammation and rbm thickening [162]. However, in a further cross-sectional study in a different group of infants, median age 3, we have shown that the presence of wheeze confirmed on a videotape is associated with both eosinophilic inflammation and rbm thickening [163]. The changes were less marked than those we have shown in later childhood [161]. This pathological data confirms epidemiology in showing the likely long-term importance of events in the first 3 years of life.

### Genetic studies

#### The fetal genotype

The possible role of maternal and fetal genotype has been mentioned in a previous section; in summary, both may lead to important interactions with environmental influences. It is important to remember when trying to determine the effects of polymorphisms in antioxidant genes in COPD that the effects may have been modulated early on, as well as when the subject starts to smoke.

#### COPD genes: Are important clues to be found in antenatal lung development?

The importance of early life events has implications for the hunt for COPD susceptibility genes. It is likely that early genetic effects will be increasingly masked by environmental influences as the child grows up, only to resurface at the time of lung aging. The obvious targets for COPD susceptibility have long been genes related to protection against oxidative stress, and those related to inflammatory pathways. The hypothesis advanced here would open up a completely different avenue to explore, namely genetic polymorphisms related to lung growth and development. There are some confirmatory data connecting genes important in lung growth with those affecting the susceptibility to COPD. This will be illustrated by reviewing the ADAM33, the beta-receptor, the fibroblast growth factor (FGF) and GSTM genes.

ADAM33 was identified as a potential gene for asthma by positional cloning, and has numerous putative effects [164]. ADAM33 is expressed in the developing lung during branching morphogenesis, increases throughout gestation [165], and may have a role in the developmental regulation of airway caliber. Polymorphisms in the ADAM33 have been associated with impaired early life lung function [166]. The Manchester group showed that the SNP F+1 was a determinant of lung function age 3 years. Carriers of the A allele had poorer sRAW at 3 years of age, and AA homozygotes had worse sRAW at 5 years of age, independent of sex, smoking, and allergen exposure. Polymorphisms in ADAM33 are known to be associated with asthma and bronchial hyperresponsiveness in different adult populations [167]. Two studies have demonstrated that ADAM33

polymorphisms are important in COPD. The first demonstrated an association between polymorphisms that were known to convey susceptibility to COPD and rate of lung function decline in the general population [168]. The same group showed that SNPs in ADAM33 also were associated with the degree of inflammation and airway reactivity in COPD [169]. These data suggest a common genetic factor at the start and end of life, suggesting that further probing of this theme might be rewarding.

Another gene linking early lung function, asthma, and COPD is that for the beta-receptor. Although there have been many studies of beta-receptor function in asthma, much less is known about any role in early life. In a UK cohort in whom VmaxFRC and BHR had been measured in the first month of life, the possession of any Glyn 27 allele was predictive of airflow obstruction [40]. The same result was found with any Arg16 allele. In both cases, the association was independent of maternal smoking or atopy. There was no effect of genotype on BHR in either the newborn period or when restudied at age 11 years nor was there any effect of beta-receptor genotype and lung function at age 11; this may reflect the small numbers studied. This was a high-risk population (>80% with a parental history of asthma), and may not be generally applicable. The Perth group [170] found an association between the haplotype arg16gln27 and the prevalence of positive BHR at age 6. The gly16gln27 haplotype was associated with better spirometry at age 6 and age 11. In contrast, arg16gln27 was associated with worse spirometry at age 11. Children with the gly16gln27 haplotype were less likely to have asthma-ever or doctor-diagnosed asthma at age 11. They concluded that haplotypes of beta-receptor polymorphisms were associated with lung function, BHR, and asthma susceptibility in childhood. Another group genotyped the polymorphisms at positions 16 and 27 in >1100 people with a variety of respiratory problems, including asthma and COPD, as well as a control population and found associations with beta-receptor haplotypes [171]. The Arg 16 homozygotes had an increased risk of COPD, asthma, and wheeze. The Glyn 27 homozygotes had a greater risk of asthma and AHR. The Arg16/Glyn27 haplotype was predictive of asthma and COPD, and more respiratory symptoms. Beta-receptor polymorphisms have also been found to be a predictor of persistence of asthma symptoms from childhood into adult life [172] but predict only a small component of long-term prognosis. This is not to say, however, that they may not be of interest in the study of biological mechanisms.

Another illustration of an association between genes important in lung growth and later susceptibility to COPD concerns FGF-1, FGF-2, and their receptor FGF1-R. FGFs are important in lung growth (reviewed in Ref. [173]), and bind to one of four transmembrane, tyrosine kinase receptors FGFR-1 to 4. In an *in vitro* study, human airway smooth muscle cells were shown to proliferate when exposed to FGF1 and 2. *In vivo*, there was cytoplasmic expression of FGF-2 in epithelium, and nuclear localization in airway smooth muscle cells, in COPD patients when compared with controls. There were also elevated levels of FGF-1 in airway smooth muscle cells, and FGF-1, and FGFR-1 in bronchial epithelial cells, in COPD patients as compared with controls [174]. There were inverse associations between $FEV_1/FVC$ ratio and both FGF-2 and FGFR-1 expression in airway smooth muscle. Epithelial FGF-1 correlated with smoking history.

The effects of GSTM polymorphisms in mother and child, and early lung function and symptoms, have been discussed earlier. A study in mid-childhood showed that [175] GSTM1 and GSTP1 polymorphisms are associated with defects in lung growth, particularly in children with asthma. GSTT1 deficiency is also associated with an accelerated decline in lung function, a known risk factor for COPD, in middle aged men, and in another study, a combination of polymorphisms in all three GST genes were associated with accelerated decline in lung function [176]. There is a significant interaction with active smoking. However, the effect of the polymorphisms is independent of smoking history, and thus presumably reflects not later smoke exposure but the antenatal and immediate postnatal effects of this gene on airway growth and development.

In summary, the geneticist looking for COPD susceptibility genes might be well advised to consider genes important in early life events.

## PREVENTION OF ASTHMA AND LATER COPD

### Smoking in the young

The most obviously beneficial measure would be the prevention of smoking in young people. The public health measures of many governments have been ineffectual, although the increasing momentum to ban smoking in the work place is to be welcomed [177, 178]. If we are not to continue to jeopardize the future of our children, we must build on this:

- Have a total ban on cigarette smoking in ALL public places; this has been shown not to increase the exposure to passive smoke in children at home [179].
- Totally ban the display of tobacco products in any commercial site.
- Have a total ban on advertising tobacco, and the depiction of smoking under any circumstances.
- Purchase of tobacco requiring the production of photo-identity.
- Dramatically increase taxes on tobacco, so each cigarette costs at least £25.
- Introduce really severe penalties, including closing down of businesses and imprisonment for those who sell cigarettes to children.
- Test saliva and urine of high-risk children for cotinine, and take evidence of exposure very seriously.

In this way, hopefully we can prevent young women in particular taking up smoking, and smoking throughout their pregnancies.

In addition, a campaign needs to be targeted in antenatal clinics:

- If you smoke during pregnancy, your unborn baby is smoking too.
- This will affect the baby throughout their life.
- Even if you became pregnant without having given up smoking it is not too late; if you give up early in pregnancy, you can avoid harming the baby.
- (Preferably) link maternity benefits to quitting smoking, with objective checks on urine or salivary cotinine levels.

The benefits of a really effective and hard-hitting campaign now will be felt for generations to come. It is now not sufficient to focus just on quitting smoking, because irreparable damage may in the meantime be done to the next generation; preventing the uptake of this addictive drug is needed to prevent future cases of COPD.

## Viral infections?

It is likely that severe RSV infection is a marker for previous damage, not a cause of subsequent problems (above). Admittedly there is some evidence for latent RSV infection, analogous to latent adenovirus infection [180, 181], but whether this is clinically significant awaits further study. At the moment, the likelihood that RSV immunization (even if it could safely be performed) would prevent later COPD is not great. Since RSV infection is virtually universal in the first 2 years of life, and COPD is not universal even in adults who smoke, one would have to postulate other factors in a model whereby RSV was causative of COPD. However, there may be genetic interactions with RSV (polymorphisms in proinflammatory genes for example [182, 183]), and it is possible that there are subgroups of children with anatomical damage, who also have polymorphisms in particular genes, in whom RSV infection may cause an increased likelihood of later COPD, over and above the effects of antenatal factors and the polymorphisms themselves.

Severe adenoviral infections are uncommon in childhood, but the prevention of more mild infections, which may possibly become latent with long-term deleterious effects, may contribute to a reduction in subsequent COPD. The role of other childhood viruses, and mycoplasma and chlamydia, also needs further study. In summary, although there may be a role for viral infection over and above that of airflow obstruction due to antenatal factors, at the moment it seems likely to be minor. We need studies with a clearly focused hypothesis to delineate any possible interactions between genes, environment, antenatal airway damage, and viral infections to move the field forward.

## Nutrition?

Obesity is the current childhood epidemic. The relationship between obesity and respiratory disease is not clear – if you are fat, you will become breathless on exertion, while not necessarily having a lung problem. However, obesity may adversely affect BHR [184], and, in combination with obstructive sleep apnea, cause neutrophilic airway inflammation. There have also been reports on adverse effects of eating "fast food" and the benefits of other dietary manipulations [185, 186]. Clearly, healthy eating is a good thing in its own right, but it is likely only to make a minor contribution to the prevention of COPD.

## Ensuring optimal obstetric outcomes

It may seem even more bizarre to urge that COPD is an obstetric as well as a pediatric disease, but as discussed above, maternal obstetric problems may have long-term effects. Optimal obstetric care is clearly desirable in its own right, but it may have the spin-off of also preventing prematurity and its consequences, and promoting good lung health in term infants.

## DIAGNOSIS OF ASTHMA

All children cough, many are said sometimes to "wheeze" and get breathless, but most children are normal. "Normal" causes of sometimes quite prolonged respiratory symptoms include pertussis and similar syndromes, characterized by paroxysmal coughing, sometimes with a whoop, posttussive vomiting, or color change; "Nursery School Syndrome", usually in firstborn children who are placed early in a child care facility, and get a succession of viral colds, which merge into each other; and prolonged postviral cough. None of these respond to asthma therapy; in my practice, I now spend more time telling parents their children do not have asthma than actually making a new diagnosis. Importantly, the vast majority of children with asthma are diagnosed most appropriately on the basis of history and physical examination, supplemented in the older child with simple physiological tests. More detailed investigation is unnecessary for the vast majority of asthmatic children; if they are contemplated they should be carefully directed.

## History

As discussed in the definition, the hallmark of asthma is breathlessness with either or both of wheeze and excessive cough. The first point to determine is what the family actually means by the word "wheeze." Wheezing due to airway narrowing sounds like a high-pitched, musical whistle, akin to organ music or the wind whistling in chimneys. However, many parents use the same word to describe many other different noises, for example a palpable crackling in the chest, a noise as if the child needs to clear his throat, or even nasal snuffling [187–189]. The studies using a video-questionnaire [190], or objective recording of lung sounds [191], have demonstrated the unreliability of parental recognition of wheeze. Differentiating stridor from wheeze in the tachypnoeic child may be difficult for parents. The significance of these sounds is very different, and time must be spent on the history to determine exactly what is meant. The evaluation of chronic

cough is also notoriously difficult. Coughing is universal in childhood at least at the time of viral upper respiratory infections. There is only poor correlation between objective measures of cough such as diary cards or tape recorders and perception of severity by observers [192, 193]. Ambulatory cough monitoring has been used predominantly in older children [194–196] to document how much coughing is normal, but is not routinely available in clinical practice. Finally, it is important to determine who has the problem; if the *child* makes respiratory noises, but does not have any breathlessness or impairment of quality of life, does the *child* have a problem, or indeed asthma? Having established whether the child truly wheezes, and as far as possible whether there is excessive cough, the next step is to identify the pattern and severity of symptoms. The key distinction in the pattern of symptoms is to determine whether the child has symptoms solely at the time of a viral cold (episodic [viral] wheeze), or additional symptoms in between colds. If the latter, then symptom frequency and triggers should be determined. Specific triggers may include exercise, excited emotional behavior including laughing or crying, dust, exposure to furry pets (the English disease), weather or environmental temperature change, strong perfumes or aerosol sprays, and smoke from cigarettes or open fires. The therapeutic approach to episodic (viral) wheeze is completely different to that to the child with chronic symptoms in between viral colds.

The severity of symptoms should next be determined, both in terms of the disruption to the child and also to the family, in order to ensure that treatment is appropriately focused. The family of a child who coughs intermittently but is not particularly breathless may merely be seeking reassurance that there is no serious underlying disease, rather than seeking a prescription for regular inhaled medication. Conversely, the family of a child who is a so-called fat, happy wheezer may be well aware that their child is not in danger of death, but are very eager for some treatment to try to ensure a good nights sleep. Other factors, which may influence treatment decisions, are a history of atopy in the child or first-degree relatives, which would probably make one more likely to trial prophylactic treatment.

Particularly in the child with symptoms between colds, specific questions which should be asked are summarized in Table 65.2. The upper airway can be the forgotten area of pediatric respirology [197]. Much the commonest cause of chronic cough in the community is the catarrhal child with postnasal drip. Symptoms suggestive of obstructive sleep apnea should be sought, including snoring, apnoeic pauses, restlessness, daytime somnolence, and poor concentration. Adenotonsillectomy may be completely curative of the chronic cough, and prevent the (rare) dangers of nighttime respiratory failure. In general, the earlier the onset of symptoms, the more likely that an important diagnosis will be found. Symptoms from the first day of life should always be investigated; they must be distinguished from symptoms starting at a few weeks of age, which may be due to an asthma syndrome. The mother should be asked whether the problem started literally from day 1 of life. If this is the case, structural abnormalities of the airway should be excluded. If there is prominent and persistent rhinitis from birth (almost inevitably and fatuously diagnosed as the baby being born with a viral cold), then primary ciliary dyskinesia

**TABLE 65.2** Points to seek in the history suggesting an underlying serious diagnosis. A detailed history, targeted towards other respiratory conditions is an essential first step in evaluating the child with non-specific respiratory symptoms.

- Are the child/family really describing wheeze or some other noise?
- Upper airway symptoms – snoring, rhinitis, sinusitis
- Symptoms from the first day of life
- Very sudden onset of symptoms
- Chronic moist cough/sputum production
- Worse wheeze or irritable after feed, worse lying down, vomiting
- Choking on feeds
- Any feature of a systemic immunodeficiency
- Continuous, unremitting or worsening symptoms

(PCD, Kartagener's syndrome) should be considered [198]. The very sudden onset of symptoms is strongly suggestive of endobronchial foreign body. Parents may not volunteer the history, and should be asked specifically whether choking on a foreign body is a possibility [199]. Note that even babies too young to bring their own hands to their mouth may have older siblings who may have pressed small objects onto their face. Possible endobronchial foreign body should be referred by telephone for immediate investigation.

Chronic sputum production or a moist cough when the child does not have a viral cold should always be a cause for concern. It is helpful to distinguish recurrent bouts of cough, usually with viral colds and with cough-free periods between bouts, from chronic continuous wet cough with no periods of remission. There is good agreement between parental reports of a wet cough and the presence of lower airway secretions at fibreoptic bronchoscopy [200]. *A child who has had more than 6–8 consecutive weeks of a productive cough merits further investigation.* Two series [201, 202] have shown that a proportion of such children have chronic bacterial airway infection, with a neutrophilic BAL and a positive bacterial culture, usually with *Haemophilus influenza*. The (yet unproven) assumption is that such children will go on to develop bronchiectasis if not aggressively treated. Causes of chronic pulmonary sepsis such as cystic fibrosis (CF), PCD, and agammaglobulinaemia may need to be excluded. In areas where there is universal newborn screening for CF, it might be thought that this diagnosis will no longer need to be considered. However, mild atypical cases may still be missed by screening; the child may have been born in regions where screening is not performed; and the child may have missed out on screening due to administrative or other issues. Thus, a new diagnosis of CF will be rare, but not non-existent, and diagnostic alertness will need to be increased, not reduced with the advent of screening.

Gastro-oesophageal reflux (GER) is suspected in an infant who is worse after feeds, is an irritable feeder (often arching away from the breast or bottle) and who vomits or possets easily. A therapeutic trial of thickening of feeds, acid reduction (proton pump inhibitor or $H_2$ antagonist) and prokinetic therapy (low dose erythromycin, domperidone) is reasonable on clinical suspicion without further investigation. Choking on feeds, particularly in a child with known neurodevelopmental handicap or neuromuscular disease suggests that incoordinate swallowing due to bulbar or pseudo-bulbar

palsy may be the cause of symptoms. Laryngeal cleft or H-type tracheo-oesophageal fistula may present with symptoms at the time of feeding.

Another pointer to the need to refer is whether there are any periods of remission. Although symptom-free periods do not exclude the possibility of a serious underlying disease, the child who has no days free of symptoms certainly merits critical consideration of alternative diagnoses. Finally, a history of systemic infections or poor weight gain in the context of chronic respiratory disease should never be dismissed lightly.

## Does cough-variant asthma exist?

There is considerable controversy as to whether cough *on its own* can be a manifestation of asthma. There is no doubt that "cough-variant asthma" is greatly over-diagnosed [203]; large epidemiological studies show that *in a community setting*, where by definition the vast majority of children are well, isolated cough is rarely due to asthma and rarely responds to asthma medications [204, 205]. Chronic non-specific cough frequently improves with time and without treatment [206, 207]. However, in a specialist clinic, where a highly selected group of children are seen, children who cough in response to typical asthma triggers, and improve when treated with asthma medications are occasionally seen [208]. My diagnostic criteria are

- Abnormally increased cough, preferably associated with breathlessness and respiratory distress, with no evidence of any nonasthma diagnosis.

- Clear-cut response to asthma medications (measurements of lung function and its variability are mandatory in the child old enough to perform the maneuvers).

- Relapse on stopping medications with second response to recommencing them.

Many children with chronic cough, in fact, have only a non-specific problem and have been shown on bronchoscopic and blind lavage studies to have no evidence of eosinophilic airway inflammation [209, 210]. Follow-up studies show that most will get better over 1–2 years. A few will show evidence of deterioration of BHR over time, wheeze, and develop the picture of classical asthma [211]. If coughing is troublesome and the precautions outlined above are followed, then there is little to be lost attempting a brief therapeutic trial. The only danger is that ineffectual and potentially harmful medication may be continued long term unless a trial off therapy is rigorous. In older children who can perform lung function, there is no justification for a therapeutic trial without making every attempt to document variable airflow obstruction.

## Physical signs

Most often there will be no physical signs. Digital clubbing is an obvious and important sign, but will not be found if not actively sought. My experience has been that children are not uncommonly referred with obvious chronic clubbing which

**TABLE 65.3** Points to seek on examination suggesting an underlying serious diagnosis. Most children will have no physical signs; however, none will be found unless they are actively sought.

- Digital clubbing, signs of weight loss, failure to thrive
- Nasal polyps
- Really severe chronic secretory otitis media, otorrhea
- Moist sounding cough
- Enlarged tonsils and adenoids, prominent rhinitis
- Unusually severe chest deformity (Harrison's sulcus, barrel chest)
- Fixed monophonic wheeze
- Stridor (monophasic or biphasic)
- Asymmetric wheeze or other auscultatory signs
- Crackles, particularly if coarse in a "well" child
- Palpable rattles
- Signs of cardiac or systemic disease

has never been noticed. The upper airway should be inspected for rhinitis, and also nasal polyps the latter being virtually pathognomonic of CF in this age group. The nature and severity of any chest deformity should be noted; although a severe Harrison's sulcus and pectus carinatum can be due to uncontrolled asthma, the more severe the deformity, the greater the likelihood of another diagnosis. The child should be asked to cough as part of the respiratory examination; a wet cough is usually a sign of the presence of lower airway secretions. Palpation of the chest with the palms of the hands during quiet breathing or, in an older child, during blowing or huffing may be a better way of detecting airway secretions than auscultation. Careful auscultation may however elicit unexpected findings such as crackles, fixed monophonic wheeze, asymmetric signs, or stridor, all of which mandate a further diagnostic work up. Finally, signs of cardiac and systemic disease should be sought. Key features to be sought on physical examination are given in Table 65.3.

