No responsibility is assumed by the publisher for any injury and/or damage to persons
or property as a matter of products liability, negligence or otherwise, or from any use
or operation of any methods, products, instructions or ideas contained in the material
herein. Because of rapid advances in the medical sciences, in particular, independent
verification of diagnoses and drug dosages should be made

Medicine is an ever-changing field. Standard safety precautions must be followed, but as
new research and clinical experience broaden our knowledge, changes in treatment and
drug therapy may become necessary or appropriate. Readers are advised to check the most
current product information provided by the manufacturer of each drug to be administered
to verify the recommended dose, the method and duration of administrations, and
contraindications. It is the responsibility of the treating physician, relying on experience
and knowledge of the patient, to determine dosages and the best treatment for each
individual patient. Neither the publisher nor the authors assume any liability for any
injury and/or damage to persons or property arising from this publication

ELSEVIER    BOOK AID
International    Sabre Foundation

# Preface to the 2nd Edition

In the 6 years since the publication of the first edition of *Asthma and COPD* there has been substantial progress in understanding the biological basis of both of these obstructive diseases. In contrast both our understanding of the physiological basis of these conditions and their treatment has improved very little. We firmly believe that the progress made in understanding the basic disease biology that has accrued since 2002 will lead, in the years to come to new and better treatments of these crippling obstructive airway diseases. As our knowledge advances, we now appreciate the areas of overlap and distinction between these two conditions which share many physiological similarities. Most of the chapters of this book highlight both the similarities and differences between these conditions.

In this era of widely available information on the internet it is reasonable to ask what value is served by a book of this type? The answer is simple. The editors have assembled the world's experts on these topics and commissioned them to write succinct reviews focusing on their particular area of expertise. For the student of the biology or treatment of these conditions, this compilation is an important resource of up-to-date information. For the researcher or clinician, the investigative or clinical problems that each of face on a daily basis are clearly illuminated by topic experts. We hope that you will find this summary of value to you in understanding these two highly variegated, closely similar but clearly distinct entities at the biological and clinical level.

# About the Editors

**Peter J Barnes**, **DM, DSc, FRCP, FMedSci, FRS**, is a Professor of Thoracic Medicine at the National Heart and Lung Institute, Head of Respiratory Medicine at Imperial College, and Honorary Consultant Physician at Royal Brompton Hospital, London. He qualified at Cambridge and Oxford Universities and was appointed to his present post in 1987. He has published over 1000 peer-review papers on asthma, COPD, and related topics and has edited over 40 books. He is also amongst the top 50 most highly cited researchers in the world and has been the most highly cited clinical scientist in the United Kingdom and the most highly cited respiratory researcher in the world over the last 20 years. He was elected a Fellow of the Royal Society in 2007, the first respiratory researcher for over 150 years. He is currently a Member of the Scientific Committee of the WHO/NIH global guidelines on asthma (GINA) and COPD (GOLD). He also serves on the Editorial Board of over 30 journals and is currently an Associate Editor of Chest and Respiratory Editor of PLoS Medicine. He has given several prestigious lectures, including the Amberson Lecture at the American Thoracic Society and the Sadoul Lecture at the European Respiratory Society.

**Neil C Thomson**, **MD, FRCP**, is a Professor of Respiratory Medicine at the University of Glasgow, Head of Respiratory Medicine within the Division of Immunology, Infection & Inflammation, and Honorary Consultant at Gartnavel General Hospital, Glasgow. He graduated from the University of Glasgow and undertook postgraduate training in Glasgow, London and McMaster University, Canada. He is a former Member of the Committee for Safety of Medicine and former Chair of the Scientific Committee of the British Lung Foundation. He has co-edited several textbooks on asthma and COPD and published over 150 peer-reviewed papers on asthma. His current research interests include corticosteroid insensitivity in smokers with asthma, biomarkers in asthma and COPD and assessment of novel treatments for asthma.

**Jeffrey M Drazen**, **MD**, was born in St. Louis, Missouri. He graduated from Tufts University with a major in Physics, and from Harvard Medical School. He served his medical internship and residency at Peter Bent Brigham Hospital in Boston and was a Clinical Fellow and Research Fellow at Harvard Medical School and Harvard School of Public Health. Thereafter, he joined the Pulmonary Divisions of the Harvard hospitals and served for many years as Chief of the Combined Pulmonary Divisions at Beth Israel and Brigham and Women's Hospitals.

Currently, he is a Senior Physician at the Brigham and Women's Hospital, and the Distinguished Parker B. Francis Professor of Medicine at Harvard Medical School, as well as Professor of Physiology, Harvard School of Public Health, and adjunct Professor of Medicine at Boston University School of Medicine.

He has served on the NIH Respiratory and Applied Physiology Study Section, the NIH Pulmonary Disease Advisory Council, the NIH Lung Biology and Pathology Study Section, and the NHLBI Advisory Council.

Through his research, he defined the role of novel endogenous chemical agents in asthma. This led to four new licensed pharmaceuticals for asthma used in the treatment of millions of people worldwide. He has published nearly 500 papers and edited 6 books.

He has been a member of the Editorial Boards of many prestigious journals, including the *Journal of Applied Physiology*, *American Journal of Physiology*, *Pulmonary Pharmacology*, *Experimental Lung Research*, *Journal of Clinical Investigation*, *American Journal of Respiratory Cell and Molecular Biology*, and the *American Journal of Medicine*. In addition, he has been an associate editor of the *Journal of Clinical Investigation* and the *American Review of Respiratory Disease*.

In 2000, he assumed the post of Editor-in-Chief of the *New England Journal of Medicine*. During his tenure, the *journal* has published major papers advancing the science of medicine, including the first descriptions of SARS and papers modifying the treatment of cancer, heart disease, and lung disease. The journal, which has more than half a million readers every week, has the highest impact factor of any medical journal publishing original research.

**Stephen I Rennard, MD,** is Larson Professor of Medicine in the Pulmonary and Critical Care Medicine Section of the Department of Internal Medicine at the University of Nebraska Medical Center in Omaha, Nebraska, and courtesy Professor of the Department of Pathology and Microbiology and the Department of Genetics, Cell Biology and Anatomy. He received an AB with honors in Folklore and Mythology from Harvard University and an MD with honors from the Baylor College of Medicine, Houston, Texas. He completed internal medicine training at Barnes Hospital, Washington University, St. Louis, Missouri and trained in Pulmonary Diseases at the National Institutes of Health where he remained for seven years, conducting research in the cell biology of lung disease.

He joined the University of Nebraska in 1984 as Chief of Pulmonary and Critical Care, a position he retained until 1997. He was the Director of the Nebraska Office of Tobacco Control and Research from 1997 until 2008.

Dr. Rennard currently serves on the Board of Directors of the COPD Foundation and the Alpha-1 Foundation. He is a member of the American Thoracic Society Committee on Corporate Relations and the National Heart Lung Education Program Executive Committee. He is an external advisor to the Thomas Petty Aspen Lung Conference and the University of California-Davis Pulmonary Training Grant.

Dr. Rennard is active in several professional societies and has previously served on the Board of Directors for the American Thoracic Society, the Council of the American Lung Association and was a Governor for the American College of Chest Physicians. He served on the American Board of Internal Medicine, Pulmonary Section and was a member of the expert panel which prepared the global GOLD guidelines for COPD for the WHO/NHLBI. He has served on several task force committees, including the ATS/ERS task force that prepared the ATS/ERS joint COPD Standards.

Professor Rennard maintains an active program of clinical investigation in COPD and smoking cessation and a program of basic research in the mechanisms of lung tissue repair and remodeling, including the role of stem cells in disease pathogenesis and repair.

# Definitions, Epidemiology, and Genetics of Asthma and COPD

# Definitions

**A. Sonia Buist**

**Division of Pulmonary and Critical Care Medicine, Oregon Health and Sciences University, Portland, OR, USA**

Definitions of diseases evolve over time as our understanding of them changes. For example, until recently, the presence or absence of *reversibility* was considered to be the key distinction between asthma and chronic obstructive pulmonary disease (COPD) – with reversible airflow obstruction the hallmark of asthma, and irreversible airflow obstruction the hallmark of COPD. Better understanding of both diseases has brought new definitions that acknowledge the overlap and highlight the similarities and differences between them. The important change in our understanding is the recognition that chronic inflammation underlies both diseases. The nature of the inflammation differs, however, as does the response to anti-inflammatory medications, as described in detail in later chapters. This chapter draws heavily on the latest information on asthma and COPD that is included in the guidelines on the diagnosis and management of these diseases from two widely respected global initiatives, the Global Initiative for Asthma (GINA) [1] and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) [2], as updated in 2006.

## DEFINITIONS

### Asthma

Most of the definitions for asthma have emphasized the characteristics of fluctuations over time in bronchoconstriction and the reversible nature of the disease [1, 3]. As the pathophysiological basis of asthma became clearer, definitions began to include a statement about the pathological characteristics. The 2006 revision of the GINA Guidelines [1] proposes an operational description of asthma as:

> *a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment.*

This is very similar to the definition proposed by the National Asthma Education and Prevention Program in their 1997 guidelines [3]. Both definitions imply that asthma is one disorder, rather than multiple complex disorders and syndromes – a notion that is receiving increasing attention [4, 5].

## COPD

Until quite recently, definitions of COPD used to include the terms "chronic bronchitis" and "emphysema". The GOLD Guidelines, first published in 2002 [6], and revised in 2006 [2], the American Thoracic Society/European Respiratory Society (ATS–ERS) Guidelines published in 2004 [7], and the NICE Guidelines [8, 9] published in 2004 deliberately omitted these terms and used just the umbrella term COPD. The main reason for this is that the use of many different terms for COPD has led to confusion on the part of health-care providers and the public. This in turn has stood in the way of COPD becoming widely recognized.

The 2006 revision of the GOLD guidelines [2]defines COPD as:

*a preventable and treatable disease with some significant extrapulmonary effects that may contribute to severity in individual patients. Its pulmonary component is charac-terized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associ-ated with an abnormal inflammatory response of the lung to noxious particles of gases.*

This definition includes the phrase "preventable and treatable" to emphasize the importance of a positive attitude to outcome and encourage a more active approach to man-agement. This definition also stresses that extrapulmonary effects [10, 11] are an integral part of COPD and need to be taken into consideration in the diagnosis and management.

## SIMILARITIES AND DIFFERENCES

Over the past 30 years, the thinking about asthma and COPD has swung between the concept of asthma and COPD belonging to a spectrum of diseases that all cause airflow obstruction, to the concept of them as very differ-ent diseases, and most recently to them both being inflam-matory diseases with important similarities and differences, a theme that is taken up more fully in subsequent chapters. The present thinking is illustrated in Fig. 1.1 from the 2006 GOLD guidelines, which shows both diseases involving an inflammatory response that causes airflow limitation, but through gene–environment interactions with different sen-sitizing agents, cell populations, and mediators. The airflow limitation ranges from completely reversible (the asthma end of the spectrum) to completely irreversible (the COPD end of the spectrum). It is important to emphasize that COPD and asthma often coexist, so the clinical picture may reflect both conditions which may complicate the diagnostic proc-ess and the pathological features. For example, some patients with COPD have features of asthma and a mixed popula-tion of inflammatory cells; some patients with longstanding asthma develop the pathological features of COPD.

Although the similarities between the diseases are striking, it is the differences in the inflammatory processes between the two diseases that define their natural histories, clinical presentations, and approaches to management. The major differences in the pulmonary inflammation between

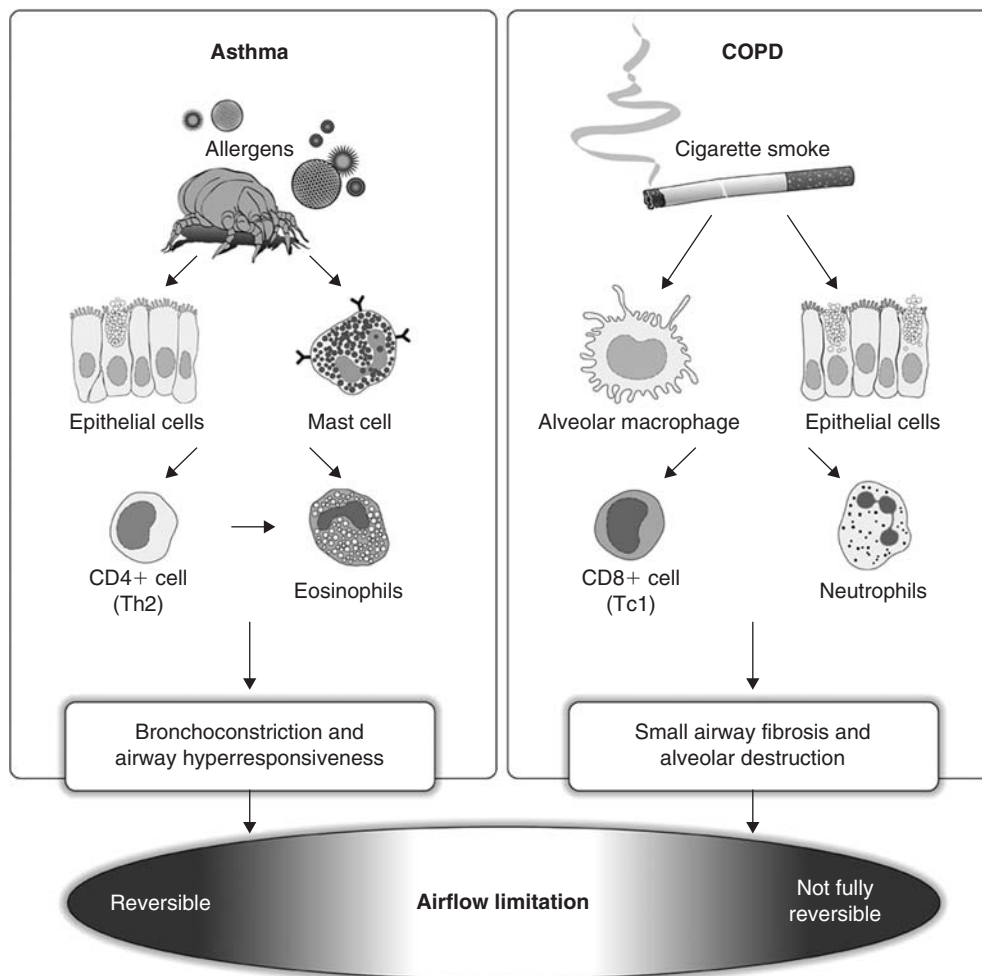

**FIG. 1.1** Inflammatory cascade in COPD and asthma (adapted from Ref. [2] with permission).

**TABLE 1.1** Differences in pulmonary inflammation in COPD and asthma.

| | COPD | Asthma | Severe asthma |
|---|---|---|---|
| Cells | Neutrophils ++<br>Macrophages +++<br>CD8$^+$ T-cells (Tc1) | Eosinophils ++<br>Macrophages +<br>CD4$^+$ T-cells (Th2) | Neutrophils +<br>Macrophages<br>CD4$^+$ T-cells (Th2), CD8$^+$ T-cells (Tc1) |

*Notes*: NO: nitric oxide; b/d: bronchodilator.

asthma and COPD are described in Table 1.1 from the 2006 GOLD report. These differences are further explored in later chapters.

## Severity classification

Both asthma and COPD are often stratified by severity, but the reason for this stratification is different for the two conditions. In the 2006 GINA guidelines, the emphasis has changed from using a severity classification to guide management to using a classification based on asthma control to guide management. The GINA guidelines now recommend that asthma classification based on severity should now only be used for research purposes. Tables 1.2 and 1.3 show the GINA severity classifications based on lung function and asthma control, respectively.

For COPD, a severity classification based on spirometry is recommended for educational purposes, but not for guiding management (Table 1.4). The current recommendation is that treatment of COPD should be driven by the need to reduce and control symptoms, not by level of lung function.

## Differentiating between asthma and COPD

It would be easy to differentiate between asthma and COPD if the latter occurred only in smokers and asthma in non-smokers. In fact, there is a clear diagnostic bias on the part of physicians, with COPD more likely to be diagnosed in men and asthma in women [12]. It is important to emphasize that both conditions may coexist in an individual, so many will have the clinical and pathophysiological features of both

**TABLE 1.2** Classification of asthma severity by clinical features before treatment.

*Intermittent*

Symptoms less than once a week
Brief exacerbations
Nocturnal symptoms not more than twice a month
- FEV$_1$ or PEF ≥ 80% predicted
- PEF or FEV$_1$ variability < 20%

*Mild persistent*

Symptoms more than once a week but less than once a day
Exacerbations may affect activity and sleep
Nocturnal symptoms more than twice a month
- FEV$_1$ or PEF ≥ 80% predicted
- PEF or FEV$_1$ variability < 20–30%

*Moderate persistent*

Symptoms daily
Exacerbations may affect activity and sleep
Nocturnal symptoms more than once a week
Daily use of inhaled short-acting $\beta$2-agonist
- FEV$_1$ or PEF 60–80% predicted
- PEF or FEV$_1$ variability > 30%

*Severe persistent*

Symptoms daily
Frequent exacerbations
Frequent nocturnal asthma symptoms
Limitation of physical activities
- FEV$_1$ or PEFs 60% ≤ predicted
- PEF or FEV$_1$ variability > 30%

*Source*: From Ref. [1] with permission.

**TABLE 1.3** Levels of asthma control.

| Characteristic | Controlled (all of the following) | Partly controlled (any measure present in any week) | Uncontrolled |
|---|---|---|---|
| Daytime symptoms | None (twice or less/week) | More than twice/week | |
| Limitations of activities | None | Any | |
| Nocturnal symptoms/awakening | None | Any | Three or more features of partly controlled asthma present in any week |
| Meed for reliever/rescue treatment | None (twice or less/week) | More than twice/week | |
| Lung function (PEF or $FEV_1$)[a] | Normal | <80% predicted or personal best (if known) | |
| Exacerbations | None | One or more/year[b] | Once in any week[c] |

*Source*: From Ref. [1] with permission.

[a] Lung function is not a reliable test for children 5 years and younger.

[b] Any exacerbation should prompt review of maintenance treatment to ensure that it is adequate.

[c] By definition, an exacerbation in any week makes that an uncontrolled asthma week.

**TABLE 1.4** Spirometric classification of COPD severity based on post-bronchodilator $FEV_1$.

| | |
|---|---|
| Stage 1: Mild | $FEV_1/FVC < 0.70$<br>$FEV_1 > 80\%$ predicted |
| Stage II: Moderate | $FEV_1/FVC < 0.70$<br>$50\% < FEV_1 < 80\%$ predicted |
| Stage III: Severe | $FEV_1/FVC < 0.70$<br>$30\% < FEV_1 < 50\%$ predicted |
| Stage IV: Very severe | $FEV_1/FVC < 0.70$<br>$FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted plus chronic respiratory failure |

diseases. This makes differentiating the diseases sometimes challenging for the clinician, especially in older adults who are or have been smokers.

The clinician can be guided by information in the clinical history such as smoking history, age of onset of symptoms, history of atopic conditions, and description of acute episodes of shortness of breath (see Table 1.5).

Asthma usually has its onset in early childhood. However, adult-onset asthma does exist, and many are unable to remember childhood events that would provide a clue to the early stages of asthma. Therefore, unless symptoms are continuous from childhood, the onset of asthma symptoms in adult life may be hard to interpret, especially in the presence of other risk factors such as smoking. COPD typically becomes clinically apparent in the sixth and seventh decades of life. If an individual is physically active, he or she may notice reduced exercise tolerance earlier.

COPD in developed countries is mostly a disease of smokers. This is not necessarily true in developing countries

where other risk factors, such as heavy outdoor and indoor/occupational air pollution, may be important risk factors that are causally related to COPD [2]. The relationship between asthma and smoking is complex. Individuals with asthma may be non-smokers, smokers, or ex-smokers. Since asthma genes and genes leading to the susceptibility to develop airflow obstruction with smoking are common in the population, the likelihood that an individual may have both is high. Likewise, COPD may occur in lifetime non-smokers [13–15]. In some, this may be longstanding asthma that may have been undiagnosed. In others, genes that are as yet unrecognized may be responsible. Alpha-1 antitrypsin deficiency is the model for such a genotype.

Pulmonary function tests can also provide guidance. Both diseases are characterized by airflow obstruction except in the early or mild stages. In asthma, lung function either remains normal or can be normalized with treatment in patients with mild intermittent or mild persistent disease [1]. COPD, in comparison with asthma, is defined by irreversible

airflow limitation, and this becomes progressively greater as the disease advances. Lung function in asthma is characterized by reversibility and variability. *Reversibility* refers to the short-term response to an inhaled bronchodilating agent, and is preferably measured with spirometry or peak flow (acceptable but not as helpful as spirometry). *Variability* refers to the improvement and deterioration in symptoms and lung function over time (both short- and long-time periods) that is characteristic of asthma. The GINA guidelines [1] recommend that *reversibility* be defined as a ≥20% improvement post-bronchodilator in the 1-second forced expiratory volume ($FEV_1$) or peak flow (PEF). GINA further defines *variability* as a diurnal variation in PEF of more than 20% (with twice daily reading, more than 10%).

The GOLD COPD guidelines [2] recommend that spirometry be used to establish that the airflow limitation is not fully reversible (defined as a post-bronchodilator $FEV_1/FVC$ ratio of <0.7 and $FEV_1$ < 80% predicted), and to stage the severity of the disease. However, GOLD emphasizes that bronchodilator reversibility testing does not predict a patient's response to treatment or predict disease progression.

## OVERLAP BETWEEN ASTHMA AND COPD

Not acknowledged in the definitions is the fact that longstanding asthma can lead to airway remodeling and partly irreversible airflow obstruction [16]. So, in many (but not all) with longstanding asthma, there is an appreciable component of chronic irreversible airflow obstruction with reduced lung function and incomplete response (or at least, not complete reversibility) to a short-acting bronchodilator or to oral or inhaled corticosteroids [17]. This complicates the diagnosis of asthma in older adults, and requires that the goals of treatment be modified since maintenance of normal lung function can no longer be a realistic goal.

Whether longstanding asthma with remodeling can be called COPD is intensely controversial. In so far as there is irreversible or poorly reversible airflow obstruction in the remodeled lungs, the term seems appropriate. Conceptually and practically, the recognition that remodeling is a feature of longstanding asthma in many (but not all) reinforces the notion that these diseases constitute a spectrum of disease, as illustrated in Fig. 1.1, ranging from fully reversible to fully irreversible.

## EXACERBATIONS

The definition of asthma highlights the importance of exacerbations as a feature of asthma, and emphasizes the fluctuations of the disease [1, 3]. The definition of COPD does not include any mention of exacerbations [2, 6–8]. Nevertheless, they may be as important in the natural history of COPD as they are in asthma [1] and account for approximately 70% of the COPD-related costs in the United States [2].

## LIMITATIONS OF THE DEFINITIONS

Definitions for both asthma and COPD have limitations since they can reflect only our current understanding of the diseases, which is quite limited. Both diseases will continue to be redefined as our understanding of them deepens, and as new effective preventive strategies and treatments become available.

## DEFINING THE DISEASES

### Asthma

The study of asthma epidemiology has been plagued by lack of consensus regarding standards for diagnosis. Most definitions have included variable airflow obstruction, but asthma is a clinical syndrome, without a widely accepted case definition. Epidemiology studies have used questionnaires to assess for the presence of disease, but are limited by recall and misclassification bias. Some have suggested that symptoms should be assessed in conjunction with airway hyperresponsiveness [1]. Others argue that airway hyperresponsiveness and symptoms should be analyzed separately owing to the poor correlation between clinical asthma and hyperresponsiveness [2]. Population-based epidemiology studies have demonstrated a low sensitivity of airway hyperresponsiveness for detecting individuals with physician-diagnosed asthma versus a sensitivity of greater than 90% in clinic studies [3]. A standard definition of asthma is as a chronic inflammatory disease of the airways. A commonly referenced formal definition is that promulgated in the Global Initiative for Asthma (GINA) guideline, which defines asthma as

*a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation causes an associated increase in airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment [4].*

However, this definition is non-specific and does not provide absolute criteria to facilitate differentiating asthma from other airway diseases [5].

Beyond definitions, there are differences between languages for the words used to describe asthma symptoms. A novel approach to this problem has been used in the International Study of Asthma and Allergies in Children (ISAAC), which includes an asthma video questionnaire demonstrating clinical signs of asthma, as an attempt to improve uniformity in surveying for asthma [6]. This multi-modality approach represents an improvement in asthma surveillance and has captured more individuals with asthma. However, diagnostic heterogeneity remains, as even within the ISAAC project, prevalence estimates of current asthma may vary depending upon the assessment tool used (i.e. video versus questionnaire).

### Chronic obstructive pulmonary disease

COPD includes chronic bronchitis, small airways disease and emphysema, and is characterized by airway obstruction that is fixed or only partially reversible. The diagnosis of COPD attached to a given patient varies depending on the degree of airflow obstruction considered diagnostic within a given set of guidelines. Thus the long-standing lack of international standardization of criteria for diagnosis of COPD makes understanding relative incidence and prevalence quite challenging. This is well illustrated by a study by Lindberg *et al.* [7], who compared COPD prevalence rates using European Respiratory Society (ERS), British Thoracic Society (BTS), Global Initiative for Chronic Obstructive Lung Disease

(GOLD), and clinical and spirometric American Thoracic Society (ATS) criteria. In this study, ERS criteria revealed a 14.0% prevalence of COPD, BTS criteria 7.6% prevalence, GOLD criteria 14.1% prevalence, clinical ATS criteria 12.2% prevalence, and spirometric ATS criteria 34.1%.

This example highlights the difficulty of comparison between international studies/standards and the efforts to understand COPD epidemiology on a global scale. Similar prevalence differences depending upon reference criteria have been observed by other authors [8, 9], further highlighting the challenges inherent in making comparisons between populations.

Recently, an international committee convened to refine and promote standardization of a COPD definition. The GOLD has defined COPD as

*a preventable and treatable disease with some significant extra pulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases [10].*

GOLD stages are defined using post-bronchodilator spirometry, with an $FEV_1$/FVC ratio of less than 0.7 defining the presence of obstruction, and the $FEV_1$ reduction translating into the severity of COPD. A key element of this updated definition is that it includes capturing features of extra-pulmonary co-morbidities which have relevance for disease severity [11]. The GOLD initiative has aimed to promote studies to understand the increasing prevalence of COPD worldwide, as well as to standardize the collection of data for international comparison of research [12].

In summary, for many years both asthma and COPD have lacked widely accepted case definitions, but international efforts have been developed to rectify this. Definitions of both diseases include both symptoms and spirometric features. Refining the standardization of clinical diagnosis will facilitate comparability in epidemiological studies. However, given the wide variability in disease definitions for both diseases, comparisons of studies of asthma and COPD between populations and between countries must be viewed in the light of differences in criteria used for disease diagnosis. Although the GINA and GOLD guidelines have brought some standardization and consensus to diagnosing asthma and COPD respectively, diagnostic heterogeneity remains and further refinement of these guidelines is an important goal.

## INCIDENCE

Incidence rates for asthma and COPD vary depending on the age of the population under consideration. For example, asthma is commonly diagnosed in early childhood and COPD is commonly diagnosed after age 60. Interestingly, cases of adult-onset asthma and early-onset COPD predominate in women, suggesting that there may be a common hormonal influence on the age-of-onset of these diseases [13, 14].

Global burden of disease estimates suggest that at least 300 million people worldwide have asthma, with the potential for an additional 100 million more cases by the year 2025 [15]. In childhood, incidence rates for asthma are highest among the youngest age groups and among male children until puberty [16–21]. In a study of an adult Swedish population, Toren and Hermansson [22] found the incidence rate for adult-onset asthma to be highest among females of all ages greater than 20, with an incidence of 1.3 per 1000 person-years; among women 16–20 years of age the rate was 3 per 1000 person-years. Analysis of data from a prospective cohort study in Finland demonstrated no increase in asthma incidence from 1982 to 1990 in adults aged 18–45 years [23]. Early investigation into the increasing prevalence of asthma in the United States was noted in a review of medical records from Olmsted County, Minnesota, where the annual incidence of asthma was found to increase from 183 per 100,000 in 1964 to 284 per 100,000 in 1983. The most significant increase was in children aged 1–14 years, suggesting a potential cohort effect early in life. Despite this increased incidence in asthma among children from 1964 to 1983, constant rates were observed among adults [16].

Although these data indicate that asthma incidence has been increasing, minimal information has been available for trends in COPD incidence. One challenge of studying COPD incidence is that the disease is usually moderately advanced at diagnosis, and thus true incidence rates have remained elusive. However, a recent study observed that cough and phlegm may identify a group at high risk for incident COPD [24]. This study by de Marco and colleagues focused on a cohort of 5002 subjects without asthma and with normal lung function. The observed incidence rate of COPD was 2.8 cases/1000/year; the incidence rate ratio for chronic cough and phlegm was 1.85 (95% CI 1.17–2.93) with a 10-year cumulative incidence of COPD in the overall cohort of 2.8%. Two other studies have reported on incidence rates of COPD using GOLD criteria, with a 10-year cumulative estimate of 13.5% noted by Lindberg *et al.* [25], and a 9-year cumulative incidence of 6.1% in a study by Johannessen *et al.* [26].

## PREVALENCE

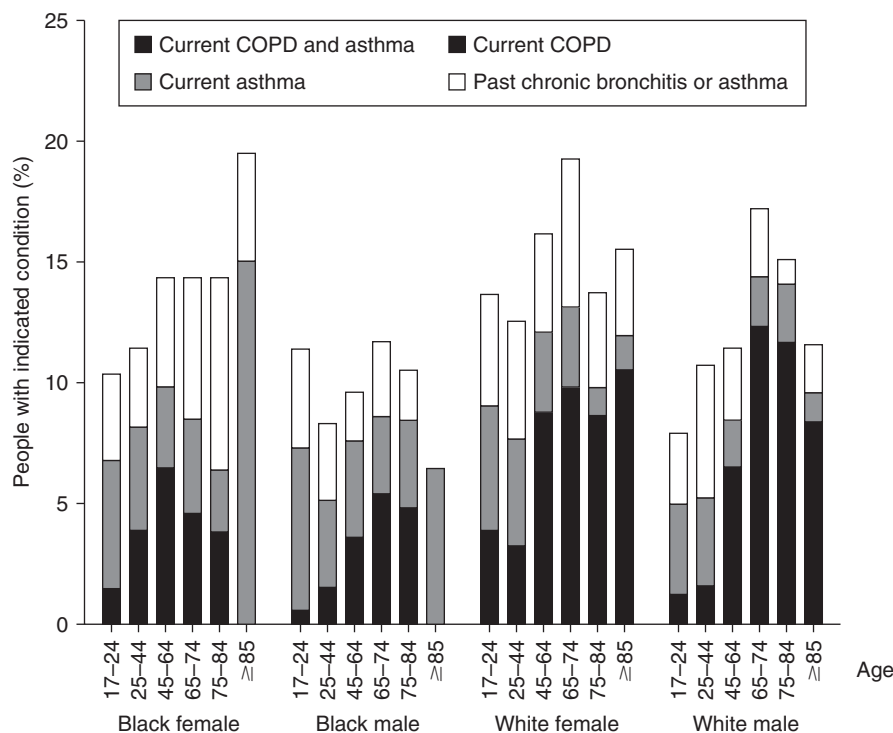
Trends in the prevalence of obstructive lung disease have been suggested by an analysis of the Third National Health and Nutrition Examination Survey (NHANES III) [27]. This survey included subjects with asthma, chronic bronchitis, and emphysema (Fig. 2.1). In this cohort, the case definitions were a physician diagnosis of chronic bronchitis, asthma or emphysema, respiratory symptoms, and low lung function. Of note, the investigators defined low lung function as present when the $FEV_1$/FVC ratio was <0.70 and the $FEV_1$ was less than 80% of predicted. Of the investigated population of 20,050 adults, 6.8% had low lung function as thus defined; 7.2% of the population had an $FEV_1$/FVC ratio less than 0.70 with an $FEV_1$ greater than 80% predicted, and were not included as having low lung function. Of the entire population, 8.5% reported obstructive lung disease. Importantly, 63.3% of those with documented low


**FIG. 2.1** Age-specific percentage of individuals, stratified by race and sex, with COPD and asthma, current COPD, current asthma, and past chronic bronchitis or asthma. lung function had no current or prior doctor diagnosis of obstructive lung disease. In addition to prevalence information regarding low lung function, NHANES III data suggest that there is still a significant proportion of disease that goes undiagnosed in the mild stages, leading to an underestimation of the true prevalence of obstructive lung disease.

## Asthma

Data from the United States have suggested an increase in prevalence of asthma in children as well as in older adults (Fig. 2.2) [28]. During the last several decades studies have suggested an increase in prevalence worldwide of 5–6% per year. Data from the National Health Interview Survey (NHIS) reveal a 75% increase in self-reported asthma rates from 1980 to 1994. This trend was demonstrated in all age and race strata as well as in both genders. The most significant increase demonstrated by the NHIS was among children 0–4 years of age (increase of 160%) and persons 5–14 years of age (increase of 74%) [29].

Repeatedly, the prevalence of asthma amongst inner-city children has been demonstrated to be much higher than among similar aged children living outside the inner city [29–31]. It has been suggested that a doctor's diagnosis of asthma is made less frequently than asthma symptom reporting, raising concern that despite increasing prevalence there is still a tendency to under-diagnose asthma, and consequently underestimate true prevalence values [32].

The GINA project [15] has compiled asthma prevalence data for 20 regions of the world, with the main sources of data in children including the ISAAC project,

and the main source of prevalence data in adults including the European Community Respiratory Health Survey (ECRHS). Higher prevalences of asthma (>10%) have been noted in developed countries including Canada, the United States, United Kingdom, New Zealand, and The Republic of Ireland [15]. In parallel with urbanization, the rates of asthma have increased in developing countries as well.

The ISAAC has as its aim to describe, across 155 centers, the prevalence and severity of asthma in children in 56 countries [6]. Phase 1 of this trial has demonstrated a large variation in the prevalence of asthma symptoms in children throughout the world, with the highest prevalence in centers from Australia, New Zealand, the United Kingdom, and Ireland [32–35]. While the prevalence of allergic rhinitis has been noted to be scattered in the groups with the highest prevalence of asthma, the lowest prevalence for rhinitis has been found in countries where the asthma prevalence was lowest, such as in Eastern Europe, Indonesia, Greece, and India. In addition to defining prevalence rates, the ISAAC study represents an effort to establish an international standard to facilitate comparability of data from epidemiological studies of asthma. The rising asthma prevalence rates in children heralds rising asthma rates for adults, as two-thirds of children with asthma still have symptoms by early adulthood [36].

## Chronic obstructive pulmonary disease

COPD is best understood by understanding first the trends for smoking in populations. Although projected smoking rates throughout the world have increased, smoking prevalence in
**FIG. 2.2** Changes in the prevalence of asthma and asthma symptoms in children and young adults. Reproduced from Ref. [28], with permission.

the United States has been decreasing. Estimates from the year 2005 suggest that 21% of Americans smoke cigarettes, with cigarette smoking prevalence rates varying by both sex and race. Recent prevalence estimates [37] for smoking were highest for American Indian/Alaska Natives (37.5% men and 26.8% women). The prevalence of current smoking is 20.0% in white women, 17.3% in African American women, 24.0% in white men, and 26.7% in African American men.

However, in the context of COPD, susceptibility to cigarette smoke is not uniform and varies as a function of the amount of cigarette smoking [38]. Stang *et al.* [39] utilized smoking rates to create a mathematical model for estimating COPD prevalence. Using their model, they estimated that 15.3 million people in the United States aged 40 years or more have COPD; this was a reasonable estimate compared to the spirometric prevalence of 17.1 million as estimated by the NHANES III. Using this model, they also predicted the prevalence of COPD in Germany (2.7 million), the United Kingdom (3.0 million), Spain (1.5 million), Italy (2.6 million), and France (2.6 million), and suggested smoking rates as a useful surrogate for estimating COPD prevalence.

The World Health Organization prediction is that by 2020 COPD will rise from being the twelfth to the fifth most prevalent disease worldwide, and from being the sixth most common cause of death to the third most common [40]. Prevalence estimates of COPD in the United States in 1996, before widespread implementation of GOLD criteria, indicated approximately 15 million people have COPD with

14.1 million with chronic bronchitis and 1.8 with emphysema. By these measures, there was no change in the prevalence of emphysema from 1982 to 1996, although from 1983 to 1995 the prevalence of chronic bronchitis continued to increase. In a study of the Canadian population, prevalence rates of COPD were 4.6% in the 55–64 age group, 5.0% in the 65–74 age group, and 6.8% in the greater than 75 age group [41]. These data may be an underestimation, as there is a suggestion that COPD prevalence rates are underestimated in the elderly, especially in those with lower incomes [42]. By 2001, in distinction to the many asthma prevalence studies, only 32 prevalence surveys of COPD were reported (Fig. 2.3) [9] with comparability somewhat limited by COPD case definitions. The Burden of Obstructive Lung Disease (BOLD) project is a large-scale study of COPD, with one goal of measuring COPD prevalence using standard GOLD criteria. A recent report from the study in 1258 subjects reported a 26.1% prevalence of at least GOLD Stage 1 COPD, and 10.7% for GOLD Stage 2 or higher [44]. Pooled estimates based on GOLD criteria have suggested a prevalence of GOLD Stage 1 or higher COPD of 5.5% and 9.8% for GOLD Stage 2 or higher [9].

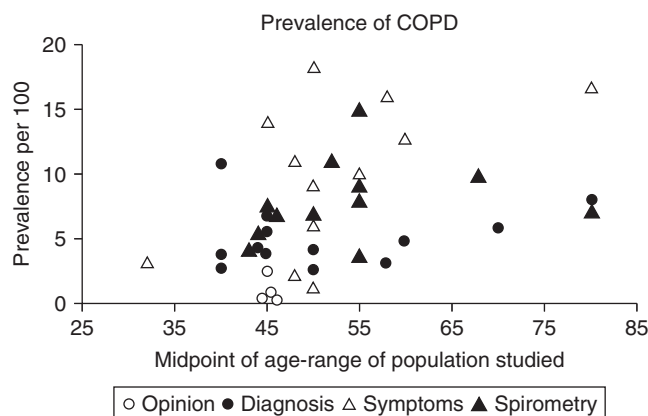
COPD is likely under-diagnosed in both North American and European populations. For example, the IBERPOC Project (*Estudio Epidemiologico de la EPOC en España*) was a population-based study of prevalence of COPD in Spain [45]. The prevalence of COPD in this population (26% current smokers, 24% ex-smokers, 76% men), defined according to ERS criteria, was 9.1%. Only


FIG. 2.3  Prevalence of COPD using estimates from expert opinion, physician diagnosis symptoms and spirometry. Data from Ref. [9] as reproduced in Ref. [43], with permission.

22% of those diagnosed had a prior diagnosis, while 48% had prior respiratory symptoms. More recently, despite prevalence estimates for GOLD Stage 1 or higher COPD in the BOLD study in Salzburg, only 5.6% of subjects reported ever receiving a doctor diagnosis of COPD [44]; the prevalence has yet to translate into widespread use of spirometry for COPD screening.

The high-prevalence estimates for both asthma and COPD have translated into significant morbidity associated with both diseases. In 2001, asthma was ranked as the 25th leading contributor to disability adjusted life years (DALYs) worldwide; COPD was ranked 12th. In this context, together with the high-prevalence estimates for both disease, the global burden of disease and economic costs for both diseases are high.

In summary, the prevalences of both asthma and COPD are increasing in both Western developed and developing countries. As both asthma and COPD are both likely under-diagnosed, the prevalence estimates underestimate the true burden of these diseases. Variability in definitions of both asthma and COPD contribute to inexact prevalence estimates and problems with comparisons of prevalence data. ISAAC (for childhood asthma), ECRHS (for adult asthma), and GOLD (for COPD) represent international efforts underway to standardize the definitions used in studies to enhance comparisons of incidence, prevalence, and burden of disease.

## HEALTHCARE UTILIZATION AND HOSPITALIZATION TRENDS

In the United States, the estimated cost for year 2000 for asthma was projected to be 12.7 billion dollars (8.1 for direct cost, 2.6 related to morbidity, 2.0 related to mortality) and 30.4 billion dollars for COPD (14.7 for direct cost, 6.5 related to morbidity, 9.2 related to mortality). Utilization of health services has continued to increase for both diseases. An increase in health service use has been documented in many countries, including the United Kingdom, Canada, and the United

States; the utilization increase has been concomitant with the documented increase in asthma prevalence [46–48].

Increased hospital visits have been documented worldwide, including in England, New Zealand, the United States, Greece, Australia, and Canada [49–56]. In capturing the epidemiology trend from the 1960s to the 1980s, Evans *et al.* reported on a 200% increase in rates of hospitalization of adults with asthma (and a 50% increase for children with asthma) [57]. Overall, hospitalizations with asthma as a primary diagnosis increased most steeply in the 1970s until the mid-1980s and then remained constant; this is in contrast to asthma as a secondary diagnosis which increased until 1997. From 1975 to 1995, office visits for asthma more than doubled, from 4.6 to 10.4 million [29].

Based on the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey, in 1998 more than 14 million visits were made to physicians for diagnoses related to COPD, and this was an increase from 5.5 million visits reported in 1980. In 2000, there were approximately 726,000 hospitalizations coded as COPD or allied conditions [58]. Care must be taken in interpretation of these data because of non-uniform case definitions; more than half of the discharge diagnoses were non-specifically coded as COPD or allied conditions.

In summary, increased health service utilization has occurred for asthma and COPD during the last two decades. Overall, hospital admissions and discharges have increased for both diseases.

## MORBIDITY AND MORTALITY

### Asthma

The New Zealand epidemic of asthma in the 1970s prompted a review of asthma deaths in Western countries; among such countries there was a notable increase of 1.5- to 2-fold in the asthma mortality rates between the mid-1970s and the mid-1980s [59]. The highest mortality rates in the United States have been in the inner-city regions, with particularly high-risk populations studied in East Harlem, New York City, and Cook County, Chicago [31, 60]. One study observed that socioeconomic and racial disparities were attributable to higher incidence of asthma exacerbations among inner-city children, with no excess utilization of medical resources [61].

International comparisons of mortality rates have been limited by differences in recording statistics of cause of death [62]. There is variability in the mortality rates ascribed to asthma, with significant variation by region of the world (Fig. 2.4), with the highest asthma case fatality rates in China (36.7/100,000 asthmatics) [15]. Mortality rates for asthma have decreased over the past 20 years, likely due to improvements in pharmacotherapy, although it has been suggested that most deaths from asthma now occur in adults, potentially consequent to medical non-compliance [63]. Comparison of mortality rates is difficult also because of the lack of standardized definitions for the disease, and because of environmental, genetic, socioeconomic, and occupational influences unique to a given population.

Countries shaded according to case fatality rate (per 100,000 asthmatics)

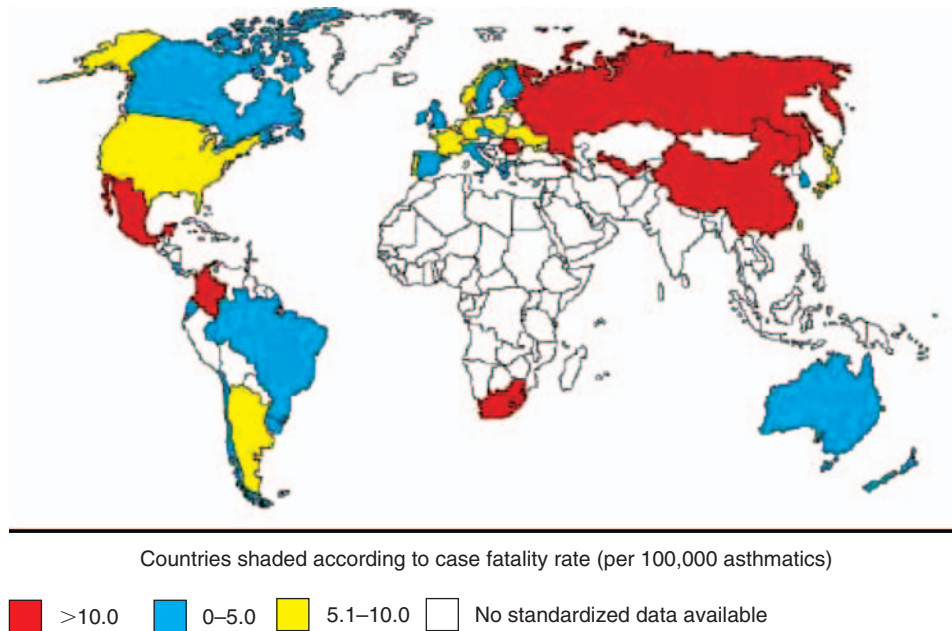
█ >10.0    █ 0–5.0    █ 5.1–10.0    □ No standardized data available


**FIG. 2.4** Asthma case fatality rate in individuals 5–34 years of age calculated as the number of deaths per 100,000 cases of asthma. Reproduced from Ref. [15], with permission.

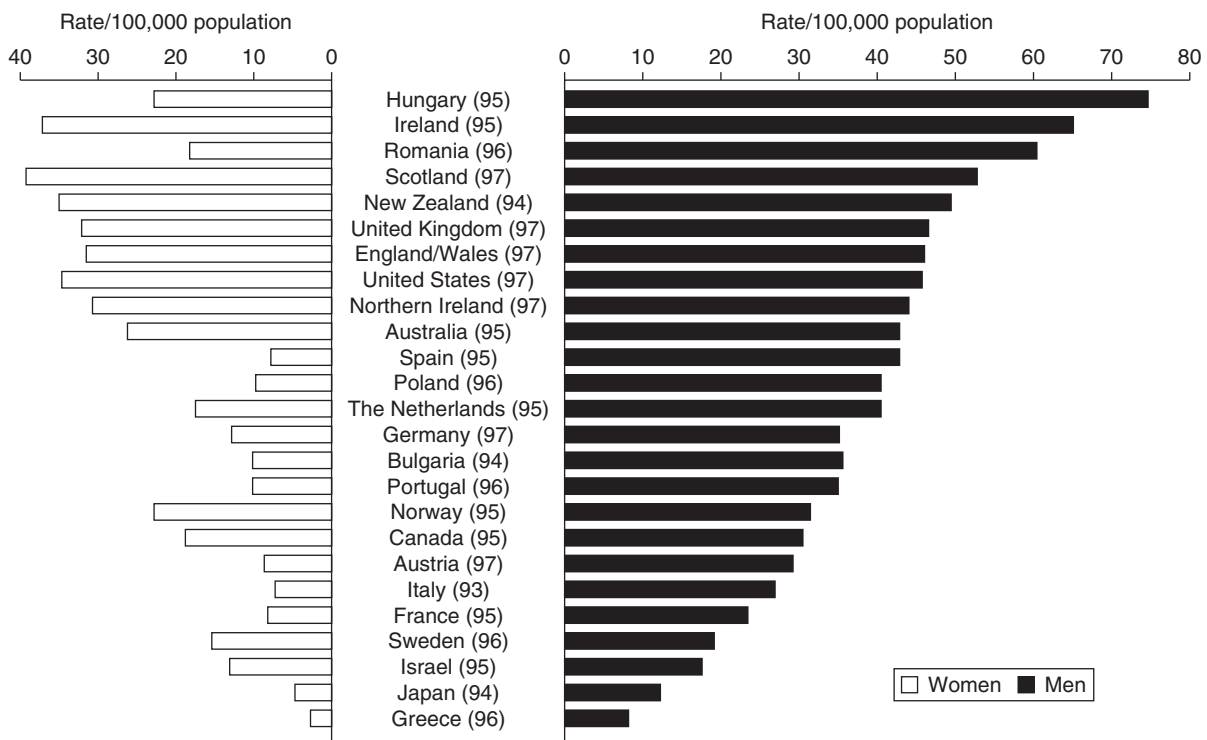

**FIG. 2.5** Age-adjusted death rates for COPD by country and sex, for individuals aged 35–77. The year of data is shown in parentheses. Reproduced from Ref. [12], with permission.

## Chronic obstructive pulmonary disease

Since 1960 mortality associated with COPD has continued to rise. In the year 2000, the number of women who died from COPD surpassed the number of men [58], and standardized mortality rates have been observed to be higher in women versus men with COPD (4.8 versus 2.7 respectively)

[64]. In longitudinal follow-up of 13,756 individuals in the Atherosclerosis Risk in Communities (ARIC) study, rapid lung function decline over a 3-year period was associated with an increased risk for COPD-related hospitalization and death [65].

International mortality trends demonstrate high rates of deaths for COPD in many countries. These differences

may be accounted for in part by different smoking behaviors, which include tobacco type, along with other environmental, infectious, and genetic factors. Differences among these death rates are striking (Fig. 2.5), but again lack of standardization in coding practices and death certification as well as practice differences and quality of care are relevant when comparing estimates [12].

Although overall asthma mortality remains low compared with COPD, mortality rates for both asthma and COPD have increased in the last decade. Differences in death rates for asthma and COPD between countries are multifactorial (genetic, environmental, occupational, socioeconomic), but differential coding of cause-of-death statistics hinders accuracy of estimates for both diseases.
## SMOKING

Burrows and colleagues [38] have demonstrated that, for a given level of tobacco smoke exposure, $FEV_1$ varies substantially (Fig. 2.6). In addition, the dose–effect relationship between cigarette smoking and $FEV_1$ decline depends on the year of life when an individual is exposed. Dose and timing of tobacco smoke exposure have a differential effect on $FEV_1$ depending on the stage of the life cycle (Table 2.1). Cunningham *et al.* [66] observed that maternal smoking during pregnancy resulted in a 1.3% reduction in $FEV_1$ when children were 8–12 years old. Tager *et al.* [67] found that adolescents who smoke when aged 15–20 have an estimated

8% reduction in $FEV_1$. The Vlagtwedde/Vlaardingen study [68] demonstrated a large effect of cigarette smoking in decreasing maximal lung function in individuals less than age 20; this effect exceeded the effect of cigarette smoking on lung function decline seen in older subjects.

Smoking is a notable risk factor for both asthma and COPD in children and adults, and active smoking perpetuates pulmonary (and likely systemic) inflammation. Overall, smoking is associated with an increase in asthma incidence [69, 70], as well as an increased symptom severity, increased morbidity and lung function decline, and an increased risk of death [71–74]. Passive exposure to cigarette smoke increases the risk for the development of asthma and allergic sensitization [75–77]. There has also been a suggestion that non-specific airways responsiveness is increased by environmental and personal smoke exposure [78].

Maternal smoking is a risk factor for the development of asthma in children up to 1 year of age [79]. In a case-control study of children whose mothers were heavy smokers, one group demonstrated an odds ratio of 2.15 among 3–4-year olds for the development of asthma; these data were controlled for family history, past infections, gender, and other demographic variables [80]. In a 6-year follow-up, the odds ratio for asthma among those exposed to maternal smoking was 3.8 [81].

As noted above, the single most significant risk factor for COPD is tobacco smoking. Although an oft quoted estimate is that only 10–15% of smokers actually go on to develop obstructive lung disease, this is a marked underestimate, with many researchers suggesting that all individuals

FIG. 2.6  Distribution of percentage predicted forced expiratory volume in 1 s ($FEV_1$) in adults with varying smoking histories as measured in pack-years. The proportion of smokers with normal flow decreased with increasing pack-year histories. Yet, many have near-normal $FEV_1$ with extensive smoking history. Subjects with "respiratory trouble" before age 16 were excluded. Medians and means ±1 SD are shown for each group in the abscissae. Note that among the 425 persons with 20+ pack-years, only 15% have an $FEV_1$ of 60% of predicted or less. Reproduced from Ref. [38], with permission.

**TABLE 2.1** Effects of cigarette smoking at different stages of the life cycle.

| Life phase (gender) | Cigarette dose | Total $FEV_1$ reduction | $FEV_1$ reduction (ml/year per packs/day) |
|---|---|---|---|
| *In utero* (M and F) | Variable exposure for 9 months | 27.3 ml[a] | 36 |
| Adolescence (M) | 15 cigarettes/day for 5 years[b] | 390 ml | 104 |
| Adolescence (F) | 10 cigarettes/day for 5 years[b] | 340 ml | 136 |
| Adult (M) | Variable | N/A | 13[c] |
| Adult (F) | Variable | N/A | 7[c] |

*Notes:* M: male; F: female.

[a] Adjusted for gender and maternal smoking in the past year; based on 1.3% reduction and mean $FEV_1$ = 2.1 l, 1 pack/day in smoking mothers during pregnancy is assumed for relative $FEV_1$ reduction (Ref. [65]).

[b] Median values for cigarette smoking (Ref. [66]).

[c] Estimated values (Ref. [67]).

who smoke will go on to develop COPD. Among those smokers already with a decreased $FEV_1$, lung injury and subsequent decrements in lung function secondary to cigarette smoking are more dramatic. In the Lung Health Study, middle-aged smokers (with $FEV_1$ between 55% and 90%) who continued smoking for 5 years had further losses of several hundred milliliters of $FEV_1$ [82]. However, COPD has been identified in non-smokers as well. Prevalence has been noted to increase with age, to be higher in women than in men, to be particularly high in Hispanic individuals, and to be higher in low income versus affluent individuals [83]. Recent data from NHANES III suggests that 25% of cases of COPD in the United States occurs in lifelong non-smokers [84], a finding that is echoed by estimates of 23% in the United Kingdom [85] and 23% in Spain [86]. These observations reinforce that although cigarette smoking is the most important risk factor for COPD, it is not *necessary* for the development of irreversible airflow obstruction.

In summary, smoking has a lifetime influence on asthma and COPD. This starts *in utero* and continues into older age. Smoking is associated with enhanced airway responsiveness, both in asthma and COPD. Smoking is sufficient but not necessary for the development of COPD. Smoking is only one of several risk factors for asthma.

## INTERMEDIATE PHENOTYPES

### Allergy

Allergy represents immediate hypersensitivity to an antigen and is associated with an increased production of a specific immunoglobulin by sensitized lymphocytes. Elevations in specific IgE and/or total IgE, total eosinophil counts, and skin test reactivity to specific allergens have been used clinically to detect allergic individuals. As measured by skin test reactivity, allergy increases with age until about age 15, at which point it is maximal. The decline in skin test reactivity after age 35 confounds the measurement of this phenotype in older individuals. This reported association between skin test reactivity and decline in $FEV_1$ is not consistent in the literature. In retrospective studies, Taylor *et al.* [87] and Frew *et al.* [88] demonstrated no relation of skin test positivity to decline in $FEV_1$. However, Gottlieb *et al.* [89] investigated this prospectively in the Normative Aging Study and found that skin test positivity predicted increased annual rates of decline in both $FEV_1$ and $FEV_1$/FVC ratio.

Allergic inflammation is characteristic of asthma; 80–90% of childhood asthmatics are atopic, and the degree of atopy appears to be associated with prognosis in childhood asthma [90]. Studies have demonstrated that the asthmatic phenotype is associated with elevated serum IgE levels more so than skin test positivity [91], and that increased airways responsiveness is related to total serum IgE levels [92].

Weiss has suggested that immediate type I hypersensitivity is a risk factor for the development of chronic obstructive lung disease, and suggests that atopy may influence childhood asthma and limit maximal lung function, accelerate $FEV_1$ decline, and potentially enhance interaction with cigarette smoking to result in $FEV_1$ decline progressing to the development of COPD [93]. Hargreave and Leigh [94] demonstrated, in a subset of COPD patients, that eosinophilic inflammation is important in COPD exacerbations, and potentially leads to a decline in lung function. As well, an inverse association of serum IgE with the $FEV_1$/FVC ratio has been observed [95]. These data indicate that allergen sensitization may represent an intermediate phenotype which needs to be considered in understanding disease onset and progression in both asthma and COPD.

## Airways responsiveness

Airways responsiveness to methacholine and histamine has been used in population-based studies to help define individuals susceptible to the development of obstructive lung disease. This intermediate phenotype is a feature of both asthma and a subset of patients with COPD. Baseline levels of lung function, allergy, age, and cigarette smoking history all influence airways responsiveness.

Airways hyperresponsiveness has been demonstrated to predict accelerated decline in lung function and the development of COPD [96]. More recently, airways responsiveness has been demonstrated to predict COPD mortality [97].

Airways responsiveness has been demonstrated to predict the development of asthma [98]. The prevalence of airway hyperresponsiveness exceeds the prevalence of asthma; the former is about 20% in the general population. Data from the Childhood Respiratory Disease Study demonstrate that increased airway responsiveness predicts the development of asthma in children and young adults with a 2- to 3-fold risk [99]. Some have observed this risk to be increased as much as 5-fold [100].

Airways hyperresponsiveness in COPD patients may be demonstrated in more than two-thirds of individuals in situations where it is actually measured [101]. Some individuals who develop COPD have an allergic asthma phenotype, as suggested by the Dutch hypothesis [102]. Alternatively the hyperresponsiveness may be a consequence of COPD. Results from a 25-year longitudinal study in the Netherlands revealed that increased airways responsiveness is an independent risk factor for $FEV_1$ decline [103]. Among individuals with early-onset COPD, the degree of baseline airways responsiveness determined the response to cigarette smoking; those with early-onset COPD who have increased airways responsiveness appeared more sensitive to the effects of cigarette smoke and had an accelerated decline in $FEV_1$ [104]. Thus, airway hyperresponsiveness, together with features of allergy and smoking, likely represent common risk factors for both asthma and COPD.

## Gender/sex-related influences

The impact of gender and sex-biology-related features on airway disease are complex, and include both social paradigms (gender-related) as well as hormonal and genetic (sex-related) influences.

The epidemiology of asthma is characterized by age-related sex differences. Asthma and wheezing have been demonstrated to be more prevalent in young boys than young girls [20]. This trend disappears during puberty [105]. A recent analysis of the European Respiratory Health Survey [106] found that girls had a lower risk of developing asthma than did boys during childhood; about the time of puberty the risk was equal. After puberty, the risk in young women was higher than in young men, and this was a consistent trend in the 16 countries included in this study.

Women older than 20 years have higher prevalence and morbidity rates from asthma, and women are more like to present to the emergency department and be admitted with a diagnosis of asthma [107, 108]. In the multicenter Asthma Collaboration Study [109], women were more likely to be admitted to the hospital and report ongoing symptoms at follow-up, although overall men had less outpatient care and lower pulmonary function. Although it is unclear why women have more severe disease and higher mortality from asthma, hormonal, genetic, environmental, and social factors are likely contributory [110].

For many years COPD has traditionally been considered a disease of men, as men have been noted to have a higher prevalence of COPD at the population level. Yet, Prescott *et al.* [111] have suggested that women are more susceptible to the development of COPD, and observed that smoking was associated with a greater decrement in $FEV_1$ per pack-year of cigarette smoked, when compared to male smokers. Mannino *et al.* [112] analyzed data for deaths from obstructive lung disease from 1979 until 1993 and found that the mortality rates for men with COPD have started to stabilize but were continuing to increase among women, likely reflecting smoking trends. In the year 2000, the number of women dying from COPD has surpassed the number of men. Women have been observed to be more susceptible to the effects of tobacco smoking [113],

more susceptible to develop severe early-onset COPD [14], have worse quality of life [114], and higher mortality from COPD [115] than men. These gender/sex differences most likely represent influences of both dose of tobacco exposure and underlying genetic and hormonal susceptibilities, and is a topic of active research.

In summary, in the adult years women have a higher prevalence of asthma. The prevalence of COPD in women is increasing, in keeping with the historical trends of cigarette smoking and disease. The gender and sex differences between asthma and COPD highlight the importance of hormonal and genetic influences relevant to disease expression in men versus women.

## DEMOGRAPHICS

In the United States, morbidity from asthma has been demonstrated in multiple studies to be greater in children of African American descent. In the United States, physician-diagnosed asthma has been reported in 13.4% of African American children and 9.7% of white children [116]. African American children have also been reported to have greater limitation on activity due to asthma, with more hospital admissions and fewer doctors' visits when compared with white children [117]. Mortality from asthma has been higher for African American children when compared with children of other races since the mid-1980s [47, 57, 118–121]. Data from the NHANES II and the Hispanic Health and Nutrition Survey have noted that the prevalence of childhood asthma was higher in children of Puerto Rican versus African American descent (20.1% versus 9.1% respectively) [122]. An extensive review on the topic has noted that amongst the different ethnic groups living in the United States, the prevalence of asthma is highest in Puerto Ricans [123].

Studies in Chicago have demonstrated socioeconomic gradients and differing outcomes by race. In 1996, asthma hospitalization rates were more than twice as high as the United States' rates overall. Age-adjusted mortality was 4.7 times higher in non-Hispanic African Americans than in non-Hispanic whites [124]. An association with poverty has been suggested [125], and it has also been suggested that severe asthma may occur more frequently in poorer communities [126, 127]. The association of lower socioeconomic status with increased asthma prevalence is most likely multifactorial: the effects of indoor air pollution, passive cigarette smoke exposure, allergen exposure, and reduced access to medical care may all be relevant.

Some have suggested, based on the use of education as a surrogate for lower socioeconomic status, that there is an association of socioeconomic status with the development of obstructive lung disease. Bakke *et al.* [128] demonstrated that completion of only primary schooling was associated with an odds ratio of 2.9 for the development of obstructive lung disease when compared with those who achieved university level education. Exposure to smoking and occupational hazards decreased with increasing educational status.

## AGE

Infants born prematurely, when compared to those born at term, have a risk for asthma that is increased approximately 4-fold [129]; reduced lung function measured with birth has been associated with incident asthma by age 10 [130]. There are data that breastfeeding is protective against asthma and, as previously noted, the risk for asthma increases in children exposed to cigarette smoke both *in utero* and during childhood. Asthma that begins after age 50 is thought to be more severe and less reversible than asthma that is incident in childhood [131]. In childhood, the remission of asthma before adulthood has been suggested to be about 50% [69, 132, 133]. Less information is available on the epidemiology of asthma in the middle-aged and elderly, yet some suggest that older patients are more severely affected than younger patients [134].

Some data support the proposition that individuals may "outgrow" asthma (with remission rates decreasing with increasing age) [135]. Other data suggest that remission of asthma and respiratory symptoms are uncommon [136]. Aging has been associated with increased airway obstruction overall [137] and asthma is a risk factor for COPD in adult lifetime never smokers [84]. The association of aging with the development of COPD most likely represents the cumulative insult of a lifetime of smoking and environmental exposure interacting with a susceptible host.

## CONCLUSION

Ninety percent of all childhood asthma is diagnosed before the age of 6 years. Since there is a crude inverse relationship between respiratory symptoms and level of lung function, it is not surprising that as lung function increases in childhood respiratory symptoms decrease and often disappear. Thus, a large number of individuals are left with the intermediate phenotypes of increased airways responsiveness and/or allergy at the time that they reach their maximally attained level of lung function between the ages of 15 and 30. These intermediate phenotypes represent definable host characteristics that confer increased susceptibility to a variety of environmental exposures encountered in adult life, such as viral respiratory illness, occupation, allergen exposure, and perhaps most importantly, cigarette smoking.

The most clearly defined (non-genetic) susceptibility factors for premature or early-onset COPD are cigarette smoking, childhood asthma, increased airways responsiveness, and allergy. It is now clear that most airways hyperresponsiveness in adults antedates, precedes, and predicts the development of COPD. Obviously, this construct suggests that most genes that predict susceptibility to asthma may also be important genetic predictors of COPD susceptibility, and this is a topic of ongoing research.

Both asthma and COPD are defined as syndromes, and the definitions are loose; thus it is not surprising that there is substantial overlap between the conditions at any given age. Indeed, there are no substantive data to suggest that individuals cannot have both reversible and fixed airflow obstruction, and hence asthma and COPD at the same time.

The importance of early life and *in utero* events for the subsequent development of disease is a theme that is common to a variety of complex traits. These same issues also present themselves with disorders of the airways. The major barrier to applying a life-cycle approach to disease risk factors and natural history relates to the problem of recall bias and potentially missing or inadequate information about past events in both childhood and adult life, which may then distort the clinical picture. It is only through careful analysis of longitudinal cohort data that the true history of the relationship between the major environmental exposures and disease natural history can be deduced. We need to continue to gather such data, particularly data to link childhood asthma with adult COPD.

# Natural History

**Stefano Guerra and Fernando D. Martinez**

Arizona Respiratory Center and Mel and Enid Zuckerman College of Public Health, University of Arizona, Tucson, AZ, USA

## INTRODUCTION

There is increasing interest in developing a better understanding of the natural history of the two most frequent chronic lower respiratory diseases, asthma and chronic obstructive pulmonary disease (COPD). The main reason for this interest is the shift in the therapeutic approach to both conditions. In the case of asthma, a growing body of evidence suggests that, although several current treatments for the disease are extremely effective in controlling symptoms, none can change its natural course. It is thus evident that new approaches to the primary and secondary prevention of asthma are needed. These approaches will require a thorough understanding of the factors that determine the inception of asthma and its progression with age. In the case of COPD, it is apparent that, although smoking is the main demonstrated cause of this condition, a simple strategy of discouraging tobacco consumption has proven insufficient to prevent the enormous impact of nicotine addiction on public health. A new understanding of the factors that increase the risk of COPD in smokers seems a more realistic approach, and could perhaps contribute to palliate the increasing social toll of COPD.

When discussing the natural history of asthma and COPD, an important issue is the overlap between these two conditions [1]. It has been conclusively shown that, at the population level, adults who report asthma are more likely to also report chronic bronchitis and/or emphysema as compared with subjects with no asthma [2] and recent epidemiological evidence shows that active asthma is a strong risk factor for acquiring a subsequent diagnosis of COPD [3]. This overlap may be explained by the fact that asthma and COPD share common risk factors or, alternatively, by the possible progression of persistent asthma into chronic airflow limitation, the clinical hallmark of COPD [4]. It is often not possible to determine whether persons with airflow limitation have asthma or COPD. However, understanding the natural history of the disease will have critical implications for identifying optimal prevention and treatment strategies.

## METHODOLOGICAL APPROACH

Any discussion about the natural history of a chronic condition ought to address the different hypothetical phases that such condition undergoes during its lifetime course (Fig. 3.1).

There is first a pre-illness period during which subjects without overt disease have the susceptibility for the development of the condition, because of a genetic predisposition or because of injuries or developmental variations that have mutated one or more of the individual's disease-associated phenotypes. During this pre-illness phase, the susceptible individual is not yet destined to develop the disease. More likely, he or she may be exposed to environmental factors that, in the presence of genetic variants that predispose to the chronic condition, can further modify their phenotype. This model applies to both asthma and COPD, as they are both likely to represent heterogeneous diseases with multiple ways to reach final common pathways and an array of diverse pathogenetic mechanisms giving rise to more or less reversible airway obstruction.

It would obviously be of great help for any prevention strategy if markers of susceptibility were identified that could be measured during
**FIG. 3.1** Hypothetical representation of the natural history of a chronic condition. For explanation see text.

**FIG. 3.2** Hypothetical yearly peak prevalence of wheezing for three different phenotypes in childhood. Prevalence for each age interval should be the sum of the areas under each curve. The dashed curves suggest wheezing can present different curve shapes due to many different factors, including overlap of groups. Adapted from Ref. [15].

this pre-illness phase. But the absence of a marker in a specific individual may not exclude susceptibility if that is not the pathway that may be active in that individual. Thus, because the marker *phenotype* may be influenced by determinants other than the factors that influence asthma or COPD risk, ascertainment of a marker may be fraught with difficulties. This "context-dependency" [5] of the phenotypes of markers of disease creates a further layer of complexity for the identification of susceptible individuals.

The above discussion points to the importance of determining the "true" time of incidence of the disease under study. Although the event that is easiest to ascertain is the age of initiation of symptoms, this event is modified by patients' perceptions. What is important is that time of onset ought to be ascertained before the disease has become chronic, that is before the individual has evidence of physiological or anatomical changes caused by the disease itself and that predispose to persistent or recurrent symptoms. During this *initial phase of the disease*, the affected individual has some clinical manifestations, but the condition has not yet fully developed. Moreover, some individuals may not go beyond this initial phase, because remission or stabilization may be fostered by the presence of environmental or genetic protective factors. During this initial phase secondary prevention is possible, but again knowledge of the natural history becomes essential.

## NATURAL HISTORY OF ASTHMA PHENOTYPES

Asthma is a heterogeneous condition, and one of the main obstacles in understanding its natural history has been the lack of well-defined markers for the different disease phenotypes grouped under this common label. This hurdle has been addressed lately by a series of longitudinal studies that have assessed incidence and prevalence of asthma at different ages or defined the outcome of persons with asthma-like symptoms enrolled at different ages and especially during childhood [6–13].

### Most cases of chronic, persistent asthma start in early life

Several longitudinal studies have confirmed that, in most cases of chronic, persistent asthma, the initial clinical

manifestations of asthma occur during the first 5 years of life [6, 11, 13]. Studies have ascertained this age of onset of symptoms either by asking parents about the prevalence of wheezing or other asthma-like symptoms in their children at different ages, or by reviewing previous clinical charts in subjects who present to outpatient clinics with signs and symptoms of asthma at any age. Although these studies strongly suggest that asthma started at an early age in these individuals, a simple connection between these two phenomena is not warranted. Many children have asthma-like symptoms during viral infections in their preschool years, but most have transient conditions that subside with age, and only a minority will go on to have persistent asthma [14]. Thus it is difficult to distinguish who will go on to develop chronic asthma from those who will not.

Studies of this issue have suggested that there are at least three quite distinct groups of children with asthma-like symptoms coexisting up to the adolescent years (Fig. 3.2). The great majority of infants who wheeze during the first 1–2 years of life do so during viral infections, especially those caused by the respiratory syncytial virus (RSV) and by rhinovirus. Most of these children will have one or only a few episodes of wheezing, with no further symptoms beyond the age of 2–3 years. This condition, which has been identified as *transient wheezing of infancy* [16], is the most frequent form of recurrent airway obstruction in this age group, affecting over two-thirds of all infants with asthma-like symptoms. The main predisposing factors for transient wheezing of infancy are maternal smoking during pregnancy and lower levels of lung function, as assessed during the very first months of life and before any wheezing episode has occurred. Interestingly, infants (especially females) whose mothers smoke during pregnancy do have lower levels of lung function early in life than those whose mothers do not smoke [17]. This has suggested the possibility that both inherited and acquired characteristics of the lung, the airways, or both may create the structural conditions for

the development of airway obstruction during lower respiratory illnesses [18].

The factors that determine the remission of early life wheezing in these children are not well understood, but it is likely that growth of the airways may outpace that of the lung parenchyma after age 2–5 months, the period of the highest incidence of wheezing episodes [19]. Since the airways are growing faster than the parenchyma, the conditions required for airflow to be dynamically obstructed may not be easily reached and noisy breathing is less likely [19]. It is also possible that changes in the regulation of airway tone may result in decreased bronchial hyperresponsiveness and decreased likelihood of respiratory symptoms with age [20, 21]. However, despite remission of wheezing with age in this group, children with early transient wheezing appear to have lower levels of lung function, in terms of $FEF_{25-75}$, $FEV_1$, and $FEV_1/FVC$ ratio values, throughout childhood as compared with their peers who did not wheeze in the first 6 years of life [22]. It is established that individuals who enter adulthood with lung function deficits are more likely to develop COPD during the late adult years, suggesting that children with early transient wheezing may be particularly predisposed to COPD in adult life if exposed to cigarette smoking. Whether this is the case is at present unknown.

The factors that determine enduring or newly developed abnormalities in lung function during the first years of life are the subject of intense scrutiny, because they seem to be clearly associated with the risk of persistent asthma. Zeiger et al. [23] showed an inverse relationship between duration of symptoms and level of lung function in school-age children with asthma, and this suggests that the earlier onset of asthma symptoms is associated with greater losses in lung function. Sensitization to local aeroallergens is strongly associated with increased risk of chronic asthma-like symptoms into adult life. Using this knowledge, Halonen et al. [24] divided children who had a diagnosis of asthma by age 6 years into two main groups: those who at age 6 were skin-test positive for Alternaria, the main aeroallergen associated with asthma in the study area [25], and those who were not. They observed that, in the majority of children in both groups, symptoms had started before age 3 years. However, among children with asthma who were skin-test negative to Alternaria, inception of the disease had occurred mainly during the first year of life; while in those who were skin-test positive to Alternaria, peak incidence occurred during the second and third years of life (Fig. 3.3).

The fact that young children who will go on to develop chronic, atopy-related asthma by age 6 are diagnosed 1 or 2 years later than those with nonatopic asthma suggests that the mechanisms of disease are likely to be different in these two groups. Support for this contention comes from a slightly different analysis of the data from the same cohort on which Halonen and coworkers based their report quoted above. Stein et al. [14] assessed the outcome of children with confirmed lower respiratory tract illnesses due to RSV (RSV-LRI), after adjusting for all other known risk factors for subsequent asthma, including skin test reactivity, maternal history of asthma and birth weight, among others. They found that, as previously reported, risk of wheezing during the school years was higher in children

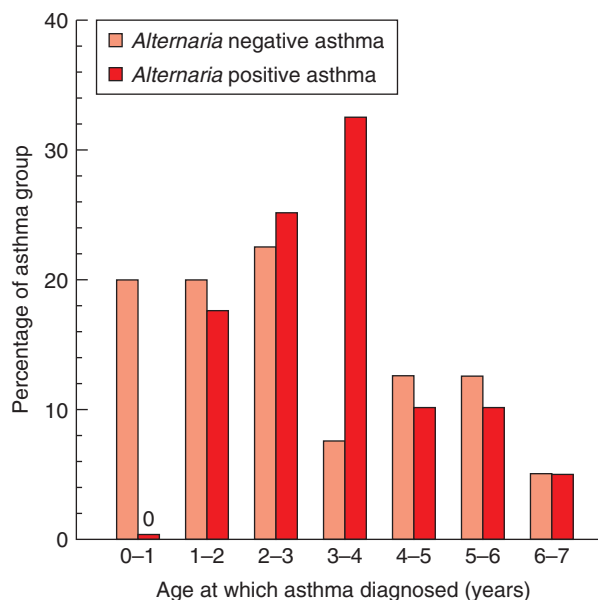

**FIG. 3.3** Age of diagnosis of asthma for children who are skin-test positive for Alternaria or skin-test negative for Alternaria at age 6 in the Tucson Children's Respiratory Study. Adapted from Ref. [24].

with a history of RSV-LRI than in those with no such history. However, the risk decreased with age and was not statistically significant by early adolescence. There was also no association between RSV-LRI and subsequent risk of sensitization to local aeroallergens either at age 6 or at age 11 years. The only factor that was strongly associated with RSV-LRI in early life was diminished baseline levels of $FEV_1$, as measured at age 11. Interestingly, these deficits were reversed by use of a bronchodilator, suggesting that they were likely to be due to increased bronchomotor tone. Longitudinal studies performed in the early 1980s had also suggested that the outcome of RSV-LRIs is usually benign and unrelated to increased allergic sensitization [26].

It thus appears that at least three different forms of "asthma" coexist during infancy and early childhood (Fig. 3.2). Transient infant wheezing is quite frequent, is usually triggered by viruses (especially RSV), and, although it is confined to the first 3 years of life, may be associated with long-term lung function deficits. Other children who wheeze during viral infections in early life continue to have recurrent respiratory symptoms during the early school years. This form of nonatopic wheezing is associated with lower levels of lung function during the school years, but these lower levels seem to be reversible after use of a bronchodilator. Finally, children who will develop atopy-related asthma start having symptoms mainly during the second and third years of life.

## Chronic asthma is most often related to atopy

There is now strong evidence indicating that, as a group, individuals with chronic asthma at any age between the elementary school years and mid-adult life are either sensitized

to local aeroallergens, have elevated total levels of circulating IgE, or both [27]. Although the association between asthma and total and specific IgE is well established, the nature of the association is not well understood. For years it was thought that sensitization to specific allergens, especially in early life, was a cause of asthma [28], and that development of specific IgE against these allergens was the first step in the natural history of the disease. The strong association between risk of having asthma and sensitization to the allergens of house dust mites in coastal regions seemed to argue in favor of this hypothesis, and strategies for the primary prevention of asthma based on avoidance of exposure to these allergens were proposed [29]. However, several studies performed in desert areas with low exposure to house dust mites showed that the prevalence of asthma was either similar or even higher in these regions than that observed in zones where mite infestation rates were high [25, 30]. In desert regions, the allergens of the mold *Alternaria* appeared to be strongly associated with asthma. Moreover, studies in northern Sweden, where indoor exposure to either dust mites or molds is very low, showed that the prevalence of school-age asthma is very similar to that observed in southern Sweden, where exposure to house dust mites is high [31]. Interestingly, only 50% of all schoolchildren with asthma are sensitive to known aeroallergens in northern Sweden (especially cat and dog), compared with over 90% of children in more temperate regions, but skin-test negative children with asthma have significantly higher IgE levels than nonasthmatic children [31]. These observations suggest that, regardless of the nature of the association between elevated IgE and asthma, this link is not allergen-specific.

Recent epidemiological studies have challenged the view of a unidirectional link between atopy and asthma. Our group found that parental asthma is a strong predictor not only for asthma in the child (as one would expect), but also for the child's total IgE levels and skin test reactivity [32]. These relationships remained significant after adjusting for the intensity and other characteristics of parental atopy, supporting independent effects of parental asthma on the development of atopy in the child. Previous studies had also shown that, although the level of allergen exposure early in life predicts the development of allergic sensitization and allergic sensitization is associated with subsequent development of asthma, no direct link between allergen exposure early in life and subsequent development of asthma could be demonstrated.

All these studies suggest that the essential causal mechanism associated with asthma is not sensitization to any specific allergen, but more likely is an alteration in the regulation of responses to many different antigens with the potential of eliciting IgE responses, and especially to aeroallergens. IFNγ production might be among these altered immunological responses. In the Tucson cohorts of the Children's Respiratory Study [33, 34] and the Infant Immune Study [35], our group found strong associations between reduced IFNγ production from polyclonally stimulated peripheral blood mononuclear cells in the first year of life and the subsequent development of both allergic sensitization and asthma-related respiratory symptoms. Reduced IFNγ responses may be related to a delayed maturation of the immune system and, in turn, they may lead to susceptibility to viral infections, favor a Th2 skewed polarization of the immune system, and affect airway growth. Whether deficits of early IFNγ responses can explain the link between asthma and atopy or simply represent one of multiple pathways that are shared by these two phenotypes remains unknown.

## Outcome of childhood asthma in adolescence and adult life: Remission of mild asthma and persistence of severe disease

Only a few population-based studies have addressed the outcome of childhood asthma in adolescence and adult life. These studies have used longitudinal assessment of asthma symptoms and lung function in children who were enrolled at birth [12] or during the early school years [36, 37] or who were part of birth cohorts for which assessment of asthma symptoms in early life was made through retrospective questionnaires [7, 8, 10, 38].

The transition of asthma from childhood into adolescence has been studied in the birth cohort of the Tucson Children's Respiratory Study [12]. In that study, most children who experienced only infrequent wheezing during childhood had remission of wheezing after puberty. However, almost 60% of children with frequent wheezing and/or a physician-confirmed diagnosis of asthma experienced wheezing at some point during adolescence. These results challenge the commonly held view that most children with asthma outgrow the disease in adolescence and suggest that complete remission of the disease may be the exception rather than the rule, at least among cases of moderate to severe asthma.

This link between severity and persistence of asthma has been confirmed by long-term prospective studies that have followed cohorts of children into mid-adult life. The longest such ongoing study is that initiated by Williams and McNicol in Melbourne, Australia [39]. Children with a history of recurrent episodes of wheezing were enrolled at the age of 7 years, together with a small group of controls without such a history. These individuals were then periodically reassessed, and the latest published data refer to information collected when their mean age was 42 years. Information about the age upon initiation of symptoms was obtained by use of questionnaires and, as a consequence, data on a crucial period of life for the development of asthma was possibly biased by preferential recall [36, 40]. The second study was the British 1958 birth cohort, in which over 18,000 subjects born between March 3 and March 9, 1958 were enrolled [8]. Of these persons, 31% contributed information for ages 7, 11, 16, 23, and 33 years. As with the Melbourne study, information for the first 7 years of life was obtained retrospectively at age 7. Similarly, in the Dunedin Multidisciplinary Health and Development Study (New Zealand) parents completed first respiratory questionnaires when children were already 9 years old. To date, participants have been followed up to age 26 with repeated questionnaires and lung function measurements [7]. Finally, the Tasmanian asthma survey enrolled over 8000 children born in 1961 who were also first contacted at age 7

[10]. Two thousand randomly chosen individuals were re-examined when they were 29–32 years of age.

The most important findings of all four studies were that asthma remits, at least transiently, in early adulthood in a sizable proportion of asthmatic children, and that the severity of asthma tracks significantly with age. This second point is important because it reflects a "stability" in the disease: most children with severe symptoms still have severe symptoms as adults, and asthmatic children with mild symptoms either have no asthma or have mild asthma as adults.

- Children enrolled in the Melbourne study were divided at the time of enrollment into five groups according to their previous history of wheezing: a control group (no wheezing), a group with mild wheezy bronchitis (less than five lifetime episodes of wheezing associated with colds), a group with wheezy bronchitis (five or more such episodes), a group with asthma (wheezing apart from colds), and a group with severe asthma (selected at age 10 based on severe impairment of lung function). At age 42 years, less than a quarter of children with either form of wheezy bronchitis showed frequent asthma episodes (wheezing during the previous 3 months, but less than once a week) or persistent asthma (once a week or more). However, 52% of children with asthma and 76% of those with severe asthma at the time of enrollment had frequent or persistent wheeze at age 42 [40].

- Similar results have been reported based on the British 1958 study: 27% of all children whose parents reported they had wheezed before age 7 reported wheezing during the previous year at age 33 [8].

- In the Dunedin study, 37% of children who ever wheezed had wheezing that persisted from childhood to adulthood or that relapsed after remission [7].

- For the Tasmanian study, 25.6% of subjects with "asthma or wheezy breathing" by age 7 reported current asthma at the age of 29–32 years, compared with only 10.8% of subjects without parental reports of childhood asthma [10]. As with the Melbourne study, those who had a history of more than 10 attacks of asthma by age 7 were almost twice as likely to have persistent wheezing as adults than those who did not.

A consistent factor associated with persistent asthma in all four cohorts was evidence of an allergic predisposition. In the Melbourne study, severe asthma in early life was associated with significantly higher prevalence of allergic rhinitis at age 35. In the British cohort, allergic symptoms (e.g. allergic rhinitis or eczema) were significantly associated with persistence of symptoms into adult life. In the Dunedin cohort, skin sensitization to house dust mites increased more than twice the odds for both persistence and relapse of wheezing, independent of other predisposing factors [7]. Finally, in the Tasmanian cohort, having a history of eczema in early life was also significantly associated with persistent wheezing at ages 29–32.

Childhood deficits in lung function are another factor that has been consistently associated with persistence of asthma into adult life across different cohorts. In the Tasmanian, the Melbourne, and the Dunedin studies, low lung function as measured in early school age was a significant predictor of subsequent persistent wheezing. In the Melbourne study, lung function for each subgroup of subjects classified according to their wheezing history by age 7 was repeatedly assessed up to the age of 42 years. Children with severe asthma at age 10 had very low initial levels of lung function, and this was to be expected because deficits in lung function were used to classify them as having severe asthma in the first place. When compared with their peers, these children did not show further deficits in lung function growth with age, and by age 42 their position relative to subjects with milder symptoms or with no asthma was substantially unchanged. A similar pattern of relatively stable lung function growth was observed for patients with mild asthma who had shown loss of lung function at enrollment, albeit much less pronounced than persons with severe asthma. Similarly, in the Dunedin study children with persistent wheezing had consistently lower values of the $FEV_1/FVC$ ratio from age 9 up to age 26, as compared with controls. The mean deficit was almost 7%, but no significant differences in the slopes of change in the $FEV_1/FVC$ ratio were found between persistent wheezers and controls. Thus, persistent wheezers had decreased values of $FEV_1/FVC$, but not steeper slopes of decline. These findings are very relevant for our understanding of the natural history of COPD, and will be discussed in more detail below.

The potential role of bronchial hyperresponsiveness in school age has been explored in two of the above referenced cohorts. In the Dunedin study, the presence at 9 years of age of either a value of methacholine $PC_{20} < 8\,mg/ml$ or an increase of $FEV_1 > 10\%$ from baseline in response to a bronchodilator was associated with fourfold increased odds for persistent wheezing and with almost sevenfold increased odds for relapse of wheezing [7]. In that study, bronchial hyperresponsiveness remained significantly associated with both outcomes after adjusting for other risk factors. In the Tucson Children's Respiratory Study, we found 68% of the children whose asthma persisted after the onset of puberty to have had a positive test for bronchial hyperresponsiveness at age 11, as compared with only 37% of children whose asthma remitted during adolescence [12]. Another interesting finding of that study was the strong association between childhood obesity and persistence of asthma after the onset of puberty. Multiple recent reports have consistently linked obesity not only to persistence but also to incidence of asthma [41–44]. The nature of this association remains at present not fully understood and warrants further research.

## Relapse of asthma symptoms in patients whose asthma remitted in childhood

Little is known about prevalence and risk factors for relapses of asthma in adult life among subjects whose symptoms remitted during childhood. Taylor and colleagues found one-third of subjects who had childhood asthma that was in remission at age 18 to have relapses of the disease in young adulthood [45]. In the British cohort study, a group of over 1300 persons with a history of wheezing illnesses from birth to age 16 years had symptom remission by age 23. This group was 50% more likely to report wheezing at age 33

than those with no history of asthma or wheezy bronchitis during childhood [8]. These findings suggest that complete remission of asthma in adulthood may be less common than previously thought and are consistent with results from clinical studies supporting the presence of active, subclinical forms of the disease among asthmatics in clinical remission. In a Dutch cohort of 119 patients who were diagnosed with asthma during school age and re-examined 30 years later (at age 32–42), bronchial hyperresponsiveness and/or reduced lung function were present among 57% of those who were in clinical remission as adults [46]. Previous studies have shown that indicators of airway inflammation, such as eosinophils and IL-5 in bronchial biopsies, eosinophil percent in bronchoalveolar lavage, and exhaled nitric oxide levels, are higher among children and adolescents in clinical remission of asthma, as compared with their peer controls [47–49]. Bronchial hyperresponsiveness and other clinical abnormalities among these apparently remitting asthma cases may pose these subjects at increased risk for obstructive lung disease in adult life and their potential role as determinants of COPD will be discussed below.

**FIG. 3.4** Hypothetical mechanisms that may lead to a critically low level of lung function in adult life and to chronic airway obstruction (horizontal line): (a) normal growth and decline; (b) impaired lung growth with a lower plateau phase but a normal rate of decline compared to (a); (c) normal plateau with rapid initial decline in lung function and a subsequent normal rate of decline; (d) normal plateau with normal initial rate of decline but a subsequent accelerated loss in lung function. Adapted from Ref. [51].
## NATURAL HISTORY OF COPD

According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD) [50], the pulmonary component of COPD is characterized by airflow limitation that is not fully reversible, usually progressive, and associated with an abnormal inflammatory response of the lung to noxious particles or gases. Thus, the natural history of COPD overlaps extensively with that of the level of lung function (usually $FEV_1$, expressed as percent of predicted value in relation to a certain height) during adulthood. Three are the main factors that can determine the level of lung function achieved at any age during adult life (Fig. 3.4).

First, the individual may either start life with a low level of lung function or show a significant decline in lung function growth during the first years of life (line "b" in Fig. 3.4). The individual's level of lung function will fall after a certain age, at the same rate as normal peers, but at a lower level overall. The level of lung function attained by late adolescence or early adult life will thus be lower. Through the normal process of aging, decline in lung function will naturally occur, and this decline, although parallel to that occurring in all the population, will nevertheless predispose to the attainment of a level of lung function (expressed as percentage of normal level in early adulthood) that will be lower than the threshold for the expression of clinical symptoms of airway obstruction.

A second potential mechanism is that of an early decline in lung function occurring either at the end of adolescence or in early adult life (line "c" in Fig. 3.4). Again, the main result of such a mechanism would be the attainment of lower level of lung function in these individuals as compared with the rest of the population.

A third mechanism is that of a faster rate of decline of lung function during adult life (line "d" in Fig. 3.4). This may obviously occur both in individuals with a normal level of lung function at the beginning of adult life as in individuals who already have a diminished level of lung function to begin with.

The essential determinants of the natural history of COPD are the rate of growth of lung function up to late childhood, the timing and length of the plateau phase, and the rate of decline of lung function during adult life.

## Growth of lung function during childhood

The three most important determinants of growth of lung function during childhood are:

- the level of lung function at birth,
- the incidence of lower respiratory illnesses during the first years of life,
- the development of persistent asthma-like symptoms during childhood.

### Level of lung function at birth

The availability of lung function tests that can be performed shortly after birth, and which appear to show good correlation with more invasive tests of airway function [52], has allowed us to study the potential role of the development of the lung *in utero* on subsequent levels of lung and airway function attained by the individual. Since these methods have been available only for the last 25 years, it is not possible to determine the role of airway function in the postnatal period on events occurring beyond young adult life. Nevertheless, it is now apparent that there is quite significant tracking between the level of lung function measured shortly after birth and that measured during childhood [53, 54], adolescence [22], and up to young adulthood [55]. This may explain, at least in part, the strong association between lower respiratory illness

in early life and level of lung function in late childhood and early adulthood (see the discussion below).

The factors that determine growth of lung and airways *in utero* are only partly understood. The two main determinants of the level of lung function measured shortly after birth are gender and exposure to tobacco smoke products *in utero* [56]. Boys have been found to have consistently lower maximal flows at functional residual capacity ($V_{max}$FRC) throughout the first year of life in comparison with girls. Indeed, females have larger airway size, relative to the size of lungs and to body size, as compared with males both at birth and during childhood, up to the plateau of lung growth [57]. However, the role of these gender differences in influencing airway function and predisposing to obstructive lung disease is not well understood. Maternal smoking during pregnancy is associated with lower levels of $V_{max}$FRC in both genders in comparison with unexposed infants [56]. Postnatal exposure to tobacco smoke appears to be less important than prenatal exposure, at least in most developed countries [58]. The effects of intrauterine exposure to tobacco smoke products persist for the first year of life [56], and even beyond the first year up to the early adolescent years [59].

Independent of what factors determine *in utero* lung growth, evidence has been accumulating that lung function at birth affects lung health far beyond infancy. In addition to the well-established association between reduced $V_{max}$FRC shortly after birth and wheezing in the first years of life [18, 56, 59, 60], recent studies have associated lung function measured in the first month of life to persistent wheezing and asthma at 10–11 years [54, 61]. Turner *et al.* found wheezing at 11 years to be associated with a reduced mean z score for $V_{max}$FRC at 1 month of age [54], whereas a reduced fraction of expiratory time to peak tidal expiratory flow to total expiratory time ($t_{PTEF}/t_E$) as assessed 3 days after birth predicted asthma and bronchial hyperresponsiveness at age 10 years in a Norwegian birth cohort [61]. Of note, in the latter study $t_{PTEF}/t_E$ at birth did not correlate with $FEV_1$ or FVC at 10 years of age. These findings are complemented by results from the Tucson Children's Respiratory Study, in which we found $V_{max}$FRC measured at 2 month of age to correlate strongly with $FEV_1$ and the $FEV_1$/FVC ratio assessed at age 11, 16, and 22 years [55]. Participants in the lowest quartile for infant $V_{max}$FRC had a 5% mean deficit in the $FEV_1$/FVC ratio through age 22 compared to the upper three quartiles and this association was independent of wheezing and asthma status. Taken together, this evidence suggests that lung function at birth accounts for part of the lung function levels attained in young adult life and, in turn, may influence predisposition to subsequent obstructive lung disease.

## Role of lower respiratory illnesses in early life

It has been known for decades that children who have lower respiratory illnesses during the first years of life have lower levels of lung function during childhood and into adult life [62]. One possible explanation for this association is that viral infections, which are the main etiological factor for lower respiratory illnesses in early life, may damage lung and airways, and this may predispose for lower levels

of lung function [63]. This hypothesis seemed attractive, because it suggested a potential strategy for the prevention of early losses in lung function that could predispose to COPD. However, several studies in which the techniques to assess lung function in infants, described earlier, were used showed that children who developed lower respiratory symptoms during viral infections in early life had diminished pre-illness levels of lung function [18, 56, 59]. The hypothesis was thus suggested that lower levels of lung function observed after lower respiratory illnesses in early life could be explained by preexisting diminished lung function, the latter being therefore the link between early life episodes of airway obstruction and subsequent deficits in lung function.

Unfortunately, the number of infants in whom lung function has been ascertained in early life and who have been followed for a number of years after birth is rather small. Therefore, the possibility that lower respiratory illnesses by themselves may alter lung and airway growth in groups of susceptible individuals cannot be excluded. It is unlikely that pre-illness lung function may explain all forms of infection-associated wheezing during early childhood, and it is legitimate to surmise that immune responses to the viruses themselves may also play a significant role.

Evidence from studies in the United Kingdom would support the validity of both hypotheses [64–66]. In a cohort of children enrolled in 1964 and reassessed in 2001 for current lung function, smoking status, and respiratory symptoms, a significant linear trend was found between birth weight and $FEV_1$ at age 45–50 years after adjusting for confounders, including smoking [65]. This association was confirmed by a recent meta-analysis [66] of eight studies reporting a pooled increase of 48 ml in $FEV_1$ per 1 kg in birth weight. As modest as this association may appear, these findings support a direct influence of *in utero* growth on lung function in adulthood. However, another very long-term study in England provides evidence in support of additional effects of childhood respiratory infections on adult lung function [64]. In this study, men born between 1911 and 1930, whose birth weights, weights at 1 year, and childhood respiratory illnesses were recorded in early life, were studied at ages 59–70 years. Death from chronic obstructive disease, $FEV_1$, and respiratory symptoms were the main outcome variables. The main early life determinants of the level of $FEV_1$ in old age were birth weight and history of bronchitis or pneumonia in infancy, and these effects were independent of smoking habit and social class. These data would thus suggest that both intrauterine growth (and presumably lung development) and lower respiratory illnesses during the first years of life exert independent effects on the level of lung function attained late during adult life, and thus may be important determinants of the risk of COPD.

## Persistent asthma-like symptoms during childhood

Epidemiological evidence supports that persistent asthma-like symptoms are a significant risk factor for the development of lower levels of lung function in childhood and young adult life [7, 36] and, in turn, may predispose to the

development of COPD. One proposed explanation for these associations has been that asthma is a progressive disease [67]. It has thus been proposed that the presence of chronic airway inflammation is associated with significant lung remodeling and that the latter fosters a significant alteration in lung growth.

Although some studies were able to show impairment in the development of lung function in children with asthma [67, 68], the main outcome variable used in these studies was pre-bronchodilator lung function. The Childhood Asthma Management Program (CAMP) study was specifically designed to test the hypothesis that mild to moderate childhood asthma is associated with significant deterioration in airway growth and that treatment with inhaled anti-inflammatory therapy could reverse this deterioration in lung function [69]. Children aged 6–12 years were treated for 4–6 years with either an inhaled corticosteroid (budesonide), nedocromil, or a placebo. Post-bronchodilator $FEV_1$ was considered the outcome variable, because pre-bronchodilator $FEV_1$ could be affected by the degree of activity of the disease at the time of testing. The results of the study showed that, although children with asthma have levels of lung function that are significantly lower than those of children without the disease at any time between the ages of 6 and 15, these levels do not further deteriorate even among subjects who are not systematically treated with anti-inflammatory therapy. Moreover, systematic treatment with anti-inflammatory therapy improves bronchial hyperresponsiveness, but is not associated with a significant improvement in lung function with time. Based on these findings, more recently the Prevention of Early Asthma in Kids (PEAK) trial was designed to determine whether the lack of sustained effects of inhaled corticosteroids on the natural history of childhood asthma was attributable to the initiation of the intervention too late in life. In fact, the PEAK trial failed to detect any long-term effects of a 2-year treatment with inhaled corticosteroids on the natural history of asthma in a group of high-risk preschool children, despite the temporary beneficial effects of the treatment on disease symptoms and exacerbations [70].

An interpretation of these results is that, in children with a diagnosis of asthma, most of the deterioration in lung function observed during the school years occurs early in life. The results of studies by our group suggest that children who go on to have persistent asthma-like symptoms during childhood start life with levels of lung function that are slightly lower than those of children who will not have these persistent symptoms [71]. It is also possible that persistent childhood asthma affects lung function through mechanisms that are at least partly unrelated to airway inflammation and, therefore, insensitive to corticosteroid treatment. Finding the answer to these questions will have crucial implications for the prevention of long-term obstructive lung disease among these children.

## Determinants of early losses in lung function

Very little is known about the factors that determine early losses in lung function at the age in which the plateau level of lung function is reached in early adult life. Xuan *et al.* [72] observed that, between the ages of 17 and 19 years, when growth in height had stopped, $FEV_1$ continued to grow in both males and females. However, children who had recent episodes of wheeze and those with evidence of bronchial hyperresponsiveness showed a reduced rate of growth in airway caliber. Unfortunately, lung function was not assessed after use of a bronchodilator, and it is thus not possible from these data to assess whether the changes are due to increased airway tone or to irreversible alterations in airway structure. In addition to active wheezing and bronchial hyperresponsiveness, early initiation to cigarette smoking has been associated with detrimental effects on the plateau level of lung function. Holberg *et al.* [73] showed that, at age 16, the level of lung function achieved by males who had started smoking was significantly lower than that of those who had not. No such effect was observed in females.

## Determinants of increased slope of lung function decline

Several longitudinal studies have addressed the role of different intrinsic and extrinsic factors on the rate of decline of lung function after the plateau phase. The role of cigarette smoking has been clearly and consistently established. Camilli *et al.* [74] examined changes in $FEV_1$ in over 1700 adults enrolled in a prospective study of a general population sample. Individuals who smoked more than 10 cigarettes per day had excessive rates of decline in $FEV_1$ as compared with nonsmokers. The excess decline of smokers was age dependent, particularly in men: much of the excess loss of lung function occurred between 50 and 70 years of age. Interestingly, ex-smokers showed declines in $FEV_1$ values that were similar to those of nonsmokers. The authors also examined the effect of quitting smoking on the decline of $FEV_1$. In subjects younger than 35 years, quitting smoking during follow-up was associated with an actual increase in $FEV_1$. In men above 50 years, smoking cessation early in the study led to a return to normal rate of functional decline during follow-up. In addition to cigarette smoking, exposure to other toxic gases and particles – including environmental tobacco smoke, indoor and outdoor pollution, occupational dust, gases, and fumes – has been consistently associated with COPD and a steeper decline of lung function [75, 76].

However, the observation that only a more [77] or less [78] sizable fraction of smokers develop COPD strongly suggests the existence of intrinsic factors that can modify the effect of smoking and other deleterious exposures on the rate of decline of lung function. Bronchial hyperresponsiveness has been long hypothesized to be one of these factors [79, 80]. Indeed, bronchial hyperresponsiveness has been consistently shown to be a strong and independent risk factor for accelerated decline of lung function in prospective studies among smokers with early COPD as well as asymptomatic individuals [81–83]. Findings from these epidemiological studies have been confirmed in the clinical setting. For instance, Postma and coworkers [84] assessed the course of lung function after 2–21 years of follow-up in 81 nonallergic patients with considerable lung function

impairment (<55% $FEV_1$/FVC ratio) at the beginning of the study. They reported that a more favorable rate of change in $FEV_1$ was not only associated with fewer pack-years of smoking but also with less nonspecific bronchial hyperreactivity and a higher degree of reversibility of airflow obstruction. These effects were independent of baseline $FEV_1$ value, both in smokers and in ex-smokers. Whether the association between bronchial hyperresponsiveness and decline in lung function is the consequence of an ongoing COPD-related inflammatory process and to what extent this inflammatory process differs from that associated with bronchial hyperresponsiveness in asthma remain at present open questions.

Airway inflammation and its structural *sequelae* may be also involved in the causal mechanisms linking accelerated decline of lung function in smokers with two other risk factors: chronic bronchitis (i.e. chronic cough and phlegm) and lower airway colonization/infection. Although the predictive value of chronic bronchitis for the development of COPD remains somewhat controversial [85, 86], this phenotype has been consistently associated with steeper rates of $FEV_1$ decline [87, 88]. It has been suggested that the clinical impact of chronic bronchitis may be dependent upon the stage of COPD, with this phenotype having stronger effects on the severe forms of COPD when lower airways become colonized and/or infected [89]. Acute exacerbations and lower airway colonization are strongly associated with decline of lung function among smokers and patients with COPD. In a prospective study [90], patients with frequent exacerbations (mean number of episodes per year >2.9) had a significantly faster decline of $FEV_1$ than infrequent exacerbators. Lower respiratory illnesses had a similar deleterious effect on decline of $FEV_1$ over 5 years among smokers in the Lung Health Study [91].

Of note, airway infections may also affect lung function decline through mechanisms that are independent of (and may indeed precede) the presence of COPD. Burrows and coworkers reported that smokers who recalled a history of "respiratory trouble" before 16 years of age had significantly steeper rates of decline in lung function as compared with those with no such history [92]. This effect was independent of a current or past diagnosis of asthma. It thus appears that intrinsic factors that modify the effects of smoking may be related to events occurring during the first years of life. This conclusion is compatible with the observation by Barker and coworkers quoted earlier [64], that elderly individuals with a history of lower respiratory illness early in life were more likely to have lower levels of lung function than those with no such history.

Although it is not well established how the effects of these intrinsic and extrinsic factors on the rate of decline of lung function are modulated, genetics are likely to play a major role. In the large cohort of the Tucson Epidemiological Study of Airway Obstructive Disease (TESAOD), our group observed significant intra-family correlation in the rate of decline of lung function within smokers [93], suggesting that these rates of decline have an important genetic component. However, the identification of the genetic components of COPD, as well as of those of asthma, is proving a challenging task and at present deficiency of α1-antitrypsin remains the only established genetic risk factor for this disease.

## INTERSECTION OF THE NATURAL HISTORY OF ASTHMA AND COPD

It is not uncommon in the clinical setting to observe patients with asthma showing COPD-like phenotypes, and *vice versa*. Consistently, it has been long known that diagnoses of asthma, chronic bronchitis, and emphysema are frequently associated at the population level [2]. This evidence indicates that the natural history of asthma and COPD can converge in some cases during adult life. A possible explanation for these observations is that a significant proportion of cases with severe and/or persistent asthma can develop in the long-term COPD-like phenotypes. Support for this contention is provided by another report from the TESAOD study [19], in which adult subjects with active asthma were found to have a 12 times higher risk of acquiring a diagnosis of COPD over time than subjects with no asthma, after adjusting for covariates including smoking.

Since chronic airflow limitation is the central hallmark of COPD, much attention has been paid to understand the natural history of lung function of patients who develop COPD as a *sequela* of asthma. Much like for individuals from the general population (Fig. 3.4), in patients with asthma $FEV_1$ deficits can develop mainly as a result of either lower $FEV_1$ levels at the beginning of adult age or an accelerated $FEV_1$ decline during adulthood [51]. Interestingly, most birth cohort studies – including the Dunedin Multidisciplinary Health and Development Study [7], the Melbourne Asthma Study [36], and the British 1958 Birth Cohort [94] – have shown that, in a significant proportion of cases of persistent childhood asthma, lung function deficits are established before the early adult years, and track over time. These findings, together with the observation that, among children who start life with low levels of lung function, expiratory flows remain lower than those of their peers throughout childhood and adolescence [22], point toward the importance of early events in affecting lung growth and/or airway remodeling in childhood and, in turn, in influencing early predisposition to COPD. As for the second potential mechanism of lung function impairment (i.e. accelerated decline of lung function) in asthmatics, prospective cohort studies on adult populations have provided somewhat inconsistent findings. In the Busselton Health Study [95] and in the Copenhagen City Heart Study [96], asthmatics showed both initial $FEV_1$ deficits at age 20 years and an increased slope of $FEV_1$ decline in adulthood. However, the increase in $FEV_1$ decline associated with asthma was only 4 ml/year in the Busselton Study.

A possible reconciliation for these inconsistent results is provided by a recent study from the TESAOD cohort. We identified adult participants who had $FEV_1$/FVC ratio consistently lower than 70% (as a hallmark of persistent airflow limitation) and compared the natural history of their lung function based on the presence of asthma. Patients with asthma accounted for about one-third of all cases of persistent airflow limitation. Persistent airflow limitation was strongly associated with smoking among nonasthmatics and with eosinophilia among subjects who had asthma onset ≤ 25 years. Most importantly, the natural course of
**FIG. 3.5** Natural history of lung function among participants in the TESAOD study who had persistent airflow limitation with or without asthma. The black line refers to subjects with no asthma and persistent airflow limitation. The red line refers to subjects with asthma onset ≤ 25 years and persistent airflow limitation. The gold line refers to subjects with asthma onset >25 years and persistent airflow limitation. Predicted values for subjects with no asthma and no airflow limitation (healthy controls, green line) are also reported for comparison. Depicted values represent predicted values for a 175-cm tall male from the best-fitting random coefficients model. Adapted from Ref. [96].

lung function differed substantially between the two groups (Fig. 3.5), with subjects with asthma onset ≤ 25 years having lower $FEV_1$ levels at age 25 but not steeper $FEV_1$ decline in adulthood as compared with expected values from healthy controls. In contrast, subjects who developed persistent airflow limitation but had no asthma showed only moderate $FEV_1$ deficits at age 25 years but had greater than expected $FEV_1$ loss between age 25 and 75. Interestingly, the natural course of lung function of subjects who had adult-onset asthma (after age 25 years) included both moderate $FEV_1$ deficits in young adulthood and accelerated $FEV_1$ decline thereafter.

Taken together, findings from this and previous studies suggest that: (1) asthma accounts for a sizable fraction of COPD cases at the population level; (2) while development of traditional COPD is strongly associated with exposure to noxious agents (e.g. cigarette smoking), patients with asthma may develop persistent airflow limitation through pathways that are independent of smoking and related to allergic and eosinophilic inflammation; (3) among subjects who had severe and/or persistent asthma in childhood significant deficits in lung function are already present in early adult life; (4) during adulthood accelerated decline of $FEV_1$ might be present for subgroups of asthmatics, but this accelerated decline is likely to account for a limited proportion of the asthma-related deficits in lung function up to mid-adult life; (5) childhood versus adult-onset asthma may be associated with a different natural history of lung function that might explain part of the inconsistencies of results on $FEV_1$ decline in asthmatics across different studies.

The implications of these conclusions for prevention and treatment are crucial because they indicate that the timing and nature of prevention strategies for COPD-like phenotypes need to be different for subjects with and without asthma. While smoking prevention and cessation is vital against inception of traditional COPD, any intervention to prevent development of persistent airflow limitation among patients with childhood asthma will need to target these patients before they enter adult life because by then the bulk of their lung function impairment is already established. Similarly, the different trajectories by which patients with traditional COPD and patients with asthma may develop chronic airflow limitation in their adult life support the phenotypic heterogeneity that has emerged from clinical studies on these two groups [97]. Future research is required to determine whether multiple functional, morphological, and immunological assessments can be developed to capture the heterogeneity of these diseases and to identify optimal prevention and treatment strategies for these patients.

## INTRODUCTION

It is now a well-established fact that genetic factors contribute to the development of asthma and chronic obstructive pulmonary disease (COPD). This chapter sets out the current knowledge focusing on the heritability of asthma and COPD and the genes found by positional cloning and association studies. It also focuses on particular genes to provide insight into the current knowledge on genetic approaches to understanding diseases like asthma and COPD.