## Physiology

Although there are many techniques for the measurement of lung function in infants and preschool children, these are largely the provenance of the research laboratory. In the older child, a number of techniques are available to demonstrate variable airflow obstruction. The utility of these tests will depend on the context in which they are applied; a negative result of most of these tests cannot exclude asthma, but the harder it is to demonstrate any variability in airway caliber, the less likely it is that of asthma diagnosis is correct. Possible tests include

- Peak flow or spirometry at rest, with a significant increase after inhalation of a $\beta_2$-agonist. In most asthmatic children, baseline lung function is normal, and so no bronchodilator response could be expected.

- A drop in lung function in response to an exercise test. Field exercise tests are often not very specific, and that the use of controlled laboratory testing is more reliable.

- Home peak flow monitoring for a short period may reveal diurnal variation. The accuracy of these records is often not high when used for monitoring over prolonged

periods, but the accuracy when the purpose is diagnostic may be different.

- A histamine or methacholine challenge may occasionally be useful. If there is no response to the highest dose of challenge agent, then the child's symptoms are most unlikely to be due to asthma. A positive challenge test is not diagnostic of asthma.

## Allergy testing

Allergy testing (usually either skin prick testing, total IgE, or specific RAST tests) can be used (a) to determine if the child is atopic, because if in particular the asthma is thought to be severe, but the child is nonatopic, the diagnosis may need to be revisited; (b) to guide environmental manipulations (discussed later); and (c) possibly to predict prognosis in the wheezy child. Both skin prick tests and RAST testing have the disadvantage of a high false negative rate particularly under age 3. However, if positive, they are likely to be significant.

Atopic status may be clinically obvious in a child with typical flexural eczema. If there is no skin disease, then testing to determine the presence of atopy may be a guide to treatment; most would be more ready to treat an atopic wheezy child with inhaled steroids, although many atopic children will not have airway eosinophilia and will outgrow their symptoms within 2 years even in the absence of anti-inflammatory treatment [212]. Furthermore, even atopic preschool children often respond poorly to inhaled steroids.

A more novel use of allergy testing is to try to predict long-term outlook. One study suggested that a positive RAST to egg was predictive of long-term wheeze [213]. Further prospective studies are needed to clarify whether this or any other allergy test is predictive of prognosis.

## Inflammometry

There have been no formalized studies of the measurement of inflammatory markers in the diagnostic process as there have been in adults. Anecdotally, an elevation in exhaled nitric oxide $FeNO_{50}$ to twice the upper limit of normal [214], or the demonstration of an eosinophil count of $\geq 3\%$ on induced sputum would be considered supportive of a diagnosis of asthma, but there are insufficient data to know the likely positive and negative predictive values of these tests. The role of $FeNO_{50}$ measurements in preschool children is even less clear, and they remain largely a research technique.

## Response to a therapeutic trial

Especially in preschool children, the only way to settle or otherwise the diagnosis of asthma is a therapeutic trial (below). In a child, old enough to perform lung function tests, these should be incorporated as an endpoint, but in general, the diagnosis should not require a trial of therapy. The second indication is in a child known to have asthma to determine the extent of fixed airflow obstruction (discussed in section "Really Severe Asthma").

**TABLE 65.4** Disease which present as recurrent cough and wheeze. These conditions need to be considered and excluded prior to escalating therapy. Most will require referral if suspected in general practice.

- Upper airway disease – adenotonsillar hypertrophy, rhinosinusitis, postnasal drip
- Congenital structural bronchial disease – complete cartilage rings, cysts, webs
- Bronchial/tracheal compression – vascular rings, pulmonary arterial sling, enlarged cardiac chamber or great vessel, lymph nodes enlarged by tuberculosis or lymphoma
- Endobronchial disease – foreign body, tumor
- Esophageal/swallowing problems – reflux, incoordinate swallow, laryngeal cleft or H-type tracheo-esophageal fistula
- Causes of pulmonary suppuration – cystic fibrosis, primary ciliary dyskinesia, persistent bacterial bronchitis [201, 202], any systemic immunodeficiency including agammaglobulinaemia, severe combined immunodeficiency
- Miscellaneous – bronchopulmonary dysplasia, congenital or acquired tracheomalacia, pulmonary edema secondry to left to right shunting or cardiomyopathy

**TABLE 65.5** Investigations to be considered in the child with recurrent cough and wheeze. A selective approach is necessary, depending on what clues have been elicited from history, examination and simple investigations. Most of these tests will be carried out only after referral to a specialist.

- Suspected upper airway disease – polysomnography, RAST or skin prick tests (radiograph of postnasal space is rarely useful), MRI or CT of sinuses
- Known or suspected neuromuscular disease with dysfunctional swallow – speech and language therapy assessment, which may be combined with videofluoroscopy
- Suspected aspiration with normal neurology and no reflux – rigid bronchoscopy to exclude laryngeal cleft and H-type fistula
- Suspected esophageal disease – pH probe, barium swallow, tube oesophagram, oesophagoscopy
- Suspected cystic fibrosis – sweat test, nasal potentials, genotype, stool elastase, three day fecal fat collection
- Suspected primary ciliary dyskinesia – saccharine test, nasal ciliary motility, electron microscopy including orientation studies, nasal and exhaled nitric oxide, culture of ciliary brush biopsy, genetic studies becoming available
- Suspected systemic immunodeficiency – immunoglobulins and subclasses; vaccine antibodies; lymphocyte subsets; lymphocyte and neutrophil function tests; HIV test; referral to Pediatric immunologist
- Suspected structural airway disease – fibreoptic bronchoscopy
- Suspected tuberculosis – Heaf test, fibreoptic bronchoscopy and/or gastric lavage, combined with culture and PCR; ELISPOT
- Suspected cardiovascular disease – echocardiogram, barium swallow to exclude a vascular ring or pulmonary artery sling, angiography
- Suspected bronchiectasis – high resolution CT scan, investigations for local or systemic immunodeficiency

## DIFFERENTIAL DIAGNOSIS OF ASTHMA

This encompasses most of pediatric respiratory medicine, and will not be considered in detail. A summary guide to differential diagnosis is provided in Table 65.4. Confirmatory diagnostic tests, usually performed after hospital referral, for some of these conditions are listed in Table 65.5. These should not be considered as a catalog to be applied uncritically, but only as guided by history and physical examination. More details of individual conditions can be found in standard texts.

## PHARMACOLOGICAL MANAGEMENT OF ASTHMA IN THE PRESCHOOL CHILD

There are two indications for treatment, the immediate relief of symptoms and the prevention of disease progression, in the case of the preschool child from intermittent to continuous symptoms. Prediction of those at high risk for such progression has been discussed above. Detailed evidence based guidelines have been published for all ages, which should be read in conjunction with the commentary below. However, for preschool children, there seems to be a disconnect between knowledge gained from epidemiological and pathological studies, and treatment recommendations.

### General use of medications

Critical in the choice of medication is an understanding of the biological basis for the different phenotypes of preschool wheeze (Table 65.6). These are not mutually exclusive, and indeed, if they coexist in a single individual, the relative contributions may be difficult to unravel. What syndrome, for example, would be diagnosed in an infant who was born prematurely and ventilated for a few weeks, has atopic eczema, developed RSV positive bronchiolitis, and now wheezes only with viral colds? The majority of children either have viral associated wheeze or will eventually turn out to have persistent asthma. These can only be diagnosed in retrospect. However, intermediate phenotypes often confuse the picture, and ultimately, a therapeutic trial may be needed to determine best treatment in such a child.

### Chronic lung disease of prematurity

This should be obvious from the history. Summarizing the studies of airway function, in mid-childhood, survivors of chronic lung disease (CLD) of prematurity exhibit reduced indices of expiratory airway function ($FEV_1$ and indices of flow at low lung volumes); increased bronchodilator responsiveness; and BHR [215]. There is limited evidence for airway inflammation, and little evidence that anti-inflammatory medication is helpful. The long-term importance of this group is discussed later.

**TABLE 65.6** Features of the different pre-school 'asthma syndromes'. It should be noted that overlap syndromes are very common.

| Preschool asthma syndrome | Inflammatory component | Extent of BHR | Extent of PAL |
|---|---|---|---|
| **1**. Chronic lung disease of prematurity | ? (probably none) | + (Probably related to distal airway narrowing) | + (antenatal onset) |
| **2**. Post-bronchiolitis (usually RSV) | ? (probably none) (Some evidence for neurogenic inflammation) | + | + (antenatal onset) |
| **3**. Episodic (viral) wheeze | − | − | + (antenatal onset) |
| **4**. Atopy associated wheeze | + (probably often eosinophilic in later child, not at age 12 months) | + | + (probably antenatal and postnatal onset) |
| **5**. Obliterative bronchiolitis (e.g. post adenoviral infection) | − | − | + (postnatal onsetl) |
| **6**. Non-atopy associated, later onset wheeze | ?present, ?type | Probably present | + (probably at least postnatal onset) |

BHR: Bronchial hyper-reactivity; PAL: persistent airflow limitation; RSV: respiratory syncytial virus. ? = Unknown; + = Present; − = Absent.

### Atopy associated wheeze

It should not be assumed that an atopic baby who wheezes has eosinophilic inflammation [162], although, in particular after the age of 3 years, this may be the case. This group will contain some with airway pathology similar to atopic asthma in older children and adults, but some will have a noninflammatory phenotype.

### Post-bronchiolitic cough and wheeze

RSV is ubiquitous worldwide, and by the age of around 2 years, virtually all infants have serological evidence of infection. Prolonged respiratory symptoms are common after RSV bronchiolitis. It is unclear whether RSV infection causes asthma, merely unmasks an asthmatic tendency, or is not related to asthma at all. There is a lack of proper prospective studies, with characterization of the atopic status of the children before their RSV infection. For example,

atopic children may be more likely to be admitted to hospital with RSV bronchiolitis [124, 216]. In studies of lung function before and after bronchiolitis, it would appear that severe bronchiolitis was seen in those with pre-existing airflow limitation akin to the situation in virus-associated wheeze [120].

Airway lavage studies [217, 218] and autopsy data [219] show that RSV bronchiolitis is a neutrophilic, not an eosinophilic airway disease. In humans invasive studies are not easily performed in the acute phase of RSV bronchiolitis, so it is difficult to know how important eosinophilic inflammation actually is in mild disease. An autopsy study, which by definition would only contain the really severe cases, showed a low number of eosinophils in the bronchial wall [219]. It is also clear from randomised controlled studies that treatment with inhaled or nebulized steroids at the time of RSV bronchiolitis or for subsequent symptoms is ineffective [220]. There is increasing animal and human evidence that neurogenic inflammation may be important after RSV infection [221, 222].

### Episodic (viral) wheeze

Isolated wheezing with colds is not due to an inflammatory airway phenotype, but due to reduction in baseline airway caliber, almost certainly on a developmental basis, discussed in detail above. Postnatal physiological studies have demonstrated that infants who wheeze with colds have evidence of airway obstruction *before the first wheezing episode*. Wheezing with viral colds may not be associated with either BHR [39] or airway inflammation [223]. Those who present in infancy with recurrent, viral episodic wheeze have little likelihood of persistent asthma in later childhood [224, 225].

### Obliterative bronchiolitis

This syndrome is characterized by PAL, absence of BHR and absence of inflammation, usually the result of adenovirus bronchiolitis, or severe reflux and aspiration. Other causes (lung transplant rejection, drug reactions, and collagen vascular disease) are rare or diagnostically obvious.

### Nonatopic, later onset wheeze

Although atopy is a major factor in pediatric asthma, there are children with onset of wheeze in the preschool period or later, who are not atopic by any conventional criterion. This may be more common in developing countries. Little is known of the pathological basis of this group.

## Medications to treat symptoms

The first approach is intermittent therapy at the time of symptom episodes. First line therapy would be with either or both of an inhaled anticholinergic (ipratropium bromide) and a $\beta_2$-agonist (salbutamol, terbutaline). Although by tradition younger infants, respond better to ipratropium, in practice it is worth trying both medications at any age.

If this approach does not work, a trial of a leukotriene receptor antagonist should be considered. A number of studies have shown that viral infection is associated with transiently elevated levels of the cysteneyl leukotrienes [226, 227]. Traditionally, leukotriene receptor antagonists are prescribed continuously, but a recent study has suggested that they are equally efficacious when given intermittently, for at least 7 days with viral colds [228]. Another approach is to use relatively high doses of inhaled steroids just at the time of viral exacerbations, for example budesonide 1 mg twice daily for 5 days [229]. There are no data on combining this approach with a leukotriene receptor antagonist, although this would seem a reasonable approach for resistant cases. However, although there may be benefits from this approach, a recent study also highlighted that high dose even intermittent fluticasone may cause side effects [230]. The final option for intermittent therapy is parent initiated prednisolone. However, this was not shown to be effective in preventing admission to hospital in a large randomised controlled trial [231].

If intermittent therapy is unavailing, what is the role of continuous therapy? If the child is having really severe exacerbations or symptoms on at least a near daily basis even between viral colds, a therapeutic trial may be justified. This will usually be with inhaled corticosteroids; cromones are not effective, and there is no evidence that continuous leukotriene receptor antagonists are any better in this context than when given intermittently. A therapeutic trial may also be justified if there is doubt as to whether the child has a steroid sensitive asthma phenotype; if this is contemplated, it is important to note that many childhood symptoms improve spontaneously, and it is crucial not to confuse changes with therapy with changes over time. Thus a three stage protocol is advised.

- *Step one*: Commence inhaled corticosteroids at a moderate dose, for example budesonide 400 mcg twice daily

- *Step two*: Reassess at 8 weeks. If there has been no response, the child does not have a steroid sensitive phenotype, so treatment is stopped and the trial terminated. If symptoms have disappeared, the treatment is also stopped.

- *Step three*: If the symptoms which previously regressed return, then treatment is restarted. If the symptoms respond a second time, then the child is considered to have a steroid sensitive phenotype, and the dose of inhaled steroids tapered to the lowest which keeps the child symptom free.

It should be noted that, for the vast majority of preschool children, especially under two years of age long term inhaled steroids bring little benefit. Even in a high-risk group, the increased number of symptom-free days/year was not high despite a dose of inhaled steroids sufficient to cause reduction in linear growth [232].

It might be thought that an oral steroid trial, as in older children and adults, might be more appropriate. However, prednisolone will treat upper airway disease, for example adenoidal hypertrophy, which may confuse the issue, so inhaled steroids are to be preferred.

## Medications to prevent progression of airway changes (disease modification)

Clinical experience is that most children with atopic asthma in mid-childhood initially present with intermittent wheeze. Four studies have evaluated whether the early institution of inhaled corticosteroids prevents the progression from intermittent to continuous wheeze. Whether these are administered continuously [232–235] or intermittently just with viral colds [236], they have no effect on disease progression, and are not disease modifying. An initial study suggested that the use of cetirizine may prevent subgroups of children with atopic dermatitis progressing to asthma [237], but this has not been confirmed subsequently (Warner J.O., personal communication). There is an urgent need for discovering new strategies to intervene in the putative window between 12 of age, when there are symptoms but no airway changes, and 30 months, when the first signs of airway inflammation and remodeling are present, in order to prevent long-term morbidity.

### Delivery devices

In the preschool years, the choice lies between a spacer, with a mask in children under age three, or a nebulizer. For all but the most severe attacks of acute asthma, spacers are at least as effective as nebulizers, cheaper, and easier to use [238]. Nebulized, as against inhaled, corticosteroids, are rarely if ever indicated. The proper use of inhalers and spacers is summarized in Table 65.7. If a nebulized therapy must be used, it is essential that a tight-fitting mask is used; if the nebulizer cup is hopefully waved near the infants face, lower airway drug deposition will be exactly zero.

## PHARMACOLOGICAL MANAGEMENT OF ASTHMA IN THE SCHOOL AGE CHILD

### General use of medications

The stepwise approach has been well summarized in evidence based guidelines [1], which are underpinned by the reasonable assumption that the pathology of asthma is similar in adults and children over five [239, 240]. The dangers of extrapolation from adult studies to the pediatric age group have been discussed, and there are, however, important differences in the adult and pediatric literature with regard to response to medication.

### Medications to treat symptoms

The least difficult aspect is that very mild, intermittent symptoms are treated with as required $\beta_2$-agonists. Thereafter there are a large number of unanswered questions:

- How frequently can intermittent $\beta_2$-agonists be given before prophylactic inhaled corticosteroids are prescribed?

**TABLE 65.7** Proper use of spacers in pre-school children.

| Instruction | Comment |
|---|---|
| Shake inhaler between each activation | Multiple activations reduce drug delivery |
| No delay between activating inhaler and applying mask to face | Delay leads to medication being adsorbed onto sides of chamber and not inhaled |
| Do not give to crying infants | There will be no drug delivered to the airways, even though the infant appears to be inhaling deeply |
| Wash (non-metal) spacers weekly with washing up liquid, do not rinse or rub dry | Minimizes medication adsorption onto sides of chamber |

- Should inhaled corticosteroids be started at a high dose, and weaned down (previous set of BTS guidelines [241]) or started low and worked up (current BTS guidelines [1])?
- At what level of inhaled corticosteroids should a second prophylactic agent be added?
- What prophylactic medication should be added to inhale corticosteroids? Should it be long-acting $\beta_2$-agonists, leukotriene receptor antagonists, or low dose theophyllines? Or, should the dose of inhaled corticosteroids be increased further in some children?

It may be that the right approach is to ask, why the asthma has not responded to low dose inhaled corticosteroids? In some, there may be residual BHR, and the best option may be a LABA; in others, it may be relatively steroid resistant eosinophilic inflammation, mandating more inhaled steroids, or leukotriene receptor antagonists; or even, neutrophilic inflammation, which might respond to theophyllines or even macrolide therapy. These phenotypes could be differentiated by simple measurements, such as bronchodilator response, induced sputum, or $FeNO_{50}$. However, this is currently speculative.

A new issue relates to the philosophy of therapy. Should the aim be to suppress every possible symptom of asthma [242], or use flexible, single inhaler treatment with a combination of budesonide and eformoterol [243]? It is not clear in children that big doses of inhaled steroids can suppress all symptoms, even in combination with LABAs, and the risks of side effects are well known. It may be that it is better in the long run to accept that intermittent mild symptoms and a lower dose of baseline medication may be preferable. However, another study has cast doubt on the use of combination therapy in mild asthma in children, suggesting fluticasone alone is superior to either combination therapy or single agent montelukast in at least some aspects of asthma control [244]. The converse approach, single inhaler treatment of symptoms, relies on the ability of the child to detect symptoms and act on them, which may be

questionable. There is a real need for a long-term study comparing these two approaches in children.

## Medications to prevent progression of airway changes (disease modification)

A retrospective, observational study in children suggested that delay of more than >2 years in initiating inhaled corticosteroid therapy may lead to a worse outcome in terms of pulmonary function [245], similar to the findings in a prospective randomised controlled study in adults [246]. However, even in adults, the concept that even mild asthmatics should be treated with inhaled corticosteroids is losing ground [247], and in pediatrics, the CAMP study has also suggested that inhaled corticosteroids do not help preserve lung function. In this study, inhaled corticosteroids, nedocromil and placebo were compared in mild asthmatics over several years. Overall, 75% maintained their lung function, and 25% showed a deterioration. The proportion of deteriorating was the same in each treatment group, in other words, inhaled corticosteroids were not effective in preventing deterioration in lung function [248]. Thus, as with preschool children, we do not have available a truly disease-modifying therapy in school age children.