## HERITABILITY OF ASTHMA AND COPD

It has been known for centuries that asthma clusters in families (familial aggregation).

The first segregation studies in families with an asthmatic proband already showed that no single-gene accounts for a major part of the expression of the disease. A polygenic model with some evidence of oligogenic loci (i.e. a handful of loci being responsible for most of the genetic control) provided the best fit to the data [1].

For COPD, a role for genetic factors has been less obvious, because cigarette smoking is such a major environmental risk factor. The identification of alpha 1-antitrypsin (AAT) deficiency in the 1960s proved that genes could influence COPD susceptibility [2]. AAT deficiency is largely caused by homozygosity for the Z allele (PI ZZ) at the SERPINA1 locus, although multiple other rare deficiency alleles have been identified. PI ZZ subjects are at markedly increased risk for COPD, especially if they smoke cigarettes. However, the development of COPD among PI ZZ subjects is highly variable, and environmental, developmental, and genetic factors likely contribute to this variability. DeMeo and colleagues recently confirmed that male gender and asthma (especially in childhood), as well as cigarette smoking, are risk factors for COPD in PI ZZ subjects [3].

Evidence that COPD unrelated to AAT deficiency is also influenced by genetic factors has been provided by many familial aggregation studies. Pulmonary function levels in the general population cluster in families [4]. Moreover, studies of relatives of COPD subjects have confirmed familial aggregation of COPD, probably related to gene-by-smoking interactions. Silverman and colleagues found that first-degree relatives of severe, early-onset COPD subjects who smoke, had an approximately threefold increased risk of airflow obstruction and chronic bronchitis [5]; nonsmoking relatives had increased risk for abnormalities in sensitive spirometric measures such as FEF25-75 but not for severe airflow obstruction [6]. McCloskey and colleagues confirmed that COPD showed familial aggregation, which was only apparent in smokers [7]. Multiple genes likely contribute to the susceptibility for COPD and its phenotypic expression.

In the studies of the heritability of asthma and COPD, the absence of unambiguous criteria for their diagnosis and the fact that asthma and COPD are not one disease entity but are both heterogeneous diseases, for example COPD can encompass both chronic bronchitis and emphysema and the latter occurs homogeneously or locally in the lung, have been major obstacles to pinpointing the exact polymorphisms in genes contributing to disease development. Another explanation for the failure to identify loci may lie in the genetic component

of the disease. For instance, different genes can be involved in the same phenotype (genetic heterogeneity) or the same genotype may result in different phenotypes (pleiotropy). Mutated genes do not always express the phenotype (incomplete penetrance) and vice versa. The specific phenotype under study can be expressed without the genetic mutation (phenocopy).

## ASSESSING GENES FOR ASTHMA AND COPD

The human genome consists of approximately 3 billion base pairs. The sequence of the whole human genome has recently been published [8]. The genetic distances are expressed in centiMorgans (cM). One cM is about 100,000 base pairs on a physical map and corresponds to 1% recombination during meiosis. This means that one crossing-over event between two loci that are one cM apart occurs in every hundred meioses. The estimation of the total number of genes in the human genome is about 20,000 [9]. Most genes in the population have multiple locations where more than one variant is commonly found; the variants at these polymorphic locations are known as alleles. Only a minority of human DNA is responsible for the coding for a biological product.

The main strategies to identify susceptibility genes are positional cloning and the candidate gene approach.

*Positional cloning* starts with the investigation of families without a predetermined hypothesis regarding the location or identity of the underlying susceptibility gene or genes. Markers are randomly spaced throughout the entire genome and tested for linkage (i.e. coinheritance) with a disease phenotype. After the finding of linkage between a particular marker and a phenotype, further fine spaced typing of genetic markers (fine mapping) is required to pinpoint the exact gene causing the linkage. The approach is time consuming, as in-depth analysis of a particular region of linkage that still can cover a large part of a chromosome, requires considerable molecular analysis.

An alternative approach is to select candidate genes that putatively contribute to the underlying pathological process of the disease. The gene is screened for polymorphisms, which are tested for association with the disease or phenotype in question. The results can be interpreted in three ways, as shown in Box 4.1.

Replication of any genetic study is required to exclude spurious findings especially if multiple genes are involved in the disease process, like in asthma and COPD.

Candidate genes of unknown function or unknown role in disease pathogenesis can also be selected for genetic analysis based on their differential expression in diseased versus normal tissue [10, 11]. Another approach is to select a gene that is a proven cause of a monogenic syndrome that has the disease of interest as a component of its syndrome constellation. The hypothesis that can be tested is that mutations in the gene with a milder functional effect can contribute to the development of a complex genetic disorder in the general population. The gene *SPINK5* that encodes the serine protease inhibitor LEKTI on chromosome 5q32 as the cause of Netherton syndrome is such an example [12]. Netherton syndrome is a severe autosomal recessive disorder with a congenital skin disease associated with defective cornification and severe atopic manifestations. A common coding polymorphism of *SPINK5*, E420K, has been shown to be associated with atopy and atopic dermatitis in two independent family cohorts [13], although replication attempts have had varying success [14, 15]. In COPD, cutis laxa is a rare dermatological syndrome related to abnormal connective tissue elasticity; some cases are caused by mutations in the distal part of the elastin (ELN) gene. Emphysema often occurs in cutis laxa at a very early age. Kelleher and colleagues found a rare mutation in the first base of the last exon of ELN in an early-onset COPD subject [16]. This variant, which was not a private mutation in that pedigree, interfered with the assembly of the elastic fiber, changed the proteolytic pattern of the ELN protein, and altered cellular adhesion of the ELN molecule. Thus, in both asthma and COPD, the assessment of candidate genes from monogenic syndromes has led to some insights into the disease etiology.

Both the positional cloning and the candidate gene approaches have their own limitations. Population association between a disease and a genetic marker can arise as an artifact of the population structure. Linkage studies with modest numbers of affected sib pairs may be underpowered and fail to detect linkage, especially if there is genetic heterogeneity. Furthermore, although linkage analysis has been successful to identify genes underlying single-gene disorders, in complex diseases it is frequently very difficult to sufficiently narrow a region of linkage to just a single gene. Nevertheless positional cloning in asthma has identified some genes.

A truly comprehensive genetic association study must consider all putative causal alleles in a gene of interest or in the entire human genome if resources are available. Until recently, this was practically impossible. With the completion of the International HapMap Project [17], it is now

---

### Box 4.1.   POTENTIAL CAUSES OF GENOTYPE–PHENOTYPE ASSOCIATION

**1.** The trait of interest is due to a genotyped variant in the candidate gene.

**2.** The trait is determined by one or more genetic variants in linkage disequilibrium with a genotyped variant; that is, a genotyped variant is very close to the disease gene.

**3.** The association is the result of population admixture, that is, a certain trait has a higher prevalence in a specific ethnic subgroup within a mixed population. Any allele with a higher frequency within this subgroup will show association with the trait.

possible to target a large proportion of the genetic variation across the genome, either directly or indirectly (via LD). HapMap is a freely available reference panel of genotype data from different worldwide populations (http://www.hapmap.org). This resource can be used to guide the design of disease association studies and prioritization of single nucleotide polymorphism (SNP) genotyping assays. With this dataset, it is possible to study genetic variants for any locus of interest. The HapMap dataset has clearly demonstrated the existence of correlations between nearby variants. By taking advantage of these correlations, one can select informative SNPs (tagging SNPs) that provide information about neighboring variants that are not genotyped. Only a small fraction of SNPs need to be genotyped to capture the full information in a specific region. If a causal variant is not genotyped, its effect can be indirectly tested with the correlated tag SNP that has been genotyped.

The single-gene approach described earlier can also be extended to the entire genome. Genome-wide association scans are emerging as powerful tools to identify genes involved in complex diseases. On the basis of phase I HapMap data, it was shown that approximately 250,000–500,000 SNPs are required to capture all common SNPs in human populations. Although these numbers appear impressive, current technologies can evaluate 1,000,000 SNPs simultaneously [18, 19]. By selecting SNPs properly, we can now interrogate the entire genome in one assay. This allows us to undertake genome-wide association studies, combining the fine mapping and power of association analysis and the ease of case–control cohort recruitment with a genome-wide hypothesis–independent approach. These promising tools will certainly have a major impact on our understanding of the genetic basis of complex diseases such as asthma and COPD. Genome-wide association studies have already led to important and novel insights into the genetic architecture of a rapidly expanding list of complex diseases, including age-related macular degeneration and adult-onset diabetes mellitus [20, 21]. Although not yet reported in COPD, Moffatt and colleagues have performed a genome-wide association analysis in asthma [22]. They identified a region of highly significant association to asthma on chromosome 17q, which was replicated in several other study populations. Using microarray gene expression data, they observed that the expression of one of the genes in that region, ORMDL3, was strongly associated with the same SNPs that were associated with asthma – suggesting that asthma susceptibility is related to ORMDL3 gene expression.

## LINKAGE ANALYSIS OF ASTHMA AND COPD

Linkage analysis includes a group of genetic epidemiological methods that are used to identify chromosomal regions that are likely to contain one or more genetic determinants influencing a phenotype of interest. A panel of genetic markers is genotyped within family units, which can be as small as sib pairs or as large as extended pedigrees, and

the linkage between the markers and a hypothetical disease susceptibility locus is determined. The evidence for linkage is often expressed as an LOD score, which is the logarithm to the base 10 of the odds for linkage. Depending on the study design, LOD scores above 3.3 (for extended pedigrees) or 3.6 (for sib pairs) correspond to significant linkage [23]. Although the location of genes for classic Mendelian disorders can usually be determined quite accurately by linkage analysis, the locations of complex disease susceptibility loci are typically less precisely localized due to genetic heterogeneity, incomplete penetrance, and environmental phenocopies. Linkage can be assessed for quantitative phenotypes as well as disease affection status.

A large number of genome scan linkage studies have been performed in asthma, which were summarized by Celedon and colleagues [24]. Based on follow-up studies after linkage analyses, six potential susceptibility genes for asthma have been reported using positional cloning [25–30]. The only published genome scan linkage studies in COPD have been performed in the Boston Early-Onset COPD Study, implicating chromosomes 2q, 12p, and 19q as likely locations of COPD susceptibility genes [31, 32]. Of interest, a linkage study of spirometric phenotypes in a set of families unselected for respiratory disease identified chromosome 2q, a location of significant linkage to COPD, and chromosome 5q, a location of significant linkage to asthma, as likely locations for genetic influences on $FEV_1/FVC$ in the general population [33]. In an adjacent region on chromosome 2q, Postma and colleagues found significant evidence for linkage to $FEV_1/VC$ in families ascertained through asthmatic probands [34]. Thus, there may be genetic influences on asthma, COPD, and pulmonary function in the general population located within chromosome 2q.

## ASSOCIATION STUDIES IN ASTHMA AND COPD

A large number of SNPs in the promoters and coding regions of a wide range of candidate genes have been examined for genetic association in asthma. There are now over 500 studies that have examined polymorphisms in over 200 genes for association with atopy and allergic disease phenotypes [35–37]. These studies have provided us with increasing insight into genetic susceptibility to asthma, the role of gene–environment interaction and the role of genetic variation in inter-individual response to treatment.

In this part we will focus on five of the candidate genes that have the best evidence for involvement in asthma susceptibility (Table 4.1); these genes have been identified in various ways, including positional cloning (ADAM33) and positional and/or biological candidates (IL-13, IL-4, IL-4R, CD-14). We will also review an example from asthma pharmacogenetics (ADRB2).

Subsequently, we will consider five of the COPD candidate genes with the strongest evidence for association to COPD susceptibility, including positional candidates (TGFB1 and SERPINE2) and biological candidates (GSTP1, EPHX1, and SOD3) (Table 4.2).

**TABLE 4.1** Summary of positive and negative association studies in the genes *ADAM33*, *IL-3*, *IL-4*, and *IL-4Rα* with asthma and its related phenotypes.

SNPs in the IL13/IL4 pathway have been reported as single gene association. When interaction was present, this has been assigned as interaction+, and when interaction was absent, this has been assigned as interaction −.

## ASTHMA GENETIC ASSOCIATION STUDIES

### Gene found by positional cloning: ADAM33

*ADAM33* was discovered by positional cloning in 460 Caucasian families from the US and UK on chromosome 20p. It was associated with asthma, specifically when bronchial hyperresponsiveness (BHR) was present, and there were variations in total and as well as specific IgE levels [25]. Multiple SNPs within *ADAM33* were significantly associated with asthma and BHR in a US or UK population, or with these two populations combined. The nomenclature typically used for ADAM33 SNPs is unusual; the exons have been assigned sequential letters, and the SNPs have been sequentially numbered within each exon (e.g. S_2 is the second SNP in exon S). SNPs occurring in the intron before an exon are designated with a minus sign (e.g. Q-1 is an intronic SNP before exon Q), and SNPs occurring in an intron immediately after an exon are designated with

a plus sign (e.g. F + 1 is an intronic SNP after exon F). The majority of associated SNPs were located in the 3′ half of the gene, extending from exon Q to the last exon, exon V. Subsequently, there have been a large number of case–control and family-based association studies focused on *ADAM33*, with the majority [39, 43, 45, 46, 48, 49, 82] but not all [38, 40, 42, 44], confirming the original finding (Table 4.1). For example, the Collaborative Study on the Genetics of Asthma, comprising eight US genetic centers, demonstrated positive association between SNPs in *ADAM33* and asthma as well as BHR in African-American, Hispanic, and white populations [39]. In a further study involving 1299 asthma cases, 1665 control subjects, and 4561 family members, Blakey and colleagues [48] applied a literature-based meta-analysis, which supplemented the database with new asthma cases from populations in Iceland and the United Kingdom, and demonstrated significant association for 4 of the 13 SNPs tested.

It is well recognized that in patients with chronic persistent asthma, baseline lung function declines more rapidly over time when compared with that of normal individuals [98]. Jongepier *et al.* showed in 200 patients with chronic asthma who were studied annually for 25 years [45] that the rare allele of the S_2 polymorphism (minor allele frequency = 0.25) was significantly associated with excess decline in $FEV_1$ over time and concluded that this variant of *ADAM33* was not only important in the development of asthma but also in disease progression, possibly related to enhanced airway remodeling. A further study by the same group investigated whether SNPs in *ADAM33* could also predict an accelerated $FEV_1$ decline at a population

level [99]. A total of 1390 subjects from a Dutch general population cohort were genotyped for eight asthma-associated SNPs. Individuals homozygous for the minor alleles of SNPs S_2 and Q-1 and heterozygous for the SNP S_1 had a significantly accelerated $FEV_1$ decline over 25 years follow-up of 4.9, 9.6, and 3.6 ml/year, respectively, when compared with the wild-type allele. A further analysis demonstrated a higher prevalence of the SNPs F + 1, S_1, S_2, ST + 5, and T_2 in subjects with COPD at GOLD (Global Initiative for Chronic Obstructive Lung Disease) stage II or higher. Thus, in addition to asthma, it seems that polymorphic variation in *ADAM33* also influences the rate of decline of lung function at a population level, which may then lead to COPD. Subsequently, the authors confirmed the association with COPD in a second cohort [100] and interestingly found that the same ST_5 SNP was associated with the severity of BHR in COPD patients, as well as to the number of sputum cells and CD8 cells in bronchial biopsies. This links the increase in cells in COPD with hyperresponsiveness and *ADAM33*.

Finally, the Manchester Asthma and Allergy Study, a prospective cohort study of the development of asthma and allergies in children, investigated the relation between SNPs in *ADAM33* and lung function at ages 3 and 5 [47]. At the age of 5 years, four of the SNPs were associated with reduced $FEV_1$ (F + 1, N + 1, T1, and T2; $p < 0.04$). Linkage disequilibrium mapping of *ADAM33* pointed to functional SNPs lying between F + 1 and B + 1.

Taken together, these studies support the notion that *ADAM33* may be a gene involved in lung development and further remodeling over a lifetime (Fig. 4.1). This may

then contribute to an accelerated loss of lung function and contribute as well to BHR. Given the associations with different SNPs, *ADAM33* may have differential function inducing different phenotypes in men.

## Gene–gene interaction: IL-13, IL-4, and IL-4R

Il-13 and IL-4 are cytokines produced by Th2 cells that are capable of inducing isotype class switching of B-cells to produce IgE. They also share a receptor component, IL-4Rα, which is an important factor in the development or expression of atopy and asthma. The IL-13 receptor consists of one IL-4Rα subunit and either a low-affinity IL-13Rα1 or a high-affinity IL-13Rα2 subunit. The complete receptor for IL-4 is composed of one IL-4Rα subunit and an IL-4Rγ subunit, or IL-13α subunit (Fig. 4.2). IL-4 and IL-13 are located on chromosome 5q and share the IL-4 receptor α-chain, which is located at chromosome 16p12.

In *IL-13* seven frequent polymorphisms exist of which at least three could be of functional relevance: Polymorphism G2044A alters an amino acid in the protein domain involved with receptor binding (Arg 130Gln) [71]. This SNP and two other polymorphisms in the promoter (A-1512C and C-1112T) showed association with asthma and IgE regulation in different populations [54, 65]. Results

**FIG. 4.1** The phases of lung function growth and decline: growth, plateau and decline phase. In all three phases *ADAM33* may contribute to the course of lung functions over a lifetime.

from gene expression studies and transcription factor binding analysis on C-1112T strongly support a functional role of this polymorphism in gene expression [101]. Genetic variations in *IL-13* have been associated with asthma and related phenotypes in almost all studies that assess SNPs in *IL-13* (Table 4.1), and this is present in ethnically diverse populations living in variable environmental circumstances [50–55, 57–60, 62–65, 67, 70, 72–74, 102].

In the coding region of the IL-4Ralpha gene, at least 14 polymorphisms have been identified and for some of the more frequent genetic variations, functional data is available. SNP A148G alters an amino acid in the extracellular part of the receptor (I50V) which leads to increased IgE production in B cells [102]. Polymorphisms T1432C and A1652G lead to amino acid changes Ser478Pro and Gln551Arg in the intracellular domain of the IL-4Ra chain, respectively. Different studies have assessed the effect of these polymorphisms on atopic diseases [50, 56, 59, 61, 62, 64, 66, 68, 72, 73, 103]. However, overall, the associations between *IL-4Ralpha* polymorphisms and the diagnosis of asthma as well as serum IgE levels were only minor. In 2002, Howard *et al.* published a combined analysis of two polymorphisms in the IL-4/ IL-13 pathway [62]. In a longitudinal population of Dutch adults with asthma, one polymorphism in the promoter of *IL-13* (C-1112T) and one in the *IL-4Ra* gene leading to an amino acid change (Ser478Pro) were assessed. The SNP in *IL-13* (C-1112T) was previously found to be associated with BHR in this population. The SNP in *IL-4Ra* was associated with higher levels of IgE. As both traits are associated with asthma the authors studied interaction of these genes. When individuals with polymorphic alleles in both locations were compared to individuals with wild-type alleles in both locations the risk for asthma increased fivefold.

Also, the interaction between the polymorphism in the coding region of *IL-13* (G2044A) and the promoter polymorphism C-589T in *IL-4* has been studied [64]. The *IL-13* G2044A polymorphism and haplotypes consisting of *IL-13* G2044A and *IL-4* C-589T were associated with the development of atopy and atopic dermatitis. As children in this analysis were only followed up to the age of 24 months, no information on asthma was available.

Three polymorphisms in the *IL-4 receptor alpha* gene (Arg551Glu, Ile50Val, and Pro478Ser) have been investigated in combination with a promoter polymorphism in the *IL-4* gene (C-589T) [68]. The risk for asthma increased up to an

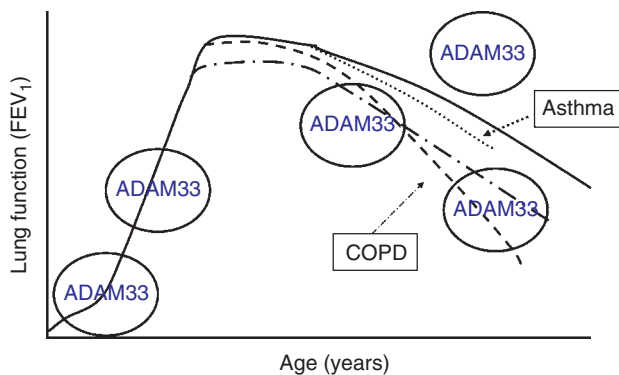

**FIG. 4.2** Interaction between IL4 and IL13 and their respective receptors, that have some similarities.

odds ratio (OR) of 1.97 (95% CI 1.07–3.71) in individuals with the Arg allele at position 551 while the other two SNPs in the *IL-4Ra* gene did not show any significant effects. The combination of the *IL-4Ralpha* Arg allele with the IL-4 589T allele increased the OR to 3.70 (95% CI = 1.07 – 12.78). This study extends the initial findings by Howard in the sense that a second combination of genes seems to interact in the IL-4/ IL-13 pathway. In a similar British study, two polymorphisms in the *IL-4Ra* gene (Arg551Glu and Ile50Val, respectively) and two in the *IL-4* gene (the highly linked SNPs C-589T and C-33T, respectively) were analyzed concomitantly. While transmission disequilibrium tests and haplotype analysis showed significant associations with asthma for both genes individually, the authors state that no interaction between the two genes was observed. However, no data and no information on how interaction was tested, is provided [66].

Other researchers also failed to replicate interactions between polymorphisms in the IL-4/IL-13 pathway. Liu *et al.* investigated six polymorphisms in *IL-4*, *IL-13*, and *IL-4Ra* in almost 1000 children who were followed from birth. The effects of genetic variation in the IL-4/IL-13 pathway on specific and total serum IgE levels were analyzed [65]. The authors confirmed a role of *IL-13* polymorphisms in the regulation of total and specific IgE, but SNPs in *IL-4* and *IL4-Ra* were only associated with specific IgE responses in that study population. Although the interaction analysis is not shown, the authors state that no significant interactions between polymorphisms in the three genes were found. A further study on *IL-4, IL-4Ra, IL-13*, and *IL-13Ra1* provided association of the *IL-13* G2044A polymorphism with asthma in two populations, without significant interaction [53]. In contrast, recent studies by Kabesch *et al.* [72] and Chan *et al.* [73] found significant interactions between the genes in the IL-4/IL-13 pathway.

Differences in observations may result from small study population sizes and from characteristics of the population under study, for example the differences due to age, gender, prevalence of atopy, high- and low-risk population and so on. Thus the findings need more study. However, it is shown that gene–gene interaction may contribute to asthma and atopy development. Analyses of genes in pathways that are relevant to atopy, asthma and or its subphenotypes like BHR need further attention.

## Gene–environment interaction: CD14

Innate immunity genes provide the interface between the immune system and microbial products. Many microbes have specific pattern molecules on their surfaces and these molecules interact with pattern-recognition receptors. CD14 is such a receptor. CD14 is part of the receptor complex for lipopolysaccharide (LPS, endotoxin) together with toll-like receptors (TLR) 2 and 4. CD14 does not have a transmembrane domain and thus does not signal itself but contributes to the affinity of the interaction between the microbial products and TLRs by formation of a receptor complex. Downstream effects include the upregulation of accessory molecules and release of cytokines, such as IL-10 and IL-12. These cytokines are potentially important in directing the adaptive immune response. The CD14 gene contains several SNPs, the most important one being the CD14/-159 (also called CD14/-260). Functional genomic studies showed that monocytic cells with the T allele are transcriptionally more active [103].

The initial study by Baldini *et al.* [104] demonstrated that the C-159T polymorphism was associated with elevated soluble CD14 levels, and reduced total serum IgE levels in children who were skin prick test positive to common aeroallergens. Not all studies have been consistent however, raising the possibility that the level of environmental exposure to endotoxin may alter the effect of CD14 polymorphisms [105]. A number of recent studies have supported this notion.

*Endotoxin.* The hygiene hypothesis proposes that microbial exposure during early life development reduces the development of asthma and allergic disease [106] and has been the subject of many genetic association studies [107]. The timing, dose, and route of microbial exposures, such as endotoxin, are likely to interact with genetic influences, thus altering the response to these exposures [106]. Exposure to endotoxin is known to occur indoors from contact with house dust. In the Barbados Asthma Genetics Study, subjects with low house dust endotoxin exposure, who had the CD14-159TT genotype had a reduced risk of asthma whereas high exposure increased the risk of asthma with this genotype [107]. Taken together, these studies provide support for an "endotoxin switch" in which there is a dose-dependent response to endotoxin exposure for specific risk genotypes [108]. Exposure to endotoxin is also encountered in occupational settings such as farming. Adult farmers with the CD14-159TT and -1691GG genotypes had significantly lower lung function and increased wheezing compared with other genotypes, possibly due to increased soluble CD14 levels interacting with inhaled endotoxin from the agricultural environment [103].

*Animal exposure.* The type of microbial exposure during immune system maturation may influence the development of atopy and asthma. In children with the CD14-159C allele who had regular contact with pets, serum IgE levels were higher than with the T allele [109]. The opposite occurred in children with regular contact with stable animals where the C allele was associated with lower IgE levels. In another study, early life farm environment and the CD14-159TT genotype combined to give the lowest risk of nasal allergies and atopy [110].

*Environmental tobacco smoke.* Exposure to environmental tobacco smoke may increase the risk of asthma in susceptible individuals. In a study of Puerto Rican and Mexican families, people with asthma who had the CD14 + 1437GG or GC genotypes and exposure to environmental tobacco smoke had a mean forced expiratory volume in 1 s that was lower by 8.6% of that predicted as compared with GG or GC subjects that were not exposed to environmental tobacco smoke [111]. In addition, people with asthma with the CD14-159TT genotype and exposure to environmental tobacco smoke had lower serum IgE levels. The mechanism for this interaction could involve exposure to endotoxin found in cigarettes. Sex differences may also exist in response to tobacco smoke. Girls whose mothers had smoked during pregnancy or whose parents had asthma had lower mean soluble CD14 levels [112].

# Asthma pharmacogenetics: The beta₂-adrenergic receptor

The therapeutic response to beta$_2$-agonists is heterogeneous in asthmatic subjects [113], a finding suggested to be due in part to genetic variation in the beta$_2$-adrenergic receptor gene (*ADRB2*). A number of *ADRB2* polymorphisms have been described [114], with the greatest attention devoted to the SNPs causing amino acid substitutions at positions 16 and 27, namely the Gly16Arg and the Gln27Glu polymorphisms [115, 116]. Many of the early studies on the acute bronchodilator response to a beta-agonist differed substantially from one another with respect to study design, type of agonist utilized, and primary outcome assessed [117, 118]. Not surprisingly, there was marked inconsistency in results between trials. Subsequently, larger studies have demonstrated that bronchodilator responses were higher and more rapid among Arg16 homozygotes as compared to Gly16 homozygotes and heterozygotes [119, 120].

The second phenotypic outcome evaluated has been the potential for downregulation of beta-agonist receptor responsivity (tachyphylaxis) with the chronic administration of beta-agonists in association with *ADRB2* genetic variants. In a key study, 255 asthmatics of mild severity were randomized to either regular (180 μg QID) or as-needed albuterol use and were assessed over a 16-week period for evidence of tachyphylaxis and clinical deterioration (as measured by fall in AM peak expiratory flow rate (PEF)). No difference in PEF variation was observed between treatment groups [121]. However, Arg16 homozygotes significantly decreased their pre-albuterol PEF with regular utilization of albuterol therapy, compared to both Arg16 homozygotes receiving as-needed albuterol and Gly16 homozygotes in either treatment group [121]. The difference in evening PEF between these groups was 31.6 ± 10.2 l/min comparing Arg16 homozygous regular users versus Gly16 homozygous regular users ($p = 0.002$) and 31.1 ± 13.0 l/min versus the Arg16 homozygous as needed group ($p = 0.02$) [122]. Similar differences in morning PEF were noted (Fig. 4.3).

$\beta_2$AR desensitization was further evaluated in a prospective, genotype-stratified study of Arg16Gly on treatment-related changes in lung function. Israel *et al.* [123] matched asthmatic individuals homozygous Arg/Arg ($n = 37$) to those Gly/Gly ($n = 41$), by level of FEV$_1$. The genotype-stratified individuals were then randomized in a double-blind, cross-over study of regularly scheduled qid albuterol therapy versus placebo over two 16-week periods. Again, those with the Arg/Arg genotype had lower morning PEF versus placebo ($-10$ l/min, $p = 0.02$), while those with Gly/Gly had higher PEF (14 l/min, $p = 0.02$). The difference between Arg/Arg and Gly/Gly genotypes was significant for morning PEF ($-24$ l/min, $p = 0.0003$), evening PEF, FEV$_1$, morning symptom score, and need for rescue medication.
Further studies have focused on asthma exacerbations as an outcome. With regular use of both short- and long-acting beta-agonists, presence of at least one Gly16 allele is protective against exacerbations [124]. Moreover, in a meta-analysis evaluating long-acting beta-agonist usage, subjects with at least one Arg allele demonstrated significant decrements in PC$_{20}$ when compared to placebo, suggesting that the downregulation of the receptor accompanying tachyphylaxis may result in decreased bronchoprotection [125].

Several studies have assessed the effects of long-acting beta-agonists [126–128]. Wechsler *et al.* showed decreased responses to salmeterol in Arg/Arg subjects compared with Gly/Gly subjects [126]. In the Salmeterol or Corticosteroids (SOCS) trial, morning peak flow worsened in Arg/Arg asthmatic subjects ($n = 12$) who were treated with salmeterol alone after inhaled corticosteroids (ICS) withdrawal when compared with subjects who received placebo; no decrease in morning peak flow was observed in Gly/Gly subjects ($n = 13$). In the Salmeterol and/or Inhaled Corticosteroid (SLIC) trial, Arg/Arg ($n = 8$) asthmatic subjects did not show a sustained improvement in lung function as compared with Gly/Gly ($n = 22$) subjects on salmeterol, regardless of whether subjects were administered concomitant ICS. As these studies were all of small size that may confound the outcome of the analyses, larger studies are required to firmly establish whether polymorphisms in the *ADRB2* gene do affect the beneficial clinical effects of long-acting beta$_2$-antagonists (LABA) treatment when added to inhaled steroids. The size of the study population is of importance, particularly given the variability of individual responses to pharmacotherapy both between subjects and within subjects on a day-to-day basis.

Finally, previous studies have illustrated that relatively few *ABRB2* haplotypes account for the majority of the haplotypic diversity of this gene, and that the frequency of common haplotypes differs between population groups [115, 129]. An effect of *ADRB2* haplotype on acute bronchodilator responses to albuterol has been demonstrated in some studies [128] but not in others [115, 130].

Studies on *ADRB2* provide evidence that the gene is likely to be associated with bronchodilator response but that genetic prediction of this response may vary by ethnic group. Additionally, individuals homozygous for Arg16 demonstrate significant $\beta_2$AR desensitization and these individuals (approximately 15% of population) are at risk of clinical deterioration with the regular use of beta-agonists. Future studies have to assess whether this is still the case if patients are being treated with ICs.

**FIG. 4.3** Change in morning PEF (Peak Expiratory Flow) with beta-agonist (albuterol) treatment, according to *ADRB2* genetic variants.

## COPD GENETIC ASSOCIATION STUDIES

### Biological candidate gene: Microsomal epoxide hydrolase

Microsomal epoxide hydrolase is a xenobiotic enzyme that detoxifies highly reactive epoxides, which are created by cigarette smoking. Thus, variation in the activity of this enzyme has been hypothesized to contribute to variable COPD susceptibility. In an early COPD genetic association study, Smith and Harrison studied two genetic variants in the EPHX1 gene [75], one of which had been reported to cause reduced activity of this xenobiotic enzyme (Tyr113His) and the other which had been reported to cause increased enzyme activity (His139Arg). They analyzed two small case groups that included 68 subjects with spirometrically proven COPD and 94 patients with both pathologically proven emphysema and lung cancer. Their control group of 203 blood donors was not phenotyped. Both their COPD and emphysema/lung cancer case groups had significantly higher frequencies of homozygosity for the His113 "slow" allele associated with reduced EPHX1 enzyme activity. Somewhat paradoxically, a higher frequency of the Arg139 "fast" allele associated with increased EPHX1 enzyme activity was also found in the COPD cases compared to controls.

In a study of 180 former poison gas factor workers in Japan, followed to determine the impact of these toxic exposures on the development of lung disease, Yoshikawa and colleagues compared the distributions of the Tyr113His and His139Arg variants in 40 subjects with COPD ($FEV_1 < 70\%$ predicted) and the remaining 140 subjects [76]. No significant differences were observed in allele frequencies between these groups. However, when they subdivided their 40 COPD cases into 20 mild ($FEV_1 > 60\%$ predicted) and 20 moderate/severe ($FEV_1 < 60\%$ predicted) subjects, a higher frequency of the "slow" His113 allele was observed in the more severely affected subjects. Thus, they speculated that EPHX1 variants were associated with COPD severity rather than susceptibility.

Two other small case–control genetic association studies, performed in Asian populations and published in 2000, found no association between the Tyr113His and His139Arg variants and COPD [78, 80]. In a subsequent study of 184 COPD cases and 212 control smokers from Taiwan, the genotype frequencies for the Tyr113His and His139Arg SNPs did not differ between the cases and controls [41]. However, using the genotypes at both positions to assign two functional EPHX1 categories (slow/very slow versus normal/fast), did lead to a significant difference between cases and controls. Moreover, homozygosity for the His113 allele was more prevalent in severe versus mild COPD cases. More recently, Brogger and colleagues studied 244 subjects meeting spirometric criteria for COPD and 248 control subjects [77]. They found that the His113 variant was associated with COPD.

Sandford and colleagues studied the impact of haplotypes formed by the two widely studied EPHX1 SNPs on rate of decline in $FEV_1$ among continuing smokers in the Lung Health Study [79]. They selected 283 subjects with the most rapid $FEV_1$ decline and 308 subjects who had no measurable $FEV_1$ decline over 5 years. EPHX1 haplotypes were associated with rate of $FEV_1$ decline, and this association was more significant among individuals who reported a family history of COPD – potentially related to other COPD genetic risk factors, which act additively with EPHX1 or which interact with EPHX1 to increase COPD risk.

Hersh and colleagues studied a total of eight EPHX1 SNPs, which included the two widely studied nonsynonymous SNPs above, in a family-based study and a case–control study [81]. The family-based Boston Early-Onset COPD Study subjects included 127 extended pedigrees (949 total subjects) ascertained through a proband with severe, early-onset COPD; the case–control study included 304 severe COPD subjects from the National Emphysema Treatment Trial (NETT) and 441 control smokers from the Normative Aging Study. None of the EPHX1 SNPs were associated with quantitative or qualitative airway obstruction phenotypes in the early-onset COPD families under an additive model. However, the Arg139 allele showed modest evidence for association to COPD in the case–control study.

Overall, there is reasonable but not uniformly consistent evidence for association between EPHX1 SNPs and COPD. The small sample sizes of many of these studies could contribute to inconsistent replication. A further explanation might be differences in ethnicities; however, another potential contribution to these inconsistent results is phenotypic heterogeneity within the COPD cases. COPD includes both emphysema and airway disease in varying proportions between different subjects, and emphysema distribution also varies widely between subjects. DeMeo and colleagues studied emphysema distribution in 282 of the 304 NETT Genetics Ancillary Study participants studied by Hersh and colleagues who had chest CT scans with densitometric and radiologist assessment of emphysema severity and distribution [131]. The EPHX1 His139Arg SNP was significantly associated with emphysema distribution assessed by densitometry ($p = 0.005$) and by radiologist scoring ($p = 0.01$). To determine whether utilizing a more homogeneous set of COPD cases would improve the ability to detect genetic association, the association results using all NETT COPD cases were compared to the results using only 171 upper lobe predominant emphysema cases; the same set of 441 control subjects was used for both comparisons. Despite including a smaller number of COPD cases, the upper lobe predominant emphysema group association analysis indicated that the Arg139 "fast" allele was more protective (OR 0.60 with $p = 0.005$) compared to the association analysis using all COPD cases (OR 0.73 with $p = 0.02$). These results suggest that phenotypic heterogeneity could contribute to the inconsistent replication of EPHX1 (and other COPD candidate gene SNPs) associations with COPD; more comprehensive phenotyping of COPD cases, including chest CT scans, should be considered for future COPD genetic studies.

### Another xenobiotic enzyme gene: GSTP1

Like EPHX1, glutathione *S*-transferase P1 (GSTP1) detoxifies oxygen radicals produced by cigarette smoke; it

has been extensively studied as a COPD candidate gene. Ishii and colleagues studied two nonsynonymous SNPs in GSTP1 in 53 COPD cases and 50 control subjects from Japan [81]. A higher frequency of Ile105 homozygotes at the Ile105Val SNP was observed in COPD cases (79% versus 52%); some evidence suggests that the Ile105 variant confers reduced functional activity of the GSTP1 enzyme [132]. In a Korean population of 89 COPD cases and 94 smoking controls, Yim and colleagues found no association of the Ile105Val SNP with COPD [84]. In the Lung Health Study, He and his colleagues compared 544 subjects with the highest baseline $FEV_1$ values (mean $FEV_1$ = 91.8% predicted) to 554 subjects with the lowest baseline $FEV_1$ values (mean $FEV_1$ = 62.6% predicted); all of these subjects had COPD based on reduced $FEV_1$/FVC ratio [85]. They observed a higher frequency of Val105 homozygotes among the low lung function group (13.2% versus 9.3%), as well as a faster rate of $FEV_1$ decline in high lung function subjects who were Val105 homozygotes.

There are multiple potential explanations for the inconsistent results of these previous studies, including population differences (ethnicity, COPD status), failure to analyze the actual functional variant in GSTP1, and small samples in several of the studies. However, it is also possible that gene–gene interactions need to be considered to identify key COPD susceptibility genes. Studies of combinations of GSTP1 variants with other potential susceptibility genes have also been performed. Calikoglu and colleagues did find a higher frequency of Ile105 homozygotes in a male Turkish population of 149 COPD cases (61%) compared to 150 control subjects (38%) [86]. They also examined the impact of including variants in GSTT1 and GSTM1 in combination with GSTP1 and found a markedly increased risk of COPD when a combination of variants in these three genes was considered. In addition to EPHX1, Cheng and colleagues also studied the GSTP1 Ile105Val variant in their set of 184 COPD cases and 212 control subjects from Taiwan [41]. Although the Ile105Val SNP was not associated with COPD when analyzed individually, the combination of at least one EPHX1 "slow" allele (His113), homozygosity for the GSTM1 Null allele, and homozygosity for the Ile105 allele was significantly more common in COPD cases (36%) versus controls (8.5%). Formal tests of interaction in large samples will be required to replicate these findings and to determine whether these results represent the combination of susceptibility alleles acting independently or significant gene–gene interactions.

## Association with a relatively uncommon allele: SOD3

Although genetic association studies typically analyze common genetic variants with allele frequencies above 10%, it is quite likely that less common variants contribute to the susceptibility, and resistance, to complex diseases like COPD. Extracellular superoxide dismutase (EC-SOD or SOD3) detoxifies oxygen radicals by scavenging superoxide anions. A variant in this gene, Arg213Gly, has been shown to have a functional effect on the processing of the EC-SOD protein, leading to substantially elevated plasma levels of the protein [133]. Young and

colleagues genotyped the Arg213Gly variant in 230 COPD cases and 210 control smokers [87]. Importantly, as the Gly213 variant was hypothesized to confer resistance to COPD among smokers, their control subjects had normal spirometry with a heavy smoking history (mean pack-years = 42). The allele frequency of Gly213 was only 1% in the COPD cases but it was 5% in the control smokers ($p$ = 0.02). Carriers of at least one Gly213 allele were significantly more common among controls than cases ($p$ = 0.005).

In the Copenhagen City Heart Study, Juul and colleagues studied the Arg213Gly variant in 9258 Danish subjects [88]. They confirmed the marked effect of this variant on EC-SOD plasma levels, with mean values of 142 ng/ml in Arg213 homozygotes, 1278 ng/ml in Arg213/Gly213 heterozygotes, and 4147 ng/ml in Gly213 homozygotes. In a multivariate model adjusting for gender, age, smoking, and occupational dust exposure, smokers who were heterozygous (Arg213/Gly213) had substantially lower risk for COPD than Arg213 homozygotes (OR 0.4, with 95% CI 0.2–0.8). Among nonsmokers, no protective effect of the Gly213 variant for COPD was observed. Only two Gly213 homozygous subjects were identified in the entire cohort. This confirms the potentially protective effect of the Gly213 allele among smokers, and it emphasizes the utility of large sample sizes – especially when studying relatively uncommon genetic variants.

## TGFB1: Convergence of biological and positional candidate gene approaches

Transforming growth factor beta 1 (TGFB1) is a cytokine that acts as a central regulator of the inflammatory response; thus, it is a logical biological candidate gene for COPD. A potentially functional variant has been identified at codon 10, which changes a leucine to a proline (Leu10Pro); individuals that carry at least one proline allele have higher TGFB1 mRNA in peripheral blood mononuclear cells and higher serum TGFB1 protein levels [134]. Wu and colleagues genotyped this nonsynonymous SNP in Caucasian subjects from New Zealand. They included 165 COPD cases and two control groups – 76 control smokers and 140 unphenotyped blood donors [89]. The Pro10 allele was less common in COPD cases (33%) than in either the blood donor controls (45%) or smoking controls (45%).

Celedon and colleagues identified TGFB1 as a positional candidate gene on chromosome 19q after performing linkage analysis in 72 extended pedigrees (585 individuals) ascertained through severe, early-onset COPD probands [91]. The initial evidence for linkage of $FEV_1$ to 19q was modest (LOD score = 1.40). However, genotyping additional short tandem repeat markers to increase the information available for linkage analysis, as well as performing a stratified analysis in smokers only (to identify genomic regions likely influenced by gene-by-smoking interactions), led to more substantial evidence for linkage (LOD score = 3.30). TGFB1 is located within the linkage region, and five SNPs were genotyped in both Boston Early-Onset COPD Study pedigrees for family-based association analysis and in a set of 304 COPD cases and 441 smoking control subjects. Three

SNPs were significantly associated with COPD phenotypes in each population, and one SNP in the promoter region of TGFB1 (rs2241718) replicated in both study populations. The Leu10Pro variant was only significantly associated in the case–control analysis, but a lower Pro10 allele frequency was noted in COPD cases – indicating the same directionality of effect as in the study by Wu and colleagues.

Following these initially supportive studies using the biological and positional candidate gene approaches, further replication efforts of TGFB1 in COPD susceptibility have had mixed results. In a small study comparing 84 COPD cases and 97 control subjects from China, significant differences in both allele and genotype frequencies were noted for two TGFB1 promoter SNPs [93]. However, association analysis of the Leu10Pro SNP and two promoter SNPs in 102 COPD cases and 159 control smokers from Korea showed no evidence for association [90]. Furthermore, in a comparison of 283 continuing smokers with rapid $FEV_1$ decline versus 307 continuing smokers with slow $FEV_1$ decline in the Lung Health Study, Ogawa and colleagues found no association between three TGFB1 SNPs (including the Leu10Pro SNP) and $FEV_1$ decline [92]. van Diemen and colleagues studied three TGFB1 SNPs including one promoter SNP (rs1800469, C-509T), one nonsynonymous SNP (rs1982073, Leu10Pro), and one 3′ untranslated region SNP (rs6957) in a general population sample of 1390 individuals in the Netherlands who were followed longitudinally for 25 years [94]. Although they found no association of TGFB1 SNPs with $FEV_1$ decline, rs6957 was significantly more common in 188 subjects meeting criteria for GOLD Stage II COPD than among the remainder of the cohort ($p = 0.001$). Additional studies of TGFB1 in COPD will be required, including larger numbers of SNPs in larger study populations, to definitively confirm or refute the role of TGFB1 genetic variants in COPD susceptibility.

## SERPINE2: Integrating genomics and genetics in COPD

Although genetic linkage studies can point to chromosomal regions that are likely to include susceptibility genes for a complex disease, such regions typically contain many genes. In addition to the approaches of selecting a biologically plausible positional candidate gene (as for TGFB1) or dense genotyping of SNP markers (not yet reported for COPD) within linkage regions, assessment of gene expression can point to promising candidate genes that would not have been suspected based on our current knowledge of disease pathobiology. DeMeo and colleagues integrated gene expression microarray results from two data sets – one data set analyzed mouse lung development and the other data set compared gene expression in human lung tissue – for the genes located within their linkage region to airway obstruction on chromosome 2q [95]. Based on these gene expression results, SERPINE2 (Serpin Peptidase Inhibitor, Clade E, Member 2) was selected as a candidate gene, and 48 SNPs were genotyped in a family-based cohort (949 individuals from 127 Boston Early-Onset COPD Study pedigrees) and a case–control cohort (304 COPD cases and 441 control smokers). Eighteen SERPINE2 SNPs were associated with airflow obstruction phenotypes in the Boston Early-Onset COPD families; a SNP-by-smoking interaction term was included in those analyses. Five of these 18 SNPs demonstrated replicated associations in the case–control cohort. Although Chappell and colleagues wrote a Letter to the Editor indicating that they could not replicate these associations in their case–control cohort [96], Zhu and colleagues recently reported their analyses of 25 SERPINE2 SNPs in both a family-based cohort of 1910 subjects and a case–control cohort from Norway including 973 COPD cases and 956 control smokers [97]. The family-based association analysis demonstrated association of five SNPs to COPD, with $p$ values as low as 0.002. The case–control analysis only found one SNP with $p < 0.05$ for COPD affection status; however, five SNPs were associated with $FEV_1/FVC$ in COPD cases; these were the same five SNPs associated with COPD in the family-based association analysis. Thus, reasonable evidence for replication has been found, supporting the utility of future studies of SERPINE2 association and function to confirm whether it is a valid COPD susceptibility gene.

## PERSPECTIVES ON GENETICS OF ASTHMA AND COPD

As demonstrated in this chapter, the research on genetics of asthma and COPD has become a promising new field. The main goal of the industries and the research institutes is to find the genes that increase susceptibility to develop asthma and COPD.

Both in asthma and in COPD the heterogeneity of the diseases with complex hereditary traits and many (sub)phenotypes are obstacles to find the right genetic information easily. Although a rapidly increasing number of genes are being implicated in asthma and COPD pathogenesis, the functional variants in these genes have not been definitively identified; this is a major area requiring investigation. In the pathogenesis of asthma and COPD it is reasonable to suspect that the interactions between multiple genes and multiple environmental triggers are important. This will require collaboration between many researchers combining their cohorts that have been carefully phenotyped for asthma and COPD. By combining large cohorts with systematic analyses of environmental risk factors, comprehensive assessment of genetic polymorphisms (including genome-wide SNP genotyping), and genetic analysis with advanced statistical techniques, we will better understand the genetic determinants and heterogeneity of asthma and COPD. Hopefully this will lead to new treatments, intervention strategies, and finally prevention of asthma and COPD.

## INTRODUCTION

Asthma is an inflammatory disease principally of the small airways but current understanding is that all the airways are involved [1]. The physiological manifestations of lung inflammation are reversible airflow limitation and airflow limitation that fluctuates widely with time; asthma can also result in persistent loss of lung function. In contrast, airflow obstruction in patients with chronic obstructive pulmonary disease (COPD) presents with both reversible and irreversible airflow limitation, the latter linked to loss of static elastic recoil due in part to the destruction of the architecture of the lung. The airflow limitation of COPD has much less temporal or periodic variation over the short term but patients with COPD usually exhibit steady consistent losses of lung function over a period of years. In reality the clinical presentation of both COPD and asthma is often quite variable and the pathophysiological data alone do not allow a definitive diagnosis. This confusing presentation of patients with features of both asthma and COPD is in keeping with the overlap observed in the epidemiology of these diseases [2, 3]. The focus of this chapter is on the pathophysiological presentation of COPD and asthma and the features that distinguish each disease as well as the similarities. This chapter will also examine the physiological processes that characterize airways disease.

## LUNG VOLUMES AND ELASTIC RECOIL

### Lung volumes and capacities

In diseases of the airway such as asthma and COPD there are characteristic increases in volume which distinguish these airway disorders from restrictive processes of the respiratory system that reduce lung volumes. Lung volumes have important bearing on the degree of disease since increases in the residual volume (RV) occur relatively early even with mild airway disease whereas increases in the total lung capacity (TLC) are usually an indication of more severe or long-standing disease (Fig. 5.1) [4–6].

The most useful lung volumes and capacities to measure are those that assess the physical limits of the lung and chest wall and define the extremes of the vital capacity (VC); TLC and RV. The volume in the lung at end expiratory position, the functional residual capacity (FRC), is important because of the influence that lung volume has on airway caliber and in turn on airflow resistance during eupnea. TLC, FRC, and RV are boundary conditions of respiration and accordingly provide the most information about the capacity and function of the respiratory system [6]. Assessing the changes in these lung volumes to evaluate disease severity and response to therapy allows one to distinguish between obstructive lung disease and restrictive lung disease (Table 5.1) [8, 9].

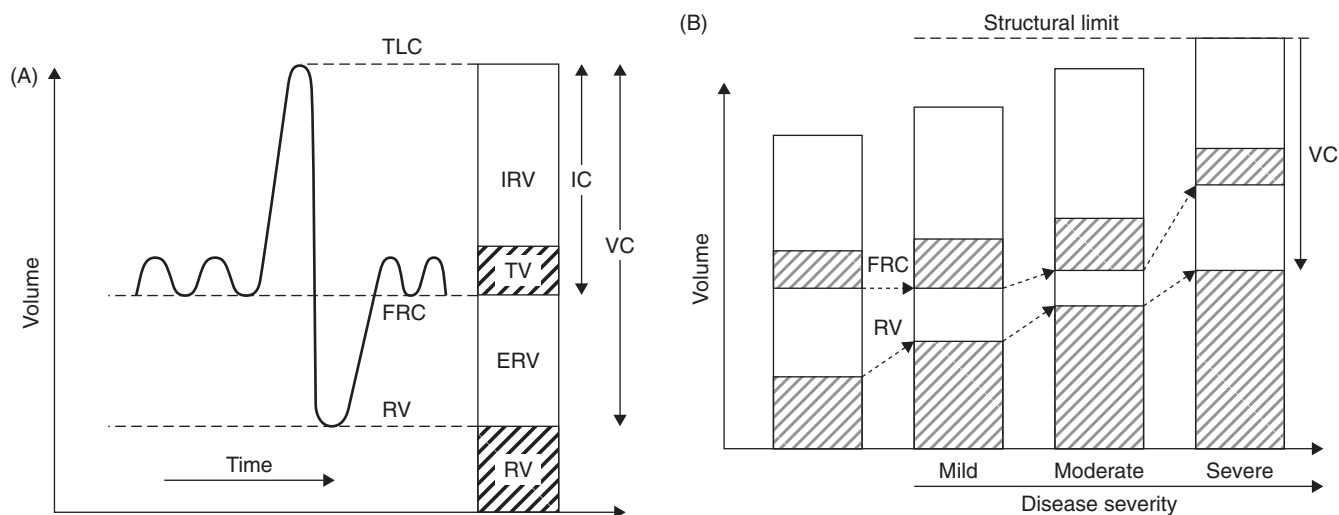
Obstructive lung diseases such as chronic bronchitis, asthma, and emphysema all result in increases in lung volume. An increase in TLC usually represents more chronic, severe disease, and in the case of COPD it is related to remodeling of the chest wall leading to the so-called barrel chest. The increase in TLC may have another more important role; that is the preservation of forced vital capacity (FVC) in face of a rise in RV that would then result in more pronounced falls in $FEV_1$ if the rise in TLC had not ameliorated the fall in FVC [4, 7]. The increase in TLC in parallel with each increase in RV can occur until the chest wall reaches some structural "limit" which probably varies from person to person [7, 10] and acutely


**FIG. 5.1** (A) The figure presents a trace of volume displacement as a function of time during quiet breathing followed by a maximal inspiration to TLC, the subject then exhales the VC until no more air exits the lung. The volume of gas remaining in the lung at this point is RV. FRC is the volume left in the lung at the end of each normal breath. Expiratory reserve (ERV) and inspiratory reserve volume (IRV) are as noted. The inspiratory capacity (IC) is the volume of air inspired from FRC to TLC and is sometimes used as a surrogate for TLC. The three boundary conditions TLC, RV, FRC provide the most useful information as to the functioning of the lung (see text). (B) The figure present the changes in lung volumes and capacities that occur with increased airway disease severity as during an asthma attack or during the progression of COPD. The first (and last) change is usually an increase in RV (mild) as airway closure increases the RV continues to rise but FVC does not fall if the TLC rises in concert [4, 7]. However, at some point in the disease process (severe) or depending on the flexibility of the chest wall a structural "limit" is reached where the TLC cannot increase further. At this point the further rise in RV results in a fall in VC, FVC, and $FEV_1$ (see text).

**TABLE 5.1** Boundaries of lung volume and physical determinants.

| Volume or capacity | TLC (%) | Determinants |
|---|---|---|
| TLC: total lung capacity | | • Respiratory muscle function<br>• Structural limits of chest wall distortion<br>• Compliance of chest wall and lung |
| FRC: function residual capacity | 50 | • Compliance of chest wall and lung<br>• Expiratory time constants<br>• Respiratory muscle activity |
| RV: residual volume | 20–30 | • Airway closure<br>• Adequate expiratory effort<br>• Children (<18 years): chest wall compliance |

*Note*: TLC (%): total lung capacity for normal persons.

during an exacerbation of disease (Fig. 5.1B). The cause of the increase in TLC is unknown but the possibilities include either a loss of an inhibitory reflex that activates the muscles of the chest wall as TLC is reduced or simple structural overdistension [10–12]. For patients with COPD it would appear that the increase in TLC may also be due to remodeling of the chest wall and is commonly observed in X-ray or CT images. Assessing changes in FRC is of particular importance because resting lung volume has such an important bearing on airway caliber and airway smooth muscle (ASM) contractility [13–19]. Determination of FRC provides a reasonable alternative to the placement of an esophageal balloon to measure the

balance of elastic forces of the respiratory system (see below). Increases in FRC observed in airways disease may represent a loss of recoil of the lung as occurs in emphysema or an increase in outward recoil of the chest wall. In the case of the latter, the inspiratory respiratory muscle in effect reset the equilibrium point of the respiratory system to a higher volume such as occurs during an asthma attack [6, 20]. For patients with asthma or COPD, the FRC increases by several mechanisms including persistent activity of the respiratory muscles [20], increased expiratory time constants [20], or alterations in recoil. Severe increases in FRC occur in patients with more severe forms of COPD because all these mechanisms occur in concert (Fig. 5.2).

## Elastic recoil

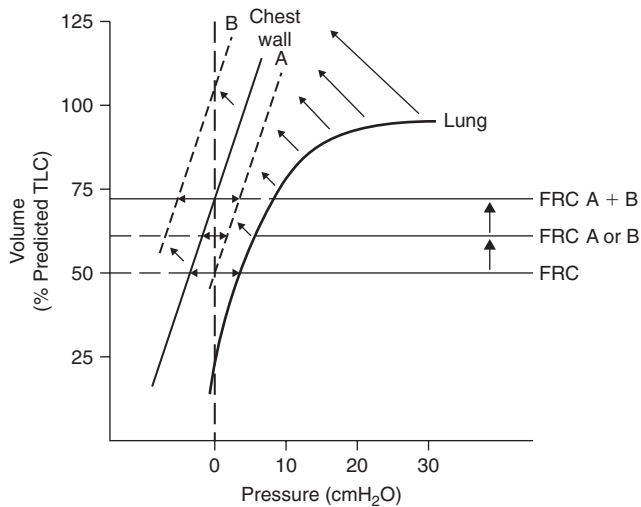
Pressure–volume (PV) relationships are used to quantitatively display the elastic recoil of the components of the respiratory system: the chest wall and the lungs. Elastic recoil is very important in a number of respects. First, the strength of the chest wall muscle when coupled to the elastic recoil of the chest wall and lungs serve to determine the static lung volumes, specifically the maximal excursion of the chest wall as assessed by TLC and RV [6]. Second, the elastic recoil as influenced by changes in lung volume, alters intrapulmonary airway caliber [13–15, 21, 22]. Thirdly, elastic recoil is the most important load to smooth muscle contraction as changes in lung volumes have a profound effect on ASM performance [18, 22]. Lastly, elastic recoil is the major driving force for effort-independent maximal airflow, influencing peak flow and in particular $FEV_1$ [23, 24].


**FIG. 5.2** Pressure–volume (PV) relationships in a normal subject (heavy solid lines), asthmatic patient (chestwall shifts to B) and in a patient with emphysema (where the lung PV shift to A and chest wall to B: A + B). The heavy solid line to the left is the PV curve of the chest wall showing outward recoil up until 66% of TLC and the line to the right is the PV curve of the lung. For the normal person the equilibrium point (FRC) where the outward recoil is equal but opposite to the inward recoil occurs at about 50% of the TLC. However, for the patient with loss of recoil of the lung (dashed line A) or chest (dashed line B) FRC rises because the inward recoil of the lung is less or the chest is more and a new equilibrium (FRC A or B) is reached. However, when both the chest wall (B) and lung PV (A) relationship change (both dashed lines) the FRC is increased further (FRC A + B).

Elastic recoil is diminished in all patients with emphysema whereas patients with asthma or the bronchitic form of COPD exhibit, on average, more normal recoil [25–27]. A caveat is that the loss of static elastic recoil in asthmatic patients has been reported by several workers [27–29]. In asthma the loss in elastic recoil can occur acutely [30], and can be reversed with bronchodilator treatment [28, 31]. Unlike emphysema where the loss of elastic recoil is thought to be due to microscopic destruction of parenchyma [32], these more acute losses in elastic recoil in some patients with asthma may relate to alterations in surface tension due to extravasation of plasma proteins from the inflammation or as a result of airway luminal fibrin formation within the airway lumen [33].

Determination of FRC coupled with an assessment of the chest wall (e.g. visual inspection) allows one to assess the likely position of the lung PV relationship without the issues associated with placement of an esophageal balloon. For example, finding a low FRC in a patient that was not overweight or obese would indicate a restrictive process; whereas an increase in measured FRC in a patient with normal appearing chest wall is suggestive of either persistent activity of the inspiratory muscles (especially if the patient has labored breathing) or a loss of inward elastic recoil of the lung or chest wall [6, 8].

Elastic recoil has a profound effect on airway caliber. As lung volume increases there is outward pull on intrapulmonary airways since these airways are embedded in the alveolar matrix of the parenchyma [34]. Hence, as lung

volume increases or decreases the airway caliber increases or decreases [13–15]. Since, the contraction of ASM is dependent upon muscle fiber length and constitutes the load against which ASM must contract, lung volume sets the starting load. The observation explains why at low lung volumes the response to an inhaled bronchoconstricting agent is enhanced [16, 18, 19]. Hyperinflation diminishes luminal narrowing caused by ASM activation as shown by animal [16, 17] or human studies [18, 19].

## DETERMINANTS OF AIRWAY CALIBER

The size of an intrapulmonary airway lumen at any given lung volume (e.g. FRC) is generally thought to depend on: (1) contents of the lumen (such as mucous plugs or liquid accumulation), (2) the structure of the airway both internal and external to the smooth muscle, (3) activation state or bronchomotor tone of the airways smooth muscle, (4) compliance or stiffness of the airway wall, and (5) tethering forces of the attached alveolar wall or lung volume. Transmural pressure ($P_{tm}$), which is the pressure inside minus pressure outside of the airway, represents the summation of forces working to open or close the airway and is resisted by the structure (or compliance) of the airway wall. In both asthma and COPD there is a considerable change referred to as remodeling of these structural components of the airway wall (Fig. 5.3).

### Contents of the lumen

The biological processes that lead to obstructive lung disease leave the airway lumen filled with liquid, cells, and mucus; this accumulation is even more marked during acute exacerbations [35]. Indeed, this pathologic feature may be the most physiologically significant as obstruction of the airway causes much of the mismatch of ventilation to perfusion and in turn results in hypoxemia (see below). Moreover removal of such an obstruction is anything but straightforward as the contents change from being serous to more mucoid in nature. Acutely lumenal obstructions appear in the peripheral branches of the dependent portions of the tracheal–bronchial tree [36, 37]. These pathological changes in the distal lung are associated with 10-fold increase in peripheral resistance [38, 39] that increases further with disease severity [40–42]. Yet even with this 10-fold increase in peripheral resistance in the mild asthmatic, spirometry can still be within normal limits.

### Structure of the airway wall

Inflammation of the airway wall characterizes all forms of obstructive airway disease. Structural alterations include increased extracellular deposits of the extracellular matrix that include fibronectin, collagen, vitronectin, and a host of other components [43]. The apparent thickening of the basement membrane below the airway epithelium is due
**FIG. 5.3** (A) A schematic representation of the cross-section of an airway in a normal person (left-hand side of A) and a patient with obstructive airways disease (right-hand side of A). The changes that occur during airway remodeling in obstructive lung disease that could either cause airway narrowing and airway hyperresponsiveness or prevent airway hyperresponsiveness are presented. In asthma and COPD several factors are operational but the relationship of these structural changes to lung function is anything but clear. The mechanisms that cause or prevent airway narrowing are several and include: (1) Debris plugging of airway lumen, (2) decreased number of folds, (3) liquid in luminal folds of epithelium, (4) thickness of the basement membrane, (5) increased in contractility and/or size of ASM, (6) breaks in the alveolar tethers, (7) loss of elastic recoil, and (8) thickening of airway wall. $P_{el}$: elastic recoil forces; Palv: alveolar pressure; Pbr: pressure in the lumen of the bronchiole; Transmural pressure: the difference in Pbr Palv; ASM: airway smooth muscle. (B) Balance of forces favoring airway narrowing or airway opening.

to type I and III collagen deposition and is observed even in mild disease [44]. ASM is also increased both in volume (hypertrophy) and in number (hyperplasia) [43]. The functional consequence of remodeling of the airway is uncertain; indeed, there is little proof that there is a functional consequence. Arguments have been made that airway remodeling can both promote and protect the size of airway lumen [45] (Fig. 5.3B).

## Activation state of the ASM

Bronchomotor tone has two consequences: first, depending on the compliance of the airway wall, smooth muscle tone narrows airways and reduces airflow but, secondly, smooth muscle tone also stiffens the airway wall as it contracts. A decrease of airway wall compliance would serve to prevent further collapse [45, 46]. This is best appreciated when ASM is activated at low lung volumes. Several studies have shown that when methacholine is inhaled in the supine posture, compared to the upright posture, more severe airway narrowing occurs [18, 19] and there is a marked increase in the maximal level of airway resistance. However, a decrease in bronchomotor tone will increase airway wall compliance and lead to dynamic airway narrowing during maximal expiratory flow [31, 47].

## Compliance of the airway wall

The structural components of the airway wall represent the load to smooth muscle shortening, thus an increase in compliance would amplify ASM contraction and a decrease in compliance would be expected to antagonize ASM shortening. Cartilage, an important structural element of the airway wall, would serve to protect the airway lumen and has been shown to soften with disease [43, 48], an effect thought to be due to inflammatory mediators and the release of metalloprotineases. Folding or buckling of the mucosa has been speculated to either prevent airway narrowing or enhance airway luminal narrowing by changing wall compliance [46, 49]. In this situation as the wall is compressed by ASM contraction, the layer internal to the ASM folds or buckles up. The folds reinforce each other which serve to prevent further narrowing with an apparent increased load to the ASM. However, if the folds are few in number [49] and/or interstices of the folds become filled with liquid because of the small radius of curvature of an individual fold and the high surface tension found in the presence of inadequate surfactant [50], the airway lumen area would be narrowed or even obstructed.

Direct *in vivo* measurements of airway wall compliance yield conflicting results. Measurements from autopsy specimens of patients with COPD showed reduced

compliance only in very small (<1 mm) airways [51]. Normal lungs show age-related decrease in wall compliance which complicates the interpretation of the losses observed in patients with COPD who are normally older [52, 53]. In asthma both increases [53, 54] and decreases [21] in wall stiffness have been reported. Decreased wall compliance or stiffening is likely the result of inflammation and/or wall thickening and hence would be related to asthma severity and disease status. Another potential mechanism of airway narrowing from the increase in wall compliance results from a decrease in forces tethering the airway open. These forces are decreased through two mechanisms. First, there are few alveolar attachments to the outer mucosa of the airway wall and second scar tissue has less tensile strength than normal tissue [55].

## Tethering forces or the coupling of lung volume and resistance

The attachments of the alveolar wall to the external wall of the intrapulmonary airway are the anatomical link between the alveoli of the parenchyma and airway. These attachments form the physical linkage system that result in airways widening and the fall in airways resistance as lung volumes increase. This tethering force is the single most important factor stabilizing and influencing airway lumen integrity [13–15]. This fact is evidenced by the profound effect lung volume has on airflow. As noted above, for a given degree of smooth muscle activation greater airway narrowing occurs at low versus high lung volumes. For example, the simple act of assuming the supine position, which is not associated with a change in smooth muscle activation, markedly increases airway resistance [15, 18]. The effects of lung volume on airways resistance are very sensitive to even small losses (~1 cmH$_2$O) in lung elastic recoil pressure [16, 17, 35]. This process is not limited to changes within the parameter of the airway as denoted by ASM, since changes external to the ASM can also uncouple the lung volume–airway resistance relationship.

Changing from the upright to the supine position leads to airway hyperresponsiveness (AHR) in asthmatics but such changes also occur in normals [18, 56]. The mechanism for this phenomenon is most likely the loss of the tethering forces, as estimated by $P_{el}$. These forces pull open the airway wall as lung volume increases, thus a loss of outward recoil tethering the airway open is termed *uncoupling*. Airway resistance and lung volume uncoupling occurs rapidly with sleep onset in the patient with nocturnal asthma and further uncoupling during the night probably as a result of inflammatory events, resultant airway wall thickening, and mechanical uncoupling [21]. In COPD the loss of elastic recoil ($P_{el}$) is both greater and more persistent than the age-dependent loss of recoil that occurs in normal persons, and when considered in regards to loss of $P_{el}$ with aging, accounts for the progressive loss of FEV$_1$ over the years.

The loss of $P_{el}$, together with breaks in alveolar attachments, results in the increased airway narrowing noted on forced expiration in patients with obstructive airway disease [47]. Smooth muscle contraction contributes to severe airway narrowing and loss of bronchodilation response

typically seen in patients with emphysema [57, 58]. For patients with COPD or severe long-standing asthma this profound alteration in the function and structure of the airway accounts for the sustained and therapeutically resistant increase in airway resistance or decrease in FEV$_1$. The dilemma for the clinician is to ascertain what portion of the loss of structure and function is reversible and what portion is not.

## AIRFLOW RESISTANCE

## Chronic obstructive pulmonary disease

A common feature of the patient with COPD is airflow limitation; this is most often assessed by the fall in FEV$_1$. The current Global Initiative for Chronic Obstructive Lung Disease (GOLD) classification system for COPD uses post-bronchodilator FEV$_1$ as a major factor in classification of disease severity and in practice this variable makes up a significant part of the case definition for COPD [59]. Airflow limitation in COPD arises in the small (<2 mm diameter at FRC) airways which exhibit neutrophilic inflammation even in asymptomatic smokers [60, 61]. When patients have mild, asymptomatic disease there are subtle changes in airflow limitation [60] with changes in distribution and homogeneity of ventilation. As the severity of COPD increases there is increased involvement of more central airways but even when FEV$_1$ has fallen to 50–60% of predicted, more than half of the increased resistance can be attributed to narrowed intrapulmonary (<3 mm) airways [42]. Airway dimensions in COPD are reduced, even when the lungs are inflated to a standard inflation pressure (typically 30 cmH$_2$O) so one must conclude that the structural remodeling of collagen, mucous gland hyperplasia, general wall thickening, and loss of tethering elastic forces contributes to the airway narrowing [62].

These alterations in structure and function lead to profound ventilatory defects and a loss of collateral ventilation [63, 64]. In turn there is a trapping of gas due to both long expiratory time constants and check valve-like processes within the obstructed and emphysematous spaces. Re-establishment of collateral pathways with intrabronchial, one-way valves, much like the spiracles of insects, leads to deflation of these overextended spaces [65] and is currently being explored as a therapeutic option to the COPD patient to relieve this trapped gas [66].

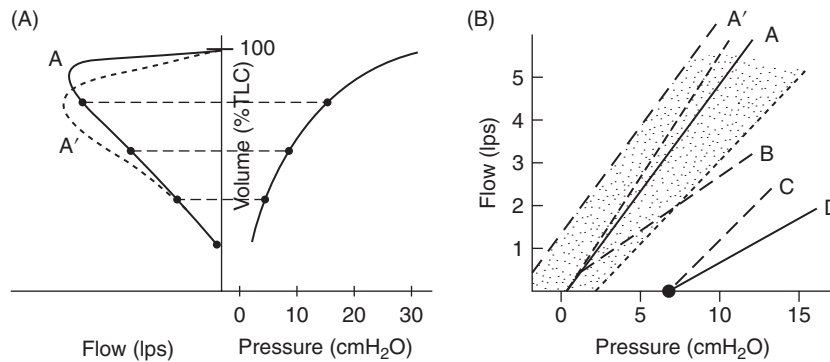
In patients with severe COPD expiratory airflow limitation is observed at all lung volumes and often occurs even when there is a minimal expiratory effort; in these patients expiratory airflow limitation occurs on expiration with each breath [67]. In more mild cases, the airflow limitation is observed only on forced expiration because: (1) flow and volume during eupnea do not reach their structural limits due to the reserve in the respiratory system and (2) dynamic hyperinflation, which increases elastic recoil by increasing lung volume, further prevents reaching these limits during eupnea. The pathogenesis of airflow limitation in patents


**FIG. 5.4** (A) The role of the loss of lung recoil and airway wall collapse in affecting a fall in maximal expiratory flow ($FEV_1$) can be assessed by constructing a MFSR curve [73, 74]. (B) The conductance (resistance) of airways downstream of the point (equal pressure point) of airflow limitation is determined as the slope of $V/P_{el}$ relationship. This $V/P_{el}$ relationship or MFSR curve comes from selecting points from the both flow–volume and pressure–volume relationships at points of isovolume (horizontal dashed lines in A). The dotted line, flow–volume loop is from volume displacement of body plethysmograph whereas the solid line flow–volume loop is integrated volume from the mouth flow signal. The shaded area in (B) is from normal subjects [75]. MFSR A' is the $V/P_{el}$ without the effect of gas (airway wall compression) whereas MFSR A includes the effect of compression; the resistance is increased. MFSR B is a patient with increased resistance (e.g. airway narrowing) of the airways. MFSR C is a patient with emphysema where the sole abnormality is a loss of recoil, airway wall collapse and lower flow rates. MFSR D is a patient with increased resistance, loss of recoil, and increase pressure (volume) at which the airways close due to collapse and/or airway dynamic compression shifting the $V/P_{el}$ relationship to the right.

with COPD or more severe forms of bronchitis and asthma accordingly is quite complex and is a reflection of the interplay between airway caliber, respiratory muscle function, lung volume, elastic recoil, and airway wall compliance [6, 14, 23, 24, 27, 62, 68].

The severity of COPD is defined as the post-bronchodilator $FEV_1$ [59], so it is useful to consider what a fall in $FEV_1$ signifies. The forced expiratory volume in 1 s – the $FEV_1$ – is a measurement taken from the volume–time relationship, known as a spirogram, during a forced exhalation from TLC. It is important to remember that the $FEV_1$ is a volume (liters) not a measure of airflow (liters per second) but it reflects the average airflow over the first second of a forced exhalation. A decrease in the $FEV_1$, as a percentage of its predicted value, indicates that the patient is unable to exhale a volume of air in 1 s similar in magnitude to that which could be exhaled by a person of the same sex, age, and height without lung disease. A considerable number of factors influence the magnitude of the $FEV_1$, but only one of these factors is airway luminal size. The magnitude of the $FEV_1$ is very much influenced by the size of the inspiration prior to beginning the forced expiration (TLC), elastic recoil, airway caliber, airway wall compliance, and size of the lung that is open. In the case of the latter as lung volume is lost by airway closure, filling or destruction, the VC, FVC, and hence $FEV_1$, decreases. It is important to realize that $FEV_1$ is a polyvalent index; where polyvalent indices are ones in which many factors contribute to the exact value of the index [69]; indeed most measures of lung function are polyvalent. Accordingly it is unclear what a low $FEV_1$ might signify, the cause of the decrease or even the best treatment needed to reverse the loss in $FEV_1$.

Empirically the $FEV_1$ is a very useful measure of overall lung function since it relates to morbidity and mortality of COPD, even death due to all causes [70]. The techniques used to measure $FEV_1$ have been well codified [71, 72]. The general performance and in particular the variability and reproducibility of the $FEV_1$ as an outcome measure is robust and for this reason the $FEV_1$ is a principal outcome variable for clinical research. Unfortunately a low $FEV_1$ is not specific for any single cause of airflow limitation, and other assessments of the loss in airflow limitation must be made.

Useful insight into the causes of airflow limitation can be gained by the construction of isovolume pressure–flow curves or maximum flow static recoil (MFSR) relationships which are determined from flow–volume and PV relationships (Fig. 5.4). To assess artifacts from compression of the gas in thorax, lung volume is measured from the volume displacement of the chest wall and is obtained by having the patient sit in a variable-volume, body plethysmograph. To measure static recoil an esophageal balloon attached to a pressure transducer is positioned in the lower esophagus to estimate pleural pressure. The subject then inhales to TLC and expires slowly to construct a deflation PV curve (Fig. 5.4A) and then the subject performs a maximal flow–volume curve. By taking a series of data pairs of flow and pressure from points of isovolume on the PV and flow–volume relationship, the MFSR curve can be constructed (Fig. 5.4B).

The slope ($\Delta V/\Delta P$) of the MFSR curve is resistance (or its inverse, conductance) of the segment of lung upstream of the point and is known as the equal pressure point, that is the point along the airway which $P_{tm}$ is zero. Because there is still elastic recoil of the lung at RV, the MFSR relationship does not intersect with zero pressure. Patients with airflow limitation will exhibit different MFSR curves depending upon the cause of the airflow limitation. For patients where airflow limitation is solely the result of loss of static elastic recoil, the slope of the curve is normal; that is upstream resistance is normal and the loss of airflow is due solely to the loss of static elastic recoil. However, in a patient with airway narrowing due to inflammation, collagen deposition and/or collapse, the slope is decreased, that

is resistance is elevated. By comparing flow–volume curves constructed from measuring both lung volumes by integrating the flow at the mouth to lung volume measured by the chest wall, the role of airway wall compression on the loss of airflow can be assessed [76]. The flow–volume curve derived from the flow and volume exiting the lung is displaced such that peak flow occurs at a higher volume but, after this initial peak, flow is lower at any given volume due to dynamic airway wall compression. In essence this analysis assesses the delay in gas exiting the lung; the more dynamic compression, the more temporal delay.

In most patients with COPD, a combination of factors contributes to airflow limitation [73–76]. Determining MSFR relationships can suggest which component might be amenable to treatment; bronchodilation for airway narrowing, pursed lip breathing for airway collapse and lung volume reduction surgery for improving static elastic recoil. In the case of the latter several studies using this analysis have shown that the effect of lung reduction surgery is a reduction of RV and the resultant increase in the VC [77] or a more complex response where both a change in volume and a change in resistance occurred [78].

## BRONCHIAL RESPONSIVENESS

Bronchial responsiveness includes either the acute response to a one-time treatment with a bronchodilator – usually a $\beta_2$-receptor antagonist – or the response to a constrictor bronchial challenge. Determination of bronchial responsiveness better defines and classifies patients with airways disease. Bronchial responsiveness assessments are often used as major outcome variables in clinical investigations and treatment trials because of the precision of the measure, its association to underlying inflammation, the relevance to asthma triggers, and the changes in bronchial responsiveness as the result of treatment.

### Bronchodilator responses

Bronchodilator responsiveness to inhaled bronchodilators is among the factors used to differentiate between whether a given patient is to be categorized as COPD or asthma. Professional Society guidelines and position statements for interpretation of spirometric results [72, 79] discuss the various consensus criteria used to derive the currently used bronchodilator criterion that identifies a significant response as one where a 12% or greater change in the post-bronchodilator $FEV_1$ or FVC from pre-bronchodilator values and a >200 ml absolute change occurs (Table 5.2).

Establishing a criterion that indicates a significant bronchodilator response has been controversial because of uncertainty as to just what constitutes a significant response [79, 80]. Various authors have suggested criteria that range from 10% to 15% change from baseline, some suggest using a change in percent of predicted or an exact volume change (e.g. 400 ml). Bronchodilator responses are reported as a percent change from the volumes obtained prior to use of a

**TABLE 5.2** Criteria recommended for acute bronchodilator responses in adults [79, 81].

|  | $FEV_1$ (%) | FVC (%) | Comments |
|---|---|---|---|
| ACCP | 15–25 | 15–25 | % of baseline in 2 of 3 tests |
| Intermountain ATS | 15 | 15 | % of baseline |
| ATS 1991 | 12 | 12 | % of baseline and 200 ml |
| ATS/ERS 2000 | 12 | 12 | % of baseline and 200 ml |

ACCP: American College of Chest Physicians; ATS: American Thoracic Society [79]; ERS: European Respiratory Society [81].

$\beta$-agonist; however, this enhances the response if the starting baseline of $FEV_1$ or FVC is low. The use of a definition that includes both an absolute change (e.g. >200 ml) or change expressed as a percent of predicted addresses this dilemma.

There are several approaches used to deliver bronchodilators to patients for assessing reversibility but two to four puffs of albuterol with or without a spacer is the most common. However, combinations of bronchodilators with or without an anticholinergic agent or the use of nebulizer treatments are sometimes used. In this case one administers the bronchodilator until side effects are observed or the total dose delivered is used [71, 72, 79–81]. A wait period is then imposed to allow for the drug to exhibit its physiological effects, for example 15–20 min in the case of albuterol. Unfortunately techniques to determine bronchodilator responsiveness are highly variable between studies and laboratories making direct comparison of study results difficult.

Bronchodilator responsiveness is commonly measured as a change in the $FEV_1$ but can also be assessed by expiratory flow–volume loops, specific airway conductance as determined with a body plethysmograph, or with the forced oscillation technique. Each technique measures different aspects of lung function and the result obtained may not be exactly equivalent. Moreover the pattern of the bronchodilator response can vary with some patients having a more central airways response (SGaw), whereas others have a more peripheral lung response as measured with FVC or the $FEV_1$ [4, 81, 82]. Such findings are of great interest in determining the inferred site of the functional defect such as central airways versus peripheral airways and have obvious ramifications to drug delivery.

### Bronchoconstriction responses

AHR is either a bronchoconstricting response (fall in $FEV_1$) to a stimulus that normally does not cause a constriction or is a heightened bronchoconstriction to the stimulus. Examples of the former are exercise, cold air, or bradykinin where examples of the latter are histamine and methacholine. Airways hyperresponsiveness is often used to define the diagnosis of asthma, however, the presence of AHR is not specific since many lung diseases are associated with hyperresponsiveness including COPD [83].

Over the last 50 years the proposed mechanisms to explain AHR included anything from enhanced cholinergic tone of the airways to the current focus on pathologic alterations (remodeling) of the airway wall. While airways smooth muscle usually has a central role in most theories, recent experimental evidence suggests that hypercontractility of the ASM is not always required [84]. Bronchial thermoplasty in which radio frequency energy is applied to airways through the bronchoscope to abate the ASM, improves asthma symptoms with only modest improvements in AHR [85]. This interesting result suggests that the ASM may not be as essential to AHR as previously thought or may serve other purposes [86].

AHR is functionally defined as a shift of the dose–response relationship to an inhaled bronchoconstrictor agonist, for example, methacholine, such that lower amount of the agent yields equivalent biological response, that is a "leftward shift" of the dose–response curve [83]. The inhaled dose of bronchial constricting agent is plotted against the fall in lung function and from this relationship the $PC_{20}$ is then measured. The $PC_{20}$ is the interpolated dose of inhaled agonist that causes $FEV_1$ to fall exactly 20%. The $PC_{20}$, decreases as asthma severity increases [83, 87]. The relationship between the amount of inhaled bronchoconstrictor agent and $FEV_1$ often has a plateau in which further doses of drug illicit smaller and smaller physiological responses. In the case of severe asthmatics often a plateau of response cannot be demonstrated [88–91]. This loss of maximal response may signify the uncoupling, loss of protective mechanisms with resultant severe bronchoconstriction [90]. In clinical, and most research practice, dose–response relationships are usually not carried out until a plateau is revealed thus the $PC_{20}$ only assesses the position (sensitivity) of the airways responsiveness relationship (Fig. 5.5).

Although there is considerable variability among subjects, AHR is considered present when the $PC_{20}$, using methacholine chloride as the bronchoconstrictor agonist, is less than 8 mg/ml [83, 87, 90]. Asthmatics will often demonstrate a reduced $PC_{20}$ even though the $FEV_1$ is normal at the onset of the test; moreover, the $PC_{20}$ in most studies does not correlate with the $FEV_1$ [88, 91]. As methacholine is well known to stimulate serous secretions from airway glands and cells, it seems reasonable to suggest the AHR of patients with mild to moderate asthma could be viewed as a measure of increased tendency for airway closure to occur.

In contrast among patients with COPD there is a correlation of $FEV_1$ to $PC_{20}$ which suggests more of a structural mechanism for AHR consistent with the observed airway wall thickening [44, 91–93]. Moreover patients with $\alpha$-1-antitrypsin deficiency demonstrated an elevated response in $FEV_1$ in concert with the loss of elastic recoil [94]. The mechanism of the fall in $PC_{20}$ in COPD also seems unlikely to be the same as asthma since inhaled corticosteroids do not lead to an improvement in AHR for COPD patients [95] whereas inhaled steroids do improve AHR in asthmatic patients [96]. AHR has important prognostic value because as AHR increases ($PC_{20}$ decreases) there is accelerated decline in $FEV_1$ in patients with COPD [97]. Taken together the data provide strong evidence that the physiological mechanisms that lead to AHR in COPD and asthma are probably quite different.

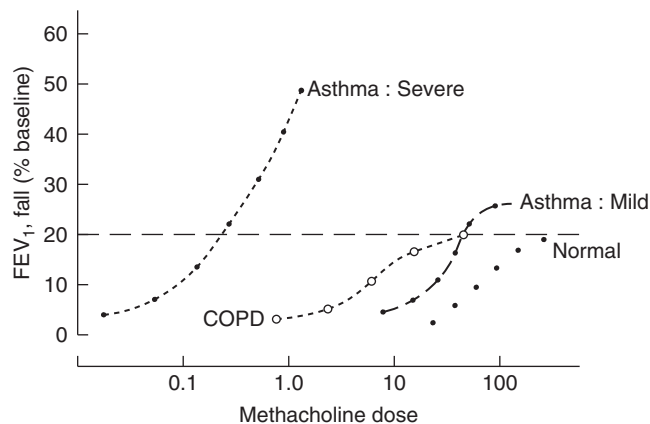

**FIG. 5.5** Dose response curves for the dose of inhaled methacholine (mg/ml) versus $FEV_1$ expressed as a percent decrease from the starting baseline. Data points are individual values up until there is a plateau in the response or 50% fall in $FEV_1$ has occurred. The dashed line is the $PC_{20}$ that is interpolated. Both mild asthma and COPD patients exhibit leftward (hyperresponsiveness) shifts of the curve without increase in the maximal response plateau. The patients with severe asthma show marked shift to the left without a plateau. Modified and redrawn from Ref. [91].

Lung volume also influences AHR based on recent studies on the effects of deep inspiration (DI). Large TLC breaths are known to be effective in some but not all asthmatics [98]. In some patients DI can even cause bronchoconstriction and such a response is associated with the degree of airway inflammation [99]. A DI can also provide protection to a subsequent bronchoconstricting response when the DI is performed prior to the inhalation of methacholine [100]. Loss of this bronchoprotective effect of DI occurs in asthmatic patients with mild disease whereas reversibility of an induced constriction by a DI is only lost as asthma becomes more severe [101, 102]. In patents with COPD the effects of DI are lost and this loss has been shown to be related to the loss of alveolar attachments [103].

## GAS EXCHANGE

The respiratory system provides oxygen ($O_2$) and removes carbon dioxide ($CO_2$) from the body and failure of this critical role of gas exchange leads to $CO_2$ retention, hypercapnia, and/or hypoxemia. For ideal gas exchange to occur the ventilation must be matched with the vascular perfusion within the individual alveolar gas exchange units. The diffusion capacity ($DL_{CO}$) or transfer factor assesses the passive transfer of a test gas, carbon monoxide (CO), from alveolus to the blood. The $DL_{CO}$ test is a frequently used measurement in the pulmonary function laboratory and is quite useful in categorizing the different types of airway disease.

## Ventilation/perfusion relationship

The concept of ventilation to perfusion matching $V_A/Q$ is commonly used in understanding how airway disease

pathology affects gas exchange. There are four mechanisms used to explain gas exchange abnormalities and include: (1) alveolar hypoventilation, (2) impaired $O_2/CO_2$ diffusion, (3) shunt, and (4) $V_A/Q$ mismatch, where the latter mechanism is by far and away the most common cause of gas exchange abnormalities in patients with obstructive lung disease.

## Chronic obstructive pulmonary disease

The obstruction of airflow to specific regions of the lung parenchyma and widespread airway narrowing coupled with the well-described pulmonary vascular abnormalities leads to marked $V_A/Q$ abnormalities and abnormal arterial blood gases. As respiratory failure ensues, alveolar hypoventilation further contributes to the observed hypercapnia and hypoxemia [104, 105]. Intrapulmonary shunt is not a major factor contributing to hypoxemia nor surprisingly is there a significant contribution of reduced gas diffusion probably because there is little ventilation of the areas that have emphysema. $V_A/Q$ mismatching appears to fully explain the hypoxemia of patients with COPD [105, 106]. In the case of very mild disease in the peripheral airways as evidenced by $FEV_1$ of 80% predicted or greater, patients have an abnormal slope of phase III on the single breath $N_2$ test, a widened A-a $O_2$ gradient and mild $V_A/Q$ mismatch but with a normal $PaO_2$ [107]. During an exacerbation of COPD the $V_A/Q$ mismatch increases and accounts for about half of the observed hypoxemia whereas the remainder is low mixed venous $O_2$ due to increased $O_2$ consumption of the body presumably due to metabolic requirements of the disease [105, 107]. The A-a $O_2$ gradient is correlated to emphysema score [108]; hence, the abnormal gas exchange of COPD is explained by the pathology of the disease.

## Asthma

Early studies with the multiple inert gas elimination technique (MIGET) in stable, mild asthmatics showed a bimodal distribution of pulmonary blood flow with about 25% of the blood flow going to units with low (<0.1) $V_A/Q$ ratios. There was no evidence of areas of shunt or areas of high $V_A/Q$ or increased dead space [109]. However, later studies showed less of this bimodal distribution and only some of the patients showed this bimodal pattern [110, 111]; whereas most patients showed widening of the distribution of blood flow. Patients in this latter study were receiving treatment with inhaled glucocorticosteroids which could explain the differences between studies. The gas exchange abnormalities of patients with mild disease were thought to be due to abnormalities in the periphery and consistent with abnormal peripheral lung function such as in RV or frequency dependence of compliance. Asthma severity is associated with widening of the $V_A/Q$ relationship [112] but most patients still exhibit a near normal $PaO_2$ until they reach the point of seeking medical assistance (Fig. 5.6) [113].

Given that measurements of lung mechanisms show marked increase in peripheral resistance due to airway closure, one might expect to observe considerable shunting as blood flows by these closed airways and unventilated

exchange units yet this is not the case [109–112]. The apparent explanation would include, preserved uploading of oxygen on the hemoglobin due to more than adequate capillary transit time, hypoxic vasoconstriction, redirecting blood away from affected areas, and adequate collateral ventilation thus bypassing the closed airway.

During an asthma exacerbation or "status asthmaticus" the presence of a bimodal pattern emerges but even in this situation little pure shunt is observed. Treatment of the asthma attack returns this pattern to normal [112] even at time of discharge from the emergency department [114]. The relative preservation of arterial blood gases up until respiratory failure is attributed to the mechanisms covered above and the high ventilatory and cardiac output that occurs during an attack. Bronchial challenge produces similar patterns but it has been noted that the disturbances in gas exchange lag behind the recovery of airflow rates [115, 116]. This pattern of recovery does not occur with leukotriene challenge, presumably because $LTD_4$ causes a more selective central airway constriction [117]. However, following exercise-induced bronchospasm airflow normalization occurs after the return of $V_A/Q$ to normal, consistent with different mechanisms of action in contrast to a naturally occurring asthma exacerbation [118]. Taken together these findings suggest that our understanding of gas exchange in asthma, unlike COPD, is unclear.

Therapy has a marked effect on gas exchange. Paradoxical hypoxemia has long been noted as a result of acute β-agonist administration [119] and has been attributed to effects of β-agonists on pulmonary blood flow. $V_A/Q$ measurement made after isoproterenol [110] showed transient (5 min) alterations in blood flow to areas low in $V_A/Q$; however, studies with a more selective β-agonist, salbutamol were without this effect [112, 120].

## Diffusion capacity (transfer factor)

The diffusion capacity, $DL_{CO}$, is a measure of the disappearance of CO, from the alveolus over a 10 s breath hold and is taken as an index of the total area of potential gas exchange surface area. Because CO combines at the same site as oxygen on the hemoglobin molecule, blood flow, hematocrit, and cardiac output significantly influence the magnitude of $DL_{CO}$. The addition of helium to the test gas mixture inhaled allows for the calculation of the starting concentration of CO and the determination of the communicating gas volume by inert gas dilution. The standard single breath $DL_{CO}$ yields two useful measurements; the $DL_{CO}$ and a measurement of TLC (VA) [121].

### Asthma & $DL_{CO}$

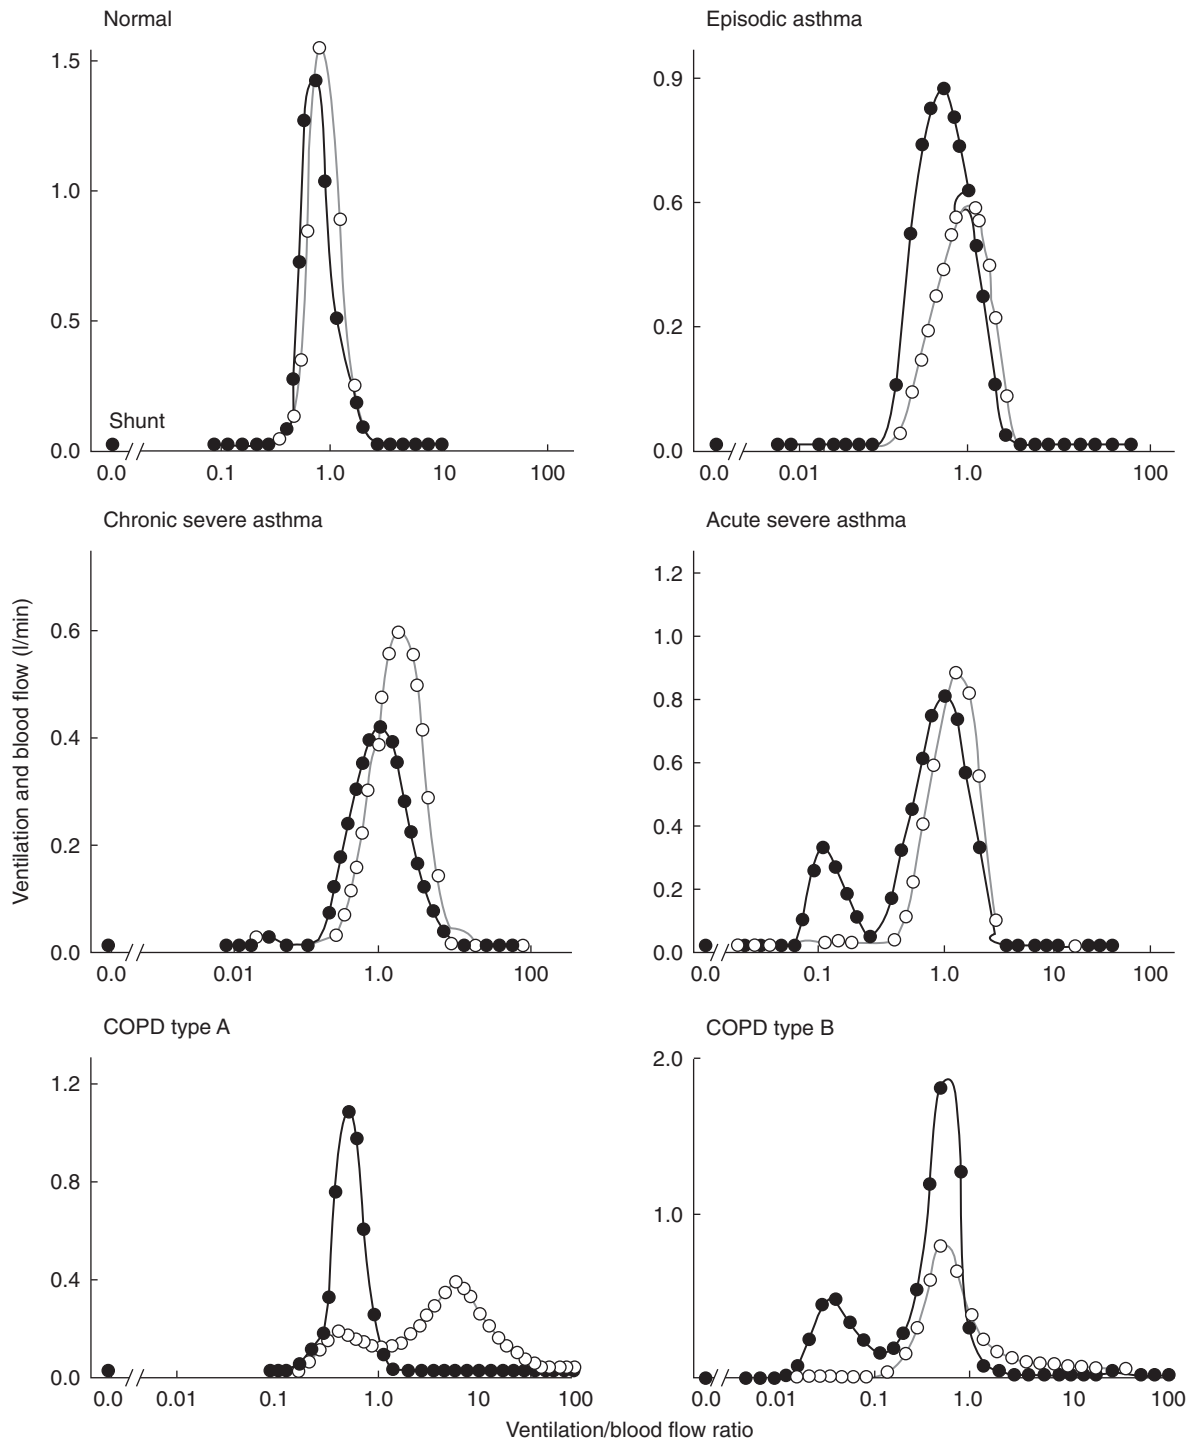
The $DL_{CO}$ in patients with asthma is either within normal limits or high depending on several factors. In asthmatic patients with preserved lung function, the $DL_{CO}$ is typically normal [122]. In moderate to severe asthma the $DL_{CO}$ is usually elevated and will also increase with bronchodilator treatment. The high $DL_{CO}$ values [123, 124] have been explained by hyperinflation, increased intrathoracic pressure, and a more likely cause, increases in pulmonary capillary


**FIG. 5.6** The $V_A/Q$ relationship as determined by the multiple inert gas elimination technique (MIGET). Note the different scaling for both axes in the various examples. The normal distribution of ventilation (open circles) and blood flow (solid circles) is over a narrow range of $V_A/Q$ ratios and is unimodal. Patients with mild or chronic asthma have wider distributions but still exhibit unimodal distributions whereas acute severe asthma is bimodal. In emphysema (COPD, type A) there is a bimodal distribution in ventilation whereas chronic bronchitis (COPD, type B) exhibits bimodal blood flow. Shunt is not present in any of the examples. Reproduced from Refs [105, 111] with permission.

blood volume or extravasation of red blood cells into the alveolus. Although not frequently commented on or because current practice is to lyse the lavage sample, the red blood cell content is high in lavage samples of asthmatics, particularly those who are more severe [125]. Increased vacularization of the lung and airways might also increase the apparent pulmonary capillary blood volume and account for the elevated $DL_{CO}$ [43].

## Chronic obstructive pulmonary disease & DL$_{CO}$

In contrast to asthma patients with emphysema exhibit a reduction in DL$_{CO}$ [121, 126]. This reduction in DL$_{CO}$ has been shown to be closely related to evidence of pathologic emphysema [126] or emphysema as measured by CT [127, 128]. In asymptomatic smokers there is a detectable 10% decrease in DL$_{CO}$ that reverses with smoking cessation likely due to reduced pulmonary capillary volume and CO back pressure [129, 130]. However, it should be noted that the correlation of the reduction in DL$_{CO}$ to disease severity in the individual patients is poor, perhaps reflecting the heterogeneity of the pathology of a given patient. The DL$_{CO}$ is typically within normal limits for COPD patients with primary chronic bronchitis. One study showed a significant relationship between the DL$_{CO}$ and 3-year survival [131], although another study did not find this to be the case [132].

The measurement of alveolar volume (VA) provides additional insight into the physiological derangements present in the patient with airways obstruction. Because VA is a single breath dilution of an inspired gas, it is affected by both the presence of non-communicating lung volume, for example emphysematous bullae and the long-time constants caused by airways narrowing. In normal subjects, and when expressed as the volume of gas at body temperature, pressure and fully saturated, the measure of VA will agree ($\pm 200$ ml) with TLC by body plethysmograph; however, patients with asthma or COPD will exhibit greater than 200 ml difference between TLC and VA [133]. The degree of difference between TLC and VA provides an approximate estimate of the total size of the non-communicating bullae and alveoli [126, 134] or gas maldistribution.

**TABLE 5.3** Physiological features of asthma contrasted with COPD.

| Physiological assessment | COPD | Asthma |
|---|---|---|
| Airflow limitation | Present | Sometimes present |
| Loss of elastic recoil | Frequently present | Sometimes present |
| Bronchodilator response | ± | Usually present |
| AHR | + | + |
| Exercise-induced AHR | − | + |
| $V_A/Q$ | Widened | Widened |
| DL$_{CO}$ | ↓* | WNL or ↑ |

*Notes*: AHR: airways hyperresponsiveness; $V_A/Q$: ventilation to perfusion ration; DL$_{CO}$: diffusion capacity of the lung.

*For emphysema, chronic bronchitis would be WNL.

**TABLE 5.4** Pattern of changes in DL$_{CO}$ and VA in patients with obstructive lung disease.

| Clinical condition | FEV$_1$ | VA | DL$_{CO}$ |
|---|---|---|---|
| Emphysema | ↓ | ↓ | ↓ |
| Bronchitis | ↓ | ↓ | WNL |
| Asthma | ↓ | ↓ | WNL or ↑ |

*Notes*: DL$_{CO}$: diffusion capacity of carbon monoxide; FEV$_1$: forced expiratory volume in 1 s; WNL: within normal limit.

## CONCLUSION

The clinical presentation of patients with obstructive lung disease often presents a confusing clinical picture (Table 5.3). Consider, for example, the patient who reports asthma-like symptoms to common triggers but who also smokes and has a greater than 20 pack per year smoking history. Such a patient might be expected to exhibit physiological features of both disorders. This is because the physiological mechanisms of asthma and COPD that differ in the details of the inflammatory processes, cells, mediators, and pathology may be very similar physiologically in terms of hyperinflation, loss of static recoil, and expiratory airflow limitation. Bronchodilator responsiveness is also not unique to asthma since patients with COPD often demonstrate reversibility of airflow limitation. Bronchial responsiveness is also present in both entities but the response to bronchoconstrictors is more related to lung function and structure in COPD and the patient with COPD generally does not respond to exercise by exhibiting bronchospasm. Gas exchange in general is similar between both diseases with increased $V_A/Q$ mismatch but with little evidence of shunt or global hypoventilation. The DL$_{CO}$ represents an important distinguishing feature between emphysema and other airways diseases and provides a means of discriminating the disease process when coupled with the measurement of spirometry and the response to a bronchodilator [135–137] (Table 5.4).

# Airway Pathology

**James C. Hogg**

**UBC McDonald Research Laboratories,
St. Paul's Hospital, University of British
Columbia, Vancouver, BC, Canada**

## NORMAL ANATOMY

The normal human bronchogram (Fig. 6.1) shows that the length of pathways from the trachea to the terminal airways differs depending on the pathway followed and it can take as few as 8 or as many as 24 divisions of airway branching to reach the gas-exchanging surface [1]. The small bronchi and bronchioles 2mm in diameter are spread out from the fourth to the fourteenth generation of airway branching [2]. The total airway cross-sectional area expands rapidly beyond the 2mm airways to provide for rapid diffusion of gas between the distal conducting airways and the gas-exchanging surface. The central conducting airways larger than 2mm internal diameter are the major site of resistance to airflow in the normal lung because of their much smaller total cross-sectional area [3, 4].

The conducting airways are lined by epithelium and surrounded by an adventitial layer [5]. The submucosa between the epithelium and outer edge of the muscle layer is often referred to as the "lamina propria," but this term is technically incorrect because many airways are not completely surrounded by muscle [6]. Bronchi are defined by the presence of a layer of fibrocartilage external to the smooth muscle and tubuloalveolar glands, which communicate with the airway lumen via ducts [7]. Bronchioles lack both cartilage and glands and become respiratory bronchioles when alveoli open directly into their lumen [7]. The lining of the trachea and major bronchi consists of pseudostratified, ciliated columnar epithelium which gradually becomes more cuboidal

**FIG. 6.1** Postmortem bronchogram from an otherwise normal 19-year-old man who died suddenly for reasons unrelated to the lung. Note the difference in airway length depending upon the pathway that is followed.
**FIG. 6.2** Photomicrograph of a bronchiole from a patient who died of asthma. This shows the location of submucosal capillaries (white arrow), connecting vessels passing between muscle bundles (dark arrow) to larger postcapillary venules located outside the muscle layer. On the right, the same features are shown at a higher magnification.

with fewer ciliated cells as the alveolar surface is approached [6–8]. Light microscopy reveals that the basal aspect of airway epithelial cells is attached to a thin basement membrane (80–90 nm width) that contains primarily type IV collagen and elastin [9]. Transmission electron microscopy shows that a true basement membrane or basal lamina can be readily distinguished from the connective tissue observed with the light microscope [6, 7]. Quantitative studies [10–12] have shown that the trachea and mainstem bronchi of normal subjects consist of by volume:

- 30% cartilage;
- 15% mucous glands;
- 5% smooth muscle; and
- 50% connective tissue matrix containing the bronchial arterial, venous, and lymphatic vessels.

With progression toward the periphery of the bronchial tree, the amount of cartilage and glands decrease, and the percentage of smooth muscle increases to account for approximately 20% of the total wall thickness in the bronchioles.

The degree to which the smooth muscle surrounds the airway lumen varies according to site. In the trachea and mainstem bronchi, the airway smooth muscle is located within the posterior membranous sheath, whereas, in the bronchioles, it surrounds the entire lumen of the airway [7, 8, 13]. Consequently, the same degree of muscle shortening has a smaller effect on the caliber of the trachea and central airways than on the distal bronchi and bronchioles [14]. The adventitial layer consists of loose bundles of collagen admixed with blood vessels, lymphatics, and nerves. In the peripheral conducting airways, this layer interacts with the surrounding lung parenchyma through alveolar attachments that are distributed along the circumference of the adventitia. These alveolar attachments have the ability to limit the amount of airway narrowing produced by smooth muscle contraction, particularly at higher lung volumes [14].

The systemic arterial supply to the bronchial tree originates from the ventral side of the upper thoracic aorta in the left hemithorax, while on the right the origin of the bronchial vessels is more variable. They may originate from the first to the third intercostal artery, from the right internal mammary artery, or from the right subclavian artery [8, 15]. Miller's classic anatomical account [8] showed that two to three arterial branches accompany each of the larger bronchi and that anastomoses between these branches form an arterial plexus in the outer wall of the airway. Small branches of this plexus penetrate the smooth muscle layer to form a capillary network below the epithelium. Short connecting branches extend from this plexus through the muscle layer to form a second plexus of venules along the outer surface of the airway smooth muscle (Fig. 6.2). In some species, this outer plexus contains large venous sinuses that can extend into the submucosal layer of the major bronchi, where there is no smooth muscle between the cartilage and epithelium [16].

The venous blood from the first two or three subdivisions of the bronchial tree drains into the azygous and hemiazygous venous systems that empty into the vena cava. The remainder of the bronchial venous flow drains directly into the pulmonary circulation, although there is debate as to how much enters at the precapillary, capillary, and postcapillary levels [8, 15]. Airway disease increases the anastomotic flow between the pulmonary and the bronchial vascular systems; and in diseases such as bronchiectasis, injection of the bronchial arteries can result in rapid filling of the entire pulmonary vascular tree right back to the pulmonic valve [15].

The bronchial circulation accounts for about 1% of cardiac output and an average cardiac output of 5 l/min delivers approximately 72 l of blood to the conducting airways over 24 h. Each liter of blood contains between 4 and $11 \times 10^9$ white blood cells, made up of approximately 60% neutrophils, 30% lymphocytes, 5% monocytes, 3% eosinophils, and 2% basophils. The neutrophils do not divide after they leave the marrow have a relatively short half life within the circulation and remain within the vascular space unless an inflammatory response is present. Although much less is known about eosinophils and basophil kinetics they are predominately a tissue cell, indicating that their transit times through the tissue compartment is much longer than that for migrating neutrophils. Monocytes on the other hand leave the vascular space even in the absence of an inflammatory stimulus and divide in the tissue to form the alveolar macrophages
**FIG. 6.3** (A) Shows a small bronchiole with a collection of lymphocytes containing a germinal center. (B) Shows another airway containing a lymphoid follicle where the germinal center stains strongly for B-cells. (C) Shows the same airway as in B where the CD4 cells appear at the edge of the follicle. (D) Shows yet another area where the wall is thickened and fibrosed and the arrow pints to the smooth muscle in the airway wall. Adapted from Ref. [17] with permission.

that are removed via the airways with very little if any re-entry into the tissue. On the other hand lymphocytes leave the circulation regularly with the assistance of specialized high endothelial cells and re-entering the circulating blood with the lymph as it drains into the venous system.

A study of lung tissue obtained from patients at all five Global Initiative for Chronic Obstructive Lung Disease (GOLD) categories of chronic obstructive pulmonary disease (COPD) severity has shown an association between the decrease in $FEV_1$ with both the extent of the accumulation of these cells (i.e. the percentage of airways containing cells) and severity of this accumulation (i.e. the total accumulated volume of cells) within small airway tissue [17]. The accumulating lymphocytes form follicles with germinal centers in both the small conducting airways [17] and the parenchyma [18] of the peripheral lung in both COPD [17, 18] and asthma [19]. These accumulations of lymphocytes (Fig. 6.3) are part of the bronchial associated lymphoid system or bronchial-alveolar lymphoid tissue (BALT) and differ from the regional lymph nodes in that they have no capsule and no afferent lymphatics. They are similar in structure to the tonsils and adenoids, the Peyers patches in the small bowel, and the appendix of the cecum which are also part of the mucosal immune system. They are organized in the same way as other lymph follicles (Fig. 6.3) in that the B-cells are found in the germinal center

of the follicle and the CD4 and CD8 T-cells are located around the edges of the germinal center. Thus dendritic cells migrating from the epithelium and subepithelium circulate through the T- and B-cell rich regions of the follicle and can present antigen to uncommitted T and B lymphocytes moving through these regions in the lymph (Fig. 6.3). Moreover the recirculation of lymphocytes though the follicle and back into the circulation enhances the opportunity for T Helper cells and B-cells that have recognized the same antigen to interact with each other and initiate an adaptive immune response. The appearance of lymphoid follicles with germinal centers in the tissue provides histological evidence that an adaptive immune response has been mounted within the peripheral lung. Some investigators have begun to study this response in detail [18].

## THE PATHOLOGY OF ASTHMA

### Postmortem studies

At postmortem, the lungs of patients who have died in status asthmaticus remain markedly hyperinflated after the thorax is opened. This hyperinflation is due to air trapping

caused by widespread plugging of the segmental, subsegmental, and the smaller conducting airways by mucus and cellular debris [20]. Although this luminal content may extend to the respiratory bronchioles, it usually stops short of these structures and does not fill the alveolar airspaces. Examination of the cut surface of the lung reveals the plugged airways, but – in contrast to parenchymal destruction seen in hyperinflated emphysematous lungs – the parenchyma of the asthmatic lung remains intact.

Huber and Koessler's [21] classic 1922 paper on the pathology of asthma reviewed 15 published cases and provided new data on 6 more. They noted that the pathology consisted of common features that allowed asthma to be distinguished from other conditions. They emphasized the presence of intraluminal mucus secretion, airway epithelial desquamation, and repair (e.g. goblet cell metaplasia), and airway inflammatory infiltrates consisting of an admixture of mononuclear cells and eosinophils and the presence of a thickened, "hyalinized" subepithelial basement membrane. Later studies based on electron microscopy and immunohistochemistry showed that this feature of the basement membrane was due to deposition of collagen fibrils and extracellular matrix below the true basement membrane, rather than thickening of the basal lamina. Huber and Koessler's report noted that the tenacious plugs that fill the airway lumen consist of an exudate of plasma containing inflammatory cells, particularly eosinophils, mixed with epithelial cells that had sloughed from the airway surface. Using an eyepiece micrometer to measure the external airway diameters, they concluded that the walls of bronchi and bronchioli of more than 2 mm outside diameter were thickened compared with non-asthmatic persons, and that this difference was due to an increased thickness of all of the components of the airway wall.

Over the next several decades, other reports confirmed and extended these findings [22–29]. Comparing Florey's [30] basic studies of the inflammatory process with these pathological findings show that the structural changes associated with asthma are consistent with an inflammatory process involving a mucus-secreting surface. However, this knowledge had relatively little impact on the allergists, pulmonary physicians, and physiologists until the 1970s [31], because they were preoccupied with the concept that asthma was due to IgE sensitized mast cells releasing mediators that caused excessive contraction of airway smooth muscle following specific antigen challenge.

## Bronchoscopic studies

The nature of the airway pathology in persons with asthma was further revealed by studies of tissue obtained through the rigid and flexible bronchoscope. These techniques allowed investigators to obtain cells from living asthmatic patients by both bronchoalveolar lavage and bronchial biopsies [31–34]. This brought physiologists and clinicians into closer agreement with the pathologist's view that the inflammatory process was important to the pathogenesis of both bronchial hyperresponsiveness and reversible airflow obstruction.

A very important conceptual development based on the discovery that murine $CD4^+$ T-cell clones showed that these cells can be divided according to the cytokine messenger RNA (mRNA) and proteins that they produce [35]. These experiments established that one type of T-cell clone (Th-1) produced IL-2 and interferon-$\gamma$ but no IL-4 or IL-5; whereas the second (Th-2) produced IL-4 and IL-5, but no IL-2 or interferon-$\gamma$. Both clones produced IL-3 and GMCSF, and interactions between Th-1 and Th-2 subtypes allowed one type of clone to inhibit the other. For example, IL-4 is a mast cell growth factor that also stimulates IgE production, and IL-5 promotes the differentiation and survival of eosinophils. Robinson and associates [36] put forward the hypothesis that asthma was the result of a "Th-2 response" based on bronchoalveolar lavage and bronchial biopsy findings. And subsequent studies of surgically resected lung specimens from asthmatic patients established that a similar inflammatory process was present in the smaller airways [37].

It has now become clear that the structural features of the airways from asthmatic patients result from an inflammatory process involving tissue with a mucus-secreting surface. This response appears to be driven by a subset of $CD4^+$ T lymphocytes producing cytokines that result in an excess of eosinophils and an overproduction of IgE. The end result is abnormal airway function, characterized by excessive airway narrowing in response to external stimuli, reversible airways obstruction, and gas trapping. Although the majority of the symptoms produced by the process can be rapidly reversed with appropriate treatment, the process can be life threatening and result in sudden death.

## The relationship between airway structure and function

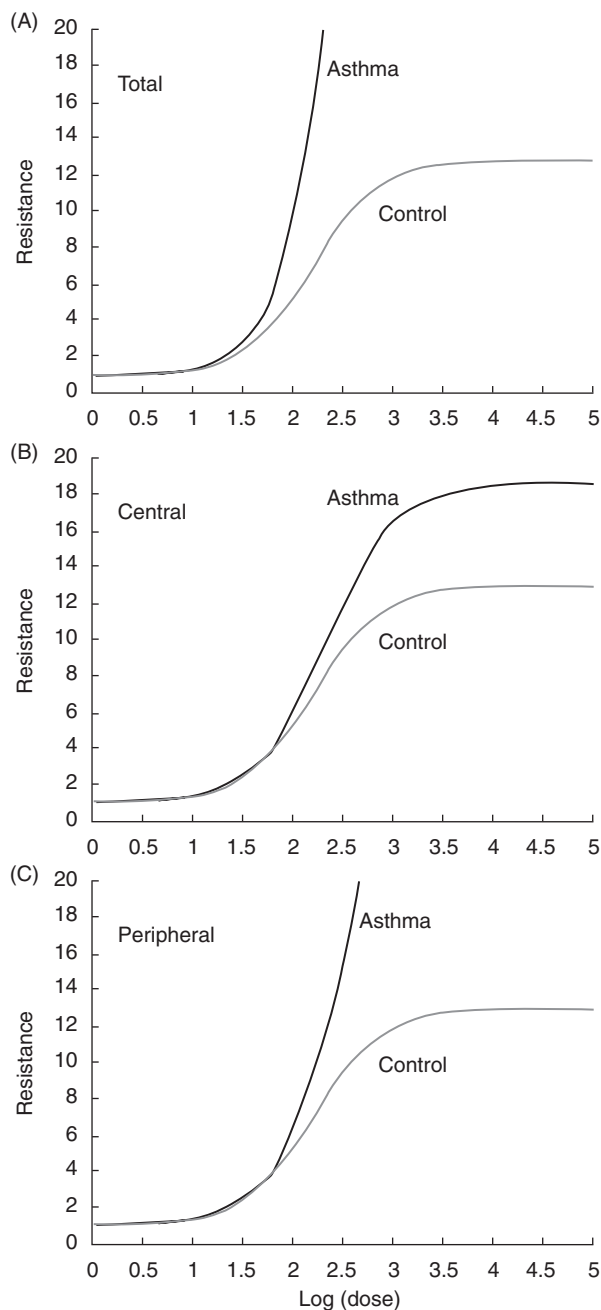
The concept that the same degree of smooth muscle shortening will cause greater reduction in airway caliber when the wall is thickened by disease has been suggested by several authors [38, 39]. Moreno and associates [39] calculated that the thickening of the airway wall observed in asthma would have only a minor effect on the caliber of the lumen of a fully dilated airway. However, when the smooth muscle in the airway shortens, the increased tissue between the muscle and lumen causes an excess reduction in airway caliber. Subsequent studies by James *et al.* [40] showed that the increase in wall thickness observed in the small airways of asthmatics was sufficient to close the lumen of these airways, even when smooth muscle shortening remained within the accepted normal range. This suggests that normal smooth muscle shortening may act in series with an abnormally thickened airway wall to narrow the airway lumen and it follows that the reduction in airway caliber produced by this mechanism would be rapidly reversed when the smooth muscle relaxed. This showed that an important feature of the pathology of asthma was the change in the structure of the airway wall produced by the remodeling of the tissue that occurs in relation to the inflammatory process. The important point is that these structural changes could result in excess airway narrowing with normal smooth muscle contraction and that excessive smooth muscle shortening will enhance the effect of these structural changes on the airway lumen.


**FIG. 6.4** Data from Wiggs *et al.* (Refs. [38, 39]) showing results from a computer model of the airways. The structural data from normal lungs were used to obtain the control measurements. These show that airway resistance increases from about 1 cmH$_2$O per liter per second to reach a plateau of 12 cmH$_2$O per liter per second, with maximum contraction of the airways smooth muscle. (A) When the structural features of asthmatic airways were used in the same computer model, the airway resistance continued to increase and did not reach a plateau at any physiologically meaningful value. (B) Data obtained from the model when the structural changes caused by asthma were limited to the central airway (i.e. those >2 mm diameter). Note that asthmatic changes in the central airways increased total resistance and resulted in a plateau slightly greater than the control lungs. (C) However, when the asthmatic changes were placed in the peripheral airway, the resistance increased without reaching a plateau. These data suggest that asthmatic changes in the peripheral airways have a much greater effect on overall airway function than changes that occur in the central airways. Reproduced from Ref. [38] with permission.

Wiggs *et al.* [41, 42] extended this concept using a computer model to test the effect of these structural changes on airway function. Their analysis (Fig. 6.4) showed that maximum stimulation of the smooth muscle caused airway resistance to increase and reach a plateau in the normal lung. This finding was consistent with previous observations by Woolcock *et al.* [43], who reported that the changes in the maximum volume of air that can be expired from the lung in 1 s (FEV$_1$) reached a plateau in normal subjects when maximally stimulated by inhaled bronchoconstrictors. However, when the data on airway structure were changed from normal values to those found in asthmatic lungs, a similar degree of airway smooth shortening resulted in a sustained rapid increase in airway resistance without a plateau. When the effect of disease on the central and peripheral airway function was examined separately, they found that the increase in airway resistance was primarily due to the effect of disease on the peripheral airways, where smooth muscle shortening produced widespread airway closure. The concept that the peripheral airways are the major site of obstruction in asthma has now been confirmed by direct measurements in living asthmatic patients reported by Yanai *et al.* [44].

The changes that are produced in the airway tissue also reduce the function of the conducting airways. Lambert [45] was the first to systematically study the normal folding pattern of the bronchial mucosa, and showed that in asthma the multiple mucosal folds that occur when normal airways narrow were replaced with fewer and larger folds that reduced airway caliber. Both Lambert and Wiggs *et al.* [46] suggested that the mucosal folding pattern was controlled by the stiffness of the subepithelial layer relative to that of the surrounding airway tissue. This analysis suggested that changes in the subepithelial connective tissue might play a key role in determining the pattern of mucosal folding. Lambert and Wiggs *et al.* argued that the formation of a large number of folds in the normal airway placed a load on the airway smooth muscle that tended to prevent airway closure at low lung volumes. It followed that a change in the mucosal folding pattern in asthma may be one way in which this disease causes peripheral airway dysfunction.

The caliber of the airway lumen is also influenced by airway surface tension that is normally low in the small airways because they are lined with surfactant [47]. Exudation of plasma and the secretion of mucus on to the small airway lumen surface should increase surface tension and cause the airways to narrow. The analysis of induced sputum has confirmed that plasma proteins, mucus, and inflammatory cells are present in the airway lumen even in mild asthma, suggesting that some of the abnormalities in airway function of asthmatics might result from the presence of this material in the lumen. Kuyper and colleagues [48] recently re-assessed the importance of the occlusion of the airway lumen by inflammatory exudates in deaths attributed to asthma. By examining the airway wall and luminal content of 275 airways from 93 patients with fatal asthma aged 10–49 years. Compared with control airways obtained from persons that died of causes unrelated to the lungs, the asthmatic airways showed much more extensive lumenal occlusion, by mucus and cells. They concluded that widespread airway occlusion

was the major cause of death from asthma and death due to closure of empty airways by excessive bronchoconstriction must be a rare event. Moreover the extensive nature of the airway occlusion observed at autopsy in these cases suggests that bronchoconstriction superimposed on airways that have become partially occluded is the most probable cause of sudden death.

## THE PATHOLOGY OF COPD

The inflammatory process contributes to the pathogenesis of chronic cough and sputum production [49], peripheral airways obstruction [3, 17, 50], and emphysematous destruction of the lung surface [51] that define COPD. As tobacco smoking produces lung inflammation in everyone, and only 15–20% of heavy smokers develop COPD, clinical disease from cigarette smoke-induced airway inflammation must develop in this minority of people because it amplified by either genetic or environmental risk factors [52].

### Chronic bronchitis

Cough and sputum production are the features of airways disease that define chronic bronchitis [53] and these symptoms can be present either with or without airways obstruction [49]. Figure 6.5 shows the histology of a normal bronchus at low power where with the connection between the epithelial lining of the bronchial lumen to the mucus duct and gland is clearly seen. Reid [54] used the relative size of the mucus glands to the airway wall as a yardstick for measuring chronic bronchitis and downplayed the influence of inflammation in driving mucus production. However, a reevaluation of this problem some years later showed that chronic bronchitis was associated with inflammation of the airway mucosal surface, the submucosal glands, and gland ducts, particularly in the smaller bronchi between 2 and 4 mm in diameter [49]. The nature of the inflammatory process present in these airways is now quite well established with several studies reporting that CD8$^+$ lymphocytes are present in excess numbers in smokers with chronic bronchitis [55, 56].

Sputum production represents the clearance of a mucoid inflammatory exudate from the lumen of the bronchi. This exudate contains plasma proteins, inflammatory cells, and small amounts of mucus added from goblet cells on the surface epithelium and the epithelial glands. Although the size of the bronchial mucous glands tends to increase [49] in chronic bronchitis, Thurlbeck and Angus [57] showed that the Reid index was normally distributed with no clear separation between patients with chronic bronchitis and controls. Chronic bronchitis also results in an increase in airway smooth muscle, a generalized increase in the connective tissue in the airway wall, degenerative changes in the airway cartilage, and a shift in epithelial cell type that increases the number of goblet and squamous cells [58–62].

**FIG. 6.5** Low-power photomicrograph of a normal bronchus showing the opening of a bronchial gland duct into the lumen and its connection with the submucosal gland. The bronchial muscle and cartilage are clearly labeled. The inflammatory process associated with chronic bronchitis involves the mucosa, gland ducts, and glands of the bronchi that are between 2 and 4 mm internal diameter. Original photograph taken by the late Dr. William Thurlbeck.

### The site of airways obstruction

The site of airways obstruction in COPD is in the smaller conducting airways that include bronchi and bronchioles of less than 2 mm diameter [3]. Direct measurements of airways resistance in dogs [4] and in similar measurements in postmortem human lungs [3] established, in the normal lung, that the small peripheral airways offer very little resistance to air flow. Although van Brabant *et al*. [63] subsequently argued that these peripheral airways account for a larger proportion of the total airways resistance in the normal lung, there is general agreement that the peripheral airways are the major site of obstruction in COPD [3, 44, 63].

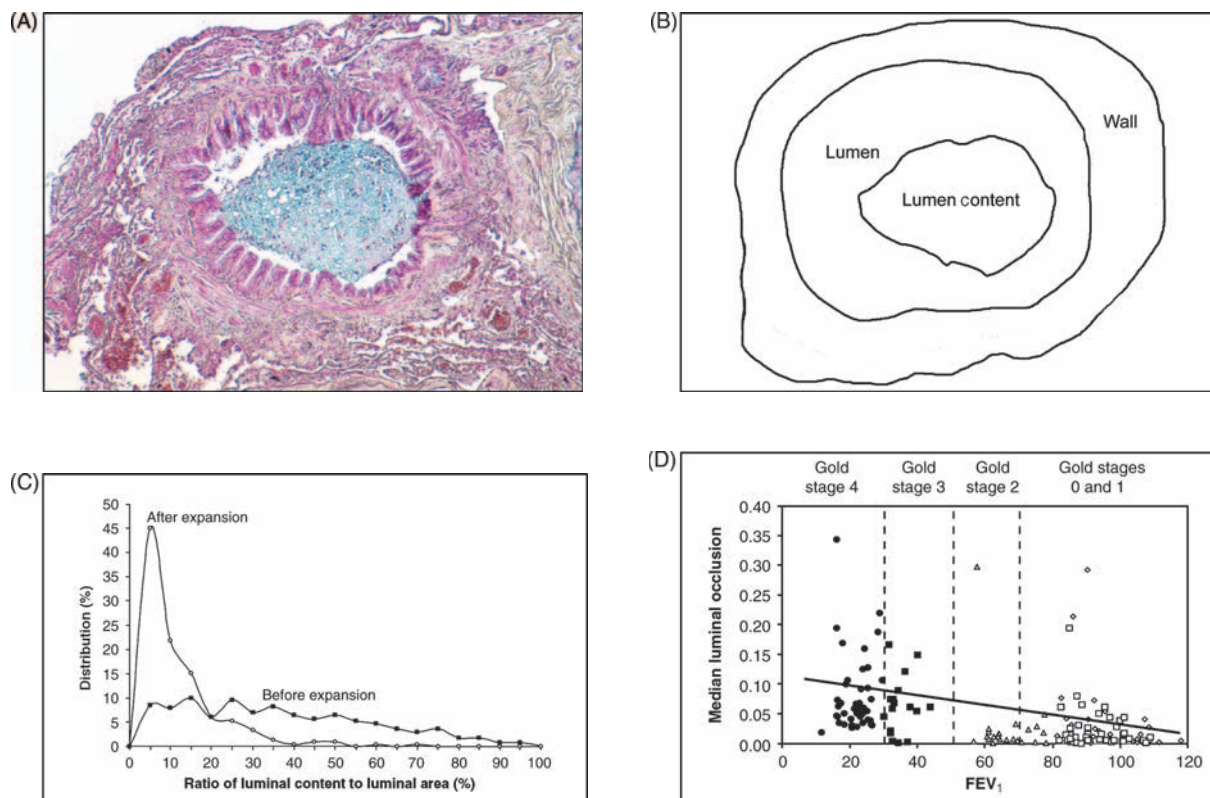
The causes of the reduced forced expiratory flow that define COPD include destruction of alveolar support of the peripheral airways [64], the loss of elastic recoil in the parenchyma supporting the airways [65], a decrease in the elastic force available to drive flow out of the lung [66], and structural narrowing of the airway lumen by a remodeling process [3, 17, 67]. Comparison of the histological appearance of peripheral airways at different degrees of severity of COPD shows a progressive increase in the magnitude of the inflammatory process with thickening of the airway walls accompanied by occlusion of the airway lumen by inflammatory mucous exudates [17]. However, multivariate analysis of


**FIG. 6.6** (A) Shows a small bronchiole from a patient with severe (GOLD-4) COPD the lumen is nearly fully occluded and the mucosa is folded because it was fixed in a collapsed state. (B) Shows a redrawing of the same airway where the lumen occlusion is less severe because the airway has been fully inflated by removing the folds from the mucosa using a computer (C) Compares the frequency distribution of the ratio of luminal content area to the total area of the lumen for >562 airways from 42 patients with GOLD-4 COPD before and after the expansion of the lumen shown in A and B. As we do not breathe at either full expansion of the lung or at minimal volume many airways must have been partially or fully occluded in the normal breathing range. (D) Shows the relationship between the severity of the occlusion of the airway lumen with the level of $FEV_1$. Adapted from Ref. [17] with permission.

these data indicated that thickening of the airway walls and the occlusion of the lumen by inflammatory exudates containing mucus explained more of the variance in the decline in $FEV_1$ than the infiltration of the airway tissue by any of the inflammatory cell types examined [17]. Interestingly the severity of the occlusion of the airways lumen by inflammatory exudates containing mucus (Fig. 6.6) *has* also associated with premature death in persons with severe (GOLD-3) and very severe (GOLD-4) disease [68].

The lung inflammatory changes that are associated with cigarette smoking have been documented in autopsy studies [69–73], resected lung specimens [49–51, 74] lung biopsies [75], and indirectly by examining bronchoalveolar lavage fluid [76–78]. Collectively these data support the concept that cigarette smoke-induced lung inflammation is present in all smokers, including those with normal lung function and that it persists long after people have stopped smoking [17]. The reasons for both the amplification of the smoking-related inflammatory process in individual that develop COPD, the persistence of this response after the smoking has stopped and the precise relationship between the inflammatory response and the remodeling process needs further clarification.

## Emphysema

Emphysema has been defined as "abnormal permanent enlargement of airspaces distal to terminal bronchioles, accompanied by destruction of their walls without obvious fibrosis" [79]. This definition emphasizes the destruction of the alveolar surface with a minimal reparative response in the lung matrix and the ability of this destructive process to reduce the gas-exchanging surface of the lung. The centrilobular form of emphysema (Fig. 6.7) resulting from dilatation and destruction of the respiratory bronchioles in the center of secondary lobule of Miller has been most closely associated with smoking [80, 82]. The panacinar form of emphysema, on the other hand, results from a uniform destruction of all of the acini in the entire secondary lobule and is characteristic of the lesions found in the lungs in $\alpha_1$-antitrypsin deficiency [83]. The terms "distal acinar," "mantle," or "periseptal" emphysema are used to describe lesions that occur in the periphery of the lobule and along the lobular septae particularly in the subpleural region. These lesions have been associated with spontaneous pneumothorax in young adults and bullous lung disease in older individuals [84]. In far-advanced parenchymal destruction such as that frequently observed in end-stage
**FIG. 6.7** (A) Normal lung photographed from the pleural surface after a postmortem bronchogram. The connective tissue outlining the secondary lobule is clearly seen (solid arrow) and a terminal bronchiole (TB) indicated by a clear arrow supplies a single acinus. (B) Photomicrograph of an acinus showing a terminal bronchiole (TB), respiratory bronchiole (RB), and alveolar ducts (AD). Their structure is represented by the fine spray of contrast at the end of the TB shown in the bronchogram in (A). (C) Diagram of the lesion in centrilobular emphysema, showing the dilation and destruction of the respiratory bronchioles. (D) Postmortem bronchogram showing a centrilobular emphysematous lesion (CLE) outlined by bronchographic material. Parts (C) and (D) reproduced from Refs [80, 81], with permission.

COPD, these descriptive terms are less helpful because centrilobular disease eventually destroys the entire lung lobule and destroyed lobules can coalesce to form much larger lesions.

The destruction of the lung by centrilobular emphysema results in a loss of elastic recoil with subsequent hyperinflation and a change in the pressure–volume relationship of the emphysematous lung tissue compared to the surrounding normal lung such that at any volume recoil pressure is less [81]. This decrease in lung elastic recoil diminishes expiratory flow by reducing the pressure available to drive air out of the lung [66], and interferes with gas exchange by reducing lung surface area [85].

## Acute exacerbations of COPD

In a hospital-based study of 1205 admissions to five hospitals for acute exacerbations of COPD, infections accounted for 520 (43%), heart failure for 260 (22%), and 122 (10%) cases were attributed to a variety of etiologies that included arrhythmia, pulmonary embolism, pneumothorax, postoperative complications, and lung cancer [86], with no cause being established in 303 (25%) of these 1205 admissions. Early studies by Stuart-Harris and associates [87, 88] showed that COPD patients with acute upper respiratory infections are more likely to have signs of infection in the lower airways than normal controls. Probably because acute viral upper respiratory tract infections increase the risk of aspiration of mucoid exudate containing large numbers of bacteria from the upper airways, but also because viral infection reduces both the mucociliary clearance and bacterial killing in the lower airways [89–91]. *Streptococcus pneumonia*, *Staphylococcus aureus*, and *Hemophilus influenzae* are the most common bacteria infecting the lower airways during an acute viral infection [90, 91], and these infections account for the positive effect of antibiotics in some exacerbations of COPD [92]. Two important early studies established an association between acute illness and serologic laboratory evidence of viral infection in patients with COPD [93, 94]. The development of polymerized chain reaction (PCR)-based viral

diagnostic techniques have improved the sensitivity of the diagnosis of viral infection and the use of real time PCR to measure viral copy numbers will likely improve its specificity. Early reports of studies based on these techniques indicate the importance of rhinoviral infection in causing acute exacerbations in an outpatient setting with influenza A and the corona virus OC-43 being more prominent causes of exacerbations that require admission to hospital [95–97].

The pathological features of the lung during acute exacerbations of COPD are incompletely defined. Primarily because postmortem studies of patients that die during exacerbations are complicated by terminal events and biopsy studies of patients with severe (GOLD-3 and very severe GOLD-4 disease during an exacerbation cannot be carried out without excess risk to the patient. One exception is an important study by Saetta *et al*. [98] in less severely ill patients with GOLD class 2 disease and a mean $FEV_1$ of $62 \pm 7\%$ predicted implicated the eosinophil as a cell of interest. Clearly more studies especially those that can make use of non-invasive or less invasive techniques than biopsy are needed to help clarify this important area of COPD.

## SUMMARY

### Asthma

The pathology of asthma is dominated by widespread plugging of the segmental, subsegmental, and smaller conducting airways that leads to hyperinflation but not destruction of the parenchyma. These airway plugs are a manifestation of the fluid and cellular exudative phase of an inflammatory process based in the airway tissue (Fig. 6.6). The cytokine and cellular content of this process is consistent with a Th-2 type of immune response [36, 37], and quantitative postmortem studies have established that the airway occlusion by plugs of this exudate is the major determinant of death from asthma [48].

### COPD

The chronic bronchitis of COPD is defined by excess cough with sputum production and is associated with an inflammatory process located in the mucosa, gland ducts, and glands of intermediate-sized bronchi between 2 and 4 mm internal diameter. The airway obstruction in COPD is the result of a similar inflammatory response in the smaller bronchi and bronchioles under 2 mm internal diameter, where the repair process associated with chronic inflammation thickens the airway wall and narrows the lumen to cause fixed airway obstruction. Emphysematous destruction of the lung surface contributes to the decline in $FEV_1$ by reducing the elastic recoil force available to drive air out of the lung and is responsible for reduced gas exchange. The acute exacerbations of COPD that occur with increasing frequency as the disease progresses have several known causes including infection, right heart failure, and pulmonary embolism but it is discouraging that in up to 25% of cases admitted to hospital the cause is unknown.

# Airway Remodeling

**Stephen T. Holgate**

School of Medicine, University of Southampton, Southampton, UK

Airway remodeling may be defined as a process of sustained disruption and modification of structural cells and tissues leading to the development of a new airway-wall structure and as a consequence, new functions. Although this process was noted as long ago as 1922 [1], interest in the underlying in asthma has risen only in recent years, the debate about asthma causation largely being driven by concepts in immunology and inflammation. In chronic obstructive pulmonary disease (COPD), although airway structural changes are well recognized [2], the underlying pathogenesis has received much less attention, possibly due to the more peripheral location of pathology and the overshadowing interest in the adjacent emphysematous tissue destruction.

In both conditions, a number of "remodeling" processes occur; but in proportion, the changes observed are quite different. Principal among these changes are airway fibrosis, an elevation in smooth muscle mass, mucous metaplasia, and glandular hypertrophy, in addition to less well defined alterations of the bronchial vasculature and nerves to create an abnormal airway wall. In asthma, segmental and subsegmental bronchial walls are thickened over their entire size range [3]. In COPD, only the inner wall area of the large airways is convincingly thicker [4]. The peripheral airways ($\sim$2 mm diameter), normally devoid of either supporting cartilage or bronchial glands, are also conspicuously remodeled in COPD [5, 6].

## NATURAL HISTORY AND CLINICAL IMPORTANCE

The natural history of remodeling is not well understood. Though it is surmised to be a consequence of long-term airways disease, studies have revealed early manifestations in asthmatics [7] and young smokers [8], suggesting that remodeling maybe as much part of the primary pathology of the disease rather than simply being a result of chronic inflammation. However, a considerable degree of variability in susceptibility to remodel the changes exists in both patient groups. Computerized tomography (CT) shows increased airway wall thickening in proportion to disease severity in both children and adults with asthma [9, 10], whereas in highly labile "brittle" asthma, this change is notably absent [11]. At a population level, asthma is associated with a greater than normal decay in lung function over time and associated loss of corticosteroid responsiveness [12]. In a small proportion of asthma patients with severe chronic disease the decline in lung function is more progressive and associated with persistence of symptoms despite corticosteroid therapy, thereby resembling a COPD-like state [13], although the pathology that underlies this in the two disorders differs [14], The accelerated decline in lung function in asthma may reflect not only the presence of airway structural modification, but also the inadequacy of currently available treatments to modify the remodeling processes.

Airway remodeling may have a number of clinical consequences for both asthma and COPD. For example, bronchial hyperresponsiveness has been postulated to be a function of the physical effects of overall airway wall thickening, in addition to airway inflammation and smooth muscle reactivity [15]. Of interest, however is the inverse relationship between airway wall thickening demonstrated by CT and by endobronchial ultrasound and airway hyperresponsiveness [16, 17]. Individual remodeling changes, such as an increased smooth muscle bulk or an

enhanced mucus producing facility, have their own implications for both symptom severity and airway function.

## MECHANISMS OF REMODELING

### Epithelial damage, airway inflammation, and epithelial repair

Responses of the airway epithelial barrier to injury and manipulation and abnormalities in the ensuing processes of repair are the most likely causes of remodeling. In both adult and children with chronic asthma, there is a good evidence that following repeated epithelial injury by environmental factors (e.g. allergens, viruses, and pollutants) the repair processes involve intercellular signaling between the damaged and regenerating epithelium and the underlying subepithelial (myo)fibroblast sheet, to influence matrix synthesis and the mass and composition of structures lying beneath [18]. Under these conditions, the asthmatic airway is behaving like a chronic wound with release of proinflammatory cytokines and multiple growth factors leading to some permanent changes to airway wall morphology. These epithelial–mesenchymal interactions have invited parallels with the intercellular communication found during branching morphogenesis, and remodeling has been suggested to reflect a reactivation of these early life processes (discussed later).

In contrast to asthma, COPD is thought to be due almost exclusively to the toxic effects of tobacco smoke. Repetitive attempts by the epithelium to protect itself and repair the injury induced by this noxious agent leads to marked structural changes to the epithelium with thickening and squamous metaplasia accompanied by an enhanced mesenchymal response at some sites and alveolar destruction at others. The airway obstruction that accompanies these changes is resistant to corticosteroids and in this respect becomes permanent or "fixed."

The importance of airway inflammation, integral and intimately linked to the process of epithelial injury, is recognized in both diseases [19]. In asthma, much interest has focused on the CD4[+] T-lymphocyte that is skewed toward a Th2 type phenotype as the orchestrator of an immune response to allergens [20]. The predominant pattern of Th2 cytokine expression results in an inflammatory phenotype where eosinophils and mast cells are prominent, but macrophages, fibroblasts, and dendritic cells are also involved [21]. The inflammatory milieu differs considerably in COPD. Eosinophils may play a role in a subset that has features in common with asthma and also during acute exacerbations [22, 23], but their significance in the majority is outweighed by the contribution of macrophages and neutrophils with a CD8[+] T-cell preponderance [24–26]. Indeed CD8[+] T-cells are assuming increasing importance in orchestrating the neutrophil-mediated injury in COPD possibly linked to chronic infection. Known perpetrators of epithelial damage in COPD include tobacco smoke toxins, viruses, and bacteria, whereas in asthma house dust mite allergen [27], fungal and pollen enzymes [28], and toxic air pollutants

are causally involved, with their effects being augmented by the airway inflammatory responses induced by these agents. Thus, the generation of reactive oxygen species and the products of infiltrating inflammatory cells including arginine-rich eosinophilic proteins [29], mast cell tryptase [30], neutrophil elastase, and metalloproteases derived from eosinophils and mast cells [31, 32], neutrophils and macrophages all induce epithelial injury. The result in asthma is a fragile bronchial epithelium with weakening of junctional adhesion structures, whereas in COPD the epithelium proliferates and thickens. Consequently, a feature of asthma is the shedding of columnar epithelial cells from their basal cell attachments [33–36]. In COPD, although atrophy and shedding of the epithelium may occur [37], focal squamous metaplasia is much more common [38, 39].

Altered airway adhesion molecule expression, a hallmark of an active repair process, has been demonstrated in asthma and COPD. This includes enhanced expression of CD44 [40], the integrins [41], and E cadherin [42] in asthma, while in both asthma and COPD there is augmented expression of ICAM-1 [43]. A recent important finding in asthma is the incomplete formation of tight junctions at the apex of the columnar epithelial cells which is preserved in tissue culture of differentiated asthmatic epithelium many weeks after removal from the patient's airways [44, 45] (Fig. 7.1).

Since tight junctions are crucial in controlling paracellular transport, their disruption in asthma could help to explain why inhaled allergens and other inhaled environmental agents initiate and maintain a chronic inflammatory response at this site. Epithelial expression of the epidermal growth factor receptor (EGFR) family is also increased in asthma, and reflects an injury and repair response seen in other epithelial tissues by interacting with six distinct ligands:

- epidermal growth factor (EGF)
- transforming growth factor $\alpha$ (TGF-$\alpha$)
- amphiregulin (AR)
- heparin-binding EGF-like growth factor (HB-EGF)
- betacellulin (BTC)
- epiregulin.

Activation of the EGFR promotes both migration and proliferation of epithelial cells [46], and there is *in vitro* and *in vivo* evidence supporting a role for this receptor in bronchial epithelial repair [47, 48]. However, in asthma, increased EGFR expression does not appear to be coupled to an appropriate proliferative response by the repairing epithelium [49]. This impairment may explain why EGFR expression, as a marker of tissue injury, correlates positively with both asthma severity, neutrophil influx [50], and the extent of subepithelial fibrosis [51]. The impaired epithelial repair response in asthma may be well linked to the actions of the profibrogenic transforming growth factor beta (TGF-$\beta$) family of cytokines, which are known inhibitors of epithelial proliferation [52] and whose level is markedly increased in asthmatic airways [53].

Although there are substantial changes in epithelial structure in COPD, relatively little is known of the factors driving this. Cigarette smoke results in enhanced EGFR

(A)

(B)
FIG. 7.1 Schematic representation of airway epithelial tight junction showing their localisation at the apex of epithelial cells (A). Confocal images of airway biopsies from atopic normal and asthmatic subjects stained by immunoflurescence for the tight junction protein ZO-1. Note the disrupted staining pattern in asthma (B).

expression in airways epithelium [54] and augmented expression of both EGF and TGF-β have been observed in subjects with chronic bronchitis [53]. Thus in both asthma and COPD, there occurs a potential imbalance between proliferative and anti-proliferative signaling in the airways in the former leading to a frustrated and incomplete response and in the latter an exuberant response.

The relationship between epithelial injury and fibrosis has been examined using co-cultures of bronchial epithelial cells and fibroblasts. In these studies, damage inflicted on the epithelial cells that resulted in enhanced myofibroblast proliferation and collagen gene expression secondary to the release of a number of growth factors including

- basic fibroblast growth factor (FGF1)
- acidic fibroblast growth factor (FGF2)
- insulin-like growth factor (IGF)
- platelet-derived growth factor (PDGF)
- transforming growth factor β (TGF-β)
- Endothelin-1 (ET-1) [55].

In addition to these, a range of other potentially important epithelial-derived products such as nerve growth factor (NGF), nitric oxide, metalloproteinases, fibronectin, (an extracellular matrix component with potent chemotactic

properties for fibroblasts [56]) and a range of proinflammatory cytokines [57–60] are produced by epithelial cells during the repair process.

## Remodeling of the extracellular matrix

The extracellular matrix is composed of a network of fibrous and structural proteins embedded in a hydrated polysaccharide gel to form the strong, resilient framework of the airway wall. Alteration in both the mass and the composition of this structure is one of the primary aspects of remodeling in both asthma and COPD, with enhanced fibroblast activity being most directly responsible.

The repair environment in the airways produces a number of changes in cytokine and growth factor expression to which the fibroblast is receptive. Studies in asthma have indicated that myofibroblasts, a cell population with morphological and biochemical features intermediate between those of fibroblasts and smooth muscle cells [61], are responsible for the particular pattern of matrix deposition in this disease. These cells, lying below and adjacent to the *lamina reticularis* in a layer referred to as the "attenuated fibroblast sheath" are major producers of collagen and proteoglycans implicated in matrix accumulation, as well as wound contraction [62]. In the absence of specific immunohistochemical markers for this cell type, myofibroblasts are identified by ultrastructural criteria and the expression of $\alpha$-smooth muscle actin ($\alpha$-SMA) which is also found in abundance in smooth muscle cells. Though myofibroblast hyperplasia has been demonstrated in the airway subepithelium in asthma [61, 63], with their numbers correlating with the extent of subepithelial collagen thickness [63, 64], the significance of this finding in relation to the remodeling response involving the full thickness of the airway wall is uncertain, however, their increased number is highly a characteristic of asthma. Myofibroblasts (or fibromyocyte as they have also been called) appear early after allergen challenge, perhaps implying a quiescent precursor cell that differentiates to acquire myofibroblast features [61]. Candidates for this include fibroblasts, smooth muscle cells, or perhaps other primitive mesenchymal or structural cells. Recent interest in the recruitment of CD32$^+$ bone marrow-derived fibrocytes from the circulation into the airways following allergen challenge is another possible source of these cells [65]. A further source of myofibroblasts is through epithelial–mesenchymal transition involving TGF-$\beta$ as described in pulmonary fibrosis [66]. A number of factors have been identified which alter fibroblast $\alpha$-SMA expression:

- TGF-$\beta$ [67]
- Heparin [68]
- Interferon-$\gamma$
- granulocyte macrophage colony stimulating factor (GM-CSF).

Proliferation and migration of resident progenitors and/or myofibroblasts already present in the airways may contribute to the increase in these cells beneath the epithelium [63]. For example, smooth muscle mitogens and fibroblast growth factors have been detected in bronchoalveolar lavage (BAL) fluid after allergen challenge [69], and fibronectin has been observed to cause selective recruitment of myofibroblasts from a population of normal fetal lung fibroblasts [70]. In COPD, studies investigating the potential role of myofibroblasts suggest an increase in peripheral airways that show the greatest tendency to remodel [71].

## The role of growth factors and inflammatory mediators

The use of transgenic animal models of mediator's over-expression has provided further evidence to link epithelial growth factor and inflammatory cytokine generation with matrix remodeling. Specifically, TGF-$\beta$, over-expressed in the rat airway epithelium by adenoviral gene transfer results in severe interstitial and pleural fibrosis [72], while over-expression of TGF-$\beta$, IL-6, or IL-11 as transgenes in the airway epithelium induces subepithelial fibrosis in the lungs of mouse models [73, 74]. Mouse models expressing the Th2 cytokines IL-5 [75], IL-9 [76], and IL-13 [77] all developed remodeling responses in their airways, although interestingly in mice over-expressing IL-4 the results are inconsistent [78, 79]. Interleukin-13 is over-expressed in asthmatic airways [80] and is being pursued as an important new therapeutic target in asthma because of its involvement in B-cell IgE isotype switching, Th2 inflammation, mucous metaplasia and remodeling effects [81]. The TGF-$\beta$ superfamily of cytokines (that include the bone morphogenic proteins (BMPs)) are among the most studied with respect to airway fibrosis and remodeling. TGF-$\beta$ is a multifunctional profibrotic growth factor and a key component in the regulation of tissue growth and differentiation during branching morphogenesis and wound repair as well as promoting smooth muscle differentiation [82]. It stimulates fibroblast growth and is responsible for the differentiation of fibroblasts into myofibroblasts [55, 83, 84]. TGF-$\beta$ promotes synthesis of extracellular matrix components by a number of cells including fibroblasts, smooth muscle, epithelial cells, and macrophages [85], and it blocks matrix degradation by inhibiting proteolytic enzyme synthesis and augmenting the action of protease inhibitors with increased expression both in asthma and COPD [53, 86, 87]. Tissue macrophage TGF-$\beta$ production is elevated in both diseases, while in asthma eosinophils and epithelial cells are also important sources [53, 88, 89], a significant correlation being demonstrated between the level of expression of TGF-$\beta$ and the extent of subepithelial fibrosis and numbers of fibroblasts [53]. TGF-$\beta$ levels in asthmatic airways are unaffected by corticosteroid treatment.

Another growth factor cluster is platelet-derived growth factor (PDGF). This is produced mainly in the airways by macrophages, epithelium, and most airway inflammatory cell types including mast cells and eosinophils as important sources of in asthma [90, 91]. PDGF promotes fibroblast chemotaxis, fibrosis, and smooth muscle mitogenesis [92] and would seem to be another very plausible mediator of airway remodeling with asthmatic bronchial fibroblasts showing enhanced responsiveness [93]. Nevertheless, it has been difficult to show increased expression of PDGF in the airways either in asthma or in COPD [94, 95], so that its relevance in these diseases has yet to be

clearly demonstrated. A family of profibrotic mediators are the endothelins (1 and 2) whose levels are increased in both diseases [96–98]. These agents, in addition to their well described vasoconstrictor and bronchoconstrictor properties, the endothelins are potent activators of fibroblasts for enhanced matrix production [99].

Although in asthma epithelial EGFR expression has been shown to correlate with the extent of subepithelial fibrosis, the EGFR as an effector of matrix remodeling mesenchymal cells is also important, along with platelet-derived growth factor (PDGF), insulin-like growth factor, fibroblast growth factors and TGF-β. Stimulation of fibroblast-bound EGF and PDGF receptors works in concert with binding of β1 integrins also present on the surface of these cells by matrix components such as laminin or fibronectin to stimulate fibroblast chemotaxis and migration [100, 101]. Thus, alterations in growth factor and receptor expression, matrix composition, and adhesion molecule binding all have the potential to influence fibroblast activity in the airway repair response. Although EGF immunoreactivity has been demonstrated in the airway mucosa of both asthmatic and COPD patients, the number of EGF-expressing cells did not correlate with either basement membrane thickness or underlying fibroblast number [53]. Increased epithelial expression of TGF-α, another ligand of the EGF family results in lung fibrosis, but the effect is mediated via the epithelium to enhance other fibroblast growth factor secretion rather than through a direct action on fibroblasts [46].

## The role of proteolytic enzymes

Alteration in matrix turnover is a critical factor in the remodeling process involving a range of proteolytic enzymes. Serine proteases and matrix metalloproteases that are produced by a variety of inflammatory and stromal cells can digest all the major components of the extracellular matrix [102]. Examples include MMP3 (stromolysin) and MMP9 in asthma [103] [104] and MMP1, MMP9, and MMP12 in COPD (with regard to their potential to induce emphysema) [105, 106]. In emphysema it is believed that a protease/anti-protease imbalance exists favoring the excessive proteolytic digestion of lung parenchyma and especially elastin, although there is now strong evidence that deposition of new matrix is an equally important component of COPD involving the more peripheral airways and contributing to increased airway stiffness [107]. Thus, although both MMP9 and neutrophil elastase levels are elevated in induced sputum of asthmatic and COPD patients, the augmented presence of these proteases is outweighed by a proportionally larger increase in their natural inhibitors TIMP1 and α1-antitrypsin [108, 109] which would favor fibrosis.

The release of growth factors that are encrypted in the extracellular matrix or from their cell membrane-bound precursors is another way that proteases may contribute to remodeling. For example, both FGF and TGF-β are bound as inactive forms to heparan sulfate and decorin respectively [110, 111] and can be released from these matrix stores by the proteolytic activity of plasmin and MMPs. In contrast, release of heparin-binding EGF (hb-EGF), a further member of the EGF family and a potent smooth muscle mitogen, is dependent on MMP3-induced cleavage of its transmembrane precursor [42]. Mast cell tryptase, acting via cellular protease activated receptor (PAR)2 acts directly on fibroblasts and smooth muscle cells to promote both mitogenesis and collagen secretion [112] and is also mitogenic for epithelialial cells and enhances profibrogenic growth factor release [113].

## Effects of the altered matrix on remodeling

The capacity of the extracellular matrix to directly and indirectly influence cell migration, proliferation, and maturation is indicative of a highly dynamic function in addition to provide structural support [85, 114]. Matrix components such as decorin, versican, and fibronectin provide stimuli for inflammatory, epithelial, and stromal cells by serving as ligands for adhesion molecules [115] and by acting as a reservoir for release of cytokines, chemokines, and growth factors such as TGF-β [116]. Glycosaminoglycans, such as hyaluronic acid (HA), found to be increased in the BAL fluid of asthmatics [117], facilitate cell migration, and proliferation during injury and repair, [118] by interacting with receptors such as CD44 [119], while survival of eosinophils is prolonged by interaction with fibronectin and laminin, which inhibit apoptosis in part through the autocrine effect of GM-CSF [120]. Indeed, fibronectin is a matrix glycoprotein that has received considerable attention regarding its role in repair [85, 121]. It is produced by bronchial epithelial cells [122] fibroblasts, smooth muscle cells, and macrophages [123] and is upregulated by growth factors such as TGF-β [124] and integrin ligation [125]. Fibronectin is incorporated into the provisional matrix that forms after injury, where it acts as a chemoattractant for both epithelial cells and fibroblasts [126]. Elevated quantities of fibronectin have been detected in bronchial lavage fluid in COPD and in asthma where it is also found abnormally deposited in the subbasement membrane along with tenascin C, another matrix glycoprotein that is chemotactic for leukocytes and repair cells [63, 127, 128].

## RESULTS OF MATRIX REMODELING IN ASTHMA AND COPD

The pattern and distribution of matrix deposition in the remodeled airway differs between asthma and COPD. Interest in asthma has centered mainly on the larger airways, whereas in COPD it is involvement of small airways where remodeling dominates the pathology. Matrix remodeling may be roughly subdivided into thickening of the subepithelial basement membrane (*lamina reticularis* or basal lamina), submucosal thickening, matrix deposition in airway smooth muscle and new matrix deposited in the airway adventitia outside the smooth muscle layer. In addition, the proliferation of new blood vessels, nerves, and muscle as well as mucous metaplasia and formation of larger and more numerous submucous glands are all part of the remodeling response.

## Subepithelial basement membrane matrix deposition in asthma and COPD

Deposition of protein beneath the true epithelial basement membrane is characteristic of asthma. Electron microscopic and immunohistochemical analysis of bronchial biopsy specimens has shown that the true basement membrane, made up of the *lamina rara* and *lamina densa*, is normal in both size and composition and that the changes occur in the *lamina reticularis*. In this region, abnormal deposition of interstitial repair collagen subtypes I, III, and V takes place [129] in addition to non-collagenous matrix components that include fibronectin [129], laminin β$_2$ [130], and tenascin C [131]. Classical epithelial-derived membrane subtypes, such as collagens IV and VII, are absent from this abnormal subepithelial matrix layer. Recent studies in asthma using the blocking anti-IL-5 monoclonal antibody, mepolizumab, have shown that depletion of IL-5 and partial depletion of airway eosinophils results in reduced immunostaining for tenascin C, lumican, and collagen III in the *lamina reticularis* [132], but, interestingly, this is not paralleled by remission of asthma [133]. Similar effects on the matrix component of the late phase allergen response have also been reported [134]. It is possible that more prolonged anti-IL-5 treatment in more severe asthma might be more clinically effective since mepolizumab is highly effective in eosinophilic oesophagitis and nasal polyposis [135].

Studies of COPD have not revealed an equivalent to the subepithelial fibrosis as observed in asthma, although in post-transplant obliterative bronchiolitis, this change occurs secondary to epithelial damage, epithelial-mesenchymal transition, and proliferation of myofibroblasts [136, 137]. Studies of COPD show reveal normal basement membrane thickness [37, 138], although in a subset of patients with COPD who display overlap with the asthmatic phenotype thickening of the *lamina reticularis* is apparent especially in the presence of eosinophils [139]. These individuals, who have a BAL eosinophilia and significant corticosteroid reversibility, also show demonstrable basement membrane thickening, but the composition remains unknown [140]. Further studies are needed to properly define the clinical and pathological characteristics of this subgroup and any overlap with late onset "intrinsic" asthma.

## Diffuse matrix deposition in asthma and COPD

Studies evaluating matrix deposition deep to the *lamina reticularis* in asthma have been few. An excess of collagen including types III and V have been found in large airway samples by some investigators [141, 142], but not by others [129, 143]. Other matrix proteins and proteoglycans found in excess in this region in asthma include decorin, lumican, biglycan, versican, and fibronectin [108]. Excess matrix deposition in COPD has been identified predominantly in the peripheral, noncartilaginous airways (<2 mm diameter) [39, 144]. However, one immunohistochemical investigation has demonstrated reduced decorin and biglycan in the peripheral airways, with staining patterns for type IV collagen and laminin similar to those observed in control lungs [145].

## MUCOUS METAPLASIA

In normal lung, submucosal mucous glands and epithelial goblet cells are distributed throughout the cartilagenous airways in. In asthma and COPD, epithelial mucous metaplasia and hyperplasia occur with hypertrophy of the submucosal gland mass. An increase in both the number and the size of mucus-secreting cells leads to enlargement of these tracheobronchial glands in both diseases [146, 147]; however, a variable degree of replacement of serous with mucous acini occurs in COPD, but not in asthma [148].

Epithelial mucous cell metaplasia is observed in both central and peripheral airways in asthma [149, 150] but there exists a substantial degree of individual variation. In those who have died due to asthma goblet cells are found in the peripheral airways [151], compatible with most asthma deaths occurring in association with excessive mucous occlusion of airways [152]. In COPD, mucous metaplasia and hyperplasia are observed both centrally and peripherally [2, 153, 154] resulting in a more even distribution of secretary cells throughout the airways. Thus, the smaller (<400 μm diameter) airways which are normally populated with very few goblet cells become important contributors to the excess mucous which characterizes this disease [155, 156]. Indeed, the mucus produced in asthma and COPD is qualitatively and quantitatively abnormal with major alterations in its cellular and molecular composition. The elevated ratio of mucous/serous acini in COPD results in secretion of a more gel-like thicker mucus, which is also lacking in anti-proteases [157]. In severe asthma, bronchial obstruction from mucus plugging occurs in both central and peripheral airways [151, 158]. In COPD, partial or complete occlusion of the small (<2 mm diameter) airways with mucous plugs is common [5]. In both diseases, reduced levels of surfactant lining the small airways results in increased surface tension, airway collapse, and difficulty in re-expansion [159].

Expression of mucin genes, which encode the mucin glycoproteins, is the principal factor governing the differentiation of epithelial cells into goblet cells [160]. Both environmental and host factors, acting on the epithelium, have been shown to stimulate mucin gene upregulation and mucin secretion. Environmental factors include infectious agents [161] and environmental pollutants [162] while host factors include inflammatory mediators [163] and cell degranulation products [164, 165]. Acrolein, a low molecular weight component of cigarette smoke, induces epithelial MUC5AC gene expression, and mucous metaplasia in rats *in vivo* [166] ,while the Th2 cytokines IL-4, IL-9, and IL-13 have been closely linked to both augmented mucin gene expression, particularly the MUC5AC and MUC2 genes, and goblet cell differentiation both *in vitro* and *in vivo* [167–170].

A central role has been postulated for the neutrophil in stimulation of airway mucin production. This is based on the observation of augmented MUC5AC expression by cultured epithelium when exposed to neutrophils [171], possibly through neutrophil elastase and oxidative stress, each of which has been shown to augment both epithelial

MUC5AC mRNA and protein expression [171–174]. The EGFR is involved in regulation of airway mucin synthesis [175, 176] as mucin gene expression results from ligand-independent transactivation of the EGFR in response to oxidative stress [177] that can be blocked by selective inhibitors of the EGFR tyrosine kinase [131]. Both EGF and EGFR expression are elevated in bronchial glandular tissue in asthmatic subjects compared with controls [178] suggesting a similar role for the EGFR in asthma. IL-13 may cause induction of mucin gene expression via an EGFR-dependent pathway.

## SMOOTH MUSCLE REMODELING

The presence of an augmented airway smooth muscle bulk in asthma and COPD is well established. In asthma, smooth muscle mass is increased in both large [179] and peripheral [180, 181] airways, although debate continues over whether hypertrophy or hyperplasia dominate. Autopsy studies suggest the existence of two distinct patterns. The type 1 pattern has increased muscle mass due to hyperplasia restricted to large central airways, while in type 2 there is smooth muscle thickening throughout the bronchial tree caused predominantly by hypertrophy, particularly in the small airways, with a mild degree of hyperplasia in the larger airways [182]. The situation is further complicated by the considerable degree of heterogeneity present. An increase in smooth muscle mass is not always demonstrated in mild asthma [183] or in post-mortem studies of asthmatics whom have died from other causes [184]. Why different patterns of smooth muscle enlargement should exist in asthma or what factors predispose some but not other asthmatics to the development of either one is unknown. Nor is it known whether smooth muscle changes occur before, in parallel with or as a consequence of the inflammation.

The peripheral airways are also the location of an increase in smooth muscle mass in COPD [183, 185–187], though it is suggested that the changes are less marked than those in asthma [183]. Studies often describe these changes under the heading of hypertrophy, but the extent to which hyperplasia plays a role is again unclear. Estimates of smooth muscle enlargement in the larger airways in COPD have varied [188]. Some investigators have observed no abnormality in smooth muscle area [179], while others report up to a twofold increase in bronchial smooth muscle thickness attributable to both hyperplasia and hypertrophy [189]. A clinical correlation with the presence of wheeze has also been suggested [190].

The mechanisms leading to the increase in smooth muscle in asthma (and COPD) are largely speculative and include the growth promoting potential of an enriched plasma environment due to microvascular leakage [191]. The mitogenic influences of mediators involved in the inflammatory response and an intrinsic abnormality of smooth muscle itself. However, most knowledge of factors that promote smooth muscle growth has come from *in vitro* cell culture studies [192].

An extensive list of smooth muscle mitogens has been identified:

- inflammatory mediators
- growth factors
- enzymes
- components of the extracellular matrix [192].

Group 1 are mediators, such as EGF and PDGF, which activate tyrosine kinase receptors. Group 2 includes those receptors coupled to GTP-binding proteins such as thrombin and mast cell tryptase [193]. Although ET-1 and LTD4 are smooth muscle mitogens in animal models, their effects on human smooth is controversial, although recent studies suggest an interaction with tyrosine kinase receptors possibly through the activation of metalloproteases and the mobilization of growth factors such as EGF ligands from their cell-bound precursors [193, 194]. TGF-$\beta$ and PDGF isoforms are both differentiation factors for airway smooth muscle, but at the time of writing their role in smooth muscle development in asthmatic and COPD airways remains speculative.

A further association between inflammation and smooth muscle function has been suggested by the enhanced expression of adhesion molecules such as ICAM-1 and VCAM-1 on airway smooth muscle cells in response to TNF-$\alpha$, IL-1, LPS, and IFNs [195]. Furthermore, the adherence of T-cells to smooth muscle cells results in stimulation of DNA synthesis [195]. The capacity of these ASM to express adhesion molecules, synthesize ECM components, and release inflammatory cytokines and chemokines including RANTES [196], eotaxin, and IL-8 [192] indicates that smooth muscle remodeling may itself be part of the inflammatory process. Towards this end, there is now good evidence that in asthma smooth muscle cells and their associated matrix support a distinct mast cell population that maybe highly relevant to the pathogenesis of hyperresponsiveness [197, 198].

In asthma and COPD, polymorphism of the disintegrin and metalloprotease 33 (ADAM33) molecule is strongly associated with BHR and an accelerated decline in lung function over time [199, 200]. ADAM33 is localized to airway smooth muscle and is implicated in vasculogenesis through release of its soluble form [201]. There is also much interest in the factors that are chemotractant for smooth muscle cells, their relationship to myofibroblasts and whether mechanisms for removal of muscle could be therapeutically beneficial. Towards this end, bronchoscopic thermoplasty is looking very promising as an entirely new approach to asthma treatment [202, 203].

## VASCULAR AND NEURAL ALTERATIONS

Elevated airway-wall blood-vessel area has been demonstrated in adult and children's asthma and is greater than in controls or subjects with COPD [180, 183, 204]. However, it is unclear whether this vascular remodeling is primarily due to the formation of new blood vessels [205] or to enlargement of the existing microvasculature. A study of the membranous bronchioles of subjects with asthma and

COPD has suggested the latter [183]. Indeed fatal asthma is known to be associated with dilatation of bronchial mucosal blood vessels, congestion, and wall edema [206]. However, Li and Wilson [207] have discovered changes suggestive of new vessel formation in mild asthma, and the microenvironment in asthma has been shown to possess the potential for angiogenesis.

Mediators such as histamine, heparin, and tryptase all possess angiogenic properties, while expression of vascular endothelial growth factor (VEGF), a potent vascular growth factor, is upregulated by agents such as TGF-$\beta$, TNF-$\alpha$, and TGF-$\alpha$ that are involved in the inflammatory milieu of the asthmatic airway. Of particular importance is VEGF which is released from epithelial cells as well as a broad range of inflammatory cells including mast cells. The pro-angiogenic function of soluble ADAM33 is also relevant here.

There is evidence in severe asthma of increased airway neural networks. This is most likely the consequence of nerve growth factor (and related neurotrophins) release from epithelial and inflammatory cells. Circulating levels of NGF relate [208] strongly to asthma severity and may prove to be a useful biomarker of this more severe phenotype [209]. In addition, in both asthma and COPD, the compromised epithelial barrier allows a greater exposure of nerve endings to environmental stimuli. Thus, the potential for release of neurotransmitters such as the tachykinins substance P and neurokinin A is increased. These agents, in addition to their effects on vascular and smooth muscle homeostasis, can contribute to local inflammation with the attraction and activation of inflammatory cells. Neurogenic inflammation is one way sensory information received from the inhaled environment could contribute to ongoing inflammation, although this has been difficult to prove in asthma or COPD but is easily shown in animal models of airway inflammation [210].

## EFFECTS OF THERAPY

Whether any of the current anti-inflammatory strategies can significantly alter the course of remodeling is unknown. Long-term corticosteroid therapy has been shown to slow the annual rate of decline in lung function in adult asthmatics [211]. However, other studies have suggested that a negative relationship exists between response to treatment and duration of disease [212]. Added to this are reports showing persistent airflow obstruction in some patients, despite both oral and inhaled therapy [208]. The implication is that early therapy may, to a limited extent, prevent remodeling, but established structural change is steroid-insensitive. Several recent birth cohort studies [213, 214] in childhood asthma have shown that inhaled corticosteroids modify asthma symptoms while being continuously administered, but they have little or no effect on the natural history of asthma. Similar findings have been reported in the large CAMP and START inhaled corticosteroid intervention studies in older asthmatic children [215, 216]. This is somewhat surprising if it is thought that airway remodeling and the increase in smooth muscle is the direct consequence of chronic

inflammation. Another possibility is that the structural changes either precede or occur in parallel rather than sequential to inflammation. While *in vitro* studies suggest possible inhibitory effects of bronchodilator drugs such as $\beta$2-adrenoceptor agonists and xanthines (e.g. theophylline) on smooth muscle and fibroblast proliferation [217, 218], similar effects on these measures *in vivo* are far from established.

It has been proposed that a more effective strategy to reduce airway smooth muscle in asthma would be to interfere with growth factor and other receptor mechanisms. Suggested approaches include blocking the actions of TGF-$\beta$ in an attempt to limit smooth muscle differentiation as well as fibrosis. Monoclonal antibodies targeted to TGF-$\beta$ are in clinical trials in diffuse fibrotic disorders such as scleroderma, but concerns over safety have so far prevented their exploration in asthma. The other functions of this growth factor such as the development of anti-inflammatory T-regulatory cells need to be taken into account as possible alternative on target side effects [219]. Whether targeting other mechanisms such as thrombin inhibitors, protease activated receptors themselves, endothelin and its receptors and other growth factors such as PDGF are very much in the early experimental stage. So far, bronchial thermoplasty seems the most promising approach although even with this, side effects of delayed airway fibrosis is a concern. One exciting possibility, however, is the inhibition of IL-13, a cytokine with multiple effects on inflammation, remodeling, and mucous metaplasia. After successfully pass in phase I safety studies, a number of human and humanized monoclonal antibodies targeting the IL-13 pathway are in clinical development in asthma. The clear advantage here is that blockade of this pathway may influence several interacting aspects of chronic asthma.

Attempts are in progress to reduce mucus secretion. While inhibiting EGFR signaling would be one route the downstream consequences of this on epithelial tissue repair responses would be serious, especially since epithelial repair in asthma is already known to be defective [220]. However, the chloride channel Gob 5 (hCLCA1) as an IL-13 sensitive mechanism that influences the secretion of mucus, is a promising target for small molecular weight inhibitors [221].

A protective role for basement membrane thickening has been postulated also in restricting inflammatory cell passage to the epithelial layer above, while smooth muscle hypertrophy may possibly help to maintain bronchiolar caliber in severe emphysema [164]. Thus if a new "anti-remodeling" agent were to emerge, the beneficial effects would have to be weighed against the consequences of interfering with what may, in some ways, be a valuable defence mechanism.

## CONCLUDING COMMENTS

While airway wall remodeling undoubtedly occurs in both asthma and COPD, its physiological significance in health and disease remains speculative. Of concern is the lack
**FIG. 7.2** Schematic representation of the epithelial mesenchymal trophic unit (EMTU) in asthma that becomes reactivated with the secretion of many growth factors by the epithelium and underlying myofibroblasts sheath.

of knowledge connecting inflammation to the structural changes. In asthma an overarching hypothesis is emerging that involves aberrant communication between a chronically damaged epithelium and the underlying mesenchyme reminiscent of reactivation of the epithelial mesenchymal trophic unit (EMTU) involved in fetal branching morphogenesis of the lung [222, 223] (Fig. 7.2). The inability of an efficient epithelial wound healing response is responsible for the production of a large number of growth factors implicated in fibrosis, vascuogenesis and new nerve formation, but whether this process is also involved in smooth muscle enhancement in asthma remains conjectural. The chronically damaged/repairing EMTU is also the source of a range of cytokines and growth factors to support chronic inflammation. Thus directing new therapies to increase resistance of the asthmatic airways to environmental insults may create a new approach to treatment.

# Asthma and COPD: Animal Models

**Stephanie A. Shore[1] and Steven D. Shapiro[2]**

[1]Molecular and Integrative Physiological Sciences Program, Harvard School of Public Health, Boston, MA, USA
[2]Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

## OVERVIEW

Animal models have been used extensively in the discovery of the biological processes that underlie asthma and COPD. For example, the demonstration by Gross *et al*. [1] that instillation of papain into the lungs of rats resulted in a syndrome similar to emphysema, contributed to the elastase/anti-elastase hypothesis regarding the pathogenesis of emphysema. Animal models have also been used to guide research into pharmacological interventions for the treatment of asthma and COPD. For example, the current use of leukotriene receptor antagonists for the treatment of asthma had its foundation partly in the demonstration of the marked broncho-constrictor potency of cysteinyl leukotrienes in guinea pigs [2]. While many species, including dogs, cats, monkeys, horses, pigs, sheep, guinea pigs, and rats have been used to study asthma and COPD, most current investigations involve the use of mice. Consequently, this review will focus on models developed using this species. The advantages of using mice include cost of housing, a short breeding period, the availability of inbred species with known characteristics, a well characterized immune system and genome, and the ability to either overexpress or delete specific genes, sometimes conditionally, that is, at specific times or in particular cells. This ability to genetically manipulate mice is a powerful tool that permits very mechanistic experiments that cannot be accomplished in human subjects and has yielded some important advances in our understanding of lung disease. The disadvantages of using mice include differences in lung anatomy, lung development, pattern and route of breathing (mice are obligate nose breathers), the pathogen-free facilities in which most mice

are housed which eliminate many environmental modifiers, and some differences in the immune system (mice have a more polarized T-lymphocyte response than humans). These disadvantages have been documented elsewhere [3–7] and may limit the utility of these models for studying human disease in some cases. Mouse models of asthma and COPD will be reviewed separately below.

## MOUSE MODELS OF ASTHMA

Human asthma is characterized by intermittent reversible airway obstruction, AHR, and airway inflammation. Pathologically, airway remodeling including increased airway smooth muscle mass, subepithelial fibrosis, mucous hypersecretion, and increased airway vascularity are observed. Asthma does not typically develop in most non-human species. Consequently, many investigators have chosen to develop animal models in which an asthma-like phenotype is induced by some intervention. The etiology of asthma is complex, and still poorly understood, and it is clear that multiple factors including exposure to allergens, exercise, exposure to air pollution, certain viral infections, and the onset of obesity can also initiate symptoms. Because of the extensive nature of this topic, we have chosen to focus on only two of these factors: allergen and obesity.

### Modeling allergic asthma

Many investigators have used models of allergic asthma in which mice are first sensitized to an allergen and then challenged with that allergen

via the lungs. The sensitization and the challenge protocols vary widely among investigators, especially depending on whether AHR or airway remodeling are being targeted. The sensitization is usually i.p. injection of the allergen with an adjuvant. Allergens used have included ovalbumin (OVA), picryl chloride, sheep erythrocytes, short ragweed extracts, and house dust mite allergen. Although not environmentally very relevant, most investigators have used OVA as the allergen, perhaps because of its relatively low cost and easy availability. Mice are usually assessed 1–3 days after the last of several daily airway challenges and the characteristics monitored are AHR, airway inflammation, and serum IgE.

Consistent features of the model are increased OVA-specific IgE and IgG1, eosinophilia (intraluminal, peribronchial, and perivascular), and recruitment of lymphocytes to the airways. Increases in Th2-type cytokines either in bronchoalveolar lavage (BAL) fluid, in lung tissue, or in lymph nodes draining the lungs also occur. These changes are generally similar to those observed in the airways of asthmatics after allergen challenge, although the kinetics of the recruitment of eosinophils and lymphocytes differ: in humans, the peak in T-lymphocyte recruitment occurs about 24 h after challenge and precedes the peak of eosinophil recruitment, whereas in mice, T-cell recruitment continues long after eosinophils have peaked and returned to baseline [8].

AHR is often, though not always observed in allergen sensitized and challenged mice. There are few reports of comparisons of the various protocols in terms of their ability to induce AHR, but those available indicate that both systemic sensitization and pulmonary challenge are required to induce AHR [9]. For example, multiple airway challenges without systemic sensitization can result in pulmonary eosinophilia, but *in vivo* AHR is not observed under these conditions [10]. The route of airway challenge (nasal or intratracheal versus aerosol) may also be a factor [11]. Mouse strain also has an important impact on allergen-induced AHR. AHR is relatively easy to induce in Balb/c and A/J mice, but more difficult to induce in other strains, including C57BL/6 mice even though airway inflammation is robust in this strain [9, 12–14]. The relative resistance of C57BL/6 mice to allergen-induced AHR is unfortunate, since many of the knockout mice that could be used to study the mechanistic basis for allergen-induced AHR are originally developed on this background.

Recently, investigators have begun using repeated allergen challenges over several weeks to months to model the airway remodeling that characterizes human asthma [15]. In general, such challenges often result in tolerance, although in the A/J strain, eosinophilia and AHR are preserved over several months, and these mice develop subepithelial fibrosis and airway smooth muscle hypertrophy [12]. However, modifications to the protocols may improve the utility of mouse models for studies of airway remodeling. A recent report by Yu *et al*. [16] indicates that elimination of adjuvant during the sensitization phase results in preserved AHR, eosinophilia, and subepithelial fibrosis even after 9 weeks of repeated weekly intranasal challenges in mice on a C57BL/6 background. Others have observed subepithelial fibrosis and increases in airway smooth muscle mass after chronic challenge over several months with very low concentrations of OVA delivered intranasally, even in C57BL/6 mice [17].

Murine models of allergic airways disease have been used to examine the role of many cells, cytokines, chemokines, enzymes, and other factors in the pathology of asthma. These studies are too numerous to document here. Instead, we focus on three issues. One, the role of lymphocytes, can be seen as a major success of these models. Two others, the role of IgE and mast cells, and the role of eosinophils are instances where the models do not appear to reproduce the human findings.

*Role of T-lymphocytes in allergen-induced airway responses*: A major accomplishment of studies using these murine models was in establishing a role for lymphocytes in the development of allergic asthma. For example, following allergen sensitization and challenge, AHR does not develop in athymic mice or in mice with severe combined immunodeficiency, but adoptive transfer of lymphocytes from wild-type sensitized and challenged mice restores AHR in athymic mice [18, 19]. A particular role for CD4$^+$ T-lymphocytes was established by experiments demonstrating that MHC Class II deficient mice lacking mature CD4$^+$ T-lymphocytes and mice depleted of CD4$^+$ T-cells do not develop AHR or airway inflammation following allergen sensitization and challenge [20, 21]. The requirement for CD4$^+$ T-cells was also underscored by the observation that reconstitution of CD4$^+$ T-cells alone is sufficient to restore allergen-induced AHR to RAG$^{-/-}$ mice which lack both B- and T-lymphocytes [22]. It has since been established that other T-cell subsets including γδ-T-cells, iNKT cells, and regulatory T-cells may have roles in enhancing or attenuating allergic airways disease in these mouse models [23–26].

A major focus of research using these models over the last decade has been to establish how T-lymphocytes contribute to allergic airway responses. Early on, it was established that the ability of these cells to generate cytokines was likely to be important. Initial work focused on IL-4, IL-5, and IL-13 [19, 20, 22, 27–31]. More recently, other cytokines, including IL-17, have received increasing attention [32–34].

*Role of IgE and mast cells in allergen-induced AHR*: Mast cells express receptors (FcεRI) on their surface that bind the Fc portion of IgE with high affinity. Crosslinking FcεRI receptors upon binding of allergen to IgE results in the secretion of a panel of mediators including histamine, eicosanoids, and cytokines, many of which have the capacity to cause bronchoconstriction and to elicit AHR, though it is important to note that IgE independent activation of mast cells can occur in response to complement proteins, neuropeptides, and other moieties. In humans, activation of mast cells by IgE is important for both early and late responses to allergen inhalation: treatment with the humanized anti-IgE antibody, omalizumab, markedly reduces both the rapid and delayed declines in FEV$_1$ that occur following inhalation of allergen [35]. An important drawback of using mice is that such airway obstruction is not easily observed [36]. Small increases in pulmonary resistance (R$_L$) (less than 50% increase) can be observed following systemic administration of activating anti-IgE antibodies [37], but R$_L$ changes little after airway challenge with allergen [36]. This is in marked contrast to many other species which develop marked increases in R$_L$ after inhalation of allergen [38–40].

Mast cells and IgE also appear to play a role in the airway inflammation that occurs after allergen challenge in asthmatics [41], but the ability of mouse models to reproduce this phenomenon has not been consistent. Kung *et al.* [42] reported that aerosol OVA challenge of systemically sensitized mast cell deficient mice resulted in fewer eosinophils in BAL fluid and lung tissue compared to congenic controls, whereas others [10, 43–45] have failed to observe any effect of mast cell deficiency or IgE deficiency on the recruitment of eosinophils. At least part of this discrepancy is likely related to the precise protocol used to sensitize and challenge the mice. Kobayashi *et al.* used two distinct protocols to sensitize and challenge mast cell deficient mice and found reduced eosinophils compared to strain matched controls when relatively mild protocols for airway challenge that resulted in relatively few eosinophils were employed, but no difference between mast cell deficient and control mice when more frequent and robust airway challenges that produced marked increases in eosinophils were used [43].

*Role of eosinophils in allergen-induced AHR*: Eosinophils contain cationic proteins such as major basic protein (MBP) that have the capacity to induce AHR [46] and experiments in mice in the late 1990s provided strong evidence that eosinophils may be responsible for the AHR associated with allergic asthma. For example, in mice, transgenic overexpression of IL-5, a differentiation, chemoattractant, and survival factor for eosinophils, led to accumulations of eosinophils and AHR even in the absence of allergen challenge [47]. Following OVA sensitization and challenge, both accumulation of eosinophils in the airways and AHR were prevented in IL-5 deficient compared to wild-type mice and reconstitution of IL-5 in these knockout mice restored pulmonary eosinophilia and AHR [48, 49]. Similar results were obtained using anti-IL-5 antibodies [50]. The observation of a good correlation between airway eosinophils and AHR across multiple strains of mice, all sensitized and challenged in the same way, also argued for a relationship between these factors [13]. Data such as those cited above were strong enough to initiate clinical trials for anti-IL-5 in human asthma. However, the results of such trials have been disappointing. For example, a recent fairly large study showed that while anti-IL-5 antibody treatment results in marked suppression of both blood and sputum eosinophils, it does not impact pulmonary function, β-agonist use, symptom or quality of life scores in patients with persistent asthma symptoms despite inhaled corticosteroid use [51], although it has been argued that the study population (one of difficult to control asthma) could have biased the study [52]. Did our mouse models lead us astray? There are certainly data from mouse models arguing against a role for eosinophils in the AHR associated with allergen sensitization and challenge [19, 53, 54]. Mouse strain and the strength of the allergen challenge appear to impact whether a role for eosinophils are observed or not: experiments performed in Balb/c mice in which milder challenges are used indicate little role for eosinophils in OVA-induced AHR [5].

*Summary*: Mice are not useful for modeling the early or late responses to allergen, but models in which mice are sensitized and then challenged with allergen have been useful in establishing a role for T-lymphocytes in asthma and are currently being used to investigate the T-cell subsets and cytokines involved. Refinements in these models involving chronic challenges may ultimately allows us to use such models to study the airway remodeling that characterizes asthma, but are currently in their infancy. The protocol used to sensitize and challenge the mice, and the choice of mouse strain are key issues and can influence outcome.

## Modeling obesity and asthma

Obesity is a risk factor for asthma. Both in adults and children, the prevalence and incidence of asthma increase with body mass index (BMI) (see recent reviews [55–58]). Obesity also appears to worsen asthma control and may increase asthma severity. In addition, both surgical and diet-induced weight loss improve many asthma outcomes. The efficacy of many standard asthma medications is altered in the obese [58, 59], suggesting that additional therapeutic strategies may be necessary in this population. Development of these strategies will require an understanding of the mechanistic underpinnings of the relationship between obesity and asthma. To that end, mice have been used to model the relationship between obesity and asthma. These studies have established that obese mice exhibit a pulmonary phenotype that includes both innate AHR, as well as increased responses to ozone ($O_3$) and allergen [60–65], and suggest a role for adipokines in the obesity–asthma relationship [66, 67].

Several types of obese mice have been used in these studies (see Ref. [68] for details). *Ob/ob* mice are genetically deficient in leptin, a satiety hormone synthesized by adipocytes and released into blood in proportion to adipose tissue mass. In the absence of leptin, *ob/ob* mice eat excessively, have a low resting metabolic rate, and by 8 weeks of age weigh at least twice as much as wild-type controls [69]. The increased body weight is entirely the result of an increase in fat mass. *Db/db* mice are genetically deficient in the long form of the leptin receptor, which is required for leptin's effect on satiety and metabolism [69]. Thus, *db/db* mice are similar to *ob/ob* mice in many respects: they overeat, are hypothermic and inactive, and massively obese. However, short forms of the leptin receptor with truncated or absent cytoplasmic domains are expressed in these mice, and are capable of some types of signaling. Hence, there can be subtle differences between *ob/ob* and *db/db* mice, including differences in their pulmonary phenotype [60]. *Cpe^{fat}* mice are genetically deficient in carboxypeptidase E (Cpe), an enzyme involved in processing of neuropeptides involved in eating behaviors. Obesity develops more slowly in these mice than in *ob/ob* or *db/db* mice, but can be quite marked [69]. Dietary obesity can also be induced by feeding weanling C57BL/6 mice a diet in which 45% or 60% of calories are derived from fat (predominantly in the form of lard). Diet-induced obesity (DIO) develops slowly and is much less marked than in the genetic obesities. All of these obese mice are hyperglycemic, hyperinsulinemic, and hyperlipidemic to some extent [68, 69].

*Innate AHR*: Airway responsiveness to intravenous methacholine is increased in *ob/ob*, *db/db*, and *Cpe^{fat}* mice, and in mice with DIO [60–65], indicating that it is a common feature of murine obesity. Consistent with the

non-specific nature of human asthma, AHR is observed following both methacholine and serotonin challenges [60]. Both the magnitude and the duration of obesity appear to play some role in the development of AHR in obese mice. For example, AHR is more marked in *ob/ob* and *db/db* mice than in *Cpe^{fat}* mice or mice with DIO. Mice do not exhibit AHR when they are raised on high-fat diets for approximately 16 weeks, but AHR is observed after 30 weeks on the diet, even though body weight averages about 40% more than low-fat fed controls at both time points [61].

The mechanistic basis for the AHR observed in obese mice is not known. However, the mice do not have any overt cellular inflammation in their lungs [60, 63]. All measurements were made in open-chested mice, mechanically ventilated at a fixed positive end-expiratory pressure (PEEP) and a fixed tidal volume, so changes in absolute or tidal volume likely do not play a role. In *ob/ob* and *db/db* mice, there are effects on lung development: despite their massive obesity, these mice have small lungs [60, 65]. However, lung size is not affected in *Cpe^{fat}* mice and mice with DIO, but these mice still exhibit AHR [61, 62]. Instead, it is likely that some aspect of the chronic low-grade systemic inflammation that characterizes the obese state [70] contributes to the AHR observed in obese mice. For example, preliminary data in both *db/db* and *Cpe^{fat}* mice indicate that treatment with anti-TNF-$\alpha$ antibodies reduces airway responsiveness [71].

*Responses to $O_3$*: Exposure to $O_3$, a common air pollutant, is a trigger for asthma. Hospital admissions for asthma are higher on days of high ambient $O_3$ concentrations [72] and in children, $O_3$ increases asthmatic symptoms even at concentrations below the US Environmental Protection Agency standard [73]. $O_3$ causes airway inflammation, as well as AHR, both of which may contribute to the ability of $O_3$ to exacerbate asthma.

Obesity impacts the effects of $O_3$ in the lung. Both the changes in pulmonary function and the AHR induced by $O_3$ exposure are increased in obese versus lean human subjects [74, 75]. Similar results are observed in obese mice regardless of the nature of their obesity. Acute exposure to $O_3$ (2 ppm for 3 h) increases $R_L$ in obese but not lean mice and induces greater AHR in obese versus lean mice [60, 62, 65]. Compared to lean controls, $O_3$-induced injury and inflammation are also greater in *ob/ob* mice, *db/db* mice, *Cpe^{fat}* mice, and mice with DIO [60–62, 65]. However, the factors that contribute to the innate AHR of obese mice appear to be different from those that contribute to their increased response to acute $O_3$: increased $O_3$-induced inflammation is observed as early as 7 weeks of age in *Cpe^{fat}* mice [76], whereas AHR is not observed until they are 10 weeks old.

At least part of the increased response to $O_3$ observed in obese mice appears to derive from differences in IL-6 signaling. Following acute $O_3$ exposure, obese mice have increased IL-6 release into BAL fluid compared to lean mice [60, 62, 65]. Treatment with anti-IL-6 antibodies ablates the accelerated neutrophil influx that is observed following acute $O_3$ exposure in *ob/ob* mice and also attenuates the enhanced $O_3$-induced epithelial injury that is observed in these mice [77]. Pulmonary expression of signal transducer and activator of transcription-1 (STAT-1) is reduced in *ob/ob* mice [77] and may modify pulmonary responses to IL-6 in these mice.

*Responses to allergen*: Some, but not all, aspects of the response to allergen are augmented in obese mice. For example, following OVA sensitization and challenge, splenocyte proliferation, IL-2 production, and mast cell numbers are increased in mice with DIO compared to lean controls [78]. Increased OVA-induced AHR is also observed in obese mice [63]. However, this increase in airway responsiveness occurs in the absence of any differences in Th2 cytokines and in the face of *decreases* in BAL eosinophils compared to lean controls, suggesting that other factors must contribute. Interestingly, OVA-induced increases in serum IgE are also greater in *ob/ob* and *db/db* mice than in lean controls. As described above, IgE and mast cells do not appear to contribute prominently in most studies of allergen-induced airways disease in mice. However, the expression of 5-lipoxygenase activating protein is substantially increased in the adipose tissue of *ob/ob* mice [79]. This could lead to greater leukotriene synthesis and subsequent release from activated mast cells and thus enhance airway responsiveness. In this context, Peters-Golden *et al.* recently reported a more beneficial effect of the leukotriene antagonist montelukast in obese versus lean asthmatics [80].

*Adipokines*: Several hypotheses have been proposed to explain the association between obesity and asthma (Fig. 8.1). For example, obesity results in changes in a variety of adipose tissue derived factors (adipokines) that may contribute to the relationship between obesity and asthma. Serum leptin is increased in obesity and two cross-sectional studies indicate that leptin is also increased in asthmatics [81, 82]. Numerous reports indicate that leptin is pro-inflammatory (see recent review [83]), and these inflammatory effects could exacerbate asthma in the obese. Leptin treatment has been shown to augment allergen-induced AHR in lean mice, without affecting eosinophil influx or Th2 cytokine expression [66]. Indeed, rather than modifying adaptive immunity, leptin could be acting on the innate immune system: exogenous administration of leptin to lean mice increases their subsequent inflammatory response to acute $O_3$ exposure [65], a response characterized by release of acute phase cytokines and chemokines, and dependent to some extent on toll-like receptor activation [84]. However, there must be factors in addition to

leptin that contribute to the augmented $O_3$ responses of obese mice, since such responses are observed not only in *Cpe^fat* and DIO mice [61, 62] that have marked increases in serum leptin, but also in *ob/ob* and *db/db* mice [60, 65], that lack either leptin or the leptin receptor.

In contrast to other adipokines, adiponectin, an insulin-sensitizing hormone, declines in obesity [85, 86]. In contrast to leptin, adiponectin has important anti-inflammatory effects in obesity [86]. In lean Balb/c mice, exogenous administration of adiponectin results in an almost complete suppression of OVA-induced AHR, airway inflammation, and Th2 cytokine expression in the lung [67]. Adiponectin has been shown to inhibit macrophage production of lymphocyte chemotactic factors [87]. An adiponectin-induced reduction in lymphocyte influx into the lungs would be expected to reduce pulmonary concentrations of Th2 cytokines and could thus be responsible for attenuating eosinophilia and AHR following OVA challenge. Three adiponectin receptors have been cloned: adipoR1, adipoR2, and T-cadherin [88, 89]. Lung tissue expresses all three adiponectin receptors. The expression of all three receptors declines in the lungs following allergen sensitization and challenge in mice [67], suggesting that asthma may be a state of adiponectin resistance. Coupled with obesity-related declines in adiponectin [85, 86] and additional declines in serum adiponectin that occur with allergen challenge [67], the data suggest that the obese asthmatic is likely to have defects in this important immuno-modulatory pathway that augment the effects of allergen challenge.

## MOUSE MODELS OF COPD

### Modeling COPD

Animal models were critical to the development of the elastase:anti-elastase hypothesis generated 45 years ago. This hypothesis remains the cornerstone of our understanding of COPD pathogenesis today. The major finding at that time was that instillation of the proteinase papain into experimental animals caused airspace enlargement, the characteristic feature of emphysema [1]. Since then animals have been exposed to a variety of molecular, chemical, and environmental agents that lead to airspace enlargement [90]. In particular elastases [91–93], cigarette smoke [94, 95], and more recently inducers of apoptosis have been most informative [96, 97]. Mouse genetic mutants have also been critical in furthering our understanding of the pathogenesis of COPD [4, 95].

*Elastases*: Ever since the initial findings with papain, a variety of proteinases have been instilled into experimental animals. Of note, only those with elastolytic activity develop emphysema, collagenases do not [91]. Of most utility has been porcine pancreatic elastase (PPE) [91, 98, 99], a potent elastase that quickly generates airspace enlargement. This model has also been useful to test agents that have the capacity to restore lung structure such as retinoic acid [100]. A recent surprise has been the usefulness of PPE to model events upstream from elastolysis. This is likely due to the

fact that elastin fragments themselves [101] are chemokines, and that the events following PPE instillation are very similar to the inflammatory cell cascade that one observes in COPD following cigarette smoke exposure. That is, initially PPE leads to acute airspace enlargement with elastin destruction and release of fragments of elastin and other matrix proteins. This results in subsequent neutrophilia followed within days by a predominant macrophage and T-cell influx. These activated inflammatory cells release endogenous elastases causing progressive airspace enlargement.

*Environmental factors*: Cigarette smoke is clearly the major etiologic factor for COPD. However, a variety of other environmental agents have been applied to determine their capacity to induce COPD. Nitrogen dioxide and ozone cause mild lung injury suggesting that they may be modifying environmental factors but unlikely primary environmental factors leading to COPD [90]. Cadmium chloride [102], a constituent of cigarette smoke, primarily causes interstitial fibrosis tethering open adjoining airspaces simulating emphysema. While this mechanism differs from airspace enlargement secondary to matrix destruction that characterizes emphysema, excess collagen deposition in the context of loss of elastin is a feature of human centrilobular emphysema.

*Cigarette smoke* [4, 94, 95]: The great strength of cigarette smoke-induced models of COPD is that we know that this is the causative agent for COPD. Hence, pathways leading to phenotypic changes of COPD mirror those of human COPD, limited only by differences in smoke exposure as well as biological differences between mice and humans. Over the years many species of mammals have been exposed to cigarette smoke using a variety of smoking chambers. Larger animals are limited by the long (years) duration of exposure required for development of COPD. Of small animals tested, the guinea pig is the most susceptible species and rat the least. Several inbred mouse strains are also susceptible to cigarette smoke-induced COPD, and hence they have dominated the literature due to our ability to manipulate gene expression as well as other advantages discussed above.

Following exposure to cigarette smoke, mice develop changes similar to humans including acute inflammation with neutrophils followed by subacute increases in macrophages, and $CD8^+ > CD4^+$ T-cells [103]. Proteinases are released and apoptosis of structural cells is observed. These processes ultimately lead to airspace enlargement that is easily detectable in most strains within 6 months. With respect to the airway, mice lose cilia upon cigarette smoke exposure, develop small airway fibrosis, and also develop goblet cell hypertophy [4, 104].

*Apoptosis*: Recently investigators have found that exposure to agents that initiate either endothelial cell death (via VEGFRII inhibition) [96] or epithelial cell death (via caspase 3 nodularin, ceramide delivery, and VEGF inhibition) [97, 105, 106] lead to non-inflammatory airspace enlargement. Clearly, to lose an acinar unit, one must destroy both extracellular matrix (ECM) and structural cells. Traditionally, we believed that inflammatory cell proteinases destroy ECM and cells unable to attach to the ECM float away and die. The apoptotic models suggest death of structural cells may be an initiating event, with subsequent release of matrix degrading proteinases.

Whether this occurs in human COPD as a primary event is uncertain, but does raise interesting testable possibilities.

*Genetic models*: Natural genetic mutants, transgenic mice, and gene-targeted mice, may develop spontaneous airspace enlargement of developmental origin. They may also develop progressive airspace enlargement acquired spontaneously over time that more closely reflects the destruction of mature lung tissue characteristic of emphysema [4, 99]. Overexpression or underexpression of a protein during development that leads to failed alveogenesis and enlarged airspaces is very informative regarding pathways required for normal lung development and hence repair in emphysema. However, this is very different from destruction and enlargement of normal mature alveoli that defines pulmonary emphysema.

If overexpression of a protein in transgenic mice leads to airspace enlargement in the adult, then *if* the protein is overexpressed in the endogenous process it is likely to play a role. For example, instillation of PPE mimics emphysema quite well, but of course PPE does not travel from the gut to the lung in true emphysema.

Of most utility in dissecting the pathogenesis of COPD are developmentally normal gene-targeted mice applied to cigarette smoke. Protection of a "knockout" with smoking suggests that the protein deleted is involved in a pathway that promotes COPD, while worsening COPD suggests a protective factor was deleted. There are many proteins that have been identified using these techniques as recently reviewed [99]. Knowledge gained from these studies will be synthesized below.

*Limitations*: The mouse lung structure is not identical to humans. Mice do not inhale cigarettes as humans would and these obligate nasal breathers bring the smoke through an extensive olfactory epithelium into the airway where there are few submucosal glands, much less airway branching, and no respiratory bronchioles – the initial site of centriacinar emphysema. Hence, mice do not develop "small airway disease" that is so important in human COPD. Nevertheless, the opportunity exists to infect mouse airways with relevant human pathogens to learn more about airway changes and exacerbations of COPD.

Mice require months of cigarette smoke exposure to develop mild emphysema. These are more likely to reflect Global Initiative for Chronic Obstructive Lung Disease (GOLD) stage I and II not the severe stages of COPD (III and IV). Moreover, there is a variety of smoking chambers now available that differ with respect to the mode, rate, and amount of smoke delivered. Particulate amounts, carboxyhemoglobin levels, and other surrogates of exposure are often measured to assess how well these mimic human exposure. The most important features are the resultant phenotypic changes in the exposed animals and their relationship to humans. One note of caution is that excessive acute exposure to smoke leads to acute lung injury with pronounced neutrophilia, which is not likely to reflect COPD.

## Lessons from mouse models of COPD

*Inflammatory cell network in COPD*: Animal models have taught us that emphysema is not caused by a single cell type or proteinase. Rather, multiple inflammatory and immune cells and mediators are involved. Investigators are now focused on teasing out mechanisms that lead to this complex network and the interactions between these cells and their mediators that leads to COPD.

Upon acute exposure to cigarette smoke one observes activation of macrophages and structural cells that leads to a mild, acute, transient accumulation of neutrophils in the lung. Over days to weeks one also observes increased number of T-cells, particularly $CD8^+$ T-cells, and macrophages [107]. Neutrophils accumulate with each acute exposure, but due to the short-half life of the neutrophil do not accumulate to high levels. The longer-lived macrophages and T-cells progressively accumulate with chronic smoke exposure. In humans, one observes B-cell accumulation in bronchial–alveolar lymphoid tissue (BALT) late in the disease. While this could be secondary to bacterial colonization in humans, it has also been observed in mice exposed to cigarette smoke in the absence of infection [108].

An undoubtedly simplistic but unified pathway, supported by data from cigarette smoke-exposed mice, can account for much of the inflammation observed in response to cigarette smoke. Cigarette smoke, via its oxidant properties, can activate macrophages leading to TNF-$\alpha$ production with latent TNF-$\alpha$ translocating to the surface whereupon MMP-12 "sheds" active TNF-$\alpha$ leading to neutrophil recruitment and activation [109].

Release of MMP-12 from macrophages and collagenases MMP-8 and MMP-13 (MMP-1 not expressed in mice) from macrophages and likely epithelial cells leads to generation of elastin and collagen fragments respectively. Elastin fragments serve as chemokines for macrophages [101] and collagen fragments promote neutrophil recruitment [110]. Indeed, in humans CXC and CC chemokines may play a significant role in inflammatory cell migration, particularly when colonized with bacteria. However, in mice under sterile conditions, elastin fragments appear to be critical to the low-level macrophage accumulation one observes in response to cigarette smoke.

T-lymphocytes, particularly $CD8^+$ T-cells, are increased in lungs of patients with COPD [111]. Overexpression of the T-cell product IFN$\gamma$ in transgenic mice, results in apoptosis, inflammation, and emphysema [112]. Moreover, IFN$\gamma$ and IFN$\gamma$-IP-10 (interferon-gamma-inducible protein-10) have been shown to be increased in $CD8^+$ T-cells from patients with emphysema, and IP-10 was also shown to induce the production of MMP-12 in human alveolar macrophages [113]. In addition to this potentially indirect influence of $CD8^+$ T-cells on emphysema, they may also directly cause cytotoxicity contributing to emphysema. The importance of the $CD8^+$ T-cell in the pathogenesis of emphysema, was recently confirmed by subjecting wild-type (C57BL/6 J), $CD8^+$ T-cell deficient ($CD8^{-/-}$) mice, and $CD4^+$ T-cell deficient ($CD4^{-/-}$) mice to a model of cigarette smoke-induced emphysema [107]. In the absence of $CD8^+$ T-cells, but not $CD4^+$ T-cells, there was a marked inhibition in inflammation and emphysema. Integrating these results into the "network," one can conclude that $CD8^+$ T-cells via production of IP-10, signal through macrophage CXCR3 to activate the macrophage leading to proteinase and cytokine production. The macrophage then recruits neutrophils, and their proteinases

then degrade ECM, particularly elastin and collagen, continuing the inflammatory cascade. Hence, $CD8^+$ T-cells may be the master regulator of inflammation in COPD. Of note, these results are entirely consistent with data from human COPD.

Defects in adaptive immunity are also likely to play an important role with respect to colonization of microorganisms in the airway and exacerbations. Prolonged cigarette smoke exposure (1 month) in mice results in a decrease in lung dendritic cell (DC) number, but DC migration to regional thoracic lymph nodes remains intact. Once in the lymph nodes, however, cigarette smoking suppresses maturation of DCs as demonstrated by the reduced expression of co-stimulatory molecules. Moreover, these cigarette smoke exposed DC cells have impaired capacity to activate $CD4^+$ T-cells with less IL-2 production and diminished T-cell proliferation [114]. Impaired $CD4^+$ T-cell activation would predispose patients to colonization with infectious microorganisms.

As discussed, B-cells and BALT are present in COPD lung tissue, however, their role in the disease process remains to be determined. Of note, recent animal [115] and human [116] studies have implicated autoimmune processes in the pathogenesis of COPD. In fact, elastin fragments themselves were shown to be an important autoimmunue target in COPD in human studies [116]. Other cell types including eosinophils, mast cells, and natural killer (NK) cells are also likely to be involved in this inflammatory cell network, but to date, they have not been carefully addressed.

*Role of oxidative stress in COPD*: Cigarette smoke, loaded with $10^{17}$ oxidant molecules per puff leads to increased oxidative stress in smokers and in patients with COPD. Oxidative stress, in part through inactivation of histone deacetylases, exposes DNA sequences and activates transcription factors for inflammatory genes, such as nuclear factor-κB (NF-κB) and activator protein (AP)-1 [117]. This finding, initially in humans, has been confirmed in rodents exposed to cigarette smoke [118]. Oxidants also have a significant role in promoting apoptosis, and although oxidants do not directly degrade ECM proteins, they might modify these proteins making them more susceptible to proteolytic cleavage. Oxidative stress also can alter the structure of pro-MMPs leading to autolytic cleavage and activation [119]. Gene deletion of Nrf-2 a master transcription factor for antioxidant genes also leads to enhanced emphysema in response to cigarette smoke exposure highlighting the importance of oxidative stress in COPD [120].

*Role of proteinases in COPD*: As mentioned at the beginning of this chapter and reviewed in depth in the "Matrix Degrading Proteinase" (Chapter 28), ECM destruction by proteinases is the cornerstone of emphysema. Animal models have played an important role in defining the contribution of different elastolytic enzymes in this process. In addition to the original instillation of papain by Gross [1], in one of the first applications of gene-targeted mice to lung disease, it was shown that macrophage elastase (MMP-12) deficient mice were protected from the development of emphysema [95]. As in several other models of disease, MMP-12 is pro-inflammatory, which in part is related to the generation of chemotactic elastin fragments [101].

Subsequently, several other animal models have demonstrated the importance of proteinases in COPD.

Lung-specific transgenic mice expressing either the Th2 cytokine IL-13 ("Dutch mice") [121] or the Th1 cytokine IFN-γ ("British mice") [112] both develop proteinase-dependent emphysema. IFN-γ overexpressors develop a cysteine proteinase/apoptosis mediated form of emphysema, while IL-13 overexpression induces inflammation with MMP-12- and MMP-9-dependent airspace enlargement. IL-13 transgenic mice also develop small airway remodeling that is believed to be due to MMP-9-dependent activation of TGF-β with airway fibrosis [122]. The role of TGF-β in emphysema was also highlighted with $a_v b6^{-/-}$ mice, that are unable to activate TGF-β in the airspace, develop macrophage inflammation and MMP-12-dependent emphysema [123]. TGF-β regulation is complex as total absence of TGF-β releases the brake on inflammation and destruction in the airspace while too much TGF-β leads to fibrosis in the airways.

Other gene-targeted mice that develop emphysema include surfactant protein $D^{-/-}$ ($SP-D^{-/-}$) mice, which exhibit macrophage activation, MMP production, and consequent emphysema [124]. TIMP-3 deficiency leads to a combination of developmental airspace enlargement combined with progressive destructive emphysema in adults [125], supporting the role of MMPs in COPD. There is also evidence from animal models that neutrophil elastase (NE), a serine proteinase long thought to cause COPD, is also involved in experimental emphysema. $NE^{-/-}$ mice develop only 40% as much airspace enlargement as wild-type mice exposed to long-term cigarette smoke [126]. These studies have uncovered several interactions between NE and MMPs. MMPs degrade α1-AT and NE degrades TIMPs, each potentiating the other's proteinase activity. Moreover, NE mediates monocyte migration and as discussed, acute neutrophil inflammation secondary to smoking is related to MMP-12-dependent TNF-shedding [109].

*Role of apoptosis in COPD*: As discussed above, induction of structural cell apoptosis leads to airspace enlargement. However, there are some aspects of these models that do not mimic human disease. They are non-inflammatory and transient, which is likely related to their lack of matrix degradation. Most importantly, however, closer pathologic and physiologic examination of at least one model of epithelial cell apoptosis demonstrates that this model is not emphysema *per se*, but acute lung injury with collapsed alveoli tethering of open adjoining airspaces to appear enlarged (Mouded M and Shapiro SD, unpublished observations). Thus, like other traditional models of epithelial apoptosis, bleomycin being the classic, the result is acute lung injury and if severe, fibrosis. Endothelial apoptosis could have a different outcome, but it is likely that apoptosis does not initiate emphysema. Apoptosis, however, is likely to be a critically important modifier in the pathogenesis of COPD. For example, as in humans, apoptosis is observed in animal models following cigarette smoke exposure, likely due to loss of basement membrane attachment +/− oxidant effects of cigarette smoke. The fate of the apoptotic cell is critical to disease progression. Clearance by macrophages leads to anti-inflammatory TGF-β production and release of growth factors that promote repair [127]. Inefficient clearance leads to secondary necrosis, augmenting inflammation and destruction.

*Role of repair in COPD*: The ability of the adult lung to repair damaged alveoli appears limited. This is likely due to the structural and functional dependence upon the elastic fiber architecture combined with the difficulty in repairing elastic fibers. Whether one can temporally and spatially bring together the multiple microfibrillar components of an elastic fiber let alone coordinate matrix repair with endothelial and epithelial migration and differentiation over an injured matrix is unknown.

With the emergence of regenerative medicine and stem cell biology, there is hope that we can one day create new functional lung tissue. However, given the complex three-dimensional nature of the lung, its regeneration presents a special challenge relative to other organs. It is currently not known whether there is a master stem cell, separate progenitors for each cell type, nor what their reparative capacity is. More importantly, given the collapse of the elastic fiber cable network, it is unclear whether stem cells alone could regenerate a functional alveolar unit.

There has been some evidence that one can repair emphysematous lung tissue in animal models. The study by Massaro *et al.* [100] discussed above, showing that all-trans retinoic acid reversed PPE-mediated emphysema, has led to hope that we might be able to promote lung repair [100]. Use of retinoic acid did not have significant effects in human trials, but has opened the door to mechanisms that could be reparative.

There have been attempts to add growth factors, such as keratinocyte growth factor (KGF) to elastase-treated lungs. The results demonstrate the ability to protect from injury, but not repair damaged tissue [128]. The advent of lineage tagged and lineage ablated genetically engineered mice will be helpful to define progenitor cells and their reparative capacity in the future.

## SUMMARY

It is important to keep in mind that there are important structural differences in the lungs of mice and humans and to interpret animal data with caution. In some instances, murine models of allergic asthma have not recapitulated the human findings, and have led to some costly failures in drug development. Nevertheless, animal models have been extremely useful in the evolution of current concepts regarding the etiology of asthma and COPD and genetically engineered mice continue to drive the generation and testing of new hypotheses.

# Inflammatory Cells and Extracellular Matrix

# Mast Cells and Basophils

**George H. Caughey**

Cardiovascular Research Institute and Department of Medicine, University of California at San Francisco, USA

Mast cells and basophils first came to attention over a century ago due to their ample stocks of intracellular granules with unusual staining characteristics. For many years their origins, normal functions, and roles in disease were obscure, and in some respects remain so. Nonetheless, knowledge of their biology increased tremendously in the past two decades [1–5].

Researchers once focused on mast cell and basophil release of histamine and eicosanoids in acute allergic events, which were considered to be a corruption of hypothesized normal function of defending against invasion by parasites such as worms and ticks. However, studies in mice now suggest that mast cells contribute to innate immune defense against airway bacteria like mycoplasma [6] and protection from immunologically nonspecific injury, as from venoms [7]. Mast cells and basophils also have the demonstrated potential to influence immune system development, regulation, and initiation of the immune response [8–11]. In some contexts, the overall contribution of mast cells is anti-inflammatory [6]. These roles deviate from traditional concepts of mast cell and basophil participation in adaptive responses involving antigen recognition by IgE.

In asthma investigations, attention is shifting from roles of these cells in acute responses to aeroallergen to roles in promoting persistent inflammation and remodeling in chronic disease. Their roles in other obstructive lung diseases have received less attention, but they may indeed contribute to conditions apart from asthma.

This chapter summarizes current thinking about roles of mast cells and basophils in obstructive airway disease.

## ORIGIN AND FATE

Mast cells and basophils have shared origins but distinct distributions and fates. Mast cells, but not basophils, are normal residents of uninflamed airways. Mature mast cells rarely appear in blood, whereas mature basophils circulate and are recruited from blood to sites of allergic inflammation. Both cell types originate from shared progenitors in bone marrow; see Lee and Krilis [12] for a review. Immature mast cells released from marrow circulate briefly, exit the bloodstream to multiple tissue destinations, then differentiate, adopting a phenotype determined by their microenvironment. Basophils, on the other hand, mature in the marrow, circulate, then home to sites of inflammation if recruited to do so. Tissue mast cells are not fixed in location, for they migrate toward airway epithelium after antigen challenge and traffic to lymph nodes from sites of antigen exposure. Mast cells probably also proliferate in tissues. Conditions such as gut parasitosis lead to large local increases in mast cells.

Both types of cell survive degranulation and can restock their secretory granules with mediators. Life span *in vivo* has not been established, but *in vitro* studies predict that basophils are short-lived compared to mast cells, which survive for weeks in culture. In humans, the aggregate mast cell mass is much larger than that of basophils, which usually comprise <1% of circulating leukocytes. Among mammals, basophil numbers vary widely, ranging from numerous in guinea pigs, few in humans and mice, to nearly nonexistent in dogs, in which they are arguably unimportant. There are genetic variants of mice with almost no mast cells but

none with an inherited, selective deficit of basophils; thus, it is easier to assess involvement of mast cells than of basophils in mouse disease models; see Galli [5] for a review.

## DEVELOPMENT AND HETEROGENEITY

Paucigranular, mast cell-committed progenitors are released from marrow expressing surface receptor tyrosine kinase c-kit and low affinity IgG receptor ($F_c\gamma RII$) but not high affinity IgE receptor, $F_c\varepsilon RI$. *In vitro*, cells with mature characteristics, including $F_c\varepsilon RI$ and protease-rich granules, differentiate from progenitors under the influence of IL-6 and kit ligand. Presumably, similar events occur *in vivo*, with kit ligand produced by endothelial, stromal, and epithelial cells being critical for mast cell survival. Mice with defective c-kit or its ligand lack mast cells. Their importance to mast cell development is underscored by gain-of-function c-kit mutations in systemic mastocytosis and mast cell malignancy, and development of generalized mastocytosis in response to exogenous kit ligand. The importance of local production of kit ligand is suggested by the finding in mice that intratracheal kit ligand provokes mast cell-dependent hyperreactivity [13].

*In vitro*, a variety of cytokines (especially IL-3, -6, -9 and -10, and TGF-$\beta$1) determines phenotype of maturing mouse mast cells. In the case of IL-9 (a candidate mouse "asthma gene"), airway overexpression in transgenic mice causes eosinophilic inflammation and hyperresponsiveness with mast cell hyperplasia [14].

Mast cells vary in features such as:

- proteoglycan and protease content;
- metachromasia;
- granule ultrastructure;
- responses to degranulating stimuli, such as substance P.

These phenotypic variations appear reversible in a given cell and changeable in cell populations in response to infection and injury. Classically, rodent mast cells are divided into "mucosal" and "connective tissue" groups, although the phenotype distribution is not strictly bimodal. Human mast cells are sorted into subsets based on content of granule proteases [15]. $MC_T$ cells express tryptases but not chymase, whereas $MC_{TC}$ express tryptases and chymase. Occasionally, chymase-only $MC_C$ mast cells are seen. Bronchi contain a mixture of types, whereas alveolar interstitium contains predominantly $MC_T$. Because mast cells develop and are stimulated in tissues, some variation is due to differences in maturation, activation, or recovery from degranulation.

Less is known of factors influencing basophil differentiation. c-Kit appears less important than for mast cells because mature basophils normally express little or no c-kit and because levels are largely unaffected by defects in c-kit causing profound mast cell deficits in mice. Nonetheless, c-kit+ human basophil-like cells circulate in asthma and atopy and manifest phenotypic changes in which c-kit could play a role [16].

## RECRUITMENT

In asthmatics, increased numbers of basophils and activated mast cells appear in sputum after allergen challenge [17], which may reflect migration from submucosal sites and bloodstream, respectively. As noted, mast cell precursors home to tissues even without inflammation. Constitutive homing and epithelial migration may involve responses to proteins such as:

- C5a;
- RANTES;
- IL-8;
- MIP-1$\alpha$;
- MCP-1;
- VEGF;
- fractalkine;
- CXCL10;
- kit ligand.

These may orchestrate movement singly or in combination. Cultured human mast cells express a broad repertoire of chemokine receptors, which diminishes as cells mature, thus limiting mast cell movement after differentiation at a tissue site.

Kit ligand is notable in that it is specific for mast cells in comparison with other leukocytes and is produced by airway cells. Mast cell migration into tissues depends on integrins and other adhesion molecules [18]. Basophils express an array of chemokine receptors. Chemokines binding to CCR3 (such as RANTES and eotaxins) may be especially important [19, 20]. The multiplicity of chemoattractants predicts redundant recruiting pathways. Several chemoattractants also prime or activate one or both types of cells [20, 21], enhancing their role in asthma pathogenesis beyond that of recruitment alone.

## ACTIVATION

### IgE-dependent activation

Classic mast cell and basophil activation involves docking of allergens to IgE via $F_c\varepsilon RI$ expressed as an assemblage of subunits ($\alpha\beta\gamma_2$) in the plasma membrane. $F_c\varepsilon RI\alpha$ expression is strongly influenced by the serum level of IgE itself [22]. Aeroallergens with repeating epitopes attach to receptor $\alpha$ chain-bound IgE, bridging receptors. Allergen-driven cross-linking initiates intracellular signaling characterized initially by phosphorylation of intracellular immunoreceptor tyrosine-based activation motif (ITAM) domains of receptor $\beta$ and $\gamma$ chains. In turn, these recruit and activate nonreceptor tyrosine kinases, especially lyn, syk, and btk, which access pathways leading to exocytosis and synthesis of eicosanoids and cytokines. Some of these activation pathway proteins have emerged as targets for new types of anti-allergic drugs

[23, 24]. For example, inhibition of syk blocks allergic airway inflammation in mice [25]. Intriguingly, syk protein is deficient in some humans with "nonreleaser" basophils [26], although the exact relationship between the nonreleaser phenotype and the asthma (or lack thereof) is not yet clear [27]. Furthermore, dexamethasone depresses syk activity, which may contribute corticosteroid efficacy in asthma [28]. The $F_c\varepsilon RI\beta$ chain is not essential in humans but amplifies the signal. $F_c\gamma RI$ signals are damped by inhibitory receptors, such as $F_c\gamma RII$ and gp49, which possess intracellular, immunoreceptor tyrosine-based inhibition motif (ITIM) domains [29].