## Delivery devices

These are covered in standard guidelines. Whatever device is chosen, it is essential that regular checks of technique are carried out in the asthma clinic. If high doses of inhaled corticosteroids are used, spacers are preferable. The special issues of adolescence are covered below.

## NON-PHARMACOLOGICAL MANAGEMENT OF ASTHMA IN CHILDHOOD

Environmental manipulation may be undertaken as part of a program of primary prevention, either in high risk or all populations, or as a secondary attempt to ameliorate the severity of established asthma. Despite research from a large number of cohort studies, it is currently not possible to design a prospective primary cohort intervention study. Specifically, it is unclear whether tolerance should be induced by high allergen exposure, or allergens should be avoided. The dose response effects may be different for different allergens, with, in at least one study, the suggestion that there is a threshold effect, above which there is very little evidence of a dose response [249]. The rest of this section details the measures which might be considered in secondary prevention.

## Environment

### Environmental tobacco smoke

Discouragement of smoke exposure is mandatory. The role of tobacco smoke causing steroid resistance is unequivocal;

it is likely that passive smoke exposure will have the same effects.

### Allergens

Some evidence has been reviewed above. It is clear that *in vitro* high allergen exposure can lead to a state of steroid resistance via an IL-2 and IL-4 mediated mechanism, the exact pathways being controversial [250, 251]. Controlled low level inhaled allergen exposure in sensitized adults, at a dose too low to cause acute bronchoconstriction, still caused worsening airway eosinophilia and deterioration in BHR [252]. Low dose allergen exposure may come from the school; cat allergic children with asthma develop a pattern of symptoms similar to occupational asthma if more than 20% of their classmates are cat owners [253].

Hence, reduction of allergen exposure should be attempted in the asthmatic child, and, the more troublesome the asthma, the more it should be pursued; this irrespective of IgE mediated senitization (above).

### Diet

The search for the food allergy which is the root cause of all symptoms is often something for which parents wish. In practice, the blind use of exclusion diets is rarely helpful, although often attempted by families; occasionally, implementation of a dairy-free diet in a preschool wheezy child may be beneficial. Anecdotally, most successes are in children who have other issues, such as eczema and GER. It is always worth inquiring not only after food allergies, but also whether the child will actually consume milk, eggs, and nuts (including peanuts); allergy may be manifest by an aversion to the food. Food allergy in asthma is managed in the standard way, but erring on the side of caution. Likewise, asthma in the food-allergic is also treated conventionally, but erring on the side of caution. This caution is because there appears to be a higher risk of acute really severe asthma in the food-allergic child, and in particular peanut and milk allergy may be a marker for increased morbidity [254].

## MONITORING ASTHMA

## Physiology

Testing can be used to make the diagnosis, monitor the effects of therapy, and as part of an asthma treatment plan. Diagnostic testing has already been covered.

### Monitoring therapy

Home peak flow monitoring may be useful to try to document the response to therapy and the course of the disease. However, compliance is notoriously poor [255, 256].

### Asthma treatment plans

Changes in therapy may be guided by asthma treatment plans. These, although excellent in theory, may be of rather less practical value than the enthusiasts would have us

believe. Since perception of dyspnea may be a real issue in asthmatics [257, 258], the idea of monitoring health objectively is fine in theory, but in pediatric practice, few comply. It is doubtful whether giving every asthmatic a treatment plan based on peak flow is a useful exercise, but in selected children, families may find this extremely helpful.

## Adverse effects of disease and treatment

All children with any chronic illness should have their height and weight measured accurately and regularly and plotted on a centile chart. Growth failure in asthmatic children may be due to the effects of uncontrolled asthma, treatment with inhaled or oral corticosteroids, or a coincident diagnosis. Recommendations for the monitoring of adrenal function are more difficult. There is no doubt that high dose inhaled corticosteroids may cause adrenal failure and acute hypoglycemic. There is evidence at least from adults that overtreatment, rather than the absolute level of therapy is what is important; in one study, plasma fluticasone levels were much higher for the same dose of inhaled fluticasone in normal adults compared with asthmatics [259]. Theoretically, regular low dose short synacthen tests should be performed in all children prescribed high dose inhaled steroids [260], although the short-term repeatability of this test has been questioned [261]. In practice, the first priority must be to control asthma, with the lowest dose possible of inhaled corticosteroid. Every effort must be made to reduce the dose of inhaled steroid, especially using adjuncts such as long-acting $\beta_2$-agonists, leukotriene receptor antagonists, and low dose theophylline. Families must be warned about possible adrenal failure, children should carry a steroid card, and emergency doctors should consider the possibility of acute hypoglycemic [262, 263].

Other potential side effects of high-dose steroids include hypertension, cataract, diabetes, and osteopenia. In most clinical practice, regular ophthalmic review and DEXA scanning are restricted to children taking regular or very frequent intermittent courses of oral steroids. It is arguable that blood pressure measurements and urinalysis should be part of routine pediatric care in any case.

## Inflammometry

Studies in adults with asthma have established proof of concept that managing asthma simply by history, physical examination, and simple physiology is no longer optimal [264]. The situation in children is less clear-cut; it is highly likely that inflammometry will have a place in selected groups of children, but what should be measured, and in whom, is more debateable.

Potential choices include measurement of exhaled breath (FeNO$_{50}$), with which there is most experience; exhaled breath condensate (EBC), which many consider a technique looking for an application; induced sputum; measurement of BHR; and more invasive techniques such as bronchoscopy, which will never be suitable for clinic monitoring. The characteristics of the ideal inflammometer are

**TABLE 65.8** The characteristics of the perfect ' inflammometer.'

| |
| --- |
| Cheap |
| Easy to maintain and calibrate |
| Completely non-invasive |
| Easy to use, no co-operation needed |
| Direct measurement of all relevant aspects of inflammation |
| Rapid availability of answers |
| Evidence of beneficial clinical outcomes |

shown in Table 65.8, and of course, there is no such device. FeNO$_{50}$ is the most potentially attractive, because it is quick and easy to measure, is even available for home monitoring, and the answer is immediately available. However, the relationship between FeNO$_{50}$ and sputum eosinophils is not a close one, at least in children [27], and the two cannot be used interchangeably. Furthermore, atopy alone, in the absence of asthma, may elevate FeNO$_{50}$. More work is needed on biomarkers of pediatric asthma, but there is sufficient evidence of proof of concept to encourage the researcher to press on with these studies.

## Tailor therapy

An important study comparing standard monitoring with a FeNO$_{50}$ based strategy showed that after a year, the FeNO$_{50}$ group had significantly improved BHR [265]. Another study using BHR as the monitoring tool, rather than an endpoint, also showed improved outcomes [266]. Measurement of BHR as a routine test in a busy clinic is not likely feasible outside a research context. However, these studies confirm that history and simple physiological testing is no longer state of the art.

## Predict natural relapse

It is unlikely that FeNO$_{50}$ measurements will predict a viral infection, although conceivably they may give advance warning in the pre-symptomatic phase. The most likely successful model is loss of control in mono-allergic, pollen sensitized children during the pollen season. If FeNO$_{50}$ measurements were standardized to the child's value when well, FeNO$_{50}$ could give an indication of exacerbation within no $>5$ days of measurement [267]. However, prospective testing of these hypothesis-generating results in the subsequent season were disappointing (unpublished data). It is likely but still not proven that daily measurements, which are now feasible using portable equipment [268, 269], will be more useful than single clinic recordings. More work is needed before these devices can be recommended as a routine in clinical practice.

## Predict relapse on stopping therapy

Guidelines rightly stress that after a period of stability, pediatric asthma treatment should be scaled down. Two studies

have explored whether inflammometry may be useful in the decision making process. In the first, children who on clinical grounds had a reduction in therapy had prior measurement of inflammatory markers. EBC was not useful. Those without detectable sputum eosinophilia always had a successful dose reduction. Receiver operating curves for FeNO and sputum eosinophils were constructed, and both were useful albeit imperfect adjuncts to clinical decision making [270]. In a second paper, a rising FeNO gave an early warning of relapse in children whose therapy had been stopped altogether [271]. Taken together, these studies suggest a role for inflammometry during treatment reduction.

## Inflammometry – what is the role now?

It is clear that inflammometry is rightly here to stay in pediatric asthma. $FeNO_{50}$ seems to be the most promising, but we are a long way from being able to treat an elevation in FeNO with no other indications of any problem. A raised $FeNO_{50}$ may be found apparently constitutionally in completely well individuals [272]. However an acute elevation in $FeNO_{50}$ should prompt a review of management. It may be a sign of an imbalance between pro-asthmatic stimuli (e.g. allergens) and anti-inflammatory therapy (either dose too low or drug delivery device incorrect, or medication not being taken) [273]. The role of home monitoring of $FeNO_{50}$ in pediatric asthma is unclear, and before any widespread introduction, we need more evidence of utility than we had before home peak flow monitoring was widely embraced. The chief needs for the future are more reliable biomarkers of asthma control and impending exacerbation; biomarkers of distal and mucosal inflammation, as well as of airway remodeling; and biomarkers, which can be used in infants and preschool children.

## ASTHMA PLUS

As well as being mimicked by conditions such as GER, asthma may coexist with them, and these comorbidities may worsen asthma control. Thus, part of the management of troublesome asthma should be the search for these conditions.

## GER

The relationship between asthma and GER is controversial. Opinions are polarized between the surgical approach ("all asthma can be cured with a Nissen's fundoplication") to the medical ("GER is irrelevant, and inhaled steroids cure everything"). The following possibilities may be difficult to distinguish

1. Asthma causes GER including by effects on intrapleural pressure and integrity of the lower esophageal sphincter.
2. GER causes aspiration and symptoms that are mistaken for asthma.
3. GER causes lower esophageal acidification without aspiration, which worsens BHR reflexly.
4. GER and asthma are coincident findings.

GER is more likely to be significant in infants, in whom an empirical trial of therapy may have gratifying results. Anecdotally, children with very severe asthma frequently are found to have GER, but treatment has been almost universally disappointing. The only way to sort out the above options above is probably by carrying out a therapeutic trial.

## Rhinosinusitis

The relationship between the upper airway and lower airway is another source of controversy. Whether treatment of allergic rhinitis will improve, asthma is disputed. A large community study suggested that children with BHR and allergic rhinitis were more likely to improve their BHR if the rhinitis was treated with topical corticosteroids [274]. In practice, most would treat any upper airway symptoms on their own merits; any improvement in asthma would be seen as an added bonus. It should be noted that extrapulmonary topical steroid treatments (nose drops, skin creams) may add significantly to the total steroid dose to which the child is exposed [275], and growth failure has been reported just with the use of potent steroid nosedrops [276], so treatment of the upper airway may introduce its own problems.

## Psychological issues

Thankfully, the days when asthma was thought to be due to low moral fiber have long gone. However, there is no doubt that there are complex interactions between the brain and the airway, possibly neurally mediated. In one study, high school students were studied at time of stress (sitting examinations) and during student idleness (mid-term). The same dose of inhaled allergen to which they were known to be sensitive produced a more marked airway eosinophilia during the time of stress [277]. This mechanistic, proof of concept study has been confirmed by a number of field studies, which have documented the associations of poor asthma control, and acute exacerbations of the disease, with psychological stresses of various kinds [278, 279]. In severe asthma in particular, anyone who treats a child as merely a pair of lungs is doomed to therapeutic failure. It is essential to explore issues of stress at home and school, in a sensitive manner, in all but the most straightforward cases of pediatric asthma.

A related and important issues are what may rather simplistically be lumped together as dysfunctional breathing disorders, a spectrum which includes hyperventilation and panic attacks, and vocal cord dysfunction (VCD), in which condition there is adduction of the vocal cords in either or both of inspiration or expiration [280, 281]. These frequently coexist with indubitable asthma. Symptoms of

hyperventilation such as peri-oral paresthesia will be missed if not actively sought. VCD is characterised by noisy breathing, which careful auscultation establishes comes from the larynx, but not from the lower airway. The child may identify that they cannot breathe in, and actually identify the upper airway as the seat of the problem.

Related to this is the "habit" or "honk" cough, a bizarre and very irritating noise, which is stereotyped, disruptive and repetitive. Those who despite the evidence persist in the unquenchable belief that isolated cough is always due to asthma (it very rarely is) may escalate steroid therapy to try to control the problem.

All these disorders have in common that (1) they do not respond to any asthma therapy and (2) the symptoms invariably disappear when the child is asleep (although they may still be present while the child is lying awake in bed, trying to go to sleep). There may be obvious gains for the child, or more subtle advantages. Management first involves identifying the problem, and ensuring the child and family know that the genuineness and significance of the symptoms is not in doubt, but that they are not due to asthma. Sometimes, symptoms may respond to relaxation and breathing exercises administered by a skilled physiotherapist; if the roots of the problem are more deep seated, then the help of a clinical psychologist may be needed. As a general point, if stress and asthma coexist, it is better to treat their both on independent merits, rather than try to unpick which is chicken and which is egg.

Adherence to therapy is a related issue. Only the minority of children actually even collect enough prescriptions to cover their prophylactic medications [282]. Indeed, complete obedience to everything the pediatrician asks may be considered to be pathological! We know that non-adherence is frequent, even when there are really severe problems with asthma. Detecting it is much more difficult. It is safe to assume that children will not admit to non-adherence. A check on the number of prescriptions dispensed, or a home visit may be useful. If the child has been prescribed prednisolone or theophylline, measurement of plasma levels (including serum cortisol in those on prednisolone) may be informative. Finally, I do not diagnose steroid resistant asthma until I have satisfied myself that there is no response to an intramuscular injection of triamcinolone.

If non-adherence is found to be an issue, sensitive exploration of the underlying problems is indicated, rather than a "blame" culture of mutual recrimination. Non-adherence remains one of the important unsolved problems in pediatric asthma; detection and management are exceedingly difficult. Finally, pediatricians should remember that their judgement about adherence is exactly as good as flipping a coin.

## ACUTE ASTHMA IN CHILDHOOD

The management of acute severe childhood asthma has been covered in standard guidelines [1]. Asthma deaths are fortunately rare in childhood, less than 40/year in the United Kingdom. In some, avoidable factors can

be identified, such as failure of the child and family to seek medical attention while giving ever larger and more frequent doses of short-acting $\beta_2$-agonists, or failure of the pediatrician to recognize the severity of the situation or give systemic steroids. In others, there appears to be a sudden unexpected acute deterioration and even in retrospect, there seems little which could have altered the outcome. All children who have survived a really severe attack of asthma should have a detailed re-evaluation of all aspects of their therapy. It is probably this group in whom treatment plans are most useful, although definitive proof is lacking.

Two particular circumstances should be considered in more detail. Those who have survived a sudden and severe attack may be considered for pre-packed, injectable adrenaline (e.g. the Epipen™). Of course, most children have sufficient time to use inhaled therapy, but for those with really sudden deteriorations may anecdotally benefit from this approach. The other scenario is the child with deteriorating asthma who is unable to recognize that things are getting worse, until a late, catastrophic decline ensues. Failure of perception is therefore a mimic of acute rapid deterioration. These children, if they can be persuaded to use it, should have a home peak flow meter and monitor their status objectively and regularly.

## ASTHMA IN SPECIAL CIRCUMSTANCES

### Really severe asthma in childhood

The definition of severe asthma has been the subject of international working groups [283, 284]. There are several different patterns of severe asthma in childhood including chronic symptoms despite high-dose therapy; and brittle asthma, either chronic wild swings of lung function or sudden really acute deteriorations on the background of apparent good control. It is likely that the underlying pathology is very different in these groups.

The commonest causes of therapy resistant asthma are non-adherence to treatment and incorrect diagnosis. Really severe, therapy resistant asthma is rare. We should distinguish "difficult" asthma (in which, when the basics are got right, asthma control is achieved) from "really severe, therapy resistant asthma," in which poor asthma control persists despite optimizing all conventional therapies. We now use a three-visit protocol to assess these children (Table 65.9). Obviously, prior to any such approach, a full diagnostic work up is undertaken, as appropriate. This is particularly important in nonatopic children, in whom an alternative or exacerbating diagnosis is found more frequently.

*Visit 1*: The aim of the first visit is to weed out those asthmatics who are not truly therapy resistant. The child undergoes a full, multi-disciplinary assessment. This includes a visit to the home by the respiratory nurse, a psychological assessment by questionnaire, and a referral to the clinical psychologist if necessary; and contact is made with the school. If not already performed, skin prick tests

**TABLE 65.9** The difficult asthma protocol.

| | Visit 1 | Visit 2 (if no improvement) | Visit 3 (4 weeks later) |
|---|---|---|---|
| **1.** Clinical Assessments | • Asthma control test<br>• Nurse lead home visit<br>• School visit<br>• Access GP records<br>• Psychological assessment as appropriate | • Asthma control test<br>• Assess symptoms, new peak flow diary | • Asthma control test<br>• Assess symptoms, new peak flow diary<br>• Allocate as steroid responder, partial responder, or non-responder on bases of all results |
| **2.** Physiological measurements | • Spirometry including response to $\beta_2$-agonist | • Spirometry, including response to $\beta_2$-agonist | • Spirometry, including response to $\beta_2$-agonist |
| **3.** Non-invasive inflammatory and other markers | • Induced sputum<br>• FeNO (variable flow)<br>• RAST or skin prick tests as appropriate<br>• Measure prednisolone and theophylline levels if appropriate | • Induced sputum<br>• FeNO (variable flow) | • Induced sputum<br>• FeNO (variable flow) |
| **4.** Invasive studies | | • Bronchoscopy, BAL, and bronchial biopsy<br>• Intramuscular triamcinolone<br>• pH study | |

are carried out. Adherence is assessed at the home visit, by checking the availability of medications; GP prescriptions are checked; and use of drug delivery devices is assessed. We found that around a third of children with severe asthma could not produce a complete set of in-date medications during a nurse-lead home visit. Environmental measures are instituted as far as possible. As a result, more than 50% of referrals need no further action.

*Visit 2*: Children who continue to have problematic asthma despite this detailed protocol are further evaluated. They undergo non-invasive measurements of airway inflammation (Table 65.9), and spirometry and bronchodilator reversibility. A fibreoptic bronchoscopy is performed under general anesthetic, with bronchoalveolar lavage and endobronchial biopsy, and an injection of depot triamcinolone administered while the child is still anaesthetized.

*Visit 3*: this takes place 4 weeks later. Lung function and airway inflammation is measured, and the child phenotyped (Table 65.10); an individual treatment plan is developed on the basis of the phenotype. It is clear that therapy resistant asthma is not one disease, but many, but it also has to be said that the utility of the above approach needs further testing.

## Exercise induced symptoms

In most cases, exercise induced asthma is a manifestation of poorly controlled asthma, and should be managed in accord with standard guidelines. Occasionally, exercise symptoms are seen in elite athletes, as the sole problem [285]. They report breathlessness and wheeze at extremes of exercise,

just when they want to reach peak performance, and at no other time. The differential diagnosis lies between exercise induced asthma, and exercise induced VCD; the differentiation may be difficult. True exercise induced asthma in the elite athlete may be a different phenotype from standard poorly controlled asthma. Although one study has suggested that fish-oil may be helpful, in practice this is not much used [285]. These athletes usually come to specialist attention because presport, high-dose $\beta_2$-agonists have failed. Anecdotally, high-dose nedocromil sodium may be useful, and other strategies include montelukast or Symbicort™ prior to exercise. It is absolutely essential that due care is paid to the requirements of the international drug abuse regulations when treating elite athletes. VCD may also be an issue, particularly if the athlete is being pushed beyond capacity. This may be very difficult to identify – sometimes a Bruce protocol exercise test to exhaustion, with measurement of flow-volume loops, may identify the problem. The standard 6 min exercise induced asthma test is useless in these athletes, because for them, it is insufficiently taxing. Anecdotally, both physiotherapy and the help of a clinical psychologist may be useful.