Phosphorylated ITIMs attract tyrosine phosphatases, such as SHIP, which may inhibit $F_c\varepsilon RI$ signaling by dephosphorylating activated proteins in the signaling pathway.

$F_c\gamma RII$'s importance is particularly compelling [30]. When IgG and IgE antibodies are raised against polyvalent antigen, "heterotypic" cross-linking of $F_c\gamma RII$ and $F_c\varepsilon RI$ by allergen bound to IgG and IgE inhibits signaling by $F_c\varepsilon RI$. This may be a means by which "blocking antibodies" reduce atopic symptoms after allergen desensitization.

## IgE-independent activation

Mast cells are activated by multiple nonimmunological inputs (Fig. 9.1). Physiological activators include:

- neuropeptides (e.g. substance P);
- purines (adenosine and ATP);
- byproducts of complement activation (e.g. C3a);
- eosinophil toxins;
- bacterial products (e.g. *E. coli* FimH);
- chemokines and lymphokines (e.g. IL-4);
- kit ligand.

These inputs are immunologically nonspecific and provide the means by which products of activation participate in neurogenic inflammation and innate host defense [31]. They also augment responses to allergen-specific mast cell activation (see below).

Thus, innate and adaptive responses are not mutually exclusive. C3a, an agent of innate immunity, is an example, for C3a receptor-null mice are protected from sequelae of airway allergen challenge [32].

It should be noted that human mast cell subpopulations do not respond uniformly to all stimuli. For example, lung mast cells tend to be less responsive than skin mast cells to substance P [33].

## PRIMING AND INHIBITION

Priming describes the response to a substance that does not release mediators by itself but enhances the effect of another stimulus, such as cross-linked $F_c\varepsilon RI$. In cultured human mast cells, priming occurs with allergic cytokines, such as IL-4 and IL-5 [34], and also with kit ligand and adenosine [35]. Mechanisms of priming may be stimulus-specific and affect mediator synthesis and release in different ways. Interactions between primers are potentially complex, and, in the case of IL-4 and -5, may involve autocrine stimulation.

**FIG. 9.1** Mast cell inputs and outputs. This contains a partial listing of factors influencing human mast cell production of mediators with postulated roles in acute and chronic airway inflammation in asthma. Inputs are divided into those directly involving immunoglobulin-mediated "adaptive" responses and those involving immunologically nonspecific "innate/natural" immunity.

In basophils, priming *in vitro* is especially impressive with IL-3, which augments release of histamine in response to MCP-4 and IL-4 in response to allergen, and is enhanced by eotaxin [21]. Basophils harvested from allergic asthmatics are primed [36], presumably by exposure to cytokines *in vivo*.

Priming may serve to activate cells when (and only when) necessary to protect the host; in asthmatics, dysregulated priming may contribute to the pathology of allergic inflammation. $F_c\varepsilon RI$-mediated activation can also be opposed by physiological influences, including adrenergic agonists and inhibitory receptors with ITIMs, as discussed above. Inhibition of activation is the basis of emerging strategies to combat allergic disease, including use of adenosine receptor antagonists, cytokine and chemokine antagonists, and activators of ITIM containing co-receptors [37].

## MEDIATORS

## Eicosanoids, histamine, and proteases

Stimulated mast cells and basophils release an astonishing variety of stored and newly synthesized "mediators". These include prostanoids (Chapter 23), leukotrienes (Chapter 24), proteases, chemokines (Chapter 26), lymphokines, growth factors (Chapter 29), and nitric oxide (Chapter 30), the properties and pharmacology of which are considered in other cited chapters and are not reviewed extensively here.

The principal eicosanoids synthesized after stimulation are $PGD_2$ (whose importance in allergic airway inflammation is demonstrated in PGD receptor-null mice [38]) and $LTC_4$, which is the major target of 5-lipoxygenase inhibitors and leukotriene receptor antagonists. The major granule-associated constituents of human mast cells are histamine, serine proteases, and proteoglycans (heparin and chondroitin). Histamine's importance is clearer in upper airway allergic disease, because antihistamines tend to be more effective in treating rhinitis than asthma. Proteases are the most abundant proteins in secretory granules [39], though this may not be true of normal basophils. As noted, human mast cells vary in expression of tryptases and chymase. In atopic and asthmatic individuals, circulating cells resembling hybrids of basophils and mast cells may express one or both types of protease [16].

Human tryptases are a polymorphic family of trypsin-like proteases implicated in asthma based on *in vitro* degradation of bronchodilating peptides, enhancement of bronchial contraction, promotion of airway smooth muscle and subendothelial fibroblast growth and collagen production, and proinflammatory properties [40]. Studies in sheep and guinea pigs suggest that inhibitors of tryptases reduce allergen-induced airway inflammation and bronchoconstriction [41].

Chymase is postulated to play roles in asthma by stimulating gland secretion and promoting airway remodeling via production of angiotensin II and activation of matrix metalloproteinases [39, 42, 43]. Apart from helping to package and stabilize proteases [44], the role of heparin and other proteoglycans is less clear. However, because heparin delivered into airways in pharmacological doses is anti-asthmatic, heparin released from stimulated mast cells may attenuate inflammatory effects of mediators released from mast cells and other effector cells [45].

There is little evidence that human basophils express mediators not also present in mast cells. However, proteins of unknown function (such as basogranulin) are recognized by monoclonal antibodies and may be basophil specific [16, 46].

## Cytokines and chemokines

Activated human mast cells express cytokines similar to those of $TH_2$ cells, including IL-4, -5, -13, -16, and TNF-$\alpha$. In airways in allergic rhinitis or asthma, mast cells are a substantial fraction of leukocytes expressing these "$TH_2$" cytokines [47].

The relative importance of mast cells and basophils versus lymphocytes as a source of these cytokines is unclear. However, mast cells differ from lymphocytes in storing cytokines in secretory granules. In the case of TNF-$\alpha$, release from mast cell stores is a critical determinant of survival from peritonitis [48]. Asthmatic basophils produce prodigious amounts of IL-4 and IL-13 after antigen-specific activation [49]. In mice, basophils may be one of the IL-4-producing cell types that skew the immune environment in the lung toward allergic, Th2-type responses [50, 51]. The importance of IL-4 and IL-13 is strongly supported by studies in genetically modified mice, which suggest that airway overproduction causes epithelial hypertrophy, mucus metaplasia, eosinophilic inflammation, and hyperresponsiveness. Cytokine-dependent proliferation of mast cells is complex and is subject to autocrine regulation, as from self-stimulation by other types of mediators, such as leukotrienes [52]. Sustained overproduction of allergic cytokines by mast cell and basophils may heighten and perpetuate asthmatic inflammation. Chemokines expressed and secreted by mast cells include IL-8 and MIP-1$\alpha$, which may recruit effector leukocytes to sites of inflammation [53].

## Growth factors

Known cellular growth factors expressed by mast cells include bFGF [54], VEGF, [55] and nerve growth factor [56]. Less known growth factors are tryptases, which are mitogens for airway fibroblasts, smooth muscle, and epithelial cells [57] and may influence endothelial cells to form vessels, thereby promoting angiogenesis [58]. Mast cell IL-4 is fibrogenic when presented in the context of cell-to-cell contact [59]. These mediators suggest mechanisms by which mast cell and basophil mediators promote airway remodeling in the setting of persistent airway inflammation. Recent data from asthmatics suggest that infiltration of airway smooth muscle by mast cells (mastitis) is a phenomenon specific for asthma, which is to say that it is not seen in related inflammatory airway disorders such as eosinophilic bronchitis [(which unlike asthma is not associated with airway hyperresponsiveness (AHR)] and smoking-associated bronchitis [60]. Brightling and colleagues propose that

airway smooth muscle mastocytosis in asthma is caused by a unique asthmatic smooth muscle phenotype, which includes production of mast cell chemoattractants like CXCL10 [61]. In turn, tryptase and other growth factors produced by mast cells recruited to airway smooth muscle may promote myocyte hyperplasia or hypertrophy [62, 63]. On the other hand, Wenzel and colleagues report a positive correlation between the chymase-positive subset of distal airway mast cells and lung function [64].

## ROLES IN HOMEOSTASIS

Basophils and mast cells are presumed to exist for reasons other than to promote sneezing, itching, and wheezing. Lacking informative animal models or natural deficiency states, investigators have few direct clues regarding normal basophil function. However, compelling evidence of roles for mast cells has emerged from studies by using mast cell-deficient mice, which suggest critical roles in innate as well as adaptive immune responses, including defense against bacterial peritonitis and pneumonia [48, 65]. In similar mouse models (reviewed in [5]), mast cells promote a variety of immunologically nonspecific forms of inflammation, for example, ozone-inflicted lung injury [66], providing further evidence that they are activated by IgE-independent pathways.

## ROLES IN ASTHMA

### Animal models

Several experiments in mice support a role for mast cells in asthma-like allergic inflammation, including eosinophilia, hyperresponsiveness, and epithelial remodeling [14, 67–70]. Other studies suggest that IgE and mast cells do not make major contributions (reviewed in [71, 72]). Together, these studies reveal that IgE- and mast cell-dependence vary with strain of mouse, choice of antigen, mode of sensitization and challenge, and choice of physiological endpoints. Mast cell dependence is easier to detect in mice sensitized and challenged locally than systemically, using lower (more physiological) amounts of antigen, without adjuvants. Overall, murine studies suggest that mast cells and IgE are not essential for development of eosinophilic inflammation but do influence kinetics and magnitude of its expression.

### Humans

Notwithstanding some studies questioning its importance in mice, IgE's long-suspected contributions to human asthma are supported by trials by using anti-IgE antibodies, which reduce circulating IgE to nearly undetectable levels and decrease symptoms and corticosteroid use in moderate, steroid-dependent asthmatics, [73] and rhinitics [74].

Anti-IgE joins a growing list of anti-asthmatic drugs influencing mast cells, basophils, and their products. These include:

- corticosteroids (which decrease mast cell numbers) [75];
- cromones;
- β-adrenergic agonists;
- theophylline;
- heparin (which inhibits degranulation);
- IL-4 antagonists (which inhibit priming) (58);
- leukotriene pathway inhibitors.

Others, effective in animal models, include tryptase inhibitors [76].

Interestingly, mast cell desensitization to chronic β-agonists used by asthmatics without corticosteroids may contribute to clinical deterioration [77]. Furthermore, corticosteroids may protect mast cells from desensitization [78].

Pharmacological evidence of roles for mast cells correlates with studies indicating activation in allergic airway disease [1, 79]. Mast cells release histamine and tryptase into bronchi following allergen challenge [80]. They appear degranulated in asthmatic airway, even in stable disease, [81, 82] and the percentage of mast cells expressing cytokines IL-4, IL-5, and TNF-α increases [47]. Mast cell and basophil numbers rise in asthmatic airways and correlate with hyperresponsiveness to acetylcholine [83]. However, fewer basophils are seen in asthmatic bronchial biopsies than mast cells or eosinophils, and they are more prominent in cutaneous than airway late-phase reactions [84]. Nonetheless, their arrival coincides with development of late-phase bronchoconstriction [85]. Airway basophils are thought to be a source of the late histamine release after allergen exposure, because this occurs without a corresponding peak in tryptase, which is more abundant in mast cells. On the other hand, other granulated leukocytes, including polymorphonuclear neutrophils, also can be sources of airway histamine [86].

More basophils appear in asthmatic sputum with late-phase responses to allergen than in those without such responses, and their numbers correlate with methacholine responsiveness [17]. This supports the hypothesis that mast cells and basophils are important in early- and late-phase responses, respectively. The further hypothesis that these cells promote chronic, persistent asthma is speculative. However, this notion is supported by the studies summarized above suggesting that proteases, cytokines, and growth factors from chronically activated mast cells and basophils promote airway remodeling and sustain $TH_2$-assisted IgE production and allergic inflammation.

## ROLES IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Several lines of evidence suggest connections between mast cells and chronic obstructive pulmonary disease (COPD) [87].

Elevated levels of histamine and tryptase in smokers' lavage fluid [88] imply that mast cells are activated by smoke. Studies in mice suggest that mast cells promote airway injury and epithelial remodeling in response to ozone [66], which could explain some human responses to smoke. Most mast cells close to human bronchial glands express chymase [89], which stimulates gland cell secretion [42] and may promote sputum production in bronchitis.

Conceivably, mast cells contribute to emphysematous lung destruction by secreting matrix altering proteases, for example chymase, tryptases, gelatinases, plasminogen activator, and dipeptidyl peptidase I [39]. Some investigators find increased mast cell numbers in proximal airways of asymptomatic smokers with mild COPD [90], although the relationship to lung function is less clear. Overall, evidence of mast cell involvement in asthma is more compelling, although further investigation of connections between mast cells and COPD is warranted.

## SUMMARY

Mast cells protect from certain types of infection and injury by contributing to innate and adaptive immune responses. The homeostatic roles of basophils are less clear. Both cell types participate in the pathology of atopy and asthma by deploying an arsenal of inflammatory mediators, including proteases, growth factors, chemokines, and "TH$_2$" cytokines. Mast cells, being permanent airway residents, are more likely to encounter aeroallergens first and to participate in acute responses. Basophils, because of the time lag of recruitment, may be more important in late-phase responses.

Support is mounting for the hypothesis that both types of cells magnify the pathology of persistent inflammation in chronic asthma, including stimulation of IgE production, recruitment of eosinophils, and remodeling of epithelium.

## INTRODUCTION

The lung contains many subsets of dendritic cells (DCs) that are distributed in various anatomical compartments. In homeostatic conditions, a fine-tuned balance exists between plasmacytoid and myeloid DCs necessary for maintaining tolerance to inhaled antigen and for avoiding overt inflammation. These subsets of DCs also play important roles in establishment of airway inflammation seen in asthma and COPD. Based on these new insights on airway DC biology, several approaches that interfere with DC function show potential as new intervention strategies for these ever increasing diseases.

Obstructive airway disease, broadly divided clinically into asthma or COPD, is a significant cause of morbidity and mortality. In allergic asthma, allergen-specific T-helper type 2 (Th2) cells produce key cytokines like IL-4, IL-5, and IL-13 that regulate the synthesis of allergen-specific IgE and control tissue eosinophilic airway inflammation and remodeling of the airways. In the lungs of COPD patients, predominantly CD8 lymphocytes and neutrophilic airway inflammation are seen, concomitant with remodeling of small airways and the destruction of distal air spaces characteristic of emphysema. It is increasingly clear that DCs are essential for inducing activation and differentiation of not only naïve but also effector CD4$^+$ T- and CD8$^+$ T-cells in response to inhaled antigen, and it has been well established that these cells play a pivotal role in the initiation and maintenance phase of airway inflammation [1]. In this chapter, we will highlight the recent discoveries in airway DC biology with special emphasis on mouse models of asthma and COPD. The applicability to the human situation and the therapeutic potential of novel findings will be discussed where possible.

## LUNG DC SUBSETS IN MOUSE AND MAN

It has long been established that the various lung compartments (conducting airways, lung parenchyma, alveolar compartment, pleura) contain numerous DCs, of which the precise lineage or origin have been poorly defined. Recently however, many groups have refined the ways in which lung DCs should be studied, both in mouse [2–5] and in human [6, 7]. It is clear that different DC subsets can be found in the lung, each with functional specialization. In the mouse, all of these express the integrin CD11c and the subsets are further defined on the basis of the expression of the myeloid marker CD11b, as well as anatomical location in the lung. The trachea and large conducting airways have a well-developed network of intraepithelial DCs, even in steady-state conditions. These cells in some way resemble skin Langerhans' cells, and have been shown to express langerin and CD103 while lacking expression of CD11b [4, 8]. In the submucosa of the conducting airways, CD103$^-$CD11b$^+$CD11c$^+$ myeloid DCs can be found, particularly under conditions of inflammation, and these cells are particularly suited for priming and restimulating effector CD4 cells in the lung [8, 9]. The lung interstitium that is accessible by enzymatic digestion also contains CD11b$^+$ and CD11b$^-$ DCs that access the alveolar lumen and migrate to the mediastinal lymph nodes (MLN) [2, 5, 10]. It should be noted that this population is contaminated with

DCs lining the small intrapulmonary bronchioles, as well as those lining the vessel walls. In the nearby alveolar lumen, CD11c$^{hi}$ alveolar macrophages control the function of these interstitial DCs. Plasmacytoid DCs are CD11b$^-$CD11c$^{int}$ cells expressing SiglecH and bone marrow stromal Ag-1 (recognized by the moAbs mPDCA-1 or 120G8). In the lungs, pDCs are predominantly found in the lung interstitium and produce large amounts of IFN$\alpha$ in response to triggering by CpG motifs or viral infection *ex vivo* [11].

The exact definition of the different DC subtypes in the human lung is incomplete and a subject of controversy. Two groups identified myeloid DC and plasmacytoid DC in single cell suspensions from digested human lung tissue by flow cytometry, using the blood dendritic cell antigen markers (BDCA) 1 through 3 [7, 12]. The Cluster of Differentiation (CD) nomenclature of these BDCA markers is as follows: BDCA1 = CD1c, BDCA2 = CD303, and BDCA3 = CD141. Within the low autofluorescent mononuclear cells of the lung digests, cells that were positive for the lineage markers, that is, CD3, CD19, CD20, and CD56, were excluded. Within the lineage negative pulmonary mononuclear cells, myeloid DC type 1 were characterized as CD1c$^+$/HLA-DR$^+$ cells, myeloid DC type 2 were characterized as CD141$^+$/HLA-DR$^+$ cells, and plasmacytoid DC were characterized as CD303$^+$/CD123$^+$ cells. *In vitro* studies suggest that Langerhans type DC (that are Langerin$^+$, CD1a$^+$, and Birbeck granule positive) derive from myeloid DC precursors that are CD1c$^+$ and CD1a$^+$ [13], and others have shown that Langerhans-type DC can be generated from monocytes under the influence of interleukin-15 [14]. It is unclear whether differences in terms of expression of surface markers reflect separate stages of differentiation of the DC, rather than different sublineages. It is tempting to speculate that, within these DC subsets, carrying different surface markers, functional specialization does occur. Indeed, pulmonary myeloid DC types 1 and 2 were shown to release proinflammatory cytokines (TNF-$\alpha$, IL-1$\beta$, IL-6, and IL-8) in response to Toll-like receptor-2 (TLR-2) and TLR-4 ligands, whereas plasmacytoid DC released high amounts of interferon-$\alpha$ in response to the TLR-9 ligand CpG oligonucleotides [6]. Moreover, myeloid DC type 1 was shown to be strong inducers of T-cell proliferation in a mixed leukocyte reaction, while plasmacytoid DC induced little T-cell proliferation and myeloid DC type 2 had an intermediate T-cell-stimulatory capacity [6].

How, where, and by which DC subset inhaled antigen is sampled from the airway lumen has been a matter of debate. Jahnsen demonstrated that, analogous to that reported in the gut, a subset of rat airway intraepithelial DCs extend their processes into the airway lumen. This "periscope up" function is constitutively expressed within the airway mucosal DC population, providing a mechanism for continuous immune surveillance of the airway luminal surface in the absence of "danger" signals [15]. In the mouse, CD103$^+$CD11b$^-$ intraepithelial DCs express the tight junction proteins claudin-1, claudin-7, and zonula-2, allowing the sampling of airway luminal contents whereas keeping the epithelial barrier function intact [4]. This subset is also found in the alveolar septa, and DCs lining the alveolar wall can take up inhaled harmless ovalbumin (OVA) or bacterial anthrax spores by forming intra-alveolar extensions

and then migrating to the MLN in a CCR7-dependent way [5, 8, 10]. It is still a matter of debate, however, whether the uptake and transport of inhaled antigen occurs exclusively by alveolar wall DCs, by intraepithelial DCs lining the large conducting airways or by both [2, 5]. Another controversial issue is the location and extent by which plasmacytoid DCs take up inhaled antigen. Two reports describe that within 24–48 h following exposure of inhaled fluorescently labeled Ag, almost 50–60% of pDCs are antigen-positive [11, 16], whereas another report saw only a minor percentage of Ag uptake in this subset [5]. It remains to be demonstrated if pDCs take up antigen in the periphery of the lung and subsequently migrate, whether they get their antigen from another migratory DC [17], or whether they take up free afferent lymph while residing in the lymph node. How much antigen crosses the epithelial barrier passively in the absence of DC uptake is unknown, but it heavily depends on the molecular weight of the Ag, its dose, as well as the potential to disrupt epithelial tight junctions. Control of epithelial barrier function could be under important genetic control as well, as many of the gene polymorphisms associated with atopy in humans control epithelial integrity (e.g. Spink5, S100 family). It is similarly possible that Ag uptake by lung pDCs would be facilitated by the presence of Ag-specific immunoglobulins acting on Fc receptors, thus enhancing endocytosis [18].

## ROLE OF DCs IN ASTHMA

### Outcome of antigen inhalation depends on the functional state of myeloid and plasmacytoid DCs

The usual outcome of inhalation of harmless protein antigen in the lungs is immunological tolerance (see Fig. 10.1 for a model depicting cellular interactions). As a result, when the antigen is subsequently given to mice in an adjuvant setting (e.g. in combination with the Th2 adjuvant alum) it no longer induces an immunological response that leads to effector cells causing inflammation [11, 19]. Inhalational tolerance is mediated in part by deletion of Ag reactive T-cells as well as induction and/or expansion of regulatory T-cells in the mediastinal nodes [17, 19–21]. The latter type of tolerance is dominant and can be transferred to other mice by adoptive transfer. Induction of tolerance to inhaled antigen is a function of lung DC subsets that migrate from the lung in a CCR7-dependent way [17]. It is often claimed that induction of tolerance is a function of "immature" DCs, meaning that these cells lack the expression of high levels of major histocompatibility complex (MHC), adhesion, and co-stimulatory molecules, However, Reis and Sousa recently argued that the term "mature DC" should be reserved for those DCs that have the potential to generate effector T-cells, and that expression of costimulatory molecules by DCs does not exclude the possibility that tolerance would be induced [22]. In the lungs, inhaled tolerance is dependent on signals delivered by CD86 and/or ICOS-L on DCs, supporting this view [20].
**FIG. 10.1** Dendritic cell function following inhalation of harmless antigen in homeostatic conditions. When an inhaled antigen reaches the deeper airways and it is not cleared by mucociliary transport or by macrophages, it will be taken up by airway DCs. Both mDCs and pDCs take up antigen. mDCs seem to do this in the periphery, whereas pDCs only do this in the mediastinal nodes. In baseline conditions, the mDCs that reach the nodes are only partly "mature" and the T-cell response that they induce is characterized mainly by division but not by differentiation to effector cells. Eventually many dividing cells die. Additionally, mDCs induce Treg cells that suppress inflammation. At the same time, the pDCs control the level of activity of the mDCs so that these cells are kept in a quiescent state. This function of pDCs is controlled by Treg control occurring via GITR–GIRL ligand and CLTA4–CD80/86 interactions. The signals involved are not precisely known but could involve IDO, or some surface expressed ligand on pDCs (programmed death ligand-1, PDL1). The function of mDCs is constantly kept in check among others by tonic inhibition by cyclooxygenase-2 (Cox-2) derived prostaglandins (PGs), as well as by complement activation acting on the C5a receptor (C5a). The precise ligand for the class A scavenger receptors (MARCO and SR-AI/II) are not known.

Conventional lung DCs (either $CD11b^+$ or $CD11b^-$) are necessary for tolerance induction [17] but are also responsible for inducing Th2 sensitization, providing there is some form of activation (either LPS or TNF$\alpha$) [23] leading to functional DC differentiation and their capacity to prime Th2 effector cells (see Fig. 10.2 for a model depicting cellular interactions leading to Th2 sensitization in the airways). In further support, Th2 sensitization can be induced by adoptive intratracheal transfer of GM-CSF-cultured bone marrow DCs, most closely resembling mature monocyte-derived $CD11b^+$ DCs, but not by Flt3L-cultured bone marrow-derived DCs that more resemble the immature steady-state DCs resident in the lymph nodes and spleen [11]. As activation of lung DCs is the common event leading to Th2 sensitization, it is likely that under homeostatic conditions, the degree of DC maturation is, therefore, constantly kept in check. One such pathway of tonic DC suppression seems to involve COX-2-derived prostaglandins or their metabolites, most likely derived from nearby alveolar macrophages [24]. Chimeric mice in which the $PGD_2$ receptor DP1 was selectively deleted on hematopoietic cells, demonstrated spontaneous maturation of lung mDCs and subsequently, response to harmless antigen was greatly enhanced, suggesting tonic inhibition of DC function by $PGD_2$ in the lung [25]. When exposed to selective PGD2 agonists, myeloid DCs induced the formation of $Foxp3^+$ Ag-specific Tregs that subsequently suppressed airway inflammation. A similar mechanism on DCs was found for stable $PGI_2$ analogs [26, 27].

When pDCs are depleted from the lungs, inhaled tolerance is abolished, and consequently pDC/mDC balance in the lung is tightly regulated among others by the cytokine osteopontin as well as complement C5a [11, 16, 28, 29]. How exactly pDC depletion leads to sensitization is still unsolved, but *in vitro* and *in vivo* data suggest that pDCs directly suppress the potential of mDCs to generate effector T-cells [11, 29]. Plasmacytoid DCs can also stimulate the formation of Treg cells, possibly in an ICOS-L-dependent way [11, 30]. Tregs expressing GITR could also induce the production of the tryptophan catabolizing enzyme indoleamine 2,3-dioxygenase (IDO) through reverse signaling in pDCs [31]. In mice depleted of pDCs, there was endogenous release of extracellular adenosine triphosphate (ATP) responsible for inducing mDC maturation and Th2 skewing potential. Th2 sensitization to inhaled OVA was abolished when ATP signaling was blocked using the broad spectrum P2X and P2Y receptor antagonist suramin. On the contrary, a non-degradable form of ATP was able to break inhalation tolerance to OVA [32]. At present, it is unclear how purinergic receptor triggering on DCs promotes Th2 development, but it could involve the formation of the inflammasome, a multi-protein complex that leads to activation of caspase 1 and processing and release of IL-1, IL-18, and possibly IL-33. One possibility is also that ATP indirectly influences DC function via the modification of mast cell and eosinophil function. Mast cells (e.g. through release of cytokines, PGD2 or sphingosine metabolites) [33]
**FIG. 10.2** Model of dendritic cell function during Th2 sensitization. Several known risk factors for atopy have been shown to interfere with DC function in the airways. Also, several experimental models have been developed in which sensitization occurs even after inhalation of harmless antigens to the lung, providing there is some form of DC activation. In these models, respiratory tolerance is broken. Some models have induced a shift in the pDC/mDC balance, and consequently mDCs induce priming because they are no longer suppressed by adequate numbers of pDCs. Activated mDCs also produce chemokines like CCL17 or CCL22 to further attract Th2 cells into the response. Some adjuvants induce proper activation of mDCs (yet not sufficient to induce IL-12) so that they now induce effector Th2 cells rather than regulatory T-cells. Some stimuli, like concomitant viral infection, might have an additional effect by inducing maturation of pDCs and their production of IFNα. This is a known maturation stimulus for mDCs and in this way, these cells might even contribute to sensitization upon viral infections. Activation of epithelial cells by proteolytic allergens, virus infection, TLR ligands, or air pollutants is an indirect way of activating and polarizing the DC network, through release of thymic stromal lymphopoietin (TSLP) or granulocyte-macrophage colony stimulating factor (GM-CSF) or interleukin 1 (IL-1). The precise source and role of endogenous danger signals such as ATP, tumor necrosis factor α (TNF-α), high mobility group box 1 (HMGB1), or uric acid is currently being investigated.

and eosinophils (through release of leukotrienes and eosinophil-specific enzymes) also influence DC function [34]. The conditions regulating ATP release in the lungs will have to be studied more carefully before we can conclude how important the pathway of purinergic signaling is in sensitization to more common allergens, like house-dust mite.

## Direct or indirect mechanisms of Th2 sensitization to inhaled antigen

Induction of tolerance or immunity to inhaled antigen by DCs is tightly controlled by signals from alveolar macrophages, Tregs, NKT cells, complement activation, nervous system interactions, and epithelial activation. While studying the literature on particular substances that can break inhalation tolerance and induce Th2 priming, one needs to wonder, therefore, whether a stimulus acts directly on mDCs or

pDCs or whether its effects are mediated indirectly through modification of any of the above interactions. For systemically administered TLR agonists, like endotoxin, the activation of DCs occurs mainly through direct recognition by TLR4 expressed on the DC, but in epithelia, the response could be clearly different [35]. As an example, low dose endotoxin was able to break inhalation tolerance to inhaled OVA by inducing mDC maturation [23]. These effects could be mediated directly via TLR and Myd88-dependent pathways in DCs but could also be mediated via TLRs on bronchial epithelial cells [36]. Bronchial epithelial cells could produce chemokines as well as crucial growth and differentiation factors that subsequently attract, activate, and polarize lung DCs to prime Th2 responses. In this regard, the epithelial cytokines thymic stromal lymphopoietin (TSLP) and GM-CSF might be crucial, as their overexpression in the lungs breaks inhalational tolerance [37, 38]. On the contrary, neutralization of these cytokines, during priming regimens, eliminates much of the

adjuvant effects of diesel exhaust particles (DEP) [39, 40] or pro-allergic effects of house-dust mite [41]. Importantly, the production of these cytokines by bronchial epithelial cells in response to these triggers might be genetically regulated and this could be the explanation why some individuals become primed to inhaled antigen under the right environmental exposure [42]. Under some conditions, predictions about sensitizers or adjuvants can be made from *in vitro* experiments. Ambient particulate matter (APM) is ubiquitous in the environment and is associated with allergic diseases in inner cities. *In vitro*, inhaled APM can act directly on human DCs as a danger signal to direct a proallergic pattern of innate immune activation, thus explaining why it acts as an adjuvant [43]. Likewise, DEP induce maturation of human DCs indirectly, via promoting GM-CSF production in bronchial epithelial cells *in vitro* [40]. In mice, DEP and APM induce altered DC maturation directly, via nuclear factor-erythroid 2 (NF-E2)-related factor 2-mediated signaling, implicating oxidative stress in the activation of DCs [44]. Whether enhancement of inflammation in Nrf-2-deficient mice, which are hypersensitive to oxidative stress, is also the result of overzealous DC activation remains to be shown [45]. Another known sensitizer is cigarette smoke. When given concomitantly with harmless OVA, it induces Th2 responses, and this response is associated with enhanced DC maturation and migration [46]. DCs developed in a nicotinic environment (nicDCs) fail to support the terminal development of effector memory Th1 cells due to their differential expression of costimulatory molecules and lack of IL-12 production. In both human and mouse, nicDCs promoted the development of Th2 responses [47]. As maternal cigarette smoking is a solid risk factor for becoming sensitized in early life, it will be important to elucidate how it leads to DC activation (e.g. whether any indirect mechanisms acting via epithelial TLR4 contribute), as this might provide novel intervention strategies. Another unsolved question is how the nearby nervous endings react to viruses or air pollution and how this could affect the way DCs react to inhaled allergen. In this regard, the remodeling that occurs in the airway unmyelinated nerves following RSV virus could partly explain the subsequent enhanced risk of Th2 sensitization in mice.

## Function of DCs in allergic inflammation and tissue remodeling

Not only do DCs play a role in the primary immune response to inhaled allergens, they are also crucial during the effector phase of asthma. The number of CD11b$^+$ DCs is increased in the conducting airways and lung interstitium of sensitized and challenged mice during the acute phase of the response [9, 48, 49]. However, during the chronic phase of the pulmonary response, induced by prolonged exposure to a large number of aerosols, respiratory tolerance develops through unclear mechanisms. During this regulatory phase, the number of mDCs as well as their costimulatory molecules in the lungs steadily decreased, and this was associated with a reduction of bronchial hyperresponsiveness (BHR), possibly mediated by the action of Treg cells [19, 50, 51]. Inflammation however reappears when mature inflammatory CD11b$^+$ DCs

are given [50]. Increased levels of class A scavenger receptors (MARCO and SR-AI/II) were found in the lungs of asthmatic mice, possibly suppressing DC-driven inflammation. These receptors are expressed on lung macrophages, DCs, and basophils. Receptor-deficient mice had more eosinophilic airway inflammation, airway hyperresponsiveness (AHR), and increased migration of DCs to the MLN [52].

The role of mDCs in the secondary immune response was further supported by the fact that their depletion at the time of allergen challenge abrogated all the features of asthma, including airway inflammation, goblet cell hyperplasia, and BHR [9]. Again the defect was restored by intratracheal injection of GM-CSF cultured CD11b$^+$CD11c$^+$ mDCs, most closely resembling monocyte-derived "inflammatory DCs". The same effects were observed when DCs were depleted in the nose in an animal model for allergic rhinitis [53]. It therefore seems that "inflammatory" DCs are both necessary and sufficient for secondary immune responses to allergen. Upon allergen challenge, lung DCs upregulate the expression of CD40, CD80, CD86, ICOS-L, PD-L1, and PD-L2, particularly upon contact with Th2 cells [9, 11, 48, 49, 54]. Costimulatory molecules might be involved in activation of effector T-cells in the tissues or in regulation of Treg activity. In allergen-challenged mice, DCs might also be a prominent source of the inflammatory chemokines CCL17 and CCL22, involved in attracting CCR4$^+$ Th2 cells to the airways, and in producing eosinophil-selective chemokines [29, 49]. In helminth infections, recruitment of Th2 cells and eosinophils depends on an IL4/IL13-responsive bone marrow-derived cell, most likely a DC or alternatively an activated macrophage population [55]. A number of cytokines and innate immune response elements control the production of these chemokines. The pro-allergic cytokine TSLP induces the production of large amounts of CCL17 by mDCs, thus contributing to the recruitment of Th2 cells to the airways, explaining how it may act to enhance inflammation [37]. The complement factor C5a suppresses the production of CCL17 and CCL22 [29]. A similar effect was seen with the cytokine IL-17, explaining how it may suppress allergic inflammation when given during allergen challenge. *In vitro*, IL-17 reduced CCL17 production and antigen uptake by DCs and IL-5 and IL-13 production in regional lymph nodes *in vivo*. Furthermore, IL-17 is regulated in an IL-4-dependent manner as mice deficient for IL-4Rα signaling showed a marked increase in IL-17 concentration with inhibited eosinophil recruitment [56]. Emerging evidence suggests that IL4Rα expression on lung DCs is an important feedback mechanism through which IL-4 producing cells (effector Th2 cells, eosinophils, basophils) might promote further Th2 polarization in ongoing responses [57].

As the number and activation status of lung CD11b$^+$ DCs during the secondary challenge seems critical for controlling allergic inflammation, studying the factors that control recruitment, survival, or egress from the lung during allergic inflammation will be important, as this might reveal therapeutic targets. In an elegant study using mixed bone marrow chimeras in which half the hematopoietic cells were CCR2$^{-/-}$ and half were CCR2$^{+/+}$, it was shown by Robays *et al.* that CCR2 (and not CCR5 or CCR6) is crucial for releasing DC precursors from the bone marrow

and attracting them into allergically inflamed lung. This was unexpected, as CCR6 is generally seen as the chemokine receptor attracting immature DCs into peripheral tissues [58]. Lung mDCs use CCR7 ligands and CCR8 for emigration to the draining lymph nodes but not the leukotriene C4 transporter multidrug-related protein-1 as they do in the skin [59]. Unexpectedly, disruption of CCR7-selective chemokines in paucity of lymphocyte T-cell (plt) mutant mice, deficient in CCL21 and CCL19, resulted in airway inflammation and Th2 activity that were enhanced [60]. Still, increased numbers of mDCs could be found in the draining lymph nodes of these mice. So, in addition to CCR7 ligands, there are other factors involved in the migration of DCs to the draining LN, including other chemokine receptors [59]. Eicosanoid lipid mediators like prostaglandins and leukotrienes can also influence the migration of lung DCs [61]. Leukotriene LTB4 promoted the migration of immature and mature skin DCs but these effects seem to be indirect [62]. It will be important to study if well-known inducers of LTB4 in the lungs, such as the environmental biopolymer chitin, derived from fungi, helminthes, and insects, also induce DC migration [63]. Additional "druggable" factors promoting the migration of DCs to the draining mediastinal nodes during inflammatory responses could be sphingosine-1-P and extracellular ATP [32, 64].

In humans, allergen challenge leads to an accumulation of myeloid, but not plasmacytoid DCs in the airways of asthmatics, concomitant with a reduction in circulating CD11c$^+$ cells, showing that these cells are recruited from the bloodstream in response to allergen challenge [65, 66]. A recent report suggests that pDCs are also recruited into the bronchoalveolar lavage (BAL) fluid but are poor antigen-presenting cells (APCs) [66]. The exact role of plasmacytoid DCs in ongoing allergen-specific responses in asthma is currently unknown. It was shown that pDCs accumulate in the nose, but not lungs, of allergen challenged atopics [67]. When pDCs were pulsed with pollen allergens, they were as efficient as mDCs in inducing Th2 proliferation and effector function [68]. Others have suggested, as in the mouse, that pDCs might also confer protection against allergic responses [16]. In children at high risk of developing atopic disease, the number of circulating pDCs was reduced.

## ROLE OF DCs IN COPD

### The inflammatory basis of COPD

COPD is an inflammatory disease of the large and small airways and the lung parenchyma, which is caused most commonly due to the inhalation of noxious particles and gases and is associated with an abnormal systemic inflammatory response. The lungs of COPD patients are infiltrated with cells of the innate immune system such as neutrophils and macrophages [69], but there is also evidence for an activated adaptive immune response with accumulation of CD8$^+$ T-cells, B–cells, and the presence of lymphoid follicles [70, 71]. Four key elements appear to be crucial in the pathogenesis of COPD: increased *oxidative stress* (caused by

cigarette smoke and by activated cells of the innate immune system, causing tissue damage), disturbance in the *protease–antiprotease balance* (with an elevated production of proteases and/or decreased levels of antiproteases such as α1-antitrypsin and tissue inhibitors of matrixmetalloproteïnases (TIMP)), increased *programmed cell death* and *profibrotic conditions* in the small airways. The exact pathogenetic mechanisms for ongoing pulmonary inflammation and damage in COPD, even after the initial inciting agent has disappeared (i.e. after smoking cessation), are poorly understood. Latent viral respiratory infections, chronic bacterial colonization of the lower airways, repetitive infectious exacerbations, auto-immune responses against changed epitopes in the lung, and genetic predisposition, are proposed as important driving mechanisms for the persistent inflammation in patients with COPD [72].

The DCs present in the human lung and lymphoid organs, linking innate and adaptive immune responses, could be a key element in the pathogenesis of COPD. In the remaining part of the chapter, we will discuss what is known about the effects of cigarette smoke on DCs and how DC populations are altered in "healthy" smokers (without airway obstruction) and patients with COPD. We will also formulate several hypotheses about the role of DC in the pathogenesis of COPD.

## DC populations in lungs of smokers and COPD patients

There have been only a few studies addressing the number and distribution of DCs in the lungs of smokers and patients with COPD. Most of these descriptive studies have a cross-sectional design, so that the sequence of events cannot be established and any evidence for causality is (very) weak. At first sight, some data in the literature appear discrepant or even contradictory, but this may be due to differences in the area of interest (bronchial biopsies sampling large airways *versus* surgical resection specimens sampling small airways and parenchyma versus BAL sampling the alveolar lumen) (Fig. 10.3), differences in the examination techniques (electron microscopy, flowcytometry, or immunohistochemistry) or differences in the immunohistochemical markers used to identify and enumerate the DCs. It is also critical to discriminate between the effects of smoking *per se* on DC numbers, phenotypic markers, or functions versus the disease-specific effects of COPD on DC, irrespective of the current smoking status (see Fig. 10.3).

When studying pulmonary DC, it is important to take into account not only the different DC subsets mentioned earlier but also the different anatomic locations (i.e. distribution) of DC within the lung. Moreover, the different compartments of the lungs (large airways, small airways, lung parenchyma interstitium and alveolar lumen) are sampled by different methods (bronchoscopy, surgical lung resections, and BAL, respectively). In the large airways (trachea, bronchi), sampled by bronchoscopy with bronchial biopsies, the number of CD1a$^+$ DC was evaluated in healthy smoking controls and current smoking COPD patients, showing no significant differences between groups [73, 74]. Others evaluated the number of DC in large airways using electron
**FIG. 10.3** Distribution of DCs in the lungs and the impact of smoking or COPD on different subsets of dendritic cells. Myeloid DCs can be retrieved in different compartments of the lung. Airway DCs are located as a network immediately above and beneath the basement membrane, either in the large airways (sampled by bronchial biopsies taken during bronchoscopy) or in the small airways (present in lung resection specimens). Alveolar DCs are present in the lumen of alveolar spaces and can be recovered by BAL, whereas interstitial DCs are located in the interstitium of the lung parenchyma between alveolar spaces (also present in lung resection specimens). The exact location of human plasmacytoid DCs has still to be elucidated. On the left side of the figure, studies evaluating the impact of cigarette smoking *per se* on the number of different myeloid DCs are indicated and summarized; on the right side, the studies comparing the number of CD1a+ DC (in large airways) or Langerin+ DCs (in small airways) between patients with COPD and healthy-smokers – without airflow limitation – are indicated. COPD: chronic obstructive pulmonary disease; DCs: dendritic cells.

microscopy, based upon morphologic criteria derived from cultured CD1c+ DC, and showed a significant decrease in the number of DCs in the large airways of smoking COPD patients versus ex-smoking COPD patients and never smoking controls [75].

In the small airways (bronchioli), which is the main location responsible for airway obstruction in COPD, the number of DC was evaluated using immunohistochemical staining for CD1a and CD1c (BDCA-1), showing no difference between smokers and non-smokers [76]. In patients with COPD, however, a significant increase in the number of CD207 (Langerin) positive cells was found compared to

never-smokers and healthy-smokers (without COPD), suggesting an accumulation of Langerhans-type DC in COPD [77]. Moreover, the number of Langerin+ DC further increased with the severity of the disease [77].

Studies sampling BAL fluid evaluated the number of DCs between never-smokers and smokers without COPD, showing a significant increase in the expression of Langerin and CD1a (markers of Langerhans cells) on myeloid DC [78] as well as an increase in Birbeck granule positive Langerhans-type DC in smokers versus non-smokers [79]. Finally, in the alveolar parenchyma, the number of CD1a+ DC was increased in smokers versus never-smokers, whereas the number of CD1c+ DC was not different [76].

Taken together, evidence points toward an accumulation of myeloid DC with Langerhans-type cell markers (CD207, CD1a, and Birbeck granules) in the small airways and alveoli of smokers and COPD patients. This is in agreement with data from experimental models of COPD, in which mice are chronically exposed to cigarette smoke and develop manifest pulmonary inflammation and emphysema. A clear accumulation of myeloid DC was seen in the BAL fluid and lungs of these mice [80], exposed to relatively high doses of cigarette smoke (with carboxyhemoglobin levels in serum comparable to the levels obtained in human smokers who smoke 20 cigarettes a day). However, exposing the mice to a lower dose of cigarette smoke appears to decrease the number of DCs in the lung in the absence of inflammation [81].

## Functional differences in DCs exposed to cigarette smoke

Evidence from the mouse model of COPD and from human lung tissue suggests an activated macrophage inflammatory protein 3α (MIP3alpha)/CC-chemokine ligand (CCL20)–CC-chemokine receptor 6 (CCR6)-axis in COPD, responsible for the accumulation of myeloid DC in the lung [77, 82]. At the epithelial surface, DCs are capable of sensing danger signals and take up antigens to process them. However, little is known about the influence of cigarette smoke on the expression and function of innate receptors of DCs, including TLR and lectin-like receptors (such as Langerin and blood DC antigen-2 [83]). Once the DC has sampled the antigen, it will process the antigen, upregulate the expression of CC-chemokine receptor 7 (CCR7), and migrate toward the secondary lymphoid organs (i.e. MLN) (Fig. 10.4).

Several *in vitro* studies have evaluated the effect of nicotine and cigarette smoke extract (CSE) on the maturation process and T-cell stimulatory capacity of myeloid DC. Human monocyte-derived DCs, which have a predominant interstitial phenotype, show increased maturation and increased IL-10 and IL-12 production upon exposure to a high dose nicotine [84], whereas a low dose of nicotine results in a decreased immature DC-dependent T-cell proliferation and a decreased IL-12 production after LPS stimulation [85]. These nicotine-exposed DCs are indeed less able to induce differentiation of naïve T-cells into T-helper 1 cells [47, 86]. When CSE is added during the last 18 h of a monocyte-derived DC culture, mimicking the
**FIG. 10.4** Possible interrelationship between cigarette smoke, airway inflammation, and DCs in the pathogenesis of COPD. Injury to epithelial surfaces by cigarette smoke and/or oxidative stress induces the release of numerous DC-attracting mediators, including macrophage inflammatory protein-3α (MIP-3α)/CC-chemokine ligand 20 (CCL20), which is the only chemokine ligand of CC-chemokine receptor 6 (CCR6). Blood DC precursors are recruited out of the blood circulation, and they migrate to the site of antigen entry and tissue damage. Immature DCs display numerous TLR, including TLR2, TLR4, TLR7, and/or TLR9, which enable myeloid and plasmacytoid DCs to sense multiple pathogen-associated molecular patterns (PAMPs), which may precipitate infectious exacerbations in patients with COPD. After antigen uptake and activation, DCs lose all chemokine receptors except CC-chemokine receptor 7 (CCR7), which mediates the migration of DCs toward the secondary lymphoid organs in response to the chemokines CCL19 and CCL21. In the lymph nodes, mature DCs express high amounts of peptide-loaded MHC molecules and T-cell costimulatory molecules (such as CD40, CD80 and CD86). In BAL fluid, an increased expression of antigen presentation markers such as CD80 and CD86 was observed on myeloid DCs of smokers compared to never-smokers, whereas the expression of the lymph node homing receptor CCR7 was significantly decreased. CCL: CC-chemokine ligand; CCR: CC-chemokine receptor; DC(s): dendritic cell(s); MIP-3α: macrophage inflammatory protein-3α; MHC: major histocompatibility complex; PAMPs: pathogen associated molecular patterns; TLR: Toll-like receptors.

exposure to mainstream cigarette smoke, the DC-induced T-cell proliferation is significantly reduced, with a reduction of IL-12 production and an increase of IL-10 production by the DC. Moreover, the T-cell priming is skewed toward a T-helper 2 response and the LPS-induced maturation of CSE-exposed DC is inhibited, with a reduced upregulation of costimulatory molecules and an inhibition of chemotactic CCR7, which is involved in migration of the DC toward the secondary lymphoid organs. In summary, these *in vitro* data suggest that CSE impairs the maturation of interstitial type DC, skews the DC induced T-cell differentiation toward a Th2 response, and could possibly alter the migration of DC toward the lymph nodes. In contrast, *ex vivo* data from human myeloid DC obtained from BAL show an increased expression of maturation markers by myeloid DC combined with a decrease of CCR7 expression in smokers compared to non-smokers [78]. Although *in vitro* – for a specific stimulus – cigarette smoke exposed DC might mature less than non exposed DC, we hypothesize that *in vivo* the overall inflammatory response and danger signals due to the damaging effect of cigarette smoke in the lungs will still enhance maturation of DC in smokers and patients with COPD.

Apart from the integration of danger signals and antigens, DCs are also capable of producing substantial amounts of proteinases, contributing to the proteinase–antiproteinase imbalance in COPD. Mouse DCs show indeed an increase of MMP-12 production upon cigarette

smoke exposure [87] and could thereby contribute to the pathogenesis of emphysema.

Further research evaluating the effects of CSE on the differentiation of DC and on the maturation of Langerhans-type DC compared to interstitial type DC is mandatory to understand the role of the DC in smoking-related diseases. Ideally, longitudinal studies sampling the large and small airways should be performed in never-smokers, smokers without COPD, and patients with COPD to enumerate the different DC subsets. Importantly, healthy-smokers and smoking COPD patients should be studied longitudinally before and after smoking cessation, to be able to discern the effects of smoking per se versus the disease-specific effects of COPD on DC numbers, phenotypic markers, and functions. Moreover, the role of the plasmacytoid DC in COPD has to be elucidated, both during stable disease and at exacerbations. As plasmacytoid DC have important antiviral and tolerogenic properties, they could play a crucial role in the pathogenesis of COPD. In addition, impaired maturational response of DC upon cigarette smoke exposure could lead to an increased susceptibility to viral and bacterial infections, contributing to the increased incidence of lower respiratory tract infections (including pneumonia and tuberculosis) in smokers and of infectious exacerbations in patients with COPD.

## DCs AS DRUG TARGETS IN OBSTRUCTIVE AIRWAY DISEASES

If DCs are crucial in mounting immune responses during ongoing inflammation in the lung, then interfering with their function could constitute a novel form of treatment for obstructive airway diseases. Additionally, pharmacological modification of DCs might fundamentally reset the balance of the pro-inflammatory immune response in favor of regulatory T-cells and thus lead to a more long lasting effect on the natural course of allergic disease as well as progression in COPD. Glucocorticosteroids are currently the cornerstone of anti-inflammatory treatment in these diseases. Inhaled corticosteroids reduce the number of lung and nose DCs in patients with allergic asthma and allergic rhinitis [88]. Corticosteroids might also interfere with a GITRL-driven induction of the enzyme IDO in plasmacytoid DCs, thus broadly suppressing inflammation [31].

Recently, several other new molecules have surfaced that may alter DC function in allergic inflammation and thus treat disease. Many of these compounds were first discovered by their potential to interfere with DC-driven Th2 sensitization. The sphingosine-1-P analog FTY720 is currently used in clinical trials for multiple sclerosis and transplant rejection. When given to the lungs of mice with established inflammation, it strongly reduced inflammation by suppressing the T-cell stimulatory capacity and migratory behavior of lung DCs [64]. Also selective agonists of particular prostaglandin series receptors might suppress DC function. The DP1 agonist BW245C strongly suppressed airway inflammation and bronchial hyperreactivity when given to allergic mice by inhibiting the maturation of lung DCs [25].

A very similar mechanism was described for inhaled iloprost, a prostacyclin analog acting on the IP receptor expressed by lung DCs [27]. Extracellular ATP might be released by platelets upon allergen challenge. Neutralization of ATP via administration of the enzyme apyrase or the broad spectrum P2 receptor antagonist suramin reduced all the cardinal features of asthma by interfering with DC function [32]. A specific small molecule compound (VAF347) that blocks the function of B-cells and DCs was also shown to be effective in suppressing allergic airway inflammation in a mouse model of asthma [89]. Finally, specific inhibitors of *syk* kinase were shown to suppress DC function and eliminate established inflammation [90].

## CONCLUSION

Our understanding of DC biology in the airways has grown considerably. The concept that different subtypes of DCs perform different functions not only during sensitization but also during established inflammation is a theme that will persist in the coming years. Slowly, therapeutic strategies are emerging from these basic studies in animal models of asthma and COPD, which can eventually reach clinical application. However, detailed knowledge of DC biology in human airways is still lacking.

# Macrophages

**Galen B. Toews**

Division of Pulmonary and Critical Care Medicine, University of Michigan Health System, Ann Arbor, MI, USA

Macrophages are a family of mononuclear leukocytes that are widely distributed throughout most tissues. They vary considerably in phenotype depending on the local microenvironment [1]. Macrophages are involved in the scavenging of dying cells, pathogens, and molecules through phagocytosis and endocytosis [2]. Macrophages secrete more than 100 substances. These secreted molecules

- induce cell movement;
- induce cell growth;
- induce cell death;
- influence cell differentiation;
- modify connective tissue structures;
- regulate blood vessel growth.

Macrophages within tissues make a vital contribution to immune and inflammatory responses [2]. Macrophages are crucial for

- early recognition of microbes, particulates, and immunogens;
- the initiation and regulation of inflammatory responses and adaptive immunity;
- the ingestion and killing of invading microbes.

## ORIGIN AND DISTRIBUTION

The mononuclear phagocyte system (MPS) is composed of strikingly diverse differentiated cell types. Two subsets of murine monocytes arise from a common hematopoeitic progenitor, the macrophage, and dendritic cell precursor (MDP, or monoblast) [3]. "Inflammatory"

monocytes express the cell surface protein Ly6c (Gr-1$^+$), the chemokine receptor CCR2 and the adhesion molecule L-selectin and are selectively recruited to inflamed tissues and lymph nodes. The second subset of monocytes ("resting") are found in resting and inflamed tissues. This subset is defined by high expression of the chemokine receptor CX$_3$CR and LFA-1 and by the lack of expression of Gr-1, CCR2, and L-selectin. Two monocyte subsets have also been identified in humans; CD14$^+$, CD16$^-$ monocytes resemble murine inflammatory monocytes and CD14$^{low}$ and CD16$^+$ monocytes resemble mouse resident monocytes [3]. Interleukin-3 (IL-3), granulocyte-macrophage colony stimulating factor (GM-CSF), and macrophage colony stimulating factor (M-CSF) stimulate a sequence of differentiation steps important in monocyte development by binding to specific receptors on progenitor cells. Cytokines released during acute inflammatory responses also regulate macrophage differentiation. Interleukin-1 (IL-1) and tumor necrosis factor (TNF-$\alpha$) enhance M-CSF and GM-CSF production. Inhibitory inflammatory cytokines involved in macrophage differentiation include macrophage inflammatory protein-1$\alpha$ (MIP-1$\alpha$) and transforming growth factor $\beta$ (TGF-$\beta$) [4].

Monocytes/macrophages require continuous reconstitution. This can be achieved by self renewal of differentiated cells, by proliferation of bone marrow-derived precursors in peripheral tissues [5] or by the continuous extravasation and differentiation of circulating mononuclear phagocyte precursors [6]. Alveolar macrophages (AMs) are derived from blood monocytes and from proliferating macrophage precursors in the interstitium of the lung. Approximately 1% of the AM population in the normal lung is proliferating at any single time [7]. AMs have a life span of months and perhaps years [8].

## RECOGNITION OF MICROBES/MICROBIAL PRODUCTS

Macrophages are a major cellular component of the innate immune system [9]. The molecular and cellular processes of the innate immune response defend the host in the first minutes or first hours after exposure to microbes. The recognition of microbes is problematic because of their molecular heterogeneity and their high mutation rates. The innate immune system uses a relatively small number of proteins encoded in the germ line to recognize a vast variety of molecular structures associated with microbes. The receptors recognize a few, highly conserved structures present in large groups of microorganisms. The receptors recognize molecular patterns rather than particular structures and accordingly have been termed pattern-recognition receptors (PRRs). The pathogen-associated molecular patterns (PAMPs) recognized by PRR are chemically quite distinct but share certain features. PAMPs are: (a) produced only by microbes and not by eukaryote hosts, (b) essential for survival or pathogenecity of the microbe, and (c) invariant structures shared by classes of pathogens. Characteristic PAMPs include lipopolysaccharides (LPSs) and teichoic acids, shared by gram-negative and gram-positive bacteria, respectively; mannans, conserved components of yeast cell walls; and the unmethylated CpG motif characteristic of bacterial but not mammalian DNA. PRRs expressed on macrophages include the mannose receptor, DEC205, CD14, scavenger receptors, integrins, and toll-like receptors (TLRs). Recognition of pathogens results in the activation of various types of innate immune receptors [10–15].

TLRs comprise a family of PRRs that recognize a variety of conserved PAMPs displayed by microbes. Ten TLRs have been described (an eleventh is functional in mice but not in man [16–22]). The principle role of TLRs appears to be induction of immune/inflammatory responses to a broad range of pathogens (viruses, helminths, bacteria, protozoa, and fungi). TLR4 is crucial for effective responses to gram-negative LPS [23]. LPS delivery to TLR4 requires the accessory proteins LPS-binding protein (LBP), CD14 and MD-2. Integrins such as CD11b/CD18 may facilitate responses to LPS [13, 24]. TLR4 also facilitates responses to *Streptococcus pneumoniae* pneumolysin and proteins of respiratory syncytial viruses [25, 26]. TLR2 mediates the responses to lypoproteins and lipoteichoic acids (LTA) from gram-positive bacteria (*S. pneumoniae*) and Mycobacteria [27, 28]. TLR2 plays a role in responses to *Borrelia burgdorferi*, *Aspergillus fumigatus*, and *Mycoplasma*. TLR2 responses are broadened by hetero-dimerization; TLR1/2 heterodimers respond to a different panel than TLR2/6 heterodimers. TLR2 and TLR4 respond to helminths.

TLR9 mediates the responses through recognition of CpG motifs in microbial DNA. TLR9 is activated by bacteria, Herpes viruses [29, 30], and *Aspergillus* [31]. TLR3 responds to double stranded viral RNA and TLR7 and TLR8 mediate responses to single stranded RNA [32, 33]. TLRs also respond to endogenous host molecules, including defensins [34], reactive oxygen species (ROS) [35], protein released from dying cells [36], surfactant protein

A [37], fibrinogen [38], and breakdown products of tissue matrix, such as fibronectin fragments [39] and hyaluronic acid oligosaccharides [40].

Activation of TLRs initiates signal transduction pathways that initiate and amplify inflammatory responses in the lung and modulate adaptive immune responses. Molecules induced by PAMP-PRR interactions include

- signals that generate inflammatory responses, including TNFα, IL-1, IL-6, interferon (IFN)α/β and chemokines;
- signals that function as co-stimulators of T-cell activation, B7.1 and B7.2;
- signals that regulate the differentiation of lymphocytes, including IL-4, IL-5, IL-10, IL-12, TGF-β and IFN-γ [41].

Activation of TLRs can also contribute to the induction of programmed cell death.

## HOMEOSTATIC REGULATION OF AM FUNCTION

Resident AMs are continually exposed to inhaled and aspirated particulates due to their position in the airway and alveolar lumen. In spite of this exposure to particulates, resident AMs produce only low levels of cytokines and are poorly phagocytic.

A mechanism by which the lung microenvironment instructs AM innate and adaptive immune functions has recently been defined [42]. Under homeostatic conditions, AMs closely adhere to alveolar epithelial cells (AECs). This cell–cell interaction induces TGF-β dependent expression of the integrin αvβ6 on AEC. Localized activation of TGF-β in the vicinity of the macrophage suppresses macrophage phagocytosis and cytokine production. This inhibition of macrophage function by the αvβ6–TGF-β complex is unique to the lung.

The mechanism whereby microbial infection overcomes suppression is also explained by AEC-macrophage-TLR responses. Infectious agents trigger TLRs which lead to a rapid loss of contact with AECs which in turn induces rapid loss of expression of αvβ6 on AEC. Under these conditions TGF-β is no longer activated and macrophage activation and innate immune functions are no longer suppressed. Macrophages can now be primed to secrete pro-inflammatory cytokines and to ingest and kill microbes. AMs lack a feed forward mechanism of amplification mediated in other mononuclear phagocytes by autocrine secretion of IFN-β. AMs thus require exogenous IFN-β for a robust response [43]

## GENERATION OF INFLAMMATORY RESPONSES

Resident AMs can effectively ingest and kill invading microbes if the bacterial burden is low and the microbe is

minimally virulent [44, 45]. However, the recruitment of polymorphonuclear neutrophils (PMN) is essential for the effective containment of most virulent encapsulated bacteria within the lung and for the eventual clearance of these virulent microbes from the host. The generation of inflammation in the lower respiratory tract is a dynamic process that involves the coordinated expression of both pro- and anti-inflammatory cytokines. After the introduction of microbes or microbial products, TLR-mediated signals result in the production of TNF-$\alpha$ and IL-1$\beta$. TNF-$\alpha$ and IL-1$\beta$ stimulate the expression of adhesion molecules on vascular endothelial cells. L-selectin on neutrophils interacts with its receptor/ligand (P- and E-selectin) on endothelial cells that lead to rolling. Intercellular adhesion molecule-1 (ICAM-1) expression is also induced on the surface of the endothelium; interactions between neutrophils and ICAM lead to firm adhesion [46, 47]. CXC chemokines and CC chemokines are also rapidly produced in macrophages following microbial stimuli. CXC chemokines include IL-8, (CXCL8), GRO$\alpha$, (CXCL1) ENA-78, and (CXCL5) are major PMN chemoattractants (Table 11.1). Thus, immediately after the recognition of bacterial products in the alveolar environment, PMNs begin to accumulate.

Macrophages also play a major role in amplifying the inflammatory response by stimulating cytokine production

**TABLE 11.1** The CXC chemokine/receptor family.

| Systematic name | Human ligand | Mouse ligand | Chemokine receptor(s) |
|---|---|---|---|

by cells that do not respond directly to bacterial products. Mononuclear phagocytes, neutrophils, and endothelial cells produce CXC chemokines in response to LPS. Alternatively, airway and AECs, pulmonary fibroblasts, and pleural mesothelial cells produce IL-8 in response to specific host-derived signals, such as TNF-$\alpha$ or IL-1 [48–50]. The importance of IL-1 and TNF-$\alpha$ as key cytokines in the initiation of this augmented inflammatory response is emphasized by the fact that all nucleated cells possess a functional receptor for IL-1 and TNF-$\alpha$.

Macrophages are also potent sources of bioactive lipids, which are important in inflammatory responses. Leukotriene (LT) synthesis is dependent on three sequential enzymes: cytosolic phospholipase A (cPLA$_2$), 5-lipoxygenase (5-LO), and 5-LO-activating protein (FLAP). These three proteins co-localize at a single membrane site to form a macromolecular complex termed a metabolon. There is now abundant evidence documenting that the nuclear envelope is the site at which this metabolon is assembled [51].

The LT synthetic pathway is initiated when cPLA$_2$ translocates from the cytosol to the nuclear envelope following activation signals. Arachidonate is released from nuclear envelope phospholipids and is bound by FLAP, an integral nuclear envelope protein. FLAP facilitates processing by 5-LO. On activation, 5-LO also translocates from its resting locale(s) in the cytosol and/or nucleoplasm to the nuclear envelope where it catalyzes the initial steps in LT synthesis [52, 53]. LTs, thus synthesized, are capable of either entering into the nucleus or being exported out of the cell [53]. Monocytes release LTB4 and LTC4 after being exposed to non-immunologic stimuli or immunologic stimuli. AMs produce a substantial excess of LTB4 compared with LTC4 after stimulation [54]. LTB4 is a potent chemotactic factor for PMNs and weaker chemotactic factor for eosinophils. LTB4 accounts for the majority of neutrophil chemotactic activity elaborated by AM immediately following stimulation [54]. LTB4 also promotes adherence of inflammatory cells to the endothelium. Leukotrienes also play a permissive role in inflammation by promoting the synthesis by macrophages of TNF-$\alpha$, IL-8, (CXCL8), GRO$\alpha$, (CXCL1) ENA-78, (CXCL5), and IL-6.

An important implication of the metabolon concept is that the site of macromolecular assembly has evolved in a manner to best serve the needs of the cell. The observation that the LT metabolon is located within the nuclear envelope suggests that the autocrine actions of bioactive lipid mediators, including those potentially mediated within the nucleus, may be of more importance than those paracrine actions that have been classically recognized. 5-LO metabolites are important modulators of mitogenesis, apoptosis, and the activation of various transcription factors. A soluble nuclear receptor for LTB4 provides additional support for such interactions; interestingly, this receptor is a member of a super-family of transcription factors and its ligation induces gene transcription. Alternatively, reactive oxygen species, which are a byproduct of arachidonate 5-lipoxygenation could exert nuclear actions by activating transcription factors or otherwise modifying nuclear constituents.

Monocytes exit the blood in inflamed tissues in response to specific chemotaxins. Monocyte recruitment is

A systematic name in parentheses means a human homologue has not been identified. A question mark indicates that the mouse ligand homologue listed may not correspond to the human ligand.

critically dependent on CC chemokines [29]. Twenty-seven different CC chemokine ligands (CCL) have been described [55]. Chemokines that act mainly on monocytes are located on a cluster on human chromosome 17q11.2. Important monocyte chemoattractant CC chemokines include MCP-1 (CCL2), MIP-1α (CCL3), MIP-1β (CCL4), and RANTES (CCL5) (Table 11.2). CC chemokines are produced by monocytes, alveolar macrophages, lymphocytes, neutrophils, epithelial cells, fibroblasts, smooth muscle cells, and endothelial cells. These cells produce chemokines in response to a variety of factors including cigarette smoke, viruses, bacterial products, IL-1, TNF, C5a, LTB4, and INFs [56–66]. Bronchial epithelial cells release monocyte chemotaxins in response to cigarette smoke [63]. TNF-α and IL-1 are among the most potent stimuli for epithelial cell cytokine production. Macrophage stimulation of epithelial cells by TNF or IL-1 likely enhances and perpetuates the initial inflammatory response. Increased epithelial expression of MCP-1 has been observed by immunohistochemistry and biopsy specimens from patients with atopic asthma, and increased levels of this chemokine are also seen in bronchoalveolar lavage (BAL) fluid of allergic asthmatics when compared with normal subjects [65, 66].

The biological effects of chemokines are mediated by seven transmembrane domain receptors that are a subset of the G-protein-coupled receptor super-family. Sixteen receptors have been identified. Redundancy and binding promiscuity exists between ligands and receptors (Tables 11.1 and 11.2). A single chemokine may bind to several receptors and a single chemokine receptor can transduce signals for several chemokines [55].

Monocytes also respond to formyl peptides, C5a, and elastin fragments. In a murine model of cigarette smoke-induced emphysema, CC and CXC chemokines are undetectable but chemotactic extracellular matrix fragments, particularly elastin fragments, are present [67–69].

## T-CELL INDEPENDENT MACROPHAGE ACTIVATION

The early nonantigen-specific activation of macrophages is one of the first events in the innate immune response and is often very effective in eliminating microbes. Innate immune macrophage activation fills a gap between microbial entry into the host and the development of antigen-specific immunity. Innate immune macrophage activation is a cytokine mediated macrophage-NK cell interaction [70]. Macrophages release IL-12 and TNF-α following microbial recognition; these cytokines induce NK cell IFN-γ which primes macrophages for microbicidal activity. IL-12 is regulated by both positive and negative feedback mechanisms. IFN-γ activated macrophages produce much higher levels of IL-12. IL-10, a product of macrophages and other cell types, is a potent inhibitor of IL-12 production [71]. Expression of IL-10 is delayed compared with the expression IL-12 *in vivo*. IL-10 is a critical component of the host's natural defense against excessive production of IL-12 and its pathological consequences.

## ROLE OF MACROPHAGES IN INITIATION OF IMMUNE RESPONSES

The activation of T-lymphocytes is a complex biological function that requires the participation of an antigen-presenting cell (APC). Most cell types cannot perform these functions; "professional APCs" (macrophages, dendritic cells (DCs), and B-cells) are required. Antigen presentation involves the display of an antigenic epitope in association with a major histocompatibility complex (MHC) molecule. Three additional molecular interactions are crucial to the interaction between an APC and a T-lymphocyte:

1. adhesion molecules that promote the physical interaction between APC and T-cells;
2. co-stimulatory molecules which are membrane bound growth/differentiation molecules that produce T-cell activation [72];
3. soluble molecules such as TNF-$\alpha$ and IL-1.

AMs are ineffective in presenting antigen to T-cells [73–75]. AMs are less effective than monocytes in inducing proliferation of blood T-lymphocytes to soluble recall antigens. AMs can, however, restimulate recently activated T-cells effectively. AMs fail to activate CD4$^+$ T-cells because of defective expression of B7 co-stimulatory cell surface molecules. AMs activated with IFN-$\gamma$ fail to express B7-1 or B7-2 antigens [76]. Resident pulmonary AMs also actively suppress T-cell proliferation induced by antigen [73].

The mechanisms whereby particulate antigens and microbial agents induce T-cell responses are being defined. DCs are present in the airways and in the interstitium of the lower respiratory tract [77]. DCs are clearly crucial for activating naive T-cells for proliferation and clonal expansion. Monocytes are also stimulatory to T-cell activation. Thus, inflammatory stimuli that recruit fresh monocytes to the lung might theoretically dilute the resident AM population with recruited monocytes and convert a normally immunosuppressive tissue milieu into one that is supportive of T-cell activation.

## INNATE IMMUNE CONTROL OF ADAPTIVE IMMUNE RESPONSES

Naive T-lymphocytes can differentiate along different pathways to become distinct effector cells. The tissue microenvironment in which the specific immune response is generated crucially regulates this differentiation process via the secretion of specific cytokine signals (Fig. 11.1). IL-12 produced by macrophages during the early innate immune response and IFN-$\gamma$ induced by IL-12 create an environment in which antigen-specific CD4$^+$ and CD8$^+$ T-cells are preferentially induced to differentiate into T1 cells that produce even higher levels of IFN-$\gamma$ [78]. IL-4 is crucial to the development of T2 responses during the priming of naive T-cells. The crucial cellular source of early IL-4 production is uncertain. Basophils, mast cells, $\gamma\delta$ cells, T2 lymphocytes, and an NK 1.1$^+$ CD4$^+$CD8$^-$ T-lymphocyte have all been reported to produce IL-4 [79].

The type of APC that presents the antigen may also be crucial. DCs preferentially activate T2 cells in certain circumstances [80]. The mechanisms by which DCs favor the expression of T2 cells remains uncertain but may be related to the ability of DCs to secrete IL-1, a co-stimulator for T2 cells but not T1 cells, and to the absence of IFN-$\gamma$ production by DCs which would inhibit the development of T2 cells. Differential expression of co-stimulatory molecules may also be crucial to this polarization process. AM fails to express B7.1 or B7.2 even when stimulated with IFN-$\gamma$. B7.2 is constitutively expressed on DCs and macrophages, whereas

FIG. 11.1 Innate immune control of adaptive immune response. The tissue microenvironment regulates adaptive immune responses. DC migration and functional differentiation state are crucial determinants of immune priming. IgE on the surface of DC may focus uptake and processing of other antigens. Density and affinity of antigens regulates differential signals following T-cell receptor engagement. Co-stimulatory molecules influence T-cell differentiation. Innate immune cell cytokines are the major regulators of T-cell differentiation. (Solid arrows indicate stimulators; broken arrows indicate inhibitor.)

B7.1 is not. The outcome of B7.1 and B7.2 co-stimulation is different. B7.2 co-stimulates the production of IL-4 as well as IL-2 and IFN-$\gamma$. Thus, after B7.2 co-stimulation, an initial source of IL-4 is available. However, B7.2 co-stimulation provides only a moderate signal for T2 cell differentiation; additional signals are almost surely required to achieve high levels of IL-4 production [81]. B7 co-stimulatory signals can be delivered by bystander APC *in vitro* with the same efficiency as the APC engaging the TCR. Accordingly, T-cell activation *in vivo* may occur with MHC-TCR engagement being provided by one APC, whereas co-stimulation is delivered by a second bystander APC-type [82].

The tissue microenvironment in which the immune responses are generated is crucial in determining the type and intensity of T-lymphocyte responses. Cytokines secreted in the tissues, where the antigen is deposited, are also crucial for the maintenance and regulation of immune responses.

## ROLE OF MACROPHAGE-DERIVED GROWTH FACTORS IN TISSUE REMODELING AND REPAIR

Fibrotic changes occur in airways and the lower respiratory tract following certain injuries. Macrophages produce numerous growth factors for fibroblasts including platelet-derived growth factor (PDGF), TGF-$\alpha$ and TGF-$\beta$, and insulin-like growth factor [83–85].

- PDGF induces fibroblast proliferation and collagen production.
- The wound healing effects of PDGF are macrophage dependent in most models [85].
- TGF-$\alpha$ stimulates the closure of wounds induced in cultures of type II AEC *in vitro*.
- TGF-$\alpha$ likely plays a role in epithelial cell repair of the lungs following injury. Macrophages also produce TGF-$\beta$, which has important effects on the turnover of matrix proteins and the proliferation of fibroblasts.
- TGF-$\beta$ activates genes that favor the production of matrix proteins. TGF-$\beta$ also down-regulates production of matrix metalloproteinases derived from PMNs and macrophages that digest matrix in the interstitium and alveolar spaces. In aggregate, these effects shift the balance in favor of matrix accumulation.

GM-CSF has a protective effect on repair processes following bleomycin. This protective effect is mediated, in part, by GM-CSF-induced production of PGE$_2$ by pulmonary macrophages [86]. PGE$_2$ has crucial down-regulatory effects on fibroblasts, including decreasing fibroblast proliferation and decreasing matrix produced by fibroblasts.

Macrophages may also play critical roles in regulating angiogenesis, which is a central biological event in repair and remodeling. CXC chemokines such as IL-8 or ENA-78 that contain the sequence GLU-LEU-ARG (ELR motif) are potent angiogenic factors. In contrast, CXC chemokines that lack the ELR motif (platelet factor 4, IFN-$\gamma$ inducible protein 10) behave as potent angiostatic factors. Non-ELR-containing chemokines can inhibit angiogenic activity of both ELR-CXC chemokines and structurally unrelated macrophage-derived angiogenic factor bFGF [87].

## Macrophages and chronic obstructive pulmonary disease

A marked increase in the number of macrophages and neutrophils in the airways of both humans and experimental animals is the most consistent, early effect of exposure to cigarette smoke [88]. Histologic studies of bronchial biopsies and lung parenchyma obtained from cigarette smokers demonstrate a predominance of macrophages and CD8$^+$ T-cells at sites of parenchymal destruction [89, 90]. The paucity of neutrophils in lung parenchyma and airway biopsies suggests neutrophils traffic rapidly from the blood into the airway lumen. The inflammatory process, once initiated, persists in ex-smokers [90, 91]. Surprisingly, the inflammatory responses persist in end-stage emphysema. Increased number of macrophages, CD8 and CD4 T–lymphocytes, and neutrophils are noted in lungs from patients undergoing lung volume reduction surgery.

Macrophages are likely to play an important role in initiating the neutrophilic inflammatory response in cigarette smokers. Macrophages may be activated by cigarette smoke and other inhaled particulates. Elevated levels of the CXC chemokines, IL-8, (CXCL8), GRO$\alpha$, and (CXCL1) are noted in cigarette smokers. IL-8 and (CXCL8) levels in sputum correlate with the magnitude of neutrophilic inflammation and with percent predicted FEV1 [92]. LTB4 is increased in the sputum of patients with chronic obstructive pulmonary disease (COPD); this potent neutrophilic chemoattractant likely participates in the generation of the neutrophilic inflammatory response.

The inflammatory response in COPD has several distinguishing features:

- Resident AMs are activated upon exposure to cigarette smoke.
- Neutrophils are rapidly recruited almost immediately after cigarette smoke exposure in response to macrophage and epithelial cell-derived chemokines and leukotrienes.
- Macrophages and CD8$^+$ and CD4$^+$ T-lymphocytes accumulate within days to weeks and continue to accumulate with time.
- The abnormal accumulation of inflammatory cells persists throughout the disease process, even when the inciting agent, cigarette smoke, is removed.

## Macrophage proteinases and COPD

Early changes of emphysema include subtle disruption of elastic fibers, bronchiolar and alveolar distortion, and the

appearance of fenestrae. Destruction of the elastic framework leads to loss of the intra-alveolar septae and macroscopic appearance of spaces of more than 1mm in diameter. This destructive process is accompanied by an increase in the mass of collagen, suggesting that active alveolar wall fibrosis occurs in the tissues which remain in otherwise emphysematous lungs [93]. The dominant, working hypothesis to explain the pathogenesis of emphysema has postulated an imbalance between proteolytic enzymes and proteinase inhibitors in the lung, favoring an excess of proteinases, particularly elastases. This hypothesis postulates that cigarette smoke, macrophages, chemoattractants, neutrophils, elastases, and proteinase inhibitors interact with lung connective tissue, primarily elastin, to cause repeated destruction and synthesis of pulmonary matrix.

Pulmonary macrophages may play an important role in this proteolytic process by releasing neutrophil chemotactic factors, which recruit neutrophils to the respiratory tract. Neutrophil elastase is believed to play an important role in COPD. Neutrophil elastase is one of the most potent elastases in the lung. Instillation of neutrophil elastase and proteinase 3 causes emphysema in animals [94–96]. Neutrophils are recruited into the lungs of animals and generate detectable elastin fragments following exposure to cigarette smoke. Neutrophil elastase is also a potent mucus secretagague.

Macrophages also secrete potent proteinases. Human AMs produce the cysteine (thiol) proteinases, cathepsins B, H, L, and S. Cathepsins L and S have relatively indiscriminate substrate specificities that include elastin and other matrix components. Cysteine proteinases are involved in lung destruction in IL-13 and IFN-$\gamma$ transgenic mice [97, 98].

Pulmonary macrophages also produce matrix metalloproteinases (MMPs). Studies of human emphysematous lung tissue have demonstrated the presence of several MMPs. A correlation between MMP-1 and MMP-9 and emphysema was noted when smokers with emphysema were compared with smokers without emphysema [99]. Studies using transgenic and gene-targeted mice also lend support for the role of MMPs in emphysema. Transgenic mice over-expressing human MMP-1 in the lung develop airspace enlargement [100]. Studies of MMP-12 knockout mice provide specific loss-of-function data that MMP-12 is importantly involved in the development of emphysema in response to cigarette smoke. Exposure of MMP-12 +/+ mice to long-term cigarette smoke led to inflammatory cell recruitment followed by alveolar space enlargement similar to that seen in humans with emphysema. Mice deficient in MMP-12 (MMP-12 −/−) were protected from development of emphysema despite long-term smoke exposure [101]. Interestingly, MMP-12 −/− mice failed to recruit monocytes into the lung in response to cigarette smoke. MMP-12 −/− mice could egress from the pulmonary vasculature in response to MCP-1 instillation. However, even in the presence of MMP-12 −/− macrophages, the lungs of mice exposed to cigarette smoke had no changes in the mean linear intercept in alveolar duct areas when compared to mice not exposed to smoke.

These findings suggest that MMP-12 is expressed by resident AMs after exposure to cigarette smoke. MMP-12 generates monocyte chemotaxins, likely fragments of elastin, which are responsible for the monocyte recruitment in response to smoke. Macrophage-mediated lung destruction after exposure to cigarette smoke is, at least in part, directly related to the presence of MMP-12, which is most likely required for direct degradation of lung tissue. The generation of chemotactic elastin fragments provides a positive feedback loop perpetuating macrophage accumulation in lung destruction.

Cigarette smoke induces a distinct pattern of AM gene expression not seen in non-smokers or patients with asthma [102]. AM from smokers strongly express MMP-12, but most of the 72 genes upregulated in smokers were not identified in two transgenic murine models of emphysema.

## MACROPHAGES AND ADAPTIVE IMMUNITY IN COPD

Cigarette smoking stimulates humoral and cellular components of the adaptive immune response. This response may provide exquisite specific memory for previous exposures to foreign materials. The histologic hallmark of an adaptive immune response is the presence of lymphoid follicles with germinal centers. Bronchial-alveolar lymphoid tissue (BALT) collections are found in 5% of smokers with normal lung function (GOLD0) and in those with mild (GOLD1) and moderate (GOLD2) severity. These collections of BALT increase sharply in severe (GOLD3) and very severe (GOLD4) COPD perhaps in response to colonization and infection of the lower airways [90].

## MACROPHAGES AND APOPTOSIS IN COPD

There is growing evidence for a role for apoptosis in COPD [103]. AMs show a markedly reduced capacity to ingest apoptotic cells relative to their avid ingestion of inert particles [104]. This capacity is further reduced in COPD with attendant increased accumulation of apoptotic cells. Apoptotic cell recognition typically induces a unique anti-inflammatory state; defective clearance might be a factor encouraging lung inflammation [105].

## MACROPHAGES AND INITIATION OF ANTIGEN-SPECIFIC T2 IMMUNE RESPONSES IN ASTHMA

Resident pulmonary AMs actively suppress T-cell proliferation induced by antigen or polyclonal stimuli [73]. Changes occur within the local inductive milieu of the lung in patients with asthma. AM suppression is reduced after exposure to allergens [106–108].

The tissue microenvironment is a crucial regulator of specific immune response generation (Fig. 11.1). The presence of IgE on APCs likely promotes the uptake and the processing of allergens and their eventual presentation to naïve T-cells. DCs express both Fc$_\varepsilon$R I and Fc$_\varepsilon$R II. These two receptors could function to capture allergen bound to allergen-specific IgE and thus focus the immune response through facilitated antigen presentation [109].

Antigens also deliver signals via quantitative variation in ligand density on APC. Peptide/MHC class II complexes that interact strongly with the TCR favor T1 responses, whereas weak interactions result in the priming of T2 responses. The overall binding affinity can be varied by modifying the peptide, which results in different signals. The mechanisms by which signals delivered via the TCR control differentiation is uncertain; differential TCR aggregation may result in differential intracellular signals that favor distinct cytokine gene expression or certain MHC–TCR interactions may favor differential co-receptor expression [110]. As noted above, co-stimulatory molecules may direct the polarization of T-cells into T1 or T2 cells; B7.2 provides only a moderate signal for T2 cell differentiation; and co-stimulatory signals may be delivered either by the APC that presents the antigen or by the bystander APC. Thus, macrophages may serve as bystander APC and influence DC-induced T-cell proliferation [111]. Soluble cytokines produced by cells of the innate immune response are likely the major regulators of T-cell differentiation (see "Innate Control of Adaptive Immune Responses" section).

## MACROPHAGES IN THE EFFECTOR PHASES OF IMMUNE RESPONSES IN ASTHMA

Macrophages are likely the sources of cell-specific chemoattractants in patients with asthma. RANTES, (CCL5), MIP-1$\alpha$, and (CCL3) are chemotactic for macrophages, eosinophils, and basophils. MCP-1 and (CCL1) are chemotactic for macrophages and basophils. IL-8 and (CXCL8) are chemotactic for neutrophils, basophils, and to lesser extent eosinophils. Additionally, macrophage-released early cytokines likely induce epithelial cells and fibroblasts to release chemoattractants and growth factors (GM-CSF, IL-8, (CXCL8), MCP-1, (CCL1), MCP-3, (CCL7), MCP4, (CCL13), MIP-1$\alpha$, (CCL3), RANTES, and (CCL9)) in patients with asthma [112–115].

Leukotrienes are perhaps the best studied macrophage-produced mediators involved in the pathogenesis of asthma. The role of macrophage-derived leukotrienes remains uncertain. Cysteinyl leukotrienes (LTC4, D4, and E4) are minor products of AMs when compared to LTB4 production [51, 53, 113]. This metabolic profile argues against a role for AMs in LT overproduction in the lung. Alternatively, several features favor a role for AMs in LT production. The cells are located on the airway surface, express plasma membrane IgE receptors, and secrete substantially more LTC4 than do PMN. Cysteinyl leukotrienes are known to promote mucus hypersecretion, airway inflammation, and marked, prolonged contraction of smooth muscles in airways.

## MACROPHAGES AND AIRWAY RESPONSES TO VIRAL INFECTION

Host innate immune responses to respiratory viral infections may play a crucial role in the pathogenesis of asthma. The site of initial viral replication is usually respiratory epithelial cells and macrophages. Host defense against virus depends on the targeted death of infected cells and the subsequent clearance of the cellular corpses by macrophages. Macrophages must avoid viral-induced death for this process to be effective. CCL5–CCR5 interactions are required to prevent apoptosis of virus infected macrophages *in vivo* and *in vitro*. Infected macrophages must resist cell death to efficiently clear virus infected apoptotic cells from the lung. If this clearance process is disrupted, pathogens are not cleared and residual apoptotic cells including activated macrophages can cause further damage [116].

# Eosinophils

**Dagmar Simon[1] and Hans-Uwe Simon[2]**

[1]Department of Dermatology, Inselspital, University of Bern, Bern, Switzerland
[2]Department of Pharmacology, University of Bern, Bern, Switzerland

Eosinophil infiltration of the airways is a characteristic feature of obstructive pulmonary diseases in particular of bronchial asthma. But eosinophils have also been connected with chronic obstructive pulmonary disease (COPD) in at least a subgroup of patients. Initially, the function of eosinophils was almost exclusively related to their destructive activity mediated by the toxic effects of the eosinophil granule proteins. In the last two decades research work has made it clear that eosinophils also play important roles in immunomodulation as well as in repair and remodeling processes. To describe the role of eosinophils in bronchial asthma or other eosinophilic diseases, we will first review their functional properties and the regulation of eosinophil numbers. We will then focus on the potential role of eosinophils in the pathogenesis of bronchial asthma and COPD. However, as the reader will realize our current knowledge on the physiologic and pathogenic role of eosinophils is still not complete.

## MORPHOLOGY AND LOCATION

Among the leukocytes, eosinophils attract attention because of their characteristic appearance revealing a bilobed nucleus with highly condensed chromatin and a multitude of coarse granules. Eosinophils can easily be identified because of their strong affinity to the acidic dye eosin in blood and tissues even when they are paraformaldehyde fixed and paraffin embedded. This characteristic inspired Paul Ehrlich to name these granular leukocytes eosinophils after discovering them in 1879 [1]. Eosinophils are released from the bone marrow into the peripheral blood, where they represent 1–5% of the leukocytes with an upper limit of $0.4 \times 10^9$/l under normal conditions [2]. Some laboratories list higher upper values, in particular in children (as high as $0.75 \times 10^9$/l). Eosinophils circulate only a few hours in the peripheral blood before they enter the tissues, where they can survive for at least 2 weeks [3, 4].

The cytoplasmic granules are composed of four distinct populations, which can be identified under electron microscopy: primary and secondary granules, small granules and lipid bodies [5]. The primary granules contain galectin-10, the Charcot-Leyden crystal protein, which binds lysophospholipases [6]. The cytotoxic cationic proteins are stored in the secondary granules. These granules are formed by a core containing major basic protein (MBP) and a matrix composed of eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), and eosinophil derived neurotoxin (EDN) [7]. Mature eosinophils also house small granules storing proteins, such as arylsulphatase B and acid phosphatase. The lipid bodies contain arachidonic acid, the basic component for eicosanoid production [8]. In addition, both the secondary granules and the lipid bodies store a number of cytokines, chemokines and growth factors [5].

In the absence of eosinophil-specific surface markers [9], MBP and ECP are widely used as targets for immunohistochemical studies. Some investigations revealed that eosinophil granule proteins are present not only in the cells, but also in the extracellular spaces suggesting eosinophil degranulation [10]. In addition, receptors, which are almost specifically expressed by eosinophils, for example, CC chemokine receptor (CCR)3 and interleukin (IL)-5 receptor alpha, or the transcription factor GATA-1 can be used as markers to identify eosinophils. Recent research using flow cytometry and microarray assay techniques demonstrated that eosinophils

express typical surface molecule patterns consisting of CCR3, Siglec-8 (Siglec-F), FIRE (F4/80–like receptor), CD62 ligand, and paired Ig-like receptor A/B (Pir-A/B) at different stages of differentiation and activation [11].

Under physiologic conditions, eosinophils are found in the bone marrow, the lymphatic organs such as spleen, lymph nodes, and thymus, and throughout the gastrointestinal tract except the esophagus [12]. Recent studies reported the essential role of eosinophils in mammary gland branch formation [13] and maturation of the pubertal uterus in mice [14]. In the gastrointestinal tract, numbers of eosinophils depend on the location as well as on the exposure to pathogens in asymptomatic individuals [15]. Under normal conditions, the baseline levels of eosinophils are controlled by eotaxin-1 [16]. Moreover, in preinvolutional human thymi, eosinophils [17] and eosinophil precursors [18] have been identified, the latter suggesting differentiation of eosinophils in the thymus. Eosinophils have been associated with major histocompatibility complex (MHC) class I-restricted selection/deletion in the thymus, pointing to an immunomodulatory function under non-pathological conditions [19].

**FIG. 12.1** Eosinophil effector molecules.

## EOSINOPHIL FUNCTIONS

The view of eosinophil function has profoundly changed in the last two decades. Eosinophils have always been regarded as destructive effector cells that release toxic granule proteins. The primary function of eosinophils has been related to the protection against helminth parasites [20]. The observation that eosinophils surround parasites in the tissue as well as a number of in vitro and animal experiments revealed a direct role for eosinophils in killing parasites. Later it became clear that eosinophils also play a role in the pathogenesis of helminth infections by causing tissue damage and organ dysfunction [20]. Results of more recent research indicate that eosinophils play an important role in repair and remodeling processes after tissue damage as well as in immunomodulation [21]. Interestingly, eosinophils produce and release a broad spectrum of cytokines, chemokines, and leukotrienes as well as express cell surface receptors for these mediators, suggesting autocrine and paracrine mechanisms in regulating eosinophil functions [21]. The main effector molecules of eosinophils are summarized in Fig. 12.1.

Activation of eosinophils is required for their migration into the sites of inflammation in the tissue, for the production and release of their granule proteins and lipid mediators, as well as for the generation of reactive oxygen species [5]. Hematopoietins, such as IL-3, IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF), increase functional responses of eosinophils to various agonists including lipid mediators, complement factors, or chemokines. This effect of hematopoietins is called priming.

### Granule protein production and release

MBP is highly cytotoxic [22] and plays an essential role in host defense against helminth infection. Because of its cationic nature, it affects the charge of surface membranes resulting in disturbed permeability, disruption, and injury of cell membranes [23]. At low concentrations, MBP stimulates mediator production by other inflammatory cells (discussed later). ECP and EDN have been identified as ribonucleases [24] and possess antiviral activity [25]. ECP damages target cell membranes through the formation of pores or transmembrane channels [26]. Besides their ribonuclease activities, both EDN and ECP are potent neurotoxins [27]. Eosinophils store abundant amounts of ECP and may release it upon repetitive stimulation with the same agonist, implying that mature eosinophils do not require significant *de novo* ECP synthesis for secretion [28]. EDN was demonstrated to induce recruitment and cytokine release by dendritic cells [29]. EPO is involved in the generation of toxic oxygen species as part of the respiratory burst.
Upon activation, eosinophils specifically release their granule proteins by exocytosis or degranulation [30]. In classical exocytosis, single secretory granules are extruded to the cell exterior, whereas in compound exocytosis fusion of intracellular granules precedes their release through a single fusion pore to effectively target surfaces as it has been shown for helminth infection [31]. Piecemeal degranulation has been identified as mechanism by which cytoplasmic secretory vesicles containing cytoplasmic crystalloid granules with core components are released from eosinophils. In addition, granule deposition in the tissue may occur after cytolysis of the eosinophil [30]. A prerequisite for exocytosis is the docking of the vesicles/granules to the cell membrane mediated by membrane-associated proteins forming soluble NSF attachment protein (SNAP) receptors (SNAREs) [32].

## Respiratory burst

The superoxide radical generation after activation of the NADPH oxidase complex presents a powerful weapon by which eosinophils dispose of pathogens; and this mechanism is even more powerful than that in neutrophils [33]. Activated NADPH oxidase catalyzes $O_2$ to $O_2^-$, which enters further redox pathways to generate hydrogen peroxide ($H_2O_2$) in the presence of superoxide dismutase, or hydroxyl and nitrogen dioxide radicals, after combining with nitric oxide. The granular protein EPO oxidizes bromide, nitrite, and thiocyanate in the presence of $H_2O_2$, which have the potency to disrupt cell membranes or cause intracellular oxidant stress [34].

## Cytokine production and release

Eosinophils are able to produce, store, and secrete a wide spectrum of cytokines and chemokines and thus may function as immunomodulatory cells. Although eosinophils are terminally differentiated cells, their capacity to generate cytokines can be quite intriguing. Eosinophils from normal individuals constitutively express IL-4 and IL-10 with further upregulation in response to inflammatory signals [35]. Both the cytokines as well as IL-2, IL-5, and IL-13 are stored in the crystalloid core. Cytokines and chemokines that may activate cytokine production by eosinophils are IL-3, IL-5, GM-CSF, interferon (IFN)-γ, tumor necrosis factor (TNF)-α, and complement factor C5a [5, 36]. In response to stimulation, eosinophils may produce proinflammatory cytokines, which may overlap the typical spectrum of both T helper 1 and T helper 2 cytokines, regulatory cytokines, and chemokines: IL-1, IL-3, IL-5, IL-6, IL-8, IL-12, IL-13, IFN-γ, tumor growth factor (TGF)-α, TGF-β, GM-CSF, TNF-α, macrophage inflammatory protein (MIP)-1α, regulated upon activation, normal T-cell expressed and secreted (RANTES) and eotaxin [4, 5, 37–40]. Recently, eosinophils have been shown to be involved in innate immune responses by expressing Toll-like receptors [41]. By generating IL-10 and TGF-β, eosinophils are suggested to modulate T regulatory cell function and suppress inflammatory events [21].

## Lipid mediator generation

In eosinophils, eicosanoid derivatives of arachidonic acid are generated by both cyclooxygenase and lipoxygenase pathways, which have been localized to the sites of the perinuclear membranes and the cytoplasmic lipid bodies [8]. Platelet-activating factor (PAF) as well as agonists of CCR3 can initiate the *de novo* formation of lipid bodies [8]. To synthesize leukotrienes (LT), eosinophils need to be both primed (e.g. by IL-3, IL-5, GM-CSF) and activated (e.g. by C5a, PAF) [42, 43]. To reach the threshold needed to phosphorylate cytosolic phospholipase $A_2$ ($PLA_2$), a concurrent stimulation of G-protein-coupled receptor and cytokine receptor resulting in an activation of the mitogen-activated protein kinase (MAPK) cascade is required [42]. The activation of $PLA_2$, which also requires calcium, is essential for leukotriene generation [42]. Because of their content of leukotriene $C_4$ synthetase, eosinophils are an important source of cysteinyl leukotrienes, predominantly $LTC_4$ and its active metabolites $LTD_4$ and $LTE_4$ [8]. Leukotrienes possess proinflammatory activities. They may act intracellularly as intracrine signaling molecules, for example, in regulating IL-4 release [8]. Leukotrienes may amplify the inflammatory cascade, for instance by acting as chemotactic factors or by triggering the release of cytotoxic proteins.

## Antigen presentation

*In vitro* experiments have demonstrated that eosinophils are able to process antigens and express costimulatory molecules and MHC class II molecules, and therefore may function as antigen-presenting cells in stimulating T-cell responses [44]. Whereas blood eosinophils from normal and eosinophilic donors do not express MHC class II molecules, HLA-DR synthesis occurs following stimulation with specific cytokines including IL-3, IL-4, GM-CSF or IFN-γ [44, 45]. During transmigration into the tissues, HLA expression is further increased [46]. By expressing costimulatory molecules, such as CD80 and CD86, eosinophils provide additional secondary signals for lymphocytes [44]. However, the role of eosinophils as antigen-presenting cells to naïve T-cells is minor compared to dendritic cells [47].

## REGULATION OF PRODUCTION, MIGRATION, AND SURVIVAL

Prerequisite for eosinophil infiltration and function in the tissues is a precise regulation of their production, migration, and accumulation as well as activation (Fig. 12.2).

## Production

In the bone marrow, eosinophils are generated from CD34+ hematopoietic progenitor cells under regulation of critical transcription factors especially GATA-1 and the eosinophilopoietins IL-5, GM-CSF, and IL-3 [4]. Eosinophils share this progenitor with basophils [48]. IL-5 specifically regulates the production rate and differentiation of the eosinophil lineage [49]. The importance of IL-5 is evident from the studies of IL-5 deficient mice, which are unable to develop eosinophilia upon allergen sensitization and challenge [50]. In contrast, IL-5 transgenic mice exhibit extensive eosinophil production and tissue eosinophilia [51]. Anti-IL-5 therapy of asthma patients was shown to lead to an inhibition of eosinophil maturation in the bone marrow and a decrease of eosinophil progenitors in the bronchial mucosa [52]. Besides IL-5, IL-3 and GM-CSF have also been shown to increase eosinophil production [53]. Whereas the release of eosinophils into the peripheral blood circulation requires IL-5 [54]; the migration into the tissues under physiologic conditions is independent of IL-5 and mainly under the control of eotaxin-1 as shown for the
**FIG. 12.2** Mechanisms and key players (bold) leading to eosinophilic inflammation in asthma.

gastrointestinal tract [55], the mammary glands [13], the uterus [14], and the thymus [16]. The receptor for the CC chemokine eotaxin is CCR3, which is expressed on both CD34+ progenitor cells and mature eosinophils [56, 57] and can be upregulated during allergic inflammation [57].

## Migration into tissues

Priming of eosinophils circulating in the peripheral blood is a prerequisite for their transmigration through the endothelial cell layer, which has been demonstrated for eosinophils of asthmatic patients in contrast to healthy individuals [58] and in response to allergen challenge [59]. Migration comprises a series of sequential events including rolling, adhesion, and transmigration through the vascular endothelium. In the initiation and regulation of these processes a number of cytokines and chemokines are involved.

The initial steps of eosinophil recruitment are adhesion mediated by interaction of the P-selectin-glycoprotein ligand (PSGL)-1 on eosinophils with P-selectin on endothelial cells and rolling, a process in which PAF and eotaxin are involved [5]. While L-selectin is constantly expressed on eosinophils, P- and E-selectins on endothelial cells are upregulated by the inflammatory cytokines IL-1 and TNF-$\alpha$ [36]. The firm attachment of eosinophils to the endothelium is mediated by eosinophil surface very late activation antigen (VLA)-4 (integrin $\alpha 4\beta 1$) and CD11b/CD18 binding to vascular adhesion molecule

(VCAM)-1 and intercellular adhesion molecule (ICAM)-1, respectively [36]. IL-4 was shown to induce the expression of the adhesion molecule VCAM-1, whereas IFN-$\gamma$ stimulates ICAM-1 expression [60]. The expression of VLA-4 on eosinophils, which significantly contributes to eosinophil inflammation in allergic responses, can be upregulated by eotaxin [61]. After transmigration through the blood vessel, eosinophils enter the extracellular matrix where they bind to matrix proteins such as fibronectin. This binding is mediated by integrins and selectins on the eosinophils. Eosinophils migrate into the tissue along chemokine gradients. Their movement is characterized by adhesion/deadhesion to extracellular matrix proteins [36].

Eotaxin and RANTES are important chemokines for eosinophils and largely contribute to the movement of eosinophils from the peripheral blood to the sites of inflammation [62]. The principal receptor involved in eosinophil attraction is CCR3 [56]. In addition to eotaxin, RANTES and monocyte chemoattractant protein (MCP)-1, 2, 3, and 4 may also bind to CCR3 [63–65]. IL-5 alone has weak chemotactic activity, but increases the effect of eotaxin by enhancing CCR3-mediated responses [65]. Priming of eosinophils leads to an upregulation of additional chemokine receptors including CCR1, the receptor for MIP-1a, RANTES, and MCP-3 [66].

Complement factors such as the anaphylatoxins C3a and C5a [67] as well as PAF [68] have also been implicated in eosinophil recruitment. Moreover, leukotrienes (LTB$_4$) and prostaglandins (PGD$_2$) were found to induce eosinophil chemotaxis [69, 70], whereas lipoxin A$_4$ blocks eosinophil trafficking [71]. All these chemoattractants, C5a, PAF, LTB$_4$, and PGD$_2$ can be produced and released by macrophages that were shown to play a role in recruiting eosinophils to the lung and peritoneal cavity during helminth infection [11]. The T helper 2 cytokine IL-13 was shown to promote eosinophilia by increasing local IL-5 and/or eotaxin expression [72].

## Survival

Tissue eosinophilia is regulated not only by recruitment of eosinophils from the bone marrow but also by eosinophil survival. Delayed apoptosis as a pathogenic mechanism has been shown in several eosinophilic diseases including asthma [73, 74]. However, resolution of inflammation is associated with disappearance of eosinophils [75]. Apoptotic eosinophils are taken up by macrophages [75] and epithelial cells [76]. In addition, eosinophils may be cleared by transepithelial migration [77]. In particular IL-5, but also IL-3 and GM-CSF delay apoptosis and prolong eosinophil survival [78, 3]. Recently, it has been shown that leptin may also block eosinophil apoptosis [79].

The signaling events important for cytokine-mediated antiapoptosis include activation of tyrosine kinases and signal transducers and activators of transcription (STAT) proteins resulting in the transcriptional activation of members of the Bcl-2 and inhibitor of apoptosis proteins (IAP) families [80–82]. IL-5 upregulates the antiapoptotic proteins Mcl-1 and Bcl-xL, and inhibits translocation of proapoptotic Bax, resulting in an inhibition of the caspase

cascade and thus preventing apoptotic cell death [83, 84]. Moreover, following IL-5 stimulation, normal blood eosinophils express the antiapoptotic molecules survivin and cIAP-2 [82]. Although TNF-$\alpha$ and TNF-related apoptosis inducing ligand (TRAIL) are death receptor ligands, they do not induce eosinophil apoptosis under normal conditions [85]. On the contrary, both TNF-$\alpha$ and TRAIL were shown to prolong eosinophil survival [86, 87]. Stimulation of CD137, another member of the TNF-family, which is expressed on eosinophils of allergic patients, by a specific antibody together with IL-5 or GM-CSF blocks the inhibitory effect of the survival factors on eosinophil apoptosis [88]. Eosinophil death can be induced by interaction of the surface death receptors CD95 (Fas) and its ligand, CD95L (FasL), which is expressed by activated T-cells [89]. Therefore, T-cells, known as main producers of eosinophil survival factors, may also limit eosinophil expansion within inflammatory sites [90].

Eosinophil

| Tissue destruction | Remodeling | Immunoregulation |
|---|---|---|
| MBP | FGF-2 | T helper 2 cytokines |
| ECP | NGF | TNF-$\alpha$ |
| EDN | VEGF | Leukotrienes |
| EPO | TGF-$\beta$ | Antigen presentation |
| Respiratory burst | IL-4 | |
| | IL-11 | |
| | IL-13 | |
| | IL-17 | |

**FIG. 12.3** Possible roles of eosinophils in the pathogenesis of asthma.
## ROLE IN LUNG DISEASES

### Asthma

Eosinophilia in the blood and/or tissues is a feature of multiple disorders. Although the initial cause and the organs vary, there are only the following two major pathways that mediate eosinophilia: (1) a cytokine-mediated increased differentiation and survival of eosinophils (extrinsic eosinophilic disorders) and (2) a mutation-mediated clonal expansion of eosinophils (intrinsic eosinophilic disorders) [2]. The most common cause of eosinophilia is the increased generation of IL-5-producing T-cells, as is observed in allergic diseases including bronchial asthma (Fig. 12.2).

There are a great number of reports in the literature demonstrating the correlation between asthma severity and levels of eosinophils and their products in blood, sputum, bronchoalveolar lavage fluid, or bronchial biopsies [91]. Eosinophils found in the airways of asthmatics are activated [92]. Since clinical trials investigating monoclonal anti-IL-5 antibody treatment in bronchial asthma provided rather disappointing results, a vehement controversy on the role of eosinophils in the pathogenesis of asthma started. Recent studies in genetically targeted mice showed that eosinophils are crucial for airway hyperresponsiveness and mucus accumulation [93] as well as for airway remodeling [94].

The different activities of eosinophils that contribute to the pathogenesis of bronchial asthma can be categorized as tissue destruction, remodeling, and immunoregulation (Fig. 12.3). During asthmatic inflammation, eosinophils interact with leukocytes including lymphocytes, mast cells, dendritic cells, macrophages and neutrophils, as well as with resident tissue cells, such as epithelial cells, endothelial cells, smooth muscle, fibroblasts, and nerve cells [21].

### Tissue destruction

The release of eosinophil granule proteins, such as MBP, EPO, ECP, and EDN, has suggested that the main eosinophil effector function, causing desquamation and destruction of the epithelium, leads to airway damage and lung dysfunction [21, 95]. MBP has been localized to the sites of epithelial damage and has been detected in the sputum of asthmatic patients [40]. Eosinophils from asthmatic patients contain, and in response to IL-5 and GM-CSF release, significantly higher amounts of EDN compared to healthy controls [96]. Increased ECP levels in blood, sputum, and bronchoalveolar lavage fluid of patients with bronchial asthma have been reported to correlate with airway obstruction and disease activity [97]. Polymorphisms in the ECP gene are associated with the development of asthma [98].

Nitrotyrosine, a product of EPO, has been observed in the airways as well as in lung parenchyma of asthmatic patients [99, 100]. Eosinophils from patients with various types of asthma were reported to excessively produce reactive oxygen species [5]. These mechanisms may contribute to the damage of resident cells in the lungs. Patients with bronchial asthma have elevated levels of nitric oxide (NO) in their expired air [101], which is thought to reflect the extent of eosinophilic inflammation of the lower airways [102]. Expired NO is used as diagnostic tool in monitoring asthma [102]. Viral and non-viral infections are known to induce asthma exacerbations, in which an increase in blood and sputum eosinophil numbers often precedes deterioration of symptoms and lung function [103]. In response to respiratory syncytial virus infection, epithelial cells of the airways express chemokines leading to the recruitment and degranulation of eosinophils [104]. EDN and ECP are RNAses and were shown to function as anti-viral agents [25]. However, granule proteins released during viral infection may also lead to bronchial hyperreactivity and asthma exacerbation in susceptible individuals [25, 40].

It should be noted that basic proteins are believed to have additional function. For instance, MBP has been described to induce histamine release from mast cells and basophils [105], eosinophil degranulation and cytokine (IL-8) production [106], as well as to increase neutrophil [107, 108] and platelet functions [109]. In addition, MBP and EPO

were reported to increase bronchial hyperresponsiveness by binding to the muscarinic M2 receptors of bronchial smooth muscles resulting in a vagal overstimulation and bronchoconstriction [110].

## Remodeling

Eosinophils are involved in airway remodeling characterized by structural changes of the lung including epithelial hypertrophy, subepithelial deposition of extracellular matrix proteins in the lamina reticularis, mucus gland hypertrophy, airway smooth muscle hypertrophy, and vascular changes [111]. The matrix deposition (collagen, fibrin) in the lungs observed upon prolonged allergen challenge was significantly increased in wild-type mice compared to eosinophil-deficient [94]. Many of the factors implicated in remodeling are expressed by eosinophils and have been found to be increased in asthmatic airway including fibroblast growth factor (FGF)-2, IL-4, IL-11, IL-13, IL-17, nerve growth factor (NGF), and vascular endothelial growth factor (VEGF) [112]. In patients receiving anti-IL-5 antibody therapy, a reduced deposition of extracellular matrix proteins (tenascin, lumican, procollagen III) beneath the bronchial basement membrane has been observed, again suggesting an essential role of eosinophils in airway remodeling [113]. This decrease of extracellular matrix proteins was accompanied by a significant reduction of TGF-β expression [113]. TGF-β by autocrine–paracrine actions may stimulate eosinophils to generate IL-11, another cytokine with fibrogenic potential, which has been found to be significantly increased in the airways of asthmatics compared to healthy controls [114]. Furthermore, eosinophils express IL-6, whose function has been related to tissue fibrosis [114]. Since eosinophil granule proteins interact with several resident cell types in the lungs, they are suggested to play additional roles in tissue remodeling. MPB interacting with IL-1 and TGF-β stimulates lung fibroblasts [115], while EPO products affect endothelial cells [116]. By secreting metalloproteinases, especially matrix metalloproteinase (MMP)-9, eosinophils may directly affect airway remodeling [117]. MMP-9 has been found to be increased in severe persistent asthma and following allergen challenge [118]. That eosinophils play a role in the late-phase reaction and remodeling processes [112] is consistent with the observation that eosinophils are abundant in the submucosa of lung tissues from patients with slow-onset fatal asthma [119].

Eosinophils synthesize proangiogenic mediators such as VEGF and FGF-2 and thus are able to promote angiogenesis, which presents an additional important mechanism in chronic inflammation and tissue remodeling [120]. In bronchial biopsies of asthmatics, eosinophils are positively stained for VEGF and FGF-2 [121]. VEGF is released upon stimulation with GM-CSF and IL-5 [122]. Furthermore, eosinophils can promote angiogenesis directly by secreting extracellular matrix-degrading enzymes such as MMP-9 and heparanase [123] or indirectly by IL-8 secretion enhancing MMP-2 and MMP-9 mRNA expression by endothelial cells [120]. In contrast; VEGF produced by inflammatory and structural cells such as macrophages, neutrophils, epithelial cells, fibroblasts, and smooth muscle cells, induces migration and mediator release by eosinophils

expressing VEGF receptors [124]. In a murine model of asthma, the administration of anti-VEGF receptor antibodies reduced eosinophil infiltration [125]. The mediators, expressed by eosinophils during inflammation, can also activate smooth muscle cells. For example, eotaxin-1 produced by eosinophils themselves can bind to CCR3, which is highly expressed on airway smooth muscle cells in asthmatic lungs [126]. Eosinophils have the capacity to generate IL-25, which has been detected in bronchial biopsies of patients with asthma, and is suggested to have remodeling functions by stimulating airway smooth muscle cells to express extracellular matrix components [114].

## Immunoregulation

The inflammation in asthma is characterized by T helper 2 immune responses leading to increased production of cytokines such as IL-4, IL-5, IL-9, and IL-13. Since eosinophils have been demonstrated to express these cytokines, they are suggested to be involved in sustaining a local T helper 2 immune microenvironment [39]. This view is supported by the observation that in eosinophil-deficient mice the production of T helper 2 cytokines is reduced in the lungs after allergen challenge [93]. By producing cytokines associated with acute inflammatory responses such as TNF-α, eosinophils may enhance the inflammation in asthma [36]. Eosinophils are an important source of the cysteinyl leukotrienes [127]. In bronchial mucosa biopsies of asthmatics, eosinophils overexpress $LTC_4$ synthetase [128]. $LTC_4$ and its derivatives $LTD_4$ and $LTE_4$ were shown not only to increase mucus secretion [129] and bronchoconstriction [130], but also eosinophil survival [131]. In asthmatic patients, antigen challenge induces HLA-DR expression on recruited eosinophils, which enables them to function as antigen-presenting cells in stimulating T-cell responses [132, 133]. Moreover, eosinophils provide costimulatory signals for lymphocytes by expressing CD40, for which an increased surface expression has been found in atopic patients [134]. Endobronchial eosinophils are able to process inhaled antigens, traffic to the regional lymph nodes where they stimulate CD4+ T-cell responses [135]. Those lymph node eosinophils phenotypically resemble dendritic cells and express MHC class II, CD80, and CD86 [136].

## Chronic obstructive pulmonary disease

In the pathogenesis of COPD, neutrophils, macrophages, and CD8+ T-cells are considered as key effector cells [137, 138]. The presence and role of eosinophils in COPD is controversial [138]. For instance, airway eosinophilia has been reported occurring during acute exacerbations of COPD [139] and has also been observed in patients with stable disease [140]. However, in one study, eosinophil numbers in induced sputum taken during a stable disease period were compared with those during an acute exacerbation in the same patients, and no differences have been observed [141]. Eosinophilia in COPD has been linked to smoking [142] as well as to an asthmatic component [143]. Moreover, airway obstruction was observed to correlate with an increase in the number of activated eosinophils in the airways [144].

Interestingly, eosinophilia in COPD does not seem to depend on IL-5 [145], but is linked to an upregulation of RANTES [146] as well as eotaxin and CCR3 [147]. The production of RANTES may be induced by TNF-α, which is increased in acute exacerbations [148]. Elevated levels of IL-6 and IL-8 were found in the sputum during exacerbations of COPD correlating with the number of inflammatory cells in particular eosinophils [141]. IL-8, although usually associated with neutrophil chemotaxis, has been suggested to recruit and activate eosinophils in COPD [139, 149].

The principal mechanisms by which eosinophils contribute to airway inflammation have been suggested as being similar to those in asthma [148]. In patients with COPD, higher numbers of eosinophils have been found in bronchial biopsies compared to healthy controls accompanied by increased eosinophil and ECP levels in bronchoalveolar lavage fluid and induced sputum [150]. In addition to ECP, EPO levels are raised in the sputum in patients with COPD [151]. Moreover, several studies reported eosinophil infiltration of the airway walls associated with increased amounts of ECP in bronchoalveolar lavage fluid and induced sputum during exacerbations of COPD [138, 148, 152]. Since COPD exacerbations may be associated with viral infections, eosinophils are suggested to have a role in antiviral host defense, for example, by releasing ECP and EDN acting as ribonucleases [138].

Eosinophilic airway inflammation is suggested to contribute to airflow obstruction and symptoms in patients with COPD [143]. The patients with sputum eosinophilia are more likely to respond to corticosteroid therapy [143]. Therefore, sputum eosinophilia may be used as predictive marker in identifying patients who will benefit from corticosteroid therapy [153].

## ANTI-EOSINOPHILIC THERAPIES

Since eosinophils exhibit a multifunctional role in the pathogenesis of asthma, therapeutic approaches aiming to reduce their numbers and/or activity seem promising. There are several potential mechanisms for how to do so: reduce eosinophil production, stop eosinophil migration into inflamed tissues, activate eosinophil apoptosis, prevent eosinophil priming and activation, stop generation and release of mediators, and/or antagonize them. Here, we shortly discuss established as well as new therapeutic options which specifically attack eosinophils.

### Immunosuppressive therapy

Corticosteroids are widely used in the treatment of bronchial asthma and COPD. Although corticosteroids increase the rate of eosinophil apoptosis [154], their main effect on eosinophils appears to be due to inhibition of cytokine and chemokine production by leukocytes, such as T-cells and resident airway cells [155]. The same mechanism is true for other immunosuppressive drugs such as cyclosporine.

### Leukotriene antagonists

Leukotriene antagonists are well-established substances in the treatment of asthma that inhibit the effect of cysteinyl leukotrienes, which are generated in high amounts by eosinophils, mast cells, basophils, macrophages, and monocytes during asthmatic inflammation [156]. A second way to interfere with leukotrienes is the inhibition of their generation by blocking the 5-lipoxygenase pathway [157].

### Interferons

The treatment with low-dose IFN-α was shown to be effective in the treatment of patients with severe corticosteroid resistant asthma with or without Churg–Strauss syndrome. The establishment of a correct T helper 1/T helper 2 balance as well as the induction of IL-10 are regarded as possible mechanisms [158]. IFN-γ therapy was shown to reduce blood eosinophil numbers in patients with severe steroid-dependent asthma. However, physiological asthma parameters, such as $FEV_1$ and peak expiratory flow rates, did not improve upon treatment with IFN-γ over 90 days [159].

### Anti-IL-5 monoclonal antibodies

The first study using a monoclonal antibody to IL-5 investigated the effect and safety of a single dose of mepolizumab in patients with mild bronchial asthma [160]. Although peripheral blood and sputum eosinophil numbers significantly decreased, this treatment had no effect either on airway hyperresponsiveness before and after allergen challenge or on the allergen-induced late asthmatic response. A second study, in which the same anti-IL-5 antibody was given over 3 months, demonstrated that the expression of activation markers and T helper 2-cytokine receptors on eosinophils as well as the number of circulating T-cells and their capacity for generating cytokines were not affected [161]. Another antibody (SCH55700) was tested in patients with severe asthma. A single dose of this anti-IL-5 antibody resulted in a short improvement of baseline FEV1 and decrease of blood eosinophil numbers, but failed to improve asthma symptoms significantly [162]. Investigating eosinophil numbers at different sites revealed that anti-IL-5 therapy produced only a partial decrease of 52% in the bone marrow, and of 55% in the airways, but a 100% decrease in the peripheral blood [163]. The anti-IL-5 antibody seemed to exclusively reduce mature eosinophils in the bone marrow and in the peripheral blood, whereas CD34+/IL-5 receptor+ progenitor cells were not reduced [52]. However, the observed decrease of eosinophil progenitor cells in the bronchial mucosa suggested that local eosinophilopoiesis was impaired upon anti-IL-5 therapy. The reason why a single anti-IL-5 treatment failed to improve asthma might be the redundancy of different cells and cytokines contributing to eosinophilia and asthma symptoms.

### Anti-TNF-α

The proinflammatory cytokine TNF-α plays a role in leukocyte recruitment and activation. Although anti-TNF-α

therapy was shown to improve asthma symptoms, it did not affect the number of sputum eosinophils [164].

## IL-12

IL-12 is a macrophage-derived cytokine that modulates T-cell responses and therefore might reduce eosinophilic inflammation. Recombinant human IL-12, administered to patients with mild asthma in three increasing dosages over 3 weeks, resulted in a decrease of eosinophil numbers in the peripheral blood and in the sputum after allergen challenge as well as in an improvement of the allergen induced airway hyperresponsiveness [165]. However, severe adverse events leading to withdrawal were seen in 4 out of 19 patients.

## Selectin antagonists

Because recruitment of inflammatory cells from the peripheral blood into the airways is a characteristic feature of asthma, targeting selectins or their ligands is a promising approach in the treatment of asthma [166]. Bimosiamose, a pan-selectin antagonist, was studied in patients with mild allergic asthma revealing an inhibitory effect on late-phase responses but not on airway hyperresponsiveness or exhaled NO after allergen challenge [167].

## CCR3 antagonists

To block the principal chemokine receptor of eosinophils, the effect of a low-molecular weight CCR3 antagonist has been investigated in a mouse asthma model. This revealed promising results as it markedly reduced eosinophil infiltration of the airways followed by a normalization of airway hyperresponsiveness, reduced mucus production and prevention of airway remodeling [168].

## Integrin inhibitors

Since intergrins are involved in migration of inflammatory cells including eosinophils from the blood vessels into the tissues, antagonizing integrins offers another promising treatment option for asthma or allergic diseases. *In vitro* and *in vivo* experiments showed that a newly developed small molecule VLA-4 (α4β1 integrin) inhibitor may prevent VLA-4/VCAM interactions resulting in reduced eosinophil migration and infiltration in the tissue [169].

# The Lymphocyte in Asthma and COPD

**James G. Martin and Manuel G. Cosio**

**Meakins-Christie Laboratories and the Respiratory Division, Department of Medicine, McGill University, Montreal, Quebec, Canada**

## INTRODUCTION

Asthma and chronic obstructive pulmonary disease (COPD) are chronic inflammatory diseases of the airways that share a high prevalence and, when severe, impose a substantial burden on affected persons and society at large. Although controversy has surrounded the extent to which these conditions may be related, distinct patterns of airway inflammation have been described in the two conditions and evidence for the participation of different T-cell subsets in the pathogenesis of the two diseases is emerging. There is, however, some evidence of convergence of the inflammatory processes in advanced COPD and in severe asthma but, for the most part, there are clear and obvious differences. In particular, although the chronic inflammatory infiltrate in both diseases results in airway obstruction, obstruction is usually reversible in asthma, and is largely irreversible and progressive in COPD. These key differences in the pathophysiology of the two diseases are due to the type and consequences of the inflammation. Inflammation is largely limited to the airways in asthma whereas both the airways and parenchyma are affected in COPD and in such a way that irreversible fibrosis of the small airways and parenchymal destruction with emphysema may result. Both diseases when fully established show evidence of an adaptive immune response with an excess of activated T-cells, but of different phenotypes, secreting type 2 cytokines in asthma and type 1 cytokines in COPD. Descriptions of the immunopathology of asthma as well as data from animal models leave little doubt about the central place of the CD4$^+$ T-cell in virtually all of the key features of asthma, ranging from the characteristic eosinophil-rich inflammation to bronchoconstriction and tissue remodeling. T-cell cytokines recruit, activate, and enhance the survival of a range of inflammatory cells that are the more direct mediators of the pathologic processes. The participation of the T-cell in COPD is relatively less well understood but involves CD8$^+$ T-cells to a greater extent. Both diseases are now known to have features mediated by an adaptive immune response to antigens, attributable to inhaled soluble antigens in asthma, and to self-antigens either newly revealed or modified by tissue injury secondary to tobacco smoke in COPD. Why the mucosal immune system of the respiratory tract responds in such different manners to the antigenic stimuli, and results in the distinct disease phenotypes is still not very clear.

In this chapter we will review the evidence for the role of T-cells in the pathobiology of these two major causes of morbidity and mortality. We will also discuss the additional roles for certain T-cell subsets, such as the potential effect of γδ T-cells in the maintenance of airway epithelial integrity, that extend the range of functions beyond the classical adaptive immune functions most commonly thought of in association with the T-cell.

## HISTORICAL NOTE

Early preoccupations with the role of lymphocytes in asthma revolved around the role of B-cells in IgE production. It was observed as early as 1975 that human asthmatic subjects appeared to have a relative lymphopenia [1] and

a defective T-cell response to stimulation by mitogens such as phytohemagglutinin and concanavalin A [2]. B-cells from atopic subjects were shown to spontaneously synthesize IgE *in vitro* and T-cells from the affected individuals were much less inhibitory of this synthesis compared to T-cells from unaffected persons [3]. Specific immunotherapy led to a correction of the reduced inhibitory T-cell subset [4]. Subsequently elevated $CD4^+$ to $CD8^+$ ratios in the blood of asthmatic subjects was also interpreted as suggesting a deficiency of suppressor T-cell function in asthmatics [5]. Differences in the ratio of $CD4^+$ to $CD8^+$ T-cells were noted following challenge of allergic asthmatic subjects as a function of whether the subjects demonstrated isolated early responses to challenge or had dual airway responses, with both early and late bronchoconstriction. The hypothesis proposed was that $CD8^+$ T-cells were recruited from the blood to the airways and prevented the development of the late airway response in single responders [6]. Activation of $CD4^+$ T-cells (surface expression of IL-2R, VLA-1, and HLA-DR) was also noted during acute asthma exacerbations [7]. HLA-DR expression on cells in bronchial biopsies of stable asthmatics was correlated with airway hyperresponsiveness [8].

A more obvious link of T-cells to airway inflammation emerged as evidence of the synthesis of high molecular weight chemotactic factors for eosinophils was obtained by injecting concanavalin A into the skin of a guinea pig [9]. However, without doubt, the single most important step forward in understanding the place of T-cells in allergic airway inflammation occurred with the description of Th1 and Th2 type $CD4^+$ T-cells in 1986 by Mosmann and colleagues [10]. For the subsequent 20 years research on the role of the T-cell in asthma has focused singularly on the exploration of this paradigm. Indeed much of the inflammatory process in allergic asthma is explained by this paradigm although added complexity has emerged as new subsets, such as regulatory T-cells, Th17 cells, $\gamma\delta$ T-cells, and *i*NKT cells that have been described, and have begun to be integrated into the pathogenetic schema of inflammatory airway disease.

Early observations on airway inflammation in subjects with COPD revealed typical innate immune inflammation. Young cigarette smokers were noted to have increased cellularity in the bronchoalveolar lavage (BAL) fluid that was attributable to macrophages but few neutrophils were present [11], while older smokers had increased numbers of both neutrophils and alveolar macrophages [12]. From these data originated the concept that the destruction of lung tissue resulted from the release of potent proteinases from these cells and the proteinase–anti-proteinase balance became the paradigm for the pathogenesis of COPD for almost 40 years. The nature and mechanisms of inflammation were reconsidered following the description by Finkelstein *et al.* of a prominent T-cell infiltration in the lungs of patients with COPD, the degree of which was strongly related to the extent of emphysema [13]. These findings suggested new mechanisms for the pathogenesis of COPD through T-cell involvement and prompted us to suggest that COPD might be an autoimmune disease triggered by cigarette smoking [14, 15].

## LYMPHOCYTES IN THE RESPIRATORY TRACT

The lymphocytes in the respiratory tract are present in the form of localized bronchus-associated lymphoid tissue (BALT) and the nasal-associated lymphoid tissue (NALT) that are organized lymphoid aggregates, comprising T- and B-lymphocytes that may mediate adaptive immune responses to inhaled antigens. BALT is present at bronchial bifurcations and may be responsible for the synthesis and secretion of immunoglobulins in response to antigenic stimulation. Humoral immune responses elicited by BALT are primarily IgA secretion. The BALT is in many respects analogous to mucosal lymphoid aggregates in the intestine that has important functions in regulating intestinal mucosal immunity (reviewed in [16]). The epithelial cells overlying the BALT lack cilia and appear to be equivalent to M-cells in the intestinal epithelium. The M-cells are derived from basal cells in the respiratory epithelium and, as in the intestine overlying Peyer's patches, have the capacity to selectively phagocytose and pinocytose particles and molecules in their immediate environment. Lymphocytes are also distributed within the epithelium and more diffusely through the airway wall, invading all of the tissues in the setting of airway inflammation.

## INCITING STIMULI

Both asthma and COPD are diseases that involve inflammation mediated by the respiratory mucosal immune system. In asthma aeroallergens are the best characterized inducers of disease although other causes such as strong irritants (often mediating damage through oxidant injury) and viral illness are also of importance. These same stimuli may trigger asthma attacks also. The place of the adaptive immune system in the pathogenesis of asthma caused by nonallergic mechanisms is not clear. It is possible that airway hyperresponsiveness may be induced as a result of airway remodeling from airway insults, bypassing the need for a major participation of adaptive immunity in the process. Model systems, based in recent years on murine and rodent models, have been heavily exploited to unravel the complex immunological reactions triggered by allergen. The literature is replete with references to murine asthma, for example, but it must be acknowledged that models based on a small number of allergen challenges model only a limited part of the disease. Growing literature on the role of viruses, such as respiratory syncytial virus and rhinovirus, will complement the results from allergen challenge to provide a more complete picture of the triggers and inducers of asthma. Likewise, the T-cell contribution to other forms of injury such as oxidant injury has received little attention. To date the mechanisms for activation of T-cells in asthma have dealt almost exclusively with allergic mechanisms.

The inflammatory reaction to cigarette smoke is central to COPD and the global initiative workshop summary for chronic obstructive lung disease (GOLD) definition of COPD states that "*the airflow limitation is usually progressive*

and associated with an abnormal inflammatory response of the lungs to noxious particles or gases"(GOLD Report update 2007, www.GOLDCOPD.com downloaded May 2008) [17]. In both disease processes there is an important contribution of the innate immune response to the pathobiology and close links to lymphocyte function. Of particular importance is the dendritic cell, but macrophages and other cells may also play a role in conditioning the T-cell response. Cigarette smoke and other pollutants (ozone, $NO_2$, diesel particles) produce an acute innate immune reaction in the lung as do the triggers of asthma. The epithelium is exposed to all of these triggers over its surface and through damage, stress, or stimulation via receptors, such as Toll receptors, is important in initiating the response. The present evidence suggests that, by sending "danger" signals in response to cigarette smoke, the epithelium is responsible for the initiation and possibly maintenance of the innate immune response seen in smokers. Over 2000 different xenobiotic compounds have been identified in cigarette smoke, and it has been estimated that there are $10^{14}$ free radicals in each puff of cigarette smoke [18]. Not surprisingly, it has been shown that cigarette smoke is cytotoxic to epithelial cells and that the extent of injury produced is directly related to the concentration of smoke to which the cells were exposed [19].

The sustained innate immune response found in the lungs of cigarette smokers (neutrophils, macrophages, eosinophils, mast cells, γδ T-cells, dendritic cells, and perhaps natural killer (NK) cells), and their products (cytokines, oxygen radicals, proteinases) are capable of producing matrix and cellular damage. Studies in mice have shown that after 24h of cigarette smoke exposure, measurable increases in desmosine, a marker of elastin breakdown and hydroxyproline, a marker of collagen breakdown, are found in BAL and their levels are correlated with the number of neutrophils in the BAL [20, 21]. Evidence of connective tissue breakdown in human smokers also exists. Increased plasma and urine levels of elastin-derived peptides and desmosine [22, 23] have been found in COPD patients when compared with nonsmokers [24, 25]. However, the levels of elastin breakdown products are also elevated in smokers without COPD [24, 26–29]. Smokers with rapid decline in lung function, likely to develop COPD, were found to excrete 36% more desmosine than low decliners [30].

However the protease–anti-protease imbalance paradigm by itself cannot explain why only some smokers develop COPD. It might be closer to reality to consider the connective tissue breakdown as one of the many consequences of the innate inflammatory reaction triggered by smoking. Furthermore, these breakdown products or peptides once revealed to the immune system may be antigenic and be presented to T-cells, eventually triggering, in some smokers, a T-cell adaptive immune response against lung antigens (autoimmunity), as has been recently shown [31]. There is extensive literature showing that infectious and environmental agents have the potential to alter "self-proteins" that may then be recognized as antigens by the adaptive immune system. Among the important protein modifiers present in smokers are free radicals/oxidative stress and xenobiotic agents which abound in cigarette smoke. Nitric oxide (NO) per se or following its conversion to peroxynitrite by superoxide or other reactive oxygen species (ROS) may produce mitochondrial damage, DNA strand breaks, structural/functional modification of proteins, and ultimately cell death. Oxidative modification of proteins has been implicated in the immune mechanisms of rheumatoid arthritis, multiple sclerosis, and arteriosclerosis [32]. Induction of organ-specific autoimmune disease following tissue trauma, inflammation, and viral or bacterial infections has been frequently reported and likely occurs via tissue damage that results in the availability of previously hidden antigens or by molecular mimicry with viral or bacterial products [33]. Infections also provide abundant cytokines that may affect the expression of co-stimulatory molecules, an additional stimulus important in the perpetuation of the immune response.

Airway or pulmonary parenchymal damage from cigarette smoke could easily follow the same mechanisms. The tissue injury and potential modification of self-proteins could generate antigens (e.g. release of cryptic antigens, modified proteins, necrotic cells, apoptotic cells, etc.) and the associated innate immune inflammation associated with smoking, could provide the necessary soluble mediators and co-stimulatory signals for the initiation or perpetuation of an adaptive immune response. That this is the case has been recently shown by Lee and coworkers who identified elastin as an antigen responsible for the T-cell response in COPD [31]. However in a disease like COPD in which multiple cells and tissues seem to be potentially injured, other cell products from necrotic, stressed, or apoptotic cells might also act as antigenic determinants. Whether a component of autoimmunity complicates asthma is not known but it would not be altogether surprising since cellular damage and oxidative stress is also a feature of the disease. This has been recently shown in smokers with COPD in which autoantibodies were found to bind at least three different autoantigens [34].

## MECHANISMS OF T-CELL ACTIVATION AND DIFFERENTIATION: MODEL SYSTEMS

### Dendritic cells, CD4$^+$, and CD8$^+$ T-cells

Adaptive immune responses are initiated by the dense network of dendritic cells in and under the epithelium [35]. These cells have projections that appear to sample the airway luminal contents and can take up antigen for presentation to T-cells (Fig. 13.1). This presentation occurs in draining lymph nodes following maturation of the dendritic cells under the influence of cytokines such as granulocyte-macrophage colony stimulating factor (GM-CSF). T-cells sample the dendritic cell surface for antigens in a more or less stochastic process. High levels of antigen on the cell surface shorten the time required for the T-cell to form stable contacts with the dendritic cell [36]. In addition to dendritic cell–T-cell contact in the lymph nodes it has also been observed that T-cells come into contact with dendritic cells in the airway wall [37]. Indeed following allergen challenge there is a marked increase in the number of dendritic cells in contact with T-cells. This interaction may short-circuit the longer process that is otherwise required
**FIG. 13.1** Dendritic cells sample antigen material in the airway lumen through the cell processes that interdigitate between the epithelial cells. The dendritic cell then migrate to the draining lymph nodes and are sampled by T-cells that respond to the antigenic peptide on the surface of the dendritic cell. Maturation of the dendritic cell in response to the conditioning by cytokines such as granulocyte-macrophage colony stimulating factor (GM-CSF) enhances its antigen-presenting ability. T-cells with antigen specificity return to the mucosal surface following their egress from the lymph node through the efferent lymphatic. Chemokines such as TARC and MDC favor movement of Th2 cells into the tissues. These chemokines are produced by epithelial cells and dendritic cells, when appropriately stimulated.

and presumably is responsible for the rapid T-cell mediated response that follows allergen challenge *in vivo.*

Following engagement with the dendritic cell the T-cell is activated, secretes IL-2, and expresses the IL-2 receptor. Clonal expansion takes place and the T-cell phenotype is subsequently established in response to a variety of influences; cytokines, lipid mediators, and toll-like receptor (TLR) ligands all play a part in the latter phenomenon. The presentation of exogenous antigen in association with major histocompatibility complex (MHC) class II molecules leads to activation of $CD4^+$ T-cells with high-affinity antigen-specific T-cell receptors (Fig. 13.2). This is the predominant pathway activated by inhaled soluble antigens that commonly trigger allergic airway responses. Antigen produced intracellularly, such as may result from the infection or injury of pulmonary cells by virus or other agents like cigarette smoke, is processed by different intracellular pathways and presentation occurs in conjunction with MHC class I molecules. $CD8^+$ T-cell activation results. The processing and presentation of soluble exogenous antigen to $CD8^+$ T-cells in an MHC class I restricted manner is called cross presentation. Soluble antigens destined for cross presentation are taken up into early endosomes whereas those destined for classical MHC class II restricted presentation are taken up in lysosomes [38]. Heat shock proteins are released from cells undergoing lytic death, but not from cells dying of apoptosis [39] and necrotic cell lysates and also stressed cells have been reported to express cell surface HSP molecules [40] that could activate dendritic cells directly through receptors including CD91 [41] and TLR-4. Cell-associated proteins [42, 43] and particulate antigens [44] are much more effective at class MHC I restricted $CD8^+$ T-cells priming than are simple soluble molecules. Cross presentation is also essential for proper stimulation and functional development of $CD8^+$ T-cell effector and memory function since these depend on the encounter of both $CD4^+$ and $CD8^+$ T-cells with the same dendritic cell and the release of stimulatory factors from the $CD4^+$ T-cell. These encounters

**FIG. 13.2** The dendritic cell interacts with the T-cell through major histocompatibility molecules that harbor the antigenic peptide and the T-cell receptor. Various co-stimulatory molecules are required to allow effector functions to be established. OX40 and OX40L interactions are important for Th2 differentiation. CD28–CD80/86 interactions are important for both Th1 and Th2 development. The binding of IgE to the FcεR1 on the dendritic cells facilitates Th2 cell differentiation.

are not random but mediated by the upregulation of the chemokine receptor CCR5 on the $CD8^+$ T-cells, which directs these cells to sites of antigen-specific dendritic cell–$CD4^+$ interaction where the cognate chemokines CCL3 and CCL4 are produced [45].

## Th1 and Th2 cells

The cytokine profile secreted by the $CD4^+$ T-cell is of critical importance in directing the inflammatory response,
**FIG. 13.3** The factors that favor the development of Th2 responses are several. Co-stimulatory molecules such as OX40 and OX40L, upregulation of OX40 by TSLP produced by basophils and structural tissue cells such as epithelial cells, IgE bound to the dendritic cell surface, TLR2 ligation by EDN, low lever TLR4 stimulation, cysteinyl leukotriene synthesis by dendritic cells and their subsequent interaction with the Cys-LT1R on the T-cell and Th2 cytokine production by a variety of cells such as mast cells, eosinophils, basophils and NKT cells all favor Th2 cell differentiation.

whether typical of allergic inflammation with a Th2 cytokine predominance or delayed type hypersensitivity typical of Th1-driven inflammation. The factors that determine the Th1 and Th2 type responses are several. The dendritic cell has an important role through the secretion of IL-12 in the case of the induction of Th1 responses and IL-4 and IL-10 in the case of Th2 and T-regulatory cell responses. Respiratory mucosal dendritic cells preferentially trigger Th2 responses, but after they have matured under the influence of cytokines such as GM-CSF they express high levels of MHC II, B7, and IL-12 and produce Th1 responses [46]. Concomitant pro-inflammatory stimuli condition the dendritic cell and its subsequent interaction with the T-cell (Fig. 13.3). Signals mediated via the TLRs are among the important stimuli of this sort. Endotoxin-poor antigen triggers Th2 responses whereas a strong concomitant stimulation of dendritic cells with lipopolysaccharide, for example, may convert the T-cell response into a Th1 response [47]. In contrast a TLR-2 agonist results in a Th2 biased T-cell response [48]. Recently it has been demonstrated that eosinophils, through eosinophil-derived neurotoxin (EDN), are involved in the process of T-cell differentiation [49]. EDN, a member of the RNase A superfamily, appears to be an endogenous ligand for TLR2. Cytokines also serve to condition the dendritic cell responses. Thymic stromal lymphopoietin (TSLP) induces OX40 ligand on dendritic cells that subsequently evokes Th2 cytokine production by CD4+ T-cells. These cells produce TNF-α and do not express IL-10, differing from those Th2 cells that produce IL-10 as a part of their cytokine profile [50]. A problem with this paradigm for driving Th2 responses was that TSLP appeared to be produced in peripheral tissues but not in the lymph nodes. This issue has now been resolved by the demonstration that

basophils may be triggered by allergen to release TSLP in lymph nodes and thereby promote Th2 cell differentiation in this site [51].

Signals that affect the T-cells are also important in directing the T-cell differentiation. It has been recognized for some time that IL-4 is important in creating a milieu that favors the development of Th2 responses. Mast cells and NK cells, as well as T-cells themselves, are sources of this key cytokine. Indeed mast cells express most of the cytokines that control T-cell differentiation pathways and may potentially regulate T-cell fate decisions (reviewed in [52]). Furthermore, signals to the dendritic cell as exemplified by TSLP and signals to the T-cell such as IL-4 synergize to produce, in this instance, a Th2 response [50]. It has long been known that the different T-cell phenotypes exert counter-regulatory effects, IFN-γ inhibits Th2 cell development whereas IL-10 inhibits Th1 cell development. Cysteinyl leukotrienes which are an important feature of allergic reactions are produced by the dendritic cells and appear to favors Th2 differentiation through an autocrine action that modulates IL-10 and IL-12 production by the dendritic cell [53]. Cys-LTs favors IL-10 production whereas inhibition of the Cys-LT1 receptor favors IL-12 production and IFN-γ synthesis by T-cells.

Other essential factors for Th1 differentiation are the transcription factors T-bet and IRF1. T-bet not only induces Th1 differentiation of naïve T-cells, but also "reprograms" polarized Th2 cells to produce the Th1 cytokine IFN-γ and negatively regulates the Th2-specific transcription factor GATA-3 thus promoting the Th1 polarization. A deficiency of T-bet is associated with an exaggerated asthmatic phenotype in mice [54].

Th1 and Th2 subsets are functionally separated based on their cytokine profiles but certain types of chemokine

receptors are selectively expressed on either Th1 or Th2 cells and appear to have an important place in determining the patterns of accumulation of T-cell subsets as a function of lung pathology. Th1 cells express CCR5, CXCR3, and CXCR6 [55] whereas Th2 cells express CCR3, CCR4, and CCR8 [56]. TSLP acts on dendritic cells resulting in the synthesis of two chemokines, thymus and activation-regulated chemokine (TARC) and macrophage-derived chemokine (MDC) that serve as chemoattractants for Th2 cells through actions on CCR4. TARC is also expressed in other sites, such as the bronchial epithelium, and may contribute to the selective chemoattraction of Th2 cells to the airways in asthma [57] whereas interferon inducible protein 10 (IP-10/CXCL10) may contribute to CD8$^+$ and CD4$^+$ Th1 cell recruitment in COPD [58]. The expression of the chemokine receptors CXCR3, CCR5, and CXCR6 correlated with disease severity; moreover, the dendritic cells produced the respective ligands for these receptors, and the levels again correlated with disease severity in COPD [55].

The elucidation of the roles of CD4$^+$ and CD8$^+$ T-cell subsets in asthma has depended heavily on the use of small animal experimental models and either adoptive transfer or antibody depletion techniques. It is impossible to review the extensive literature in detail. Dependence of allergic airway responses on CD4$^+$ T-cells has been demonstrated by the technique of adoptive transfer. T-cells isolated from the drainage lymph nodes of the site of sensitization to allergen and administered to naïve recipients that undergo allergen challenge result in typical late allergic responses [59] and airway hyperresponsiveness [60, 61]. Conversely, CD4$^+$ T-cell depletion also abolishes airway responses to allergen challenge [62]. It is now clear that mixed T-cell responses may occur in response to exposure to soluble antigen. Adoptive transfer of antigen-sensitized CD8$^+$ T-cells to naïve recipient animals that are then allergen-challenged results in delayed airway narrowing and typical TR2-type cytokine expression [63]. CD8$^+$ T-cells are also responsible for virally induced airway hyperresponsiveness in the mouse and the accompanying IL-5-driven eosinophilia [64]. In these situations the CD4$^+$ and CD8$^+$ cells share some common properties such as the secretion of eosinophilia-promoting cytokines. CD4$^+$ T-cells have also been implicated in airway remodeling in the allergic rat. Again using adoptive transfer, it was shown that the ovalbumin-sensitized and challenged rat developed epithelial remodeling and airway smooth muscle remodeling through hyperplasia and reduction in apoptosis [65]. The capacity of ovalbumin stimulated CD4$^+$ T-cells to cause hyperplasia of isolated airway myocytes was demonstrated in culture, and was contact dependent.

The study of the roles of CD4$^+$ and CD8$^+$ T-cells in COPD lags years behind that of asthma. Until recently the evidence of the role of these cells in the immunity of COPD was mainly circumstantial. Recently it has been shown in mice exposed to cigarette smoke that the development of pathological and functional emphysema is dependent on the presence of CD4$^+$ and CD8$^+$ T-cells [66, 67] and only the animals with emphysema showed significant expression of Th1 cytokines. In another study it was shown that mice depleted of CD8$^+$ T-cells had a blunted inflammatory response and did not develop emphysema when exposed to long-term cigarette smoke, indicating an important role of these cells in the development of emphysema [68]. Proof of the concept that CD4$^+$ T-cells, and autoimmunity, may play an important role in COPD has been provided by demonstrating the induction of emphysema in naïve rats by the adoptive transfer of vascular endothelial-sensitized CD4$^+$ T-cells from antigen-induced emphysema animals [69].

## Tc1 and Tc2 cells

In addition to their cytotoxic properties CD8$^+$ T-cells also show distinct subsets [Tc1 (Fig. 13.4) and Tc2] with cytokine profiles resembling the Th1 and Th2 patterns with IL-2 and IFN-$\gamma$ production and IL-4, IL-5, and IL-10 production respectively [70]. These subsets termed Tc1 and Tc2 evoke similar degrees of delayed-type hypersensitivity reactions but the latter cells also cause a somewhat greater degree of eosinophilia [70].

## Th17 cells

The Th17 cells produce large quantities of pro-inflammatory cytokines, most typically IL-17, and seem to be important in antibacterial responses and autoimmune diseases. Bacteria prime human dendritic cells to promote IL-17 production in memory Th cells through the actions of muramyldipeptide (MDP) on the innate pathogen recognition receptor nucleotide oligomerization domain 2 (NOD2). MDP enhanced TLR agonist induction of IL-23 and IL-1, promoting IL-17 expression in T-cells [71]. In mice, Th17 cells differentiate from naïve CD4$^+$ T-cells in response to transforming growth factor-$\beta$ (TGF-$\beta$) and IL-6 and also require IL-23 for their maintenance or expansion. IL-23 signaling requires IL-12Rb1, a receptor component shared with IL-12. Differences in signaling involving IFN-$\gamma$-induced transcription factor appear to determine whether CD4$^+$ Th1 or Th17 cells are produced [72]. In a murine model, IL-17 is required during antigen sensitization to develop an allergic phenotype, as shown in IL-17R-deficient mice [73]. The increase in IL-17 expression with allergen challenge is inhibitory of the allergic response. Neutralization of IL-17 augments allergic responses whereas exogenous IL-17 reduces eosinophil recruitment and bronchial hyperreactivity. Eotaxin (CCL11) and TARC are downregulated by IL-17 as are IL-5 and IL-13 production in regional lymph nodes. IL-4 plays an inhibitory role in the magnitude of IL-17 expression. IL-17 is also responsible for a neutrophilic component to the bronchial inflammation induced by allergen challenge of sensitized mice [74]. Th17 cells have not yet been reported in COPD but it would be surprising if they did not play a role in smokers since they have a crucial role in the induction of autoimmune tissue injury. Furthermore IL-6 whose expression is elevated in smokers has the potential to prevent the TGF-$\beta$ mediated differentiation of T-cells into regulatory T-cells (Tregs) by inhibiting the expression of FOXP3 and inducing the expression of IL-17 [75].
**FIG. 13.4** Oxidative stress, matrix metalloproteinase release by inflammatory cells leads to degradation of the matrix with release of cryptic antigens from elastin fibers. These fibers elicit a cytotoxic T-cell response which induces apoptosis of alveolar epithelial cells by mechanisms that involve perforin, granzyme and the FAS–FASL pathways.

## T-regulatory cells

There is growing evidence that a significant aspect of the inflammatory reaction in the airways is caused by a failure of suppression of the response. Active regulation appears to be important to peripheral tolerance to allergens in nonallergic individuals. In this regard Tregs are receiving substantial attention. A rapidly growing number of studies addresses the role of these cells in allergic processes and in models of asthma. Tolerance to allergens is associated with the synthesis of IL-10 and TGF-β by FOXP3 expressing $CD4^+CD25^+$ T-cells. The precise mechanisms by which T-cell inhibition is produced are still not well worked out. It appears that $CD4^+CD25^+$ Tregs are capable of inhibiting allergic responses even if they are harvested from IL-10-deficient mice and adoptively transferred into wild-type mice. The suppression of the Th2 responses is mediated by IL-10 producing $CD4^+$ T-cells that are activated by the transferred Tregs [76]. Intratracheal administration of $CD4^+CD25^+$ T-cells inhibits allergic airway responses (airway hyperresponsiveness and inflammation) through an IL-10-dependent mechanism acting through TGF-β expression. The T-cells required IL-10 treatment prior to transfer and even when unable to synthesize IL-10 themselves, they were still able to inhibit the allergic response [77]. The inflammatory process that follows allergen challenge in a murine model of allergic asthma and the ensuing airway hyperresponsiveness can be attenuated by Treg cells that are recruited into the airway mucosa [78]. These cells appear after the initial inflammation that is triggered by allergen inhalation and suggests that these cells may normally serve to limit the extent of the allergen-induced asthmatic reaction.

## γδ T-cells

Important T-cell subsets that do not share the usual T-cell receptor, such as the γδ TCR-bearing cells and NK T-cells, have substantial importance for pulmonary defense and airway function. T-cells expressing the γδ T-cell receptor have a particular association with mucosal epithelial surfaces, but what they do is still largely enigmatic [1]. In contrast to αβ T-cells that recognize peptide antigens the γδ T-cells recognize small nonpeptidic molecules and in some cases nonclassical MHC molecules such as CD1. γδ T-cells are important in defense against intracellular organisms such as *Listeria, Pneumocystis carinii and Mycobacterium tuberculosis* [79]. However their functions extend beyond their innate immune defense properties. These cells produce large quantities of IFN-γ and have been shown to potently downregulate IgE responses to sensitization [80, 81]. As such these cells are important mediators of allergen tolerance. They also synthesize trophic factors such as keratinocyte growth factor (KGF) that is important in epithelial cell regeneration [82], at least in the small intestine and likely also in the airways. The administration of KGF is able to protect the epithelial barrier function in face of allergen challenge. IFN-γ production by $CD8^+$ γδ T-cells is potently inhibitory of late allergic airway responses in the rat [83]. However, in the mouse there are both pro-inflammatory and anti-inflammatory properties associated with γδ T-cells. In OVA-sensitized and challenged mice, γδ T-cells expressing Vγ1 enhance airways hyperresponsiveness [84], whereas cells expressing Vγ4 strongly suppress airways hyperresponsiveness [85]. The airways hyperresponsiveness-regulatory γδ T-cells had only minor effects on airway inflammation in these experiments in contrast to rodent models where

they also inhibit Th2 inflammation. Cigarette smoking induces an increase of γδ T-cells both in human [15] and in mice [66] exposed to cigarette smoke, but their function in smokers is not clear.

## *i*NKT-cells

*i*NKT cells express CD3 and an invariant T-cell receptor α-chain (reviewed in [86]). They respond to glycolipid antigens that are presented by CD1d, and produce large quantities of IFN-γ and IL-4 [87]. The role of *i*NKT cells in host defense in the lung has largely been inferred from experiments in knockout mice that lack *i*NKT cells, which show increased susceptibility to a wide range of bacterial and viral pathogens and parasites. It has recently been proposed that *i*NKT cells also have a role in asthma pathogenesis: experiments with *i*NKT-deficient mice show reduced responses to sensitization and challenge that can be largely reconstituted by the adoptive transfer of *i*NKT cells [87]. In a murine model, when stimulated by α-galactosylceramide *i*NKT cells produce IL-13 and mediate airway hyperresponsiveness and eosinophilic inflammation, providing an additional innate immune mechanism for an asthma phenotype [88].

## T-CELL CYTOKINES IN MODELS OF ASTHMA AND COPD

The effects of the administration of cytokines to animals have been examined and provide some clues as to mechanisms of the links between the T-cells and airway responses. IL-2 administered to naïve rats leads to airway hyperresponsiveness to inhaled methacholine [89]. In high doses, it causes peribronchial edema and an eosinophilic airway inflammation. Low doses of IL-2 augment allergic responses, in terms of both the magnitude of bronchoconstriction and the degree of eosinophilic inflammation [90]. The increase in late response is attributable to an increase in sensitivity to leukotrienes rather than by enhanced synthesis [91, 92]. IL-4 is important in the sensitization phase to allergen in murine models and is necessary for allergen-induced airway hyperresponsiveness. However neutralization of its actions at the time of challenge does not abrogate hyperresponsiveness [93]. In contrast, IL-13 is of importance to airway hyperresponsiveness at the time of challenge to allergen [94–96], and its effects depend on intact signaling pathways for IL-13 in the epithelium [97]. How the epithelium transduces the effects of IL-13 is as yet unknown. Interestingly, the asthma phenotype caused by T-bet deficiency in mice is also attributable to IL-13, both airway hyperresponsiveness and airway remodeling were ameliorated by neutralization of IL-13 [98]. IL-5 has been shown in some models but not in others to mediate airway hyperresponsiveness [93, 99–101]. Recent studies help to clarify the issue of the controversial roles of IL-5 and eosinophilia in allergic asthma. When eosinophilia is absent, as in IL-5 and eotaxin-deficient mice, or in mice genetically engineered so as to lack eosinophils specifically,

there is an abrogation of the allergic responses and airway hyperresponsiveness [102, 103]. However the mechanism appears to reflect an attenuated Th2 response and reduced expression of important cytokines such as IL-13. These findings are perhaps explained by the effects of cationic proteins, such as EDN on immune responses, as reviewed above. The adoptive transfer of genetically engineered T-cells overexpressing IL-10 is inhibitory of allergic airway responses and airways hyperresponsiveness [104], consistent with the emerging concept of this cytokine as an inhibitory cytokine when produced by T-cells in the airway. The induction of airway hyperresponsiveness by repeated ozone exposures has been recently demonstrated to require both IL-17 and NKT cells [105], expanding the range of pertinent stimuli that activate airway T-cells.

There is evidence that CD8$^+$ T-cells in the lungs of COPD patients express IFN-γ [106] which would enhance the inflammatory reaction in the lung in addition to that caused by their cytotoxicity. Transgenic overexpression of IFN-γ causes emphysema in the murine lung and IFN-γ-deficient mice are protected against cigarette smoking-induced increases in alveolar cell apoptosis. Transgenic overexpression of IL-13, a critical cytokine in asthma, causes emphysema with enhanced lung volumes and compliance, mucus metaplasia, and inflammation, in the adult murine lung. Matrix metalloproteinase (MMP)-2, -9, -12, -13, and -14 and cathepsins B, S, L, H, and K were induced by IL-13 in this setting. In addition, treatment with MMP or cysteine proteinase antagonists significantly decreased the emphysema and inflammation, but not the mucus in these animals. These studies demonstrate that IL-13 is a potent stimulator of MMP and cathepsin-based proteolytic pathways in the lung. They also demonstrate that IL-13 causes emphysema via an MMP- and a cathepsin-dependent mechanism(s) and highlight common mechanisms that may underlie COPD and asthma [107]. Transgenic overexpression of IL-18 also results in murine emphysema, and appears to result from the combined effects of both IL-13 and IFN-γ overproduction in the lung [108].

## T-CELLS IN THE PATHOGENESIS OF ASTHMA: HUMAN STUDIES

T-cells are frequent in the airway wall. Most intraepithelial T-cells express CD8, whereas CD4$^+$ T-cells are more frequently found in the lamina propria. Both subsets mainly have an effector- and/or memory-cell phenotype, as defined by their expression of CD45RO (reviewed in [86]). In asthma the number of T-lymphocytes in the airway wall increases substantially. In agreement with the paradigm for T-cell subsets defined on murine T-cell cytokine profiles, a predominance of Th2 expressing CD4$^+$ T-cells has also been observed in the BAL cells from mild atopic asthmatics [109]. Furthermore, Th2 cytokine expressing cells increase in the BAL fluid of asthmatic subjects following allergen challenge [110]. In fact IL-4 and IL-5 mRNA expressing T-cells can be detected even in sputum samples from

asthmatic subjects [111]. Consistent with various cellular and animal models there is also an upregulation of GATA-3, the principal transcription factor for Th2 cytokines in asthmatic airway tissues [112]. Lung lavage following segmental allergen challenge of the airways of asthmatic subjects has demonstrated that the CD4, CD8, and γδ T-cells all contribute to the Th2 response through the expression of IL-5 and IL-13 [113].

Bronchial biopsies from asthmatics are frequently positive for IL-5 mRNA expression that is related to the degree of eosinophilia and is consistent with a key role for this Th2 cytokine is causing eosinophilia in asthma [114]. In certain forms of occupational asthma involving low molecular weight sensitizers eosinophilia appears to be associated with IL-5 production by CD8$^+$ T-cells [115]. Anti-IL-5 antibody administration markedly reduces eosinophils in the sputum of asthmatics [116], and although tissue eosinophilia is affected also it is more resistant to the neutralizing antibody [117]. It has been difficult to demonstrate therapeutic benefits of anti-IL-5 treatments on surrogates for asthma such as airway hyperresponsiveness or late allergic airway responses. However, favorable effects on tissue matrix protein deposition were observed, likely through downstream effects on TGF-β, which is synthesized by eosinophils in asthma. Although it is widely believed that eosinophils are the major site of synthesis of cysteinyl leukotrienes in asthma there is no formal proof that they are indeed responsible for the cysteinyl leukotriene synthesis associated with late allergic responses.

Other Th2 cytokines, such as IL-4 and IL-13, are also expressed in the airway mucosa of asthmatic subjects, as is the Th1 cytokine IFN-γ and these cytokines are predominantly expressed in T-cells [118]. Clinical trials of a soluble IL-4 receptor have demonstrated only minor therapeutic effects [119]. A subsequent trial utilizing Pitrakinra, a recombinant mutant form of the wild-type human IL-4 that targets the effects of both IL-4 and IL-13, demonstrated that the late allergic airway response could be attenuated by inhalation of the biological [120]. There is increasing recognition of alternative mechanisms of inflammation mediated by T-cells. The presence of a neutrophil-rich infiltrate in some asthmatics is not well explained by the classical Th2 paradigm. IFN-γ is often associated with more severe asthma and the neutrophil chemoattractant CXCL8 (IL-8) is also found. The family of cytokines that includes IL-17 may help shed light on these alternative patterns of inflammation. IL-17 itself may also be a contributor to neutrophilic airway inflammation. IL-17 mRNA can be found in asthmatic sputum where it correlates with CXCL8 expression [121] and in bronchoalveolar lavage cells from asthmatic subjects ranging in severity from mild to severe [122].

Regulatory T-cells are being increasingly recognized to participate in inflammatory diseases and may suppress inflammation in asthma. It is a plausible hypothesis that defective inhibitory influences are as important in the genesis of inflammation as pro-inflammatory pathways. Indeed induction of regulatory T-cells by an appropriate education of the mucosal immune systems in early life is now proposed as an alternative hygiene hypothesis. Probiotics have been explored for their beneficial effects on eczema but clinical trials in asthma are lacking and data on modification

of T-cell populations in the respiratory mucosa are also required before any definite statement about such a strategy can be recommended.

*i*NKT cells have been recently implicated in airway pathophysiology. The extent to which findings from murine models can be extrapolated to human asthma is unclear. Elevated numbers of CD4$^+$ *i*NKT cells have recently been reported in BAL from patients with asthma [123], but other studies have failed to confirm these findings and have concluded that these cells are relatively uncommon, representing less than 2% of the T-cells in the airways in either asthmatic or COPD patients [124]. Therefore it is not clear how pertinent current findings are to asthma in general. It is also not known what the appropriate stimulus for activation of *i*NKT cells is or how these cells may be activated by aeroallergens.

The final characteristic of asthma, namely remodeling has been linked to T-cell function in animals and human T-cells will also trigger proliferation of airway smooth muscle cells [125]. Recent studies describe T-cells among smooth muscle bundles in asthma [126], but their phenotype and possible effects on airway smooth muscle structure or function are as yet unknown.

## T-CELLS IN THE PATHOGENESIS OF COPD: HUMAN STUDIES

We now recognize that antigens, specifically elastin or its by-products (probably among others) derived from the injury of the lung by the innate inflammatory response, are also an important trigger for the development of COPD. These antigens are taken up by dendritic cells not in the larger airways, like in asthma, but deeper inside the lung, small airways, and parenchyma, where the lung tissue suffers the most injury by cigarette smoke. There is evidence in the literature that cigarette smoking is associated with an expansion in the dendritic cell population in the lower respiratory tract [127] and with a marked increase in the number of mature cells in the lung parenchyma [128]. This is an indication that the lung response to cigarette-smoke exposure follows the established immune response design, including innate immunity and readiness for an adaptive immune response, if necessary. There is a similarity between asthma and COPD in that they are both initiated by the presentation of soluble antigenic products to dendritic cells. However, very dissimilar inflammatory patterns result from the dendritic cell–T-cell interaction. In asthma, the dendritic cell triggers a Th2 T-cell response, while in COPD it results in a Th1 and a cytotoxic CD8$^+$ T-cell response that is maintained and even progresses after the challenge by cigarette smoke ceases. These differences emphasize the importance of the dendritic cell, and its interaction with the antigen and the inflammatory milieu in determining the fate of the resulting inflammation and disease.

The study that initiated the present interest in the T-cell as a possible important cell in the pathogenesis of COPD was carried out by Finkelstein *et al.* in 1995 [13]. These authors used immunohistochemistry and morphometry

to identify the inflammatory cells infiltrating the alveolar wall and to define the extent of emphysema in smokers and nonsmokers undergoing lung resection. Their findings were surprising at the time, as they reported that the most prominent inflammatory cell in the lung parenchyma of smokers was the $CD3^+$ T-lymphocyte that increased from a mean of 1546 cells/mm$^3$ in nonsmokers up to 10,000 cells/mm$^3$ in smokers. Furthermore, a clear correlation between the number of $CD3^+$ T-cells and the extent of emphysema was found, certainly suggestive of the protagonism of the T-lymphocytes in the pathogenesis of emphysema in smokers. Abundant but variable numbers of T-cells ($CD3^+$) together with other inflammatory cells were also found in the small airways of the same patient population [129, 130]. Interestingly the degree of airway reactivity, measured prior to surgery, correlated with the load of T-cells in the airways in smokers with centrilobular emphysema (CLE), but not in panlobular emphysema (PLE) or nonsmokers. Because similar total numbers of $CD3^+$ T-cells were present in the two forms of emphysema, we speculated that the T-cells in CLE were behaving differently, possibly indicating a mixed phenotype of Th1 and Th2 subsets. In support of this possibility is the finding that Th2 type cytokines IL-4 and IL-5 mRNA, typically found in asthma, are abundantly expressed by inflammatory cells in the wall of large airways in some smokers with chronic bronchitis and COPD [131] and it is possible that clones of T-cells in smokers with CLE may express a Th2 cytokine profile that might induce airway reactivity in these cases.

Following the report by Finkelstein *et al.* [130] proposing a role for the T-cell in COPD, several authors identified the $CD8^+$ T-cell as the predominant lymphocyte in the airways of smokers with COPD [132, 133]. Saetta showed that the only significant difference in the inflammatory cell infiltrate in asymptomatic smokers and smokers with COPD was the increase in $CD8^+$ T-cells in the small airways of patients with COPD. Furthermore, the number of $CD8^+$ T-cells were negatively correlated with the degree of airflow obstruction, as measured by the $FEV_1$, again suggesting a possible role for these cells in the pathogenesis of the disease. $CD4^+$ T-cells are also found, albeit in smaller numbers, in the airways of smokers with COPD and these cells express IFN-$\gamma$ and activated signal transducer and activator of transcription 4 (STAT 4), a transcription factor that is essential for activation and commitment of the Th1 lineage. The number of T-cells expressing activated STAT 4 correlated with the degree of airflow obstruction [134]. These findings go along with the previously mentioned expression of CXCR3 and CCR5 by $CD4^+$ and $CD8^+$ T-cells and the ligand IP-10 and MIG in lung tissue and strongly support the idea that COPD is mediated by an active Th1 immune reaction in the lung comprising both $CD8^+$ and $CD4^+$ T-cells.

Majo while studying lungs from nonsmokers and smokers obtained at surgery found that the $CD8^+$ T-cells are also the predominant T-cells infiltrating the alveolar wall in smokers with COPD [15, 133], although $CD4^+$ T-cells are also increased [15, 135]. Furthermore, the number of both $CD8^+$ and $CD4^+$ increased with the amount smoked in smokers with COPD, but not in healthy smokers, indicating that the $CD4^+$ T-cell are also involved in the inflammatory process in COPD. Majo *et al.* also

quantified and found an increased number of apoptotic cells in the lungs of smokers with COPD which correlated with the numbers of $CD8^+$ cytolytic T-cells in the alveolar wall [15]. This and other reports, showing an increased number of structural lung cells undergoing apoptosis in emphysematous lungs [136] support the idea that $CD8^+$ T-cells are inducing apoptosis of endothelial and epithelial cells in emphysema.

The predominance of $CD8^+$ T-cells over $CD4^+$ T-cells in the lungs of patients with COPD, resembles the inflammatory reaction seen in many viral diseases like Epstein-Barr and LCMV virus in which the numbers of $CD8^+$ T-cells are much greater than the $CD4^+$. Cell-associated proteins [42, 43] and particulate antigens [44] usually presented with HSP and apoptotic cells presented by phagosomes, are much more effective at MHC class I restricted $CD8^+$ T-cells priming than are simple soluble molecules and it can be speculated that these antigenic forms mimic the tissue debris associated with cell injury or viral infections [40] stimulating a larger $CD8^+$ proliferation.

The relatively mild infiltration with $CD8^+$ and $CD4^+$ T-cells found in patients with mild to moderate disease increases markedly in the lungs [135] and airways of severely diseased patients. All inflammatory cells, except B-lymphocytes, were found to be increased in the lungs of patients with severe emphysema, even though these patients had not smoked more than the control subjects. By far, the more numerous cells were the $CD4^+$ and the $CD8^+$ T-cells but neutrophils, macrophages, and even eosinophils were also increased. These studies are of importance showing that, in COPD, inflammation with an abundance of T-lymphocytes and other inflammatory cells continues late into the disease process.

An important finding in one of these studies was that the average duration of smoking cessation in the severe COPD subjects was 9.2 years [137] indicating that the adaptive immune system continues to be involved after smoking cessation, a phenomenon typically found in other autoimmune diseases. In favor of this possibility is the recent finding of oligoclonality of T-cells in the lungs of patients with COPD, a finding supportive of the idea that these cells are accumulating in the lung secondary to antigenic stimulation. If correct, COPD may be considered to have an autoimmune component to its pathogenesis that is triggered by smoking, as previously suggested [14, 15, 138].

Supporting the idea of COPD as an autoimmune disease is the key paper by Lee and colleagues characterizing antielastin antibodies and T-helper type Th1 type responses in human subjects, which correlate with emphysema severity [31]. In response to elastin peptides, but not collagen, T-cells from smokers with COPD produced IFN-$\gamma$ and IL-10 but no IL-13 and these responses were decreased by blocking MHC class II molecules. A humoral response was also found in these patients that showed circulating antibodies against elastin but not collagen, findings that implicate not only the T-cell but the B-cell in the autoimmune reaction in COPD. T-regulatory cells have been well described in COPD and they may play an important role in the development of COPD in smokers. Lee [31] and Barcelo [139] have shown a lower number of Tregs in the

lungs of smokers with COPD when compared with non-smokers. Furthermore smokers with normal lung function had significantly higher Tregs in the lung than nonsmokers, suggesting an enhanced protective role by these T-cells, possibly controlling the development of autoimmunity and disease in smokers with normal lung function. It has been shown that $CD8^+$ expressing $\gamma\delta$ T-cells have immune regulatory properties and might play a role in the development of COPD in some smokers. Pons described that, as seen with Tregs, smokers with normal lung function have increased numbers of $\gamma\delta$ $CD8^+$ T-cells in the lungs while smokers with COPD do not [140]. These findings suggest a possible dysregulation of tolerance in smokers with COPD.

## B-CELLS IN ASTHMA AND COPD

About one-third of adult patients with asthma are classified as nonatopic and they often suffer from more severe disease. The popular term intrinsic asthma became unpopular following the observation that IgE was elevated compared to control subjects in all asthmatics, irrespective of the skin test reactivity [141] which tends to wane with age. The systemic reaction to sensitization with the expression of specific IgE reflects an important B-cell contribution to this disease and there has been renewed interest in the contribution of IgE to asthma since the introduction of antibody treatment directed against IgE. Some further insights into the potential role of IgE have been obtained through recent observations examining IgE synthesis locally in airway tissues. IgE is characterized by its $\varepsilon$ heavy-chain and it is produced after heavy-chain switching in B-cells from IgM, IgG, or IgA to IgE. The switch to IgE is initiated by the cytokines IL-4 or IL-13, produced principally by $T_H2$ cells, which drive $\varepsilon$ germline gene transcription. Local IgE synthesis was first shown to occur within the nasal mucosa of patients with allergic rhinitis [142]. More recently immunopathological comparisons of bronchial biopsies from atopic and nonatopic patients with asthma have demonstrated expression of $\varepsilon$ germline gene transcripts and expression of the high affinity IgE receptor, $Fc\varepsilon RI$ mRNA. Evidence acquired by the examination of bronchial biopsies from atopic and nonatopic patients with asthma and appropriate controls suggested elevated synthesis of mature IgE in the asthmatic bronchial mucosa by local B-cells. It was argued that local IgE synthesis may well account for most, if not all, biologically significant IgE production, and circulating IgE may reflect spillover of IgE from synthesis at mucosal sites. It is therefore quite possible that synthesis of bronchial mucosal IgE contributes to both atopic and nonatopic asthma, making distinctions based on skin reactivity unnecessary and uninformative, except where it is necessary to document systemic sensitization as may be required in cases of occupational asthma. These observations also raise questions about current criteria for the restriction of monoclonal anti-IgE antibodies, such as omalizumab, to patients that are more obviously atopic. Clearly further studies are required in this area to clarify the situation.

B-cells have been shown to also play an important role in COPD. Lymphoid follicles containing monoclonal B-cells, dendritic cells, and T-cells, predominantly $CD4^+$, have been recently described in the airways [143] and parenchyma [144] of patients with COPD and also in mice with cigarette smoke-induced emphysema. These follicles function as inducible secondary lymphoid tissue for immune responses, where antigen presentation can be accomplished without lymphatic node migration. This could explain why dendritic cells found in the lungs of COPD patients express markers of maturation, such as CD80 and CD86 [145] but not CCR7 the homing receptor for lymph nodes [146]. It has been suggested that lymphoid follicles may develop in relation to microbial colonization and infection occurring in the later stages of COPD. However no bacterial or viral products were seen in the follicles suggesting that the B-cells in the follicles, which are monoclonal, proliferate in response to specific lung antigens. The recent demonstration of IgG autoantibodies with avidity for epithelial and endothelial cells along with the deposition of antigen–antibody immune complexes and complement in the lungs of patients with COPD further support this interpretation. Altogether these findings fulfill the conventional criteria that define the presence of antibody responses against self-antigens as autoimmunity [34]. Furthermore since the B-cells were producing IgG antibodies the participation of the $CD4^+$ T-cells primed for the same antigens as the B-cell is essential and suggest that a complex immunological process involving CD4 and CD8 T-cells along with the deposition of immune complexes and complement are involved in the mechanism of lung destruction in COPD.

## CONCLUSIONS

The role of the T-cells in mediating the defining characteristics of asthma is still unclear. Airway inflammation is associated with findings that are quite consistent with the findings from animal models. Th2 type inflammation follows allergen challenge as expected. However, in certain subsets of asthma, such as severe asthma, there is often a neutrophilic inflammation and expression of cytokines and chemokines that are not associated with allergen-driven Th2 models. Airway hyperresponsiveness continues to defy elucidation and it likely has multiple causes. In acute murine models IL-13 is the best single cytokine candidate to explain allergen-induced changes in airway responsiveness. However, it is likely that complex cascades are involved in such reactions in human asthma and that airway hyperresponsiveness is the expression of these diverse pathways. While the understanding of the mechanisms of COPD has lagged behind the exploration of the inflammatory basis for asthma it is now clear that an antigen-driven adaptive immune reaction is also crucial in the production of the disease. It should be clearly understood that new emphasis on the adaptive immune response involving T-and B-cells does not detract from the importance of the innate immune inflammation, neutrophils, macrophages, $\gamma\delta$ T-cells but rather completes

the picture. These cells are responsible for the initial tissue injury and the production of antigens that result in the subsequent adaptive immune response. The autoimmune paradigm in COPD could explain why only a proportion of smokers develop COPD. Immunological tolerance based on Tregs is not an all or none phenomenon but may show various degrees of efficacy, so that disease may occur in the susceptible subject [147]. Different degrees of tolerance to self-antigens could explain the variable T-cell inflammation, wide range in function, and disease severity in response to similar degrees of cigarette exposure in smokers. Autoimmunity in COPD could also contribute to the widely recognized systemic manifestations of this disease. Hopefully the increased understanding of the mechanisms of these diseases will provide improved treatment options in time.

# The Neutrophil and Its Special Role in Chronic Obstructive Pulmonary Disease

Elizabeth Sapey[1] and Robert A. Stockley[2]

[1]Department of Medicine, Birmingham University, Birmingham, UK
[2]Lung Investigation Unit, University Hospital Birmingham, NHS Foundation Trust, Edgbaston, Birmingham, UK

## INTRODUCTION

There is a substantial body of evidence to support the hypothesis that the neutrophil is the primary effector cell in chronic obstructive pulmonary disease (COPD) and that neutrophil proteinases, especially neutrophil elastase (NE), are responsible for the main pathological features seen.

Studies have shown that patients with COPD have increased numbers of neutrophils in sputum [1, 2] and bronchoalveolar lavage fluid (BALF) [3] compared with asymptomatic smokers, and that the percentage of neutrophils in BALF is higher in patients with the greatest degree of airflow obstruction [4, 5]. Furthermore, in a recent study of bronchial biopsies, small airways intraepithelial neutrophil counts were greater in patients with COPD compared with both smoking and nonsmoking controls, and correlated with airway obstruction [6]. Increased neutrophil counts have been found in the bronchial walls and in the BALF samples from patients during exacerbations of COPD [7, 8], with increased neutrophil sequestration in the pulmonary microcirculation and such episodes relate to subsequent progression of airflow obstruction [9]. Resolution of the neutrophilic inflammation occurs approximately 5 days after appropriate treatment of the exacerbation, which coincides with clinical recovery [10]. In addition, a recent study by Donaldson et al. [11] reported that patients with higher numbers of neutrophils in sputum had a faster decline in $FEV_1$ compared with those with lower neutrophil counts, losing approximately 1% more than predicted each year.

Furthermore Parr et al. [12] demonstrated that baseline markers of neutrophilic inflammation relate to subsequent decline of lung function

and CT quantification of emphysema over the subsequent 4 years. Gas transfer (the most direct physiological measure of emphysema) has been shown to be inversely proportional to the levels of neutrophil-associated markers, such as myeloperoxidase and human neutrophil lipocalin, in patients with COPD [13]. Both clinical and subclinical emphysema (noted on HRCT) are associated with an increase in NE and other neutrophil proteins in BALF [14, 15] and in established emphysema, severity is proportional to NE immunoreactivity in tissue [16] and enzyme activity in BALF [17]. Finally, both neutrophil counts and NE concentration appear to decline with smoking cessation [18] which is consistent with the benefits of this intervention.

COPD, while primarily a lung disease, is associated with increased co-morbidity including cardiovascular disease and systemic pathology such as muscle wasting and dysfunction. It has been hypothesized that persistent low grade inflammation may drive the co-morbidity and the systemic effects noted with this disease [19]. The systemic manifestations of COPD are important, as they are not only associated with increased morbidity, but are also predictive of disease outcome, especially body mass index (BMI) which forms part of the BODE index (body mass, airflow obstruction, dyspnea, and exercise capacity) [20]. There is controversy concerning whether increased and sustained pulmonary inflammation causes increased systemic inflammation. However C-reactive protein (CRP) (a generic marker of systemic inflammation) is raised in patients with COPD compared to healthy controls [21] irrespective of cigarette smoke exposure and ischemic heart disease (an independent cause of a raised CRP). It is unclear whether these systemic changes are incidental or driven by pulmonary inflammation. In a recent

study of 16 patients with moderate to severe COPD, a relationship was present between absolute sputum neutrophil counts, CRP, and BMI less than 21 (see Fig. 14.1). These data indicate an association between the neutrophil load in the lungs and systemic manifestations of the disease, again highlighting the central role of this cell in many aspects of COPD.

The neutrophil was first implicated in the pathogenesis and progression of COPD in 1963, where it was noted that severe emphysema in early adulthood was linked with a deficiency of alpha 1 antitrypsin ($\alpha_1$-AT), the serum inhibitor of the proteolytic enzyme NE [22]. Since then, the Proteinase/ Anti-proteinase theory has dominated research in COPD. This states that in health, proteinase activity is controlled by anti-proteinases, such as $\alpha_1$-AT and secretory leukocyte proteinase inhibitor (SLPI), thereby limiting tissue damage. In COPD, an imbalance is believed to exist, either from the increased activity of proteinases or a real or functional deficiency in anti-proteinases, which leads

to excessive tissue destruction [23] Tables 14.1 and 14.2 provides an overview of neutrophil proteinases and anti-proteinases in COPD.

This chapter provides an overview of the role of the neutrophil in COPD, starting with neutrophil maturation and structure. Cytokines and chemoattractants which are important in neutrophil activation and recruitment will be discussed and neutrophil migration into lung and neutrophil apoptosis will be outlined, with particular reference to COPD. The evidence for the actions of neutrophil proteinases in the pathogenesis of COPD will be reviewed, highlighting *in vitro* and *in vivo* work. Finally, the role that neutrophils may play in asthma, likely through similar pathogenic mechanisms is discussed briefly.

## NEUTROPHIL STRUCTURE, FUNCTION, AND APOPTOSIS

Neutrophils have a characteristic multilobed nucleus and abundant storage granules in their cytoplasm. The mature neutrophil has three chemically distinct granule types, which

**FIG. 14.1** The relationship between BMI and absolute sputum neutrophil counts in patients with moderate to severe stable COPD and chronic bronchitis. The relationship between absolute sputum neutrophil counts and BMI in 12 patients with stable moderate to severe COPD according to GOLD criteria and chronic bronchitis. Neutrophil counts were obtained from spontaneous sputum samples produced over 4 h from waking; $r = -0.8, p = 0.01$.

**TABLE 14.1** Overview of neutrophil serine proteinases.

|  | Neutrophil elastase | Cathepsin G | Proteinase 3 |
|---|---|---|---|
| Size | 218 amino acids | 235 amino acids | 222 amino acids |
| Mass (kDa) | 39 | 28.5 | 29 |
| Substrate specificity | Val – Xaa > Ala – Xaa | Aromatic acids in P1 position | Same as NE, accepts basic amino acids in P1 position |
| Elastolytic activity |  | 20% potency of NE | 40% potency of NE |

**TABLE 14.2** Endogenous inhibitors of neutrophil proteinases.

| Inhibitor | Source | Target proteinase | Inhibition |
|---|---|---|---|
| Alpha 1antitrypsin | Produced in the liver Found in serum | NE, CG, PR3 | Irreversible |
| Alpha 1 antichymotrypsin | Liver and macrophages | CG | Reversible |
| Alpha 2 macroglobulin | Liver and macrophages | NE, CG, PR3, MMP-8, MMP-9 | Irreversible |
| Secretory leukoproteinase inhibitor | Mucosa | NE, CG | Reversible |
| Elafin | Mucosa | NE, PR3 | Reversible |
| Monocyte-neutrophil elastase inhibitor | Neutrophils/monocytes | NE, CG, PR3 | Irreversible |

appear at different stages of maturation (see Table 14.3). The neutrophil differentiates and matures within bone marrow, developing from a bipotential progenitor cell, the granulocyte-macrophage colony forming unit. In the first developmental stage, the cell divides and differentiates from myeloblasts to promyelocytes. During this stage the azurophilic or primary granules are produced. These granules contain myeloperoxidase (MPO), antibacterial proteins (such as defensins, lysozyme, and azurocidin), and three serine proteinases, NE, cathepsin G (CG), and proteinase 3 (PR3). The proteinases are produced as preproenzymes, with gene expression stopping at the metamyelocyte stage [24] and are activated by a lysosomal cysteine proteinase, dipeptidyl peptidase [25]. The specific or secondary granules are formed as the cell enters the myelocytic stage. These granules contain lysozyme, lactoferrin, collagenase, and various membrane receptors. The small storage granules are formed last, at the metamyelocyte stage, and contain gelatinase and cathepsin B and D. At maturation (which takes approximately 2 weeks) each neutrophil contains a full complement of proteins which provide the mechanisms of cell migration, opsonophagocytosis, and a formidable arsenal against pathogens. However, the neutrophil proteinases (especially NE) also have the capacity to be intensely destructive, degrading structural lung proteins (including elastin, collagen, and gelatin) and appear to be involved in the posttranslational processing of enzymes, cytokines, and receptors [23]. Fully mature neutrophils leave the bone marrow in a nonactivated state and have a half-life of 4–10 h before marginating and entering tissue pools [26]. Once in tissue, neutrophils are usually removed by apoptosis leading to their recognition and phagocytosis by macrophages in the main and by other neutrophils when the macrophage clearance system is

overwhelmed [27]. This mechanism prevents cell necrosis and the release of the remaining cellular content of proteinase and other mediators.

Apoptosis is regulated cell death, which allows the elimination of unwanted or damaged cells. At the present time, three caspase-dependent apoptosis pathways have been described. The first pathway is triggered in response to extracellular signals (the receptor-mediated extrinsic pathway), mediated by the binding of tumor necrosis factor related proteins (such as Fas ligand) to death receptors on the cell surface. This results in the formation of the death inducing signaling complex (DISC), which activates a series of caspases, leading to DNA fragmentation by DNAse [28–32]. A second pathway, the mitochondrial intrinsic pathway, responds to stress signals by the release of cytochrome c from mitochondria. Cytochrome c, apoptotic protease activating factor-1 (Apaf-1), and caspase-9 activate caspase-3 leading to apoptosis [33–35]. Finally, in the endoplasmic reticulum pathway, caspase-12 is activated in response to stress signals such as hypoxia [36, 37].

Clearance following apoptosis has no inflammatory sequelae. However, if phagocytosis fails, apoptotic cells undergo secondary necrosis with cell rupture, which is inflammatory in nature and increases both the proinflammatory proteins and proteinase burden in the lung [38]. Figure 14.2 describes the appearance of neutrophils during induced lung inflammation, showing both activated and apoptotic cells, apoptotic cells undergoing secondary necrosis, and neutrophils containing phagosomes with neutrophilic cell remnants.

The increased numbers of neutrophils seen in the lungs of patients with COPD may accumulate because of an increased influx from peripheral blood or because of prolonged neutrophil survival. Exposure to cigarette smoke

appears to stimulate neutrophil differentiation and maturation, causing peripheral leukocytosis, [39, 40] which has been found to correlate with the severity of airflow obstruction [41, 42]. This suggests that a peripheral neutrophilia facilitates an increased neutrophil transmigration into the lung, leading to a higher proteinase burden with subsequent tissue damage. Platz and colleagues [43] described a reduction of peripheral neutrophil apoptosis (based on Annexin V-PE binding and nuclear morphology) during exacerbations of COPD compared with healthy controls, which returned to control levels upon resolution of symptoms. This increased-cell longevity would facilitate increased neutrophil egression into lung, again predisposing to enhanced lung damage. Once in the lungs, it has been suggested that reduced neutrophil apoptosis may account for the high numbers seen in the lung and the increased inflammation described in COPD although recent studies present conflicting results [44]. Rytila *et al.* [45] found no differences in the proportion of apoptotic neutrophils in induced sputum, or in the *in vitro* anti-apoptotic activity detected in the sputum fluid phase in patients with COPD, healthy smokers or

healthy controls despite patients with COPD having a significantly higher percentage of neutrophils in the samples. The authors suggested that the increased neutrophilic presence in COPD was due to an increased influx rather than a reduction in apoptosis. Yoshikawa *et al.* [46] also found higher numbers of neutrophils in induced sputum from patients with COPD compared with healthy controls, but described a reduced neutrophilic chemotactic response to IL-8 and *N*-formyl methionyl-leucyl phenylalanine (fMLP) in the COPD patients which worsened with increasing disease severity. In this study, the authors postulated that an increased influx could not explain the higher numbers of cells seen in COPD, and that increased survival should be considered. This issue has yet to be resolved.

## PROMIGRATORY STIMULI

Neutrophils migrate into the lung in response to soluble mediators. Promigratory stimuli can be classified as nonchemotactic cytokines, chemotactic cytokines, or chemoattractants.

Cytokines comprise families of molecules including interleukins, lymphokines, monokines, growth factors, interferons, and chemokines. Two of the most important proadhesive cytokines in COPD are tumor necrosis factor alpha (TNF-$\alpha$) and interleukin-1$\beta$ (IL-1$\beta$).

TNF-$\alpha$ is produced by activated monocytes and macrophages (but also epithelium, endothelium, and probably smooth muscle cells) and has been implicated in the pathogenesis of COPD [47, 48]. Increased levels of TNF-$\alpha$ have been measured in serum, sputum [49], and in bronchoalveolar lavage samples from patients with COPD, and in smokers demonstrating a dose-dependent relationship with cigarette exposure, [50] with further increases during exacerbations [51]. TNF-$\alpha$ has also been associated with the systemic manifestations of COPD, including a low BMI [52, 53] (perhaps via leptin, [54]) and abnormal resting energy expenditure [55]. TNF-$\alpha$ overexpression (due to genetic polymorphism) has been linked to early COPD development or rapid progression [56]. In support of this, mouse models with an inducible TNF-$\alpha$ gene construct have shown that overexpression of TNF-$\alpha$ is associated with the development of emphysema associated with a general increase in lung inflammation [57] probably by inducing MMP production [58]. Conversely TNF-$\alpha$ receptor knock-out mice demonstrate reduced smoking or elastase-induced emphysema in comparison with the wild type [59, 60] suggesting a central role for this cytokine.

IL-1$\beta$ is also produced by macrophages (although neutrophils and epithelial cells produce the cytokine) and increased levels have been found in sputum of patients with stable COPD, which increase further during exacerbations [61]. Furthermore, IL-1$\beta$ production is enhanced by cells cultured from smokers with COPD following cigarette smoke exposure compared with controls [62] and there is some evidence that overexpression of IL-1$\beta$ (caused by polymorphisms such as the −511 SNP with a cytosine/thymine transition) may increase susceptibility to COPD [63, 64]. In a study of patients with severe COPD, data from our
**FIG. 14.3** The relationship between IL-1β and disease severity in COPD. Patients had moderate to severe COPD (as defined by GOLD) and chronic bronchitis. Each data point represents the average of 11 measurements of IL-1β and a single BMI (A) or (B) $FEV_1$ for one patient over 1 month. Spontaneous sputum samples were collected over a 4 h period from waking. The regression lines are drawn and the correlation co-efficient ($r$) and significance ($p$) are as follows: IL-1β and BMI $r = -0.7$, $p = 0.01$; IL-1β and $FEV_1$ $r = -0.56$, $p = 0.02$.

group have shown a negative correlation between plasma IL-1β and $FEV_1$ and sputum sol IL-1β and BMI, clearly linking IL-1β with COPD disease severity (see Fig. 14.3). Furthermore, animal studies using inducible IL-1β systems and complex knock-out mice have described a neutrophilic infiltrate, distal airspace enlargement, increased thickness of the conducting airways, and enhanced mucin production when IL-1β was overexpressed [65].

TNF-α and IL-1β are not directly chemotactic, but they act by increasing expression of integrins on the neutrophil surface and increasing endothelial expression of selectins and intercellular adhesion molecule 1 (ICAM-1), aiding capture and firm adhesion of neutrophils to the vascular endothelium (see later). They also increase the production of directly chemotactic mediators from endothelial cells to enhance the migration process.

Neutrophils possess at least five receptors for chemotactic stimuli and a number of chemotactic mediators have been implicated in the pathogenesis of COPD, especially the chemokine CXCL8 and the neutrophil chemoattractant LTB4.

CXCL8 is primarily produced by leukocytes (monocytes, T-cells, neutrophils, and natural killer cells) and airway epithelial cells. Production is not constitutive but is induced by proinflammatory cytokines, such as IL-1β and TNF-α [66], bacteria and bacterial products, [67, 68] viruses, such as adenovirus and rhinovirus [69, 70], and oxidants, for example, from cigarette smoke [71]. Once secreted, CXCL8 binds to CXC receptors (1 and 2) on leukocytes resulting in activation of protein kinase B and GTPases, which lead to enhanced neutrophil adherence to endothelial cells (by increasing expression of $\beta_2$-integrins) and directed cell migration. CXCL8 also activates Ras and "eventually" mitogen-activated protein kinases and extracellular signal-related kinases in neutrophils, causing degranulation.

In COPD, sputum CXCL8 correlates with levels of neutrophil activation markers, such as MPO and NE [72], and relates to airflow obstruction, [73] oxygen saturation, cigarette exposure [49], and progression of emphysema quantified by CT scan [12]. It has been suggested that oxidative stress (caused by cigarette smoke and bacterial and viral infections) induces CXCL8 production in both airway

epithelial and endothelial cells, leading to neutrophil adhesion, chemotaxis, and degranulation.

LTB4 is mainly produced by monocytes, alveolar macrophages, and activated neutrophils and its production is upregulated by a number of inflammatory mediators including C5a, IL-1β, TNF-α, granulocyte-macrophage colony stimulating factor (GM-CSF), PAF, NE, and even LTB4 itself [74, 75]. LTB4 enhances neutrophil aggregation and chemotaxis via two neutrophil surface receptors. A low affinity receptor induces degranulation and increases oxidative metabolism whereas a high affinity receptor induces aggregation, chemokinesis, and adhesion via the integrin Mac-1 [76]. LTB4 may also activate endothelial cell monolayers *in vitro* enhancing neutrophil emigration [77]. LTB4 concentrations are elevated in sputum [78] and exhaled breath condensate [79] from patients with COPD. Concentrations correlate with the degree of airway neutrophilia [80] and increase further during bacterial exacerbations [10] returning to baseline once bacteria have been successfully eradicated [81]. In addition, LTB4 concentrations also correlate with the subsequent decline in gas transfer implicating neutrophilic infiltration [12].

*In vitro* chemotaxis studies, using functional antibodies against CXCL8 and an LTB4 receptor antagonist, have demonstrated that 30% of the chemotactic activity of sputum can be accounted for by CXCL8, and up to 50% by LTB4 [82, 83]. Furthermore, Woolhouse and colleagues [82] found that LTB4 concentrations correlated with the overall chemotactic activity of sputum, suggesting that LTB4 in particular may be central to the neutrophilic influx seen in COPD, at least in the stable state.

It is unclear whether other inflammatory mediators are important in the pathogenesis of COPD. At least five other chemokines mediate neutrophil responses in humans; three forms of growth related oncogenes (GRO) (α, β, and γ), epithelial cell derived neutrophil activating peptide (ENA)-78, and neutrophil-activated peptide (NAP)-2. GROα is detectable in bronchial secretions [84] and both GROα and ENA-78 have been measured in BALF [85]. One study has suggested that chemotaxis toward GROα and NAP2 is increased in COPD compared with healthy controls and smokers, [86] but their contribution to the

pathogenesis of COPD is unknown. A number of other inflammatory mediators including C5a, fragments of fibrin, elastin and collagen, $\alpha_1$-AT polymers, and bacterial products such as fMLP, are also neutrophil chemoattractants found in the lung, but their importance in neutrophil recruitment in COPD has yet to be established. The numbers of fMLP receptors is elevated in both healthy smokers and subjects with COPD who smoked, but not nonsmoking patients with COPD [87] suggesting that fMLP may play a role in the recruitment of neutrophils leading to the development of disease and its progression whilst smoking and especially during bacterial exacerbations (where bacterial formyl peptides may be most important).

The individual importance of each proinflammatory or promigratory protein in COPD has yet to be unraveled, certainly many of these proteins appear to have similar actions and a degree of overlap or redundancy is likely to exist in the inflammatory cascade. However, there is increasing interest in identifying the key inflammatory mediators in COPD as potential targets for therapeutic interventions. To date, trials which have aimed to block a specific mediator have not proved helpful [88] including a recent trial of anti-TNF-$\alpha$ [89]. It is likely that a greater understanding of each mediator, its naturally occurring antagonists and their relation to COPD is required to develop and clarify more successful treatment strategies. However, Gompertz *et al.* were able to show in a short phase-2 study that antagonism of five lipoxygenase activating proteins reduced LTB4 in the airway secretions and subsequent markers of neutrophilic inflammation [90]. Although not dramatically effective, this may provide a model for future studies.

## NEUTROPHIL MIGRATION

Neutrophils are present at both the bronchial and alveolar level in COPD, and therefore it is likely that neutrophil migration occurs from the bronchial and pulmonary circulation. Most of our understanding of neutrophil migration has been derived from *in vitro* studies using systemic vessels in the mesentery and dermis. Studies using samples of lung tissue suggests that while migration in the bronchial circulation occurs in a similar fashion to migration in other tissues, migration in the pulmonary capillaries may depend on distinct mechanisms.

## Neutrophil migration in the bronchial circulation

### Initiation of migration

In the bronchial circulation, neutrophils migrate from vessel to tissue in a step-like process, dictated by the sequential activation of adhesive proteins and their ligands on neutrophils and endothelial cells.

Migration begins with the capture of neutrophils from flowing blood which causes the cell to roll along the endothelial surface. Tethering and rolling of the neutrophil along the vessel wall is a normal feature of circulating neutrophils and is due to reversible binding of transmembrane glycoprotein adhesive molecules called "selectins," which are found both on neutrophils and endothelial cells [91].

Leukocyte Selectin (L-Selectin) is constitutively expressed on projecting microvilli on the surface of neutrophils and binds an endothelial ligand which is believed to be a sialomucin oligosaccharide (potentially a fucosylated variant of CD34). L-Selectin-induced neutrophil capture can be transient in noninflamed tissue ("stick and release"), however, during both nonpathogenic and pathogenic rolling interactions, L-Selectin, once bound, is shed from neutrophils [92]. Both L-Selectin binding and shedding is enhanced in the presence of inflammatory products such as TNF-$\alpha$, CXCL8, fMLP, and LPS [93]. Once bound and cleaved, L-Selectin molecules cannot be replaced and low expression has been associated with neutrophil apoptosis [94].

In the presence of inflammation, at least two further endothelial bound selectins are expressed,

Platelet Selectin (P-Selectin) and Endothelial Selectin (E-Selectin): P-Selectin is stored intracellularly in Weibel-Palade bodies in endothelial cells [95] and can be mobilized rapidly in response to various inflammatory mediators including oxygen-free radicals, components of the complement cascade, and many cytokines [96]. Its neutrophilic counterligand is P-Selectin glycoprotein ligand-1 (PSGL1) which is uniformly expressed on the surface of neutrophils. P-Selectin–PSGL1 interactions occur after L-Selectin–ligand interactions, and have greater longevity. In the presence of other adhesion molecules, P-Selectin/PSGL1 binding slows neutrophil rolling velocities and eventually causes cell tethering to the endothelium but in the absence of other adhesive events, binding is also transient [97].

E-Selectin is not stored, and peak expression is seen 4–6 h after endothelial exposure to inflammatory mediators [98]. It binds to E-Selectin ligand 1 [99] and it is thought to maintain neutrophil tethering after P-Selectin has been downregulated. E-Selectin expression is increased in both serum and BAL in patients with COPD and relates to lung function [100] suggesting a common causality.

### Firm adhesion

The next step in neutrophil migration is the transition from reversible rolling to firm adhesion with the endothelium. This is achieved by the sequential activation of neutrophil receptors called integrins [101, 102].

The integrins are heterodimeric transmembrane glycoproteins that comprise an $\alpha$ and a $\beta$ subunit, which together form an extracellular binding site. Integrins are found on many haematopoietic cells, with differing $\alpha$ and $\beta$ subunits. The two most important integrins in neutrophils share a $\beta_2$ subunit (CD18), and are called macrophage antigen 1 (MAC-1; CD11b/CD18) and lymphocyte-associated function antigen 1 (LFA-1; CD11a/CD18). A third CD18 integrin, p150,95 can also promote neutrophil trafficking, but MAC-1 appears to be the most important integrin in models of neutrophil migration [103, 104].

MAC-1 is stored in secretory granules [105, 106] and is rapidly mobilized to the cell surface after exposure to inflammatory stimuli (including fMLP, TNF-$\alpha$ and LPS).

Inflammatory stimuli also promote transcription and translation of the MAC-1 gene via a G-protein, Rho, [107] further increasing its surface expression [96]. Some MAC-1 is expressed constitutively on the neutrophil, but these proteins are incapable of binding ligands unless activated by intra or extracellular signals, where conformational changes occur exposing a requisite binding epitope [108]. Neutrophils from patients with COPD have increased baseline surface expression of MAC-1, which increases further following activation, [109] suggesting that this adhesion molecule may play a role in neutrophil migration in this disease.

MAC-1 has a high affinity for ICAM-1, an immunoglobulin-like protein that is expressed in low numbers on the endothelial cell surface, but is rapidly induced in inflammation [110]. Vascular cell adhesion molecule-1 (VCAM-1) is also an immunoglobulin-like molecule expressed by endothelial cells which it binds selectively to $\alpha_4\beta_1$-integrin [called very late antigen-4 (VLA-4)] on neutrophils [111]. MAC-1/ICAM-1 interactions cause enhanced expression of both ICAM-1 and VCAM-1 on endothelial cells, suggesting that both may be important in inflammatory driven neutrophil migration [112] and levels of ICAM-1 are raised significantly in COPD in contrast to asthma or healthy controls and correlate with overall pulmonary neutrophil infiltration [113].

## Migration

The final step of neutrophil recruitment from the bronchial circulation to the lungs is transendothelial migration. This occurs preferentially at tricellular junctions [114] and depends upon activation of platelet endothelial cell adhesion molecule (PECAM1) [115] which is distributed evenly around the neutrophil and at intercellular junctions of endothelial cells. PECAM1 is thought to act as a homing beacon that directs migration toward cellular junctions and blocking PECAM1 on either neutrophils or endothelial cells using antibodies does not prevent adhesion but does prevent migration through the basement membrane both *in vitro* and *in vivo* [116].

Once through the endothelial cell layer, leukocytes bind to matrix components such as collagen and laminin via $\beta_1$ integrins, with VLA-6 and -9 being perhaps the most important in allowing neutrophils to move through venule basement membrane and lung tissue [117–119]. Endothelial/neutrophil PECAM1 interactions lead to increased neutrophil surface expression of VLA-6 ($\alpha_6\beta_1$) and VLA-6 facilitates passage thorough the basement membrane and beyond. To support this, neutrophils from PECAM1 knock-out mice do not have the associated rise in VLA-6 which is seen in the wild type [120]. Migration is accompanied by release of neutrophil proteinases especially NE, [121] which may facilitate passage by matrix degradation, exposing laminin for VLA-6 binding.

## Direction of migration and neutrophil movement

Neutrophils migrating within the lung encounter multiple chemoattractant signals in complex spatial and temporal patterns as endothelial, epithelial cells, and immune cells respond to infection or injury. Individual chemoattractants can vary in their ability to affect neutrophils and *in vitro* models have demonstrated that neutrophils can migrate up and down chemical gradients, responding to one signal, migrating to its concentration peak and then migrating up a novel, more distant chemoattractant gradient, from endothelium to tissue.

Neutrophils can ignore a high concentration source (due to receptor saturation, desensitization, and/or receptor sequestration) and preferentially respond to novel chemoattractants [122]. Evaluations of chemotaxis by the under-agarose method has suggested that neutrophils are able to migrate in the direction of the vector sum of two or more differing signals [123]. If two sources of the same agonist are used, migration toward the second attractant is poor, [122] so two distinct agonists are required for precise targeting. These findings may account for the observation that activated cells characteristically secrete multiple induced chemoattractants concurrently. Cells can regain their prior sensitivity, but this process takes time, requiring recycling of receptors. For example neutrophils preincubated with low chemotactic levels of LTB4 showed a significant reduction in chemotaxis to LTB4 which improved after 10 min [122].

Neutrophil movement itself is achieved by the formation of locally protruding actin-rich pseudopods while retracting other regions of the cell body [124]. In order to achieve this, directed neutrophil chemotaxis begins with cell polarization. Extracellular chemoattractant gradients causes the localized accumulation of PtdIns(3,4,5)P$_3$ on the side of the cell facing the highest chemoattractant concentration. PtdIns(3,4,5)P$_3$ signaling guides the localized polymerization of F-actin (filamentous actin), which in turn leads to pseudopod extension, which confers cellular motility. The persistent presence of PtdIns(3,4,5)P$_3$ at a particular site on the plasma membrane causes cells to acquire an elongated shape in which one F-actin enriched pseudopod becomes the leading edge of the migrating cell, whereas retraction of pseudopods at the rear and sides of the cell is mediated by cortical myosin II [125]. Although there may be many proximal signal pathways by which polarization is regulated, the key event appears to be activation of the RhoGTPases, Rho and Rac via integrins [126]. The $\alpha_4\beta_1$ integrin forms a complex with paxillin and GIT1 which inhibits Rac activation at the sides and rear of the cell, but this inhibitory complex is impeded at the leading edge of the cell by phosphorylation of the $\alpha_4$ integrin cytoplasmic tail, which allows Rac activation [127]. At the front of the cell Rac activation leads to the F-actin polymerization while at the rear of the cell Rho activation leads to assembly of myosin, with both GTPases working in a co-operative manner to establish and stabilize cell polarity [128].

Recent studies have elucidated how the neutrophil "steers" from one direction to another. Pseudopods are made in spatially restricted sites by splitting of the leading edge of the cell, and the generation of these protrusions appears to be random in both their direction and timing. In a study where cells were exposed to a promigratory stimulus, which was then relocated once an accurate trajectory was established, pseudopod generation occurred randomly, but pseudopods that extended toward the stimulus were more likely to be retained, while those which extended in inaccurate directions were retracted (see Fig. 14.4). Therefore it appears that neutrophils migrate up chemoattractant gradients by
**FIG. 14.4** Neutrophil migration by pseudopod generation toward a promigratory stimulus. (A) A polarized (elongated) neutrophil migrating toward IL-8 in a Zigmond chamber. The direction of the chemoattractant gradient is shown by the large arrow. (B) A representation of pseudopods generated over the time course. Here, pseudopod generation was noted across the breadth of the leading edge of the cell in a random fashion. (C) Pseudopods generated toward the stimulus were more likely to be retained (the sustained pseudopods over the time course is shown schematically). (D) Pseudopods that extended in inaccurate directions were more likely to be retracted (the retracted pseudopods over the time course are shown schematically). It appears that neutrophils migrate up chemoattractant gradients by choosing the best aligned of competing randomly generated pseudopods.

choosing the best aligned of competing randomly generated pseudopods [129].

### Transmigration through extracellular matrix

Neutrophil proteinases are released during migration through extracellular matrix [121] but it has been difficult to ascertain whether proteinases are necessary for neutrophil migration. Chemotaxis through artificial substrates in response to fMLP can be inhibited by 50% by $\alpha_1$-AT [130] and CG antibodies; synthetic inhibitors of CG and $\alpha_1$-antichymotrypsin ($\alpha_1$-ACT) also reduce neutrophil migration [131]. Furthermore, fMLP-stimulated migration across an artificial basement membrane is also reduced by inhibitors of both NE and MMP-9 [132]. However, *in vitro* studies of endothelial monolayers and basement membrane matrices have shown consistently that proteinase inhibitors are ineffective at stopping neutrophil migration [133, 134] although degradation of basement membrane components is reduced [135]. In animal studies, neutrophils from mice whose genes for NE and CG had been "knocked out" showed normal migration both *in vitro* and *in vivo* when exposed to LPS although pathogen clearance was impaired [136] and mice deficient in gelatinase B had normal neutrophilic migration into the lungs [137]. However, animal studies of cigarette smoke inhalation suggest that neutrophil influx into the lung is reduced in the presence of proteinase inhibitors [138, 139].

Therefore the exact mechanisms remain unresolved, but the conflicting results may well reflect the study model used, including the density of the ECM studied and in particular the presence or absence of cross-linked collagen (compare, e.g. [140, 141]). The majority of recent studies have used tumor cells, but there is evidence to suggest

that migrating cells can change their behavior depending on the matrix and stimuli they are exposed to. For example, in a noncross-linked collagen 3D matrix, cells migrate along fibers, but can squeeze between fibers in the presence of anti-proteinases, therefore migration is not inhibited but redirected. On the other hand in a dense cross-linked collagen 3D matrix, cells require proteinases to migrate and migration is inhibited in the presence of anti-proteinases. Cell-derived matrices are cross-linked but have gaps and migrating cells appear to preferentially seek out these gaps to migrate, which may or may not therefore require proteinases, depending on the size of the gap [142]. If neutrophil migration *in vivo* is partially proteinase dependent, *in vitro* migration may not require degradation of "loose" extracellular matrix by proteinases to allow cell passage, but instead the generation/activation of inflammatory chemokines and cytokines or modulation of adhesion molecules (enhancing expression, increasing their activation, or exposing binding sites [117]) by proteinases may be sufficient, and this may be more easily decreased or prevented by inhibitors, explaining the apparent experimental contradictions.

## Neutrophil migration in the pulmonary circulation

The majority of neutrophils appear to enter the lung from the pulmonary capillary network rather than the postcapillary venules [143, 144]. Neutrophil emigration into the lung from the pulmonary circulation is less well understood than from the bronchial circulation, however there seem to be important differences in mechanism, probably due to the size of capillary networks. 40–60% of pulmonary capillary segments are narrower than a spherical neutrophil, which on average is 7–8 μm in diameter [145, 146]), so neutrophil rolling is unlikely because of size constraints. Neutrophils entering the pulmonary capillary network have to undergo a shape change, from a sphere to an oblong, to allow passage through these narrow vessels. This slows their transit time, and indeed, radiolabeled neutrophils from patients with stable COPD have been shown to have a slower transit time in the pulmonary circulation compared with red blood cells [147]. When activated, neutrophils become less deformable due to actin polymerization, and this slows their progression through the capillary network further [148]. In such circumstances there is no need for transient adhesion via the selectins to initiate neutrophil rolling along the endothelium, as the leukocytes are already in close contact with the endothelium, and indeed there is evidence to suggest that some migration can occur without adhesion molecules [149, 150].

In the bronchial circulation, adhesion and migration appear to be primarily dependent upon ICAM-1 interactions, however, in the pulmonary circulation both CD18-dependent and -independent adhesion pathways have been described and the path utilized appears to be stimulus-specific. For example, in animal models, bacteria such as *Streptococcus pneumoniae* and *Staphylococcus aureus* and hydrochloric acid have induced CD18-independent neutrophil migration, while human studies have demonstrated CD18-independent

migration toward host-derived chemoattractants such as LTB4, CXCL8, and sputum [150,151]. In contrast, IL-1, phorbol myristate acetate, and gram-negative bacterial stimuli including LPS elicit migration via pathways predominantly mediated by CD18 [152–155] CD18-dependent migration may not only be stimulus-driven but also inflammatory mediator driven. Rabbits produce both CXCL8 and TNF-α during a bacterial pneumonia but CXCL8 and TNF-α production during a gram-negative pneumonia are 2- and 10-fold greater respectively than seen during a gram-positive pneumonia [156]. It may be the varying concentrations of these proinflammatory stimuli which elicit a CD18-dependent response, perhaps by inducing nuclear factor-κβ [152] rather than the bacterial insult itself. Animal models have suggested that selectins are required where CD18-dependent migration occurs, but not for CD18-independent migration. For example, L-Selectin knock-out mice had significantly less neutrophil recruitment into the lungs in response to LPS (a CD18-dependent stimulus) while recruitment in response to Streptococcus pneumoniae (a CD18-independent stimulus) was unaffected [157].

## Migration in COPD

Current evidence suggests that the increase in neutrophils in the lungs is not due to delayed apoptosis and it has been hypothesized that neutrophils in COPD reflect an enhanced chemotactic response. Certainly, neutrophils from patients with chronic bronchitis and emphysema demonstrate enhanced migration toward common chemoattractants *in vitro* compared with healthy controls [158].

Unfortunately, studies examining the expression of adhesion molecules have produced conflicting results. Noguera [109] measured MAC-1, LFA-1, and L-Selectin expression on neutrophils from controls and patients with COPD, prior and poststimulation with TNF-α. Neutrophils from patients with COPD had enhanced expression of these adhesion molecules compared with controls, and differences were even more pronounced following stimulation with chemoattractants. Woolhouse *et al.* [159] demonstrated upregulation of CD11b (a component of MAC-1) on neutrophils from smokers with COPD compared with controls. However, Gonzalez [160] found no differences between levels of adhesion molecules in smokers with and without airflow obstruction and Yoshikawa *et al.* [161] found reduced chemotaxis toward sputum sol in patients with COPD compared with healthy controls.

The increased neutrophil migration and degranulation seen in COPD has led to a belief that neutrophils may be different from those in health. The differences may be accounted for by genetic polymorphisms and be apparent during maturation in bone marrow. Alternatively neutrophils could be "primed" following their release into the circulation, perhaps by inflammatory cytokines, so that they are more responsive, with an increased ability to degranulate compared with those of healthy individuals. This priming may also occur during transmigration and studies have confirmed differences between neutrophils prior to and following migration even in healthy controls with increased expression of proteinases on the cell surface, increased adhesion molecule expression, and enhancement of the respiratory burst [162, 163]. However, none of these options have been studied in COPD. Whatever the differences in neutrophils, they cannot reflect environmental factors (such as prolonged cigarette smoke exposure) as only a proportion of smokers develop significant airflow obstruction indicating a genetic susceptibility [23]. In susceptible individuals, environmental exposure may lead to increased neutrophil pooling in the lung, increased degranulation and hence increased tissue damage; although it remains unclear whether current observations reflect a predisposing factor for COPD or a consequence of the disease.

## THE EFFECTS OF NEUTROPHIL PROTEINASES IN COPD

### The actions of neutrophil elastase

A significant physiological role of NE is bacterial killing. This is achieved when opsonized bacteria are ingested in phagosomes which fuse with lysozymes containing proteinases and oxidants. NE is also intensely destructive and this is believed to be the primary cause of lung damage seen both in emphysema and in chronic bronchitis. NE was the first of the serine proteinases to be shown to produce emphysema in animal models. Intratracheal instillation of purified NE-induced emphysema in dogs and hamsters [164–166] and intratracheal instillation of other elastases have given similar results in various animal models–Papain (plant elastase) in rats, [167] neutrophil lysates in dogs [168], and porcine pancreatic elastase in rats and hamsters [169, 170]. In fact the development of emphysema is specific to elastase activity with emphysema severity relating proportionally to the elastolytic potency of the elastase used [169, 170] and in these models emphysema can be prevented by specific elastase inhibitors [171, 172].

NE acts upon a wide range of proteins and can degrade elastin, fibronectin, and collagen, [173, 174] and can also decrease the activity of immunoglobulins and activate components of the complement cascade [175, 176]. NE may also affect wound healing, by its actions on transforming growth factor β and the epithelins [177,178]. During activation, azurophil granule proteinases (including NE) are expressed on the neutrophil membrane [179] and *in vitro*, over 95% remains associated with the cell by a charge-dependent mechanism, while less than 5% is released into the liquid mileu or directly onto tissue. Thus NE most commonly causes damage by close contact between cells and matrix [180, 181]. Recent elegant studies have shown that NE polarizes toward the leading edge of the neutrophil as it migrates. Some is then left behind as the cell moves on where it may cause collateral damage for instance to the connective tissue [182].

Free NE activity has been detected in secretions of patients with COPD [72] and this is felt to be fundamental in the development of the condition *in vivo*. Free NE may accumulate from degranulating neutrophils, or (in contrast with apoptotic cells) may be freely released during cell

necrosis [183]. Also the process of phagocytosis may cause the release of significant quantities of proteinases into the media ("sloppy eating"), especially during "frustrated phagocytosis," when cells attempt to ingest large particles [184]. Free NE can also be released from activated macrophages, which scavenge the proteinase from apoptotic neutrophils via endocytosis and subsequently release it during the first 24h of their own inflammatory response [185]. This is important, as although cell-associated proteinases have partial resistance to native inhibitors such as $\alpha_1$-AT, [180] free NE is more readily inactivated by both serum- and tissue-based inhibitors [186] if sufficient quantities are present, which means that in health, free NE should be completely inactivated at a short distance from the activated cell.

Indeed, it has been shown that the concentration of free NE released from neutrophils falls exponentially away from the cell [187]. In healthy subjects, the serum concentration of $\alpha_1$-AT is 30µMol, which is at least two orders of magnitude lower than NE concentrations in the neutrophil granule, and inhibits NE on a one to one molar basis. Therefore following degranulation NE cannot be completely inhibited until it has diffused far enough to reduce its concentration to 30µMol. This phenomenon is called quantum proteolysis [187] and was clearly demonstrated in a series of experiments using serum from patients with normal or deficient $\alpha_1$-AT where an area of obligate enzyme activity existed even with serum from healthy subjects but was far greater using serum from patients with $\alpha_1$-AT deficiency [188]. Membrane bound NE is less susceptible to anti-proteinases [180] and the combination of increased free and membrane bound NE present in COPD may be sufficient to overcome local inhibitors, causing the tissue destruction which is characteristic of the disease.

NE interacts with matrix proteins and cells, and this affects not only its own activity, but also the efficacy of its inhibitors and other proteinases. For example, although free NE is irreversibly inhibited by $\alpha_1$-AT, elastin bound NE is poorly inhibited by $\alpha_1$-AT, while the inhibitory effect of SLPI is unaffected [189]. Adhesion to goblet cells appears to alter the neutrophil membrane, enhancing the release of membrane bound NE into the intercellular space [190] potentially causing mucus secretion. Furthermore, animal models have demonstrated that NE can induce secretory cell metaplasia which is prevented by NE-specific inhibitors [190–192]. It has been suggested that mucous gland epidermal growth factor receptor interacts with NE as part of a signaling cascade [193]. In human studies, there is a clear relationship between the amount of mucus production and the concentration of active NE in the lung secretions.

NE can damage the respiratory epithelium *in vitro* [194], reduce ciliary beating [195], and trigger a state of oxidative stress in cells [196] all of which are abrogated by NE inhibitors. NE can also induce apoptosis of epithelial cells [197] and detachment of bronchial epithelial cells from the extracellular matrix [198] and both PR3 and NE induce detachment and apoptosis of endothelial cells [199] which has also been implicated in the pathogenesis of COPD [200].

NE stimulates the release of LTB4 by macrophages [201] and may cause release of CXCL8 from bronchial epithelial cells, which enhances neutrophil migration into the lung. This inflammatory response is greater in patients with $\alpha_1$-AT deficiency who have higher levels of LTB4 and elastase providing an amplification to neutrophilic recruitment and subsequent increase in the potential for tissue destruction compared with patients with normal anti-proteinase function thereby explaining the more severe and rapidly progressive disease of $\alpha_1$-AT deficiency patients [78].

The most important risk factor for COPD is cigarette smoke exposure and the relationships between smoke inhalation and NE have been studied. In animal models NE knock-out mice are partially protected (45%) against the development of emphysema, [202] however, these models are limited, as CG and PR3 persist, and CG has been shown to cause secretory cell metaplasia [166] whereas PR3 causes both emphysema and secretory cell metaplasia [203]. Furthermore, animal models have suggested that both synthetic [171] and natural NE inhibitors [172, 204, 205] can limit emphysema when delivered simultaneously with the elastase insult. Most animal models suggest that neutrophil influx is greatest during the early stages of lung damage with macrophage influx, and their metalloproteinases accumulating at a later stage [206, 207]. However, even when given in established disease, NE inhibitors still limit inflammation and connective tissue breakdown [138].

COPD is characterized by periods of stability of symptoms punctuated with exacerbations [which are intermittent worsening of symptoms and (most probably) of the inflammatory load [208]]. NE activity relates to sputum purulence, which is due to MPO which can be graded visually [10]. During bacterial exacerbations of COPD, sputum purulence, neutrophil influx, NE activity, and tissue degradation products increase [10, 209, 210] and therefore it is likely that proteinase-induced tissue damage also increases. More frequent exacerbations are associated with a faster decline in lung function as well as increased morbidity and mortality and it may be that the increases in NE load and activity during these periods causes progressive lung damage which is reflected in markers of disease severity [208]. Table 14.4 summarizes the actions of NE in COPD.

## Matrix metalloproteinases

There have been significant advances in our understanding of the role of matrix metalloproteinases (MMPs) in COPD. Both neutrophils and macrophages produce large amounts of MMPs and their inhibitors, the tissue inhibitors of metalloproteinases (TIMPs). The MMPs are proteolytic enzymes that are secreted as proenzymes (activated by other MMPs and NE) and remain bound to cell membranes. MMPs not only degrade matrix proteins, but also inactivate anti-proteinases such as $\alpha_1$-AT and $\alpha_1$-ACT, activate enzymes involved in the clotting cascade, and interact with cytokines and adhesion molecules, so their potential role in the pathogenesis of COPD is complex and wide ranging.

Over 24 mammalian MMPs have been described, and although they are primarily grouped according to the proteins they degrade (collagenases, gelatinases, etc.), most can degrade many substrates and together they can degrade all extracellular substrates. MMPs are inhibited by $\alpha_2$-macroglobulin and by the four TIMPs described to date

**TABLE 14.4** The actions of neutrophil elastase in COPD

| | |
|---|---|
| Bacterial killing | Intracellular: engulfed organisms in phagosome |
| | Extracellular: targeting and cleaving bacterial virulence factors in released granule proteins |
| Degradation | ECM components |
| | Cystatin C |
| | TIMPs |
| | T-Lymphocyte surface antigen |
| Activation | MMP-2, MMP-3, MMP-9, Cathepsin B |
| Modification of inflammatory mediators | Enhances epithelial secretion of CXCL8 |
| | Enhances macrophage secretion of LTB4 |
| | Inhibits cellular response to TNFRII prolonging half-life of TNF |
| | Increases SLPI expression but reduces secretion of SLPI |
| | Increases elafin expression |
| | Increases alpha 1 antitrypsin expression by monocytes and alveolar macrophages |
| Cell migration | NE/alpha 1 antitrypsin complexes are chemotactic for neutrophils |
| | Modification of ICAM-1 expression enhancing adhesion |
| Cell apoptosis | Increases epithelial and endothelial cell apoptosis |
| Cell function | Disruption and detachment of epithelial cells |
| | Reduces ciliary beating of columnar epithelium |
| | Enhances oxidative stress |
| | Increases mucin MUC5AC protein content |
| | Increases bacterial adherence and colonization |

This table is not exhaustive and references are not included for reasons of space. For an excellent review of the cell signaling by neutrophil proteinases see Ref. [211].