## Adolescent asthma

Normal adolescence is a taxing time for all concerned, and is complicated if there is a comorbidity such as asthma. This big subject has been reviewed in detail recently [286]. The tasks of normal adolescence include establishing increasing independence and autonomy, and, in the context of asthma, taking more responsibility for treatment (or lack of it). Asthma

**TABLE 65.10** Summary of proposed difficult asthma management, at the conclusion of the protocol studies.

| Clinical scenario | Presumptive diagnosis | Suggested action |
|---|---|---|
| 1. Continued airflow obstruction, no inflammation, no reversibility to $\beta_2$-agonists | Presumed obliterative bronchiolitis, or remodeling secondary to chronic inflammation etc. | • Inspiratory and expiratory CT scan if not already performed<br>• Consider viral and autoimmune studies<br>• Use minimum treatment which maintains lung function |
| 2. Continued airflow obstruction, no inflammation, but with reversibility to $\beta_2$-agonists | Presumed steroid resistant, non-inflammatory bronchial reactivity | • Continuous subcutaneous terbutaline treatment<br>• High dose eformoterol by inhalation |
| 3. Persistent eosinophilic inflammation, with either or both of airflow obstruction and symptoms | Presumed steroid partial or complete resistance | • Look for causes of secondary steroid resistance<br>• Treat with either prolonged high dose steroids or steroid sparing agent |
| 4. Persistent eosinophilic inflammation, with no airflow obstruction or symptoms | ?Lagging of clearance of inflammation ?Risk of ongoing remodelling despite no symptoms | • Observe closely with repeated spirometry and non-invasive measures of inflammation |
| 5. Presumed inflammation completely resolved with steroids (normal lung function, no symptoms) | Steroid sensitive asthma, but requiring high dose treatment | • Look for causes of secondary steroid resistance<br>• Taper steroids to level at which symptoms are controlled without side-effects<br>• Steroid sparing agent (often less effective in this phenotype) |
| 6. Persistent non-eosinophilic inflammation | Presumed other inflammatory mechanisms (other cells e.g. neutrophilic inflammation; neurogenic mechanisms) | • Reduce steroid treatment to minimum level needed to control eosinophilic inflammation<br>• Consider macrolide therapy, 5-lipoxygenase inhibitor, or theophylline if neutrophilic inflammation |
| 7. Apparently normal lung function, no inflammation, but ongoing symptoms | Poor symptom perception Psychological problems Not asthma at all | • Exercise test with Borg scale<br>• Review by Psychologist |

? = Possible.

may remit, return or worsen in adolescence, or present for the first time; epidemiological data are conflicting. Diagnosis of a new presenting asthma may be difficult, with atypical presentations such as chest pain being not uncommon. Management may be very difficult. Risk-taking behaviors by adolescents may be considered almost normal, but smoking and substance abuse do not help asthma control. Compliance is almost always an issue; adolescents often do not want to be different from their peers, and will not take medications for this reason. They may worry about adverse effects of therapy; or probably most usually, be too idle and disorganised to be bothered. Control is frequently poor. Management is very difficult, with many theoretically good ideas being trial, which are often very time-consuming, and with very little objective evidence of benefit. Specialist adolescent clinics are advocated, in which teenagers are seen on their own, at least initially without their parents, in an age-appropriate environment. It is believed that a non-directive, non-threatening approach is optimal, with negotiation over what treatment is reasonable. Others like this author merely hope to weather the storm until adulthood is reached, whereupon the young person is referred to the calm waters of the adult clinic!

## THE "NEW" COPD: SURVIVORS OF PREMATURE BIRTH

The skills of neonatal intensive care mean that ever more premature and smaller babies are surviving to go home, and many can be presumed will survive into adult life. The nature of CLD (bronchopulmonary dysplasia, BPD) is also changing, with probably a greater component of alveolar hypoplasia in more recent, very preterm survivors who have received very different ventilatory strategies [287, 288]. Follow-up studies have recently been reviewed in detail [215]. In summary, survivors of CLD are likely to have combinations of airflow obstruction and alveolar-capillary hypoplasia. There is a tendency for improvement of the symptoms and physiological abnormalities in later childhood. The issue that needs attention is what will happen during lung aging, and what follows is surmise, because yet we have no data. By analogy with the episodic (viral) wheezers, who also have early airflow obstruction, an accelerated rate of decline is to be anticipated, and these children are likely to present to adult clinics perhaps as young as in their thirties. The first to arrive

will be the "old" BPD patients (relatively big babies, ventilated at slow rates with high pressures, who did not receive surfactant in the newborn period); next, or perhaps simultaneously because they may be younger, "new" BPD survivors, who may have less airflow obstruction and more alveolar-capillary hypoplasia. They will present likely as "COPD" but the significance of their dramatic early life events will not be appreciated unless a good history is taken. These may well provide novel challenges in the COPD clinic of the future.

# Treatment for Stable COPD

Stephen I. Rennard

Pulmonary and Critical Care Medicine,
University of Nebraska Medical Center,
Omaha, NE, USA

## INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is, for most individuals, a relentlessly progressive disorder, a feature which is recognized in the definition of COPD included in the Guidelines prepared by the Global Initiative for COPD (GOLD) as well as the American Thoracic Society and The European Respiratory Society [1, 2][1]. "Stable" COPD, therefore, is an incorrect term, which is generally applied to individuals who are in their usual state of deteriorating health, that is, not experiencing an acute exacerbation. While the current therapies available to treat so-called stable COPD only partially meet therapeutic goals, these therapies can often offer considerable benefit. It is likely that many patients with COPD, however, are undiagnosed and even those with a diagnosis are inappropriately under treated. The current chapter will outline the current therapeutic strategy for the management of COPD patients who are "stable," that is in their usual state of health.

The medications used to treat patients with COPD are, in many cases, identical to those used to treat patients with asthma. The strategy for the use of these medicines, however, differs importantly between COPD and asthma. Effective patient management, therefore, requires that the clinician make an appropriate diagnosis, accurately stage the severity of disease in an individual patient, and define clearly therapeutic goals. The pharmacology relating to individual classes of drugs is provided in detail in accompanying chapters as is information relating to non-pharmacological

treatments. The current chapter will describe the overall strategy for the use of these treatments in various stages of COPD.

A number of guidelines are available for COPD management. Global guidelines for the diagnosis and management of COPD resulted from the collaboration of the World Health Organization and the National Heart Lung and Blood Institute, USA, the Global Initiative for Chronic Obstructive Lung Disease (GOLD Guidelines) [2]. A number of professional societies including the American Thoracic Society and the European Respiratory Society [1] as well as a number of national organizations have also prepared guidelines for the diagnosis and the management of COPD. These guidelines are generally consistent with the GOLD guidelines, but often emphasize issues relevant for specific populations or health care systems.

## DIAGNOSIS AND STAGING

Airflow limitation is a characteristic feature of both asthma and COPD. In asthma, the airflow limitation is generally reversible either spontaneously or with treatment. In COPD, in contrast, there may be some degree of reversibility, but expiratory airflow limitation, to some extent, is always present (see Chapter 41). Some definitions of COPD have specifically excluded patients with airflow reversibility [3]. This has led to considerable confusion as bronchodilators are first-line therapy for patients with COPD (see below).

In clinical practice, the distinction between COPD and asthma is often a difficult one for several reasons. Some patients with

COPD may have a considerable degree of reversibility. Such individuals have *both* COPD and asthma, and asthma can progress to the development of fixed airflow limitation [4, 5]. Nevertheless, defining whether asthma and COPD are each present is more than semantic; the therapeutic plans for asthma and COPD differ in important respects and each needs to be addressed and maintained properly.

There are multiple therapeutic goals for the stable COPD patient (Table 66.1). As COPD progresses, the relative importance of the various therapeutic goals change. Appropriate management of the COPD patient, therefore, requires an accurate assessment of disease stage and, as is increasingly recognized, thorough diagnosis of comorbidities. Current staging of COPD depends on quantitative assessment of expiratory airflow to grade disease severity. Since airflow limitation can result from several distinct physiologic processes (see Chapters 5 and 34), this parameter represents an integration of several distinct processes. In addition, many of the features of COPD are very weakly related to the $FEV_1$ (see below). An accurate staging of the COPD patient using $FEV_1$, however, can serve as an initial guide to therapeutic intervention and can help the clinician determine appropriate therapeutic goals.

## The GOLD staging system

The GOLD Guidelines represent an attempt to develop generally applicable guidelines for COPD and, of necessity, balance a number of factors [2]. The objectives of GOLD include increasing the awareness of COPD among health care professionals, health care authorities, and the general public, stimulating research and improving the diagnosis, management, and prevention of COPD.

## GOLD staging

Both the diagnosis and staging of severity in the GOLD system are based on spirometric assessment of $FEV_1$.

Stage 1. Mild: $FEV_1/FVC < 0.7$, $FEV_1 > 80\%$ predicted. While population differences are well recognized, expiratory airflow is generally considered to be normal if greater than 80% predicted. An individual starting at 100%,

therefore, can lose up to one-fifth of their expiratory airflow and remain within the normal range. Early in the development of COPD, however, lung volumes frequently increase due to loss of lung elastic recoil [6]. As a result, the vital capacity is relatively well preserved. This makes the ratio of $FEV_1/FVC$, termed the Tiffeneau Index, a more sensitive measure of early COPD. Stage 1, therefore, recognizes the earliest physiologic abnormalities as a reduction in the $FEV_1/FVC$ ratio, while the $FEV_1$ remains within the normal range (that is greater than 80% predicted).

Because the $FEV_1$ declines with age more rapidly than the FVC, however, the use of the fixed ratio will result in an increased diagnosis of individuals with COPD with increasing age [7, 8]. This potential for overdiagnosis of mild COPD that would occur in the elderly was not felt to be a practical problem for the clinician, particularly as therapy is largely driven by symptoms.

Stage 2. Moderate: $FEV_1/FVC < 0.7$, $50\%$ predicted $< FEV_1 < 80\%$ predicted. This stage includes patients with reductions in expiratory airflow beyond the normal range but generally excludes those likely to have respiratory failure.

Stage 3. Severe: $FEV_1/FVC < 0.7$, $30\%$ predicted $< FEV_1 < 50\%$ predicted. Severe COPD is intended to indicate patients who are likely to require a high degree of support, may have increasingly frequent exacerbations. Severe patients are appropriate for increasingly aggressive therapeutic interventions. The care of these patients is a major determinant of overall health care expenditures for COPD.

Stage 4. Very severe: $FEV_1/FVC < 0.7$, $FEV_1 < 30\%$ predicted, or $FEV_1 < 50\%$ predicted with concurrent respiratory failure. These individuals are very likely to need ICU management and are candidates for aggressive treatment including surgical options, if appropriate.

The GOLD Guidelines emphasize early diagnosis and early physiologic staging. While many patients in the early stages of COPD may not present to the physician with complaints, often these individuals may be experiencing alterations in their lifestyle suggesting that therapeutic interventions designed to improve performance and reduce symptoms might be appropriate. This approach is supported by data from the National Health and Nutrition Examination Survey (NHANES) Study suggesting that nearly two-thirds of adults in the United States with airflow limitation have never been diagnosed [9]. More than half of these individuals, moreover, report some symptoms suggesting a significant burden results from undiagnosed disease.

Current guidelines do not recommend screening of asymptomatic individuals for COPD [2, 10]. However, many COPD patients will be "asymptomatic" despite severe physiologic limitation [11]. A careful and aggressive history, therefore, is needed in order to determine which patients should be further evaluated with spirometry to establish a diagnosis and to stage severity by $FEV_1$.

## Limitations in current COPD staging

It is widely recognized that many features of COPD correlate very poorly with the $FEV_1$ [12, 13]. Several investigators

have suggested multidimensional staging systems for COPD which could independently stage features in addition to $FEV_1$ [14, 15]. The BODE index, which combines a dyspnea measure, body mass index, and walking distance with $FEV_1$ is a better predictor of survival than is $FEV_1$ alone, and has been found to be an effective measure of outcome for clinical interventions [16–18]. One analysis using a dataset from a clinical trial [14] suggests that as many as six dimensions may be relatively independent clinical features in COPD (Table 66.2). Several large trials with less homogeneous groups of COPD patients are being conducted with the intent of characterizing the heterogeneity of the disease [19, 20]. Thus the clinician must recognize that the GOLD COPD staging, while useful as a guide to therapy (Fig. 66.1), is not a complete clinical description. GOLD staging, therefore, must be supplemented with careful clinical assessment. The following therapeutic strategies are based on this approach.

**TABLE 66.2** Potential independent dimensions for assessment of COPD patients.

## Comorbidities

It has become clear that COPD is a multisystem disorder (see Chapters 44 and 45). Often disease outside the lung is a major clinical problem. Appropriate clinical suspicion is required for appropriate diagnosis of these conditions (Table 66.3).

# THERAPEUTIC GOALS IN COPD

## Prevent disease progression

The risk factors which contribute to the development of COPD are discussed in detail in Chapter 34. Exogenous risk factors for the development of COPD include cigarette smoking, air pollution, viral and bacterial infections, nutritional deficiencies, and diseases that can affect lung development. Airways hyperreactivity is also a risk factor, which may depend on an interaction of exposures and genetic factors. It is likely that a number of genetic factors will influence the development of COPD (see Chapter 4). The best characterized of these is severe deficiency of $\alpha$-1 protease inhibitor.

## Cigarette smoking

The major means to prevent disease progression in COPD is to eliminate relevant risk factors. Far and away the most important risk factor is cigarette smoking [21]. Addressing cigarette smoking, therefore, is the most important measure to prevent disease progression. The problem of smoking is best addressed within the context of a comprehensive program designed to prevent smoking initiation and to encourage and facilitate smoking cessation [22, 23] (see Chapter 47). Other approaches, for example harm reduction strategies, may play a role but cannot at present be advocated due to lack of supporting data [24].

While social- and community-based approaches to the problem of smoking are essential, it is equally important for the clinician to recognize and appropriately treat the medical aspects of cigarette smoking. The vast majority of smokers are addicted, and nicotine is the major addicting component in cigarette smoke. Smoking, therefore, is most correctly regarded as a chronic disease, which is characterized by frequent remissions (quit attempts that succeed for varying lengths of time) and relapses. In this context, COPD can be regarded as one of the many secondary consequences of the primary disease: smoking.

Smoking should be addressed with every COPD patient on a regular basis. Nonsmoking patients who have developed COPD must be counseled not to begin as they have already demonstrated their unusual susceptibility. Former smokers should be regularly interviewed and counseled in order to anticipate and prevent relapse. Relapse, for example, is common at times of stress and is often associated with concurrent use of alcohol [25]. Finally, COPD patients who continue to smoke should be counseled and encouraged to make quit attempts which can then be properly supported.

A defeatist attitude toward smoking cessation in COPD patients is clearly unwarranted. Smoking cessation can be achieved in COPD patients as documented in several studies [26, 27]. When COPD patients quit, moreover, it is likely that benefits ensue. In one study, symptoms of cough and sputum production were greatly reduced among smokers who quit [28]. The frequently reported complaint that smoking cessation is associated with an increase in cough, therefore, does not appear to be supported among the majority of smokers. The Lung Health Study [26], moreover, in a large

**FIG. 66.2** Benefits of smoking cessation. Individuals with mild COPD who quit smoking initially improve lung function then decline at a rate similar to that estimated for nonsmokers. In contrast, continuing smokers decline at an accelerated rate. Reproduced from Ref. [26] with permission.

randomized prospective trial, clearly demonstrated that when smokers with mild COPD quit, the accelerated rate of loss of lung function, which characterizes these individuals normalizes (Fig. 66.2). In the first year after quitting, lung function improves slightly among quitters. After a year of stability, lung function decline resumes, but the rate of decline resembles much more closely that of nonsmokers rather than that of smokers with mild COPD. This study, therefore, clearly demonstrates that progressive lung function loss can be slowed in COPD by smoking cessation. Whether such benefits would accrue in more severe disease where the pathophysiologic processes may be different remains to be determined. Nevertheless, smoking cessation must be considered a therapeutic goal of prime importance for all patients with COPD.

Several therapeutic strategies are effective in helping smokers quit. These are presented in detail in Chapter 47. Behavioral interventions which can be as brief as a few minutes of personalized practical advice can increase quit rates several fold above the spontaneous quit rate [22]. Increasing the intensity, duration, and number of sessions can increase behaviorally based quit attempts [29]. Several medications are available that can increase success with quitting: five formulations of nicotine replacement therapy and bupropion increase success of quitting about twofold. Varenicline increases success more than threefold. (see Chapter 47 for details in the use of these medications). Current guidelines recommend that each smoker be given combination treatment with non-pharmacological support and pharmacotherapy to assure that each quit attempt has the highest possible likelihood of success [23].

## Pharmacologic interventions in continuing smokers

Current concepts suggest that smoke-induced inflammation leads to tissue damage and structural alterations causing

airflow limitation in smokers. Agents that modify these pathophysiologic processes are plausible candidates for reducing lung function loss. Unfortunately, no therapeutic intervention based on these concepts has yet been found to alter lung function loss in COPD sufficiently to warrant a clinical recommendation that it be used for this purpose.

Several studies have assessed the effect of inhaled glucocorticoids lung function loss based on the rationale that, as anti-inflammatory agents, they may mitigate inflammation-induced lung damage [30–32]. None of the studies was able to show a statistically significant effect on lung function loss. Meta-analyses have suggested a small effect, although whether it was statistically significant depended on the type of analysis [33, 34]. The TORCH trial, which was a 3-year study of more than 6000 subjects designed to assess the effect of intervention on COPD mortality, also assessed serial $FEV_1$ [35]. This large trial was able to demonstrate a statistically significant effect on the rate of lung function decline of inhaled fluticasone (42 ml/year), inhaled salmeterol (42 ml/year), and of the combination (39 ml/year) compared to placebo (55 ml/year) [36]. Whether these improvements in the rate of lung function loss are clinically important is not established. However, if sustained for a number of years, this difference in rate would represent a substantial clinical benefit.

The Lung Health Study [26], in addition to evaluating smoking cessation, also evaluated the anticholinergic bronchodilator ipratropium based on the concept that airways reactivity is a risk factor for the development of COPD. While ipratropium had a bronchodilator effect and, therefore, acutely improved airflow, it was completely without effect in altering the progressive loss of lung function. The dose of ipratropium used, however, may have been suboptimal. A 1-year trial with the long-acting anticholinergic bronchodilator tiotropium suggested that lung function might be preserved by this drug [37]. This has led to the UPLIFT trial, a very large 4-year trial evaluating the effect of tiotropium on lung function loss [38]. At the present time, this study has yet to report its results.

## Pollution

Indoor and outdoor air pollution as well as exposures to dust and fumes in the workplace are recognized risk factors for the development of COPD [39–42]. It is reasonable to counsel COPD patients regarding these risks, although specific therapeutic interventions to mitigate the risks associated with air pollution have not been assessed. In particular, episodes of worsening pollution, particularly those associated with particulates, are associated with increased exacerbation rates and increased mortality [43], especially the risk of death from cardiac events [44]. Cautioning COPD patients about acute exposures to traffic pollution would seem reasonable.

## Infections

Infections in childhood have been suggested to contribute to COPD pathogenesis [45, 46]. To date, no specific antiviral strategies have been assessed to alter COPD natural history. Colonization of the airways with bacteria and acute infections with viruses in adulthood, however, are believed to contribute both to acute exacerbations and, possibly, to progressive lung function loss [47]. It is reasonable, therefore, to advocate vaccination for influenza and for pneumococcus. Whether these will affect progressive lung function loss, however, is not known.