[212]. The main MMPs secreted by neutrophils are MMP-9 (Gelatinase B), which degrades collagen, elastin and gelatin; and MMP-8 (neutrophil collagenase) which degrades collagen type's I–III.

MMP-9 is increased in lung tissue, BALF, and plasma taken from patients with COPD, [213, 214] and levels are negatively correlated with airflow obstruction and relate to the number of sputum neutrophils [215, 216]. MMP-9 not only acts as a proteinase, but also modifies cellular functions by regulating cytokines and matrix bound growth factors and therefore may have a role in lung remodeling after the inflammatory insult resolves [217, 218]. MMP-9 deficient mice exposed to intratracheal LPS showed no differences in histological tissue damage, neutrophil migration, or infiltration compared to the wild-type mouse, suggesting a limited role for this MMP in the pathogenesis of

COPD [137]. In a further study, MMP-9 knock-out mice displayed greater neutrophil influx than the wild type, perhaps because MMP-9 can degrade neutrophil chemoattractants [191]. However smoke-exposed guinea pigs displayed a reduction in the severity of emphysema and MMP-9 activity in BALF after introduction of a broad spectrum MMP inhibitor, although this may also have reflected inhibition of other metalloproteinases [219]. Genetic polymorphisms of MMP-9 have, however, been identified which cause enhanced protein expression, and in a Japanese study, polymorphism −1562C/T has been associated with an increased risk of smoking-induced emphysema [220] although this has yet to be replicated in other populations [221].

MMP-8 has been less studied in COPD compared with MMP-9, however one study described both raised concentrations and increased activity of MMP-8 in the induced sputum of patients with COPD compared with smokers without evidence of COPD. Furthermore both the levels and activity of MMP-8 correlated inversely with $FEV_1$ and positively with sputum neutrophil counts [222]. There are currently no animal studies to elucidate the importance of MMP-8 in COPD.

## INTERACTIONS BETWEEN MMPS AND NE IN COPD

It is likely that the serine proteinases and MMPs act synergistically in lung disease. NE degrades TIMPs [223] facilitating MMP activity, and can activate several MMPs converting proenzymes, including MMP-9, to the active form [224]. Conversely MMP-12, for instance, inactivates $\alpha_1$-AT thereby enhancing NE activity [225]. The majority of animal "knock out" models of emphysema support a multifaceted pathogenic process in the disease, as inhibition of serine, cysteine, or MMPs all show partial protection from the development of emphysema [138, 191]. The noticeable exception is MMP-12 and there have been several conflicting animal studies comparing MMP-12 activity, macrophage and neutrophil influx, and emphysema. MMP-12 knock-out mice (Line 129 mice) exposed to cigarette smoke did not develop emphysema and lung inflammation was reduced, although macrophage recruitment to the lungs was normal in response to monocyte chemoattractant protein-1 (MCP-1). All elastolytic activities in the wild-type mice were derived from MMP-12 and emphysema severity was increased following instillation of MCP-1 suggesting a very specific mechanistic pathway [226]. In a study of Sprague-Dawley rats, neutrophil numbers increased in the first month following smoke exposure, but breakdown of connective tissue and the development of emphysema occurred later and related to a subsequent increase in macrophages [206]. Furthermore, neutrophil depletion (with a significant reduction in NE activity) did not protect against smoke-induced emphysema, while macrophage depletion (with normal neutrophil activity) did. These results have questioned the importance of the neutrophil in the pathogenesis of COPD (at least in rodents) and have suggested that the macrophage was the only effector cell.

However, in a further study BALF from cigarette smoke-exposed mice showed an acute influx of neutrophils with evidence of both elastin and collagen degradation in a dose-dependent manner at 6 and 24 h. This had resolved by 48 h and was reduced by neutrophil depletion or the administration of the serine proteinase inhibitor $\alpha_1$-AT [207] although macrophage numbers were not affected. Other animal models have also found an early rise in neutrophil number and activity, and a corresponding rise in matrix breakdown products after exposure to cigarette smoke [138]. In guinea pigs, NE inhibitors reduced TNF-$\alpha$ and emphysema by approximately 30%, but only if given at the start of exposure and when inhibitors were given after 4 months of exposure, these effects were not seen.

TNF-$\alpha$ receptor knock-out mice were also protected from the acute neutrophil infiltrate and connective tissue breakdown seen following cigarette smoke exposure in wild-type mice [211] and mice that produce lower levels of TNF-$\alpha$ following an inflammatory insult (Line 129 mice) also appeared to have less neutrophils and less emphysema compared with the wild-type mice [197, 211]. In fact TNF-$\alpha$ appears to be central to about 70% of the tissue destruction

seen following cigarette smoke in mouse models, probably by enhancing neutrophil migration into the lung [227].

In order to understand the relationship between macrophages and neutrophils in COPD, MMP-12 knock-out mice were studied further. Cigarette smoke exposed MMP-12 knock-out mice did not display the early neutrophilic infiltrate or the release of desmosine and hydroxyproline (matrix breakdown products) that is characteristic of wild-type mice, although low levels of macrophage infiltration did occur. When the MMP-12 knock-out mice underwent intratracheal instillation of normal macrophages, a neutrophil influx was seen and the use of an MMP inhibitor also prevented a neutrophilic infiltrate and subsequent matrix breakdown [211]. Following these observations, studies demonstrated that cigarette smoke-induced production of TNF-$\alpha$ from alveolar macrophages in wild-type mice, but not in MMP-12 knock-out mice while levels of TNF-$\alpha$ mRNA were the same in both groups. It was surmised that MMP-12 processes TNF-$\alpha$ after secretion and it is likely, therefore, that MMP-12 is needed to activate TNF-$\alpha$ which in turn initiates neutrophil recruitment, leading to degranulation and tissue damage [228]. Figure 14.5

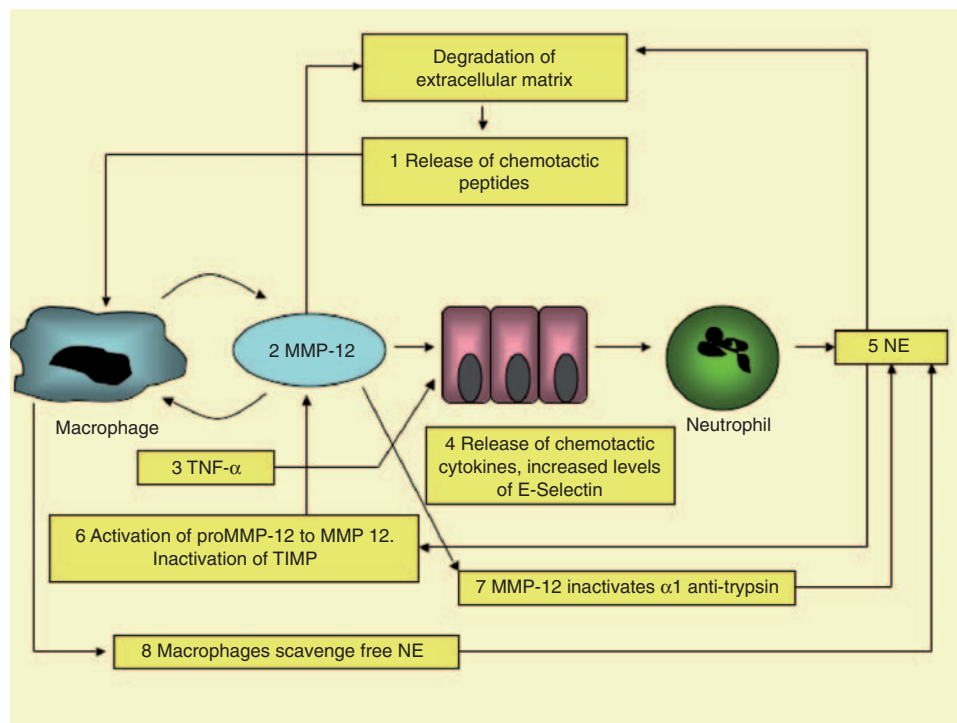

**FIG. 14.5** The proinflammatory actions of MMP-12 and the interactions between neutrophils and macrophages

1  Cigarette smoke causes the release of chemotactic peptides which recruit macrophages and neutrophils to airways.
2  Activated macrophages secrete MMP-12 which activates epithelial cells and causes degradation of extracellular matrix components.
3  MMP-12 facilitates the release of active TNF-a which activates epithelial cells further.
4  Activated epithelial cells release chemotactic cytokines and increase the expression of proadhesive proteins such as E-Selectin.
5  Neutrophils migrate to areas of activated epithelium and release free NE during frustrated phagocytosis or sloppy eating. NE promotes epithelial cell apoptosis and increases expression of proinflammatory mediators such as LTB4 and CXCL8.
6  NE proteolytically converts proMMP-12 to active MMP-12 and proteolytically inactivates TIMP, both of which enhance MMP-12 activity.
7  MMP-12 proteolytic inactivation of a1-AT causes the further release of promigratory proteins and allows increased NE activity.
8  Macrophages scavenge free NE which is then reused to further degrade extracellular matrix components.

summarizes the proinflammatory properties of MMP-12 and macrophage/neutrophil interactions.

When interpreting results from *in vitro* work and animal models, it is crucial to consider that there may be important variations in the pathogenesis of COPD between cell types and differing species, and indeed, conflicting results are common. However it seems likely that neutrophil infiltration is an early event and that both neutrophil numbers and elastolytic activity relate well to lung damage in the early stages of disease. Macrophages seem central to neutrophil recruitment, probably via activation of TNF-α by metalloproteinases, and may be needed to sustain the inflammatory process and hence development of emphysema.

## THE NEUTROPHIL IN ASTHMA

Although current concepts of asthma pathogenesis focus primarily on $CD4^+$ T cells and eosinophilic inflammation, there are robust data suggesting that the neutrophil may also be important in the pathophysiology of asthma. Absolute neutrophil counts appear to be raised in a subset of patients with asthma, and indeed, in one study up to 60% of patients studied had non-eosinophilic airway inflammation present in induced sputum samples [229]. Measures of chronic asthma severity, such as $FEV_1$, correlate with the degree of airway neutrophilia in stable disease [230–233]. Furthermore, neutrophilic inflammation has been clearly documented in acute exacerbations of asthma, in status asthmaticus, and in nocturnal asthma [234–236] and has been reported as the predominant cell type in fatal asthma [237, 238]. These findings cannot be explained by patient's smoking status, co-morbidity, or the presence of acute infection alone, suggesting that neutrophils may well have an important role in this disease [239]. Finally, although eosinophilic inflammation is sensitive to corticosteroid treatment, neutrophils respond poorly to this treatment modality, and may be the underlying cause of steroid resistant cases of asthma [240, 241].

It has been proposed that neutrophils enter the airways in response to infection. In murine models, pulmonary infection with mycoplasma or Sendai virus is associated with a neutrophilic infiltrate. This leads to a chronic (and in most cases a permanent) airway hyperresponsiveness that persists long after the infection has resolved [242, 243]. *In vivo* there is serologic and polymerase chain reaction derived evidence associating chronic asthma with airway infection with both viruses and atypical bacteria (which have in turn been associated with increased neutrophil counts) [244, 245]. However, even if infection initiates neutrophil influx into the lungs, treatment of the infection has not been associated with a reduction of symptoms, suggesting that on-going infection may not be sustaining the neutrophilic features of the disease process.

Asthmatic epithelial cells constitutively hypersecrete both IL-8 and IL-17 (both of which are chemotactic for neutrophils), [246, 247] and it has been suggested that these cells are abnormal in asthma, both when quiescent and active, driving inflammation by the release of proinflammatory mediators [248]. This theory has yet to be fully explored.

Whatever the stimulus, once present, neutrophils have the potential to cause the pathological features seen by the release of proteinases and reactive oxygen species, as described previously. In particular there is destruction of the epithelial cell layer [194], which is often a feature of the airways in asthma [249]. Indeed recent studies have confirmed the importance of proteinase function in both the acute inflammatory response and the subsequent mucous cell metaplasia that accompanies postinfectious murine models of asthma, [24] although these findings have yet to be confirmed in humans. Further work is required, but current evidence seems to support the premise that while eosinophils may be dominant in the early stages of disease in atopic individuals, neutrophils form a key feature of more severe, nonatopic asthma [250].

## CONCLUSIONS

There is strong evidence supporting the belief that the neutrophil is central to the pathogenesis of COPD. The neutrophil is the only cell that has been shown to be able to cause all of the pathological changes of the disease including emphysema, mucus hypersecretion, epithelial destruction, and reduced ciliary beating. *In vitro* models, animal models, and human studies have led to conflicting results regarding the importance of various components of the inflammatory response. However, based upon current evidence it appears likely that the neutrophil and in particular, NE is associated with at least the initial lung damage seen in COPD although macrophages appear necessary either to initiate the acute neutrophilic response (via TNF-α) and/or sustain the subsequent inflammatory response causing initiation and progression of emphysema. Studies so far have not provided a means to study the effects of other complex processes, such as the recurrent exacerbations in COPD, or the effect of smoking cessation and to clarify our understanding of the overlapping actions of proteinases. Detailed studies of cells and chemoattractants in man will remain crucial in dissecting the mechanisms. Although studied in much less detail, it is likely that neutrophils also play a role in asthma, with the involvement of similar pathways.

## INTRODUCTION

Fibroblasts are typically spindle-shaped cells with an oval flat nucleus found in the interstitial spaces of organs. In the lung, they reside in highly complex multicellular environments, usually closely apposed to the epithelium or endothelium. They are the primary source of extracellular matrix (ECM) proteins, which, in addition to providing a scaffold for cells, play key roles in determining cell phenotype and function. In these contexts, fibroblasts contribute to injury responses in both the initiation and the resolution phases.

In chronic lung diseases including asthma, chronic obstructive pulmonary disease (COPD), and idiopathic pulmonary fibrosis (IPF), there are changes in the number and phenotype of fibroblasts. These changes play a critical role in the loss of normal tissue architecture and function associated with these diseases. Although considerable research effort has focused on modulating leukocyte function and inflammation, relatively few studies have investigated the effects of existing or novel therapies on fibroblast function. Moreover, there have not been sufficient efforts to develop new approaches to regulate fibroblast function in these diseases. This chapter explores the current knowledge about the role of fibroblasts in lung homeostasis and pathological disorders associated with chronic remodeling. A better understanding of the phenotypes of disease-associated fibroblasts may highlight pathways specific to disease pathologies, giving rise to targeted therapeutics. Finally, we review the potential of opportunities arising for better therapeutic intervention strategies targeting fibroblasts that will either halt or potentially reverse fibrosis.

## FIBROBLAST FUNCTION

Fibroblasts play a myriad of important roles in normal tissue function. In the lung, they coordinate organogenesis and budding of the lung from the foregut, through intimate bi-directional communication with adjacent epithelial cells. They are also key cells in the production and homeostasis of the ECM. In the lung, the greatest number of fibroblasts are found in the subepithelial layer of the conducting airways and the interstitium of the lung parenchyma. Here they are in a prime location to interact with the epithelial and endothelial cells. These interactions are likely important in disease settings and will be further discussed in this chapter. Fibroblasts are metabolically active cells – capable of synthesizing, secreting, and degrading ECM components – including collagens, proteoglycans, tenascin, laminin, and fibronectin. These cells continually synthesize ECM proteins although the amount they secrete is tightly regulated. For example, up to 90% of all procollagen molecules are degraded intracellularly prior to secretion, depending on tissue and age. Further, fibroblasts generate matrix metalloproteinases (MMPs) and their inhibitors, tissue inhibitor of metalloproteinases (TIMPs), thus controlling tissue architecture and matrix turnover rates.

MMPs exert proteolytic activities on various proteins including many ECM components and are thus central to ECM formation [1]. They have been shown to be elevated in asthma and COPD (reviewed in [1]); as well as in IPF where MMP1, 2, and 9 were colocalized to the epithelium surrounding fibrotic lesions, whereas increased TIMP2 was also observed suggesting that the MMP activity may be inhibited and that the fibrotic region not degraded [2].

Another function of MMPs is to activate growth factors and chemokines, thus potentially promoting the fibrotic and inflammatory milieu [3–5].

## MYOFIBROBLASTS

Myofibroblasts express α-smooth muscle actin (α-SMA) and have contractile and secretory properties that are central to controlling tissue architecture [6]. They express a panel of markers that have been correlated with the site of origin. For example, myofibroblasts found in the peripheral and subpleural regions of fibrosis express α-SMA, vimentin, and desmin, whereas cells found in other regions of the lung do not express desmin [7]. *In vitro*, fibroblast-to-myofibroblast *trans*-differentiation can be induced by transforming growth factor-β1 (TGF-β1), and it has been hypothesized that TGF-β1 found locally at sites of fibrosis *trans*-differentiate resident fibroblasts into myofibroblasts [8, 9].

It has been proposed that the contractile properties of myofibroblasts are central to wound healing by limiting the amount of exposed wound area [10]. However, the sustained presence of contractile myofibroblasts in the interstitium of the lung may cause a retraction of parenchymal tissue mediating alveolar collapse and resulting in the characteristic honeycombing seen in the lungs of IPF patients, or add to the increase in alveolar size, which is characteristic of COPD [11]. There is also a significant increase in myofibroblast numbers in the airways of asthmatic patients following allergen challenge [12], which correlate with subepithelial collagen deposition [13].

In normal wound healing, myofibroblasts sequentially perpetuate and then dampen inflammation via the secretion of chemokines, cytokines, arachidonic acid metabolites, and protease inhibitors [14]. When activated, they express cell surface adhesion molecules allowing specific interactions with immune and inflammatory cells, including lymphocytes, mast cells, and neutrophils. If these processes become dysregulated, fibrosis may ensue with catastrophic consequences for lung function.

Given the importance of myofibroblasts to wound healing and fibrosis, defining both the origin and the mechanisms leading to their clearance will greatly add to our understanding of the role of this cell in fibrotic diseases. At sites of normal wound healing, once sufficient ECM has been deposited and remodeled, fibroblasts and myofibroblasts undergo apoptosis [15, 16]. This serves to limit the excessive deposition of ECM and also dampen the pro-inflammatory and pro-fibrotic milieu. However, for reasons still unclear, myofibroblasts persist in fibrotic conditions.

## FIBROBLASTS AND FIBROSIS

Most insight into the potential role of fibroblasts at driving pulmonary remodeling, as well as phenotypic differences in fibroblasts found in fibrotic regions versus those located in normal tissue, has been garnered from *in vitro* studies by using fibroblasts isolated from IPF lungs. Fibroblasts isolated from fibrotic environments are phenotypically different from non-fibrotic fibroblasts [17–19]. Furthermore, fibroblasts from a pro-fibrotic environment exhibit both altered responsiveness to growth factors and enhanced chemokine receptor expression, which has also been observed in murine models of pulmonary remodeling [20]. Taken together, these studies suggest a distinct heterogeneity in fibroblast function and phenotype in the fibrotic lung.

The progression and the severity of many lung diseases, notably IPF, are tightly associated with regions of fibroblast accumulation and proliferation; the extent of these regions, termed fibroblastic foci, has become a reliable indicator of survival. The increased number of (myo)fibroblasts seen in these diseases implies that they are hyperproliferative and/or resistant to apoptosis. However, whether they proliferate faster than normal fibroblasts is still controversial [17, 21, 22]. We and other investigators have reported that fibroblasts derived from IPF lungs proliferate faster than the cells derived from normal lung tissue [17]. In contrast, few others have also shown that the growth rate of IPF fibroblasts was significantly slower than that of normal fibroblasts. However, the specific techniques used to isolate primary fibroblasts differ between laboratories; therefore direct comparisons may not be suitable.

Moreover, discrepancies may be due to the site in the lung from which fibroblasts are harvested, since the magnitude of inflammation and fibrosis are heterogeneous in distribution. Thus, areas of active fibrosis may yield hyperproliferative fibroblasts, compared to the areas of established fibrosis where cells may be hypoproliferative.

To begin to address this diversity, recent studies have used microarray technologies to profile global gene expression in pulmonary fibrosis in man and mouse models. These studies have showed that the expression of almost 500 genes are increased more than twofold in fibrotic lungs, including many genes related to cytoskeletal reorganization, ECM, cellular metabolism and protein biosynthesis, signaling, proliferation, and survival [8]. Studies examining human lung fibroblast global gene expression in response to TGF-β1 have shown almost 150 genes upregulated, representing several functional categories described earlier. These included 80 genes that were not previously known to be TGF-β1-responsive [8]. There was excellent concordance between gene expression in human and experimental models, giving us some confidence in the value of our efforts to model human disease.

## ORIGIN OF FIBROBLASTS AND MYOFIBROBLASTS: PLASTICITY OF RESIDENT FIBROBLASTS

As remodeling of the lung is associated with the accumulation of fibroblasts and myofibroblasts, understanding the derivation of these cells is critical to our understanding of disease processes. Current thinking suggests that there may be multiple pathways through which fibroblasts and myofibroblasts are derived [14]. These include proliferation and plasticity of

resident cells, such as fibroblasts and epithelial cells. Further, emerging data highlight a significant role of circulating, bone marrow-derived cells at remodeling lung architecture [23].

## FACTORS INVOLVED IN FIBROBLAST–MYOFIBROBLAST DIFFERENTIATION

As has been described, fibroblasts can be induced to differentiate into myofibroblasts. It is becoming increasingly accepted that the fibroblast–myofibroblast transition begins with the appearance of the protomyofibroblasts that are hyperproliferative and migratory but do not synthesize significant amounts of ECM proteins [24]. Under specific conditions, the protomyofibroblast evolves and may result in a transition into a differentiated myofibroblast, characterized by the presence of organized stress fibers containing α-SMA. Myofibroblasts can, according to the experimental or clinical situation, express other smooth muscle cell contractile proteins, such as myosin heavy chains or desmin. Generally, these cells are thought to be hypoproliferative but responsible for secretion of the bulk of collagens I and III.

Although the processes involved in the appearance of protomyofibroblasts are at present not well explored, the transition from the protomyofibroblast to a differentiated myofibroblast has been related to the production of TGF-β1 by inflammatory cells, and possibly by fibroblasts themselves. The action of TGF-β1 also depends on the local presence of the cellular fibronectin ED-A splice variant. Thus, myofibroblast differentiation is regulated by both a cell product and the ECM. Moreover, it is becoming more accepted that mechanical factors play an important role in both transitions through either TGF-β generation [25] or TGF-β activation [26].

## EPITHELIAL CELLS: EPITHELIAL–MESENCHYMAL TRANSITION

Another potential pool of fibroblasts may arise by a process called epithelial–mesenchymal transition (EMT). EMT is a dynamic process by which epithelial cells undergo phenotypic transition to fully differentiated and motile mesenchymal cells, such as fibroblasts and myofibroblasts [27, 28]. This process occurs normally during early fetal development where there is seamless plasticity between epithelial and mesenchymal cells. The differentiation between airway epithelial cells of one type and another, for example type I pneumocytes transitioning into goblet cells, has been previously described [29–32]. However, the switching of an epithelial cell into a phenotype that moves beyond the original cell's embryonic lineage has recently been hypothesized as a driving factor in fibrosis [33–35].

Epithelial cells exposed to TGF-β1, alone or in combination with other growth factors such as epidermal growth factor (EGF), begin the process of EMT by the increased expression of MMPs that enable basement membrane degradation and cell detachment. The cells also undergo cytoskeletal changes as well as altered expression of surface molecules. For example, a downregulation of E-cadherin and zona occludens 1 (ZO-1) with a concomitant upregulation of vimentin as well as the ED-A fibronectin is needed for migration and transition to a mesenchymal phenotype [36, 37]. The majority of the work evaluating EMT has been performed *in vitro*; however, the full extent of this pathogenic pathway *in vivo* is currently being evaluated. In animal models of kidney fibrosis, it has been estimated that up to 20% of the fibroblasts found in the fibrotic lesions were derived from the epithelium through EMT [33]. The idea of EMT promoting the fibrosis observed in asthma and IPF is rapidly beginning to evolve [32]. It is still not known whether EMT contributes to the excess ECM deposition. Future work correlating the timecourse of EMT induction with disease staging will also be very insightful. This pathogenic process may provide novel therapeutic targets such that inhibiting or reversing EMT may provide clinical benefit to patients with fibrosis-associated diseases.

## CIRCULATING PROGENITOR MESENCHYMAL CELLS

Along with the epithelium, recent studies have also highlighted a role for bone marrow-derived circulating cells, or fibrocytes, in promoting lung fibrosis by differentiating into fibroblasts or myofibroblasts [23, 38].

Fibrocytes appear to be pleiotropic in function and a variety of extracellular and intracellular markers have been used to characterize them, including CD45, indicating haematopoietic origin; CD34 or CD13; and various chemokine receptors which have been demonstrated to modulate migration *in vitro* and *in vivo* [39–43]. However, the underlying features of fibrocytes are that they are derived from the bone marrow and are positive for type I collagen. Moreover, it has recently been postulated that an overexuberant recruitment of these cells to sites of pulmonary injury contributes to the aberrant deposition of collagen, which ultimately induces pathologic fibrosis [44–48].

Fibrocytes are pleuripotent in their ability to differentiate into other cell lineages, as has been demonstrated with fibrocyte-derived adipocytes [49]. Furthermore, these cells are extremely plastic *in vitro*, making both the derivation and the characterization of these cells unclear. Exposure of fibrocytes to TGF-β1 *in vitro* results in the cells transitioning into a myofibroblast phenotype and producing fibronectin and type III collagen [48]. Using an adoptive transfer model of bone marrow cells from green fluorescent protein (GFP) transgenic mice into recipient mice challenged with intratracheal bleomycin (to initiate lung injury), recruited GFP+ fibrocytes were shown to differentiate into fibroblasts while resident lung fibroblasts differentiated into myofibroblasts [39]. These data would indicate that the fibrocytes may serve to replenish the pool of fibroblasts from which myofibroblasts are derived.

There is increasing evidence that fibrocytes may also have a pathogenic role in asthma [41, 48]. A correlation in the number of fibrocytes in the basement membrane of

asthmatics and the extent of subepithelial fibrosis has been recently described [50]. Increased numbers of these cells have been reported in the airways of asthmatics and allergen challenge further increased cell recruitment to the subepithelial region [48]. Interestingly, CD34 colocalized with α-SMA, suggesting that CD34+ fibrocytes traffic to sites of active remodeling and differentiate into myofibroblast-like cells [48]. Further studies are necessary to delineate the fate of fibrocytes and the total impact of this pathway to other diseases such as COPD.

## FIBROBLAST ACTIVATION

Fibroblasts are activated by numerous signals such as mechanical forces imposed during bronchoconstriction, ECM interactions, and hypoxia. Furthermore, a large number of mediators, produced by various cell types, and proteases of the coagulation cascade are known to promote fibroblast proliferation, collagen synthesis, migration, and differentiation.

### Transforming growth factor β

TGF-β is one of the most potent pro-fibrotic mediators *in vitro* and a strong candidate as a central player in remodeling diseases including asthma and IPF. The emergence of therapeutics directed against the TGF-β pathway will shed light on the role of this growth factor in diseases. Although antagonism of TGF-β by a number of strategies ameliorates experimental fibrosis, inhibition of this growth factor family as a valid therapeutic target requires rigorous interpretation, since it plays an important role as an inhibitor of immune responses and normal cell differentiation.

TGF-β1 is upregulated in the lungs of IPF patients and asthmatics [51–56] (reviewed in [57]). Interestingly, expression of TGF-β1 is nearly absent in the bronchial epithelial cells but is highly expressed in inflammatory cells beneath the basement membrane where subepithelial fibrosis predominates [58]. Transient over-expression of TGF-β1 or pulmonary delivery of this cytokine to mouse lungs induces a pronounced interstitial fibrosis mediated by aberrant ECM generation and deposition, as well as the presence of myofibroblasts [59]. Further, over-expression of TGF-β1 in the lungs of mice also induces a fibrotic response through modulation of apoptotic and inflammatory pathways, as well as aberrant expression of MMP12 [60, 61]. Epithelial cells and eosinophils also produce large amounts of TGF-β2, especially following allergen challenge [62–65]. However, the role in remodeling and fibrosis is not as well studied as that of TGF-β1, although it has been shown to induce epithelial cell mucus production [63] and exert pro-fibrogenic effects [66].

TGF-β1 regulates numerous biological activities, such as proliferation, apoptosis, and differentiation via Smad-dependant and Smad-independent mechanisms [67, 68] (Fig. 15.1). TGF-β is produced in an inactive form tethered to a latency-associated peptide (LAP) by covalent bonding. Activation of, and signaling through, its receptors requires exposure of the active site of the ligand either through conformational change (as induced by integrin-mediated activation) or through cleavage of the LAP.

Using a transgenic mouse model of Smad-3 deficiency, TGF-β/Smad-3 signaling was shown to be required for alveolar integrity and ECM homeostasis, and this pathway is involved in pathogenic mechanisms mediating tissue destruction and fibrogenesis [69]. TGF-β signaling pathway involves the phosphorylation of downstream Smad proteins, comprising the receptor-regulated (R)-Smad (Smad 2, 3), the

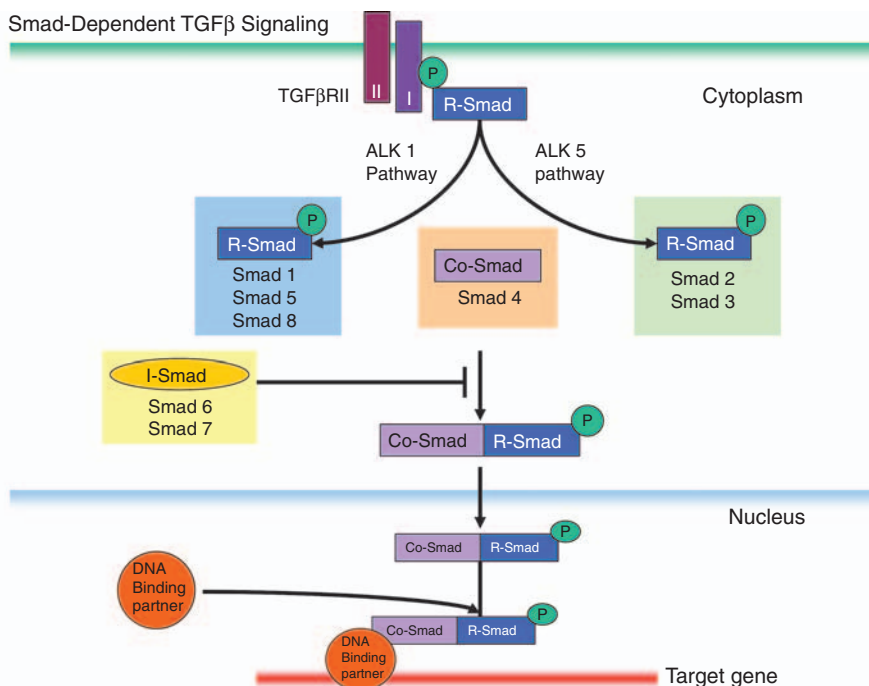

**FIG. 15.1** TGF-β signaling pathways. TGF-β is believed to be a major signaling pathway regulating fibroblast functions. All three TGF-β isoforms bind to the TGF-βRII which then phosphorylates the TGFRI chain. This activates the kinase activity of TGF-RI, which then activates Smad proteins. These, in turn, bind Smad 4, translocate to the nucleus, and modulate gene expression. Inhibitory Smads, including Smad 6 and 7, can inhibit Smad signaling. TGF-β can also signal through a variety of Smad independent pathways. Activation of these pathways may occur through the kinase activity of either TGF-βRI or TGF-βRII.

co-Smad, Smad 4). These activated Smad complexes translocate to the nucleus, bind to specific consensus sequences on target DNA to upregulate the transcription of many genes. Regulation of this pathway occurs through the synthesis of the inhibitory Smad-7. Although Smad signaling is generally considered the predominant pathway, Smad-independent signaling through P38, Akt/PI-3 K, and extracellular signal-regulated kinase (ERK) pathways is also observed. These pathways generally lead to different cellular responses [70, 71]. In this regard, while Smad signaling generally arises through activation of the type I TGF-β receptor, P38 signaling occurs through activation of the type II receptor, implying different mechanisms of activation and regulation [70].

### IL-13 and IL-4

Interleukin (IL)-13 and IL-4 are pleiotropic, Th2-associated cytokines, with numerous distinct and overlapping functions. They share overlapping but not redundant roles due to the shared IL13Rα1 receptor subunit. IL-13 is elevated in the lungs of IPF patients and is associated with fibrotic pathologies and aberrant remodeling at various tissue sites [72, 73]. The pro-fibrotic role for IL-13 in asthma and pulmonary fibrosis has been recently reviewed [74, 75]. There are differences in the downstream events following IL-4 or IL-13 signaling. IL-13 activates epithelial cells and goblet cells causing mucous production, goblet cell hyperplasia and EMT [76, 77]. Various animal models of pulmonary fibrosis have indicated a more pro-fibrotic role for IL-13 than IL-4. Indeed it has been hypothesized that IL-4 is involved in the initiation of fibrosis whereas IL-13 is central to the maintenance of the fibrotic response, reviewed in Chapter 8 [78].

Both IL-13 and IL-4 induce pro-fibrotic responses in fibroblasts, responses that are comparable to those induced by TGF-β1 [79, 80]. Both IL-4 and IL-13 induce fibroblast proliferation [81]. Interestingly, IL-4 and IL-13 induced greater fibroblast proliferation from patients with mild asthma compared to responses elicited on fibroblasts derived from severe asthma patients [82]. This suggests an altered fibroblast phenotype which is dependent on disease staging. IL-13 and IL-4 have also been demonstrated to play pro-fibrotic roles on airway epithelial cells by promoting epithelial cell proliferation and also by inducing mitogenic TGF-β2 production from these cells [83]. Interestingly, IL-13 and not IL-4 promotes the differentiation of fibroblasts to myofibroblasts [81, 82]. The other mechanism by which IL-13 can mediate fibrosis is via the second IL-13 receptor, IL-13Rα2 [84]. This receptor was, until very recently, thought to be a decoy receptor as it has a very short cytoplasmic tail and is frequently shed from the surface of cells [85, 86]. However IL-13 binds to IL-13Rα2 with a much higher affinity than IL-13Rα1 [87, 88]. Recent data suggests that IL-13Rα2 has signaling capabilities resulting in TGF-β1 secretion from macrophages [84].

### Thrombin and coagulation pathway-associated proteases

Thrombin and several other proteases of the coagulation pathway have been implicated in a number of pulmonary diseases where fibrosis is often a feature. These include acute respiratory distress syndrome (ARDS), and the interstitial lung diseases including IPF [89–93]. In one of these studies, thrombin was shown to represent a large proportion of the fibroblast proliferation capacity of bronchoalveolar lavage (BAL) fluid in patients with lung fibrosis, suggesting that it might be a major player [91]. Animal models have strengthened the connection between these proteases and the occurrence of fibrosis. For example, increased thrombin is found in the lungs of mice challenged with bleomycin and pharmacological inhibition of thrombin significantly reduced the collagen deposition [90, 94].

It is now clear that proteases of the coagulation cascade, including factor VIIa, factor Xa, and thrombin, exert pro-inflammatory and pro-fibrotic effects via the protease-activated receptors (PAR). The PAR comprise four members, PAR1 to PAR4 and between them the coagulation proteases of the extrinsic pathway can target all four receptors. In terms of influencing fibroblast function, PAR1, the high affinity thrombin receptor, is the major receptor by which thrombin and factor Xa exert their potent pro-fibrotic effects. This receptor has emerged as a promising new target to prevent fibrosis in the setting of both IPF and ARDS, based on studies demonstrating that thrombin inhibition partially blocks experimental fibrosis [95] and that mice deficient for PAR1 are protected from lung inflammation, pulmonary edema, and lung collagen accumulation following bleomycin injury [96]. Recently, the role of PAR has been linked to epithelial cell activation of TGF-β. It has been known for some time that mice deficient for the $\beta_6$ subunit are protected from pulmonary fibrosis due to a defective ability to activate TGF-β [97] but recent studies suggest that activation of PAR1 leads to the activation of latent TGF-β via this $\alpha_v\beta_6$-dependent mechanism [94]. Together these data suggest thrombin may be upstream to the activation of TGF-β.

The PAR have also been implicated in airways diseases (reviewed in [98–100]). The mechanism for this effect is still being explored but it may be due to pro-inflammatory effects of PAR activation. For example, PAR-2-deficient mice had decreased eotaxin/CCL11 influx along with reduced eosinophilia following antigen challenge in an allergen sensitization and challenge model of asthma [101, 102]. In relation to COPD, Churg and coworkers recently suggested that $\alpha_1$-antitrypsin inhibition of TNF-α and MMP12 production in animals exposed to cigarette smoke may in part be due to inhibition of serine proteases activating PAR1 on macrophages [103].

## CLINICAL TARGETING OF FIBROSIS IN LUNG PATHOLOGIES

Currently there are no therapeutic molecules in use in clinical respiratory medicine that specifically target fibroblasts or fibroblast function. Further, myofibroblasts are likely to be a key to the chronicity of IPF and other related diseases and therefore strategies that modulate the functions of

these cells may have a significant impact on the treatment of fibrotic remodeling.

Data emerging suggests that targeting-specific mediators during asthma, such as IL-13, may impact disease through modulating fibroblast function. Moreover, increased pathogenic functions ascribed to fibroblasts indicate that this cell type may be attractive to target therapeutically. Aberrant activation of fibroblasts during fibrosis results in excessive collagen deposition, which ultimately results in a loss of tissue function. As more is learnt about fibroblasts and cells capable of generating excess ECM, specific cell markers may be identified that could allow for a selective targeting with minimal detriment to normal tissue. Therefore, targeting fibroblasts directly may result in a decrease in ECM synthesis and a potential beneficial clinical outcome, but unlike immunosuppressants and non-specific anti-inflammatory agents, novel therapeutics would leave cellular defense mechanisms necessary for host defense in the lung intact.

# Epithelial Cells

## INTRODUCTION

Respiratory tract epithelial cells constitute a front-line physical barrier between the organism and the environment. They serve vital functions in host physiology and mucosal defense and are central to the pathogenesis of asthma and chronic obstructive pulmonary disease (COPD). This chapter concisely addresses epithelial cell development, structure, cell lineages, integrated function in mucus clearance, and presents an overview of their role in immune responses relevant to asthma and COPD.

## LUNG DEVELOPMENT AND EPITHELIAL CELL DIFFERENTIATION

The tracheo-bronchial and lung epithelium are endoderm-derived, originating as a foregut evagination at 3.5 to 7 weeks of gestation in humans [1]. Complex, reciprocal molecular interactions between epithelium and the underlying mesenchyme govern development, resulting in elaborate branching morphogenesis that forms the airways and lungs [2]. There is a centrifugal pattern of cyto-differentiation and structural development that culminates in the normally formed bronchial tree and lungs at end gestation, including maturation of the pulmonary surfactant system. Detailed discussion of molecular regulation of lung epithelial development and abnormalities surrounding premature birth is beyond the scope of this chapter.

Survival of premature birth and its complications has increased dramatically in recent years, creating a growing population of individuals born at early gestational age that are exposed to variable treatment regimes, including differing preparations of exogenous surfactant [3], conventional versus high-frequency oscillatory ventilation [4], nitric oxide [5], and inhaled versus systemic glucocorticoids [6]. The spectrum of lung disease resulting from premature birth has also evolved and now presents a histopathologic picture characterized by diffuse developmental abnormalities in lung structure [7]. Wheezing is more common after premature birth, especially in susceptible populations and in the presence of chorioamnionitis [8]. Lung function may normalize somewhat during later childhood and despite a higher prevalence of respiratory symptoms, airway hyperactivity was not present in one cohort of adults born prematurely [9, 10]. Time will tell if those born prematurely are predisposed to COPD, especially if they smoke.

Prenatal airway and lung development sets the stage for the transition to air breathing at birth, including the essential function of lung liquid absorption, which depends on presence of epithelial ion channels [11]. Available evidence also indicates a period of dynamic postnatal adaptation and maturation of the epithelium. For example, in both animals and humans, mucous secretory cells are induced in late gestation and are highly abundant in the neonatal period but normally regress by adulthood [12–17]. Although a few studies exist [16, 17], there is a relative paucity of quantitative data on airway epithelial cell kinetics and differentiation during the late prenatal and early postnatal stages of normal human airway development. Environmental exposures and infections during infancy and early childhood mold airway and lung structure and function and likely have a lasting influence on the ultimate development of disease. There is intense interest and controversy regarding the hygiene

hypothesis, which proposes that inadequate or inappropriate early postnatal stimulation skews the immune system, promoting the development of allergy, asthma, and autoimmunity [18, 19]. Environmental exposures and infections occur in the context of a dynamic airway epithelial proliferation and cyto-differentiation program during which responsiveness to various stimuli (pollution, second-hand tobacco smoke, infection) is likely altered. However, the basic cellular composition of the developing and maturing postnatal human airway epithelium is still inadequately described. Mechanisms regulating changes in epithelial proliferation and maturation, differential sensitivity to relevant stimuli and the impact of any differences on interactions with the developing immune system during this potentially critical period are still not well understood.

## STRUCTURE OF THE EPITHELIUM AND "TROPHIC UNITS"

In the normal adult human, epithelial cell populations vary systematically as a function of airway level. Portions of the nasal passages and the trachea to approximately the 6–10th generation bronchi are lined by a tall columnar pseudostratified mucociliary epithelium consisting principally of basal, intermediate, ciliated, and mucous secretory (goblet) cells (Fig. 16.1). In this region, submucosal glands are abundant. Proceeding distally, cartilage support and glands diminish and become absent in the bronchioles, which are initially also lined by a columnar pseudostratified epithelium. In terminal and respiratory bronchioles, the epithelium transitions to a simple columnar and eventually cuboidal epithelium, where Clara cells replace mucous secretory cells [20]. Individual pulmonary neuroendocrine cells (PNECs) and highly innervated collections of PNECs (neuroendocrine bodies) are distributed within the pseudostratified, columnar, and cuboidal epithelial zones and extend into the proximal alveolar region [21]. PNECs have been implicated in lung development, in supporting epithelial stem cell niches, and possibly as peripheral chemosensors that alter postnatal growth and adaptation [22]. Finally, the alveolar region epithelium is composed mainly of thin type I and cuboidal type II alveolar epithelial cells with critical roles to create the thin diffusion barrier and produce surfactant, respectively. Just as the relative abundance of surface cell types changes along the respiratory tract axis, each segment is characteristically vascularized, innervated, and variably populated by mesenchymal and bone marrow-derived cells.

The epithelium, its underlying matrix, submucosal cells, and tissue structures constitute the "epithelial-mesenchymal trophic unit" [23]. Reciprocal cellular communication within the trophic unit underlies lung development and likely regulates steady-state cell behavior and repair after injury, for example by the activation of TGF-β [24]. Studies in a primate model suggest that neonatal environmental pollutant and allergen exposure alter the epithelial-mesenchymal trophic unit, resulting in a permanent compromise of airway growth and development [25]. Pathologic epithelial-mesenchymal interactions occurring via IL-1β and TGF-β have been recently implicated in the development of airway

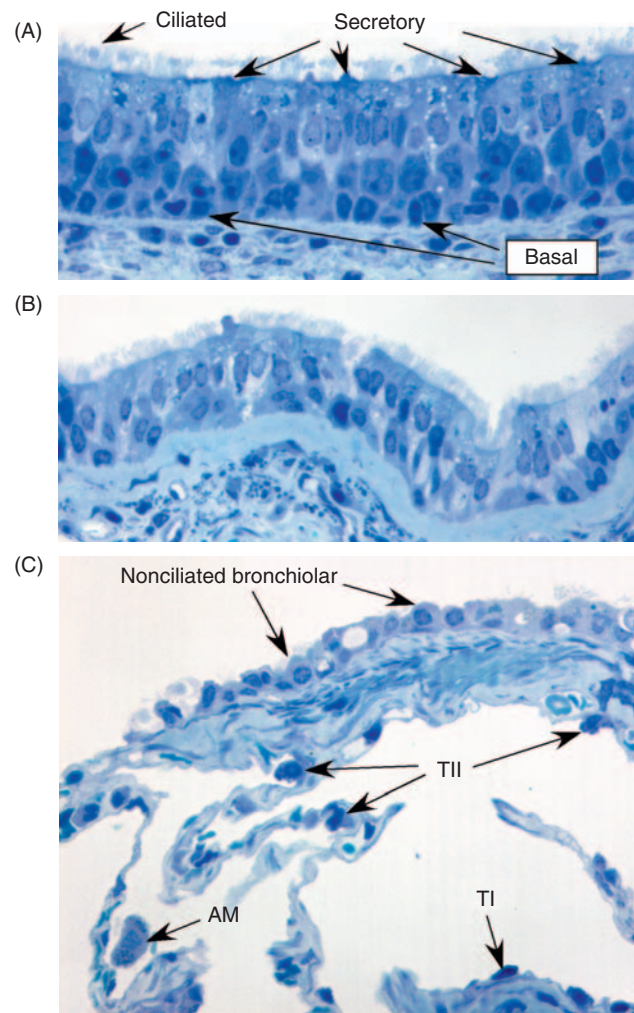

**FIG. 16.1** Lung epithelial cell morphology. (A) Normal human bronchus, (B) bronchiole, and (C) terminal bronchiole and alveoli. epithelilal squamous metaplasia and sub-epithelial fibrosis that is characteristic of COPD [26]. Sub-epithelial remodeling, including basal lamina thickening, airway wall fibrosis, increased vascularity, and smooth muscle hypertrophy/hyperplasia, similarly contribute to the pathophysiology of asthma [27, 28]. However, the detailed cellular composition and molecular mechanisms of communication within epithelial-mesenchymal trophic units at each level in the human airway in health and disease are not well understood. Airway epithelial cell renewal during the steady state and after injury occurs within the context of the trophic unit.

## LUNG EPITHELIAL STEM AND PROGENITOR CELLS

In thoroughly studied epithelia such as the epidermis and intestine, temporal and spatial patterns of cell renewal,

and the regulation of progenitor–progeny relationships are becoming well understood [29, 30]. Stem cells reside in specific niches and proliferation, migration, and cell differentiation are highly orchestrated within and between the epithelium and mesenchyme. Stem cell niches in the airway and lung epithelium are less understood than in many other organs, but there has been recent progress. The subject of lung epithelial stem cells has been recently reviewed [31]. It is important to note that most studies of cell lineages have been performed in rodent models and strict translation to humans remains unknown. Briefly, metabolic pulse labeling with DNA precursors has long shown that both basal and columnar secretory cell types of the normal adult pseudostratified airway epithelium divide, albeit relatively infrequently [32, 33]. However, repair of epithelial damage is brisk. Many cell types rearrange their cytoskeleton and migrate to cover denuded basal lamina. Subpopulations of cells proliferate and ultimately re-differentiate [34–36]. There has been controversy, but it appears that while ciliated cells actively participate in repair by migration and "dedifferentiation" [37], they do not enter the pool of dividing cells [38]. Subsets of cells within both the basal and columnar cell populations can reconstitute a full mucociliary epithelium in an *in vivo* transplantation model [39, 40]. Thus, many cell types can serve as progenitors during repair of injury. This high degree of "plasticity" in the airway epithelium is likely driven by the necessity for rapid epithelial repair to prevent fibrotic ingrowth and airway obliteration.

Classically, stem cells are defined by their capacity to both self-renew and differentiate, whereas progenitor cells have limited self-renewal capacity. The applicability of classical definitions from well-known model systems to the highly "plastic" airway epithelium is questionable, but there does appear to be a hierarchy of "stemness" within the pool of identified progenitor cells. Colony formation on plastic dishes *in vitro* [41], clonal growth [42], lineage tracing [43], and DNA label retention [44] suggest that although many cells can contribute to repair of injury, basal cells likely represent a stem cell compartment in the adult pseudostratified epithelium (Fig. 16.2).

The simple columnar to cuboidal bronchiolar epithelium of rodents is composed of Clara, ciliated, PNEC, and brush cells. Secretoglobin (SCGB) 1a1, also known as CC10 or CCSP, commonly serves as a marker for Clara cells. However, SCGB1a1 is expressed in a spectrum of cells, present in multiple airway levels, with varying differentiation potentials and behaviors. Following oxidant gas exposure of rodents which damages ciliated cells, surviving bronchiolar Clara cells proliferate to restore the epithelium [45, 46]. When the toxin naphthalene is administered to mice, almost all Clara cells are killed due to selective metabolic activation in this cell type. Ciliated cells shed their cilia and migrate to cover the denuded bronchiolar basal lamina, but do not re-enter the cell cycle [38], whereas surviving Clara cells proliferate [47]. A population of naphthalene-resistant Clara cells resides within, or close to, PNEC clusters and DNA label retention studies suggest that this unit constitutes a stem cell niche [48]. Following naphthalene injury, PNECs also proliferate, but they are apparently a distinct lineage system not requiring, nor generating, Clara cells [49]. A second stem cell niche has been proposed in

**FIG. 16.2** Cell hierarchy in the pseudostratified airway epithelium. In this model, a subset of basal cells gives rise to transiently amplifying cells with basal and intermediate cell morphologies that generate differentiated cells (straight black arrows). The circular arrows represent growth capacity. The red arrows indicate plasticity-differentiated cells are capable of "dedifferentiation" (backwards arrows), "redifferentiaton," and phenotypic conversion during repair of injury. Reproduced, with permission, from Randell SH. Airway epithelial stem cells and the pathophysiology of chronic obstructive pulmonary disease. *Proc Am Thorac Soc* 8: 718–25, 2006.

the broncho-alveolar junction zone [50, 51]. Here, specific Clara-like cells co-express SCGB1a1, SP-C, SP-A, CD-34 and Sca-1, and proliferate in response to naphthalene or bleomycin injury [51]. The cells reportedly grow clonally *in vitro*, differentiate into both Clara and distal lung type I and type II epithelial cells, and generate adenocarcinomas when expressing an active K-ras oncogene *in vivo* [51]. Epithelial cell lineages in the bronchioles and proximal alveolar region are illustrated in Fig. 16.3. It is important to confirm, in humans, the dual airway and alveolar potential of the putative broncho-alveolar stem cells found in mice.

It has been known for many years that alveolar type II cells proliferate to repair injuries that damage the large, thin, and putatively fragile type I alveolar epithelial cells [52]. Palisades of reactive, cuboidal type II cells are frequently present when there is chronic distal lung injury. Although there is evidence for a spectrum of proliferative potential amongst the type II cell population in the distal alveolar epithelium [53], epithelial stem cell hierarchies in the distal alveoli are still poorly understood. The importance of effective epithelial repair in the alveolus is underscored by the
**FIG. 16.3** Cell hierarchy in the bronchiolar epithelium. The circular arrows represent growth capacity and differentiation potential. The pulmonary neuroendocrine cell (PNEC) lineage is apparently separate from other epithelial cell types in the adult. Variant Clara cells present in association with PNEC bodies serve as progenitor cells of the bronchiolar epithelium. Variant Clara cells found near the bronchiole-alveolar junction may generate both bronchiolar and alveolar epithelium. Reproduced, with permission, from Randell SH. Airway epithelial stem cells and the pathophysiology of chronic obstructive pulmonary disease. *Proc Am Thorac Soc* 8: 718–25, 2006.

recent discovery that mutations in telomerase reverse transcriptase or the RNA component of the telomerase complex are a cause of idiopathic pulmonary fibrosis [54, 55]. In these cases, deficient chromosome maintenance due to telomerase deficiency likely impairs epithelial regeneration, resulting in aberrant epithelial–mesenchymal interactions that ultimately cause progressive fibrosis. Altered airway epithelial–mesenchymal interactions, whether due to deficient epithelial repair or not, may similarly result in airway sub-epithelial fibrosis and remodeling in asthma and COPD. The relationship between epithelial repair capacity and the development of pulmonary emphysema has not yet been defined.

Two somewhat controversial topics have entered the lung epithelial stem cell dialogue. The first is whether circulating cells become epithelial cells by undergoing a process called "trans-differentiation." In the original report it was claimed that, following lethal doses of ionizing radiation and bone marrow transplantation, circulating cells of bone marrow origin reconstituted a substantial percentage of airway and alveolar epithelial cells [56]. Subsequent studies suggest that apparent replacement of the epithelium from circulating cells may be due to fusion events between myeloid cells and epithelial cells and that transdifferentiation is unlikely [57]. A recent analysis of cord blood stem cell conversion to epithelium is illustrative, and suggests that if transdifferentiation occurs, circulating cells may generate only a very small percentage of the epithelium [58]. The growing consensus is that most epithelial replacement occurs via lung tissue-specific resident or so-called somatic, stem cells. The presence of regional-specific stem cells as the target cells for transformation and cancer initiation may underlie the heterogeneity of lung cancer types [59]. A second area of recent interest is epithelial to mesenchymal transition (EMT), which is a normal developmental process, for example in kidney development, where epithelial cells loose polarity and gain features of mesenchymal cell types. Recent studies suggest that lung epithelial cells exposed to TGF-β *in vitro* may convert into myofibroblast-like cells and that EMT occurs in lung fibrosis models in animals and in human idiopathic pulmonary fibrosis [60, 61] (reviewed in Ref. [62]). The significance of EMT for airway remodeling in asthma

and COPD remains unknown. The metastasis of lung cancer cells is thought to involve a process similar to EMT that is regulated by TGF-β and the extracellular matrix [63].

Due to the promise of regenerative medicine for chronic lung disease after neonatal respiratory disorders or for more typical adult forms of pulmonary emphysema, there is intense interest in lung stem cells. Furthermore, the important issue of lung cancer initiating cells and stem cells within lung cancers is highly related to stem cell biology in the normal lung. Recent advances point towards additional studies needed to characterize lung stem cells and their niches, and to elucidate steady state and repairing cell lineages. The identification of unique gene and protein markers indicative of cell position in the lung epithelial stem cell hierarchy will enable generation of novel transgenic animals that will foster more extensive and precise lineage mapping, which is claimed to be the gold standard by some stem cell authorities [64]. Furthermore, such markers may enable purification and functional testing of candidate stem and progenitor cell populations from both animals and humans. A greater understanding of the molecular pathways regulating normal cell behavior and disease phenotypes underlies rational approaches to cellular therapy for lung diseases, whether it involves augmenting epithelial repair by stimulating growth or by inhibiting growth as in the case of epithelial hyperplasia/metaplasia and lung cancer.

## INTEGRATED EPITHELIAL FUNCTION

A continuous epithelial layer, composed of characteristic cell types along the respiratory tract axis, forms a physical barrier between the outside environment and the underlying matrix and circulatory system. The airways deliver warmed and humidified inhaled air to the alveoli while protecting gas exchange structures from potentially harmful airborne chemicals, particles, and pathogens. The epithelium provides both general and regionally specialized functions that are key to normal physiology and host defense. The airway

epithelium is a principal generator of nitric oxide [65] and coordinates fluid and mucous secretion to foster effective mucociliary transport and productive cough [66]. The distal lung alveolar epithelium plays a key role in lung fluid balance, the prevention and resolution of alveolar edema after injury [67] and is the source of pulmonary surfactant. Furthermore, the epithelium in both the conducting and respiratory zones plays a key role during "innate" and "adaptive" immune responses.

## MUCOCILIARY AND MUCUS CLEARANCE

A layer of fluid and mucus normally flows over conducting airway surfaces toward the pharynx. This cleansing action is a critical, physiologically regulated, protective mechanism of the airways and lungs, whose failure causes recurrent infections characteristic of the genetic diseases cystic fibrosis and primary ciliary dyskinesia [68]. Effective mucus clearance results from coordinated secretion of mucins and other proteins along with sufficient water for hydration, which is locally regulated by airway epithelial ion transport. Adequately hydrated mucus is propelled by beating cilia and, when necessary, by cough. The combination of mucociliary and cough clearance equals mucus clearance. As measured by movement of inhaled and deposited radioactive tracer particles, mucus clearance declines in proportion to airflow obstruction in acute exacerbations of asthma, and returns toward normal after effective therapy [69–71]. Several studies indicate that mucus clearance is decreased by tobacco smoking and in COPD [72–75]. The accumulation of inflammatory mucoid secretions in the small airways in COPD, which likely reflects both increased local mucin production and decreased clearance [76], is correlated with the degree of physiologic impairment [77]. Drug therapies such as β-adrenergic agonists, cholinergic antagonists and corticosteroids used to treat asthma and COPD may have beneficial effects on mucus transport, but consistent positive effects on mucus clearance have been difficult to substantiate [78, 79]. Additional specific therapies directed toward balancing mucin production and ion and water transport to improve mucus clearance will likely be useful.

## MUCINS AND MUCUS

Mucus is composed of mucins, proteins, lipids, ions and water present on mucosal surfaces. Mucins are highly glycosylated proteins that can be released from mucous secretory cell granules and/or by shedding from the surface of many cell types. Intermolecular disulfide bonds within the principal gel-forming lung mucins, MUC5AC and MUC5B, enable multimerization and extensive interdigitation creating a visco-elastic network capable of trapping a wide variety of inhaled particles [80]. Increased mucous secretory cell number and increased mucin gene expression and glycoprotein production characterize both asthma and COPD. Regulations of airway epithelial secretory cell differentiation, mucin gene and glycoprotein expression and the secretory pathways that mediate mucin release have been reviewed [81–83]. In addition to the surface epithelium, submucosal glands in the cartilaginous airways are a significant source of fluid, mucins, and other proteins such as anti-microbial factors [84–86]. Gland hypertrophy is a pathologic hallmark of both asthma and COPD and likely contributes to mucin hypersecretion [27, 28].

## CILIATED CELLS

Ciliated cells have long and branched microvilli plus approximately 200 cilia per cell that occupy a large percentage of the normal airway epithelial luminal surface (Fig. 16.4). Cilia in the trachea and bronchi are denser and longer than in the bronchioles, but cilia average approximately 250 nm in diameter and 6 μm in length. The shaft, or axoneme, of motile cilia consists of nine outer microtubule doublets, a central microtubule pair, inner and outer dynein arms, nexin links, and radial spokes. The axoneme enters the ciliated cell and is anchored by a cytoplasmic basal body similar to the centriole of mitotic cells. Greater than 200 unique proteins constitute the cilia and basal body [87]. In normal airways, cilia beat at 10–20 Hz in a coordinated manner that generates directional, metachronal waves to assist in the propulsion of fluid, mucus and trapped particles towards the pharynx.

**FIG. 16.4** Ciliated cell ultrastructure. Conventional transmission electron microscopy of a normal human nasal biopsy. (A) Longitudinal section across the apical border of a ciliated cell showing a clear area near the cell surface with cilia tips enmeshed in viscous material. Original magnification = 12,000 X. (B) Cross sections of cilia axonemes, illustrating the 9 + 2 arrangement of microtubules in motile cilia. ODA: outer dynein arm; IDA: inner dynein arm; RS: radial spoke, original magnification = 50,000 X.

# ION AND WATER TRANSPORT AND INTEGRATED FUNCTION FOR EFFECTIVE MUCUS CLEARANCE

Mucous secretory and ciliated cells distinctly contribute to mucociliary clearance which, combined with cough, constitutes mucus clearance, a key airway defense mechanism [88]. Collectively, the system is organized and physiologically regulated to balance mucin production with ion and water transport to maintain surface hydration at levels sufficient to foster mucus transportability. Airway surface liquid is normally present in two layers, an overlying viscous mucus layer and a periciliary layer (PCL) in which cilia can freely beat. A "slip" layer provides "lubrication" at the interface of these two layers [66]. The mucus layer and the PCL can be visualized after special fixation techniques of tissues or in culture preparations of live, differentiated airway epithelial cells [89–91] (Fig. 16.5). By balancing $Cl^-$ secretion and $Na^+$ absorption at the epithelial luminal membrane, the airway epithelium regulates PCL volume to fully hydrate the PCL and maintain its depth at the height of the outstretched cilia [90, 92, 93]. There are two principal apical membrane channels, the cystic fibrosis transmembrane conductance regulator (CFTR) and the $Ca^{2+}$-activated $Cl^-$ channel (CaCC), that mediate $Cl^-$ transport. $Na^+$ transport occurs through the epithelial $Na^+$ channel (ENaC). CFTR, CaCC, and ENaC activity is locally and coordinately regulated by changes in the PCL concentration of nucleotides and nucleosides [94–97]. In this system, ATP released by cells activates $P2Y_2$ purinergic receptors, which stimulates $IP_3$ formation, causing $Ca^{2+}$ release that activates CaCC. Decreased $PIP_2$

is thought to coordinately inhibit ENaC. ATP can also be metabolized to adenosine, which will activate $A_{2B}$ adenosine receptors, generating cAMP and activating protein kinase C to ultimately open CFTR. Active CFTR is also reported to directly inhibit ENaC. Apical membrane $Cl^-$ secretion through CFTR and/or CaCC increases airway surface hydration whereas $Na^+$ entry through ENaC decreases airway surface hydration. Water follows its osmotic gradient transcellularly through aquaporins and, a small part, via para-cellular pathways. In the distal lung, similar processes, mainly involving $Na^+$ absorption through ENaC but also involving CFTR, are thought to regulate normal alveolar fluid balance and are important in the resolution of pulmonary edema after acute lung injury [67].

Endogenous mediators active in regulation of airway and lung surface liquid have additional roles, which may pose conundrums relevant to potential therapies for asthma and COPD. For example, although ATP promotes airway surface hydration via activation of epithelial $P2Y_2$ purinergic receptors, ATP is also a "danger signal" involved in regulation of the immune system [98]. Excess airway ATP may contribute to an asthma-like phenotype via pro inflammatory effects, including the recruitment and activation of dendritic cells (DCs) [99]. Similarly, adenosine activation of epithelial $A_{2B}$ receptors is important to activate CFTR and hydrate the epithelial surface, but high adenosine levels in adenosine deaminase deficient mice promotes inflammation, and inhaled adenosine causes broncho-constriction in asthmatic humans [100]. Pharmacologic therapies directed at reducing adenosine or antagonizing adenosine receptors may have the unwanted effect of creating a cystic fibrosis-like

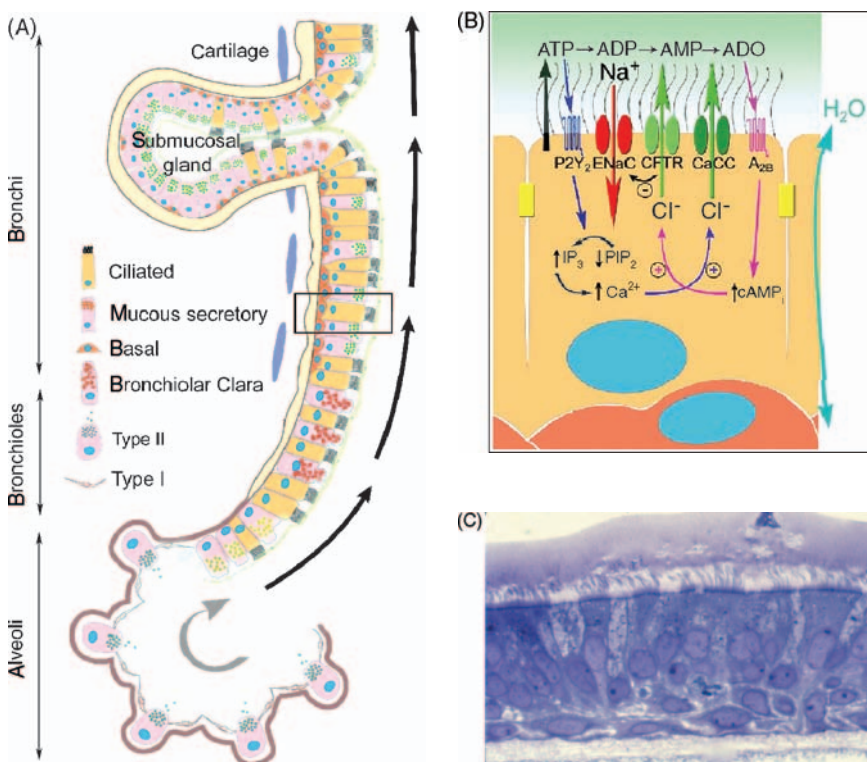

**FIG. 16.5** Respiratory tract ion and water transport and mucus clearance. (A) The airway epithelium coordinates fluid and mucous secretion to foster effective mucus clearance. It is still uncertain how much alveolar lining fluid leaves the distal lung via the airways (gray arrow). (B) Ion channels in the apical plasma membrane, regulated by local concentrations of nucleotides and nucleosides, maintain adequate airway surface hydration. (C) Airway surface liquid consists of two layers, a clear periciliary layer and overlying mucus. Perflurocarbon-$OsO_4$ fixed, well-differentiated human bronchial epithelial cell culture, thin plastic section, original magnification = 500X, Richardson's stain. (A) and (B) are adapted, with permission, from Ref. [68].

phenotype [97]. Furthermore, although elevated adenosine produces "whole animal" pro-inflammatory effects, adenosine acting via $A_{2A}$ receptors on macrophages is anti-inflammatory [101]. The pleiotropic effects of mediators such as ATP and adenosine are likely concentration-, compartment-, receptor-, and cell type-specific and must be considered when proposing therapies based on manipulation of their levels or receptors.

## LUNG EPITHELIAL FUNCTION IN IMMUNITY

The mammalian immune system is broadly divided into "innate" and "adaptive" branches. Innate immunity is the first line of defense that is constantly on guard and requires no prior exposure to harmful substances or pathogens to induce a protective response. Adaptive immunity takes time to develop via specific, antigen triggered cellular interactions between DCs, T-, and B-cells and has profound memory. The two branches are highly intertwined. For example, the cell and chemical milieu produced by the innate immune system is critical for the development of adaptive immunity, and conversely, products of adaptive immune cells can alter the function of cells involved in innate immunity. The airway and lung epithelium is integral to innate and adaptive immunity and is both an effector and target in the altered immune function characteristic of asthma and COPD.

## ROLE IN INNATE IMMUNITY

The airway and lung epithelium is a selective physical barrier that coordinates removal of potentially harmful substances by mucus clearance. It also plays important roles in host defense by secreting a wide spectrum of protective, antimicrobial, homeostatic, and immune regulatory factors including antioxidants, defensins, collectins, complement components, lactoferrin, lysozyme, and protease inhibitors (reviewed in Refs [102, 103]). Normally protective innate immune functions can be enhanced when pathogen/microbial associated patterns or other chemical danger signals are recognized by innate immune system receptors expressed by epithelial cells. The receptors include transmembrane molecules such as the toll-like receptors (TLRs) [104], protease-activated receptors (PARs) [105] and purinergic receptors [98] as well as cytosolic proteins including the nucleotide-binding, leucine-rich repeat receptors (NLRs) [106] and the retinoic acid-inducible gene I-like helicases (RLHs) [107]. The substances detected by these multiple classes of receptors include endogenous homeostatic factors such as ATP as well as molecules derived from microbes and pathogens including bacterial lipopolysaccharide and viral RNA.

Receptor engagement induces downstream signaling that modifies cellular behavior in many ways to eliminate the perceived danger. Airway epithelial ion channels can be activated to induce fluid secretion accompanied by mucin release and increased cilia beating to "flush away" the offending

stimulus. Preformed substrates such as arachidonic acid can be metabolized and released and/or gene expression/stability can be modified to change patterns of epithelial cell mediator production. Receptor engagement and downstream signaling may induce pro-inflammatory cytokines and chemokines that selectively attract neutrophils, monocytes, eosinophils, and basophils to ostensibly eliminate pathogens. The process is dynamic, and repeat or chronic exposure to substances that activate innate epithelial cell immune system receptors will modulate epithelial cell behavior upon subsequent exposure [108]. The epithelium thus plays a vital innate immune role to perceive and respond to danger, with mechanisms in place to modulate and orchestrate inflammation depending on the type, degree, and chronicity of stimulation. Functional polymorphisms in genes involved in epithelial innate immunity are likely important modifiers related to the development of lung disease.

## ROLE IN ADAPTIVE IMMUNITY

Beyond regulating luminal dwell time and permeability of allergens and pathogens, the airway and lung epithelium play key regulatory roles in adaptive immunity. Cytokines, chemokines, and other molecules produced by the epithelium at steady state, and especially after innate immune stimulation, modulate adaptive immunity by attracting DCs, T-, and B-cells and altering their function (reviewed in Ref. [109]). In turn, the epithelium responds to products of adaptive immune cells, establishing complex feedback loops that ultimately determine tissue inflammation and lesion development. The epithelium also plays a functional role by facilitating the transport of secretory immunoglobulin.

The conducting airway epithelium and alveolar interstitium contain resident DCs that sample the luminal microenvironment and present antigens to T-cells locally, or after migrating to regional lymph nodes. The numbers of DCs in the airways and lungs, and their functional state, are altered by numerous chemokines, cytokines, and other molecules involved in DC attraction and activation that are secreted by epithelial cells [110]. Chronic inflammatory diseases are regulated by T-cell activation and polarization and recent discoveries have added new T-cell subsets to the landscape. Organ parenchymal cells participate in the differentiation of $Th_1$, $Th_2$, $Th_{17}$, and T-regulatory ($T_{reg}$) cells from naïve T-cells and create feedback loops that regulate and sustain local responses. For example, epithelial IL-6 production positively reinforces $Th_{17}$ cell polarization [111]. Conversely, T-cell products affect the epithelium, such as the well-known induction of mucin by the $Th_2$ cytokine IL-13 [112, 113]. $Th_{17}$ cell production of IL-22 and its action on the epithelium appears to play an important role in epithelial repair and mucosal defense against gram-negative bacteria [114]. The airway and lung are populated by immunoglobulin secreting plasma cells. B-cell stimulation and class switching is strongly influenced by other adaptive immune cells but there is mounting evidence that epithelium-derived factors participate in regulation of B-cell class switching and immunoglobulin production [109]. The epithelium plays an integral

role in adaptive immunity by transporting secretory immunoglobulin from the lamina propria where it is produced into the lumen, a process that may be impaired in asthma and COPD [115].

To summarize, complex reciprocal interactions between the epithelium and the adaptive immune system regulate the integrated response to allergens and infectious agents and play important roles in asthma and COPD.

# Airway Mucus Hypersecretion in Asthma and COPD: Not the Same?

**Duncan F. Rogers**

**Section of Airway Disease,
National Heart & Lung Institute,
Imperial College, London, UK**

## INTRODUCTION

Patients with asthma or chronic obstructive pulmonary disease (COPD) invariably exhibit characteristics of airway mucus hypersecretion, comprising sputum production [1, 2], excessive mucus in the airway lumen [3] (Figs. 17.1 and 17.2), goblet cell hyperplasia [3–6] and submucosal gland hypertrophy [3, 4] (Fig. 17.3). The pathophysiological sequelae of mucus hypersecretion are airway obstruction, airflow limitation, ventilation-perfusion mismatch, and impairment of gas exchange. In addition, compromised mucociliary function, with reduced mucus clearance, can encourage bacterial colonization leading to repeated chest infections and exacerbations, particularly in COPD. In COPD, a city-wide epidemiological study in Copenhagen showed that a number of clinical parameters, including deterioration in lung function, risk of hospitalization and death, were increased in patients with COPD who had chronic mucus hypersecretion compared with patients with either no sputum production or with only a small amount of intermittent sputum production [7] (Fig. 17.4). In addition, patients who had chronic airway mucus hypersecretion and were also susceptible to chest infections showed increased mortality and morbidity compared with patients with mucus hypersecretion but without infections (Fig. 17.4). In contrast, there is much less information on the contribution of mucus to pathophysiology and clinical symptoms in asthma. However, excess mucus may not only obstruct the airway lumen, but also contribute to the development of airway hyperresponsiveness [8]. The latter possibilities led to the suggestion that chronic mucus hypersecretion reflects lack of asthma control, leading in turn to accelerated loss of lung function and increased mortality [7].

The association of airway mucus hypersecretion with asthma and COPD is not necessarily cause and effect. The excess mucus may merely be a result of the inflammatory processes causing the disease. Consequently, treating the mucus problem will not inevitably treat the disease, especially if the changes that have led to increased mucus production are irreversible. Nevertheless, as discussed above, mucus hypersecretion does contribute to clinical symptoms in certain groups of patients with asthma and COPD. This suggests that it is important to develop drugs that address the airway mucus problem in these patients. The first issue pertaining to the rational development of drugs to treat airway mucus hypersecretion is to understand the nature of the underlying disease processes in asthma and COPD and how these relate to the mucus hypersecretory phenotype in each condition. Secondly, it is important to know which aspect(s) of mucus hypersecretion should be targeted.

The present chapter addresses the above issues by discussion of similarities and differences in the pulmonary inflammatory "profile" between asthma and COPD and how these may relate to the generation of the airway mucus hypersecretory state in the two conditions. To set these discussions in context, the chapter begins with consideration of sputum, airway mucus, and mucins, followed by an outline of the characteristics of mucus hypersecretion in asthma and COPD, emphasizing differences between the two conditions and the theoretical requirements for drugs aimed at effectively inhibiting airway mucus hypersecretion.
**FIG. 17.1** Mucus obstruction of the airways in asthma and COPD. (A) Mucus plugging in asthma. Complete occlusion by mucus plugs (M) of an intrapulmonary bronchus (arrow), cut in longitudinal section, in a patient who died of an acute-severe asthma attack. (B) Bronchoconstriction and luminal mucus in fatal asthma. Intrapulmonary airway (transverse section) of a patient who died of an acute-severe asthma attack showing airway epithelium (arrow) thrown into folds by smooth muscle contraction, and occlusion by mucus (M) of remaining luminal space. This relatively small amount of mucus would not be expected to significantly reduce airflow in the relaxed, non-constricted airway. (C) Airway mucus "tethering" in asthma. Transverse section through a bronchiole of a patient with asthma showing incomplete release, or "continuity," of secreted mucin from airway epithelial goblet cells (arrows). Similar appearances of mucus tethering are not observed in the airways in COPD. (D) Mucopurulent secretions (M) in an intrapulmonary bronchus in a patient with COPD.

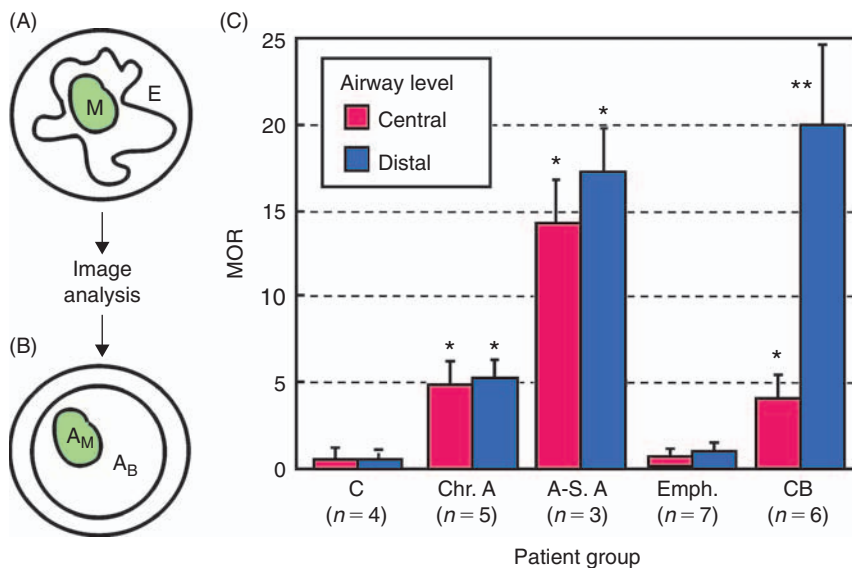

**FIG. 17.2** Relative amounts of airway luminal mucus in asthma and COPD. (A) Lungs from patients dying either of causes other than lung disease (controls, C), or from chronic asthma (Chr. A), acute-severe asthma (A-S. A), emphysema (Emph.), or chronic bronchitis (CB), were cut in histological section and stained with hematoxylin–eosin and elastica–Goldner stains to visualize mucin (M). The stained sections were viewed by light microscopy and intrapulmonary airways assessed for amount of luminal mucus. E: bronchial epithelium. (B) Airways of interest were subjected to computer-based image analysis. The irregular perimeter of the bronchial epithelium was digitally converted to a circle, from which the area of mucus ($A_M$) was expressed as a ratio of the area of the bronchus ($A_B$), to give a mucus-occupying ratio, MOR ($A_M/A_B$), as shown in panel C. *$p < 0.01$, **$p < 0.01$ compared with controls. Redrawn from data in Refs [3, 4].

## SPUTUM

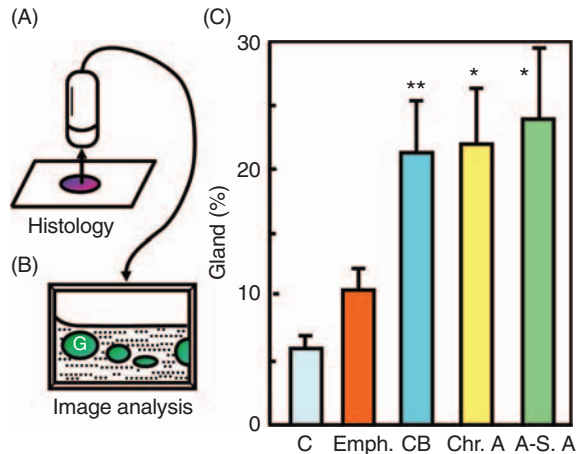
Coughing or "hawking" to bring up "phlegm" is a sign of respiratory disease [2, 9]. It indicates airway mucus hypersecretion, coupled with impaired mucus clearance and mucus retention, and is a feature of many patients with asthma [10] or COPD [11]. The expectorated excessive secretions are referred to as sputum. The characteristics of sputum change


**FIG. 17.3** Relative size of airway submucosal glands in asthma and COPD. (A) Lungs from patients dying either of causes other than lung disease (controls, C), or from chronic asthma (Chr. A), acute-severe asthma (A-S. A), emphysema (Emph.), or chronic bronchitis (CB), were cut in histological section and stained with hematoxylin–eosin and elastica–Goldner stains to visualize the submucosal glands. The stained sections were viewed by light microscopy and intrapulmonary airways assessed for size of glands. (B) Airways of interest were subjected to computer-based image analysis, and the area proportion of glands (G) expressed as a percentage of the wall area, as shown in panel C. $*p < 0.01$, $**p < 0.01$ compared with controls. Redrawn from data in Refs [3, 4].

with infection and inflammation. Inflammation leads to mucus hypersecretion, ciliary dysfunction, and changes in the composition and biophysical properties of airway secretions [12]. Inflammatory cells, particularly neutrophils, which are recruited to the airway to combat infection, disappear from the airway either through programmed cell death (apoptosis) or by necrosis. Necrotic neutrophils release proinflammatory mediators that damage the epithelium and recruit more inflammatory cells. They also release DNA [13] and filamentous actin (F-actin) from the cytoskeleton. DNA and F-actin copolymerize to form a second rigid network within airway secretions [14, 15]. Neutrophil-derived myeloperoxidase imparts a characteristic green color to inflamed airway secretions, which are termed mucopurulent (17.1). Excessive infection turns the secretions dark yellow, green, or brown, and these are termed purulent.

## AIRWAY "MUCUS"

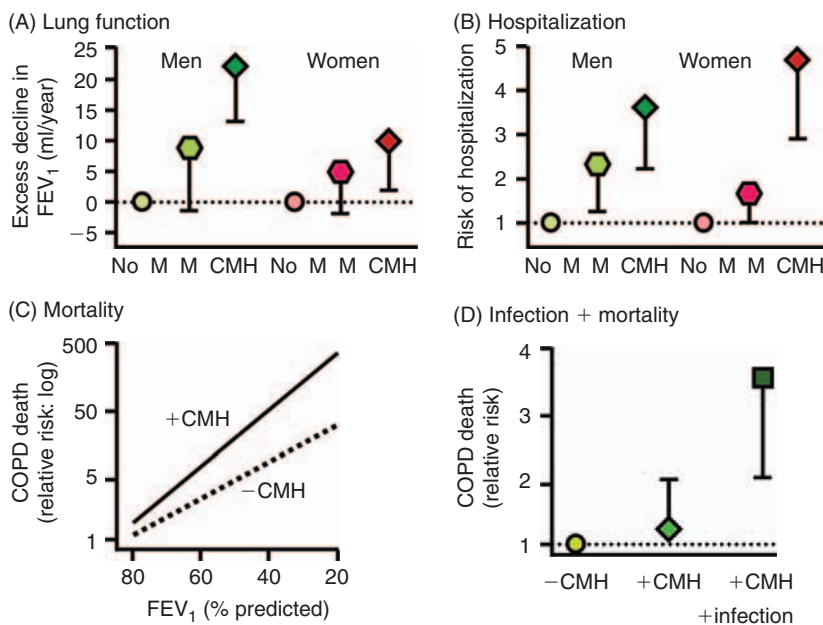
Airway mucus is a complex dilute aqueous solution of lipids, glycoconjugates, and proteins. It comprises salts, enzymes and anti-enzymes, oxidants and antioxidants, exogenous bacterial products, endogenous antibacterial secretions, cell-derived mediators and proteins, plasma-derived mediators and proteins, and cell debris such as DNA. Airway mucus is considered to form a liquid bi-layer whereby an upper gel layer floats above a lower, more watery sol, or periciliary liquid, layer [16] (Fig. 17.5). There may be a thin layer of surfactant lying in between, and separating, the gel and sol layers [17]. The functions of the sol layer are debated, but are presumed to include "lubrication" of the beating cilia. The surfactant layer might facilitate spreading of the gel layer over the epithelial surface. The gel layer traps particles and is moved on the tips of the beating cilia. The inhaled particles are trapped in the sticky gel layer


**FIG. 17.4** Clinical impact of airway mucus hypersecretion in COPD. The Copenhagen Heart Study [7] showed that patients with chronic mucus hypersecretion (CMH), as defined by long-term phlegm production, had an accelerated decline in lung function (A), increased risk of hospitalization (B), increased risk of death (C), and a further increased risk of death when linked with pulmonary infection (D), when compared with subjects without mucus production (−CMH) or patients with some sputum production but without infection. No M: no sputum (mucus) production; M: non-chronic sputum (mucus) production. Redrawn after data in Ref. [7].

and are removed from the airways by mucociliary clearance. When the mucus reaches the throat, it is either swallowed and delivered to the gastrointestinal tract for degradation or, if excessive, as in respiratory disease, it is coughed out [18].

Respiratory tract mucus requires the correct combination of viscosity and elasticity for optimal efficiency of ciliary interaction [19, 20]. Viscosity is a liquid-like characteristic and is the resistance to flow and the capacity to

**FIG. 17.5** Airway mucus secretion and hypersecretion. Upper panel: In healthy airways, mucus forms a bi-layer over the epithelium, with surfactant (dotted line) separating the gel and sol layers. Mucins secreted by goblet cells and submucosal glands confer viscoelasticity on the mucus which facilitates mucociliary clearance of inhaled particles and irritants. Mucus hydration is regulated by salt (and, hence water) flux across the epithelium: the glands also secrete water. Plasma proteins exuded from the tracheobronchial microvasculature bathe the submucosa and contribute to the formation of the mucus. The above processes are under the control of nerves and regulatory mediators. Lower panel: Airway inflammation (in asthma and COPD) induces changes associated with a mucus hypersecretory phenotype, including increased plasma exudation (more prominent in asthma than COPD), goblet cell hyperplasia, via differentiation from basal cells, and associated increased mucus synthesis and secretion, and submucosal gland hypertrophy (with associated increased mucus production), leading to increased luminal mucus (and airway obstruction).

absorb energy when moving. Elasticity is a solid-like property and is the capacity to store the energy used to move or deform it. Viscoelasticity confers a number of properties upon the mucus that allow effective interaction with cilia. These properties have been variously described in terms of spinnability, adhesiveness, and wettability [21]. An important characteristic of mucus is that it is non-Newtonian: its viscosity decreases as the applied force increases [22]. Consequently, the ratio of stress to rate of strain is nonlinear, with the result that the more forcefully the cilia beat, the more easily the mucus moves. Viscoelasticity is conferred on the mucus primarily by high molecular weight mucous glycoproteins, termed mucins.

## RESPIRATORY TRACT MUCINS

In health, mucins comprise up to 2% by weight of the airway mucus [23]. In the airways, mucins are produced by goblet cells in the epithelium [24] and sero-mucous glands in the submucosa [25], which in respiratory diseases such as asthma and COPD may increase in number (hyperplasia) and size (hypertrophy) respectively (Fig. 17.5). Mucins are long, thread-like, complex glycoconjugates. They consist of a linear peptide backbone (termed apomucin), which is encoded by specific mucin (MUC) genes (see below), to which hundreds of carbohydrate side-chains are O-linked, but also with additional N-linked glycans [26]. The glycosylation pattern is complex and extremely diverse [27], and is associated with complimentary motifs on bacterial cell walls, thereby facilitating broad-spectrum bacterial attachment and subsequent clearance [28, 29]. Within the main protein core are variable numbers of tandemly repeated serine- and/or threonine-rich regions which are unique in size and sequence for each mucin [18], and represent sites for mucin glycosylation. These complex glycoproteins are polydisperse, linear polymers that can be fragmented by reduction to give monomers termed "reduced subunits" [30–33]. There are at least two structurally and functionally distinct classes of mucin, namely the membrane-associated mucins and the secreted (gel-forming or non-gel-forming) mucins (Table 17.1). Membrane-tethered mucins, which have a hydrophobic domain that anchors the mucin in the plasma membrane, contribute to the composition of the cell surface [18]. Secretory mucins are stored intracellularly in secretory granules and are released at the apical surface of the cell in

**TABLE 17.1** Human mucin genes expressed in the airways and lung.

| Classification of gene product | Genes |
| --- | --- |
| Membrane associated | MUC1, MUC4, MUC11, MUC13, MUC20 |
| Secreted, cysteine rich (gel forming) | MUC2, MUC5AC, MUC5B, MUC19 |
| Secreted, cysteine poor | MUC7 |

Airway Mucus Hypersecretion in Asthma and COPD: Not the Same?

17

response to stimuli. It would appear that mucus production is such a fundamental homeostatic process that virtually all acute interventions examined trigger airway mucin secretion (Table 17.2). In addition, many of these same mediators when administered more chronically not only induce mucin secretion but also upregulate mucin gene expression, with concomitant increases in mucin synthesis and goblet cell hyperplasia (Table 17.2).

## MUCIN GENES AND GENE PRODUCTS

Twenty human mucin (MUC) genes have so far been identified. Of these, only nine, namely MUC1, MUC2, MUC4, MUC5AC, MUC5B, MUC7, MUC11, MUC13, and MUC20 are expressed in the human respiratory tract [18] (Table 17.1). Of these, only MUC2, MUC5AC, and MUC5B, the classic gel-forming mucins, are found in airway secretions. However, only MUC5AC and MUC5B glycoproteins, localized adjacent to each other on chromosome 11p15.5, are considered the major gel-forming mucins in both normal respiratory tract secretions as well as in airway secretions from patients with respiratory diseases [34–39]. Small amounts of MUC2 may, however, be found in secretions from "irritated" airways (see below).

Advances in biochemistry, molecular biology, and biophysics mean that the structure and functions of the airway MUC gene products are becoming better characterized [23, 26]. The predicted sequences of the MUC1, MUC 4, MUC11, MUC13, and MUC20 mucins suggest they are membrane bound, with an extracellular mucin domain and a hydrophobic membrane-spanning domain (Table 17.1). In contrast, MUC2, MUC5AC, MUC5B, MUC6, and MUC7 gene products are secreted mucins (Table 17.1). The technology for studying the contribution to physiology and pathophysiology of the individual MUC gene products lags well behind that of investigation of gene expression [18]. MUC1, MUC2, and MUC8 genes are expressed in both the epithelium and submucosal glands, whereas MUC4, MUC5AC, and MUC13 are expressed primarily in the epithelium. In contrast, MUC5B and MUC7 genes are expressed primarily in the glands. Use of currently available antibodies confirms that the MUC5AC gene product is a goblet cell mucin, whilst MUC5B predominates in the glands, albeit that some MUC5AC and MUC7 is also usually present [23]. Interestingly, MUC4 mucin localizes to the ciliated cells. The mucin content of secretions from patients with hypersecretory respiratory diseases may differ from normal (see below).

## MUC5AC

MUC5AC mucin, initially isolated as a tracheobronchial mucin [40], is found in airway secretions pooled from healthy individuals [35, 37]. Increased levels of MUC5AC protein have also been shown to be present in the airways of patients with asthma [5], which suggests that this mucin may contribute to the pathophysiology of asthma. MUC5AC is the main mucin produced by the goblet cells in the tracheobronchial surface epithelium. However, MUC5AC can be found highly expressed not only in human bronchial epithelium, but also in bronchial submucosal glands, nasal mucosa, gastric epithelium, endocervix epithelium, and submucosal glands. This mucin has been found to be highly oligomerized, which makes it an ideal gel-forming molecule. The expression of many genes, such as MUC5AC, in airway epithelial cells is regulated by various neurohumoral factors and inflammatory mediators (Table 17.2).

## MUC5B

MUC5B mucins are also a major component of tenacious mucus plug from the lungs of a patient who died in *status asthmaticus* [38, 41] and in sputum from patients with chronic bronchitis [39], which suggests that MUC5B is a major component of lung mucus from patients with obstructive lung diseases [42]. MUC5B mucin exists as differently charged glycoforms (termed the low-charge and high-charge glycoforms) and is secreted primarily by the mucous cells in the bronchial submucosal glands [34, 38, 43, 44]. However, it has been shown that MUC5B mucins are also synthesized by goblet cells [39], and are expressed in the tracheal and bronchial glands, salivary glands, endocervix, gall bladder, and pancreas. MUC5B is unique in that it does not appear to be polymorphic.

From the above, it appears that, in healthy individuals, MUC5B is mainly expressed in the airway submucosal glands, which are restricted to the more proximal, cartilaginous airways. In contrast, MUC5AC expression is generally restricted to goblet cells in the upper and lower respiratory tracts [45, 46]. Thus, the composition of normal mucus can be altered depending on the relative contribution to the secretions of these different cellular sources [47]. In respiratory diseases associated with airway mucus hypersecretion, such as asthma and COPD, further changes in the composition of the mucus, and in the mucus secretory phenotype in general, are observed, as discussed below.

## AIRWAY MUCUS HYPERSECRETORY PHENOTYPE IN COPD

COPD comprises three overlapping conditions, namely chronic bronchitis (airway mucus hypersecretion), chronic bronchiolitis (small airways disease), and emphysema (airspace enlargement due to alveolar destruction) [10] (Fig. 17.6). The following discussion considers the "bronchitic" component of COPD. The airways of patients with COPD contain excessive amounts of mucus [6], which is markedly increased above that in control subjects [3, 48]. The excessive luminal mucus is associated with increased amounts of mucus-secreting tissue. Goblet cell hyperplasia is a cardinal feature of chronic bronchitis [6], with increased numbers of goblet cells in the airways of cigarette smokers either with chronic bronchitis and chronic airflow limitation [49] or with or without productive cough [50]. Submucosal gland hypertrophy also characterizes chronic bronchitis [3, 6, 51, 52], and the amount of gland correlates with amount of luminal mucus [3].

The number of ciliated cells and the length of individual cilia is decreased in patients with chronic bronchitis [53]. Ciliary aberrations include compound cilia, cilia with an abnormal axoneme or intracytoplasmic microtubule doublets, and cilia enclosed within periciliary sheaths [54]. These abnormalities coupled with mucous hypersecretion are presumably associated with reduced mucus clearance and airway mucus obstruction in the bronchitic component of COPD.

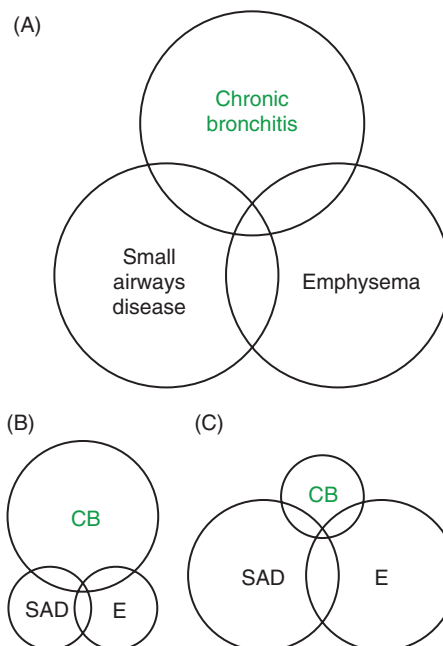

**FIG. 17.6** The pathophysiological components of COPD. (A) COPD comprises three interlinked conditions, namely chronic bronchitis (CB: long-term airway mucus hypersecretion), small airways disease (SAD: also known as chronic bronchiolitis), and emphysema (E: alveolar destruction). The relative contribution to airway obstruction in any one patient of each component is invariably unclear. (B) Patient in whom mucus hypersecretion predominates (may be identifiable by excessive sputum production). (C) Patient in whom mucus hypersecretion contributes proportionally less to airflow limitation than SAD and E.

## AIRWAY MUCUS HYPERSECRETORY PHENOTYPE IN ASTHMA

Asthma is a chronic inflammatory condition of the airways characterized by variable airflow limitation that is at least partially reversible, either spontaneously or with treatment [55, 56]. It has specific clinical and pathophysiological features [57], including mucus obstruction of the airways [8]. The latter is particularly evident in a proportion of patients who die in *status asthmaticus*, where many airways are occluded by mucus plugs [58–60]. The plugs are highly viscous and comprise plasma proteins, DNA, cells, proteoglycans [61], and mucins [41, 58, 61]. Incomplete plugs are found in the airways of asthmatics who have died from causes other than asthma [62], which indicates that plug formation is a chronic, progressive process. There is also more mucus in the central and peripheral airways of both chronic and severe asthmatics compared with control subjects [4]. Analysis of asthmatic sputum indicates that the mucus comprises DNA, lactoferrin, eosinophil cationic protein, and plasma proteins such as albumin and fibrinogen [63–65], as well as mucins [5, 64, 66]. The increased amount of lumenal mucus reflects an increase in amount of airway secretory tissue, due to both goblet cell hyperplasia [4, 5] and submucosal gland hypertrophy [58], although the latter is not characteristic of all patients with asthma [4].

Airway epithelial fragility, with epithelial shedding in extreme cases, is a significant feature of asthma [67]. Shedding includes loss of ciliated cells, with presumably a concomitant reduction in mucus clearing capacity. As in COPD above, abnormalities in airway ciliated cells and cilia have been described in asthma. The ciliated cells themselves may be damaged, with loss of cilia, vacuolization of the endoplasmic reticulum and mitochondria, and microtubule damage [68–70]. These abnormalities could be caused by some of the inflammatory mediators generated in the airways of asthmatic patients, for example, eosinophil major basic protein [71]. A variety of other ciliostatic and ciliotoxic compounds are also present in asthmatic airway secretions [72].

In summary of this section, the combination of an increased amount of mucus-secreting tissue, with associated mucus hypersecretion, the production of viscid mucus, and abnormal ciliary function leads to reduced mucus clearance and the development of airway mucus obstruction in asthma.

## MUCOCILIARY CLEARANCE IN ASTHMA AND COPD

Clearance of mucus from the airways is impaired in patients with a variety of respiratory diseases, including asthma and COPD [73]. However, it should be noted that there are often discrepancies in results between studies that are invariably due to differences in methodology [74, 75], but may also be due to observations made at different stages of disease.

## COPD

Mucus clearance is generally considered to be impaired in patients with COPD [73]. However, the validity of these studies is dependent upon patient selection and the exclusion of patients with asthma. For example, patients classified as having obstructive chronic bronchitis and with a bronchial reversibility of less than 15% had slower lung mucus clearance than patients with reversibility greater than 15% and who, therefore, were likely to be asthmatic [76]. Nevertheless, mucus clearance is significantly reduced in heavy smokers [77] and in patients with chronic bronchitis [78]. Lung mucus clearance differs between patients with chronic airway obstruction, with or without emphysema [79]. Both groups of patients were smokers or ex-smokers and had productive cough, but lung elastic recoil pressure was reduced in the emphysema group. Mucus clearance from central airways was similar. In contrast, clearance from the peripheral lung was faster in the emphysema group than in the patients without emphysema. Importantly, forced expirations and cough markedly increased peripheral clearance in the non-emphysema group but not in the emphysema group. Comparable findings in a subsequent study led to the suggestion that cough compensates relatively effectively for decreased mucus clearance in patients with chronic bronchitis [80]. Conversely, cough is not so effective in COPD patients with impaired lung elastic recoil.

## Asthma

Airway mucociliary clearance is well documented as being impaired in asthma [72]. Clearance is impaired even in patients in remission [81] and in those with mild stable disease [82]. Mucus clearance is proportionally reduced in symptomatic asthmatics [83] and during exacerbations [84]. In addition, the normal slowing of mucus clearance during sleep is more pronounced in asthmatic patients [85, 86], and this could be a contributory factor in nocturnal asthma. The mechanisms underlying the reduced mucus clearance in asthma are not clearly defined, although airway inflammation is considered to be a major contributor [72].

## MECHANISMS OF DEVELOPMENT OF AIRWAY GOBLET CELL HYPERPLASIA

Airway goblet cell hyperplasia is a predominant feature of asthma and COPD (see above), and is an often-used end point in animal models of respiratory disease [87]. The cellular composition of the airway epithelium can alter both by cell division and by differentiation of one cell into another [88]. There are at least eight cell types in the airway epithelium of the conducting airways. Of these, the basal, serous, and Clara cells are considered progenitor cells with the capacity to undergo division followed by differentiation into "mature" ciliated or goblet cells. In specific experimental conditions, for example, exposure to cigarette smoke, goblet cell division contributes in part to the hyperplasia. However, differentiation of non-granulated airway epithelial cells is a major route for production of new goblet cells [88–90]. In experimental animals, production of goblet cells is usually at the "expense" of the progenitor cells, most notably serous and Clara cells, which decrease in number as goblet cell numbers increase. Serous-like cells and Clara cells are found in macroscopically normal bronchioles in human lung [91]. Whether there is a reduction in number in respiratory disease is not reported, but merits investigation. Reduction in the relative proportion of serous and Clara cells has pathophysiological significance because they produce a number of antiinflammatory, immunomodulatory, and antibacterial molecules vital to host defence [92, 93]. For example, serous cells produce lysozyme, lactoferrin, the secretory component of IgA, peroxidases, and at least two protease inhibitors. Clara cells produce Clara cell 10-kDa protein, also known as uteroglobulin, Clara cell 55-kDa protein, Clara cell tryptase, β-galactoside-binding lectin, possibly a specific phospholipase, and surfactant proteins A, B, and D. Thus, in respiratory diseases associated with airway mucus hypersecretion it seems that not only is there goblet cell hyperplasia, with associated mucus hypersecretion, but also a reduction in serous and Clara cells, with concomitant potential for impaired host defence.

# DIFFERENCES IN MUCUS HYPERSECRETORY PHENOTYPE BETWEEN ASTHMA AND COPD

In order to develop appropriate models of airway mucus obstruction and devise drugs to aid mucus clearance, it is necessary to understand the similarities and differences in the features of mucus obstruction for different hypersecretory conditions. There are a number of differences in the pathophysiology of airway mucus hypersecretion between asthma and COPD (Fig. 17.7).

## Airway inflammation in asthma and COPD

Any differences in airway mucus hypersecretory phenotype are presumably related, either directly (genetic predisposition) or indirectly (environmental exposure), or a combination of the two, to differences in the airway inflammatory phenotype. Thus, although the underlying pulmonary inflammation of asthma and COPD shares many common features, there are specific characteristics unique to each condition [94–96]. These differences in turn may contribute to differences in pathophysiology of airway mucus hypersecretion between the two conditions.

Asthma is invariably an allergic disease that affects the airways, rather than the lung parenchyma, and is characterized by Th2-lymphocyte orchestration of pulmonary eosinophilia. The reticular layer beneath the basement membrane is markedly thickened and the airway epithelium is fragile, features not usually associated with COPD. The bronchial inflammatory infiltrate comprises activated T-cells (predominantly CD4$^+$ cells) and eosinophils. Neutrophils are generally sparse in stable disease. In contrast, COPD is currently perceived as predominantly a neutrophilic disorder governed largely by macrophages and epithelial cells. It is associated primarily with cigarette smoking. Three conditions comprise COPD, namely mucous hypersecretion, bronchiolitis, and emphysema. The latter two features are not associated with asthma. In addition, and in contrast to asthma, CD8$^+$ T-lymphocytes predominate and pulmonary eosinophilia is generally associated with exacerbations.

**FIG. 17.7** Putative differences in the airway mucus hypersecretory phenotype between asthma and COPD. Compared with normal, in asthma, there is airway inflammation (predominantly eosinophils and Th2 lymphocytes), an increased amount of luminal mucus with an increased content of MUC5AC and MUC5B mucins, with the probability of an increased ratio of the low-charge glycoform (lcgf) of MUC5B to MUC5AC, the appearance of small amounts of MUC2 in the secretions, epithelial "fragility" with loss of ciliated cells, marked goblet cell hyperplasia, submucosal gland hypertrophy (although, in contrast to COPD – see below – without a marked increase in mucous cell to serous cell ratio), "tethering" of mucus to goblet cells, and plasma exudation. In COPD, there is airway inflammation (predominantly macrophages and neutrophils), increased luminal mucus, increased amounts of MUC5AC and MUC5B mucins, an increased ratio of lcgf MUC5B to MUC5AC above that in asthma, small amounts of MUC2, goblet cell hyperplasia, submucosal gland hypertrophy (with an increased proportion of mucous to serous cells), and a susceptibility to bacterial infection. Many of these differences require further investigation in greater number of subjects.

Both asthma and COPD have a characteristic "portfolio" of inflammatory mediators and enzymes, many of which differ between the two conditions [97, 98]. At a simplified level, histamine, interleukin (IL)-4, and eotaxin are associated with asthma, whilst IL-8, neutrophil elastase, and matrix metalloproteinases are associated with COPD. Thus, there are specific differences between asthma and COPD in their airway inflammation and remodeling. These differences may in turn exert different influences on the development of airway mucus obstruction in the two conditions (Fig. 17.7).

## Airway mucus in asthma and COPD

Airway mucus in asthma is more viscous than in COPD, with the airways of asthmatic patients tending to develop, and subsequently become blocked by, gelatinous "mucus" plugs [8]. Whether or not mucus in asthma has an intrinsic biochemical abnormality is unclear. In general terms, sputum from patients with asthma is more viscous than that from patients with chronic bronchitis [65, 99, 100]. Mucus plugs in asthma differ from airway mucus gels in chronic bronchitis in that they are stabilized by non-covalent interactions between extremely large mucins assembled from conventional sized subunits [41]. This suggests an intrinsic abnormality in the mucus due to a defect in assembly of the mucin molecules, and could account for the increased viscosity of the mucus plugs in asthma. Plug formation may also be due, at least in part, to increased airway plasma exudation in asthma compared with COPD [101, 102]. In addition, in direct contrast to COPD, exocytosed mucins in asthma are not released fully from the goblet cells, leading to "tethering" of luminal mucins to the airway epithelium [103]. This tethering may also contribute to plug formation. One explanation of mucus tethering is that neutrophil proteases, the predominant inflammatory cell in COPD [10], cleave goblet cell-attached mucins. In asthma, the inflammatory cell profile, predominantly airway eosinophilia [57], does not generate the appropriate proteases to facilitate mucin release.

## Mucin species in asthma and COPD

Different mucin species, or at least different proportions of these species, appear to be present in respiratory tract secretions in COPD and asthma. MUC5AC and a low-charge glycoform of MUC5B are the major mucin species in airway secretions from patients with COPD and asthma [35–37, 39, 47]. There is significantly more of the low-charge glycoform of MUC5B in the respiratory diseases than in normal control secretions [47]. An interesting difference between the disease conditions is that there is a proportional increase in the MUC5B mucin over the MUC5AC mucin in airway secretions from patients with COPD compared with secretions from patients with asthma [37]. The above data require confirmation in more samples. The significance of the change in MUC5B glycoforms between the different diseases is unclear. However, it may relate to differences in propensity of bacterial colonization of the lungs.

It is noteworthy that it is COPD, a disease in which patients are prone to infection [11], that has the proportional reduction in serous cells, rather than asthma, a condition in which patients are not so notably prone to chest infection.

## Goblet cells in asthma and COPD

In contrast to normal airways, goblet cells in the airways from patients with COPD contain not only MUC5AC but also MUC5B [39, 104] and MUC2 [23, 105]. This distribution is different to that in the airways of patients with asthma, where MUC5AC and MUC5B show a similar histological pattern to normal controls [106, 107]. It is noteworthy that although MUC2 is located in goblet cells in irritated airways, and MUC2 mRNA is found in the airways of smokers [48], MUC2 mucin is either not found in airway secretions from normal subjects or patients with chronic bronchitis [35], or is found only in very small amounts in asthma and COPD [47, 108]. The significance of the above combined observations is unclear, but suggests that there are differences in goblet cell phenotype between asthma and COPD.

## Submucosal glands in asthma and COPD

A notable difference between asthma and COPD is in the bronchial submucosal glands [109]. In asthma, although hypertrophied, the glands are morphologically normal with an even distribution of mucous and serous cells. In contrast, in chronic bronchitis, gland hypertrophy is characterized by a markedly increased number of mucous cells relative to serous cells, particularly in severe bronchitis. The reduction in number of gland serous cells may have clinical significance. The serous cells are a rich source of antibacterial enzymes such as lysozyme and lactoferrin [25]. Thus, the airway mucus layer in COPD patients may have a reduced antibacterial capacity compared with that in asthma. This reduction, coupled with the change in MUC5B glycoforms in COPD (see above), could further explain, at least in part, the much higher incidence of bacterial chest infections in COPD compared with asthma.

## Ciliated cells in asthma and COPD

It is not clear whether or not there are differences in the airway ciliary abnormalities between COPD and asthma (see above). However, epithelial fragility and shedding are features of asthma rather than COPD [95], which suggests that there may be greater loss of, and damage to, the ciliated cells in asthma compared with COPD.

From the above, it may be seen that there are theoretical and actual differences in the nature of airway mucus obstruction between COPD and asthma. How these relate to pathophysiology and clinical symptoms in the two conditions is, for the most part, unclear. However, these dissimilarities indicate that different treatments are required for effective treatment of airway mucus obstruction in different respiratory diseases.