Exacerbations of COPD (see Chapter 67) have been associated with a modest increase in the rate of lung function decline. Both long-acting bronchodilators and inhaled glucocorticoids can reduce exacerbation rates. Whether this accounts for the modest beneficial effect on lung function loss noted above remains to be determined.

## Alpha-1 protease inhibitor

Severe congenital deficiency of alpha-1 protease inhibitor (A1PI, formerly termed alpha-1 antitrypsin) is a major risk factor for the development of COPD (see Chapter 4). Deficient individuals are at increased risk for developing emphysema at an early age, particularly if they smoke. Deficient individuals can also develop airways reactivity and chronic bronchitis [48]. Purified A1PI is available for intravenous infusion. Definitive, controlled, randomized trials with A1PI have not yet been done although two are currently in progress. Two registry studies, however, suggest that alpha-1 antitrypsin replacement may slow lung function loss [49, 50]. One smaller prospective-controlled trial also showed a trend in favor of replacement based on CT scan [51]. Replacement is now recommended by the Canadian Thoracic Society [52]. As only a subset of alpha-1 deficient patients will develop COPD, current recommendations are that therapy be offered only to individuals with evidence of compromise of lung function. Therapy is not recommended for continuing smokers as cigarette smoke can inactivate A1PI. The currently available products are purified from pooled human plasma. The product is relatively expensive and, while it is tested for HIV and hepatitis, has the potential for transmission of disease. Therapy requires intravenous infusions generally given at weekly intervals. Interestingly, replacement therapy may also be associated with a reduction in acute exacerbations in deficient individuals [53].

## Comorbidities

Awareness of the comorbidities that may be associated with COPD (Table 66.3) is essential to assure that appropriate preventive therapies are initiated (see Chapters 44 and 45). In particular, interventions can successfully reduce the risk of acute cardiac events, osteoporotic fractures, venous thrombosis, and regular exercise can help prevent loss of muscle strength.

## RELIEF OF SYMPTOMS

## Dyspnea

The primary strategy to improve symptomatic dyspnea in COPD patients is based on the concept that symptoms are

secondary to compromised lung function. Improvement in lung function, therefore, is the proximate goal, with improvement in symptoms the desired consequence. To this end, bronchodilators represent the first-line symptom-based pharmacologic intervention in COPD. The connection between bronchodilation and dyspnea relief, however, is likely indirect. There are several factors which contribute to dyspnea [54, 55] (see Chapter 5). It is likely, however, that in COPD the major determinant of dyspnea is increased inspiratory work [56, 57]. This work depends in part on airway caliber and bronchodilators, by improving airflow might have some benefit. A more important determinant of inspiratory work, however, is likely dynamic hyperinflation which develops in many COPD patients with increasing respiratory rate [58, 59]. This mechanism likely accounts for the marked increase in dyspnea on exertion experienced by COPD patients who may be relatively asymptomatic at rest. This also likely accounts for why many COPD patients have greatly restricted activity levels, that is inactivity has been adopted to reduce the risk of dyspnea.

Pulmonary rehabilitation, which does not improve lung function, likely improves both exercise tolerance and dyspnea, in part, because it permits COPD patients to exercise with less tachypnea and, therefore, with less dynamic hyperinflation (see Chapter 5).

Bronchodilators also may reduce the dynamic hyperinflation [60] and thus contribute to reduced dyspnea by a mechanism not directly reflected by the measurement of airflow, for example $FEV_1$, at rest [61]. The strategic use of bronchodilators in COPD differs fundamentally from the strategy with which they are used in asthma. In asthma, the basic strategy is to prevent episodes of bronchoconstriction with the use of anti-inflammatory agents. Bronchodilators are used only when this approach fails. Dyspneic COPD patients in contrast, will always have significantly impaired lung function. Bronchodilators, even if they are of limited effectiveness, by virtue of improving lung function, have the potential for reducing dyspnea. For this reason, bronchodilators are first-line therapy in the treatment of symptomatic dyspnea in COPD patients, and they are most often used on a regular basis. Paradoxically, therefore, bronchodilators are of higher priority in COPD than in asthma even though COPD patients will, in general, have a more modest response to bronchodilators. It is likely that the optimal use of bronchodilators is when they are combined with a rehabilitation program [62] (see below).

## Bronchodilators: Choice of drug and formulation

Several classes of bronchodilators are available and, within each class, there are several agents and formulations available. The pharmacology of these agents is discussed in detail in Chapters 48–50.

The magnitude of the bronchodilator response achieved in most COPD patients is relatively modest and is generally in the range of 100–300 ml improvement in the $FEV_1$. This response is similar to the improvement in airflow achieved in normal individuals given bronchodilators and may represent inhibition of "normal" airway tone. The

modest improvement achieved, however, is relatively more important the more severe the airflow limitation. That is, a 300 ml improvement for an individual with a 4 liter $FEV_1$ represents a 7.5% improvement. This would generally not be regarded as a positive response. The same improvement, however, for an individual with a 1 liter $FEV_1$ would represent a 30% improvement and would be a very gratifying clinical response. A number of definitions have been used in order to characterize responders to bronchodilators among COPD patients. Despite the definition used, however, the number of patients showing a response increases as the disease becomes more severe likely because the modest improvements are more meaningful when they are added to a relatively more severe baseline lung function [63].

Bronchodilator response among most COPD patients is distributed as a single normal distribution [64]. The response of a given patient, moreover, is, to some degree, variable [63]. Most likely this reflects varying airway tone, as the pre-bronchodilator $FEV_1$ is more variable than the post-bronchodilator value [65]. This means that it is not strictly correct to classify patients as bronchodilator-responsive or nonresponsive. Patients who have a marked bronchodilator response and who normalize their lung function should be considered as likely having asthma. Patients who have a very modest response, however, may still derive considerable clinical benefit from bronchodilators, and bronchodilator therapy should not be denied based on pulmonary function testing in a laboratory setting. This is particularly true as the effect of bronchodilators in reducing hyperinflation is likely of more importance in reducing dyspnea than the direct effect on airflow.

Current guidelines do not recommend any specific bronchodilator as being superior as an initial therapeutic choice. Clinical studies suggest that response to individual drugs can be highly variable. In the set of clinical trials of over 800 COPD patients tested with the β-agonist albuterol and the anticholinergic ipratropium, 25% responded (with at least a 200 ml or 12% improvement in $FEV_1$) only to albuterol, 25% responded only to ipratropium, 30% responded to both, and 25% responded to neither [66, 67]. The choice of an agent, therefore, should depend on a number of factors including local availability and cost, the ability to provide adequate support for training in the use of devices required and, importantly, on individual patient response both with regard to efficacy and side effects (Table 66.4). The GOLD Guidelines recommend that, when possible, bronchodilators be administered via an inhaled route [2]. This offers an increase in the therapeutic index, thus maximizing benefit compared to side effects. Inhaled medications, however, may not be appropriate for some individuals. Oral agents, however, are generally more convenient and, in some populations, have a higher degree of acceptability and such agents should be considered by the clinician for selected patients.

When utilizing bronchodilators, the most appropriate strategy is for the clinician to accurately diagnose and stage each patient, initiate therapy, and then to gauge response. Spirometric assessment of airflow will provide objective measures to complement clinical assessments of the individual patient. More sophisticated physiologic assessment such as exercise testing or lung volume measurement is not

recommended as a routine. It is appealing to quantify the response of hyperinflation by measuring the inspiratory capacity before and after an exercise challenge, for example, with a 6-min walk test, however, this is not currently standard of care, and the degree to which such a strategy will impact clinical care is not established [68].

For patients in whom the clinical response is suboptimal, several issues should be addressed. First, for individuals using inhalation devices, assurance that the device is being used correctly is essential. Several studies suggest that with both metered dose and dry powder inhalers, patient compliance with proper technique is poor and deteriorates significantly with time [69–72], although dry powder inhalers are generally regarded as easier to use. Continual patient education in the use of these devices, therefore, is required. Wet nebulizers are not believed to have any benefits over hand-held devices for most patients [73, 74]. These devices require maintenance and cleaning and do not offer the convenience of portability. Nevertheless, many patients prefer them [75, 76], and they may be particularly beneficial for subjects with altered mental status, in those whose inspiratory flow rate is too low to permit effective inhalation, or in individuals who, in other ways are unable to use hand-held devices [77]. Some patients may prefer wet nebulizers as they are often better reimbursed by health care providers than other formulations.

If the medication is being taken correctly and clinical response is unsatisfactory, it is recommended that bronchodilators of several classes be combined. Combinations of anticholinergic and short-acting β-agonist bronchodilators can be taken as separate inhalers, or these medications can be administered together in the same device [78–80]. The combination device results in better bronchodilation and a slightly prolonged duration of effect [81]. While administration as a combination decreases the ability to regulate the dose of individual components, combination inhalers have achieved a high degree of patient acceptance likely due to both their increased convenience and the improved efficacy that likely accompanies both improved compliance and dual pharmacological benefits. A variety of anticholinergic/β-agonist combinations

have been evaluated, and the combination always appears to offer benefits [82, 83]. Interestingly, when ipratropium was combined with salmeterol, the benefits of a single combined inhalation persisted for the entire 12 h of monitoring, despite the fact that the ipratropium, which is generally believed to have a 4–6-h duration of action was not re-administered [84]. Similarly when tiotropium was administered with once daily formoterol benefits were observed that exceeded the 12-h duration expected of the formoterol [83]. These observations are suggestive of potential synergies between anticholinergic and β-agonist bronchodilators. In addition, both anticholinergics and β-agonists can be combined with theophylline [85, 86]. Finally, inhaled corticosteroids (see below and Chapter 51) can also be combined with bronchodilators with increased clinical benefit.

Most COPD patients will have progressive disease. It is likely, therefore, that as disease worsens, bronchodilator therapy will have to be intensified. This suggests that most COPD patients will, eventually, be treated with combination therapy. It also suggests that empirical clinical trials assessing the therapeutic benefit of bronchodilators should be repeated in an organized fashion on a regular basis as disease progression occurs.

## Frequency of use/duration of action

Short-acting bronchodilators can be used on an as-needed basis for episodic dyspnea in COPD patients. This "rescue" use, however, is more appropriate for the treatment of asthmatic patients who experience episodes of severe bronchospasm. Patients with COPD are always airflow limited, and episodic dyspnea is more likely related to episodes of increased exertion. Episodic treatment after the fact with a short-acting bronchodilator, therefore, is less likely to be of benefit than is regular maintenance therapy with bronchodilators [87]. Short-acting bronchodilators, even when taken on a regular basis, result in lung function which will be increasing and decreasing throughout the day. In practice, regular use of short-acting agents was not better than PRN use [88]. For this reason, there may be significant advantages in the use of long-acting bronchodilators in patients with COPD. Not only are these agents more convenient, but they also avoid periods of bronchodilation interspersed with relatively poor airflow (Fig. 66.3). Long-acting bronchodilators are recommended for regular use in the GOLD Guidelines.

Perhaps more importantly, long-acting broncodilators reduce the frequency of acute exacerbations (see below).

## Glucocorticoids

Glucocorticoids are not bronchodilators. Nevertheless, they may result in a modest improvement in lung function and can, therefore, be considered for patients who do not have an adequate response to aggressive combined bronchodilator treatment. The recommendation made in former guidelines suggesting a 2-week trial with oral glucocorticoids to determine responsiveness [89] was not supported in a clinical trial [32]. Oral challenge is no longer recommended.
**FIG. 66.3** Comparison of bronchodilator response to a short-acting bronchodilator (ipratropium) given every 6 h with a long-acting bronchodilator (salmeterol) given every 12 h. While the maximal bronchodilator effects are similar, the long-acting agent provides more consistent bronchodilation throughout the day. Reproduced from Ref. [66] with permission.

If glucocorticoids are to be given on a trial basis to improve lung function in COPD, inhaled medication is the preferred modality. A clinical trial of 3–6 months may be required and care must be taken to assure adequate compliance before the trial is deemed unsuccessful [32]. The response to glucocorticoids, in terms of $FEV_1$ improvement, however, is likely to be modest. The large trials assessing the effect of glucocorticoids on COPD natural history noted an improvement compared to placebo of about 50 ml [90, 91]. Caution should be taken if the decision is made to discontinue inhaled glucocorticoid therapy, as discontinuation of the medications may be associated with precipitation of COPD exacerbation [92]. As noted above, inhaled glucocorticoids have a modest effect in reducing the rate at which lung function is lost; the use of inhaled glucocorticoids to reduce the frequency of acute exacerbations is discussed below.

## Pulmonary rehabilitation

Pulmonary rehabilitation can also help control symptoms of dyspnea (see Chapter 58). It is likely that rehabilitation can help control symptoms of dyspnea by several mechanisms [93]. First, regular conditioning may decrease the psychological anxiety, which may amplify the subjective perception of the symptoms. In as much as anxiety contributes to tachypnea, this may exacerbate dynamic hyperinflation. Second, improved training may decrease oxygen requirements and, therefore, the increased ventilatory requirements associated with exercise. Finally, it is likely that conditioning allows patients to exercise with a reduced respiratory rate and, therefore, with less dynamic hyperinflation which in turn. Whatever the mechanisms, rehabilitation can contribute greatly to improved symptom control and functionality in COPD patients [93].

In a highly informative study, subjects who received the bronchodilator tiotropium improved exercise tolerance more than those who received placebo [62]. All subjects then received rehabilitation, which was much more effective than tiotropium alone. However, the effect of rehabilitation was greater in subjects treated with tiotropium than in those treated with placebo, suggesting a true synergy between these modalities. This is consistent with the concept that the bronchodilator permitted exercise to greater degrees of intensity, due to reduced dynamic hyperinflation. The exercise at higher levels of intensity, in turn, permitted more effective rehabilitation [62]. Independent of the mechanism, this study supports the approach of optimal bronchodilator therapy combined with rehabilitation to achieve the best clinical results.

While rehabilitation is widely recognized as an important therapeutic intervention for subjects with severe COPD, exercise training is likely important for individuals with milder disease as well [93, 94]. As noted above, many COPD patients deal with symptoms of mild dyspnea on exertion during the early phases of their disease by decreasing their level of activity. This "strategy," however, likely contributes to the severe deconditioning which characterizes COPD patients and likely contributes to their functional compromise. Maintaining a high level of exercise activity in mildly affected patients, therefore, should be an important therapeutic goal. Appropriate use of bronchodilators in order to optimize lung function and thus permit regular sustained activity at a high level can, therefore, be appropriate in patients with relatively mild disease. Long-acting bronchodilators may be particularly important in order to permit a sustained high level of activity throughout the day. As many patients may be "asymptomatic," the clinician should specifically inquire about changes in activity levels, which may be very insidious over time.

## Narcotics

As COPD progresses, symptoms of dyspnea can become severe despite maximal functional support. Opiates, likely through a central action, can decrease the subjective perception of dyspnea. These drugs carry significant hazard as they can also significantly depress ventilation and lead to $CO_2$ retention. They may also suppress cough and may lead to retained secretions. Any subjective effect on dyspnea is not accompanied by an improvement in exercise tolerance [95–99]. The use of opiate narcotics, however, in end-stage COPD may be considered as a potential palliative measure for individuals suffering from severe dyspnea [2]. In this context, the use is analogous to the use of these medications in the control of severe pain for patients with other terminal illnesses recognizing that the predictable adverse effects of the medications may be acceptable in order to relieve suffering. If used for this purpose, systemic administration is generally recommended as administration via inhalation has been demonstrated to have no significant advantages [95, 97, 100].

## Surgical interventions in COPD patients

Two surgical options have been suggested for COPD patients: pneumoreductive surgery and lung transplantation (see Chapter 59). Pneumoreductive surgery, by removing

areas of relatively nonfunctioning lung in individuals with severe emphysema and hyperinflation can restore the ability of the chest and diaphragm to function as a bellows thus improving function [101–103]. The therapy is most effective in individuals with localized disease, without severe limitation in diffusion capacity and who do not have a beneficial response to maximal medical treatment [104]. In these selected individuals, significant improvement in symptoms and survival have been observed in a controlled randomized trial [104]. This surgery should be distinguished from bullectomy in which isolated nonfunctional bullae are resected. Recent attention to pneumoreductive surgery has re-emphasized the advantages of bullectomy as well, and the availability of CT scanning to define the presence of such lesions has created surgical options for an increasingly large number of COPD patients.

Transplantation can be offered to COPD patients when appropriate. As COPD is, however, generally a disease which progresses with age and as many patients are or have been smokers who have concurrent comorbidities, most patients with COPD are not appropriate candidates for pulmonary transplantation at the present time. For selected individuals such as those with A1PI deficiency, this may represent an important therapeutic option, although whether transplantation improves survival for COPD patients in general, at present is unclear [105, 106].

### Cough and sputum production

Cough and sputum production are often major complaints disturbing patients with COPD. As noted above, these symptoms correlate poorly with $FEV_1$ and may be present in individuals with normal lung function where they can serve as an indicator of disease risk. Management of cough and sputum, however, represent important clinical goals for the COPD patient. Despite the very long history of drugs designed to treat cough and sputum [107], no therapeutic interventions are currently available which have been demonstrated to have sufficient evidence to recommend their routine use [2].

Despite the lack of evidence for their benefit, a number of mucoactive agents in use in various countries are often popular. One large trial evaluated *N*-acetyl cysteine, which has both antioxidant and mucoactive actions for its effect on COPD exacerbations and $FEV_1$. No clinical benefits were observed [108].

A number of preparations are able to suppress cough likely through a central mechanism [109]. Opiates are particularly potent in this regard. Regular use of these medications, however, is not recommended due to concerns that suppression of cough can lead to retention of secretions and increased risk for infection [2].

### Treatment of weakness

COPD patients are frequently bothered by symptoms in addition to cough, sputum, and breathlessness. Weakness is a major feature of COPD. This may, in part, be due to the deconditioning, which characterizes COPD patients. In addition, weakness may result from alterations in skeletal muscle which are secondary to the disease process itself [110, 111]. Weakness in COPD patients, moreover, is a

better correlate of exercise performances than is $FEV_1$ [13, 112]. Therapeutic agents which increase muscle mass are available, but have not yet demonstrated clinical benefit in COPD patients and are not currently recommended [2, 93, 113]. Nevertheless, there are several important considerations for the clinician. First, drugs that could contribute to weakness, particularly systemic glucocorticoids, should be avoided. Second, adequate nutrition should be maintained, particularly at times of intercurrent illness when catabolism may be high and lean muscle mass may be at hazard. Finally, activity levels should be kept high, with or without the benefit of an exercise training program.

### Antidepressants

COPD patients are frequently depressed. Whether depression is a consequence of the chronic illness or represents a manifestation of the disease process is undetermined. It is interesting, however, that endogenous depression can increase the risk of an individual to become a smoker and to remain a persistent smoker. Such individuals, of course, would be at risk for developing COPD. As the disease progresses, they may manifest their underlying depression. As depression can sometimes be exacerbated by cigarette smoking cessation, smoking cessation attempts may also unmask underlying depression in these individuals. Close clinical observation should be maintained. If depression develops, an accurate diagnosis and treatment with an appropriate antidepression regimen should be initiated. This may be essential not only in optimizing patient function, but also in preventing smoking relapse.

Depression may have other, indirect effects complicating the management of COPD [114]. Depressed patients are less likely to be compliant with medications, particularly those such as inhalers which require attention to detail to assure proper use. Depressed patients, moreover, are less likely to comply with an exercise program. Mortality is higher among depressed patients [115]. Treatment of depression, therefore, may improve compliance with other aspects of disease management. Conversely, a successfully implemented exercise program can greatly reduce depression [114].

## Other management issues

### Health status

With the availability of standardized instruments to assess health status (sometimes termed "quality of life"), it has become clear that COPD patients experience symptomtology in a number of quantifiable domains [116, 117]. While groups of COPD patients show a reasonable relationship between $FEV_1$ and health status, for individual patients, the relationship is very weak [12]. It is reasonable, therefore, for health status to be regarded as a separate therapeutic goal in COPD. Several bronchodilators including ipratropium [64, 66], salmeterol [66, 118], and formoterol [119] have shown improvements in health-related quality of life using these instruments. To date, no drug has regulatory approval for this specific indication, however. Improvement in quality of life, however, should not be regarded as a surrogate

for physiologic improvement. Health status measures reflect a variety of inputs, and it is likely that information gained from the use of these measures can help the clinician more effectively develop a strategy to utilize medications. Health status instruments are probably not helpful for clinical management of an individual patient. Recognizing that a number of domains can improve and that they may improve independently, however, can encourage the clinician to continue therapy when spirometric improvements are modest, but a patient relates individual benefit.

Several studies have suggested that therapeutic interventions may slow the rate of decline in health status [32, 35, 93]. Whether this is due to a reduction in exacerbation frequency or severity, an improvement in functional capacity or to another mechanism remains to be determined.

## Prevention of exacerbations

As noted above, inhaled glucocorticoids and long-acting bronchodilators reduce exacerbation frequency in COPD [91, 120]. The mechanisms for these effects remain undetermined, but short-acting bronchodilators do not appear to have the same benefits. Although, reduction in exacerbations with therapy with the antioxidant *N*-acetylcysteine was supported by meta-analyses [121, 122], a large prospective randomized trial failed to demonstrate an effect [108]. The immuno-stimulator OM-65 also has been shown to have an effect in reducing the severity of exacerbations [123].

Prevention of exacerbations represents a therapeutic goal distinct from improvement in lung function. This has important clinical implications. If therapy is initiated in order to prevent exacerbations, it will, generally speaking, be impossible for the clinician to gauge whether therapy in an individual patient has been beneficial. That is, patients are likely to experience a small number of exacerbations on an irregular basis. Whether exacerbation frequency is decreased in response to therapy, therefore, may be extraordinarily difficult to gauge in an individual patient. For this reason, when therapies are initiated in COPD patients, clear therapeutic intent should be defined by the clinician. Initiation of bronchodilator therapy to improve symptoms should be reassessed and therapy modified based on functional and clinical (symptomatic) response. Initiation of therapy for exacerbation prevention, in contrast, is likely to be continued life long, barring the onset of adverse side effects.

## Prolongation of life

It is frequently stated that oxygen therapy is the only treatment in COPD which has clearly been demonstrated to prolong life. The incorrect implication of this often-quoted (and correct) statement is that other treatments for COPD do not prolong life. Fortunately, several interventions have shown promise in this regard.

Several studies demonstrate the life-prolonging effect of oxygen (see Chapter 54). The first, the MRC trial, compared no oxygen with nocturnal oxygen in hypoxic COPD patients with evidence of right-heart failure [124]. Oxygen supplementation at night time significantly prolonged life. A study conducted under the auspices of the NIH in the United States compared continuous oxygen therapy (actually administered about 19h/day on average) and found superior survival compared to oxygen administered at night time only [125]. These two studies, which have been supported by several subsequent studies, have led to our current practice of oxygen administration.

Several subsequent studies have also evaluated survival in hypoxic COPD patients [126–128]. These studies, interestingly, show a progressive improvement in the survival of hypoxic COPD patients. While there are a number of potential reasons to explain this historic trend of improving survival including changes in diagnosis (with enrollment of milder patients with a better prognosis), with better concurrent care of non-COPD comorbidities or with more effective utilization of oxygen therapy with current devices, it is also possible, even likely, that some improvement in survival is due to current management of COPD compared to that available 20 years ago [129].

Several studies have utilized mortality as an endpoint for interventions in the management of stable COPD. The National Emphysema Treatment Trial (NETT) (see Chapter 59) demonstrated a survival benefit for selected patients who received volume reduction surgery compared to medical therapy and, conversely, a survival benefit for other patients who received medical therapy [104]. The TORCH trial was designed to prospectively assess survival of a glucocorticoid/long-acting β-agonist combination versus placebo. A 17.5% reduction in the risk of death was observed, although this did not reach the prespecified level of statistical significance ($p = 0.052$) [35]. The UPLIFT trial, which is currently in progress, will assess the effect of tiotropium on mortality. A problem with these large trials is that, over time, there is significant drop-out of the placebo group, many of whom subsequently take the study drug, which is generally available. As a result, these studies have a design bias against demonstrating a benefit of the intervention [91]. In addition, a number of retrospective analyses have suggested improved survival in patients treated with inhaled glucocorticoids [130, 131]. Nevertheless, in the absence of a prospective randomized trial demonstrating a benefit, current guidelines do not indicate a survival advantage for pharmacotherapy [2].

## Comorbidities

COPD is associated with a number of comorbidities (Table 66.3, and Chapters 44 and 45). While many of these are common problems that may be associated by chance, there is increased prevalence in COPD. Further, while these conditions share etiologic factors such as smoking, the associations appear to be present even when "adjusted" for smoking status. The association of COPD and cardiac disease, moreover, is present even among nonsmokers [132].

Comorbidities need to be properly diagnosed and treated as this represents reasonable medical care. Interestingly, however, there may be other benefits. Previous recommendations were that β-blockers be avoided in COPD. Perhaps because of the cardiac comorbidity, the use of β1 selective agents has been found to be of significant benefit in COPD patients [133]. Further, retrospective database analyses suggest a reduction in COPD-related complications among patients treated with statins [134–136], and possibly a reduction in the rate of lung function

decline [137]. The association of comorbidities raises the interesting possibility of shared mechanisms that may be addressed by specific therapies. The evaluation of comorbidities and the reasons for their association with COPD will be an active area of research in coming years.

## End of life issues

COPD is a relentlessly progressive disease. Patients, therefore, will deteriorate and, as the disease progresses, will be increasingly likely to experience episodes of respiratory failure. These episodes may require implementation of invasive and heroic measures such as mechanical ventilation (see Chapter 57).

In communities where such treatments are available, they can frequently be life saving, at least over the short term. Prognosis for COPD patients, however, is limited once respiratory failure has ensued. In one study, patients hospitalized with a $PCO_2$ of greater than 50 experienced a 2-year mortality of 49%. Thus, while many individuals will survive for extended periods following episodes of respiratory failure many will not (see Chapters 57 and 67). As disease worsens, the concerns of patients and caregivers, which include functional limitations and concerns about oxygen, are somewhat different from those of health care providers [138]. Finally, whether heroic measures should be initiated and to what degree such measures should be extended are issues which should be discussed with COPD patients in advance. Obviously, such decisions are always subject to reconsideration. Nevertheless, careful attention toward preparing advance directives can frequently expedite the delivery of appropriate care as COPD progresses.

# Acute Exacerbations of COPD

**Jadwiga A. Wedzicha**

**Department of Respiratory Medicine, University College of London, London, UK**

## EPIDEMIOLOGY OF COPD EXACERBATION

There has been considerable recent interest into the causes and mechanisms of exacerbations of chronic obstructive pulmonary disease (COPD) as COPD exacerbations are an important cause of the considerable morbidity and mortality found in COPD [1]. COPD exacerbations increase with increasing severity of COPD. Some patients are prone to frequent exacerbations that are an important cause of hospital admission and readmission, and these frequent exacerbations may have considerable impact on quality of life, disease progression, and mortality [2] (Fig. 67.1). COPD exacerbations are also associated with considerable physiological deterioration and increased airway inflammatory changes [3] that are caused by a variety of factors such as viruses, bacteria, and possibly common pollutants. COPD exacerbations are commoner in the winter months and there may be important interactions between cold temperatures and exacerbations caused by viruses or pollutants [4].

Earlier descriptions of COPD exacerbations had concentrated mainly on studies of hospital admission, though most COPD exacerbations are treated in the community and not associated with hospital admission. A cohort of moderate-to-severe COPD patients was followed in East London, UK (East London COPD study) with daily diary cards and peak flow readings, who were asked to report exacerbations as soon as possible after symptomatic onset [2]. The diagnosis of COPD exacerbation was based on criteria modified from those described by Anthonisen and colleagues [5], which require two symptoms for diagnosis, one

of which must be a major symptom of increased dyspnoea, sputum volume, or sputum purulence. Minor exacerbation symptoms included cough, wheeze, sore throat, nasal discharge, or fever (Table 67.1). The study found that about 50% of exacerbations were unreported to the research team, despite considerable encouragement provided and only diagnosed from diary cards. But there were no differences in major symptoms or physiological parameters between reported and unreported exacerbations [2]. Patients with COPD are accustomed to frequent symptom changes and thus may tend to underreport exacerbations to physicians. These patients have high levels of anxiety and depression and may accept their situation [6, 7]. The tendency of patients to underreport exacerbations may explain the higher total rate of exacerbation at 2.7 per patient per year, which is higher than that of previously reported by Anthonisen and co-workers at 1.1 per patient per year [5]. However in the latter study, exacerbations were unreported and diagnosed from patients' recall of symptoms.

Using the median number of exacerbations as a cutoff point, COPD patients in the East London Study were classified as frequent and infrequent exacerbators. Quality of life scores measured using a validated disease-specific scale, the St. George's Respiratory Questionnaire (SGRQ), was significantly worse in all of its three component scores (symptoms, activities, and impacts) in the frequent, compared to the infrequent exacerbators. This suggests that exacerbation frequency is an important determinant of health status in COPD and is thus one of the important outcome measures in COPD. Factors predictive of frequent exacerbations included daily cough and sputum and frequent exacerbations in the previous year. A previous

study of acute infective exacerbations of chronic bronchitis found that one of the factors predicting exacerbation was also the number in the previous year [8], though this study was limited to exacerbations presenting with purulent sputum and no physiological data was available during the study.

In a further prospective analysis of 504 exacerbations, where daily monitoring was performed, there was some deterioration in symptoms, though no there were significant peak expiratory flow changes [9]. Falls in peak expiratory flow and $FEV_1$ at exacerbation were generally small and not useful in predicting exacerbations, but larger falls in peak expiratory flow were associated with symptoms of dyspnoea, presence

of colds, and longer recovery time from exacerbations. Symptoms of dyspnoea, common colds, sore throat, and cough increased significantly during the prodromal phase, and this suggests that respiratory viruses may have early effects at exacerbations. The median time to recovery of peak expiratory flow was 6 days and 7 days for symptoms, but at 35 days peak expiratory flow had returned to normal in only 75% of exacerbations, while at 91 days, 7.1% of exacerbations had not returned to baseline lung function. Recovery was longer in the presence of increased dyspnoea or symptoms of a common cold at exacerbation. The changes observed in lung function at exacerbation were smaller than those observed at asthmatic exacerbations, though the average duration of an asthmatic exacerbation was longer at 9.6 days [10, 11].

The reasons for the incomplete recovery of symptoms and lung function are not clear, but may involve inadequate treatment or persistence of the causative agent. The incomplete physiological recovery after an exacerbation could contribute to the decline in lung function with time in patients with COPD. However to date, there is no evidence that patients with incomplete recovery of their exacerbation have a greater decline in lung function, and further studies on the natural history of COPD exacerbations are required. A recent audit performed by the Royal College of Physicians, London, showed that ∼30% of patients seen at hospital with an index exacerbation will be seen again and possibly readmitted with a recurrent exacerbation within 8 weeks [12]. In a cohort of moderate-to-severe COPD patients 22% of patients had a recurrent exacerbation within 50 days of the first (index) exacerbation, and this event can be separated discretely from the index exacerbation [13]. Thus, exacerbations are complex events and careful follow-up is essential to ensure complete recovery.

The association of the symptoms of increased dyspnoea and of the common cold at exacerbation with a prolonged recovery suggests that viral infections may lead to more prolonged exacerbations. As cold is associated with longer exacerbations, COPD patients who develop cold may be prone to more severe exacerbations and should be considered for therapy early at onset of symptoms. COPD exacerbations are also prone to recurrence in that one exacerbation is more likely to be followed by another one.

## INFLAMMATORY CHANGES AT EXACERBATION

COPD exacerbations are associated with rises in airway (upper and lower airway) and systemic inflammation [2, 14]. Increases in systemic markers seen at exacerbations are most likely driven by increases in airway inflammation with exacerbation as the changes in airway and systemic inflammation at exacerbation are directly related [14]. Obviously, biopsy studies are difficult to perform at exacerbation in COPD patients. However in one study, where biopsies were performed at exacerbation in patients with chronic bronchitis, increased airway eosinophilia was found, though the patients studied had only mild COPD [14]. With exacerbation, there were more modest increases observed in neutrophils, T-lymphocytes (CD3), and TNF-$\alpha^+$ cells, while there were no

changes in CD4 or CD8 T-cells, macrophages, or mast cells. Qiu and co-workers have studied biopsies from COPD patients who were intubated and showed that there was considerable airway neutrophilia, neutrophil elastase expression with upregulation of neutrophil chemokine expression [15]. However, intubated COPD patients may have secondary airway infection and thus results may be difficult to interpret. Oxidative stress also plays an important role in the development of airway inflammation at COPD exacerbation. Markers of oxidative stress have been shown to rise in the airways during exacerbations such as hydrogen peroxide and 8-isoprostane, and these markers may take some time to recover to baseline stable levels [16]. Patients with severe exacerbations associated with hospitalization-assisted ventilation showed evidence of increased oxidative stress [17].

Most studies on airway inflammatory markers at exacerbation have been performed using sputum samples, either spontaneous or induced. Sputum inflammatory markers such as IL-6, IL-8, and myeloperoxidase (MPO) rise at the start of the exacerbation and usually recover to normal by 14 days, though in some cases higher airway inflammatory markers may persist for some time, suggesting incomplete recovery of exacerbations. Perera and colleagues also showed that systemic inflammation may persist after the exacerbation and those patients with an elevated C-reactive protein (CRP), 2 weeks after the onset of an exacerbation were more likely to develop an early recurrent exacerbation [13]. Patients with a history of frequent exacerbations have also increased airway and systemic inflammation in the stable state, compared to patients with infrequent exacerbations [2, 18].

## ETIOLOGY of COPD exacerbation

COPD exacerbations have been associated with a number of aetiological factors, including infection and pollution episodes (Table 67.1). COPD exacerbations are frequently triggered by upper respiratory tract infections [19], and these are commoner in the winter months, when there are more respiratory viral infections in the community. Patients may also be more prone to exacerbations in the winter months as lung function in COPD patients shows small but significant falls with reduction in outdoor temperature during the winter months [4]. COPD patients have been found to have increased hospital admissions, suggesting increased exacerbation when increasing environmental pollution occurs. During the December 1991 pollution episode in the UK, COPD mortality was increased together with an increase in hospital admission in elderly COPD patients [20]. However, common pollutants especially oxides of nitrogen and particulates may interact with viral infection to precipitate exacerbation rather than acting alone [21].

## Viral infections

Viral infections are an important trigger for COPD exacerbations [19, 22, 23]. Studies have shown that at least one-third of COPD exacerbations were associated with viral infections, and that the majority of these were due to human rhinovirus, the cause of the common cold

[19, 22, 23]. Viral exacerbations were associated with symptomatic colds and prolonged recovery of the exacerbation [9]. Using molecular techniques, Seemungal and colleagues also showed that rhinovirus can be recovered from induced sputum more frequently than from nasal aspirates at exacerbation, suggesting that wild-type rhinovirus can infect the lower airway and contribute to inflammatory changes at exacerbation [22]. They also found that exacerbations associated with the presence of rhinovirus in induced sputum had larger increases in airway IL-6 levels [22], suggesting that viruses increase the severity of airway inflammation at exacerbation. This finding is in agreement with the data that respiratory viruses produce longer and more severe exacerbations and have a major impact on health care utilization [9, 24]. Other viruses may trigger COPD exacerbation, though coronavirus was associated with only a small proportion of asthmatic exacerbations and is unlikely to play a major role in COPD [25]. RSV (respiratory syncytial virus), influenza, parainfluenza, and adenovirus can all trigger exacerbations. Influenza has become a less prominent cause of exacerbation with the introduction of immunization, though this is still likely to be an important factor at times of influenza epidemics. RSV infection has been found at COPD exacerbation [26], but it is not clear if RSV is a cause of COPD exacerbation as RSV can be frequently detected in the airways of COPD patients when stable [27].

## Bacterial infection

Over the past years, the role of bacterial infection at COPD exacerbation has been somewhat controversial as airway bacterial colonization is found when patients are stable state and the same organisms are isolated exacerbations. These include *Haemophilus Influenzae*, *Streptococcus Pneumoniae*, *Branhamella cattarhalis*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa.* [28]. In a study in patients with moderate-to-severe COPD, bacteria were found in 48.2% of patients in the stable state and at exacerbation, bacterial detection rose to 69.6%, with an associated rise in airway bacterial load [29]. The case for involvement of bacteria has come from the studies of antibiotic therapy as exacerbations often present with increased sputum purulence and volume and antibiotics have traditionally been used as first-line therapy in such exacerbations. Anthonisen and colleagues in a classical paper investigating the benefit of antibiotics in over 300 acute exacerbations demonstrated a greater treatment success rate in patients treated with antibiotics, especially if their initial presentation was with the symptoms of increased dyspnoea, sputum volume, and purulence [5]. Patients with mild COPD obtained less benefit from antibiotic therapy. A meta-analysis of trials of antibiotic therapy in COPD has concluded that antibiotic therapy offered a small but significant benefit in outcome in exacerbations [30]. Sethi and colleagues have suggested that isolation of a new bacterial strain in COPD patients who were regularly sampled was associated with an increased risk of exacerbation [31], though this also does not conclusively prove that bacteria are direct causes of exacerbations as not all exacerbations were associated with strain change, and not all strain changes resulted in exacerbation.

At COPD exacerbations both respiratory viruses and bacteria may be isolated. A greater systemic inflammatory response has been reported in those exacerbations associated with both *H. influenzae* and rhinovirus isolations, and if the isolation of *Haemophilus* was associated with new or worsening coryzal symptoms (a surrogate of viral infection) such infections were more severe as assessed by changes in symptoms and lung function at exacerbation onset [29]. This has been confirmed in a further study demonstrating greater lung function impairment and longer hospitalizatons in exacerbations associated with viral and bacterial co-infection [32]. It has also been suggested that atypical micro-organisms such as chlamydia and mycoplasma may cause COPD exacerbations, though evidence on their role is conflicting and these infective agents may interact with other bacteria and viruses in the airways [33, 34].

## PATHOPHYSIOLOGICAL CHANGES AT COPD EXACERBATION

In patients with moderate and severe COPD, the mechanical performance of the respiratory muscles is reduced. The airflow obstruction leads to hyperinflation, with the respiratory muscles acting at a mechanical disadvantage and generating reduced inspiratory pressures. The load on the respiratory muscles is also increased in patients with airflow obstruction by the presence of intrinsic positive end-expiratory pressure (PEEP). With an exacerbation of COPD, the increase in airflow obstruction will further increase the load on the respiratory muscles and increase the work of breathing, precipitating respiratory failure in more severe cases. The minute ventilation may be normal, but the respiratory pattern will be irregular with increased frequency and decreased tidal volume. The resultant hypercapnia and acidosis will then reduce inspiratory muscle function, contributing to further deterioration of the respiratory failure.

Hypoxaemia in COPD usually occurs due to a combination of ventilation–perfusion mismatch and hypoventilation, although arterio-venous shunting can also contribute in the acute setting. This causes increase in pulmonary artery pressure, which can lead to salt and water retention and the development of edema. The degree of the ventilation perfusion abnormalities increases during acute exacerbations and then resolves over the following few weeks. Acidosis is an important prognostic factor in survival from respiratory failure during COPD exacerbation, and thus early correction of acidosis is an essential goal of therapy.