## POTENTIAL THERAPIES FOR AIRWAY MUCUS HYPERSECRETION

Current and potential therapies for asthma and COPD are discussed elsewhere in this volume. However, there are a number of avenues for specific treatment of airway mucus hypersecretion that are worthy of brief mention. Some of the mechanisms for development of airway goblet cell hyperplasia and the associated mucus hypersecretory phenotype in asthma and COPD are becoming clearer [8, 110]. Many regulatory and inflammatory mediators and enzymes increase mucus secretion and induce MUC gene expression, mucin synthesis, and goblet cell hyperplasia in experimental systems (Table 17.2). These mediators are intermediates in a cascade of pathophysiological events leading from initiating factors (such as allergen exposure in asthma or cigarette smoking in COPD) setting up a chronic inflammatory/ repair response, which in turn leads to mucus hypersecretion and associated airway obstruction and clinical symptoms (Figs 17.5–17.7). A small number of key molecules may be involved in translating the actions of the different inflammatory mediators into airway mucus hypersecretion, namely epidermal growth factor (EGF) and its receptor tyrosine kinase signaling pathway [111], the mitogen-activated kinase kinase and extracellular signal-regulated kinase (MEK/ERK) pathway [112], calcium-activated chloride (CLCA) channels [113, 114], and the retinoic acid receptor (RAR)-$\alpha$ signaling pathway [115]. A wide variety of small molecule antagonists and inhibitors of these pathways are currently in pharmacotherapeutic development [12]. In addition, inhibition of the process of mucin exocytosis, with concomitant inhibition of secretion and, thereby, mucus hypersecretion, is currently receiving attention from two different directions. Firstly, MARCKS protein is a chaperone molecule essential for movement of newly synthesized mucin-containing granules to the apical surface of mucin-secreting cells [116]. Inhibition of MARCKS by a MARCKS-related peptide inhibits mucin secretion *in vitro* in human airway epithelial secretory cells [116] and mucus hypersecretion in a mouse model of asthma [117]. Secondly, SNARE complex proteins are essential for the "docking" of mucin granules to the internal apical surface of mucin-secreting cells. We have developed a fully recombinant fusion protein comprising the translocation domain and endopeptidase of *Clostridium botulinum*, which normally enters nerves and cleaves SNARE proteins mediating neurotransmission [118], with EGF to target EGF receptors on airway mucus-secreting cells. This molecule now cleaves SNARE proteins linking mucin granules with mucous cell apical membranes, and thereby inhibits mucin secretion from human respiratory epithelial cells [119] and mucus hypersecretion in a rat model of COPD [120].

## CONCLUSIONS

Production of airway mucus is a vital homeostatic mechanism that protects the respiratory tract from a barrage of inhaled insult. However, abnormal production of mucus can contribute to respiratory disease. Airway obstruction by mucus is a common feature of a number of severe respiratory conditions, including asthma and COPD. These diseases share pulmonary inflammation and remodeling as a pathophysiological characteristic, although with differing profiles of inflammatory cells and mediators. One aspect of the remodeling is airway mucus hypersecretion, associated with the shared features of goblet cell hyperplasia and submucosal gland hypertrophy. They also each have a number of unique features that characterize their airway mucus obstruction. For example, plasma exudation, mucus plug formation, and mucus tethering are features of asthma, whereas submucosal gland hypertrophy with a disproportionate increase in the ratio of mucous to serous cells is a significant feature in COPD. Understanding of the relative importance of the differences and similarities in the pathophysiology of the different mucus hypersecretory phenotypes between these two respiratory diseases should lead to rational development of pharmacotherapeutic interventions. At present, there is considerable interest in inhibitors of EGF receptor tyrosine kinases, MEK/ERK and CLCA channels to suppress goblet cell hyperplasia, and in molecules to selectively interfere with mucin exocytosis (such as MARCKS-related peptide and retargeted clostridial endopeptidases) and thereby inhibit airway mucus hypersecretion.

## INTRODUCTION

Airway smooth muscle (ASM) functions as the primary effector cell that regulates bronchomotor tone. In asthma and chronic obstructive pulmonary disease (COPD), bronchoconstriction evoked by smooth muscle shortening promotes airway obstruction, a hallmark of asthma and COPD. Recent evidence also suggests that ASM may undergo hypertrophy and/or hyperplasia and modulate inflammatory responses by secreting chemokines and cytokines. This chapter reviews current studies focusing on excitation–contraction coupling, signaling pathways modulating ASM growth, and cytokine-induced effects on ASM synthetic responses.

## REGULATION OF CALCIUM SIGNALING IN ASM

Because increases in cytosolic calcium directly regulate the initiation and the development of ASM contraction, changes in calcium homeostasis may promote bronchial hyperresponsiveness in asthma. Evidence suggests that various mediators and cytokines important in the pathogenesis of asthma, which augment agonist-induced contractile function, also directly alter calcium signaling. This section reviews (1) the critical calcium-dependent mechanisms involved in the regulation of ASM contraction, and (2) the potential molecular mechanisms that regulate calcium signaling.

## Calcium responses induced by bronchoconstrictor agents

Using the fluorescent dye Fura-2, studies performed on ASM cells have shown that agonist-induced elevation of the cytosolic free calcium ($[Ca^{2+}]_i$) concentration is biphasic. The initial rapid and transient phase of $[Ca^{2+}]_i$ elevation results from the depletion of inositol-1,4,5 trisphosphates ($IP_3$)-sensitive calcium stores; see the review by Amrani and Panettieri [1]. This transient increase in intracellular calcium initiates the contraction process through activation of a calcium–calmodulin-dependent myosin light chain kinase and subsequent phosphorylation of the 20 kDa myosin light chain, the central regulatory mechanism of ASM contraction; see the review by Giembycz and Raeburn [2]. The subsequent sustained elevation of intracellular $[Ca^{2+}]_i$ is regulated by the activation of a calcium influx across the plasma membrane since depletion of extracellular calcium or the use of calcium channel inhibitors prevents this sustained phase [3, 4]. The role of the calcium influx in ASM cells after agonist stimulation is not completely understood, but evidence suggests that calcium entry plays an important role in maintaining the plateau phase of ASM contraction via a PKC-dependent mechanism [2].

## Pathways regulating $[Ca^{2+}]_i$ influx

Although agonist-mediated increases in $[Ca^{2+}]_i$ have been extensively characterized, much less is known about the cellular mechanisms linking the

transient and the sustained phase. In 1986, Putney proposed the concept of store-dependent calcium entry (also called the capacitative model) where depletion of intracellular stores directly regulates calcium entry at the plasma membrane via store-operated calcium channels (SOCC). This calcium influx contributes to the refilling of the internal stores [5]. The existence of capacitative calcium entry in excitable cells, such as smooth muscle cells, was demonstrated using drugs, such as thapsigargin, that cause depletion of sarco-endoplasmic reticulum (SER) by directly inhibiting the activity of the SER-associated calcium-ATPases (SERCA) [6].

In human ASM cells, although thapsigargin-sensitive SERCA2a and 2b isoforms exist, SERCA2b is the predominant isoform. In these cells, depletion of intracellular calcium stores in response to thapsigargin activates a calcium influx with a magnitude that is dependent upon the duration of stimulation with thapsigargin [1]. These data suggest that pathways that activate calcium influx in ASM are linked to the filling state of SERCA2b-associated internal calcium stores. Release of calcium from SER also regulates calcium-dependent chloride and nonselective cation channels, leading to membrane depolarization and opening of voltage-dependent channels; see the review by Janssen [7]. Pretreatment of human ASM cells with thapsigargin also abrogates the calcium responses induced by bradykinin, histamine, or carbachol, suggesting that thapsigargin-sensitive calcium stores involve, at least in part, those activated by the contractile agonists [3].

By mobilizing the same calcium stores, it is plausible that both thapsigargin and agonists activate similar SOCC-dependent calcium influx pathways in ASM. This is supported by the fact that the amplitude of the sustained increase in $[Ca^{2+}]_i$ is dependent on the amplitude of the initial transient phase [3]. Whether additional mechanisms are involved, such as concomitant activation of receptor-operated calcium channels (ROCC) previously described in ASM [3, 4] or involvement of a released soluble mediator controlling calcium influx [8], remains unknown.

Collectively, these data show that the thapsigargin-sensitive intracellular calcium stores in ASM not only serve as a source of calcium to initiate the transient response to agonists, but also participate in the regulation of calcium influx in ASM cells as proposed by the capacitative model. Figure 18.1 summarizes the potential sources of calcium mobilized by contractile agonists to regulate ASM contraction.

## Calcium homeostasis in ASM: A possible target for proinflammatory agents

### Amplification of contractile receptor-coupled calcium signaling

The observation that cultured ASM cells derived from hyperresponsive Fisher rats have an enhanced calcium signal to serotonin suggests the existence of altered calcium metabolism in a model of airway hyperresponsiveness [9]. The underlying mechanism is unknown, but evidence shows that proinflammatory factors may play an important role in regulating calcium metabolism in ASM. Recent studies

**FIG. 18.1** Sources of calcium involved in the regulation of agonist-induced ASM contraction. Contractile agonists activate G-protein-coupled receptors that stimulate PLC and evoke contraction via the mobilization of calcium from IP₃-sensitive internal stores. The increase in $[Ca^{2+}]_i$ activates calcium-/calmodulin-sensitive myosin light chain kinase (MLCK), with subsequent phosphorylation of the 20-kDa myosin light chain (MLC) and initiation of the cross-bridge cycling between actin and myosin. The sustained phase of contraction is thought to involve calcium entry through both ROCCs and SOCCs. In contrast to ROCCs that remain open as long as the contractile agonist is present, SOCCs are triggered by the filling state of sarco-endoplasmic reticulum calcium ATPases (SERCA)-associated internal stores.

demonstrate that tumor necrosis factor (TNF)-α and IL-1β enhance bovine smooth muscle contractility to acetylcholine and other contractile agonists by involving an increased mobilization of intracellular $[Ca^{2+}]_i$ [10]. Accordingly, proinflammatory cytokines may "prime" ASM cells for a nonspecific increase in calcium responsiveness, an effect that appears not to involve a change in the receptor affinity for its ligand [11, 12]. The fact that TNF-α potentiates increases in calcium induced by thapsigargin, which depletes SER calcium stores, suggests a possible modulatory effect of TNF-α on SER-associated regulatory proteins such as SERCA. In addition, TNF-α and IL-1β also augment agonist-evoked phosphoinositide turnover, suggesting that cytokines may modulate receptor-coupled phospholipase C (PLC) activity; see the review by Amrani *et al.* [11]. In support of this hypothesis, TNF-α also enhanced calcium signals in response to NaF [1], an agent that directly activates G-proteins in ASM cells, and upregulated expression of $G_q$ and $G_i$ proteins in human ASM cells [13].

Together, these data suggest that TNF-α can induce a "hyperresponsive" phenotype by enhancing signaling pathways downstream from G-protein-coupled receptor (GPCR) activation.

**TABLE 18.1** Potential modulators of calcium metabolism in ASM cells.

| | Factors | Effect | Species | References |
|---|---|---|---|---|
| Modulation of receptor-coupled signal transduction | IL-1β, TNF-α | ↑ $Ca^{2+}$ transient, $IP_3$ turnover | Human | [11, 12] |
| | Acrolein | ↑ $Ca^{2+}$ transient and frequency oscillations | Rat | [14] |
| | Major basic protein | ↑ $Ca^{2+}$ transient and plateau | Bovine | [15] |
| | Mechanical strain | ↑ $IP_3$ turnover | Bovine | [16] |
| | $PLA_2$ | ↑ $Ca^{2+}$ signals | Bovine | [17] |
| | Allergen challenge | ↑ $Ca^{2+}$ signals, ↓ $IP_3$ 5-phosphatase | Rat | [9] |
| | Chronic hypoxia | ↑ $Ca^{2+}$ frequency oscillations, receptor affinity for agonist | Rat | [18] |
| Modulation of receptor density | Fenoterol | ↑ Histamine H1 receptor | Bovine | [19] |
| | IL-1β | ↑ Bradykinin B2 receptor | Human | [12] |
| | TNF-α | ↓ Muscarinic receptor | Human | [1,13] |

(↑) increase; (↓) decrease; ($IP_3$) inositol 1,4,5 trisphosphate.

Other reports have also described that proinflammatory stimuli modulate GPCR/PLC signaling pathways in cultured ASM cells (Table 18.1). Pretreatment of bovine ASM cells with either eosinophil-derived polycationic proteins or myelin basic protein increased bradykinin-induced transients as well as sustained elevations of $[Ca^{2+}]_i$ [15]. Incubation with either the aldehyde pollutant acrolein or the proinflammatory enzyme $PLA_2$ significantly increased the intensity as well as the frequency of calcium transients in response to acetylcholine [14, 17]. Finally, other experimental conditions, such as chronic hypoxia or mechanical strain, also modulate calcium signaling induced by agonists in ASM cells. Belouchi et al. [18] reported that the amplitude of calcium transients in response to low concentrations of acetylcholine was significantly higher in freshly isolated tracheal smooth muscle cells from hypoxic rats than in those obtained from normoxic animals. Investigators also showed that mechanical strain augmented carbachol-induced $IP_3$ turnover through the regulation of G-protein and/or PLC activities [16].

### Alteration in the density of contractile receptors

Exposure of cultured ASM to various proinflammatory mediators also modulates the density of contractile agonist receptors. ASM cells exposed to TNF-α have a dramatic decrease in muscarinic receptor density [3, 13]. In contrast, levels of the bradykinin B2 receptor are rapidly increased in human bronchial smooth muscle exposed to IL-1β via a prostanoid-dependent regulation of gene transcription [12]. Surprisingly, fenoterol, a $β_2$-agonist, as well as other cAMP-elevating agents, significantly upregulates the expression of histamine H1 receptor in bovine ASM cells, an effect that involves both increased gene expression and mRNA stability [19]. This increase in H1 receptor expression was associated with an increase in ASM responsiveness to histamine in contraction studies. This may be important since

fenoterol may lead to the worsening of asthma by modulating, at least in part, bronchial hyperresponsiveness; see the review by Beasley et al. [20]. Figure 18.2 summarizes the potential mechanisms involved in the modulation of agonist-evoked calcium signaling in response to various stimuli.

### Increase in the calcium sensitivity of the contractile apparatus

Increase in the sensitivity of myofilaments to calcium also represents a mechanism by which the contractile function of ASM can be enhanced. Abnormal calcium sensitivity has been described in ASM derived from allergen-sensitized animals or from passively sensitized tissues; see the review by Schmidt and Rabe [21]. The role played by proinflammatory agents in the impairment of calcium sensitivity has been suggested in vitro. Nakatani et al. [22], by simultaneously measuring $[Ca^{2+}]_i$ and isometric tensions in response to acetylcholine, showed that brief exposure to TNF-α enhanced the calcium sensitivity of contractile elements in bovine tracheal smooth muscle. Surprisingly, TNF-α did not affect the calcium signals induced by acetylcholine. In guinea pig tracheal smooth muscle, short-term treatment with TNF-α also increased calcium sensitivity of the contractile apparatus [23].

Together, these studies suggest that, in addition to the modulation of receptor-coupled signal transduction, increase in calcium sensitization of contractile elements represents another downstream target potentially modulated by proinflammatory agents.

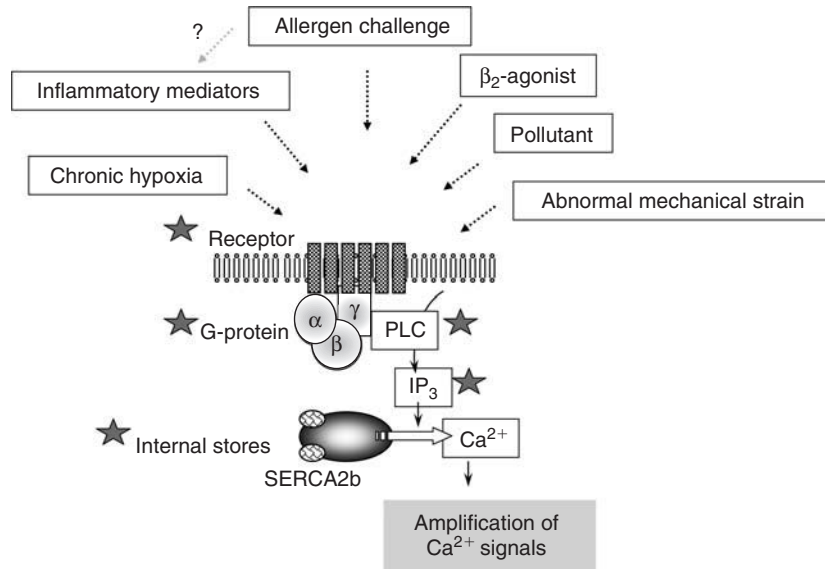
Because ASM is an essential effector cell modulating bronchoconstriction, changes in ASM properties can be regarded as a potential mechanism contributing to the increased ASM contractility associated with asthma. A variety of stimuli present in asthmatic airways may induce hyperresponsiveness by modulating calcium signaling in


**FIG. 18.2** Potential modulators of contractile receptor-coupled calcium signaling in ASM. A variety of stimuli may induce a "hyperresponsive" phenotype, which modulates G-protein-coupled receptor activation in response to agonists. (?) indicates the possible role played by inflammatory mediators in allergen-induced changes in calcium responsiveness to contractile agonist. The potential intracellular targets underlying the increase in calcium responsiveness induced by these various stimuli are shown with a bold star. IP$_3$: inositol-1,3,5 trisphosphate; PLC: phospholipase C; [Ca$^{2+}$]$_i$: intracellular calcium.

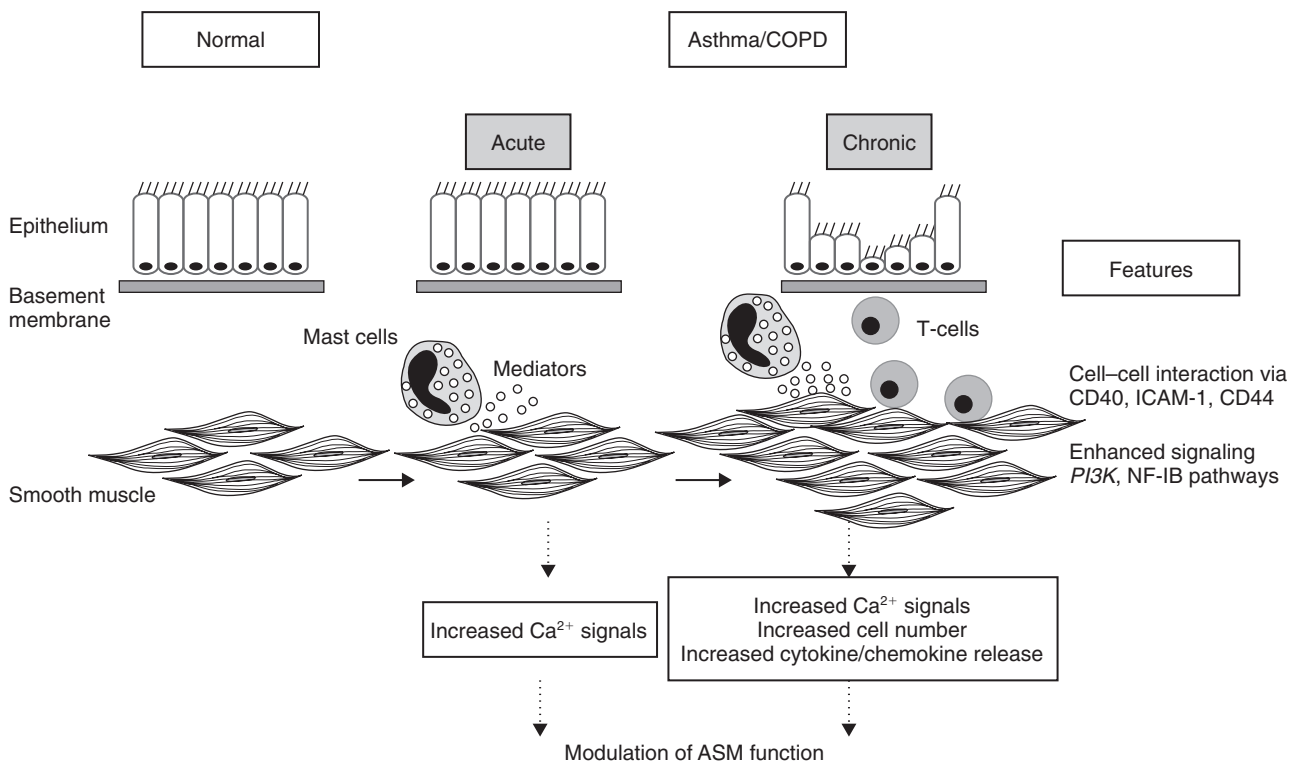

**FIG. 18.3** Factors affecting ASM function in acute and chronic state of asthma/COPD. During the acute inflammation, a variety of mediators, such as cytokines, can modulate ASM contractile function by enhancing calcium signaling to agonists. These mediators regulate the recruitment and activation of eosinophils and T-lymphocytes in the airway mucosa, a characteristic histopathological feature of the chronic disease. The persistence of airway inflammation via the production of cytokines and chemokines by both inflammatory as well as structural cells has the potential to directly stimulate ASM proliferation or indirectly as a result of T-cell-ASM interaction mediated by cell surface expression of various CAM proteins such as ICAM-1, CD40, and CD44. Enhanced activation of PI3K or the transcription factor NF-κB in ASM may also stimulate mitogenic and synthetic functions.

response to contractile agonists as summarized in Fig. 18.3. Whether this amplification of calcium signaling contributes to the increased contractility in asthmatic patients remains to be investigated.

## ASM CELL PROLIFERATION

Increased ASM mass is a characteristic histopathological finding in the airways of chronic severe asthmatics and of COPD patients. Although increased ASM mass is, in part, due to ASM cell proliferation, the mechanisms that regulate ASM cell growth remain unclear. Many studies have characterized the stimulation of ASM growth in response to mitogenic agents such as polypeptide growth factors, inflammatory mediators, and cytokines. The observation that contractile agonists induce smooth muscle cell proliferation may be a critical link between the chronic stimulation of muscle contraction and the myocyte proliferation [24]. Although the specific cellular and the molecular mechanisms by which agonists induce cell proliferation remain to be elucidated, similarities exist between signal transduction processes activated by these agents and those of known growth factors, which can also stimulate smooth muscle contraction. The complex interaction between signaling pathways that induce myocyte proliferation and those that inhibit cell growth by stimulation of apoptosis may promote airway remodeling as seen in the bronchi of patients with asthma, bronchiolitis obliterans, or chronic bronchitis.

Smooth muscle cell proliferation is stimulated by mitogens that fall into two broad categories:

1. those that activate receptors with intrinsic tyrosine kinase activity (RTK);
2. those that mediate their effects through receptors coupled to heterotrimeric GTP binding proteins (G-proteins) and activate nonreceptor-linked tyrosine kinases found in the cytoplasm.

Although both pathways increase cytosolic calcium through activation of PLC, different PLC isoenzymes appear to be involved. Activated PLC hydrolyzes phosphatidylinositol bisphosphate ($PIP_2$) to inositol trisphosphate ($IP_3$) and diacylglycerol (DAG). These second messengers activate other cytosolic tyrosine kinases as well as serine and threonine kinases (protein kinase C, G, and N) that have pleiotropic effects including the activation of proto-oncogenes, which are a family of cellular genes (*c-onc*), that control normal cellular growth and differentiation. Recent reviews attempted to summarize current progress in our understanding of cellular mechanisms leading to smooth muscle cell proliferation [25–28]. This section will focus on the role of PLC activation and the phosphatidylinositol 3-kinase (PI3K) signaling pathway in smooth muscle cell mitogenesis.

### PLC activation

Receptors with intrinsic tyrosine kinase activity and those coupled to G-proteins both activate specific PLC isoforms. These PLCs are the critical regulatory enzymes in the activation of the PI pathway. The $\gamma$ family of PLC contains src-homology SH2 and SH3 domains and is regulated by tyrosine phosphorylation. In ASM cells, some growth factors which activate receptors with intrinsic tyrosine kinases have been identified. Platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) in human ASM cells [29–31] and IGF-1 in bovine and rabbit ASM cells [32–34] have been shown to induce myocyte proliferation. However, the role of PLC-$\gamma_1$ activation in modulating ASM cell growth remains unknown.

Other PLC isoforms are controlled by G-proteins and/or calcium. Although the role of PLC activation in mediating G-protein-dependent cell growth is complex, G-protein activation appears critically important in transducing contractile agonist-induced cell growth. G-proteins are composed of three distinct subunits, $\alpha$, $\beta$, and $\gamma$, the latter two existing as a tightly associated complex [35]. Although $\alpha$-subunits were considered the functional components important in downstream signaling events, recent evidence suggests that $\beta\gamma$-subunits also play a critical role in modulating cell function [36].

Advances in single-cell microinjection techniques in combination with the development of neutralizing antibodies to specific G$\alpha$ subunits have enabled investigators to characterize the role of G-protein activation in cell proliferation. Using these techniques, studies with 3T3 fibroblasts have determined that, while both thrombin and bradykinin required $G_q$ activation to mobilize cytosolic calcium, to generate $IP_3$ and to induce mitogenesis, thrombin, but not bradykinin, induces cell growth by stimulating $G_{i2}$ [37]. These studies determined that a single mitogen may require functional coupling to distinct subtypes of G-proteins in order to stimulate cell growth. Collectively, these data also provide a mechanism to explain why some, but not all, agonists induce cell proliferation while mobilizing comparable levels of cytosolic calcium.

Recently, the role of PLC activation and $IP_3$ in mediating contractile agonist-induced ASM cell growth has been explored. Several contractile agonists, which mediate their effects through GPCRs, induce ASM cell proliferation. Studies have determined that histamine [38] and serotonin induce canine and porcine ASM cell proliferation. Endothelin-1, leukotriene $D_4$ and U-46619, a thromboxane $A_2$ mimetic, induce rabbit ASM cell growth [39], and thrombin induces mitogenesis in human ASM cells [30]. Although the mechanisms that mediate these effects are unknown, agonist-induced cell growth probably is modulated by activation of G-proteins in a manner similar to that described in vascular smooth muscle (VSM).

Using human ASM cells, Panettieri *et al.* [30] examined whether contractile agonist-induced human ASM cell growth was dependent on PLC activation and $IP_3$ formation. These investigators examined the relative effects of bradykinin and thrombin on myocyte proliferation and PI turnover. Thrombin, but not bradykinin, stimulated ASM cell proliferation despite a fivefold greater increase in [$^3$H]-inositol phosphate formation in cells treated with bradykinin as compared with those treated with thrombin. Inhibition of PLC activation with U-73122 had no effect on thrombin- or

EGF-induced myocyte proliferation. In addition, pertussis toxin completely inhibited thrombin-induced ASM cell growth but had no effect on PI turnover induced by either thrombin or bradykinin [30]. Taken together, these studies suggest that thrombin induced human ASM cell growth by activation of a pathway that was pertussis toxin-sensitive and independent of PLC activation or PI turnover.

Compared to RTK-dependent growth factors, contractile agonists, with the exception of thrombin and sphingosine-1-phosphate, appear to be less effective human ASM mitogens [40]. In cultured human ASM cells, $100\,\mu$mol/l histamine or serotonin induces two- to three-fold increases in [$^3$H]-thymidine incorporation as compared with that obtained from unstimulated cells. EGF, serum, or phorbol esters, which directly activate protein kinase C, induce 20–30 fold increases in [$^3$H]-thymidine incorporation [41]. In rabbit ASM cells, endothelin-1 induces cell proliferation by activating phospholipase A$_2$, and by generating thromboxane A$_2$ and LTD$_4$ [39, 42]. In human ASM cells, however, endothelin-1, thromboxane A$_2$ and LTD$_4$ appear to have little effect on ASM cell proliferation despite these agonists inducing increases in cytosolic calcium [30, 43, 44].

Clearly, interspecies variability exists with regard to contractile agonist-induced cell proliferation. These models, however, may prove useful in dissecting downstream signaling events that modulate the differential effects of contractile agonists on ASM cell proliferation.

## PI3K signaling pathway

The PI3K signaling pathway is a highly conserved signal transduction network regulating a variety of cellular functions including cell proliferation, differentiation, transformation, cell motility, and apoptosis [45, 46]. PI3Ks are a subfamily of lipid kinases that catalyze the addition of phosphate molecules specifically to the 3-position of the inositol ring of phosphoinositides [47]. Tumor suppressor PTEN (phosphatases and tensin homolog) negatively regulates PI3K signaling by specifically dephosphorylating the 3′-OH position of the inositol ring of the lipid second messengers phosphatidylinositol-3,4,5-trisphosphate. [48–50], PI3K lipid products are not substrates for the PI-specific PLC enzymes that cleave inositol phospholipids into membrane-bound DAG and soluble inositol phosphates. The 3-phosphoinositides function as second messengers and activate downstream effector molecules such as PDK1, p70s6 kinase (S6K1), protein kinase Cζ, and Akt [47, 51]. The ability of PI3K to regulate diverse functions may be due to the existence of multiple isoforms that have specific substrate specificities and that reside in unique cytoplasmic locations within the cell [52].

PI3K isoforms can be divided into three classes based on their structure and substrate specificity. Class IA PI3Ks are cytoplasmic heterodimers composed of a 110-kDa (p110α, β, or δ) catalytic subunit and an 85-kDa (p85, p55, or p50) adaptor protein. Catalytic subunits p110α and p110β are ubiquitously expressed in mammalian cells. Catalytic subunit p110δ is expressed predominantly in lymphocytes and lymphoid tissues and, therefore, may play a

role in PI3K-mediated signaling of immune responses [53]. Class IA isoforms are mainly activated by receptor and non-receptor tyrosine kinases while Class IB p110γ is activated by Gβγ subunits of GPCRs [54]. Class II isoforms are mainly associated with the phospholipid membranes and are present in the endoplasmic reticulum and Golgi apparatus [55]. Class III isoforms, structurally related to yeast vesicular sorting protein Vps34p [56], are mammalian homologs that use only membrane phosphatidylinositol as a substrate and generate phosphatidylinositol-3-monophosphate.

PI3K activation by multiple inputs, such as growth factors, insulin, cytokines, cell–cell, and cell–matrix adhesion, provided by both receptor and nonreceptor tyrosine kinases leads to activation of serine–threonine kinase Akt (Fig. 18.4). Downstream of PI3K the tumor suppressor complex tuberous sclerosis complex (TSC)1/TSC2 is subject to direct inhibitory phosphorylation by Akt [57–59]. TSC2 forms a complex with tumor suppressor TSC1 and regulates mTOR/S6K1 signaling [60] by directly controlling the activity of the small GTPase Rheb via the GTPase activating protein (GAP) domain of TSC2 [61]. Rheb directly binds to Raptor [62, 63] and controls the activity of the mTOR/Raptor complex (mTORC1), which, in turn, directly phosphorylates and activates S6K1 (Fig. 18.4).

**FIG. 18.4** The PI3K signaling pathway is critical for regulating cell growth and proliferation. Growth-factor (GF)-induced activation of PI3K initiates a signaling cascade involving sequential activation of phosphoinositide-dependent kinase (PDK) and Akt/PKB. Akt/PKB-dependent phosphorylation of TSC2 results in dissociation of TSC1/TSC2 membrane complex and activation of Rheb. Next, Rheb activates mTOR complex 1 (mTORC1) which consists of mTOR, Raptor, and GβL. This is followed by activation of S6K1 with subsequent phosphorylation of ribosomal protein S6. In parallel, mTOR-dependent phosphorylation of the binding protein 4E releases from the inhibitory complex eukaryotic initiation factor 4E (eIF-4E), which initiates protein synthesis, resulting in cell growth and proliferation. Rapamycin-insensitive complex mTORC2, which consists of mTOR, Rictor, and GβL, regulates Akt/PKB phosphorylation; however, the precise mechanism of mTORC2 regulation by Rheb and TSC1/TSC2 remains to be elucidated. 4E-BP1: eIF-4E binding protein; Rheb: Ras homolog enriched in brain; RTK: receptor tyrosine kinase.

mTOR is a part of both complexes: the rapamycin-sensitive mTOR/Raptor (TORC1) phosphorylating S6K1, and the rapamycin-insensitive mTOR/Rictor (TORC2) phosphorylating Akt [64] and regulating Rac1 activation [65]. The PI3K-TSC1/TSC2-Rheb-mTOR-S6K1 signaling pathway is highly conserved across species, and controls cell growth and proliferation [45, 46, 61].

Studies demonstrate that PI3K signaling cascade plays a critical role in regulating human airway and pulmonary arterial VSM cell proliferation [66, 67]. Wortmannin and LY294002, two potent inhibitors of PI3K, inhibit DNA synthesis in bovine ASM, porcine, and rat VSM cells stimulated with PDGF, basic fibroblast growth factor, angiotensin II, or serum [68–71]. Stimulation of $\alpha_1$ adrenergic receptors with noradrenaline activated mitogenesis, Ras, MAPK, and PI3K in human VSM cells in a wortmannin-sensitive manner [72]. In rat thoracic aorta VSM cells, wortmannin completely blocked angiotensin II-induced Ras activation but had no effect on mitogen-activated protein kinase (MAPK) activation or protein synthesis [73]. Thrombin, which induces human ASM cell growth by activating a receptor presumably coupled to both $G_i$ and $G_q$ proteins [30], requires PI3K activation to mediate its growth effects [74]. In bovine ASM, the mitogenic effects of PDGF or endothelin-1 (ET-1) have been attributed to their ability to stimulate PI3K or S6K1. These data suggest that in both airway and VSM cells PI3K is involved in mitogenic signaling induced by numerous agents.

In order to determine whether PI3K activation is necessary or sufficient to stimulate human ASM DNA synthesis, Krymskaya *et al*. [67] used transfected cells with a chimeric model of Class IA PI3K in which the inter-SH2 region of p85 regulatory subunit was covalently linked to its binding site at the p110 N-terminal region of the catalytic subunit [75]. Transient expression of constitutively active p110* was sufficient to induce DNA synthesis in ASM cells in the absence of mitogens [67]. Interestingly, in human ASM cells the level of p110*-induced DNA synthesis was markedly lower than that induced by EGF, thrombin, or serum; and thus, although PI3K activation is sufficient to induce DNA synthesis in ASM cells, other signaling pathways that act in parallel or that are more effective inducers of PI3K may play a role in modulating mitogen-induced DNA synthesis in these cells.

In numerous cell types, PI3K has been shown to be an important mediator of S6K1 activation in response to serum and growth factors [76]. S6K1 is a critical enzyme for mitogen-induced cell cycle progression through the $G_1$ phase and translational control of mRNA transcripts that contain a polypyrimidine tract at their transcriptional start site [77].

EGF and thrombin significantly stimulate S6K1, and wortmannin, LY294002, and rapamycin completely block this activation in ASM cells [74]. Moreover, transient expression of constitutively active p110* PI3K activates S6K1 in the absence of stimulation with mitogens, while overexpression of a dominant-negative $\Delta$p85 PI3K abolished EGF- and thrombin-induced S6K1 activation [74]. Thus, EGF and thrombin induce activation of S6K1 in human ASM cells and mitogen-induced activation of S6K1 appears PI3K dependent.

A recent study demonstrated that GPCR activation by inflammatory and contractile agents can synergize with RTK activation to augment human ASM growth. In EGF-stimulated cells, GPCR-mediated potentiation does not appear mechanistically linked to increased EGFR (epidermal growth factor receptor) or p42/p44 MAPK activation but is associated with sustained activation of S6K1 for several hours after the initial early phase of activation. These findings not only provide insight into mechanisms by which inflammation contributes to ASM hyperplasia/hypertrophy in diseases such as asthma and COPD, but also suggest a general mechanism by which GPCRs and RTKs interact to promote cell growth [78].

PDGF, EGF, and thrombin, which transduce their signals by activating distinct pathways through RTKs and GPCR, induce PI3K activity in human ASM cells [67, 74, 79, 80]. Importantly, cross talk between GPCR and RTK signaling pathways occurs at the PI3K levels and promotes a synergy among growth factors and contractile agonists [78, 79, 81]. Src protein tyrosine kinase integrates GPCR- and RTK-induced signaling pathways that ultimately regulate cell proliferation, migration, differentiation, and gene transcription [82, 83]. Src kinases have a well-established role in the regulation of cell proliferation. The Src tyrosine kinase is the first tyrosine kinase to be identified and linked to the regulation of cell proliferation [82, 83]. Because more than one mechanism is involved in Src activation, this enzyme is critical in transducing signals, which originate through GPCRs and RTKs and result in integrated cellular responses, such as DNA synthesis and migration. The cellular functions regulated by Src were identified by using predominantly overexpressed Src and its mutants in established immortalized cell lines and *in vitro* assays. Using selective cell-permeable Src inhibitors PP1 and PP2, Src inhibition of DNA synthesis was demonstrated in guinea pig ASM [84] and rat aortic smooth muscle cells [85]. In our study using pharmacological and molecular approaches, we demonstrate that Src is necessary and sufficient for human ASM DNA synthesis. Interestingly, PP2 had differential effects on EGF- versus PDGF- and thrombin-induced DNA synthesis: $IC_{50}$ for EGF was $\sim5.5\,\mu M$, which is a magnitude higher compared to the $IC_{50}$ for PDGF and thrombin, which was $\sim0.3\,\mu M$ for both agonists. The high sensitivity of thrombin-induced DNA synthesis to Src inhibition is potentially due to a critical role of Src in modulating mitogenic signaling from activated GPCRs to its downstream targets [86, 87]. We also found that the differential Src regulation of cell proliferation correlated with differential activation of Src-associated PI3K. Thus, upon stimulation of human ASM cells with PDGF or thrombin, PI3K activity was associated with Src but not in cells stimulated with EGF. Since PI3K activation is critical for cell proliferation, the lack of Src-associated PI3K activation may explain the insensitivity of EGF-induced ASM DNA synthesis to blocking Src. Importantly, our previously published study identified the signaling pathway of EGF-dependent PI3K activation in HASM cells, which involved activation of the ErbB2 receptor of the EGF receptor family [88]. Collectively, these data suggest a differential role of Src in growth promoting signaling stimulated by EGF, PDGF, and thrombin.

## ASM: AN IMMUNOMODULATORY CELL

Asthma is a disease characterized, in part, by reversible airflow obstruction, hyperresponsiveness, and inflammation. COPD, which includes chronic bronchitis, emphysema, and bronchiectasis, is characterized by predominantly irreversible airflow obstruction associated with neutrophilic airway inflammation. Traditional concepts concerning airway inflammation have focused on trafficking leukocytes and on the effects of inflammatory mediators, cytokines, and chemokines secreted by these cells. ASM, the major effector cell responsible for bronchomotor tone, has been viewed as a passive tissue responding to neurohumoral control and inflammatory mediators. New evidence, however, suggests that ASM may secrete cytokines and chemokines and express cell adhesion molecules (CAMs) that are important in modulating submucosal airway inflammation. The cellular and molecular mechanisms that regulate the immunomodulatory functions of ASM may offer new and important therapeutic targets in treating these common lung diseases.

### Chemokine and cytokine release by ASM cells

The various cell types that infiltrate the inflamed submucosa present the potential for many important cell–cell interactions. Eosinophils, macrophages, neutrophils, and lymphocytes initiate and perpetuate airway inflammation by producing proinflammatory mediators. Evidence also suggests that exposure of ASM to cytokines or growth factors alters contractility and calcium homeostasis [1] and induces SMC hypertrophy and hyperplasia; see the review by Lazaar *et al.* [89].

Studies now show that ASM cells secrete a number of cytokines and chemoattractants. Studies of bronchial biopsies in mild asthmatics reveal constitutive staining for RANTES, a CC chemokine, in ASM [90]; *in vitro*, RANTES secretion is induced by TNF-$\alpha$ and IFN-$\gamma$ [91–93]. Other chemokines that are secreted by ASM cells include eotaxin, an eosinophil chemoattractant, and monocyte chemotactic proteins (MCP)-1, MCP-2, MCP-3 [93–95].

Similarly, the CXC chemokine IL-8 is also secreted by ASM in response to TNF-$\alpha$, IL-1$\beta$, and bradykinin, a contractile agonist [96, 97]. IL-8 has been described to regulate both proliferation and migratory function of ASM cells [98]. Understanding the factors that stimulate IL-8 production may be of therapeutic benefit for the treatment of asthma. Studies found that IL-8 is induced by several factors including $\beta$ tryptase, the most abundant mast cell product [99] as well as IL-17/IL-1$\beta$ via both transcription factors, AP-1 and NF-$\kappa$B [100]. Others found that the antimicrobial peptide LL-37 also induces the production of IL-8 [101] providing a novel mechanism through which inflammatory cell products could participate in the pathogenesis of asthma. Additional studies showed that IL-4 also stimulates eotaxin/CCL-11 expression in ASM cells, in part via the activation of STAT6 transcription factor [102] while Rahman *et al.* found that (p38, p42/p44 ERK, JNK) signaling pathways play a critical role in IL-17A-induced eotaxin-1/CC chemokine ligand 11 [103]. Extracellular matrix (ECM) proteins seem to play an important role in the regulation of eotaxin induced by different interleukins, IL-13, IL-1$\beta$, or TNF-$\alpha$ in ASM cells cultured from subjects with asthma compared with healthy donors [104]. Interestingly, increased expression of eotaxin is observed during the co-culture of ASM with mast cells [105], suggesting that cell–cell interaction is important to consider in the regulation of causes of airway inflammation.

In asthma and COPD, $\beta$-adrenergic agonists, by elevating [cAMP]$_i$, promote bronchodilation. Studies have investigated whether cAMP pathways also modulate chemokine secretion by ASM cells. In TNF-$\alpha$-stimulated ASM cells, eotaxin and RANTES expression was potently and effectively inhibited by isoproterenol, PGE$_2$, dibutyl-cAMP, or phosphodiesterase inhibitors, rolipram and cilomilast [91, 106]. TNF-$\alpha$-induced IL-8 secretion was inhibited by the combination of cAMP-mobilizing agents and corticosteroids [107]. Similarly, sphingosine-1-phosphate, which activates a Gs-protein-coupled receptor and increases [cAMP]$_i$, abrogated TNF-$\alpha$-induced RANTES secretion in ASM cells [108].

Current evidence suggests that chemokine secretion induced by inflammatory mediators is inhibited by dexamethasone in human ASM cells. Cytokine-induced secretion of RANTES [91–93], MCP [93], eotaxin [106], and GM-CSF [109] was abrogated with corticosteroids. In most of these studies, corticosteroid and cAMP-mobilizing agents also acted additively to inhibit chemokine secretion.

IL-6, a pleiotropic cytokine, induces smooth muscle cell hyperplasia [110], but also modulates B- and T-cell proliferation and immunoglobulin secretion. IL-6 secretion by ASM cells is inducible by multiple stimuli, including IL-1$\beta$, TNF-$\alpha$, TGF-$\beta$, and sphingosine-1-phosphate, a recently described mediator in asthma [91, 108, 111, 112]. Although corticosteroids are potent inhibitors of IL-6 secretion [112], agents that elevate [cAMP]$_i$ actually increase IL-6 secretion [91]. This suggests an intriguing role for IL-6 in regulating airway hyperreactivity and is in agreement with murine models in which IL-6 overexpression promotes airway hyporesponsiveness [113].

Finally, additional cytokines that are secreted by human ASM cells include IL-1$\beta$ and other IL-6 family cytokines, such as leukemia inhibitory factor and IL-11 [111, 114, 115]. ASM cells may also play a role in promoting both the recruitment and the survival of eosinophils by secretion of GM-CSF and IL-5 [109, 114, 116].

### Receptors involved in cell adhesion

CAMs mediate leukocyte–endothelial cell interactions during the process of cell recruitment and homing [117] (Chapter 21). The expression and activation of a cascade of CAMs that include selectins, integrins, and members of the immunoglobulin superfamily, as well as the local production of chemoattractants, leads to leukocyte adhesion and transmigration into lymph nodes and sites of inflammation involving nonlymphoid tissues.

In addition to mediating leukocyte extravasation and transendothelial migration, CAMs promote submucosal or

subendothelial contact with cellular and ECM components. New evidence suggests that CAMs mediate inflammatory cell–stromal cell interactions that may contribute to airway inflammation. ASM cells express intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1, which are inducible by a wide range of inflammatory mediators. Contractile agonists, such as bradykinin and histamine, in contrast, have little effect on ASM CAM expression [118]. ASM cells also constitutively express CD44, the primary receptor of the matrix protein hyaluronan [118]. Activated T-lymphocytes adhere via LFA-1 and VLA-4 to cytokine-induced ICAM-1 and VCAM-1 on cultured human ASM cells. Moreover, an integrin-independent component of lymphocyte–smooth muscle cell adhesion appeared to be mediated by CD44–hyaluronan interactions [118].

Current hypotheses suggest that steroids may directly inhibit gene expression, such as CAMs, by altering gene promoter activity and/or by abrogating critical signaling events such as NF-κB or AP-1 activation that then modulate gene expression as shown in Fig. 18.5. Interestingly, dexamethasone had no effect on TNF-α- or IL-1β-induced NF-κB activation in human ASM cells [119]. Further, cytokine-induced ICAM-1 expression in ASM cells, which is completely dependent on NF-κB activation, was not affected by dexamethasone, whereas IL-1β-induced cyclooxygenase-2 expression was abrogated [119–121]. In contrast, cytokine-induced CAM expression is sensitive to cAMP-mobilizing agents [122].

## Receptors involved in leukocyte activation and immune modulation

CAMs can function as accessory molecules for leukocyte activation [117, 123, 124]. Whether CAMs expressed on smooth muscle serve this function remains controversial. ASM cells do express major histocompatibility complex (MHC) class II and CD40 following stimulation with IFN-γ [125, 126]. Recent studies also suggest that human ASM cells express low levels of CD80 (B7.1) and CD86 (B7.2) [127]. The physiological relevance of these findings remains unknown since ASM cells cannot present alloantigen to CD4 T-cells, despite the expression of MHC class II and costimulatory molecules [125].

Functionally, however, adhesion of stimulated CD4 T-cells can induce smooth muscle cell DNA synthesis [118]. This appears to require direct cell–cell contact and cannot be mimicked by treatment of the cells with T-cell conditioned

**FIG. 18.5** Putative signaling pathways that regulate cytokine-induced synthetic responses in ASM cells. [cAMP]$_i$-mobilizing agents inhibit cytokine-induced chemokine and CAM expression. IL-6 secretion, however, is augmented by agents that increase [cAMP]$_i$. Cytokine-induced NF-κB activation in human ASM is corticosteroid-insensitive. A-kinase: cAMP-dependent protein kinase A; CRE: cAMP response element; ERK: extracellular signal-regulated kinase; GR: glucocorticoid receptor; GRE: glucocorticoid response element; Gs: guanine-nucleotide binding protein; JNK: jun kinase; NF-κB: nuclear factor κB; PDE: phosphodiesterase.

medium. In addition, ligation of CD40 on ASM increases intracellular calcium as well as IL-6 secretion, while cross-linking VCAM-1 cells activates PI3K and augments growth factor-induced ASM cell proliferation [126, 128]. These studies highlight the fact that direct interactions between leukocytes and smooth muscle cells via immune receptors, such as CD40, or adhesion receptors, such as ICAM-1 or VCAM-1, contribute to the modulation of the local milieu resulting in smooth muscle cell activation.

Increased amounts of nitric oxide (NO) have been detected in patients with asthma; see the review by Gaston *et al*. [129] and Chapter 32. NO appears to have a selective-suppressive effect on the Th1 subset of T-helper cells, suggesting that increased levels of NO may therefore lead to the predominantly Th2-type response associated with asthma. NO synthase has been demonstrated in ASM cells where it results in an inhibition of ASM cell proliferation [130, 131]. Thus the role of ASM-derived NO needs to be further defined, as it may have both beneficial and deleterious effects in the airway.

ASM cells produce large amounts of $PGE_2$, and to a lesser extent other prostanoids, following stimulation with proinflammatory cytokines [120]. Although $PGE_2$ is a potent bronchodilator, it also has significant immunological effects. For example, $PGE_2$ can decrease expression of CD23 (FcγRII), which has been shown to be expressed on human ASM cells [132], and synergize with IL-4 to induce IgE synthesis [133]. Release of $PGE_2$ by ASM cells may also be important in modulating the inflammatory milieu by inhibiting smooth muscle cell secretion of chemokines [134].

## Therapeutic modulation of inflammatory gene expression

Issa and colleagues uncovered a novel mechanism by which steroids suppress cytokine-induced inflammatory genes in human ASM cells [135]. MPK-1 was found to be essential in mediating the inhibitory action of dexamethasone on growth-related oncogene protein (GRO)-α induced by IL-1β and TNF-α, thus confirming the role of MAPK in inflammatory gene regulation. Activation of MAPK pathways by IL-1β and TNF-α seem to be important in the regulation of thymic stromal lymphopoietin, a novel factor that promotes dendritic cell-mediated T-helper (Th)-2 inflammatory responses [136]. Other steroid-sensitive genes include TLR2, TLR3, and TLR4 reported to be induced by TNF-α in ASM cells [137]. CD38 was among the steroid-sensitive genes as dexamethasone completely abrogated its expression and increased enzymatic activity following treatment with TNF-α [138]. The observation that IFN can act as an effective inhibitor on some, but not all, TNF-α-inducible inflammatory genes [139] suggests that a better understanding of the IFN-dependent pathways could provide new insight into the design of more potent anti-inflammatory drugs. Macrolides, such as erythromycin and azithromycin, have been recently shown to suppress IL-17-induced production of IL-8 and 8-isoprostane in ASM cells while immunosuppressive agents had no effect [140]. Targeting IKKβ was recently found to be an alternative option for the suppression of a number of inflammatory genes including

ICAM-1, IL-6, IL-8, GM-CSF, RANTES, MCP-1, GRO-α, and NAP-2 [141].

Whether ASM is a therapeutic target for steroids in asthma is yet unclear. Several *in vitro* studies in cultured ASM cells confirmed that glucocorticoids (GCs) are effective in suppressing induction of inflammatory genes including IL-6, eotaxin, RANTES, GM-CSF, ICAM-1, and CD38 8 to name just a few [106, 119, 142–145]. Further, *in situ* hybridization and immunohistochemistry studies revealed the *in vivo* expression of glucocorticoid receptor (GR) in ASM of both normal and asthmatic subjects [146]. We previously showed that cultured ASM cells express both GR isoforms, GR-α, and under certain inflammatory conditions, GR-β [143]. Interestingly, Roth *et al*. [147] showed GC treatment induced GR nuclear translocation from cytosol to the nucleus in bronchial smooth muscle cell lines from healthy individuals or subjects with asthma and those with emphysema. Similar results were obtained in cultured ASM obtained from Roth *et al*. in 2002 [148, 149]. The activation of GR by GC through its binding to a glucocorticoid response element (GRE) DNA sequence has also been demonstrated in cultured ASM cells [143, 147, 149].

Interestingly, although steroid effects on human ASM cells have been investigated [150], their modulatory effects on gene expression are complex and poorly characterized. First, the effects of steroids are gene specific. For example, reports showed that dexamethasone effectively inhibits cytokine-induced IL-6, RANTES or eotaxin expression, while the same steroid has little effect on cytokine-induced ICAM-1 expression [106, 119, 142]. Second, steroid-suppressive effects are time dependent since dexamethasone partially abrogates cytokine-mediated ICAM-1 expression at early time points, but has no effect at later time points [119]. Third, steroid inhibitory action is also stimulus specific. While dexamethasone significantly inhibits IL-1β-induced GM-GSF secretion, it has only a partial effect on GM-GSF secretion induced by thrombin [144].

Recently, Miller *et al*. [151], using an animal model of asthma, showed that GC treatment significantly reduced allergen-induced increases in peribronchial collagen deposition and levels of total lung collagen but failed to reduce allergen-induced increases in the thickness of the peribronchial smooth muscle. In line with this, Roth *et al*. [147] showed that GC failed to inhibit the proliferative response in bronchial ASM from patients with asthma. Further *in vitro* studies showed that the anti-proliferative and anti-migratory effects of the GC were impaired by contact of ASM with collagen. GC also failed to inhibit ASM cells cultured on collagen, but not on laminin [148], suggesting that in the collagen-rich microenvironment of the inflamed and fibrotic asthmatic airway, ASM may contribute to steroid resistance. In addition, we also recently showed that steroid-suppressive effects are dramatically impaired in ASM cells treated with multiple cytokines [143]. Indeed, the specific combination of TNF-α with IFNs, but not with IL-1β or IL-13, impairs the actions of multiple classes of GCs, fluticasone, dexamethasone, and budesonide [143] by a mechanism involving the upregulation of GR-β isoform. Recently, Tliba and colleagues [152] found for the first time that an increased level of IRF-1 by "pro-asthmatic" cytokines is insensitive to GCs and can dramatically influence the

anti-inflammatory action of steroids via mechanisms that remain to be determined. This study supports the hypothesis that inflammation is a key modulator of steroid responsiveness in structural airway cells.

Collectively, the fact that ASM cells can secrete and express different immunomodulatory proteins, combined with the functional expression of GR, give ASM cells a particular importance as cellular targets for inhaled GC. However, further *in vivo* studies are needed to confirm the aforementioned *in vitro* observations to determine the role of ASM in modulating the anti-inflammatory effects of GC, notably in steroid-resistant patients.

While ASM has long been established as a key effector cell in the pathogenesis of asthma, its role in COPD has only recently been appreciated. Several studies have demonstrated increased ASM mass in the small airways of smokers with airflow obstruction compared to smokers with normal lung function [153–156]. In contrast to asthma, however, where large, central airways are the predominant site of ASM hypertrophy and hyperplasia, ASM hypertrophy in COPD is uniquely observed in small airways with a diameter of approximately 2 mm [155, 157, 158]. The extent of ASM hypertrophy observed in small airways correlates with the severity of airflow obstruction [155, 156], though associated increases in matrix deposition in the walls of these airways may also contribute to airflow obstruction by limiting the extent to which ASM relaxation results in increased airway luminal diameter [159]. Airway inflammation appears to be one important cause of ASM hypertrophy in COPD, as activated T-lymphocytes have been demonstrated to bind VCAM-1 and CD44, inducing DNA synthesis [118].

While ASM has historically been viewed as a target tissue, regulating bronchomotor tone and responding to neurohumoral control and inflammatory mediators, emerging evidence suggests that ASM may also play an important immunomodulatory role in the small airway inflammation characteristic of COPD [160, 161]. ASM cells are capable of expressing numerous proinflammatory and chemotactic cytokines and chemokines germane to COPD, in addition to several relevant growth factors and proteases, as outlined above. Further, the pattern of ASM gene expression depends highly on the inflammatory environment [93, 96, 97, 162, 163], underscoring the importance of interactions between ASM and the nearby epithelium. A great deal of work remains to be done to elucidate the role of ASM in the pathogenesis of COPD, but all available evidence indicates that it is likely an important component of the pathologic processes leading to airway remodeling and irreversible airflow obstruction.

## SUMMARY

New evidence suggests that ASM, the major effector cell regulating bronchomotor tone, also plays an important role as an immunomodulatory cell. ASM, exposed to a variety of mediators and cytokines, can undergo phenotypic changes that may be important in the pathogenesis of asthma and COPD. ASM, which secretes chemokines and cytokines, may participate in or even perpetuate the mucosal inflammatory changes via the activation and the recruitment of inflammatory cells. Further, cytokine-induced alterations in calcium homeostasis render the ASM hyperresponsive to contractile agonists. In chronic severe asthma and COPD, ASM hypertrophy and hyperplasia may potentially render the asthmatic airway irreversibly obstructed.

Further elucidation of the cellular and the molecular mechanisms that regulate ASM function in asthma and COPD will offer new therapeutic targets in the treatment of asthma, chronic bronchitis, and emphysema.

## INTRODUCTION

Since the blood circulation typically participates in inflammatory processes at the tissue level, the vasculature of the tracheobronchial tree can be expected to undergo structural and functional changes in asthma and chronic obstructive pulmonary disease (COPD), conditions that are associated with airway inflammation. As will be shown in this chapter, there are distinct differences in the vascular abnormalities between asthma and COPD. The purpose of this chapter is to review the pathophysiological role of the tracheobronchial circulation in asthma and COPD and the vascular effects of pharmacologic interventions. The *in vivo* measurement of tracheobronchial blood flow in man usually captures subepithelial blood flow in the conducting airways, also termed airway blood flow (Qaw); therefore, this review will focus on Qaw in asthma and COPD, with a brief discussion of the normal airway circulation as background.

## NORMAL AIRWAY CIRCULATION

The airway circulation, which derives its blood from the systemic circulation, is the principal vascular supply to the airway wall (Fig. 19.1) [1]. Bronchial arteries usually arise from the aorta or intercostal arteries and form a peribronchial plexus surrounding the bronchial wall. Branches penetrate the muscular layer to form a subepithelial plexus. The two interconnected plexuses follow airways as far as the terminal bronchiole. Although bronchial capillaries anastomose freely with the pulmonary circulation

along the airways and anastomoses have been demonstrated at pre-, post-, and capillary-levels [2], venous blood from the intraparenchymal bronchial vasculature mainly drains through post-capillary pulmonary vessels [3] to the left heart [4]. Venous blood from the trachea and major bronchi drains through the vena azygos and superior vena cava to the right heart.

Under physiological conditions, total bronchial blood flow comprises 0.5–1% of cardiac output. The major part of blood flow is distributed to the subepithelial tissues where the microvasculature comprises 10–20% of tissue volume [5]. Subepithelial blood flow (Qaw) has been reported to range between 30 and 95 ml $min^{-1}$ 100 g wet $tissue^{-1}$ in different species including in human [6, 7]. Its main function presumably is to nourish the epithelium that has one of the highest metabolic rates in the body. In healthy human adults, Qaw in the tracheobronchial tree to a 200 μm depth from the epithelial surface amounts to between 25 and 40 μl $min^{-1}$ $ml^{-1}$, where ml reflects the anatomical dead space lined by the epithelium [8–10].

Qaw is influenced by a variety of factors (Table 19.1). Although adrenergic and cholinergic nerves have been demonstrated in the airway wall [11, 12], physiological and pharmacological studies suggest that the main nervous control of the airway circulation is by the sympathetic nervous system [11]. In different animal models, sympathetic nerve stimulation [13], close-arterial injection of adrenergic agonists [14], and inhalation of selective α-adrenergic agonists [15] have been shown to induce vasoconstriction. Selective $\beta_2$-adrenergic agonists increase bronchial blood flow in sheep [6, 8], a finding subsequently confirmed in humans [16] (Table 19.1). Parasympathetic nerve stimulation and intravascular administration of cholinergic

| VEGF | |

VIP: vasoactive intestinal polypeptide; PHI: polypeptide histidine isoleucine; PHM: polypeptide histidine methionine; NO: nitric oxide; SP: substance P; NKA: neurokinin A; CGRP: calcitonin gene related peptide; PAF: platelet-activating factor; 5-HT: serotonine; PG: prostaglandin; VEGF: vascular endothelial growth factor; NPY: neuropeptide Y; LT: leukotriene; TNF-α: tumor necrosis factor-α; ET-1: endothelin-1; GCS: glucocorticosteroids.

agonists cause vasodilatation in several animal models [11], whereas aerosolized acetylcholine has only minimal effects [17]. Nonadrenergic, noncholinergic mechanisms have also been described. Vasoactive intestinal polypeptide (VIP), polypeptide histidine isoleucine (PHI), or polypeptide histidine methionine (PHM) released by parasympathetic nerves are vasodilators, whereas neuropeptide Y (NPY) released by sympathetic nerves is a vasoconstrictor in the tracheobronchial circulation [13, 14]. Sensory neuropeptides, as substance P (SP), neurokinin A (NKA),

and calcitonin gene-related peptide (CGRP) released from unmyelinated sensory afferents induce vasodilation [11]. Nitrergic mechanisms have recently been reported to regulate bronchovascular tone and partially mediate β-adrenergic vasodilator responses [15, 18, 19]. Finally, physicochemical stresses including hydrostatic pressure, temperature, humidity, deviations from normal osmolarity, hypoxia, and acid–base relations have all been reported to influence airway blood flow [20]. These factors may be of relevance in asthma and COPD where hydrostatic airway and pleural pressures are altered by the abnormal lung mechanics; there may be disturbances in gas exchange; there is airway inflammation; and there may be hemodynamic changes with elevated pulmonary arterial, right atrial, and left atrial pressures due to secondary pulmonary hypertension or cardiovascular comorbidity.

## AIRWAY CIRCULATION IN ASTHMA

Allergic and non-allergic inflammation is considered a major factor in the vascular changes that have been associated with asthma [82]. The inflammatory mechanisms include the complex actions of inflammatory cells and mediators, neurotransmitters, and neuropeptides on vascular endothelial and smooth muscle cells. The main vascular manifestations are hyperemia, hyperpermeability, and edema formation.

### Structure

It has been recognized for many years that asthmatics have an increased cross-sectional submucosal vascular area, an
FIG. 19.2 Airway blood flow (Qaw) in healthy non-smokers (HNS), healthy ex-smokers (HES), current smokers (CS), COPD, COPD after long-term treatment with an inhaled corticosteroid (COPD p.ICS), asthma (A), and asthma after long-term treatment with an inhaled corticosteroid (A p.ICS). Mean values with SE in brackets. Adapted from Refs [9] and [29].

increased size and number of vessels in their airway wall, and intimal thickening [21–24]. This can be considered the vascular component of airway wall remodeling. The stimulus for new vessel formation in asthma is unclear, although various endothelial growth factors, inflammatory cytokines, and other putative angiogenic factors have been proposed [25–27]. It appears that the structural changes are already present during childhood and may even be present in atopic children without clinical asthma [28].

## Function

### Airway blood flow

Allergic and non-allergic airway inflammation has been shown to be associated with an increase in Qaw (Fig. 19.2) [6, 14]. This is also the case in subjects with stable asthma [8–10, 30]. An increase in Qaw is generally thought to result from dilatation of resistance arteries. Numerous inflammatory mediators have a vasodilator effect [8]. Histamine has a triphasic effect characterized by an initial vasodilation, followed by vasoconstriction and then a long-lasting vasodilation [8]. Sensory neuropeptides released from afferent nerves are also strong vasodilators. Reflex bronchial vasodilation is largely mediated by cholinergic and noncholinergic parasympathetic vagal pathways [31]. Not all hemodynamically active inflammatory mediators are vasodilators. For example, endothelin-1, a potent vasoconstrictor is increased in the airway of asthmatics [32]. Its release may be induced by pro-inflammatory cytokines such as tumor necrosis factor-$\alpha$ [33]. However, the net effect of inflammatory mediators is vasodilation.

While baseline Qaw is increased in asthma, vascular reactivity is markedly deranged, with blunted $\beta_2$-adrenergic vasodilator responsiveness and enhanced $\alpha$-adrenergic vasoconstrictor responsiveness (Fig. 19.3) [8, 9, 30, 34]. The former observation suggests abnormal endothelium-dependent vasodilation in the airway circulation.

FIG. 19.3 Effects of inhaled methoxamine and albuterol on airway blood flow (Qaw) in 11 healthy (A) and 11 asthmatic (B) subjects. Mean values ±SE. *$p < 0.05$ versus baseline. Reproduced from Ref. [8].

### Microvascular hyperpermeability

Asthma-associated leakage of macromolecules from the microvasculature occurs through endothelial pores and vesicles or through the formation of intercellular gaps in post-capillary venules. Inflammatory mediators and sensory autonomic nerve stimulation have been shown to increase microvascular permeability by producing intercellular gaps [11, 27] and induce interstitial edema formation. In addition, plasma components can collect in the airway lumen by passing through paracellular gaps between epithelial cells thereby contributing to excessive airway secretions. Vasodilation and hyperperfusion-related microvascular congestion have been shown to potentiate microvascular hyperpemeability [35]. In this regard, blood flow is related to edema formation.

## AIRWAY CIRCULATION IN COPD

### Structure

Early reports on the structure of the airway circulation in COPD suggested that intrapulmonary bronchial artery branches are obliterated or narrowed in emphysematous regions of the lungs and that the bronchial venous system is greatly expanded [36, 37]. These findings have not been supported by recent studies that showed increased airway wall vascularity in stable COPD with a slight increase in the number of vessels in small airways, but to a much lesser degree than in asthma, where there is an increased vascularity throughout the bronchial tree [29, 38]. Thus, in contrast to asthma, angiogenesis in the airway wall does not appear to be a typical feature of COPD.

However, in patients with COPD accompanied by bronchiectasis, there is an extensive remodeling of the airway circulation with a marked proliferation and enlargement of the bronchial arteries and numerous pre-capillary anastomoses between the pulmonary and bronchial circulation [39–41]. This vascular remodeling is a likely cause of hemoptysis encountered by patients with bronchiectasis. It is also likely that the primary stimuli for the development of bronchiectasis and airway vascular hypertrophy are suppurative airway infections that typically are seen in these patients. In support of this assumption, chronic lung abscesses also have been shown to lead to a localized hypertrophy and hyperplasia of the airway circulation [41].

### Function

We found no significant difference in Qaw among ex-smokers with COPD ($51 \pm 3 \mu l \, min^{-1} ml^{-1}$ anatomical deadspace), healthy ex-smokers (HES) ($41 \pm 3 \mu l \, min^{-1} ml^{-1}$), healthy current smokers ($46 \pm 2 \mu l \, min^{-1} ml^{-1}$) and healthy lifetime non-smokers ($41 \pm 4 \mu l \, min^{-1} ml^{-1}$), although the values tended to be higher in COPD patients (Fig. 19.2) [29]. Similarly, Paredi *et al*. [38] reported normal Qaw values in COPD. These findings are consistent with the morphological observations that do not support the presence of significant new vessel formation in stable COPD in contrast to asthma. However, airway blood flow is increased in patients with COPD and bronchiectasis, reflecting the above described hyperplasia of the airway circulation in bronchiectasis [37].

Albuterol-induced vasodilation is blunted in ex-smokers with COPD (Fig. 19.4) [29], similarly to patients with asthma [8, 9]. Albuterol-induced vasodilation has been used as an index of endothelium-dependent vasodilation and endothelial function, especially in current smokers [43]. Since the COPD patients were ex-smokers and the asthmatics lifetime non-smokers, it cannot be assumed that the abnormal albuterol responsiveness was due to endothelial dysfunction. However, inasmuch as oxidative stress has been closely associated with endothelial dysfunction [43, 44] and endogenously generated oxidants have been implicated in the pathogenesis of both COPD and asthma,

**FIG. 19.4** Airway blood flow reactivity to inhaled albuterol (180 µg) in healthy non-smokers (HNS), healthy ex-smokers (HES), current smokers (CS), COPD, COPD after long-term treatment with an inhaled corticosteroid (COPD p.ICS) and after washout of the medication (COPD p.w/o), asthma (A), and asthma after long-term treatment with an inhaled corticosteroid (A p.ICS) and after the washout of the medication (A p. w/o). Vertical axis: change in airway blood flow. Mean values with SE in brackets. Adapted from Refs [29] and [42].

it is conceivable that the blunted albuterol responsiveness of Qaw reflects an abnormality in endothelium-dependent relaxation. To what extent the defective vascular reactivity contributes to the development of COPD is unknown. It could be speculated that the blunted vasodilator response in the airways reflects systemic vascular disease that often co-exists with COPD [45, 46].

### Cigarette Smoking

#### Acute effects

In several extrapulmonary vascular beds, smoking a cigarette has been shown to decrease blood flow transiently [47–49]. The airway circulation is the first and only systemic vascular bed to be exposed to cigarette smoke directly and is exposed to the highest concentration of cigarette smoke constituents. Their effects on airway blood flow therefore may be different from their systemic vascular effects. In anesthetized pigs, cigarette smoke increases airway blood flow transiently during the duration of inhalation, an effect that resembles inhalation challenge with NO [50, 51]. This could be interpreted as indicating a vasodilator effect of NO contained in cigarette smoke. Inasmuch as cigarette smoke is an irritant, more prolonged vascular effects could be expected in conscious humans. Furthermore, cigarette smoke contains nicotine, a sympathomimetic that has variable hemodynamic actions in different vascular beds [52, 53].

We found that Qaw increased by a mean of 81% at 5 min after smoking a cigarette and returned to baseline by 30 min in healthy smokers [54], whereas nicotine administered by nasal spray (systemic action) or oral inhalation (local and systemic action) had no effect on Qaw, suggesting a pharmacologic or irritant effect of other cigarette smoke constituents. Thus, smoking a cigarette seems to cause transient vasodilation in the airway and vasoconstriction in extrapulmonary systemic vascular beds. Whether or not

repetitive vasodilator responses to cigarette smoking have a role in the pathogenesis of COPD is not known.

### Long-term effects

While healthy current and ex-smokers have a near-normal baseline Qaw as mentioned above, they have an abnormal vasodilator response to albuterol, presumably as a manifestation of endothelial dysfunction as shown by Mendes *et al.* [29] (Fig. 19.4). There was a partial recovery of albuterol responsiveness in healthy ex-smokers while albuterol responsiveness remained blunted in the ex-smokers with COPD. The partial reversibility of albuterol responsiveness after smoking cessation in healthy ex-smokers but not in ex-smokers with COPD suggests that the abnormal vascular reactivity is sustained in COPD, possibly due to ongoing airway inflammation.

It may well be that the abnormal albuterol responsiveness in smokers reflects systemic endothelial dysfunction and that there is a correlation between systemic endothelial dysfunction and albuterol-induced vascular relaxation in the airway among healthy smokers. This remains to be investigated.

## FUNCTIONAL CONSEQUENCES

The vascular changes described above could participate in the physiological and clinical manifestations of asthma and COPD; however, this is still a matter of debate.

### Mucosal thickness

As vessels are known to occupy a significant portion of the inner airway wall, it is possible that the vascular component of inflammation increases mucosal thickness enough to increase airflow resistance. Airway vascular engorgement, submucosal edema, and luminal fluid accumulation have all been proposed to contribute to the excessive airway narrowing and enhanced airway responsiveness in asthma. Several animal and human studies have examined this experimentally; the results have been conflicting with respect to the effects of vascular congestion on airway caliber [55–59]. The observation that rapid infusion of intravenous fluids causes airway obstruction in humans supports this theory [57]. However, another study has not been able to confirm this finding [58, 59]. There is less controversy on the effect of airway edema on airway caliber: edema of the inner wall internal to the smooth muscle contributes to airway hyperresponsiveness as the same degree of muscle shortening causes greater luminal narrowing than in the normal airway [60].

### Drug, mediator, and cell transport

Inflammation-associated blood flow, permeability, and interstitial barrier changes could alter transport functions of the airway vasculature as suggested by previous studies. Desmopressin uptake by the nasal mucosa was enhanced when blood flow was increased [61], whereas inhaled histamine [62] and antigen challenge-induced [63] bronchoconstriction were prolonged when bronchial blood flow was decreased. Therefore one might speculate that the inflammatory increase in airway blood flow would enhance the clearance of locally released inflammatory substances (e.g. spasmogens) and decrease the magnitude and duration of the effect of inhaled bronchoactive drugs. In addition, increased airway blood flow could favor the distribution of systemically administered drugs to the airways and the accumulation of inflammatory cells in the airway wall. Thus, the inflammatory increase in airway blood flow appears to have clinically beneficial as well as undesirable effects on inflammation and its drug treatment.

### Heat and water exchange

Exercise-induced bronchoconstriction is a common condition in asthmatics. Reactive hyperemia in response to airway cooling and increased airway liquid and interstitial osmolarity caused by water loss have been proposed to have a critical role [63, 64]. The former may narrow the airway while the latter may promote mediator release from inflammatory cells. However, while hyperventilation with frigid air, a substitute for exercise-related hyperventilation, has been shown to cause a marked increase in Qaw in healthy subjects [81], this may not be the case in asthmatics, who have a blunted vasodilator responsiveness. This remains to be studied.

### Mucociliary clearance

The role of airway blood flow in supporting the mucociliary apparatus is incompletely understood. Mucociliary clearance was impaired in the immediate postoperative period after lung transplantation [65], and clearance of inhaled particles was significantly impaired when bronchial blood flow was stopped in sheep [66]. The effect of increased airway blood flow on mucociliary clearance in asthma has not been examined.

## PHARMACOLOGIC INTERVENTIONS

In asthma and COPD, the dearth of physiological data on the pathogenetic role of the airway circulation precludes the formulation of meaningful therapeutic recommendations. An exception may be the reversal of microvascular hyperpermeability, an intervention that is likely to increase airway patency and decrease airflow resistance. Although such an effect is difficult to demonstrate experimentally, anti-inflammatory agents, especially inhaled glucocorticosteroids can be expected to reduce airway edema by inhibiting microvascular hyperpermeability based on observation in extrapulmonary vascular beds [36, 37, 67]. In contrast, the physiological and clinical consequences of the increased Qaw and the blunted vasodilator responsiveness (e.g. to $\beta_2$-a-drenergic agonists) of the airway circulation in asthma

and COPD are not known. These vascular changes could contribute to the pathogenesis of the disease or constitute a vascular adaptation that may counteract the effects of airway inflammation on airway function. Likewise, the blunted vasodilator response in the airways of patients with COPD may be contributing to or mitigate the airway disease of COPD.

It therefore might be more useful to focus on the effects of adrenergic agonists and glucocorticosteroids on Qaw because these agents remain the mainstay of pharmacotherapy in obstructive lung disease.

## Adrenergic agonists

Inhaled methoxamine, an $\alpha$-adrenergic agonist, causes a dose-dependent transient decrease in Qaw, with an enhanced responsiveness in asthmatics compared to healthy subjects (Fig. 19.3) [8]. Higher doses of methoxamine cause bronchoconstriction in asthmatics. However, the vasoconstrictor effect is already seen at methoxamine doses that do not cause bronchoconstriction or have systemic side effects. Thus combining an inhaled $\beta_2$-adrenergic agonist or glucocorticosteroid with a low dose of an $\alpha$-adrenergic agonist might increase residence of the former drugs in the airway tissue and enhance and prolong their biological effects.

The vasodilator effect of inhaled albuterol, a $\beta_2$-adrenergic agonist, is blunted in asthmatics and patients with COPD (Fig. 19.3) [8, 9, 30, 34]. In as much as vasodilation may be an undesirable side effect of inhaled $\beta_2$-adrenergics when administered for bronchodilation, the vascular hyporesponsiveness to this drug in asthma and COPD could be considered a therapeutic advantage. Unfortunately, inhaled glucocorticosteroids that are typically co-administered with $\beta_2$-adrenergic agonists restore vasodilator responsiveness to albuterol [42]. This effect is seen after long-term glucocorticosteroid treatment and after pretreatment with a single dose of a glucocorticosteroid, suggesting that both genomic and non-genomic glucocorticosteroid actions are involved [34].

## Glucocorticosteroids

There is increasing evidence that glucocorticosteroids have profound effects on the airway vasculature. Among other actions, such as reduction of microvascular hyperpermeability, glucocorticosteroids regulate Qaw.

### Acute vasoconstriction

Inhaled glucocorticosteroids decrease Qaw rapidly and transiently by a non-genomic action that is mediated by the noradrenergic nervous system as the effect can be blocked with an oral $\alpha_1$-adrenoceptor blocking agent. Thus a single dose of inhaled fluticasone (880 and 1760 mg) causes a decrease in Qaw within 30 min, with a return toward baseline by 90 min in asthmatics and healthy subjects [68]. Other inhaled glucocorticosteroids such as bleclomethasone and budesonide have similar effects (Fig. 19.5) [10].

### Reversal of increased Qaw in asthma

Treatment with inhaled fluticasone (440 mg daily) for 2 weeks reverses the asthma-associated increase of Qaw independent

**FIG. 19.5** Airway blood flow (Qaw) before and after the inhalation of fluticasone (•), beclomethasone (o) and budesonide (Δ) in asthmatic subjects ($n = 10$). Data are presented as mean ±SD. * $p < 0.05$ versus baseline value. Reproduced with from Ref. [10].

of the acute vasoconstrictor action of the drug, presumably through a genomic action (Fig. 19.4) [42]. A similar effect is seen with oral montelukast, suggesting that Qaw is a marker of airway inflammation in asthma [69]. The observed restoration of a nearly normal Qaw by long-term glucocorticosteroid treatment may reflect a reversal of inflammatory vasodilation and/or an effect on vascular remodeling. For instance, inhaled beclomethasone (200–1500 mg daily) has been reported to decrease the subepithelial area occupied by vessels in asthmatics [70]. The underlying mechanism is not known, but glucocorticosteroids have been reported to reduce vascular endothelial growth factor expression in pulmonary vascular smooth muscle cells [71].

### Restoration of $\beta_2$-adrenergic vasodilation

In patients with asthma and COPD in whom inhaled albuterol fails to increase Qaw, inhaled glucocorticosteroid therapy restores normal albuterol responsiveness (Fig. 19.4) [29, 42]. Inasmuch as $\beta_2$-adrenergic vasodilation is mediated by the endothelium, these conditions may be associated with a defect in endothelial function, and glucocorticosteroids may turn out to have a role in the treatment of endothelial dysfunction. Given the prevalence of cardiovascular disease in COPD and its relation to endothelial dysfunction [45, 46], there is a need to examine the effects of glucocorticosteroids on endothelial function in the extrapulmonary systemic circulation as well. Data base studies indeed have suggested that inhaled glucocorticoteroids have a beneficial effect on cardiovascular morbidity and mortality in COPD [72–74].

### Glucocorticosteroid—$\beta_2$-adrenergic interaction

These stress hormones have been shown to potentiate each other's effect in target tissues including the airway. It has been known for some time that through a genomic action, glucocorticosteroids can upregulate the synthesis and G-protein coupling of $\beta_2$-adrenergic receptors, thereby enhancing the tissue responsiveness to $\beta_2$-adrenergic agonists [75, 76].

In addition, glucocorticosteroids have acute, non-genomic actions in the airway that can potentiate the effects of $\beta_2$-adrenergic agonists as shown above. Inhaled $\beta_2$-adrenergic agonists are cleared from the airway tissue by local metabolism and vascular clearance. Glucocorticosteroids inhibit within minutes the uptake of organic cations including adrenergic agonists into non-neuronal cells containing the agonists' metabolizing enzymes [77–80]. This could increase the concentration of adrenergic agonists at adrenergic receptor sites in airway tissue, thereby potentiating the agonists' effects on airway and airway vascular smooth muscle. The latter effect has now been demonstrated *in vivo* in patients with asthma in whom pretreatment with a single glucocorticosteroid dose potentiated the vasodilator response to albuterol within minutes [34]. In addition, the acute vasoconstrictor action of inhaled glucocorticosteroids could reduce the vascular clearance thereby further enhancing the biological effect of inhaled $\beta_2$-adrenergic agonists. Although these effects thus far have not been studied with long-acting $\beta_2$-adrenergic agonists, the current practice of treating obstructive lung disease with long-acting $\beta_2$-adrenergic agonist-glucocorticosteroid combination formulations is supported by the above shown rapid interaction between the two classes of drugs.

# Pulmonary Vessels

**Roberto Rodríguez-Roisin and Joan Albert Barberà**

Servei de Pneumologia, Hospital Clínic, IDIBAPS, Universitat de Barcelona, Barcelona, Spain

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE

### Introduction

Pulmonary vascular circulation abnormalities are common in chronic obstructive pulmonary disease (COPD). It is likely that, pulmonary hypertension associated with COPD is the most frequent form of pulmonary hypertension. Concepts gathered in the systemic circulation have contributed to a better understanding of changes occurring in pulmonary vessels. This has promoted a change in the notion of the pathogenesis of pulmonary hypertension from a vasoconstrictive phenomenon to a cell proliferative disorder. Some of the concepts used to explain the pathogenesis of the most severe forms of pulmonary hypertension have been extrapolated to COPD, yielding to new approaches to its pathobiology. In this section, we will review the current knowledge on the mechanisms of pulmonary vascular changes associated with COPD.

### Lung structure

Pulmonary vascular remodeling is broadly defined as an active process of profound structural changes reflecting an abnormal tissue repair response to an acute and/or chronic insult. In COPD, the latter process results from profound fibrocellular changes that lead to an enlargement of the vessel wall – an active process that affects preferentially small and pre-capillary arteries of the pulmonary vasculature identified at different degrees of COPD severity.

In patients with end-stage COPD and pulmonary hypertension or *cor pulmonale*, postmortem studies have shown deposition of longitudinal muscle, fibrosis, and elastosis that cause intimal enlargement in pulmonary muscular arteries [1, 2]. In the arterioles there is a development of a medial coat of circular smooth muscle, bounded by a new elastic lamina, with deposition of longitudinal muscle and fibrosis of the intima. As compared with patients with mild COPD and healthy nonsmokers, Santos *et al.* [3] showed substantial enlargement of the intima in lung tissue specimens obtained from lung volume reduction surgery. Conversely, medial thickness was slightly reduced in patients with severe emphysema when compared with patients with milder form of COPD.

In patients with mild-to-moderate COPD, morphometric studies of pulmonary muscular arteries have shown enlargement of the intimal layer with luminal reduction [4–7] (Fig. 20.1). Intimal enlargement occurs in muscular arteries of different sizes, although it is more pronounced in small arteries with an external diameter less than 500 µm [5]. In addition, the number of small pulmonary muscular arteries, with a diameter <200 µm, is increased [8], indicating muscularization of arterioles. Intimal hyperplasia results from proliferation of poorly differentiated smooth muscle cells and deposition of elastic and collagen fibers [9]. Changes in the media of muscular arteries are less conspicuous and the majority of morphometric studies have failed to show differences in the thickness of the muscular layer when comparing patients with mild-to-moderate COPD with control subjects [5]. Moreover, the magnitude of this intimal thickening, not different from that shown by mild
**FIG. 20.1** Photomicrograph of a pulmonary muscular artery from a patient with COPD showing prominent intimal hyperplasia and lumenal narrowing. Immunostaining with antibody against α-smooth muscle actin reveals marked proliferation of smooth muscle cells in the intima.

COPD patients, is also present in heavy smokers with normal spirometry [6, 7].

## Clinical background

In COPD pulmonary hypertension is considered to be present when mean pulmonary artery pressure (PAP) exceeds the upper normal limit of 20 mmHg [10]. In general, the degree of pulmonary hypertension in COPD is of low-to-moderate magnitude and rarely exceeds 35–40 mmHg. Both right atrial pressure and pulmonary capillary wedge pressure tend to be normal, as well as the cardiac output [10], a pattern at variance with other pulmonary hypertensive conditions (i.e. idiopathic pulmonary arterial hypertension, congenital heart disease, thromboembolic disease) in which PAP can reach extremely high levels, close to those of the systemic circulation, usually in the context of a reduced cardiac output.

Pulmonary hypertension in COPD evolves over time and its severity correlates with the degree of airflow obstruction and the impairment of pulmonary gas exchange [11, 12]. However, the rate of progression of pulmonary hypertension in COPD is slow and usually PAP is only moderately elevated, even in patients with advanced stages [11]. Weitzenblum *et al.* [11] studied the natural history of PAP in a cohort of over 100 COPD patients followed up to 5 years with PAP increases on an average of 0.6 mmHg/year. Although the rate of increase of PAP was slightly higher in patients without pulmonary hypertension at the onset of the follow-up compared with those who already had pulmonary hypertension, the PAP increase was more closely related to the progress of gas exchange disturbances than to the initial PAP values [11].

The beginning of pulmonary hypertension in the natural history of COPD has intrigued investigators. Kessler *et al.* [13] assessed the outcome of pulmonary hemodynamics in patients with moderate COPD without pulmonary hypertension at rest and observed 7 years later that PAP had increased by 2.6 mmHg (annual rise, 0.4 mmHg/year),

thus 25% of the patients already having pulmonary hypertension at rest. The incidence of resting pulmonary hypertension was greater in the subset of patients who initially developed pulmonary hypertension during exercise (32%), as compared with those without exercise-induced pulmonary hypertension (16%), such that increased PAP during exercise was an independent predictor for the subsequent development of pulmonary hypertension [13]. These results indicate that in COPD pulmonary circulation, derangement can be present years before pulmonary hypertension is apparent at rest. Further, this study suggests that exercise tests might be of interest to demonstrate pulmonary circulation disturbances, which are consistent with morphometric studies that show conspicuous structural changes in pulmonary muscular arteries in mild COPD patients [4, 6].

Pulmonary hypertension is a common complication of COPD. Its presence is associated with increased mortality, more frequent exacerbations, and greater use of health-care resources. At present, there is no specific and effective treatment for this condition in COPD. However, recent advances in the understanding of the pathobiology of pulmonary hypertensive states, along with the development of effective treatments for pulmonary arterial hypertension, have opened a new perspective that might be relevant in COPD. Nevertheless, the actual prevalence of pulmonary hypertension in COPD remains elusive, because it has not been assessed systematically using right heart catheterization across the wide clinical spectrum of COPD. Hemodynamic data currently available are limited to patients with advanced disease.

Three studies have provided data in a large series of patients. The first study is of patients with severe emphysema screened for lung volume reduction surgery and the incidence of pulmonary hypertension (PAP > 20 mmHg) was very high (91%), although of mild-to-moderate magnitude (20–35 mmHg); [13] in 5% of patients, however, PAP values exceeded 35 mmHg. Although there were significant but modest correlations between PAP and $FEV_1$ and arterial $PO_2$, PAP was more closely related to pulmonary artery occlusion pressure, slightly increased in most of the patients, suggesting that gas trapping may contribute to this increased capillary pressure. The second study is a retrospective analysis of over 1000 COPD patients. The prevalence of severe pulmonary hypertension (PAP > 40 mmHg) was 1.1% [14]. This cohort of patients with disproportionate pulmonary hypertension had moderate airflow limitation, severe hypoxemia, hypercapnia, and very low diffusing capacity, indicating that these patients may share some characteristics of idiopathic pulmonary arterial hypertension. In a third study with approximately 200 COPD patients who were candidates for lung volume reduction surgery or lung transplantation, [15] pulmonary hypertension (i.e. PAP > 25 mmHg) was observed in 50% of the patients, although of mild severity (26–35 mmHg). In 10% of the patients, pulmonary hypertension was moderate (36–45 mmHg) and, in 4% of the patients, severe (>45 mmHg). A cluster analysis identified a subset of patients characterized by moderate impairment of airway function and high PAP values, along with severe hypoxemia, supporting the concept of the existence of a cohort of COPD patients with "disproportionate" pulmonary hypertension.

## Pathophysiology

Hypoxic pulmonary vasoconstriction, right ventricular function, peripheral edema, and exercise are four key factors influencing the development of pulmonary hypertension.

Pulmonary vasoconstriction in response to hypoxia reduces perfusion in poorly ventilated or nonventilated lung units and diverts blood flow to better-ventilated units, thereby restoring ventilation–perfusion ($V_A/Q$) imbalance toward normal and increasing $PaO_2$. Teleologically, hypoxic vasoconstriction plays a fundamental role in matching pulmonary blood flow to alveolar ventilation. Failure to maintain this balance, and the consequent $V_A/Q$ mismatching, is the major cause for both hypoxemia and hypercapnia in COPD [16]. Studies using inert gases [17] have shown that hypoxic pulmonary vasoconstriction release while breathing high oxygen concentration worsens the underlying $V_A/Q$ imbalance in patients with different degrees of COPD severity [16]. In general terms, the contribution of hypoxic vasoconstriction to correct or restore $V_A/Q$ matching tends to be greater in patients with less severe COPD [18]; conversely, hypoxic vasoconstriction remains less influential in patients with severe structural derangement of pulmonary muscular arteries [4]. Furthermore, the magnitude of contraction in isolated pulmonary artery rings induced by a hypoxic stimulus is negatively correlated to endothelial function and directly related to the arterial $PO_2$ [19], suggesting that the vascular dysfunction is associated with an altered response to hypoxia that further worsens gas exchange. Accordingly, the contribution of hypoxic vasoconstriction to gas exchange in COPD should be taken into account when administering vasodilators that might potentially inhibit such a response since they may also impair gas exchange [17].

In patients with COPD and pulmonary hypertension, the PAP is not markedly elevated and the rate of progression of pulmonary hypertension is slow. Therefore, the right ventricle has time to adapt to the modest increase in afterload. When PAP is chronically elevated the right ventricle dilates and both end-diastolic and end-systolic volumes increase. The stroke volume of right ventricle is usually maintained, whereas the ejection fraction decreases. Subsequent hypertrophy of the right ventricular wall in persistent pulmonary hypertension reduces its tension and hence the afterload. The reduction in right ventricular ejection fraction (RVEF) is inversely related to PAP; nonetheless, a decrease in RVEF does not imply that there is a true ventricular dysfunction [20]. Measurements of end-systolic pressure–volume relationships have shown that a stable COPD contractility of the right ventricle lies within normal limits, irrespective of the PAP values [21, 22]. However, during COPD exacerbations, when PAP increases markedly, the contractility of the right ventricle is reduced in patients presenting clinical signs of right heart failure [23, 24]. Cardiac output in COPD is usually preserved and might rise during exacerbations [25, 26], even when right heart failure is apparent. Therefore, the usual definition of heart failure as a reduction in cardiac output does not apply to COPD. These questions relating to the nature of right heart failure in COPD have led to a reassessment of the concept of *cor pulmonale*. The suggestion has been made that this term should be abandoned in favor of a more precise definition based on objective evidence of right ventricular hypertrophy, enlargement, functional abnormality, or failure.

Although peripheral edema may be a sign of venous congestion due to upstream transmission of right ventricular filling pressures, in advanced COPD edema is more related to hypercapnia rather than to raised jugular pressures [27, 28]. Some patients may present peripheral edema without hemodynamic signs of right heart failure or PAP changes [29, 30]. This has lead to reconsideration of the mechanisms for peripheral edema formation in COPD [29, 30–32].

In COPD, peripheral edema results from a complex interaction between the hemodynamic changes and the balance between edema promoting and protective factors. In COPD patients with pulmonary hypertension and coexisting chronic respiratory failure, hypoxemia and hypercapnia aggravate venous congestion by further activating the sympathetic nervous system, which is already stimulated by right atrial distension. Sympathetic activation decreases renal plasma flow, stimulates the renin–angiotensin–aldosterone system and promotes tubular reabsorption of bicarbonate, sodium, and water. Vasopressin, which also contributes to edema formation, is released when patients become hyponatremic and its plasma levels rise in patients with hypoxemia and hypercapnia [31].

Atrial natriuretic peptide is released from distended atrial walls and may act as an edema-protective mechanism since it has vasodilator, diuretic, and natriuretic properties. Nevertheless, these effects are usually insufficient to counterbalance the edema-promoting mechanisms. Peripheral edema may develop or worsen during episodes of COPD exacerbation. Weitzenblum *et al*. [26] identified a subgroup of patients with more marked peripheral edema that was attributed to hemodynamic signs of right heart failure (increase in end-diastolic pressure). Compared with patients with normal end-diastolic pressure, patients with right heart failure had more marked increase in PAP, and more severe hypoxemia and hypercapnia. This suggests that worsening of pulmonary hypertension during exacerbations contributes to edema formation.

Physical exercise produces abnormal increases in PAP, especially in patients who have pulmonary hypertension at rest [33]. As noted above, patients that appear to be more prone to the development of pulmonary hypertension may show an abnormal increase in PAP during exercise, years before pulmonary hypertension is apparent at rest [13]. Different studies have identified a number of mechanisms for exercise-induced pulmonary hypertension in COPD, including hypoxic vasoconstriction, reduction of the capillary bed by emphysema, extramural compression by increased alveolar pressure, or impaired release of endothelium-derived relaxing factors [34–36]. These mechanisms may coexist hence several factors may contribute to the development of exercise-induced pulmonary hypertension in a given individual. In COPD, PAP during exercise is greater than predicted by the PVR equation, suggesting active pulmonary vasoconstriction on exertion [34]. The latter may be due to an enhancement of hypoxic vasoconstriction by decreased mixed venous $PO_2$, increased tone of the
**FIG. 20.2** Immunodetection of endothelial nitric oxide synthase (eNOS) in pulmonary muscular arteries from a nonsmoker control subject, a smoker with normal lung function, a patient with moderate COPD, and a patient with severe emphysema. Whereas endothelial cells of the nonsmoker subject show strong immunoreactivity to eNOS, the intensity of the signal is weak or absent in pulmonary arteries of the smoker subject and patients with COPD.

sympathetic nervous system, and/or decreased arterial pH [37]. During exercise, patients may develop dynamic hyperinflation due to expiratory flow limitation that results in increased alveolar pressure which is transmitted to the capillary wedge pressure [38]. Furthermore, increased ventilation during exercise, in the presence of airflow limitation, results in significant swings of intrathoracic pressure that may reduce cardiac output by altering systemic venous return or by increasing left ventricular afterload [39]. Impairment of endothelial release of vasorelaxing agents such as nitric oxide (NO) may also contribute to an impaired dilator response to increases in flow [40]. However, in a subset of COPD patients who developed pulmonary hypertension during exercise, external administration of NO did not block the abnormal increase in PAP, suggesting that the defective endogenous NO release plays a marginal role in exercise-induced pulmonary hypertension [41]. Since pulmonary hypertension may develop at moderate levels of exercise, it has been suggested that repeated episodes of pulmonary hypertension during daily activities, such as stairs climbing or walking, could contribute to the development of right ventricular hypertrophy [42].

## Pathobiology

The field of vascular biology has made a major breakthrough over the last decades since the seminal studies identified the key role of endothelium in the regulation of vascular homeostasis [43]. Endothelial dysfunction is a common disturbance in hypertensive states of both the systemic and pulmonary circulations. Vascular actions of endothelium are mediated through the balanced release of potent vasoactive mediators, such as NO, prostacyclin, endothelin-1 (ET-1), and angiotensin. Some of these mediators are also potent modulators of proliferative and inflammatory responses.

Endothelial dysfunction has been shown in pulmonary arteries of both end-stage [44] and mild [7] COPD patients. Impairment of endothelial function results from changes in the expression and release of vasoactive mediators. Endothelium-derived NO is a potent endogenous vasodilator with anti-proliferative effects in the vessel walls. In pulmonary arteries of COPD patients with pulmonary hypertension, the expression of endothelial NO synthase (eNOS) is reduced [45]. Interestingly, in smokers, eNOS expression is also reduced [46] (Fig. 20.2), likely explaining the endothelial dysfunction present in mild disease states [7]. Prostacyclin, which is also synthesized by endothelial cells, exerts similar actions to NO and we know that the expression of prostacyclin synthase is reduced in pulmonary arteries of patients with severe emphysema [47]. ET-1 is a potent vasoconstrictor that also exerts a mitogenic effect on arterial smooth muscle cells, its expression being augmented in pulmonary arteries of patients with COPD and pulmonary hypertension, [48] but not in patients with mild-to-moderate disease [46, 49]. These findings indicate that endothelial dysfunction, with changes in the expression and release of endothelium-derived vasoactive mediators that regulate cell growth, is a common characteristic finding of COPD. It may appear early in the natural history of the disease and could contribute to further changes in vascular structure and function. Hypoxia, inflammation,

and cigarette smoke might all contribute to the origin of pulmonary endothelial damage in COPD.

Hypoxia is a potential mechanism that may explain endothelial cell damage and vascular remodeling in COPD. Hypoxia may downregulate eNOS expression and induce smooth muscle cell and adventitial fibroblast proliferation [50, 51]. In addition, hypoxia elicits the contraction of pulmonary arteries. However, the role of hypoxia as the major etiological factor for pulmonary vascular impairment in COPD is now being re-assessed. First, COPD patients show a wide variation in the individual response of the pulmonary circulation to changes in inspired oxygen concentration, [52] and the correlation between $PaO_2$ and PAP remains weak [12]. Second, long-term oxygen therapy cannot reverse pulmonary hypertension completely [53]. Third, structural abnormalities and endothelial dysfunction in pulmonary arteries can be observed in nonhypoxemic patients with mild COPD and also in smokers with normal spirometry [4, 6, 7]. Therefore, hypoxia does not completely explain the pulmonary vascular changes in COPD.

Inflammation may play a role in the pathogenesis of pulmonary vascular abnormalities associated with COPD, although its precise effects have not been established yet. Inflammatory cell infiltration of small airways is

**FIG. 20.3** Small pulmonary muscular artery with several CD8[+] lymphocytes infiltrating the adventitia (arrows).

associated with intimal hyperplasia of pulmonary muscular arteries [4]. Further, there is an increased number of CD8[+] T-lymphocytes infiltrating the adventitia of pulmonary arteries in patients with mild-to-moderate COPD [7] (Fig. 20.3). Inflammatory cells are a source of cytokines and growth factors that may target the endothelial cells and contribute to the development of structural and functional abnormalities of the vessel wall. Indeed, the number of inflammatory cells infiltrating the pulmonary arteries is directly related to both endothelial dysfunction and to intimal hyperplasia [7]. Smokers with normal spirometry also exhibit an increased number of CD8[+] T cells with a reduction of the CD4[+]/CD8[+] ratio in the arterial adventitia, as compared with non-smokers [7] (Fig. 20.3). This suggests that cigarette smoking might induce inflammatory changes in pulmonary arteries before the development of lung functional disturbances.

Cigarette smoke products may directly influence pulmonary vessel structure. Smokers with normal spirometry show prominent changes in pulmonary arteries, such as smooth muscle cell proliferation [9], impairment of endothelial function [7], reduced expression of eNOS [46], increased expression of vascular endothelial growth factor (VEGF) [3], and CD8[+] T-cell infiltrate [7]. Most of these changes cannot be differentiated from those seen in COPD patients. These changes are clearly absent in nonsmokers, and have been replicated in part in a guinea pig model using chronic exposure to cigarette smoke [54]. VEGF protein content in lung tissue is reduced in severe emphysema such that the expression of VEGF varies according to the severity of COPD (Fig. 20.4). In the animal model, cigarette smoke exposure induces muscularization of pre-capillary vessels and increases PAP [55]. It is of note that vascular abnormalities are clearly shown after 2 months of cigarette smoke exposure without any evidence of emphysema [55], suggesting that cigarette smoke-induced vascular abnormalities may precede the development of pulmonary emphysema [56]. Moreover, rapid changes in gene expression of VEGF, VEGF receptor-1, ET1, and inducible NOS [57], mediators that regulate vascular cell growth and vessel contraction, likely involved in the pathogenesis of pulmonary vascular changes of COPD, are induced in this animal model.

Cigarette smoking is a well-known risk factor for the development of systemic vascular disease. Active and passive

**FIG. 20.4** Photomicrographs of pulmonary muscular arteries from a nonsmoker, a patient with moderate COPD, and a patient with severe emphysema, immunostained with antibody against vascular endothelial growth factor (VEGF). Positive cells (brown) were located in the intima. Patients with moderate COPD showed the greatest immunoreactivity to VEGF.

exposure to tobacco smoke produces endothelial dysfunction in both coronary and systemic arteries [58]. Exposure of pulmonary artery endothelial cells to cigarette smoke extract causes the inhibition of both eNOS and prostacyclin synthase at the level of protein content and mRNA expression [59, 60]. Cigarette smoke contains a number of products that have the potential to produce endothelial injury; among these, the aldehyde acrolein seems to play a prominent role since it reduces the expression of prostacyclin synthase in endothelial cells [60].

In summary, several evidences suggest that the initial event in the natural history of pulmonary hypertension in COPD could be pulmonary endothelial injury induced by cigarette-smoke products with the subsequent down-regulation of eNOS and prostacyclin synthase expression, and impairment of endothelial function. When the disease progresses, sustained exposure to hypoxemia and inflammation may induce further pulmonary vascular remodeling, thus amplifying the initial effects of cigarette smoke.

## BRONCHIAL ASTHMA

## Structural background

In patients who died of sudden fatal asthma, there is an inflammatory response in the peripheral airways characterized by lumenal occlusion, resulting from airway narrowing due to increased smooth muscle thickness, and, importantly, an inflammatory infiltrate, including both mononuclear cells and eosinophils together with airway secretions [61]. A salient finding is that the muscular pulmonary arteries neighboring inflamed and narrowed airways show an adventitial inflammatory infiltrate, mainly consisting of increased numbers of eosinophils. Increased intimal fibrous thickening with bands of longitudinal muscle within the intima and also externally to the elastica lamina, characteristic features of chronic alveolar hypoxia, were not exhibited by these vessels. That both the intimal and medial thickness of muscular pulmonary arteries was within normal limits suggested that the effects of regional hypoxia produced by mucus plugging were transient and short enough in duration to fail to induce the structural derangement usually shown in patients with chronic hypoxic lung diseases [61]. These pulmonary vasculature findings are of interest for understanding the behavior of the pulmonary circulation and its interplay with the $V_A/Q$ matching, particularly while breathing 100% oxygen. In addition to an increased smooth muscle thickness in the peripheral airways, this study [61] demonstrated an increased thickness of the non-muscular airway wall components, most likely resulting from inflammatory cell infiltrate, plasma exudate, and vascular congestion, a combination of changes possibly occurring during an acute eruption of the inflammatory cascade. However, not all the airways were occluded by mucus plugging, as almost half of the airways were without secretions, whereas the other half showed some degree of luminal occlusion.

## Gas exchange pathophysiology

Two studies have investigated the status of pulmonary gas exchange and the behavior of the pulmonary circulation in patients with stable moderate-to-severe persistent asthma. Patients with unstable, persistent asthma were characterized by longstanding severe airflow limitation ($FEV_1 < 40\%$ predicted).

One of the studies showed that the $V_A/Q$ distributions demonstrated a broad unimodal blood flow $V_A/Q$ pattern [62]. Accordingly, very little perfusion was associated with alveolar units with low $V_A/Q$ ratios and intrapulmonary shunt was conspicuously absent; areas of high $V_A/Q$ regions were also negligible and dead space was within the normal range. The overall amount of $V_A/Q$ imbalance, as assessed by the dispersion of pulmonary blood flow and that of alveolar ventilation, was slightly increased. The correlation between $V_A/Q$ markers and the degree of airflow obstruction, expressed as either $FEV_1$ or peak expiratory flow or mid-expiratory airflow rates, was very modest. Another study [63] showed similar $V_A/Q$ findings. As in the previous study [62], there was no correlation between the $V_A/Q$ mismatching and $PaO_2$, pointing to the vital role played by the extra-pulmonary determinants of pulmonary gas exchange, such as cardiac output and minute ventilation. In this study [62], pulmonary hemodynamics were within normal limits. Upon 100% oxygen breathing, it was shown that $V_A/Q$ disturbances further deteriorated. Since $FEV_1$ did not change, this $V_A/Q$ impairment may suggest, other things being equal, release of hypoxic pulmonary vasoconstriction. Despite the changes in the amount of the dispersion of blood flow distribution, it is of note that there were no changes in PAP, indicating that the $V_A/Q$ descriptors are more sensitive to hyperoxic mixtures changes than conventional measures of pulmonary vascular pressures.

# Adhesion Molecules in Asthma and Airway Diseases

**Dean Sheppard**

**Department of Medicine and Lung Biology Center, University of California, San Francisco, CA, USA**

All cells express a number of transmembrane proteins that could be characterized as "adhesion" receptors. Most of these proteins have been thus classified based on their role in facilitating attachment of cells to either components of the extracellular matrix or other cells. However, many adhesion receptors also transduce biological signals that modulate cell behavior that are either loosely connected or unrelated to such adhesion events. In this chapter, I will review the structures of some of the most important families of adhesion receptors, will summarize what is known about the patterns of adhesion receptor expression and function on cells relevant to asthma and other chronic airway diseases, and will discuss examples of *in vivo* evidence implicating some of these proteins in pathways which contribute to phenotypic features of airway diseases.

## ADHESION MOLECULE FAMILIES

Adhesion molecules can be divided into families based on their primary amino acid sequence similarity. Some adhesion molecule families principally mediate cell–cell adhesion, others are principally involved in cell adhesion to the extracellular matrix, and some are involved in both types of adhesion events. Families involved in cell–cell adhesion include claudins, occludins, cadherins, and immunoglobulin superfamily members. Claudins, occludins, and cadherins are all monomeric proteins that principally mediate homotypic cell–cell adhesion, usually through direct binding to members of the same family expressed at the lateral margins of adjacent cells (Table 21.1). These protein fami-

lies play critical roles in establishing polarity of epithelia and endothelia and in maintaining and regulating endothelial and epithelial permeability barriers. Cadherins are the core proteins of cell–cell junctions termed "adherans junctions" which serve as central organizers of epithelial and endothelial cell–cell adhesion by homotypic interactions of cadherin extracellular domains [1, 2]. Claudins are critical components of tight junctions that determine the degree of paracellular permeability of endothelia and epithelia to large macromolecules and even small ions [3]. These proteins also bind directly to family members on adjacent cells, but, in contrast to cadherins, claudins can associate with either identical family members or nonidentical members in tight junctions. Multiple claudin isoforms are expressed on airway epithelial cells [4]. Occudin [5], the product of a single gene with multiple spice variants, can serve as a central organizer of other tight junction proteins [6].

Immunoglobulin superfamily members play more complex roles in cell adhesion. Some family members, such as the endothelial adhesion protein, platelet endothelial cell adhesion molecule (PECAM), or the small subfamily of junctional adhesion molecules (JAMs), also play roles in homotypic cell–cell adhesion, but JAMs have also been reported to bind to members of other adhesion protein families (e.g., integrins) and to play roles in heterotypic cell–cell adhesion (e.g., between endothelial or epithelial cells and migrating leukocytes). Other immunoglobulin superfamily members (e.g., intercellular adhesion molecules, ICAMs and vascular adhesion molecule, VCAM) are restricted to roles in heterotypic cell–cell adhesion, principally through their roles as integrin ligands. Selectins, another small family of adhesion molecules, also principally mediate heterotypic cell–cell

**TABLE 21.1** Selected adhesion molecules of potential importance in asthma and COPD

| Name | Structure | Binding partners | Location | Comments |
|---|---|---|---|---|
| Claudins | Multiple membrane spanning (tetraspanin) | Homotypic and heterotypic bindings to Claudins | Tight junctions | Regulate ion permeability at tight junctions |
| JAMs | Single membrane spanning Ig family members | Homotypic and/or heterotypic binding to JAMS. Also bind selected integrins | Tight junction | Mediate leukocyte *trans*-endothelial migration, endothelial and epithelial cell–cell adhesion |
| Selectins | Single membrane spanning monomers with lectin domain | *Trans*-membrane proteoglycans with sialyl-Lewis X motif | Platelets, leukocytes, and endothelial cells | Mediate leukocyte rolling, can initiate intracellular signals. Potential drug target for asthma |
| VCAM1 | Single membrane spanning Ig family member | Integrins $\alpha 4\beta 1$ and $\alpha 9\beta 1$ | Endothelial cells, tumor cells, smooth muscle, pericytes | Counter-receptor for integrins $\alpha 41$ and $\alpha 9\beta 1$. Important for recruitment of leukocytes |
| ICAM1 | Single membrane spanning Ig family member | $\beta 2$ Integrins | Endothelial and epithelial cells | Counter-receptor for $\beta 2$ integrins. Possible drug target for asthma |
| $\alpha 4\beta 1$ Integrin | Transmembrane heterodimer | VCAM1, fibronectin, ADAMs proteins | Endothelium, pericytes, smooth muscle, lymphocytes, eosinophils, and mast cells | Potential drug target for asthma |
| $\alpha v\beta 6$ Integrin | Transmembrane heterodimer | TGF$\beta$1 and -3, fibronectin, tenascin C | Epithelial cells | Activates TGF-$\beta$. Negatively regulates macrophage protease expression and emphysema |
| $\alpha v\beta 8$ Integrin | Transmembrane heterodimer | TGF$\beta$1 and -3, vitronectin | Airway epithelial cells, fibroblasts, dendritic cells, and T-cells | Activates TGF-$\beta$. Involved in cross talk between airway fibroblasts and epithelial cells |

interactions, in that case through interactions with carbohydrate components of proteoglycan counter-receptors.

Receptors for components of the extracellular matrix can also play complex roles in cell biology. Syndecans are transmembrane proteoglycans that appear to function solely as receptors for components of the extracellular matrix. However, integrins, initially identified as extracellular matrix receptors, are now known to recognize a wide variety of spatially restricted proteins as ligands, including cellular counter-receptors, growth factors, and proteases [7].