## TREATMENT

### Inhaled bronchodilator therapy

Beta$_2$ agonists and anti-cholinergic agents are the inhaled bronchodilators most frequently used in the treatment of acute exacerbations of COPD. In patients with stable COPD, symptomatic benefit can be obtained with bronchodilator therapy in COPD, even without significant changes in spirometry. This is probably due to a reduction in dynamic hyperinflation that is characteristic of COPD and hence leads to a decrease in the sensation of dyspnoea especially during exertion [35]. In stable COPD greater bronchodilatation has been demonstrated with anti-cholinergic agents than with $\beta_2$ agonists, which may be due to the excessive cholinergic neuronal bronchoconstrictor tone [36]. However, studies investigating bronchodilator responses in acute exacerbations of COPD have shown no differences between agents used and no significant additive effect of the combination therapy, even though combination of anti-cholinergic and bronchodilator has benefits in the stable state [37, 38]. This difference in effect between the acute and stable states may be due to the fact that the larger doses of drug delivered in the acute setting produce maximal bronchodilatation, whereas the smaller doses administered in the stable condition may be having a sub-maximal effect.

Methylxanthines such as theophylline are sometimes used in the management of acute exacerbations of COPD. There is some evidence that theophyllines are useful in COPD, though the main limiting factor is the frequency of toxic side effects. The therapeutic action of theophylline is thought to be due to its inhibition of phosphodiesterase that breaks down cyclic 3'5' adenosine monophosphate (AMP), an intracellular messenger, thus facilitating bronchodilatation. However studies of intravenous aminophylline therapy in acute exacerbations of COPD have shown no significant beneficial effect over and above conventional therapy [39, 40]. There are some reports of beneficial effects of methylxanthines upon diaphragmatic and cardiac function, though these mechanisms require further study in patients with COPD exacerbations.

## Corticosteroids

Only about 10% to 15% of patients with stable COPD show a spirometric response to oral corticosteroids [41] and, unlike the situation in asthma, steroids have little effect on airway inflammatory markers in patients with COPD [42, 43]. A number of early studies have investigated the effects of corticosteroid therapy at COPD exacerbation. In an early controlled trial in patients with COPD exacerbations and acute respiratory failure, Albert and co-workers found that there were larger improvements in pre- and post-bronchodilator FEV$_1$ when patients were treated for the first 3 days of the hospital admission with intravenous methylprednislone than those treated with placebo [44]. Another trial found that a single dose of methylprednisolone given within 30 min of arrival in the accident and emergency department produced no improvement after 5 h in spirometry, and also had no effect on hospital admission, though another study reduced readmission [45, 46]. A retrospective study comparing patients treated with steroids at exacerbation compared to those not treated showed that the steroid group had a reduced chance of relapse after therapy [47].

Thompson and colleagues gave a 9 day course of prednisolone or placebo in a randomized manner to out-patients

presenting with acute exacerbations of COPD [48]. Unlike the previous studies, these patients were either recruited from out-patients or from a group that were pre-enrolled and self reported the exacerbation to the study team. In this study patients with exacerbations associated with acidosis or pneumonia were excluded, so exacerbations of moderate severity were generally included. Patients in the steroid-treated group showed a more rapid improvement in $PaO_2$, alveolar–arterial oxygen gradient, $FEV_1$, peak expiratory flow rate, and a trend toward a more rapid improvement in dyspnoea in the steroid-treated group.

In a recent cohort study by Seemungal and colleagues, the effect of therapy with prednisolone on COPD exacerbations diagnosed and treated in the community was studied [9]. Exacerbations treated with steroids were more severe and associated with larger falls in peak expiratory flow. The treated exacerbations also had a longer recovery time to baseline for symptoms and peak expiratory flow. However, the rate of peak expiratory flow recovery was faster in the prednisolone-treated group, though not the rate of symptom score recovery. An interesting finding in this study was that steroids significantly prolonged the median time from the day of onset of the initial exacerbation to the next exacerbation from 60 days in the group not treated with prednisolone to 84 days in the patients treated with prednisolone. In contrast, antibiotic therapy had no effect on the time to the next exacerbation. If short course oral steroid therapy at exacerbation does prolong the time to the next exacerbation, then this could be an important way to reduce exacerbation frequency in COPD patients, which is an important determinant of health status [2].

Davies and colleagues randomized patients admitted to hospital with COPD exacerbations to prednisolone or placebo [49]. In the prednisolone group, the $FEV_1$ rose faster until day 5, when a plateau was observed in the steroid-treated group. Changes in the pre-bronchodilator and post-bronchodilator $FEV_1$ were similar suggesting that this is not just an effect on bronchomotor tone, but involves faster resolution of airway inflammatory changes or airway wall edema with exacerbation. Length of hospital stay analysis showed that patients treated with prednisolone had a significantly shorter length of stay. Six weeks later, there were no differences in spirometry between the patient groups, and health status was similar to that measured at 5 days after admission. Thus, the benefits of steroid therapy at exacerbation are most obvious in the early course of the exacerbation. A similar proportion of the patients, ~32% in both study groups required further treatment for exacerbations within 6 weeks of follow-up, emphasizing the high exacerbation frequency in these patients.

Niewoehner and colleagues performed a randomized controlled trial of either a 2-week or an 8-week prednisolone course at exacerbation compared to placebo, in addition to other exacerbation therapy [50]. The primary end point was a first treatment failure, including death, need for intubation, readmission, or intensification of therapy. There was no difference in the results using the 2 or 8 week treatment protocol. The rates of treatment failure were higher in the placebo group at 30 days, compared to the combined 2 and 8 week prednislone groups. As in the study by Davies and colleagues, the $FEV_1$ improved faster in the prednisolone-treated group, though there were no differences by 2 weeks. In contrast, Niewoehner and colleagues performed a detailed evaluation of steroid complications and found considerable evidence of hyperglycaemia in the steroid-treated patients. Thus, steroids should be used at COPD exacerbation in short courses of no more than 2 weeks duration to avoid risk of complications.

## Antibiotics

Acute exacerbations of COPD often present with increased sputum purulence and volume, and antibiotics have traditionally been used as first-line therapy in such exacerbations. However, viral infections may be the triggers in a significant proportion of acute infective exacerbations in COPD and antibiotics used for the consequences of secondary infection. As discussed previously, antibiotic therapy at exacerbations is most useful if patients present with symptoms of increased dyspnoea, sputum volume, and purulence [30]. A randomized placebo-controlled study investigating the value of antibiotics in patients with mild obstructive lung disease in the community concluded that antibiotic therapy did not accelerate recovery or reduce the number of relapses, though patients had mixed pathologies [51].

## Management of respiratory failure

Hypoxaemia occurs with more severe exacerbations and usually requires hospital admission. Caution should always be taken in providing supplemental oxygen to patients with COPD, particularly during acute exacerbations, when respiratory drive and muscle strength can be impaired leading to significant increases in carbon dioxide tension at relatively modest oxygen flow rates. However, in the vast majority of cases, the administration of supplemental oxygen increases arterial oxygen tension sufficiently without clinically significant rises in carbon dioxide. It is suggested that supplemental oxygen is delivered at an initial flow rate of 1–2 l/min via nasal cannulae or 24–28% inspired oxygen via Venturi mask, with repeat blood gas analysis after 30–45 min of oxygen therapy.

Hypercapnia during COPD exacerbations may be managed initially with the use of respiratory stimulants. The most commonly used is doxapram, which acts centrally to increase respiratory drive and respiratory muscle activity. The effect is probably only appreciable for 24 to 48 h; the main factor limiting use being side effects which can lead to agitation and are often not tolerated by the patient. There are only a few studies of the clinical efficacy of doxapram and short-term investigations suggest that improvements in acidosis and arterial carbon dioxide tension can be attained [52]. A small study comparing doxapram with non-invasive ventilation (NPPV) in acute exacerbations of COPD suggested that NPPV was superior with regard to correction of blood gases during the initial treatment phase [53]. Increases in pulmonary artery pressure during acute exacerbations of COPD can result in right-sided cardiac dysfunction and development of peripheral edema. Diuretic therapy may thus be necessary if there is edema or a rise in jugular venous pressure.

# Ventilatory support

## Non-invasive ventilation

The introduction of noninvasive positive pressure ventilation (NPPV) using nasal or face masks has had a major impact on the management of acute exacerbations and has enabled acidosis to be corrected at an early stage. Studies have shown that NIPPV can produce improvements in pH relatively rapidly, at 1 h after instituting ventilation [54, 55]. This will allow time for other conventional therapy to work, such as oxygen therapy, bronchodilators, steroids, and antibiotics and thus reverse the progression of respiratory failure and reduce mortality. With NIPPV, there are improvements in minute ventilation, reductions in respiratory rate and in transdiaphragmatic activity. Thus, NIPPV can improve gas exchange and allows respiratory muscle rest in respiratory failure.

With the use of NIPPV patient comfort is improved; there is also no requirement for sedation with preservation of speech and swallowing. The technique can be applied in a general ward, though a high-dependency area is preferable and intensive care is unnecessary. Patient cooperation is important in application of NIPPV. The main advantage of the use of NIPPV is the avoidance of tracheal intubation and the ability to offer ventilatory support to patients with respiratory failure due to severe COPD, who would be considered unsuitable for intubation. A lower incidence of nosocomial penumonia has also been reported with the use of NPPV compared with conventional intubation and ventilation.

Following a number of uncontrolled studies, randomized controlled trials have shown benefit of NIPPV in acute COPD exacerbations. A UK study showed that with the use of NIPPV in exacerbations of respiratory failure, earlier correction of pH can be achieved, together with reduction in breathlessness over the initial 3 days of ventilation, compared with a control standard therapy group [54]. A study from the United States showed a significant reduction in intubation rates with NIPPV from 67% in a group receiving conventional therapy to 9% in the NIPPV group [55]. A third study showed convincingly that in patients with exacerbations of respiratory failure, the use of NIPPV with pressure supports ventilation, reduces the need for intubation and mortality is significantly reduced from 29% in the conventionally treated group to 9% in the NIPPV group [56]. Complications, which were specifically associated with the use of mechanical ventilation, were also reduced. The difference in mortality disappeared after adjustment for intubation, suggesting that the benefits with NIPPV are due to fewer patients requiring intubation. This was also the first study to show that hospital length of stay can be reduced with use of NIPPV. A recent study showed that NPPV can be applied on general wards, though patients with more severe acidosis had a worse outcome [57].

These studies have treated patients where the pH was below 7.35, rather than just below 7.26, when the prognosis of COPD worsens. A number of these patients may have improved without NIPPV, though it seems that the major effect of NIPPV is the earlier correction of acidosis and thus avoidance of tracheal intubation, with all its associated complications. Studies have shown that NIPPV can be successfully implemented in up to 80% of cases [58, 59].

NIPPV is less successful in patients who have worse blood gases at baseline before ventilation, are underweight, have a higher incidence of pneumonia, have a greater level of neurological deterioration, and where compliance with the ventilation is poor [58]. Moretti and colleagues have recently shown that "late treatment failure" (after an initial 48 h of therapy with NPPV) is up to 20% and that patients with late failure were more likely to have severe functional and clinical disease with more complications at the time of admission [60]. Identification of patients with a potentially poor outcome is important as delay in intubation can have serious consequences for the patient.

## Indications for invasive ventilation

If NIPPV fails, or is unavailable in the hospital, invasive ventilation may be required in the presence of increasing acidosis. It may be considered in any patient when the pH falls below 7.26. Decisions to ventilate these patients may be difficult, though with improved modes of invasive ventilatory support and better weaning techniques, the outlook for the COPD patient is better.

Patients will be suitable for tracheal intubation if this is the first presentation of COPD exacerbation or respiratory failure, or there is a treatable cause of respiratory failure, such as pneumonia. Information will be required on the history and quality of life, especially the ability to perform daily activities. Patients with severe disabling and progressive COPD may be less suitable, but it is important that adequate and appropriate therapy has been used in these patients, with documented disease progression. The patient's wishes and those of any close relatives should be considered in any decision to institute or withhold life supporting therapy.

# Supported discharge

Many hospital admissions are related to exacerbations of COPD and thus reductions of admissions especially during the winter months when they are most frequent is particularly desirable. Over the last few years a number of different models of supported discharge have been developed and some evaluated [61–63]. Patients have been discharged early with an appropriate package of care organized, including domiciliary visits made to these patients after discharge by trained respiratory nurses.

Cotton and colleagues randomized patients to discharge on the next day or usual management and found that there were no differences in mortality or readmission rates between the two groups [61]. There was a reduction in hospital stay from a mean of 6.1 days to 3.2 days. In another larger study by Skwarska and colleagues, patients were randomized to discharge on the day of assessment or conventional management [62]. Again there were no differences in readmission rates, no differences in visits to primary care physicians and health status measured 8 weeks after discharge was similar in the two groups. The authors also demonstrated that there were significant cost savings of around 50% for the home support group, compared to the admitted group. However, other considerations need to be taken into

account in organizing an assisted discharge service in that resources have to be released for the nurses to follow the patients and the benefits may be seasonal, as COPD admissions are a particular problem in the winter. Further work is required on the different models of supported discharge available and the cost effectiveness of these programmes.

## PREVENTION OF COPD EXACERBATION

There has been much recent emphasis on prevention of exacerbations in patients with COPD. As respiratory tract infections are common factors in causing exacerbation, influenza, and pneumococcal vaccinations are recommended for all patients with significant COPD. A study that reviewed the outcome of influenza vaccination in a cohort of elderly patients with chronic lung disease found that influenza vaccinaiton is associated with significant health benefits with fewer outpatient visits, fewer hospitalizations, and a reduced mortality [64].

Long-term antibiotic therapy has been used in the past in patients with very frequent exacerbations, though the evidence was not strong for benefit. However with the advent of novel and more specific antibiotics against airway organisms, the topic of long-term antibiotic therapy in COPD is currently being revisited and results of the first trials are awaited. Recently there has been a report of the effects of an immunostimulatory agent in patients with COPD exacerbations, with reduction in severe complications and hospital admissions in the actively treated group [65]. However, the mechanisms of benefit are not clear, and further studies on the effects of these agents in the prevention of COPD exacerbation are required.

Long-acting bronchodilators (LABA) have been shown to reduce exacerbations. In the recently reported TORCH (Towards a Revolution in COPD Health) study, salmeterol, a long-acting beta agonist, reduced the frequency of exacerbations [66], while a number of other studies have shown that the long-acting anticholinergic tiotropium reduces the exacerbation rate and also a trend to reduction in hospital admission [67–69]. However, there is no good evidence at present that long-acting anticholinergic agents possess anti-inflammatory activity [70], and it is likely that tiotropium reduces exacerbations by reducing dynamic hyperinflation and thus dyspnoea. Combinations of long-acting beta agonists and inhaled corticosteroids have been also evaluated and reduced exacerbations more than the individual components [66]. A direct comparison of inhaled tiotropium with the salmeterol/fluticasone (SFC) combination in the recently reported INSPIRE study in moderate-to-severe COPD patients showed that both interventions had an equal effect on exacerbation rates [71]. However, patients taking tiotropium required more courses of oral corticosteroids with exacerbations whereas patients on the SFC combination required more courses of antibiotics [71]. This for the first time, it has been shown that different interventions have different effects on exacerbations.

The Optimal study recently evaluated the combination of tiotropium with inhaled LABA (salmeterol) and inhaled steroids (fluticasone) [72]. The triple combination reduced hospitalization as a result of exacerbation, but not the total number of exacerbations. In addition a trend was observed in the reduction of the number of exacerbations with the triple combination, which did not reach statistical significance due to the relatively small size of the study and the high dropout rate. Triple therapy may be more effective than other therapies and further studies of these combinations are now required with adequately powered studies.

# Education and Self-Management

**Martyn R. Partridge**

The Faculty of Medicine, Imperial College, London, UK

Globally, twice as many people have asthma as the total population of the Russian Federation. In the United States of America alone, the number of people with chronic obstructive pulmonary disease is equivalent to the combined populations of Denmark, Sweden, Finland, Norway, and the Baltic States. For some of these people, we have therapies that can dramatically influence their diseases. Others have persisting and regular symptoms, and all have to live with a long-term condition. It is likely that the majority have only 30–60 min of contact on average with a health professional in any 1 year and this means that for the other 364 days and 23 h, these patients are self managing their own condition. As health professionals we have a responsibility to ensure that these patients are equipped with the tools, knowledge, and skills necessary to self manage and self treat their own condition.

This chapter is concerned with patient education and self-management and will review the evidence in favor of those interventions and highlight similarities and differences between self-management education in asthma and chronic obstructive pulmonary disease (COPD).

## WHAT IS PATIENT EDUCATION?

The term patient education has an unpleasant inference suggesting some inadequacy on the patient's behalf which needs rectifying. It seems preferable to make the concept more positive and to list the constituent parts. Van den Borne [1] has defined patient education as "a systematic learning experience in which a combination of methods is generally used, such as the provision of information and advice and behavior modification techniques, which influence the way the patient experiences their illness and/or their knowledge and health behavior, aimed at improving or maintaining health or learning to cope with a condition, usually a chronic one."

For the health care professional an essential prerequisite to patient education is an understanding of how the patient feels about their long-term condition and its management.

## HOW DOES IT FEEL TO HAVE COPD?

COPD is largely a smoking-related disease. In many countries the prevalence of smoking is low amongst health care professionals, especially amongst doctors. Personal experience of the condition is therefore likely to be uncommon. Surveys of the views, opinions, and concerns of those with COPD are less numerous than are those amongst people with asthma, and the population affected less diverse – being mainly a disease of the fifth, sixth, and seventh decades. Currently more men than women are affected, but this is rapidly changing.

Those with COPD frequently suffer feelings of guilt about having caused the disease by smoking, and they experience great sadness when they see others around them smoking and proceeding along their path. They frequently report lack of support on social issues, financial issues, and from health care professionals. Professionals imbued with a culture of curing and obsessed with the writing of prescriptions may not actually say "There is nothing I can do for you," but they can convey such negativity by body language or attitude. The late Trevor Clay, a nurse who died from lung disease associated with an inherited condition wrote "There is no cure, no magic, but there is always something that can be

done!" He also wrote "Having a long-term condition is not about dying – that only takes a few minutes or less – but I've been struggling to breathe for over 20 years and I've been living a lot and suffering as little as possible"[2].

Others may find it less easy to be positive. Anxiety, frustration, and depression are frequently experienced by sufferers and they may become socially isolated [3].

Psychiatric disorders may reach a prevalence of 50% in those with COPD, [4] and Dudley *et al*. [5] observed those with severe COPD to be in "emotional strait jackets" – no longer able to become angry, depressed, or even happy, as any significant emotional changes triggered distressing symptoms. The mind/body interaction can thus become a vicious cycle with symptoms leading to anxiety, and emotional distress aggravating the symptoms. Psychological impairment may also follow from derangement of blood gases leading to diminished levels of alertness, irritability, restlessness, headaches, and confusion and loved ones may be unaware of the reasons for these factors in their partners. Psychological and personality profiles of those with severe COPD may also influence survival. One study of males with severe COPD showed a significant difference in personality and psychological profile between those who died and those who were alive at the end of 4 years of follow-up, irrespective of the degree of impairment of pulmonary function or oxygenation [6].

In those at the severe end of the spectrum of COPD, a common therapeutic intervention is the use of supplementary oxygen. When this is recommended to be used long term, it could impact significantly upon the patient's life and may enhance feelings of social isolation [7]. In another survey of those on long-term oxygen from oxygen concentrators, the results were more positive. Eighty-three percent of those surveyed reported marked improvement in general well-being on oxygen, 82% reported improvement in breathing and 62% mobility, and 52% reported improvement in sleep pattern. A third thought that the concentrator was too noisy. Sadly, a third of those prescribed long term oxygen continued to smoke [8].

It is also important to be aware of patients' fears, concerns and expectations. Studies of those with COPD which have used rigorous mathematical techniques such as discrete choice modeling, have shown that patients most fear being hospitalized, housebound or bedridden and they fear more attacks in the future [9, 10]. These fears and concerns are greater than those related to the symptoms of the disease, such as breathlessness or a productive cough. Indeed exacerbations of COPD have the most negative impact upon our patients and 50% need additional help with simple tasks during exacerbations and nearly half of all patients have to stop all activities during such exacerbations. It should also be noted that the word "exacerbation" whilst used between health professionals, is not understood by over 60% of patients who are more likely to talk of "a crisis," "an attack," breathing difficulty or "a chest infection."

## HOW DOES IT FEEL TO HAVE ASTHMA?

The ages of those suffering from asthma is more diverse than those suffering from COPD. Furthermore, whilst long-term disability and daily symptoms are common in asthma, the symptoms may be more variable. Such variability can induce additional stresses, and uncertainty invokes an unpleasant emotion with fears of holidays, celebrations, or important work events being interrupted by unexpected exacerbations. Denial of the diagnosis or its implication is common [11] and feelings of stigma frequent, but there is no easy comparison to suggest whether it is higher or lower than in COPD. Fears and concerns regarding the medication are common, although steroid phobia amongst patients and parents may be perceived by health professionals to be more common than it really is. Dissatisfaction with dependency on long-term medication may be one of the most common reactions and patients frequently stop medication just to confirm continued need. What is unclear is why there is such a large difference between the goals for asthma management as outlined in guidelines, and the control as discovered by surveys of patients. In one large UK study, 44% of respondents reported at least one activity was "totally or very limited" by their asthma and 20% reported three or more activities to be so limited [12]. Another survey conducted 400 interviews with current asthma patients in seven countries. Over one-third of children and half of the adults reported daytime symptoms at least once a week. Sleep disruption every night was reported by 6.7% of children and 5.3% of adults. A total of 36% of children and 27.9% of adults required an unscheduled urgent care visit in the past 12 months. One or more emergency room visits due to asthma were reported for 18% of children and 11% of adults in the past year [13]. In that survey, only 25% of the patients were taking regular maintenance therapy and it is not therefore clear whether the ongoing morbidity reflected undertreatment or an inadequacy of treatment. A more recent study has looked only at those using regular maintenance therapy and studied over 3400 adults with asthma in several European countries and also in North America and Australia. No significant differences were seen between countries but despite the use of regular medication, over three quarters of these patients needed rescue therapy each day and using the Juniper asthma control questionnaire, only 28% of these patients were shown to be well-controlled. Furthermore, many of these patients perceived their asthma to be better controlled than the ACQ suggested [14]. Some of this morbidity may genuinely reflect the fact that we do not have treatments to control the asthma symptoms of all our patients, but in other cases the patients may be undertreated or may not be reviewed by health care professionals with the result that treatment is not optimized. Only half of those surveyed in the UK [12] had their peak flow measured by a doctor or a nurse in the past year, and 45% of respondents said they had neither had, nor wanted, regular asthma review. Without such review there is a danger that adaptation leads to acceptance of ongoing morbidity. Even with review, there is a danger that the patient may not "offer" symptoms for fear that it may lead to further prescriptions, and the doctor may falsely conclude that all is well.

For these reasons it has been recommended that at each consultation every patient with asthma is asked three questions: [15]

In the last week or month

- Have you had difficulty sleeping because of your asthma symptoms (including cough)?

- Have you had your asthma symptoms during the day (cough, wheeze, chest tightness, or breathlessness)?
- Has there been any limitation of activities (time off work or school or inability to undertake hobbies) because of asthma. Has your asthma interfered with your usual activities (e.g. housework, work/school, etc.)?

Other validated measures of control also exist.

The willingness of patients with asthma to take control of their condition is probably greater than doctors recognize. In one study, whilst patients varied in their desire to be involved in treatment decisions, 55% were less involved than they wished to be [16] and in another study, only 20% of patients had actually been offered a written asthma action plan but when questioned regarding their possession of asthma action plans, over 60% of patients wished to have one [17]. It has also been shown that those with asthma willingly admit to using medication as and when necessary, and express a desire to adjust their dose of maintenance therapy to the changes of their asthma and express concern at being on too much medication when they are well [14]. This suggests an intrinsic willingness on behalf of our patients to take control of their own condition if instructed in the appropriate manner.

## COMPLIANCE IN ASTHMA AND COPD

The term noncompliance is used to describe a situation where, for whatever reason, the patient does not take treatment or other actions in a manner as previously discussed with their health professional. Recent trends have been to replace the word compliance with "adherence" or "concordance," but this seems unnecessary if it is emphasized from the outset that the term is not being used in any way in a pejorative sense. Noncompliance may involve noncompliance with lifestyle advice (e.g. continued smoking), failure to attend for follow-up, failure to undertake recommended monitoring, or failure to take therapy. The size of the problem is likely to be large and underestimated.

Noncompliance with medication is either inferred from the presence of poorly controlled disease or confirmed by monitoring drug taking, which may involve measurement of drug levels in urine, plasma or saliva, or by prescription monitoring. More modern methods involve the fitting of microprocessors to the lids of bottles or inhaler devices [18–20]. Such methods are inappropriate at a clinical level and it is preferable to accept that noncompliance is common, and instead make efforts to consider the factors involved and work with the patient to tackle the underlying causes. It is likely that the size of the problem is of similar magnitude in asthma as in COPD, and these two diseases probably do not differ from other long-term conditions such as hypertension or arthritis. Some of the causes may however be disease-specific and possibilities are listed in Table 68.1.

Perhaps the most essential is to understand the importance of good communication between patient and health care professional. In one UK study, [21] only 22% of those with asthma reported having had a good discussion with their doctor, and in another study a median dissatisfaction

**TABLE 68.1** Factors which may be involved in noncompliance with the taking of medication in asthma and COPD.

| *Factors associated with medication* |
| --- |
| Use of the word "drug" |
| Difficulties with inhaler devices |
| Regimens involving multiple medications |
| Awkward four times daily dosing regimens |
| Side-effects |
| Cost of medication |
| Difficulty getting to the doctor (for a prescription) or the pharmacy (for it to be dispensed) |
| Perceived lack of effectiveness of medication |
| *Nonmedication factors* |
| Denial of diagnosis |
| Fears of side-effects |
| Unexpressed/unanswered concerns |
| Dissatisfaction with health care professionals |
| Misunderstanding or lack of instruction |
| Anger, stigma, or depression |
| Underestimation of severity |
| Forgetfulness or complacency |
| Cultural issues |

**TABLE 68.2** General guidelines on ways to improve communication with patients and their families.

| Be attentive |
| --- |
| Elicit underlying concerns |
| Offer reassuring messages that alleviate fears |
| Immediately address any concerns that are mentioned |
| Use interactive dialog (open-ended questions, analogies) |
| Tailor the therapeutic regimen to lifestyle |
| Provide a written management plan |
| Use appropriate nonverbal engagement |
| Use praise when patient has undertaken correct management strategies |
| Elicit goals; share goals |
| Help the patient plan longer-term care and self-management |

Adapted from Ref. [47].

rate of 38% with medical communication was reported [22]. The effect of this upon compliance may be considerable. In one study, 50 adults with moderate to severe asthma were studied and compliance with inhaled steroid therapy electronically monitored. Mean adherence was 63%. Factors associated with poor adherence included less than 12 years of formal education, and a low household income, but poor patient/clinician communication was independently associated with poor adherence. Those with at least 70% adherence scored the patient/clinician communication significantly better than those with less than 70% adherence [23]. Key elements of good communication are shown in Table 68.2.

## WHAT ARE THE CONSTITUENT PARTS NECESSARY FOR SUCCESSFUL EDUCATION AND SELF-MANAGEMENT IN COPD: WHO SHOULD PROVIDE IT AND WHERE?

Clear, evidence-based advice regarding education and self-management is far harder to offer to those with COPD than it is for asthma. In both disease groups there is a problem in published reports that often give too little information about the intervention offered and do not describe the self-management advice given. In studies involving COPD, this is further compounded by a difficulty in separating the educational components from the support and the physical exercise components of pulmonary rehabilitation programs. It is likely that education and self-management programs for COPD should cover the ground outlined in Table 68.3. Self-management involves both alterations in lifestyle and alterations in treatment, and it is immediately apparent that the balance between these two is different for COPD than it is for asthma (as shown in Table 68.4).

One study of such interventions allocated 56 subjects with COPD to either usual care or to receiving a booklet (outlining advice presumed to be similar to that in Table 68.3), an action plan, and a reserve supply of steroids and antibiotics. After 6 months there were no differences in quality of life scores or pulmonary function, but those given the self-treatment advice were significantly more likely to have started steroids or antibiotics in response to deteriorating symptoms [24]. Numbers were too small to look at effects upon hospitalization rates and larger studies would need to include cost-effectiveness evaluation. Some pretest/posttest nonrandomized studies have suggested that "education" may reduce hospitalization rates, [25] but a 2003 systematic review of eight previous studies which looked at self-management education in COPD *alone* (i.e. excluding studies which included multiple interventions such as pulmonary rehabilitation) concluded that there was too little evidence to yet say that self-management in COPD was associated with positive outcomes [26]. The reasons why the benefits of self-management education in COPD appears equivocal compared to the definite advantages in asthma are unclear but the systematic review did highlight the fact that, whereas action plans have been

**TABLE 68.3** Self-management advice for those with COPD.

| Lifestyle changes | Treatment changes |
|---|---|
| 1. Stop smoking (and avoid smoky environments) | 1. Continue regular bronchodilators – usually a combination of anticholinergic agents and β-agonists |
| 2. Use nicotine replacement therapies as appropriate as advised | 2. At times of worsening symptoms increase dose, frequency, and possibly route of administration for example, spacer or nebulizer |
| 3. Use effective breathing methods | 3. If sputum changes color, consider starting reserve course of antibiotics |
| 4. Use effective coughing methods | 4. If much more breathless, and lessening response to bronchodilators, consider a course of steroid tablets according to doctor's advice |
| 5. Undertake your exercise program as advised during your pulmonary rehabilitation course | 5. Use oxygen as advised – either long-term or supplementary during exertion – know when to increase this and be aware of the importance of early morning confusion or headaches which might suggest $CO_2$ retention. |
| 6. Eat a balanced diet: include plenty of fresh fruits and vegetables and drink plenty of fluids to help keep mucus thin. Avoid gas-forming foods such as broccoli, cabbage, onions, beans, and sauerkraut. If eating makes you breathless, use supplementary oxygen whilst chewing, or liquidize solids | |
| 7. Adjust daily activities of living. Sit down to do personal tasks such as washing or shaving or doing household tasks such as washing up or preparing meals. Use a stool in the shower and use a hairdryer to dry feet or back. | |

**TABLE 68.4** Self-management advice for those with asthma.

| Lifestyle changes | Treatment changes |
|---|---|
| 1. Allergen avoidance | 1. If you have no symptoms and your peak flow is better than 80–85% of your best peak flow, continue your regular preventative treatment, or talk to your doctor or nurse about taking less treatment |
| 2. Avoiding smoking and smokey environments | 2. If you get a cold, or have your asthma symptoms during the day or at night, or if your peak flow is less than 80–85% of your best peak flow, increase your preventer treatment according to your written personal action plan |
| 3. Avoid exercising outdoors, especially on the outskirts of cities, at times of high pollution levels | 3. If you are increasingly breathless, and your reliever therapy is less effective and your peak flow is less than 60–70% of your usual best peak flow, start steroid tablets according to your written personal action plan and contact your doctor |
| 4. Eat a balanced diet | 4. If you are too breathless to speak, or your peak flow is less than 40–50% of your usual best peak flow, continue to use your reliever, take 8 of the 5 mg prednisolone tablets, and call your doctor or an ambulance urgently |

shown to be an important part of asthma self-management, in only two of the studies included in the COPD systematic review were action plans part of the intervention. In one of those studies, the action plan which had been issued was in fact an asthma action plan and did not include the patient self-treating with antibiotics and in the other an appropriate COPD action plan was given but the study was not powered to look at harder outcomes. A subsequent systematic review of the use of action plans in COPD was still only able to find three studies and whilst this demonstrated that use of an action plan in COPD increased the patients' ability to recognize a severe exacerbation and increased their use of antibiotics and steroid tablets, it was not able to demonstrate any effect on health care utilization, quality of life, or symptom scores [27]. A study of the use of self-management plans in the primary care of patients with COPD in New Zealand showed that the use of self-management plans within a structured education program was associated with higher levels of self-management knowledge but actually had no effect on quality of life, health care utilization, or self-reported outcomes [28]. It seems likely that the magnitude of any benefit from self-management education in COPD alone is limited, despite the fact that such tools can alter patient behavior. This may reflect the lesser magnitude of benefit of, for example, steroid tablets in the treatment of exacerbations of COPD compared with that in asthma. We should not preclude the use of action plans on these grounds alone, for we know, for example, that the quicker an exacerbation of COPD is treated, the more effective the intervention and self-treatment is always likely to be quicker than that associated with the inevitable delay in contacting health professionals. Such self-management advice probably begins to contribute to improved outcomes when it is combined with other interventions, such as case management and pulmonary rehabilitation. A multicenter French-Canadian study suggested that amongst those who had one hospitalization for an exacerbation of COPD, such multiple interventions may lead to up to 40% reduction in further emergency department attendances or admissions to hospitals [29].

Most reports of educational and self-management activities in COPD have involved respiratory nurse specialists, physiotherapists, or respiratory therapists. Most studies have been outpatient based. Where outreach home-based programs have been assessed, they have shown no significant reductions in hospitalization rates, but there may be some health-related quality of life gains [30].

## PATIENT EDUCATION AND SELF-MANAGEMENT IN ASTHMA

In contrast to the situation in COPD, studies of this area involving those with asthma are numerous and the results in adults and older children are almost always positive, especially involving those who have attended hospital-based programs [31–33]. The key constituents of such interventions are shown in Table 68.4.

A Cochrane review of the subject of self-management education for adults with asthma was undertaken by Gibson and colleagues in 2002 and compared self-management education and follow up with usual care in 36 studies [34]. Self-management education was associated with reduction in hospitalization rates, emergency room visits, unscheduled visits to the doctor, days off work or school, and nighttime asthma. Self-management programs that involved a written action plan showed greater reduction in hospitalization rates than those that did not, and people who managed their asthma by self-adjustment of their asthma treatment using an individualized written plan had better lung function than those whose medications were adjusted by a doctor.

Fewer studies have been undertaken of the value of self-management in children, but good randomized controlled trials involving self-management interventions in those who have been hospitalized, have shown significant reduction in readmission rates [35–36]. Studies of the cost-effectiveness of the teaching of self-management skills in those with asthma have shown significantly beneficial cost-benefit ratios [37–38].

This wealth of evidence in favor of self-management education, regular follow up, and the use of written action plans has not unfortunately led to widespread implementation. In the first British Asthma Guidelines, published in 1990 [39], it said: "As far as possible, patients should be trained to manage their own treatment rather than being required to consult their doctor before making changes." Unfortunately, if we use the possession of a written asthma action plan as a marker of how satisfactorily this process has been undertaken, a UK study 10 years after those Guidelines showed that only 3% of patients had such a plan [40]. However, that figure did rise to 28% of 378 individuals who were surveyed 1 week after need for unscheduled health care because of out-of-control asthma and this could imply some targeting of advice to those most at risk [41]. A more recent study again showed 20% of patients having such a plan [17]. Even in Australia, where with national publicity campaigns they had once reached 48% of patients having action plans, the latest figures show that has fallen to 18.5% of patients owning an asthma plan [42]. The reasons why doctors are not implementing a core part of self-management education which is of proven benefit are not clear, but probably revolve around a perceived lack of time, lack of suitable templates, and possibly a lack of understanding as to what is involved in this process and what needs to be written down for patients. As computer decision support systems evolve, and it becomes easier to link consultation records with information materials, it's likely that ease of issuing of personalized action plans will improve.

## HEALTH LITERACY

When offering education and information materials to our patients, it is important to ensure that the patients have the capacity to process and understand the information which we have given them. This entails ensuring not only that spoken information is provided at an appropriate level but that

How to take your asthma medicines

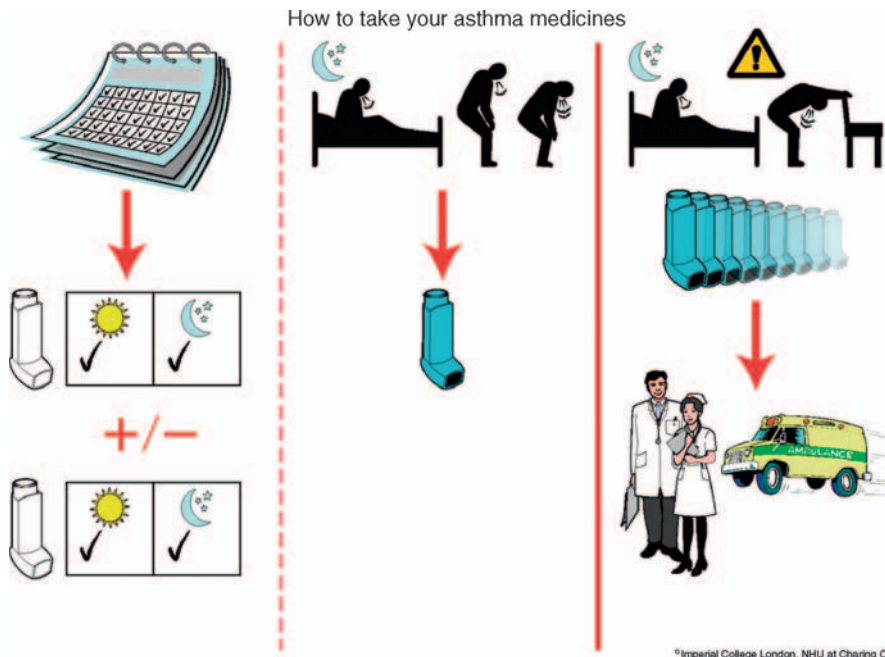

**FIG. 68.1** An example of a pictorial asthma action plan.

written materials are readable and reliable. It is possible to formally test patients' ability to use materials using tests such as the Rapid Estimate of Adult Literacy in Medicine (REALM) [43] or the Test of Functional Health Literacy in Adults (TOFHLA) [44]. When such tests have been utilized in studies, 15% of those with rheumatoid arthritis attending a hospital rheumatology clinic in Glasgow had been shown to be functionally illiterate [45] and 13% of patients with asthma attending a US hospital were similarly unable to use the written word in a meaningful manner [46]. Such formal testing is neither possible nor appropriate in clinical practice but we should be aware of the likely magnitude of this problem and consideration should be given not only to producing written materials with an appropriate reading age but also to the possibility of reinforcing the spoken word, not with the written word but for example by the use of pictograms. Such tools have been shown to enhance retention of information, even amongst the fully literate. An example of a pictorial asthma action plan is shown in the Fig. 68.1.

a suitable format to ensure it is usable by those with varying literacy skills.

Current evidence is that self-management education is of significant value in those with asthma but more marginal value in COPD, where it may only be beneficial if combined with other interventions such as pulmonary rehabilitation and case management.

## SUMMARY

- Living with a long-term illness can be difficult.
- Health care professionals need an understanding of how their patients feel, and good communication is essential if we are to understand fully what our patients want of us, and how best we can provide optimal care.
- It is important to offer the information the patient wants, rather than what we perceive they need.
- Personalized self-management advice which helps them to adjust their lifestyle or treatment to keep themselves well, is necessary. Such advice needs to be produced in