Integrins were initially identified based on their ability to mediate stable adhesion to fixed extracellular matrix ligands. Integrin-mediated cell adhesion depends on the ability of $\beta$ subunit cytoplasmic domains to bind to a group of adaptor proteins that link integrins to the actin cytoskeleton (Fig. 21.1). By connecting the relatively rigid extracellular matrix to the relatively rigid actin cytoskeleton, integrins play important roles in maintaining cohesion of multicellular organs and organisms. These factors also position integrins as essential components of cellular force transducers which allow cells to detect and respond to mechanical deformation. The proteins involved in linking integrins and actin are highly conserved from *Caenorhabditis elegans* to humans.

**FIG. 21.1** Integrin functions. Integrins evolved to link the actin cytoskeleton and the extracellular matrix, a function that is highly conserved from *C. elegans* to humans (shown on right). This linkage is accomplished through formation of a highly conserved multiprotein complex that includes talin, tensin, and the integrin-linked kinase to the integrin $\beta$ subunit cytoplasmic domain. In vertebrates, integrins have evolved to recruit a multitude of additional cytoplasmic and transmembrane adaptor and signaling proteins to these complexes, allowing these receptors to modulate a wide variety of cellular behaviors (shown on left).

During the evolutionary transition from invertebrates to vertebrates, there was a rapid increase in the size of the integrin family, and integrins have been adapted to bind to a number of additional ligands and to modulate a wide variety of cellular behaviors, including cell proliferation, differentiation, and survival [8]. These new functions have been accomplished by recruitment of cytoplasmic kinases (such as src and focal adhesion kinase) to the multiprotein complexes assembled on integrin cytoplasmic domains and by lateral associations with a number of additional signaling molecules and adaptor proteins (e.g., tetraspanins, growth factor receptors, urokinase receptor, u-PAR, and the integrin-associated protein).

## ROLES OF ADHESION RECEPTORS ON LEUKOCYTES AND ENDOTHELIAL CELLS IN REGULATING AIRWAY INFLAMMATION

Airway and lung parenchymal inflammation are important features of asthma and chronic obstructive pulmonary disease (COPD). Inhibition of recruitment of specific populations of inflammatory cells into the airways has thus been considered as a potential therapeutic intervention in these diseases. Recruitment of inflammatory cells from the bloodstream into tissues is a multistep process [9], as outlined in Fig. 21.2. Key steps in this process include initial slowing of rapidly moving cells, a process called rolling [10]. These slowed cells must then undergo firm adhesion to completely arrest their movement in the bloodstream and then need to resume a different form of slow migration to exit the vasculature either in induced gaps between adjacent endothelial cells or by passing directly through the induced holes within individual endothelial cells. Once they have exited the bloodstream, leukocytes then migrate through the interstitial space where some arrest in the vicinity of nerves and airway smooth muscle, others arrest within the airway epithelium, and some traverse the epithelium and enter the airspaces. Each of these steps of adhesion and migration involves a suite of adhesion receptors expressed on the leukocytes, endothelial cells, or other target extravascular cells.

The first step in this process, leukocyte rolling, is principally mediated by interactions of a selectin on leukocytes (L selectin) with specific carbohydrate ligands on endothelial cells and selectins on endothelial cells (P and E selectins) with additional carbohydrate ligands on leukocytes [11]. This process is principally regulated by the induction of expression of L selectin ligands and P and E selectins only on endothelial cells that have been activated by pro-inflammatory cytokines, such as interleukin-1 and TNF-$\alpha$. In this process, selectins play a critical role in facilitating the rolling of neutrophils along the vessel wall. However, it is now clear that certain members of the integrin family, for example the integrins $\alpha4\beta1$ and $\alpha4\beta7$, can mediate rolling even in the absence of input from selectins [12, 13]. Selectin-mediated rolling may play an important role in asthma, since inhibition of selectins or their ligands has been shown to reduce allergen-induced airway hyperresponsiveness in models of allergic asthma [14, 15].

**FIG. 21.2** Multistep process of leukocyte rolling arrest and *trans*-endothelial migration.Initial slowing of leukocytes from rapidly moving blood is usually mediated by interactions of selectins on leukocytes and endothelial cells with cell surface carbohydrate ligands (left). Close contact with chemokines then triggers an intracellular signal that changes leukocyte integrins from a low-affinity to a high-affinity state and mediates stable arrest through interaction with endothelial immunoglobulin family members (center). Dynamic regulation of integrin adhesion then allows migration of adherent leukocytes across the endothelium and into and through the extravascular space (right).

The next step in leukocyte recruitment, firm adhesion to the vessel wall, is mediated principally by the interaction of integrins on leukocytes with immunoglobulin superfamily members on endothelial cells. The specific integrins involved, and the corresponding immunoglobulin family counter-receptors, vary among different leukocytes. Neutrophils were initially thought to arrest their movement by virtue of adhesion of the integrins $\alpha L\beta2$ and $\alpha M\beta2$ with the endothelial counter-receptor ICAM-1, whereas monocytes, lymphocytes, and eosinophils [16] utilize $\alpha4\beta1$, which interacts with endothelial VCAM-1 [17]. However, neutrophils also express the integrin $\alpha9\beta1$, which avidly binds VCAM-1 [18], and lymphocytes, monocytes, and eosinophils also utilize $\alpha L\beta2$ and thus arrest on ICAM-1.

As with the initial rolling step, firm arrest is tightly regulated through signaling in both leukocytes and endothelial cells. On the leukocyte side, integrins in circulating leukocytes are generally maintained in a nonadhesive (inactive) conformation. In response to signals generally initiated by the binding of chemokines to their cognate G-protein-coupled receptors (which are presented to integrins on rolling leukoctyes by virtue of their interactions with proteoglycans on the luminal surface of endothelial cells), the short cytoplasmic domains of the integrin-$\alpha$ and -$\beta$ subunits are separated by interactions with one or more cytoplasmic binding partners, and this change in subunit spacing induces a massive conformational change in the extracellular domains of both subunits that result in a high-affinity conformation that is competent to bind to endothelial ligands. On the endothelial side, the same pro-inflammatory cytokines that induce expression of P and E selectins increase transcription and subsequent surface expression of ICAM-1 and VCAM-1.

## ROLES OF INTEGRINS AND THEIR LIGANDS IN LEUKOCYTE MIGRATION AND RETENTION IN THE EXTRAVASCULAR SPACE

Whereas the molecular steps involved in rolling and firm adhesion are relatively well characterized, much less is know about how subsequent steps of extravasation and migration and retention at specific sites are regulated. These steps also require repeated cycles of adhesion and de-adhesion. Although multiple molecular pathways have been shown to modulate these steps in various *in vitro* systems, the relative significance of most of these for specific leukocyte populations *in vivo* remains to be determined. One of the steps that has just begun to receive attention is the retention of leukocytes at specific tissue sites. The potential importance of this step in asthma was demonstrated by mice lacking the metalloprotease, MMP2, which were found to have dramatically increased susceptibility to fatal respiratory failure in response to airway allergen challenge after prior allergic sensitization [19]. Mortality in these mice was shown to be associated with abnormal retention of recruited leukocytes in the pulmonary interstitium, with a marked decrease in the subsequent migration of these cells into the airway lumen.

One of the critical steps involved in retention of inflammatory cells within the airway epithelium is induced expression of ICAM-1 on airway epithelial cells. Another key step is the induction of the integrin αEβ7, which can be induced on lymphocytes and mast cells by the action of the cytokine transforming growth factor β (TGF-β), activated on epithelial cells at sites of airway injury (see below). αEβ7 recognizes an epithelial adhesion receptor, E Cadherin, as its principal ligand [20], and through this interaction increases the residence time of mast cells and lymphocytes within the epithelium. These leukocytes utilize the αEβ7-integrin and presumably E Cadherin for retention within the epithelium.

## POTENTIAL THERAPEUTIC RELEVANCE OF LEUKOCYTE CELL ADHESION RECEPTORS AND THEIR ENDOTHELIAL AND EPITHELIAL COUNTER-RECEPTORS

Because airway inflammation is a prominent feature of asthma, and because leukocytes are the principal source of cytokines (e.g., interleukin-13) known to play a major role in inducing airway hyperresponsiveness and mucus metaplasia, leukocyte adhesion molecules and their endothelial and/or epithelial ligands have been extensively studied as potential therapeutic targets. Nearly two decades ago, blockade of the β2-integrin ligand, ICAM-1, was shown to prevent airway hyperresponsiveness in a murine model of allergic asthma [21]. Subsequent studies with mice lacking the integrin β2 have confirmed an important role for this family of integrins in the specific homing of Th2 effector T cells to the lungs [22].

α4-containing integrins are more widely expressed than β2-integrins but are also expressed on a number of leukocytes, including lymphocytes, eosinophils, and mast cells. Blockade of α4-integrins has been shown to protect against induction of airway hyperresponsiveness in models of allergic asthma in mice and sheep [23, 24]. Mice lacking α4 only on leukocytes have also been shown to be protected from induction of airway hyperresponsiveness, suggesting that α4-integrins (α4β1 and α4β7) might be reasonable targets for treatment of asthma. Although this strategy was conceived as a way to prevent the recruitment of leukocytes into the airways, local delivery of blocking antibody into the airways of allergic sheep prevented the development of airways hyperresponsiveness (AHR) without affecting leukocyte recruitment [24]. These results suggest that protection from AHR might be due to inhibition of α4-integrin-mediated signals initiated on cells that are already present in the airways, rather than simply to effects on leukocyte recruitment.

Based on these encouraging pre-clinical studies, both humanized antibodies and small molecule antagonists of α4-integrins have been developed as potential drug treatments for asthma. Humanized antibody has been shown to be dramatically effective for prevention of new brain lesions in another inflammatory disease, multiple sclerosis [25]. However, the development of fatal or disabling progressive multifocal leukoencephalopathy in three patients treated with this antibody, presumably as a consequence of activation of latent JC virus infection, has dramatically slowed efforts to use system blockade of α4-integrins for treatment of asthma [26, 27]. Because of the potential effectiveness of local inhibition of these integrins, inhalational therapy with α4-antagonists is still worthy of consideration.

Selectins have also been targeted in pre-clinical studies in mice and sheep. Inhibition of one of the three selectin family members (L selectin) also inhibited airway inflammation, allergen-induced late airway narrowing, and AHR in allergic sheep [14]. As with α4-blockade, local delivery of blocking antibody to L selectin was as effective as systemic administration, suggesting relevant effects of ligation of selectins on inflammatory cells after their recruitment into the airway wall.

## ADHESION RECEPTORS ON AIRWAY SMOOTH MUSCLE

Airway smooth muscle is clearly an important target tissue in asthma. An increase in smooth muscle mass is a common feature in both human asthma and experimental models of chronic allergen challenge, and alterations in *in vivo* smooth muscle responsiveness might be an important determinant of airway hyperresponsiveness. Airway smooth muscle cells can express ICAM-1 and VCAM-1 and a number of integrins, including at least α1β1, α2β1, α3β1, α7β1, α8β1, α9β1, and αvβ3. These integrins are localized at intercalated disks that connect adjacent smooth muscle cells and are thus likely to play some role in regulating the strength of smooth muscle contraction. Airway smooth muscle cells exhibit markedly different proliferative responses and modulate their production of

pro-inflammatory cytokines when they are plated on different integrin ligands [28, 29]. Furthermore, integrins in vascular smooth muscle cells have been shown to modulate contraction by regulating the activity of associated L-type voltage-gated calcium channels [30, 31]. The *in vivo* significance of adhesion receptors on airway smooth muscle cells thus seems like a fruitful area for future investigation.

## ADHESION RECEPTORS ON PULMONARY EPITHELIAL CELLS

One potential contributing factor to increased responsiveness to environmental stimuli in asthma and COPD would be localized increases in epithelial permeability. The normal impermeable character of the airway epithelium is determined by the function of the adhesion molecules that make up adherens junctions (E Cadherin) and tight junctions (claudins and occludins). In contrast to responses in endothelial cells, where permeability can be rapidly (within minutes) increased in response to a number of physiological stimuli (e.g., VEGF, TGF-β, and thrombin), changes in epithelial permeability usually occur with a time course of several hours and are associated with loss of adhesion molecules (especially E Cadherin) from the cell surface. In the setting of chronic inflammation, for example with exposure to active TGF-β, E Cadherin is internalized and epithelial permeability increases. However, the *in vivo* relevance of these events to chronic airway disease has not been determined.

Airway epithelial cells express several members of the integrin family, including α2β1, α3β1, α6β4 α9β1, αvβ5, αvβ6, and αvβ8 [32]. Epithelial injury and inflammation can dramatically alter the expression of these integrins [33]. The integrin αvβ6, which is normally expressed at low levels in the conducting airway epithelium of healthy individuals, is upregulated in the airways of patients with COPD and asthma [34].

## INTEGRIN-MEDIATED TGF-β ACTIVATION

At least two of the integrins expressed on airway epithelial cells, αvβ6 [35] and αvβ8 [36], play a role in activating latent complexes of TGF-β. TGF-β is a pleiotropic cytokine that plays important roles in regulating tissue fibrosis, in induced proliferation of airway smooth muscle, in recruiting and retaining tissue mast cells and in negatively regulating adaptive immunity. It is thus clear that TGF-β could play important roles in several basic processes relevant to asthma and COPD. Mice with a knockin mutation of the TGF-β1 gene, which uniquely prevents integrin-mediated activation, have an identical inflammatory phenotype as mice completely lacking TGF-β1 have [37], suggesting that integrin-mediated activation may be the central *in vivo* mechanism of TGF-β1 activation. Indirect evidence suggests similar importance for activation of TGF-β3.

αvβ6 and αvβ8 have different patterns of cellular expression. Each binds to the same sequence of the latency-associated peptides of TGF-β1 and -3, but these two integrins

appear to utilize completely different mechanisms for TGF-β activation. αvβ6 is restricted to epithelial cells and activates TGF-β by mechanically deforming the latent complex (Annes). This process provides access to the active site in TGF-β without releasing free TGF-β for diffusion to distant receptors and thus spatially restricts TGF-β activity to the surface of αvβ6 expressing epithelial cells [35]. In contrast, αvβ8, which is much more widely expressed, presents the latent complex to transmembrane metalloproteinases expressed on the same cell, which cleave the latent complex allowing release of diffusible active TGF-β that could act at a distance [36].

Current evidence suggests that αvβ6 plays a central role in activating TGF-β on the surface of alveolar epithelial cells, where the activated TGF-β can exert effects on adjacent fibroblasts, endothelial cells, and alveolar macrophages which make direct physical contacts with alveolar epithelial cells. This process has been shown to play important roles in regulating pulmonary fibrosis [35] and several models of acute lung injury [38], where genetic deletion or antibody blockade of the αvβ6-integrin dramatically protects against induction of *in vivo* pathology. Microarray studies on the lungs of mice lacking the β6 subunit (and thus the αvβ6-integrin) identified the macrophage metalloprotease, MMP12 as an important target of negative regulation by this integrin, since MMP12 levels were increased 200-fold in the lungs of β6 knockout mice [39]. Induction of MMP12 leads to the development of age-related emphysema in these mice and can be prevented by expression of the integrin or low levels of active TGF-β in lung epithelium [40]. These findings suggest that αvβ6-mediated TGF-β activation plays an important homeostatic role in preventing the development of emphysema in response to normally inconsequential environmental insults (Fig. 21.3).

**FIG. 21.3** Homeostatic regulation of macrophage MMP12 expression by integrin-mediated activation of TGF-β. Environmental insults (e.g., cigarette smoke) increase macrophage expression of MMP12 (and other proteases that can degrade the extracellular matrix of the lung. In parallel, the same insults activate a pathway through which the epithelial integrin, αvβ6, activates TGF-β. Activated TGF-β binds to TGF-β receptors on macrophages, activating a signaling pathway involving transcription factors (receptor SMADs – R-SMADs) that pair with co-SMADs to shut off transcription of the MMP12 gene, thereby providing a brake for this potentially destructive process.

## INTEGRIN-MEDIATED TGF-β ACTIVATION IN THE CONDUCTING AIRWAYS

Both αvβ6 and αvβ8 are expressed on epithelial cells in the conducting airways. Under resting conditions, cultured airway epithelial cells express both integrins and secrete both TGF-β1 and TGF-β2 but do not appear to activate either isoform [41]. In response to mechanical wounding, these cells can be induced to activate TGF-β1 (but not TGF-β2) and both integrins appear to contribute to this activation. The net effect of this "autocrine" TGF-β activation is a slowing of the rate of sheet migration and subsequent wound closure. Interestingly, whereas blockade of αvβ8, like blockade of TGF-β1, accelerates the rate of wound closure, blockade of αvβ6 has no net effect on closure rates. This appears to be due to opposing effects of this integrin on activating TGF-β (which slows closure rates) and on directly enhancing epithelial migration, as shown by slowing of wound closure when anti-αvβ6 antibody was added to wounded cells in the presence of inhibitors of TGF-β or αvβ8.

In contrast to αvβ6, which is restricted in its expression to airway epithelial cells and is highly induced in response to injury, αvβ8 is also expressed on airway fibroblasts [42]. Recent work has shown that αvβ8 can mediate autocrine activation of TGF-β by airway fibroblasts and that this effect inhibits to production of hepatocyte growth factor by adjacent epithelial cells. Through this process, airway fibroblasts can also induce expression of αvβ6 on epithelial cells (which is highly inducible by TGF-β) generating a positive feedback loop that would be predicted to inhibit airway epithelial cell proliferation and contribute to the development of airway wall fibrosis.

## SUMMARY

Adhesion molecules play critical roles in maintaining the structural integrity of all components of the airway wall. In the epithelium and endothelium, occludins, claudins, cadherins, and JAMs regulate paracellular permeability. Airway injury or inflammation, as occurs in patients with asthma and COPD, can perturb epithelial and endothelial permeability by altering the expression and/or function of these proteins. Selectins, integrins, and their immunoglobulin family member counter-receptors, play central roles in the recruitment of leukocytes into the airway wall and in regulating the function of leukocytes that have been recruited. Promising pre-clinical studies suggest that members of each of these classes of adhesion molecules are potential drug targets for treatment of asthma. Integrins also contribute to signaling responses of airway cells to input from other receptor families, including growth factor and cytokine receptors, and can modulate survival, growth, and differentiation of each of the cell types present in the airway wall. Two integrins, αvβ6 and αvβ8, are also largely responsible for *in vivo* activation of two of three mammalian isoforms of TGF-β. TGF-β activation by the αvβ6-integrin is critical for the maintenance of normal alveolar homeostasis, and loss of this function could contribute to the development of emphysema. TGF-β activation by the αvβ8-integrin plays an important role in homeostasis in the airway wall, and alterations in this function could contribute to airway wall remodeling in COPD. The multiple critical roles played by adhesion molecules in airway health and disease make these proteins attractive candidates for improvements in treatment and monitoring of patients with asthma and COPD.

# Extracellular Matrix

**CHAPTER**

**Maurice Godfrey**

Center for Human Molecular Genetics, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE, USA

## INTRODUCTION

Until recently the extracellular matrix was thought of solely as a static structural support network. We now know that the extracellular matrix is comprised by a large and varied group of dynamic macromolecules and their regulatory factors [1] which provides structural support and is a physical barrier. However, it also elicits cellular responses and its interactions are involved in development and organ formation [2]. Disruption of normal extracellular matrix during disease processes can lead to an inflammatory response that exacerbate aberrant remodeling of the lung [3, 4]. Much has also been learned about the role of the extracellular matrix in asthma and chronic obstructive pulmonary disease (COPD) using mouse models [5, 6]. These studies tend to support observations of altered function in people with polymorphic variants of extracellular matrix molecules [7–9].

Extracellular matrix molecules are a part of a finely regulated system of development, maintenance, and repair. In addition to the structural macromolecules that are discussed in this chapter, there are regulatory molecules that are essential components of the extracellular matrix [10, 11]. In this chapter we will review the extracellular matrix constituents of the respiratory system.

## COMPONENTS OF THE EXTRACELLULAR MATRIX

The biomechanical properties of the lung are primarily determined by the extracellular matrix components that comprise the tissue [2, 12]. In the lung they can be largely categorized into four groups: the collagens, proteoglycans, elastic fibers, and non-collagenous proteins. Connective tissue in the lung imparts the appropriate mechanical sturdiness and elastic resilience that permits the lung to expand and relax repeatedly. In addition to this mechanical function, the extracellular matrix is organized to allow for efficient gas exchange (Table 22.1).

### Collagens

By far the most abundant of the extracellular matrix elements are the collagens. The collagens are the largest, in number, and most abundant, in content, of the extracellular matrix elements. There are more than 20 different collagen types and even more genes that encode these collagens [1, 2, 13].

Collagens are characterized by a triple helical structure whereby three polypeptide chains wind around each other. To form this helical configuration, every third amino acid must be a glycine. Glycine, with its very small side chain is the only amino acid that is able to fit in the center of the helix without causing any distortion. The primary structure of the triple helical region of collagens is described by the general pattern of $[\text{Gly-X-Y}]_n$ as a repeating triplet. About 20% of the X and Y positions in this triplet are the imino acids, proline, and hydroxyproline. The hydroxyl group of hydroxyproline is essential for hydrogen bonding which imparts stability to the triple helix. Similarly, lysine and hydroxylysine residues in the helical region are important for covalent cross-links within and between collagen molecules. Hydroxylysines are also subject to glycosylation.

**TABLE 22.1** Summary of the major extracellular matrix constituents of the lung and their localization.

| Collagens | |

| Type I | Alveolar, bronchial, vascular walls |
| Type II | Bronchial and tracheal cartilage |
| Type III | Co-localizes with Type I collagen |
| Type IV | Basement membrane |
| Type V | Basement membrane, interstitium |
| Elastin | Alveolar septa, blood vessels, bronchial walls, pleura |
| Microfibrils | Found with elastin, scaffold for elastin deposition |
| Proteoglycans | Alveolar walls, basement membrane |
| Laminin | Basement membrane |
| Integrin (receptors for extracellular matrix molecules) | Mesenchymal and epithelial cells |
| Fibronectin | Basement membrane, interstitium |

The number of glycosylated residues vary with the different collagen type [14, 15].

Collagen α-chains are synthesized as pro-α-chains with non-helical amino and carboxy terminal ends. Cleavage of the propeptides is essential for the proper stacking of triple helical collagen molecules to form an extracellular matrix. Amino acid substitutions, especially the invariant glycine residues, cause a delay (momentary pause, ie. nanoseconds) in formation of the triple helix. This delay leads to an increase in hydroxylated and glycosylated residues. These, so-called, overmodified collagens are characteristic of a number of heritable connective tissue disorders [16].

About 60% of the connective tissue protein mass in the adult lung is collagen. As expected Type I is the predominant type. The lung also contains a significant amount of Type III collagen, a major constituent of skin and vascular tissues. The Type III fibers are thin which allows for a more compliant tissue. Studies have shown that Type III collagen is essential for fibrillogenesis of Type I collagen in normal development [17–20]. Types I and III collagen provide the structural framework for the alveolar wall [2].

Type IV collagen is an important constituent of basement membranes [1, 21, 22]. The basement membrane, as visualized by electron microscopy, consists of two layers, the lamina lucida and lamina densa. In the lung, the basement membrane forms continuously along the bronchial epithelia from before 12 weeks gestation [23]. In addition to Type IV collagen, basement membranes contain other extracellular matrix molecules such as proteoglycans and laminins. The Type IV collagen appears to serve as a scaffold for binding of laminin and proteoglycans leading to the formation of the basement membrane [24]. During lung branching, the epithelium of the elongating bronchial buds and tubules are lined with Type IV collagen. Type III collagen, however, does

not appear to play a significant role in lung branching [25]. Type V collagen has also been localized in the lung. While it is found near the basement membrane, it is unclear whether this minor collagen is part of the basement membrane or solely in the nearby interstitial matrix [26]. The basement membrane of the lung also contains Type XVIII collagen, a member of the collagen subfamily called MULTIPLEXINs [27]. These multiplexins have multiple triple helical domains and interruptions, hence their name [1]. Cartilage collagens, Types II, IX, and XI along with cartilage matrix protein (not a collagen) are primary components of the trachea [28].

Despite the biochemical, immunochemical, ultrastructural in addition to molecular characterization of collagens in normal lung, their precise function and roles in pulmonary homeostasis is still not completely elucidated. Studies continue to determine the cellular influence of collagens; their mechanical properties as they relate to lung mechanics, interactions between collagen types and other matrix molecules; kinetics of maturation and turnover; and their self-assembly. Nevertheless, the extracellular matrix components of the lung show that they are part of a dynamic structure. When perturbed by environmental assault (eg. smoking, industrial polution) or disease (genetic mutations), this dynamic balance can be altered and the biomechanical properties of the lung changed [2].

## Elastin

Elastin is the main elastic protein in vertebrates and is responsible for the ability of the lung to recoil following each cycle of expansion and contraction. Thus, like collagen, elastin is an integral component of the interstitial matrix of the lung. Given its importance for this elastic resilience, elastin has been localized to the alveoli, pleura, conducting airways, and vascular tissues [29, 30]. Elastin is secreted as a monomer of so-called tropoelastin, generally by cells that are of mesenchymal origin. The exquisite ability of repeated recoil is a unique property of the elastic fiber. The ability to undergo repeated rounds of recoil are believed to be due to the high hydrophobic amino acid content of elastin [31]. These hydrophobic amino acids are arranged as to allow cross-links to form that are believed to be critical for its function. Recent studies have also shown the importance of optimal iron levels for elastic fiber integrity [32]. It is important to note that none of these extracellular matrix elements function in a vacuum. They comprise a characteristic architecture and thus a function in an interrelated and integrated fashion. Therefore, elastin provides its unique function in the context of the collagens, proteoglycans, and microfibrils.

The elastic fiber is among the most long-lasting structures in the body. Studies have shown that humans retain elastin an entire lifetime [33]. This stability appears to be due to very specific cross-links between elastin monomers in the mature elastic fibers. It is in fact these unique cross-links, formed from lysine residues, that produce novel amino acids, desmosine and isodesmosine, that are markers for the presence of elastin in tissues.

Early structural studies tended to describe elastic fibers as having an amorphous appearance. More recent studies, however, have shown a rather complex structure.

Two morphologically and chemically distinct entities have been identified. Elastin, the insoluble polymer composed of tropoelastin monomers and microfibrils. Structure and function of microfibrils are discussed below [34, 35].

Elastin, in its polymerized form, constitutes more than 90% of the mature elastic fiber. The amino acid structure of tropoelastin is highly conserved in evolution [36]. In all species studied, tropoelastin has a modular structure of alternating hydrophobic and cross-linking domains. While sequence variation exists, it is the hydrophobicity that is exquisitely conserved. The conservation appears greater in the cross-linking regions. Unlike the large variety and numerous gene products that encode the collagens, elastin is present as a single gene in a single copy. Interestingly, the various isoforms of elastin that are present are produced by alternative splicing of a common transcript [37–39]. At present, however, the functional roles of these isoforms are not understood [40].

Mouse studies have shown that animals that lack any elastin expression do not undergo normal alveogenesis. Mice with only 50% normal elastin do develop normal lungs while expression of less than 50% elastin leads to abnormal lung development [30]. Significantly, however, is the fact that injurious stimuli make mice with less than optimal elastin levels more prone to severe lung disease [30]. Recent studies have also demonstrated a polymorphic variant in human elastin causing early onset COPD in a family [41]. Severe early onset pulmonary disease has also been documented in smokers whose elastin mutation causes autosomal dominant cutis laxa [42].

## Microfibrils

Elastin-associated microfibrils have been classically defined as 10–12 nm diameter fibrils when seen by electron microscopy [43]. They were initially identified as structures that surrounded or were within mature elastic fibers. It is now known that microfibrils can also exist without the presence of elastin [44]. Analyses of developing tissues, including the lung and major blood vessels, have shown that microfibrils are deposited first followed by the deposition of elastin [45]. Thus, the hypothesis that microfibrils act as a scaffold for the deposition of elastin to produce mature elastic fibers has emerged. The complete function and, for the matter, constituents of the microfibrils are presently unknown.

Ultrastructurally, microfibrils display a "beads on a string" structure with a diameter of 8 to 12 nm and are composed of several proteins, the most abundant of which is fibrillin-1 [46]. Fibrillin-1, the product of the FBNI gene, is a cysteine rich-glycoprotein with a molecular weight of about 350 kDa. The extracellular domain structure of fibrillin-1 is divided into five distinct regions. The most abundant of these domains are calcium binding epidermal growth factor-like (EGF) motifs, that occur some 43 times. Four additional EGF motifs that do not bind calcium are also present. Interspersed between their calcium binding domains are seven transforming growth factor β1 binding protein domains each containing eight cysteine residues [47, 48]. These eight cysteine domains are globular in structure and interrupt the multiple stretches of the EGF modules that are believed to form rod-like structures. The middle 8-cysteine domains contain an RGD (arginine–glycine–aspartate) site.

RGD motifs interact with cell surface receptors to mediate cell adhesion [49]. These receptors are part of the integrin family, transmembrane proteins that interact with extracellular matrix proteins to anchor cells within the extracellular matrix. While the role of elastin in mediating elastic recoil is well established, microfibrils too appear to have some elasticity. In fact, speculation exists that microfibrils alone performed the function of elastic fibers prior to the evolution of tropoelastin. Closely related to fibrillin-1 is fibrillin-2. Fibrillin-2 shares the domain structure with fibrillin-1 and in the EGF containing regions are about 80% identical at the amino acid level. There are several important differences that may reflect differing functional roles. Fibrillin-2 contains two RGD sites and the domain that is proline rich in fibrillin-1 is glycine rich in fibrillin-2 [47, 48, 50].

Fibrillin-1 and -2 are differentially expressed both temporally and spatially. In most cases, developmental expression of the fibrillin genes displays a diphasic pattern. Thus, expression of fibrillin-2 occurs earlier in development than fibrillin-1. Studies at the level of mRNA have shown FBN2 transcript accumulation prior to tissue differentiation followed by their rapid decrease. FBN1 transcripts then begin to increase gradually. Studies have shown that fibrillin-2 is found preferentially in elastic tissues, such as elastic cartilage, tunica media of the aorta, and along the bronchial tree. The two fibrillins, therefore, may have differing functional roles. It has been hypothesized that fibrillin-2 may have a greater role during early morphogenesis in directing the assembly of elastic fibers, while fibrillin-1 is mainly responsible for load bearing [50–52].

While the fibrillins are regarded as the major constituents of microfibrils, there are additional families of proteins that are part of the microfibrils and the elastic fiber. These additional families include the latent transforming growth factor beta binding proteins (LTBPs); microfibril-associated glycoproteins (MAGPs) and microfibril-associated proteins (MFAPs); fibulins; emilin; Big-H3; and lysyl oxidase. The structural and functional roles of most of these proteins are not clear. We do know that LTBP-2 is evolutionarily the closest of the LTBPs to the fibrillins and has been isolated from tissue rich in microfibrils. MAGP-1 has also been immunolocalized to both elastin-associated and naked microfibrils. MAGP-1 interacts directly with tropoelastin monomers and may play a primary role in elastic fiber formation (see Ref. [53] for a review).

Studies in mice have shown that fibulin-5 null animals have disrupted elastic fibers and pulmonary emphysema among other phenotypes [54, 55]. Fibulin-5 mutations in people appear not to be associated with lung abnormalities [56]. The hypothesis that microfibrils play a role in TGF-β signaling has lead to uncovering of emphysema in Marfan-like mice [57]. In addition, pulmonary abnormalities in several LTBP mouse mutants have also been demonstrated [58, 59]. The effects of TGF-β signaling on lung development and branching are reviewed in Ref. [60].

It is apparent that we are just beginning to understand the roles of the extracellular matrix in forming complex tissues. The myriad of molecular interactions involved with the numerous proteins noted above that are required to build an elastic fiber are just being uncovered. The temporal or tissue specific expression of the various microfibrillar components is also largely unknown. Mouse studies will be critical for

the continued progress in elucidating the complex signaling role of the extracellular matrix.

## Proteoglycans

Proteoglycans comprise a large group of multidomain core proteins to which glycosaminoglycans are attached. Glycosaminoglycans are unbranched carbohydrate chains of repeating disaccharide units. Since most are negatively charged, they bind to other matrix molecules, cell adhesion molecules, and growth factors [61, 62]. They are integral to maintain normal pulmonary structure and function. Of the species of proteoglycans, heparan sulfate and dermatan sulfate appear to be the most abundant [2, 63]. These proteoglycans are also a reservoir for heparin. Chondroitin sulfates, proteoglycans found in cartilagenous tissues, are present in bronchioles, while heparan sulfate is the major proteoglycan of the gas exchange tissue. Heparin is also found primarily in the gas exchange tissues and pleura, but, as expected, not the cartilagenous bronchioles [63, 64]. Biochemical studies over the past quarter century have helped to elucidate the composition of lung proteoglycans, but their precise functions are still not completely understood.

Heparan sulfate interacts with laminin and appears to be essential for human development and lung branching [65–68]. Studies also demonstrate that proteoglycans are important for the function of growth factors. Much of this modulation by proteoglycans appears to involve binding and signaling of TGFβ and its receptor [69–72]. These molecules may also stimulate production of other matrix constituents or act as receptors for the extracellular matrix [73, 74].

Here again mouse targeting of perlecan, a heparan sulfate proteoglycan, have shown that null mice who survive embryonic life die perinatally due to respiratory failure [75, 76].

## Laminin

Laminins are cross-shaped molecules that comprise several different types and are a part of lung development [1, 77–79]. Analysis of the developing lung has shown the expression of some laminin chains as early as 10 weeks of human gestation [80]. Laminins are expressed along the basement membrane, but temporal and spatial expression of different laminin subunits has been documented [25, 81]. Laminin expression may play a role in cell differentiation in the lung as well as other tissues. There is some evidence to suggest that laminin may play a role in alveolar morphogenesis [82]. A laminin–heparan sulfate interaction may be essential to lumen formation and branching morphogenesis [83].

## Integrins

Integrins are cell surface glycoproteins that serve as receptors for the extracellular matrix [84–86]. Integrins are composed of many subtypes all arranged as heterodimers [85]. These heterodimers can selectively bind several different matrix constituents [87]. In fact, the RGD sequence of extracellular matrix molecules is the binding site for integrins [88, 89]. Integrins are expressed early in human lung development [90, 91]. Animal model manipulation of some integrins have resulted in reduced bronchial branching suggesting a vital role for some integrin dependent interactions in lung development [86, 88, 92, 93]. Integrins also function in signaling pathways to mediate migration and differentiation of epithelial cells [94–96].

## Fibronectin

Fibronectin is a widely distributed glycoprotein found in embryonic tissue that plays a material role in morphogenesis [97, 98]. Fibronectin plays an important role in cell attachment [99]. While it has been localized in several regions of the developing lung, it is primarily seen in regions of airway bifurcation [89]. Fibronectin is co-distributed with collagen and may be required for normal collagen deposition [100, 101]. Its precise role, however, has not yet been elucidated.

## EXTRACELLULAR MATRIX AND LUNG FUNCTION

The matrix of the normal lung imparts the strength and resilience for the continuous cycling of inspiration and expiration (Fig 22.1). For proper gas exchange, the components of the extracellular matrix are distributed in a fashion to reduce the boundary between erythrocytes and oxygen [26]. When the exquisite balance of matrix glycoproteins is disturbed, (by structural mutations of matrix components or environmental damage) the consequences on the lung are manifested by pathology. In most cases the assault on the lung leads to fibrosis. Fibrosis leads to the thickening of the alveolar walls, reduction in lung volume, reduced lung elasticity, and fundamentally anomalous gas exchange. There are a number of causes of pulmonary fibrosis in addition to those due to genetic abnormalities of matrix molecules or their modifiers (see below).

In some cases, pulmonary fibrosis is a result of some other primary disease [102]. Examples include infections (viral and fungal) or immune disorders (rheumatoid arthritis, scleroderma). As expected, environmental assaults comprise the greatest number of causes of pulmonary fibrosis. As one might predict, tobacco smoke causing emphysema is among the major causes of COPD [103]. Fibrogenic dusts, such as asbestos, toxins, and chemicals, such as insecticides and herbicides, are additional causes of fibrosis in the lung. Iatrogenic causes, such as pharmacotherapy and therapeutic irradiation may also lead to pulmonary fibrosis.

## HERITABLE DISORDERS OF CONNECTIVE TISSUE

Heritable disorders of connective tissue (HDCT) are a series of disorders caused by mutations in structural or modifying components of the extracellular matrix. Since most of these gene products are expressed in multiple tissues,

pleiotropic manifestations are observed in most HDCT. It is important to distinguish HDCT from connective tissue disorders that are autoimmune in nature such as rheumatoid arthritis and systemic lupus erythematosus. For a comprehensive review of the HDCT, see Refs [16, 104].

Despite the abundance of collagen and elastic fibers in the lung, the number of HDCT with primary and severe pulmonary disease is rather small. While there are numerous HDCT, for the purposes of this abbreviated review only those disorders caused by defects in genes expressed in the pulmonary system or with pulmonary complications will be discussed. Osteogenesis imperfecta (OI) comprises several disorders of varying severity that are caused by mutations in Type I collagen. In its most severe form, OI Type II, is characterized by sever bone fragility and stillbirth or neonatal death. Due to the small chest in these neonates, pulmonary insufficiency and failure to ventilate can cause death in the few who are not stillborn. In OI Type III, characterized by moderate to severe bone fragility, the thorax is often conical in shape. Due to the softness of the bones in the chest, an often lethal, respiratory failure may occur in neonates. Despite these findings, most individuals with OI, except of course Type II OI, do not have severe pulmonary deficiency even though Type I collagen is abundant in the lung matrix.

The Ehlers–Danlos syndromes (EDS) are another series of HDCT. The classic type, previously called Types I and II are now known to be caused by mutations in Type V collagen. The most severe form of EDS is the, so-called, vascular type, previously called Type IV EDS. This form of EDS is caused by mutations in Type III collagen.

Pulmonary complications are rare in EDS. However, some cases of mediastinal and subcutaneous emphysema and spontaneous pneumothorax have been reported. In addition, dilation of the trachea and bronchi has also been described in some cases of EDS.

Pseudoxanthoma elasticum (PXE) is an HDCT whose molecular pathogenesis has been recently elucidated. PXE is characterized by abnormalities in the skin, eyes, and vasculature. Although the mechanism of the pathogenesis remains unclear, the generalized dystrophy of elastic fibers does occasionally manifest in the lung. Degenerative changes in the walls of alveoli and miliary mottling of the lungs have been reported.

The mucopolysaccharidoses (MPS) are a large group of disorders that are defects in enzymes required in the processing of glycosaminoglycan molecules (see "Proteoglycans"). The large number of different enzymatic defects makes a comprehensive review here impossible. Nevertheless, pulmonary complications have been observed in several MPS. For example, Hurler syndrome (MPS I H) is due to defects in α-l-iduronidase. Hurler syndrome is characterized by diagnosis prior to age 2 early corneal clouding, kyphoscoliosis, mental retardation, and death by age 10. All individuals with Hurler syndrome experience severe respiratory problems. Accumulation of glycosaminoglycans in the oropharyngeal trachea leads to airway obstruction. Radical pharyngoplasty provides some temporary relief, but obstruction recurs. These individuals are also prone to repeated upper respiratory infections. Deformity of the thorax and abnormalities of bronchial cartilage contributes to reduced chest expansion and decreased vital capacity. Bronchopneumonia is a frequent cause of death.

Hunter syndrome (MPS II), caused by a deficiency in iduronate 2 sulfatase, is characterized by diagnosis prior to age 4, mental retardation, and death before age 15. A mild form has also been described with moderate skeletal and respiratory involvement and survival to adulthood without intellectual impairment. Respiratory complications include upper airway obstruction, nasal congestion, and thick rhinorrhea. As children grow older, pharyngeal hypertrophy, tongue enlargement, and supraglottic swelling may result in obstructive sleep apnea and death. Upper respiratory infections are common. Abnormalities of the trachea have been documented. MPS II is an X-linked disorder, thus virtually all effected individuals are male. Pulmonary complications are observed in the majority of individuals with the gamut of MPS types.

The chondrodysplasias are another group of HDCT often classified based on radiographic involvement of the long bones. Severe respiratory difficulty is present in a number of these disorders due to a greatly restricted thorax, which leads to early death. Defects in Type II collagen are well documented in several of these disorders.

The Marfan syndrome (MFS) is a prototypical member of the HDCT. It is now well known that mutations in the gene encoding fibrillin-1 cause MFS. Thus, MFS is due to abnormalities of the elastic fiber system. Clinically, MFS is characterized by defects in the cardiovascular, skeletal, and ocular systems. Given the presence of elastic fibers in the lung it is not surprising that pulmonary complications also occur. The principal respiratory system abnormality in MFS is spontaneous pneumothorax, which occurs in approximately 5% of affected individuals. This indicates that spontaneous pneumothorax is statistically several hundred times more likely in a person with MFS than in the general population. In fact, the diagnosis of MFS has often been made after an initial event of a spontaneous pneumothorax. Spontaneous pneumothorax may be familial even in the absence of MFS. Apical bullae are also known to occur in MFS and may be a predisposing factor for spontaneous pneumothorax. Emphysema and congenital cystic lung have also been documented in MFS.

Pulmonary function too has been studied in MFS but has been interpreted as essentially normal. In some cases of MFS, severe kyphoscoliosis may be a major contributor to pulmonary failure, however, that cannot be attributed to abnormal fibrillin in the lung, but to the generalized skeletal dysplasia.

Therefore, one can conclude that primary defects in extracellular matrix proteins or their modifying enzymes can cause an array of pulmonary disease. However, even when the pulmonary abnormality leads to premature death, the manifestations in other organ systems are often more prominent (Table 22.2).

## EXTRACELLULAR MATRIX IN ASTHMA AND COPD

Alterations in connective tissue likely play key roles in the pathogenesis of both asthma and COPD [105–107].

**TABLE 22.2** Pulmonary manifestations of primary matrix abnormalities.

| Matrix element | Disorder | Pulmonary abnormality |
|---|---|---|
| Type I collagen | Osteogenesis imperfecta (various types) | Pulmonary insufficiency; Pulmonary hypertension |
| Type III collagen | Ehlers–Danlos (vascular type) | Spontaneous pneumothorax; hemoptysis |
| Elastin | Dominant cutis laxa | Bronchiectasis; emphysema |
| Fibulin-5 | Recessive cutis laxa | Emphysema |
| Fibrillin-1 | Marfan syndrome | Pneumothorax; pulmonary blebs; emphysema |

Destruction of elastin is thought to be a major feature in the development of emphysema. Exposure of the lung to enzymes with elastolytic activity results in emphysema in animals [108]. Histologic examination of the emphysematous lung shows disrupted elastic fibers [109]. Urinary excretion of desmosine, a specific marker for degradation of elastin, has been observed in smokers and former smokers with COPD. Smokers without COPD did not excrete desmosine [110, 111]. Because individuals with severe deficiency of $\alpha$-1-protease inhibitor, an inhibitor of several serine proteases, are at markedly increased risk to develop emphysema [112], these proteases have been thought to have a major role in the destruction of elastin. Recent studies, however, suggest that the matrix metalloproteases contribute to the development of emphysema [113, 114].

In addition to tissue destruction, there is evidence of excess deposition of extracellular matrix (i.e. fibrosis in COPD). In addition to the destruction of elastin in emphysema, there is an increase in deposition of collagen [115–117]. Fibrosis of the small airways is also a regular feature of

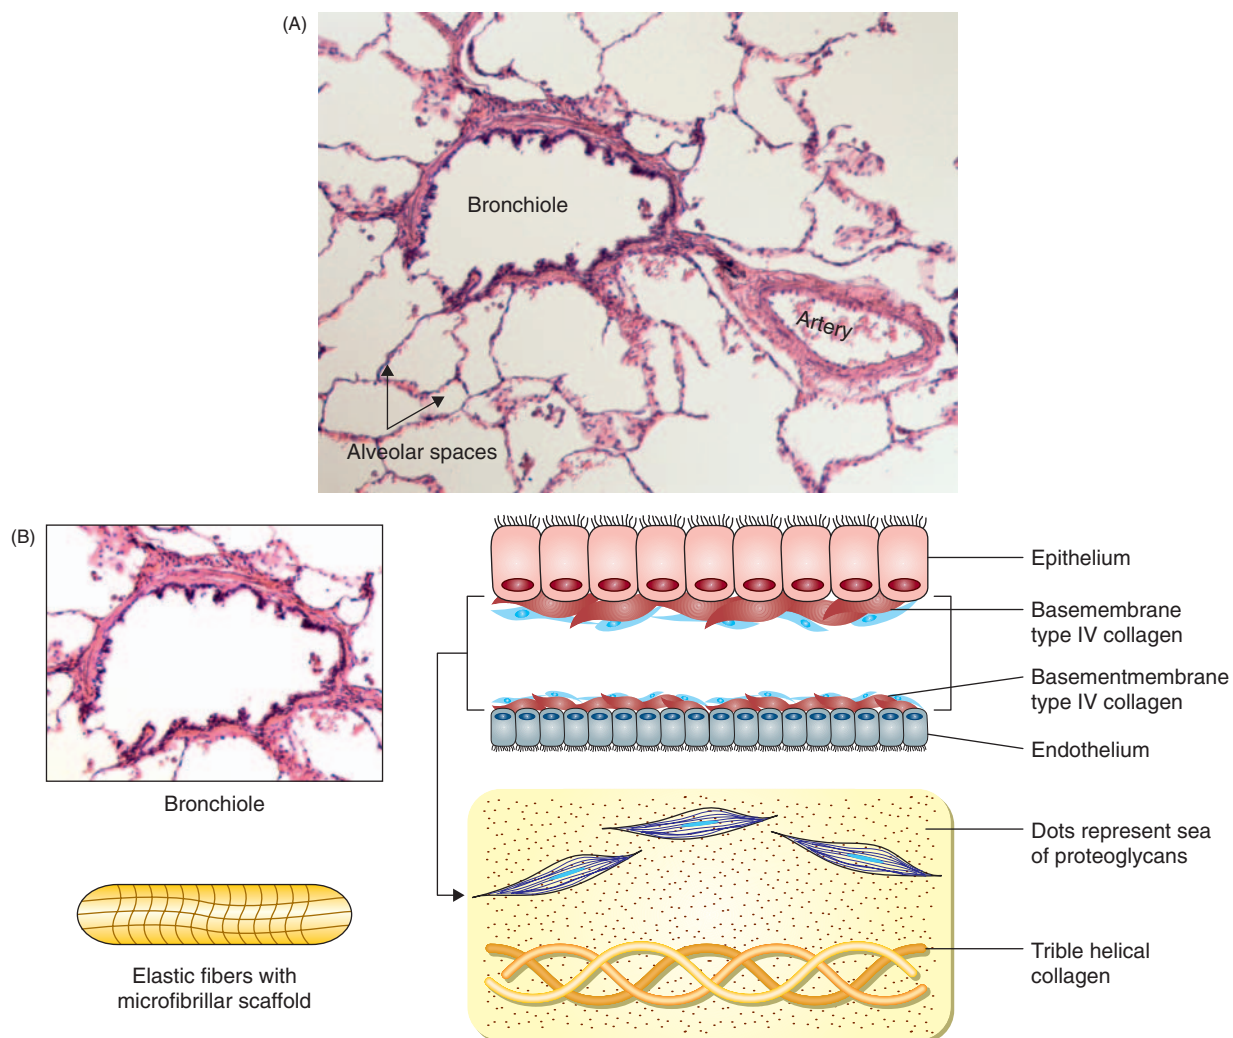

**FIG. 22.1** (A) Photomicrograph of normal H&E stained lung (original magnification 100×). Various part are labeled in the figure. (B) An artist's rendition of a bronchiole. The outer (epithelium) and inner (endothelium) cellular layers surround the extracellular matrix containing triple helical collagen, elastic fibers with their associated microfibrils, and proteoglycans.

chronic bronchitis [118] and is related to the development of airflow limitation [119, 120]. The airways in COPD are of smaller than expected diameter; this may be a direct consequence of this fibrotic process [120].

Extracellular matrix alterations have also been documented in asthma [121]. For example, the connective tissue in the large airways, include thickening of the lamina reticularis with increased deposition of collagen types I, III, and fibronectin [122]; tenascin [123]; and fragmentation of the airway elastic fiber network [124, 125]. The thickened lamina reticularis is particularly striking as the epithelium can be seen to rest on a dense nearly acellular layer of apparently homogeneous connective tissue. Whether these changes are altered with therapy of asthma is controversial [126–129], but the connective tissue changes may occur somewhat independently of measures of clinical severity [127, 130]. The functional significance of the altered connective tissue in asthma likely leads to compromised lung function [106]. Similar changes in the small airways may account for increased peripheral airway resistance, reduced airway compliance [131], and progressive airflow limitation in asthma [132, 133]. Importantly, growth factors are critical for the extracellular matrix remodeling in asthma [134, 135].

Recognizing the complexity of the extracellular matrix, it seems likely that many alterations in these structural molecules will contribute to the pathophysiology of asthma and COPD. It seems likely as well that the many genetic variations in connective tissue metabolism, which are beginning to be characterized, will contribute to the heterogeneity observed in asthma and COPD. Understanding the genetic milieu will undoubtedly help to predict those at greatest risk [4, 30, 136].

## ARACHIDONIC ACID METABOLISM

The release of arachidonic acid from cell membrane phospholipids, through the action of a family of phospholipases, can result in the production of a wide variety of mediators which may be relevant in the pathogenesis of asthma. These lipid mediators have traditionally been considered in two classes:

1. mediators which result from the action of the cycloxygenases on arachidonic acid, which are prostaglandins (PG) or thromboxane (Tx)

2. mediators which result from the action of the enzymes 5-, 12-, or 15-lipoxygenase on arachidonic acid, which are the leukotrienes (LT) and lipoxins (Lx).

Platelet-activating factor (PAF) has also been recognized to be a mediator formed during arachidonic acid metabolism.

The oxidative metabolism of arachidonic acid by cycloxygenases produces the cyclic endoperoxides $PGG_2$ and $PGH_2$ (Fig. 23.1). The subsequent action of prostaglandin isomerases produces either $PGD_2$ or $PGE_2$, reductive cleavage produces $PGF_{2a}$, while one of two terminal synthetases on the endoperoxide produces $PGI_2$ and $TxA_2$. Cycloxygenase appears to be present in most cells; however, the cycloxygenase metabolite(s) released from a particular cell are quite specific (e.g. $TxA_2$ from platelets, and $PGI_2$ from endothelial cells). This suggests that terminal synthetases are cell-specific.

At least two isoforms of cycloxygenase have been identified:

1. cycloxygenase-1 (COX-1), which is constitutively present mainly in the gastric mucosa, kidney and platelets

2. cycloxygenase-2 (COX-2), which is mainly an inducible form, although also to some extent presents constitutively in the CNS, in the juxtaglomerular apparatus of the kidney, in the lung, in platelets, and in the placenta during late gestation.

Both isoforms contribute to the inflammatory process, but COX-2 is induced during acute and chronic inflammation, resulting in an enhanced formation of prostaglandins. Some studies have indicated that associations between COX-2 polymorphisms, prostaglandin production, and the development of asthma and atopy [1], while there is evidence that COX-1 polymorphisms do not appear to play a substantial role in genetic pre-disposition for asthma or asthma severity [2].

Prostaglandins and thromboxane mediate their effects through activation of specific receptors, and there is cross-activation of these receptors by the different agonists. The receptor designation has been accepted as the most potent agonist followed by the term "prostanoid." Thus, the thromboxane receptor is designated the TP receptor, and the PGE receptor is the EP receptor. There are DP, EP, FP, and TP receptors; the EP receptors are subdivided into EP1–EP4 [3].

## ROLE IN ASTHMA

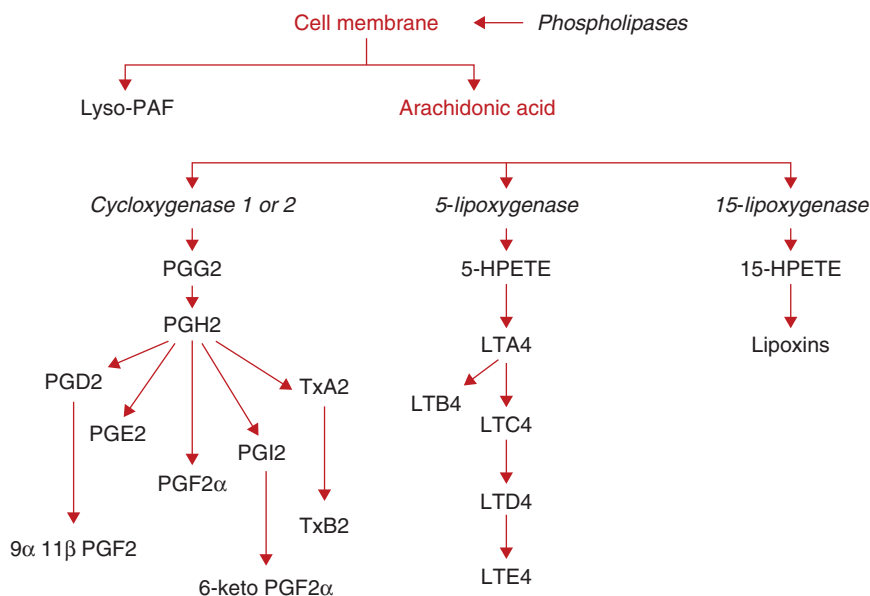
All of the cycloxygenase products of arachidonic acid metabolism have been prepared by total chemical synthesis and, with the exception of thromboxane, are readily available for study. Thromboxane has an exceedingly short half-life (about 30 s) and studies with thromboxane have been limited to a few, very circumscribed,


**FIG. 23.1** The spectrum of eicosanoids produced as a consequence of arachidonic acid metabolism.

experimental preparations, none of them in the airways. Fortunately, several stable thromboxane mimetics have been developed. These are endoperoxides which activate the thromboxane receptor and mimic the biological actions of thromboxane but have substantially longer half-lives.

Prostaglandins are believed to have a variety of effects on airway function in asthma. The prostaglandins are most easily considered in two classes. There are stimulatory prostaglandins, such as $PGD_2$, $PGF_{2a}$, and $TxA_2$, which are potent bronchoconstrictors, and inhibitory prostaglandins, such as $PGE_2$, which can reduce bronchoconstrictor responses and attenuate the release of bronchoconstrictor mediators, such as acetylcholine, from airway nerves.

Evidence has been obtained in both animal models of airway hyperresponsiveness [4] and in human subjects with asthma that cycloxygenase metabolites are involved in causing aspirin-induced bronchoconstriction [5], or bronchoconstriction after exercise [6]. There is, however, little convincing evidence that cycloxygenase metabolites are important in causing the ongoing, persisting airway hyperresponsiveness that is characteristic of asthma. This is because several studies have failed to demonstrate any effect of cycloxygenase inhibitors on stable airway hyperresponsiveness in asthmatic subjects.

The initial studies examining the role of cycloxygenase metabolites in the pathogenesis of transient airway hyperresponsiveness after an inflammatory stimulus were carried out using a cycloxygenase inhibitor, indomethacin, in dogs in whom airway hyperresponsiveness had been induced by exposure to inhaled ozone [4]. Indomethacin did not alter baseline airway responsiveness to inhaled acetylcholine, but did prevent the development of airway hyperresponsiveness after inhaled ozone. Despite the absence of airway hyperresponsiveness, the magnitude of the inflammatory response, as measured by the numbers of neutrophils in the airway epithelium, was not altered by indomethacin. This suggested that a cycloxygenase product was not responsible for the chemotaxis of acute inflammatory cells into

the airways after inhaled ozone; however, a cycloxygenase product was released during the inflammatory response which caused airway hyperresponsiveness. Subsequently, a reputed combined cycloxygenase and lipoxygenase inhibitor, BW755C, was also demonstrated to prevent the development of airway hyperresponsiveness after inhaled ozone in dogs [7]. Inhibition of cycloxygenase by indomethacin also prevents the development of airway hyperresponsiveness in other species including that which occurs after $C_{5a}$ des Arg exposure in rabbits [8] and following inhaled allergen in sheep [9].

Cycloxygenase products have been implicated in the pathogenesis of allergen-induced early asthmatic as well as late asthmatic responses in human subjects. This has been done by pretreating subjects with several different cycloxygenase inhibitors. One study reported that pretreatment with indomethacin inhibited the late response, without having a major effect on the early response [10]. Another study, however, where subjects were pretreated with indomethacin, could not confirm these observations on allergen-induced either early responses or late responses [11]. However, in this latter study, indomethacin resulted in a significant inhibition of the development of allergen-induced airway hyperresponsiveness, which suggests that a cycloxygenase product is involved in the pathogenesis of this response.

## STIMULATORY PROSTAGLANDINS

### Prostaglandin D$_2$

$PGD_2$ is known to be released from stimulated dispersed human lung cells *in vitro* and from the airways of allergic human subjects which have been stimulated by allergen [12]. $PGD_2$ synthase is present in mast cells, T helper 2 ($T_H2$) cells and other leukocytes. $PGD_2$ is rapidly metabolized (with a half-life of 1.5 min in blood), and the main

products that have been detected *in vivo* are $PGJ_2$ and $9\alpha$ $11\beta$ $PGF_2$. $PGD_2$ is a bronchoconstrictor of human airways and is more potent when inhaled by human subjects than $PGF_{2\alpha}$ [13].

The biological effects of $PGD_2$ occur through stimulation of the G-protein-coupled receptors $DP_1$, CRTH2 (also known as $DP_2$), and TP receptors [14], and in part indirectly through a presynaptic action on airway cholinergic nerves to release acetylcholine [15]. The bronchoconstrictor effects of $PGD_2$ are mediated by stimulation of TP receptors [16]. $PGD_2$ also caused vasodilatation leading to erythema and edema [17], which occurs through $PGD_2$ stimulation of the $DP_1$ receptor [18]. $PGD_2$ is also known to cause chemotaxis of eosinophils [19] and $T_H2$ lymphocytes and modulation of $T_H2$-cytokine production, and these effects are mediated by $PGD_2$ stimulation of CRTH2 [20]. CRTH2 is a receptor unrelated to $DP_1$ and which was originally described as an orphan chemoattractant-like receptor expressed by $T_H2$ cells [21] and which is now known to be selectively expressed by $T_H2$ lymphocytes, eosinophils, and basophils [22]. $PGD_2$ can stimulate the production of the cytokines IL-4, IL-5, and IL-13 by human $T_H2$ cells in the absence of co-stimulation [23]. It has been suggested that $DP_1$ and CRTH2 cooperate to promote $T_H2$-dependent allergic responses [14]. Activation of $DP_1$ promotes an environment in which polarization of $T_H2$ cells can occur, whereas CRTH2 mediates their recruitment and activation to produce cytokines. Also, stimulation of $DP_1$ by $PGD_2$ has been suggested to induce regulatory T-cells and to control the extent of airway inflammation by an IL-10 dependent mechanism [24].

Subthreshold contractile concentrations of $PGD_2$ have been demonstrated to increase airway responsiveness to inhaled histamine and methacholine in asthmatic subjects [25]. Thus, $PGD_2$ released in human airways after allergen inhalation has the potential to both cause acute broncho-constriction and increase airway hyperresponsiveness to other constrictor mediators. However, specific receptor antagonists for $PGD_2$ or inhibitors of its production are not yet available to allow a precise evaluation of the importance of this cycloxygenase metabolite in the spontaneous asthmatic response.

## Prostaglandin $PGF_{2\alpha}$

$PGF_{2\alpha}$ may also play a role as a mediator of bronchoconstriction and airway hyperresponsiveness following inhaled allergen in human subjects. $PGF_{2\alpha}$ is a potent bronchoconstrictor in asthmatic airways [26], and when inhaled at subthreshold constrictor concentrations increases airway responsiveness in dogs and human subjects [27]. $PGF_{2\alpha}$ also causes bronchoconstriction in human subjects partially through cholinergic-mediated bronchoconstriction [28]. As with $PGD_2$, there are no selective $PGF_{2\alpha}$ receptor antagonists available, which would allow identification of the specific importance of these metabolites in mediating theses airway responses. It has been suggested that all contractile prostaglandins act via the $TP_{1-}$ receptor. Therefore, differentiation of the relative importance of the contractile prostaglandins in causing asthmatic responses may prove to be difficult.

## Thromboxane $A_2$

$TxA_2$ is a potent constrictor of smooth muscle. It was originally described as being released from platelets, but it is now known to be released from other cells, including macrophages and neutrophils. As noted above, the biological half-life of $TxA_2$ is very short, so it has been implicated in disease processes through identification of its more stable metabolite thromboxane $B_2$ ($TxB_2$) in biological fluids; through the use of the stable $TxA_2$ analogs U44069 or U46619, which mimic most of the biological effects of $TxA_2$; and through the use of inhibitors of $TxA_2$ synthesis and antagonists of the $TxA_2$ receptor. Using these techniques, $TxA_2$ has been implicated in

- the pathogenesis of airway hyperresponsiveness in dogs [29] and primates [30];
- in the late cutaneous response to intradermal allergen in humans [31];
- in the late asthmatic response after inhaled allergen in humans [32];
- in airway hyperresponsiveness in asthmatic subjects [33].

Other studies, however, have demonstrated slight, but statistically significant, inhibition of the magnitude of the allergen-induced early, but not the late responses after pretreatment with a thromboxane synthetase inhibitor or receptor agonist [34, 35]. These studies suggest that thromboxane may be released following allergen challenge, and may account for a portion of the airway narrowing observed during the early asthmatic response; however, thromboxane is not important in the airway hyperresponsiveness that occurs following allergen inhalation.

## INHIBITORY PROSTAGLANDINS

The differentiation of the prostaglandins into stimulatory or inhibitory mediators is somewhat inappropriate. For example, both $PGE_2$ and $PGF_{2\alpha}$ can have different effects on the airways depending on the time after inhalation at which the response is measured [36]. However, the main action of $PGE_2$ and $PGI_2$ on airway function is to relax airway smooth muscle and to antagonize the contractile responses of other bronchoconstrictor agonists. In addition $PGE_2$ is extremely potent at inhibiting the release of acetylcholine from airway cholinergic nerves [28].

The evidence that inhibitory prostaglandins play a role in modulating the contractile responses of agonists in asthmatic subjects comes from studies which have demonstrated that tachyphylaxis (a decreased response to repeated stimulation) occurs following repeated challenges with inhaled histamine, when challenges are separated by up to 6 h [37]. Also, repeated exercise challenges in asthmatic subjects, at intervals up to 4 h, also result in less bronchoconstriction occurring after the second when compared to the initial exercise challenge [38]. This has been termed "exercise refractoriness." This inhibitory effect are abolished
**FIG. 23.2** The attenuation of exercise-induced bronchoconstriction by pretreatment with inhaled $PGE_2$. Reproduced with permission from Ref. [40].

**FIG. 23.3** The attenuation of allergen-induced early and late asthmatic responses by pretreatment with inhaled $PGE_2$. Reproduced with permission from Ref. [51].

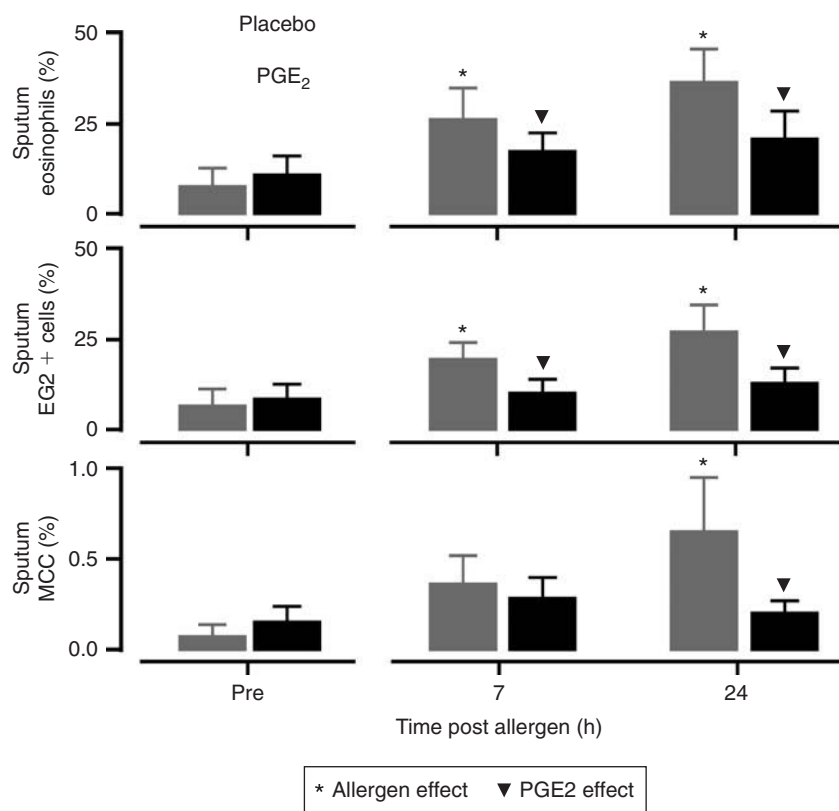
* Allergen effect ▼ PGE2 effect


**FIG. 23.4** The attenuation of allergen-induced increases in sputum eosinophils, $EG2^+$ cells (activated eosinophils) and metachromatic cells (mast cells and basophils), at 7 h and 24 h after allergen inhalation, by pretreatment with inhaled $PGE_2$. Reproduced with permission from Ref. [51].

by pretreatment with indomethacin [38]. This suggests that inhibitory prostaglandins, released as a consequence of exercise, could modify bronchoconstrictor responses in asthmatics. This hypothesis is supported by studies which have demonstrated that pretreatment of asthmatic subjects with oral $PGE_1$, in doses which do not cause bronchodi-

lation, reduce airway responsiveness to both histamine and methacholine [39], and that inhaled $PGE_2$ largely abolishes exercise-induced bronchoconstriction [40] (Fig. 23.2).

These results are consistent with studies of airway smooth muscle *in vitro*, where histamine tachyphylaxis occurs through inhibitory prostaglandin release [41] and

with studies of dogs *in vivo* where histamine tachyphylaxis is inhibited by indomethacin [42]. In addition, histamine tachyphylaxis in asthmatic subjects is blocked by pretreatment with an $H_2$ receptor antagonist in asthmatics, suggesting that $H_2$ receptor stimulation is involved with the development of histamine tachyphylaxis [43]. Contraction of asthmatic airways by histamine also reduces airway responsiveness to acetylcholine and exercise [44]. This lack of specificity suggests that either receptor downregulation or an alteration of the contractile properties or airway smooth muscle is occurring.

An initial hypothesis to explain exercise refractoriness in asthmatics was that histamine is released following exercise, causing bronchoconstriction, but this also provides partial protection against subsequent exercise bronchoconstriction, through $PGE_2$ released by stimulation of histamine $H_2$ receptors. However, several studies have suggested that this hypothesis is incorrect. First, the marked attenuation of exercise-induced bronchoconstriction by pretreatment with cysLT1, that is leukotriene (LT)$D_4$-receptor antagonists indicates that $LTD_4$, rather than histamine, is the main mediator responsible for exercise-induced bronchoconstriction [45]. Second, exercise refractoriness is not prevented by pretreatment with the $H_2$-receptor antagonists, which effectively prevent histamine tachyphylaxis [46]. Therefore, histamine-stimulated inhibitory prostaglandin release does not appear to be the cause of exercise refractoriness.

These studies raise the possibility that exercise refractoriness is caused by leukotriene-stimulated inhibitory prostaglandin release. This hypothesis is supported by evidence that there is interdependence between the cycloxygenase and lipoxygenase pathways of arachidonate metabolism in causing exercise bronchoconstriction and refractoriness in asthmatic subjects. [47]

The release of cysteinyl leukotrienes in the airways is also important in the pathophysiology of aspirin-intolerant asthma. This is associated with over-expression of the enzyme $LTC_4$ synthetase in the airways of patients with aspirin-intolerant asthma [48]. In addition, pretreatment with inhaled $PGE_2$ prevents not only the bronchoconstriction caused by aspirin, but also the increases in urinary $LTE_4$ associated with it [49]. These results suggest that, in patients with aspirin-intolerant asthma, $PGE_2$ may play a critical role in inhibiting the overproduction of cysteinyl leukotrienes, as this inhibiting effect is lost when the patients ingest aspirin or other cycloxygenase inhibitors.

Inhaled $PGE_2$ has also been demonstrated to attenuate allergen-induced bronchoconstrictor responses (Fig. 23.3) and airway hyperresponsiveness [50], and to attenuate allergen-induced airway eosinophilic inflammation [51] (Fig. 23.4). Thus, these findings suggest that endogenous $PGE_2$, produced in response to inhaled allergen, may play a role in regulating the associated airway inflammation.

## SUMMARY

In asthmatic patients, it is likely that $PGD_2$ and $TxA_2$ are involved in causing acute bronchoconstriction after stimuli such as inhaled allergen in asthmatic patients. $PGD_2$ also promotes the chemotaxis of eosinophils and Th2 cells, as well as the release of Th2 cytokines through stimulation of CRTH2. Also, there is evidence that inhibitory prostaglandins are released by asthmatic airways, which reduces bronchoconstrictor responses to stimuli such as exercise, and that this effect is mediated by leukotriene-induced $PGE_2$ release. $PGE_2$ also appears to play a role in inhibiting leukotriene overproduction in patients with aspirin-intolerant asthma. Finally, $PGE_2$ can also attenuate allergen-induced airway responses and eosinophilic inflammation. These studies suggest that endogenous production of $PGE_2$ does have an important influence on the magnitude of asthmatic responses to stimuli such as exercise or inhaled allergens.

The leukotrienes ($LTB_4$, $LTC_4$, $LTD_4$, and $LTE_4$) and lipoxins ($LXA_4$ and $LXB_4$) are molecules derived by lipoxygenation of arachidonic acid. There is evidence that each of these molecules is potentially important in the pathogenesis of asthma and chronic obstructive pulmonary disease (COPD); this chapter reviews the biology of these molecules as related to these disease entities.

## FORMATION AND METABOLISM OF THE LEUKOTRIENES

Arachidonic acid, a normal component of many cell membrane phospholipids, is commonly found esterified to these phospholipids in the middle or *sn*2 position. In the presence of an appropriately activated phospholipase $A_2$, arachidonic acid is cleaved from internal and external cell membranes and serves as the primary substrate for subsequent eicosanoid metabolism (Fig. 24.1) [1]; there is a family of phospholipase $A_2$ ($PLA_2$) molecules with this catalytic capacity [2, 3]. The two major forms of interest in leukotriene and lipoxin biosynthesis are cytosolic $PLA_2$ ($cPLA_2$) and secretory $PLA_2$ ($sPLA_2$) [4, 5].

Arachidonic acid, released as a result of $PLA_2$ action, enters into a series of reactions at the perinuclear membrane. The first of these requires a specific 5-lipoxygenase activating protein (FLAP) [6, 7], which allows arachidonate to serve as a substrate for the enzyme 5-lipoxygenase [8]. 5-Lipoxygenase sequentially catalyzes the addition of molecular oxygen to arachidonic acid to form 5-hydroperoxy eicosatetraenoic acid (5-HPETE) and leukotriene $A_4$ ($LTA_4$), respectively; $LTA_4$ is a major branch point in the formation of the leukotrienes [1].

In one major pathway, found in a variety of cells but most notably neutrophilic polymorphonuclear leukocytes (PMN), the addition of water to form $LTB_4$ is catalyzed by $LTA_4$ hydrolase. [9].

In addition to $LTB_4$, the 5-LO product ($LTA_4$) can also be enzymatically transformed to several other bioactive compounds [1]. Each of the other two major lipoxygenases in human tissues, namely 12-LO and 15-LO, can convert $LTA_4$ to a distinct class of mediators termed lipoxins for lipoxygenase interaction products [10]. Lipoxins carry 3 alcohol groups on arachidonic acid's 20 carbon backbone with 4 conjugated double bonds. The redundant pathways for lipoxin (LX) biosynthesis indicate the functional importance of these compounds. Because lipoxygenases are most commonly compartmentalized into distinct cell types, LX biosynthesis principally occurs during cell–cell interactions. For example, at sites of vascular injury or inflammation, PMN 5-LO and platelet 12-LO can interact to generate $LXA_4$ and $LXB_4$ [11]. This transcellular LX generation is also bidirectional as arachidonic acid can originate from either cell type [12]. Because the airway is lined with epithelial cells that are enriched with 15-LO activity, LX generation also occurs when leukocytes infiltrate airways during inflammatory responses [13]. Of interest, interactions between 5-LO and 12-LO generate an equal amount of $LXA_4$ and $LXB_4$, whereas 5-LO and 15-LO interactions strongly favor $LXA_4$ production [14].

Aspirin inhibits prostaglandin formation and triggers the formation of lipoxin epimers [15] as well. Acetylation of cyclooxygenase-2 at serine 516 blocks formation of $PGG_2$. When this occurs, enzymatic action results in arachidonic acids being converted to 15(R)-hydroxyeicosatetraenoic acid (15(R)-HETE).
**FIG. 24.1** Schematic showing the synthesis of leukotrienes from arachidonic acid and the site of action of various drugs in the pathway. Reproduced from Ref. [75], with permission.

This molecule can be a substrate for conversion of 5-LO to 15-epimer-LXA$_4$ (15-epi-LXA$_4$), a compound also known as aspirin-triggered LXA$_4$. This seemingly subtle switch in stereochemistry at carbon-15 leads to a twofold increase in circulating half-life and potency compared to the 15(S)-LXA$_4$ product of 15-LO [16]. Because cytochrome p450 enzymes can also catalyze 15(R)-HETE formation from arachidonate, aspirin is not required for 15-epi-LXA$_4$ production [17].

Similar to LTs, LXs are autacoids that are rapidly formed and rapidly, enzymatically inactivated [18]. The major route for LX inactivation is dehydrogenation by 15-hydroxy/oxo-eicosanoid oxidoreductase (15-PGDH), leading to the conversion of LXA$_4$ to the biologically inert 15-oxo-LXA$_4$. This compound is further converted to 13,14-dihydro-15-oxo-LXA$_4$ by LXA$_4$/PGE 13,14-reductase/LTB$_4$ 12-hydroxydehydrogenase (PGR/LTB$_4$DH). This compound is subject to additional reduction of the 15-oxo group to 13,14-dihydro-LXA$_4$ by 15-PGDH. Moreover, LXs also undergo β-oxidation *in vivo* [19].

Other cells of myeloid origin including eosinophils, mast cells, and alveolar macrophages, not only have the capacity to form LTA$_4$ from arachidonic acid, but also they possess a unique and specific glutathionyl-$S$-transferase, LTC$_4$ synthase, which catalyzes the conjugation of glutathione to LTA$_4$, at carbon 6, to form leukotriene C$_4$ (LTC$_4$) [20–22]. Once formed, LTC$_4$ exits the cell via a specific transmembrane transporter [23–25], and when it is outside the cell, LTC$_4$ serves as a substrate for γ-glutamyl transpeptidase [26, 27] or a specific leukotrienase [28], which cleaves the glutamic acid moiety from its peptide chain to form leukotriene D$_4$ (LTD$_4$; LTD$_4$ is further processed by the removal of the glycine moiety from its peptide chain to form leukotriene E$_4$, LTE$_4$) [29, 30]. LTC$_4$, LTD$_4$, and LTE$_4$ make up the material formerly known as slow-reacting substance of anaphylaxis or SRS-A and are collectively known as the cysteinyl leukotrienes.

In the presence of appropriately activated PMNs, the cysteinyl leukotrienes are degraded to their respective sulfoxides and 6-*trans* diastereoisomers of LTB$_4$ [31]. In the absence of such cells the major degradation and excretion products of the cysteinyl leukotrienes are native LTE$_4$, $N$-acetyl LTE$_4$, or the products resulting from ω-oxidation and β-elimination of LTE$_4$ [32].

## LEUKOTRIENES IN ASTHMA

Since the structural identification of the leukotrienes, a number of lines of evidence have accrued indicating a causal role for the cysteinyl leukotrienes in aspects of the asthmatic response. These are reviewed in the following sections.

## Cysteinyl leukotrienes in the pathology of chronic mild asthma

The cysteinyl leukotrienes are synthesized and exported into the microenvironment by constitutive and infiltrating cells including mast cells and eosinophils [33, 34]. Cysteinyl leukotrienes produced by these cells have numerous actions but the predominant ones in asthma are their ligation of leukotriene receptors on airway smooth muscle and the bronchial vasculature mediating airway obstruction and microvascular leak [35–37].

## Biological effects of cysteinyl leukotrienes relevant to the asthmatic response

The leukotrienes are known to have profound biochemical, immunological, and physiological effects, even in picomolar concentrations, including induction of airway obstruction, tissue edema, and expression of bronchial mucus from submucosal glands [38–40]; these pathobiological effects make them part of the panel of mediators which characterize asthmatic responses.

Although these mediators have pleotropic biological actions, the ability of the cysteinyl leukotrienes to mediate airway narrowing in normal individuals and persons with asthma is critical to the biology of asthma. Inhalation of aerosols of leukotrienes by normal subjects results in airway obstruction as manifested by a decrease in flow rates during a forced exhalation [41–52]. In addition, among normal subjects there is a relationship between responsiveness to the leukotrienes and responsiveness to reference agonists such as histamine or methacholine [46, 47]. Subjects that are more responsive to histamine are those that are more responsive to the leukotrienes.

In subjects with asthma, $LTC_4$, $LTD_4$, and $LTE_4$ are potent bronchoconstrictor agonists when administered by aerosol, as indicated by induced decrements in the $FEV_1$, in the $\dot{V}_{30P}$, or in specific conductance [46–48, 50, 53, 54]. When the latter outcome indicator is used, the nebulizer concentrations required to narrow airways in asthmatics are approximately one-tenth of those required by normal subjects to achieve the same decrement in airflow rates. Since normal subjects are approximately 100-fold less sensitive to histamine or methacholine than asthmatic subjects, whereas they are only 10-fold less responsive to the cysteinyl leukotrienes, this indicates that the relative degree of hyperresponsiveness to the cysteinyl leukotrienes is less than that observed when histamine or methacholine is used as the contractile agonist.

## Leukotriene recovery in asthma

Cysteinyl leukotrienes have been recovered after experimental challenges, which elicit clinical symptoms similar to those that occur in spontaneously occurring asthmatic conditions. Leukotrienes have also been recovered in the nasal lavage fluid after intranasal challenge with either antigen or cold air [55, 56]. Leukotrienes are recovered in significantly greater amounts in the bronchoalveolar lavage (BAL) fluid from subjects with symptomatic asthma than from subjects with asymptomatic asthma or normal subjects [57–60], as well as from exhaled breath condensate [61–63], suggesting that the leukotrienes are produced locally in the lungs of patients with asthma.

The profusion of leukotriene production can be estimated from measurements made on urine samples [64–69]. In normal human subjects, after intravenous administration of radiolabeled $LTC_4$, 12–48% of the counts are recovered in the urine with 4–13% as intact $LTE_4$ [70, 71], and it is now common to measure leukotriene recovery from the urine as an index of endogenous production of leukotrienes.

Asano *et al.* [72] examined urinary $LTE_4$ excretion rates in eight patients with mild chronic stable asthma ($FEV_1 \sim$ 70% predicted, inhaled β-agonists as the only asthma treatment) followed on a metabolic ward for 4 days. They demonstrated that, on average, patients with asthma have significantly higher urinary $LTE_4$ levels than normal subjects. However, among the asthmatics studied there were individuals who were persistent hyperexcretors of urinary $LTE_4$ and others with urinary $LTE_4$ levels that were persistently within the normal range. Among the explanations for this finding is the possibility that, among patients with asthma, whose clinical phenotype is similar, there are individuals whose asthma is associated with leukotriene production and others for whom this is not the case. These data clearly indicate that, during spontaneous, induced, or chronic stable asthma, at least in some individuals, there is enhanced urinary $LTE_4$ excretion and by inference an increased cysteinyl leukotriene production. Among patients with severe asthma, who are receiving treatment with corticosteroids, there are substantially increased levels of $LTE_4$ in the urine [73].

## Leukotriene receptor blockade and synthesis inhibition

Two classes of pharmacological agents have been demonstrated to have a salutary effect on airway obstruction in patients with asthma: leukotriene receptor antagonists and leukotriene synthesis inhibitors. As noted above there are at least two distinct receptors that when ligated transduce the biological activity of the cysteinyl leukotrienes; there are the cysteinyl leukotriene receptors type 1 and type 2 ($CysLT_1$ and $CysLT_2$) [37, 74]. Although many chemically distinct antagonists at the $CysLT_1$ receptor have been recognized, as of the present time, only three have been introduced into medical use; namely, pranlukast, zafirlukast, and montelukast [75].

With regard to leukotriene synthesis inhibitors, agents have been developed which are direct inhibitors of 5-LO, such as zileuton [76], as well as agents that inhibit the interaction between arachidonic acid and FLAP (MK-0591 and Bay x1005) [77, 78] (Fig. 24.2).

### Induced asthma

Leukotriene receptor antagonists and synthesis inhibitors have been shown to inhibit various types of laboratory-induced asthma [80–84]. Current data indicate that most

but not all of the physiological effects of aspirin-induced asthma derive from the action of the cysteinyl leukotrienes [82, 85]. It is important to note that, although all the physiological effects of aspirin-induced asthma derive from the effects of the leukotrienes, this does not mean that anti-leukotriene treatment can prevent all the clinical manifestations of aspirin ingestion in patients with aspirin-sensitive asthma. Indeed, there have been reports of aspirin-induced asthma in patients receiving treatment with CysLT$_1$ receptor antagonists [86, 87]. These findings are consistent

with the known competitive nature of $CysLT_1$ antagonists and the massive release of cysteinyl leukotrienes after aspirin ingestion in patients with aspirin-induced aspirin.

### Leukotriene inhibition in chronic stable asthma

Multiple double-blind and placebo-controlled and active compartor clinical trials in both adult and pediatric patients with mild-to-moderate chronic stable asthma reported in the archival literature; these have been the subject of multiple reviews [88–92].

The general design of these trials has been similar. They have recruited and enrolled patients whose asthma was marginally controlled solely by use of inhaled β-agonists, who had $FEV_1$ values most often between 40% and 80% of predicted, who had moderate asthma symptoms as judged from daily symptom diaries. Each trial incorporated a 1–3 week "run-in" period when all patients had their asthma control monitored while on single-blind oral placebo. During this period baseline lung function, β-agonist use, and symptom data were gathered. Patients then entered a period in which they received randomized treatment with an active agent or placebo. Patients returned on a regular basis to their clinical centers where their lung function and asthma symptom data were recorded; the results from these trials are summarized in Table 24.1.

In the course of the performance of these trials, it has been noted by many investigators that there is a marked variability among individuals in the response to antileukotriene treatment. One interpretation of this observation is that there could be genetic differences among individuals that lead to differences in the role of leukotrienes in a given individual's asthmatic responses. Polymorphisms, both with and without known functional consequences have been identified in a number of the genes encoding the proteins that make up the 5-lipoxygenase pathway [94–99]. The gene encoding 5-lipoxygenase has been shown to harbor variability that is associated with the asthma treatment response, but the specific functional variants within that gene have not been identified [97, 100].

## LIPOXINS IN ASTHMA

Lipoxins are derived from arachidonic acid, yet structurally and functionally distinct from prostaglandins and leukotrienes [1]. There is a growing body of evidence linking these counter-regulatory eicosanoid mediators to homeostatic airway responses including control of airway inflammation and reactivity [101].

### Lipoxins in the pathology of chronic mild asthma

Lipoxins and 15-epi-LXs display several features of mediators inhibiting airway inflammation [10] including inhibition *in vivo* of eosinophil and T-lymphocyte activation and TH2 cytokine release [102, 103]. LXs are generated in respiratory tissues [13] and block airway inflammation and hyperresponsiveness in an experimental model of asthma [102].

## Biological effects of lipoxins relevant to the asthmatic response

Lipoxin $A_4$ displays cell-type selective actions [10]. On the one hand, $LXA_4$ blocks PMN activation and transmigration across endothelial and epithelial cells [104–107]. Distinct from these stop signals for PMNs, $LXA_4$ stimulates monocyte locomotion and macrophage phagocytosis of apoptotic PMNs [108, 109]. $LXA_4$ also reduces eosinophil tissue accumulation [102], dendritic cell (DC) mobilization [110], T-lymphocyte cytokine release [103], and NK cell cytotoxicity [111]. In sum, LXs regulate both innate and acquired immune effector cells to reduce leukocyte entry into tissues and promote clearance of apoptotic cells, important mechanisms in the resolution of acute inflammation.

LXs also regulate airway epithelial cells [112]. $LXA_4$ blocks proinflammatory cytokine and chemokine release and gene expression via NFκB [113]. Of interest, LX signaling increases expression of bacterial permeability-inducing protein in epithelial cells to enhance mucosal bacterial killing [114]. Thus, in addition to anti-inflammation, $LXA_4$ signals carry host protective actions.

Lipoxins also potently regulate pulmonary responses. $LXA_4$ relaxes precontracted pulmonary arteries and bronchi [115]. In addition, a LX stable analog, designed using the 15-epi-$LXA_4$ structure as a template, markedly inhibits (with as little as 1 μg; ~0.05 mg/kg) allergen-driven airway hyperresponsiveness and inflammation in an experimental model of asthma [102]. Asthma is frequently worsened by aspiration of gastric acid, and LX and 15-epi-LX signaling promote restitution of injured airway epithelium and resolution of acid-initiated acute airway injury [112, 116]. Together, the impact of LXs on both cellular effectors and airway responses indicate protective roles for these counter-regulatory mediators in airway inflammation and hyperresponsiveness, important processes linked to asthma pathogenesis.

As a consequence of LXs' rapid inactivation, there is only limited information on their actions in humans *in vivo*. In one clinical trial, $LXA_4$ was administered to individuals with asthma, leading to protection from $LTC_4$-induced bronchoconstriction [117]. The recent development of new LX stable analogs that are topically and orally active should enable further investigation on LX regulation of human illness.

### Lipoxin recovery in asthma

Lipoxins have been identified in human subjects with a wide range of respiratory illnesses involving leukocyte activation [13]. Both LXs and 15-epi-LXs are generated during respiratory inflammation [101, 118]. $LXA_4$ (0.4–2.8 ng/ml) has been detected in BAL and pleural fluid from individuals with inflammatory lung disease [13, 119]. In a murine experimental model of asthma, LX formation at peak airway inflammation is similar in magnitude to the amount of $LTB_4$ formed, yet one to two log orders less than cysteinyl

LTs and $PGE_2$ [102]. Of interest, diminished formation of these counter-regulatory mediators has been identified in severe forms of human respiratory illness, including aspirin-intolerant asthma [120] and severe, steroid-dependent asthma [121]. Decreased production of these counter-regulatory substances could predispose the host to more severe, inflammatory responses in the lung.

## Lipoxin $A_4$ receptors

Lipoxins interact with one or more specific receptors to signal their counter-regulatory actions. $LXA_4$ can serve as a high affinity ligand for the $LXA_4$ receptor (ALX) [122, 123] and a receptor-level antagonist for a subclass of $LTD_4$ receptors (i.e. CysLT1) [124]. ALX is a seven-transmembrane spanning, G-protein coupled protein, binding $LXA_4$ with high affinity ($K_D = 1.7$ nM) [125]. The human, mouse and rat ALX amino acid sequences share 74% or greater homology with the highest homology found in their second intracellular loop (100% identical) and sixth transmembrane segments (93% identical) [126]. ALX receptors are expressed in several mammalian cells and tissues including human PMNs, monocytes, epithelial cells, and human and murine spleen. Interleukin-13 and interferon-$\gamma$ dramatically induce ALX expression *in vitro* in airway epithelial cells [124]. Cytokine regulation of ALX is also evident *in vivo* during disease states, as ALX is upregulated in airway epithelial and inflammatory cells during allergic airway inflammation in a murine model of asthma [102]. ALX was the initial receptor identified that binds to both lipid and peptide ligands [123]. Of interest for asthma therapy, corticosteroids induce expression of annexin 1 that is enzymatically cleaved to peptides that can also interact with ALX to initiate anti-inflammatory circuits [127]. In PMNs, ALX signals for LXs' anti-inflammatory effects, in part, by polyisoprenyl phosphate remodeling [107] and by inhibition of leukocyte-specific protein-1 phosphorylation, a downstream regulator of the p38-MAPK cascade [128]. Targeted expression of human $LXA_4$ receptors to murine leukocytes in transgenic mice also dramatically inhibits allergen sensitization, eosinophil trafficking, and airway inflammation [102].

## LEUKOTRIENES AND LIPOXINS IN COPD

## Leukotrienes and the biology of the bronchitic airway

There are fewer data concerning the role of leukotrienes in the pathogenesis of COPD than are available about this class of mediators in asthma. Introduction of leukotrienes into the microenvironment of the airway is associated with expression of mucus from glands [129, 130]. The receptor for $LTB_4$ has been detected in greater profusion on alveolar macrophages from patients who smoke and have airway obstruction than from either normal subjects or patients who smoke and do not have airway obstruction [131].

The leukotrienes have pleomorphic inflammatory actions that are relevant to the microenvironment of the airway in COPD. Although a complete evaluation of these actions is beyond the scope of this chapter, there are excellent review articles that reflect this biology [39, 40, 132–134]. These data indicate that if leukotrienes were to become available in the microenvironment of the airway that they have the potential to contribute to aspects of the bronchotic phenotype; at this time, their exact role is not known.

## Recovery of leukotrienes in COPD

Leukotrienes have been recovered in greater quantities from the airways of patients with COPD. For example they are found in the sputum, BAL fluid, or exhaled breath condensate of patients with chronic bronchitis at higher levels than from similar samples obtained from normal subjects [135–140]. In one study the concentration of $LTB_4$ in sputum was closely correlated with the number of polymorphonuclear leukocytes recovered in the sputum [140]. When patients with COPD were treated with ibuprofen, the amount of $LTB_4$ recovered in the exhaled breath condensate increased; there was no effect of rofecoxib on this measure [141]. Sputum obtained from patients in the midst of an infective exacerbation of chronic bronchitis contained high levels of $LTB_4$, which fell with treatment [142]. In these samples $LTB_4$ constituted about one-third of the total chemotactic activity at the time of disease presentation, and the importance of $LTB_4$ as a chemotactic factor fell with antibiotic treatment. These data indicate that leukotrienes, both cysteinyl and di-hydroxy moieties, are present and likely active in the airway microenvironment in COPD. While limited information is currently available on LXs and COPD, $LXA_4$ and 15-epi-$LXA_4$ are both found in increased amounts in sputum from subjects with COPD [118].

There are few data in the archival literature from studies in which agents active on various components of the 5-lipoxygenase pathway have been studied on lung function in patients with COPD. Small studies, with varying quality of controls, show that treatment of patients with leukotriene receptor antagonists modifies a number of outcome indicators in COPD. In most studies the effects are salutary, but the magnitude of clinical improvement is marginal at best [93, 143–146]. Since these data are not biologically informative with respect to the role the leukotrienes in COPD, larger better-controlled studies are needed to resolve this issue.

## CONCLUSIONS

The available data support the following conclusions as to the role of leukotrienes and lipoxins in bronchial asthma and COPD:

- They are produced by constitutive cells (mast cells/macrophages) and infiltrating cells (eosinophils, neutrophils) implicated in asthma and COPD.
- They are potent bronchoconstrictor agonists.

- Their administration results in the expression of mucus from mucous glands.

- Laboratory-induced asthma and spontaneous asthma or COPD is associated with an enhanced recovery of leukotrienes in the urine and exhaled breath condensate of subjects with asthma and sputum, BAL or exhaled breath condensate leukotrienes in COPD.

- Asthma control is enhanced (compared with placebo) by agents capable of interfering with leukotriene action or synthesis. Similar data are not available for COPD.

- The data indicate that the leukotrienes play an important role in the asthmatic response. We are not sure of the importance of the pathogenetic role of the leukotrienes in COPD.

- Lipoxins are generated in respiratory tissues in asthma and COPD and can decrease airway inflammation and hyperresponsiveness in laboratory-induced asthma.

# Reactive Oxygen Species and Antioxidant Therapeutic Approaches

**Irfan Rahman**

**Department of Environmental Medicine, Lung Biology and Disease Program, University of Rochester Medical Center, Rochester, NY, USA**

## INTRODUCTION

The lung is constantly exposed to a high-oxygen environment and, owing to its large surface area and blood supply, is highly susceptible to injury mediated by a phenomenon known as oxidative stress. Oxidative stress is described simply as an increase in the oxidant to antioxidant ratio in the lung. Reactive oxygen species (ROS) such as superoxide anion ($O_2^{\bullet-}$) and the hydroxyl radical ($^{\bullet}OH$) are unstable molecules with unpaired electrons, capable of initiating the oxidation of various molecules in the airway and airspace structures.

Biological systems are continuously exposed to oxidants that are generated either endogenously by metabolic reactions (e.g., from mitochondrial electron transport during respiration or during activation of phagocytes) or exogenously (such as by air pollutants or cigarette smoke). For example, production of ROS has been directly linked to oxidation of proteins, DNA, and lipids which may cause direct lung injury or induce a variety of cellular responses, through the generation of secondary metabolic reactive species. ROS may result in remodeling of extracellular matrix, cause apoptosis and mitochondrial respiration, and regulate cell proliferation [1, 2]. Alveolar repair responses and immune modulation in the lung may also be influenced by ROS [1, 2]. Furthermore, high levels of ROS have been implicated in initiating inflammatory responses in the lungs through the activation of transcription factors such as nuclear factor-κB (NF-κB) and activator protein-1 (AP-1); their activation leads to signal transduction and gene expression of pro-inflammatory mediators [3, 4]. It is proposed that ROS produced by phagocytes that have been recruited to sites of inflammation are a major cause of the cell and tissue damage associated with many chronic inflammatory lung diseases, including asthma and chronic obstructive pulmonary disease (COPD) [5–9] (Fig. 25.1).

The composition of inflammatory cell types that invade tissues varies widely in asthma and COPD; this suggests that there are differences in the characteristics of the ROS produced in these diseases [10–12]. This chapter reviews the evidence for the role of ROS in the pathogenesis of asthma and COPD, and discusses the molecular mechanisms (cell signaling and gene expression) and pathophysiological consequences of increased ROS release in these conditions. Moreover, it also highlights the antioxidant mechanisms in place to protect against the damaging effects of ROS. Finally, it goes on to explore possible therapeutic approaches that involve the use of a variety of antioxidants.

## CELL-DERIVED ROS

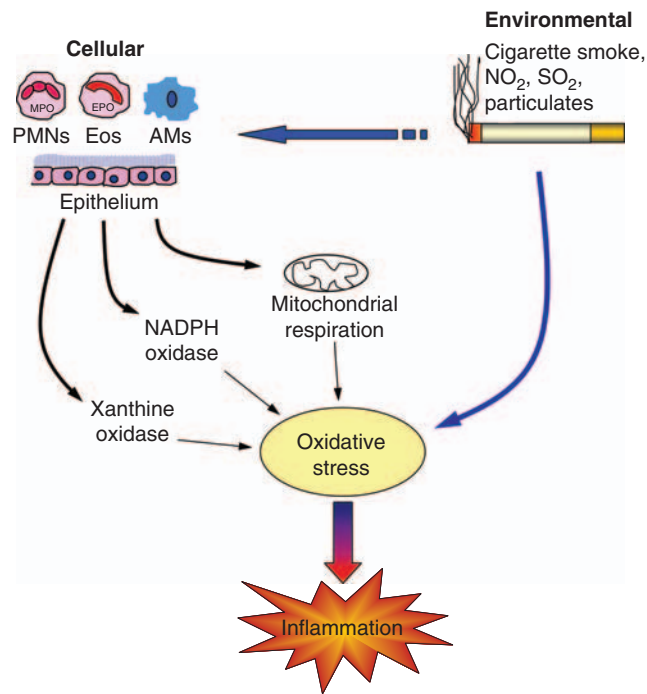
A common feature of all inflammatory lung diseases is the development of an inflammatory–immune response, characterized by activation of epithelial cells, and resident macrophages, and the recruitment and activation of neutrophils, eosinophils, monocytes, and lymphocytes. The degree to which this occurs and the cell types involved vary widely in asthma and COPD. Inflammatory cells once recruited in the airspace become activated and generate ROS in response to a sufficient stimulus (threshold concentration). The activation of macrophages, neutrophils, and eosinophils generates $O_2^{\bullet-}$, which is rapidly converted to $H_2O_2$ through


**FIG. 25.1** Sources of oxidative stress. Oxidative stress derived from either environmental or cellular origins results in inflammation. Cellular-derived oxidative stress can be produced through mitochondrial respiration, the NADPH oxidase system, or the xanthine oxidase system. Inflammation itself can have a feed-forward effect, triggering inflammatory cells to produce yet more oxidative stress, exacerbating and intensifying the inflammatory response. PMNs: polymorphonucleocytes; Eos: eosinophils; AMs: alveolar macrophages.

the catalytic action of superoxide dismutase (SOD); $^{\bullet}$OH is formed nonenzymatically in the presence of $Fe^{2+}$ as a secondary reaction. ROS and reactive nitrogen species (RNS) can also be generated intracellularly from several sources such as mitochondrial respiration, the NADPH oxidase system, and xanthine/xanthine oxidase (XO) (Fig. 25.2). However, the primary ROS generating system is NADPH oxidase, a complex enzyme system that is present in phagocytes and epithelial cells.

Activation of this enzyme system involves a complex mechanism with the assembly of various cytosolic and membrane-associated subunits, resulting in the one-electron reduction of oxygen to $O_2^{\bullet-}$ using NADPH as the electron donor. In addition to NADPH oxidase, phagocytes use heme peroxidases such as myeloperoxidase (MPO) or eosinophil peroxidase (EPO) to produce ROS. Activation of EPO results in the formation of the potent oxidants hypochlorous acid (HOCl) and hypobromous acid (HOBr) from $H_2O_2$ in the presence of chloride ($Cl^-$) and bromide ($Br^-$) ions, respectively. It is believed that the oxidant burden produced by eosinophils is substantial because these cells possess several times greater capacity to generate $O_2^{\bullet-}$ and $H_2O_2$ than do neutrophils, and the content of EPO in eosinophils is 3–10 times higher than the amount of MPO present in neutrophils [13–15] (Fig. 25.3).

The physiological consequences of EPO-dependent formation of brominating oxidants such as HOBr *in vivo* are unknown. HOBr reacts rapidly with a variety of nucleophilic targets such as thiols, thiol ethers, amines, unsaturated groups, and aromatic compounds [16].

**FIG. 25.2** Molecular consequences of oxidative stress. The relatively weak superoxide anion from both cellular and environmental sources can be transformed into more damaging and potent reactive oxygen and reactive nitrogen species, such as HOCl, the hydroxyl radical and peroxynitrite, through a series of enzymatic and nonenzynmatic steps. Xenobiotic radicals from the environment can be long lived and undergo redox cycling, such as the semiquinones, and result in further superoxide anion formation as well as more powerful radical formation in the presence of free metal ions through Haber–Weiss and Fenton chemistry. Endogenous antioxidant defenses glutathione transferase, GPx, SOD, and catalase neutralize and remove these ROS and RNS. ROS: reactive oxygen species; RNS: reactive nitrogen species; $X^-$: xenobiotic radical; $O_2^{\bullet-}$: superoxide anion; $H_2O_2$: hydrogen peroxide; $OH^{\bullet}$: hydroxide radical; HOCl: hypochlorous acid; NO: nitric oxide; $ONOO^-$: peroxynitrite; GSH: reduced glutathione; GSSG: oxidized glutathione dimers.
**FIG. 25.3** Generation of reactive nitrogen species. Model of potential pathways used by eosinophils and airway epithelial cells for generation of NO-derived reactive nitrogen and halogen species leading to nitration of proteins.

Several transition metal salts react with $H_2O_2$ to form ·OH. Most attention *in vivo* for the generation of ·OH has focused on the role of iron [17]. Iron is a critical element in many oxidative reactions. Free iron in the ferrous form catalyzes the Fenton reaction and the superoxide-driven Haber–Weiss reaction, which generate the ·OH, a ROS which damages tissues, particularly cell membranes by peroxidation of their lipid membranes. MPO- and EPO-derived ROS can also interact with nitrite ($NO_2^-$) and $H_2O_2$ to promote formation of RNS. ROS may also be released by lung epithelial cells [18] and stimulate inflammatory cells directly, thereby amplifying lung inflammatory and oxidant events. ROS interact with a variety of molecules and donate electrons in biological systems. Reactive oxygen and nitrogen species also act on certain amino acids such as methionine, tyrosine, and cysteine in proteins (e.g. enzymes, kinases), profoundly altering the function of these proteins in inflammatory lung diseases [19].

## INHALED OXIDANTS AND CIGARETTE SMOKE

Cigarette smoking, or inhalation of airborne pollutants that may be either oxidant gases [such as ozone, nitrogen dioxide ($NO_2$), sulfur dioxide ($SO_2$)] or particulate air pollution, results in direct lung damage as well as the activation of inflammatory responses in the lungs. Cigarette smoke is a complex mixture of over 4700 chemical compounds, including high concentrations of oxidants ($10^{14}$ molecules per puff) [20]. Short-lived oxidants such as $O_2^{·-}$ and nitric oxide (NO) are predominantly found in the gas phase. NO and $O_2^{·-}$ immediately react to form the highly reactive peroxynitrite ($ONOO^-$) molecule. The radicals in the tar phase of cigarette smoke are organic in nature, such as long-lived semiquinone radicals, which can react with $O_2^{·-}$ to form ·OH and $H_2O_2$ [21]. The aqueous phase of cigarette smoke condensate may undergo redox recycling for a considerable period of time in the epithelial lining fluid (ELF) of smokers [22, 23]. The tar phase is also an effective metal chelator and can bind iron to produce tar-semiquinone + tar-$Fe^{2+}$, which can generate $H_2O_2$ continuously [22, 23].

Quinone (Q), hydroquinone ($QH_2$), and semiquinone ($QH^·$) in the tar phase are present in equilibrium:

$$Q + QH_2 \rightarrow 2H^+ + 2Q^{·-}.$$
Aqueous extracts of cigarette tar contain the quinone radical ($Q^{·-}$), which can reduce oxygen to form $O_2^{·-}$, which may dismutate in the presence of $H^+$ to form $H_2O_2$:

$$Q^{·-} + O_2 \rightarrow Q + O_2^{·-}$$

$$2O_2^{·-} + 2H^+ \rightarrow O_2 + H_2O_2.$$
Furthermore, since both cigarette tar and lung ELF contain metal ions, such as iron, Fenton chemistry will result in the production of the ·OH which is a highly reactive and potent ROS. Thus, oxidants and electrophilic compounds may be the initiating or triggering factor in the underlying inflammation seen in the pathogenesis of COPD as detailed below.

## ROS AND MEMBRANE LIPID PEROXIDATION

Oxygen species such as $O_2^{·-}$ and ·OH are highly reactive, and when generated close to cell membranes they oxidize membrane phospholipids (lipid peroxidation), a process which may continue as a chain reaction. Thus, a single ·OH can result in the formation of many molecules of lipid hydroperoxides in the cell membrane [19]. The peroxidative breakdown of polyunsaturated fatty acids impairs membrane function, inactivates membrane-bound receptors and enzymes, and increases tissue permeability. Each of these processes has been implicated in the pathogenesis of many forms of lung injury. There is increasing evidence that aldehydes, generated endogenously during the process of lipid peroxidation, are involved in many of the pathophysiological effects associated with oxidative stress in cells and tissues [19]. Compared with free radicals, lipid peroxidation aldehydes are generally stable, can diffuse within, or even

escape from the cell, and attack targets far from the site of the original free radical event. In addition to their cytotoxic properties, lipid peroxides are increasingly recognized as being important in signal transduction for a number of important events in the inflammatory response [24].

Many of the effects of ROS in airways may be mediated by the secondary release of inflammatory lipid mediators such as 4-hydroxy-2-nonenal (4-HNE). 4-HNE, a highly reactive diffusible end-product of lipid peroxidation, is known to induce/regulate various cellular events, such as proliferation, apoptosis, and activation of signaling pathways [24, 25]. 4-HNE has a high affinity toward cysteine, histidine, and lysine residues. It forms adducts with proteins, altering their function. Acrolein is another example of reactive aldehyde. Both acrolein and 4-HNE have a high affinity toward cysteine, histidine, and lysine residues. These reactive aldehydes can form adducts with both intracellular proteins, such as histone deacetylase (HDAC) 2 [26] and extracellular proteins, such as collagen and fibronectin [27] altering their function which in turn can then impact on cell function [27, 28]. In contrast, the isoprostanes, are ROS-catalyzed oxidative products of arachidonic acid metabolism and are stable lipid peroxidation products, which circulate in plasma and are excreted in the urine [29, 30]. It is because of their relative stability *in vivo* that they have been used as markers of oxidative stress in both asthma and COPD [31]. However, one isoprostane member, 8-isoprostane, has been shown to possess a very potent biological activity. It has been demonstrated that 8-isoprostane is a very potent stimulus for smooth muscle contraction through initiation of transduction at the thromboxane $A_2$ receptor; this could be one of the many causes of small airway contraction in asthma and COPD [32, 33]. ROS-induced degradation of arachidonate-based phospholipids can also produce other bio-active molecules. They are pro-inflammatory affecting both monocytes and neutrophils causing increased endothelial cell interaction [34] as well as increased cytokine release [35, 36], and it is proposed that they may play an important role in various chronic inflammatory diseases [34].

## ROLE OF ROS IN SIGNAL TRANSDUCTION

ROS have been implicated in the activation of transcription factors such as NF-κB and AP-1, and in the signal transduction and gene expression involved in cellular pro-inflammatory actions [37]. Both environmental and inflammatory cell-derived ROS can lead to the activation and phosphorylation of the mitogen-activated protein kinase (MAPK) family, including extracellular signal regulated kinase (ERK), c-Jun *N*-terminal kinase (JNK), p38 kinase, and P1-3K, via sensitive cysteine-rich domains; activation of the sphingomyelinase–ceramide pathway also occurs leading to increased gene transcription [3, 4, 37]. Activation of members of the MAPK family leads to the transactivation of transcription factors such as c-Jun, activating factor-2 (ATF2), cyclic AMP response element binding proteins (CREB), CREB-binding protein (CBP), and Elk-1 [37–40]. This eventually results in chromatin remodeling and expression of genes regulating a battery of distinct pro-inflammatory and antioxidant genes involved in several cellular events, including apoptosis, proliferation, transformation, and differentiation. The intracellular molecular mechanisms responsible for these actions of ROS have not been completely characterized.

Redox-sensitive molecular targets usually contain highly conserved cysteine residues; their oxidation, nitration, and the formation of disulfide links are crucial events in oxidant/redox signaling. It is hypothesized that oxidation of sulfide groups in signaling proteins causes structural modifications, resulting in the exposure of active sites and consequent protein activation. Such molecular targets include transcription factors (NF-κB, AP-1), signaling molecules such as ras/rac or JNK, protein tyrosine phosphatases, and p21$^{ras}$. Thiol molecules such as intracellular glutathione (GSH) and thioredoxin are of central importance in regulating such redox signaling pathways, by reducing disulfide bridges or oxidized cysteine residues [37, 41].

In response to tumor necrosis factor (TNF-α) and lipopolysaccharide (LPS), which are relevant stimuli for the inflammatory response in COPD, airway epithelial cells can concurrently produce increased amounts of intracellular ROS and RNS [18]. This intracellular production of oxidants and the subsequent changes in intracellular redox status are important in the molecular events controling the expression of genes for inflammatory mediators [3]. The signaling pathways and activation of transcription factors in response to ROS are the subject of rigorous investigation.

## ROS IN ASTHMA AND COPD

In asthma, the airways are the major site of action, characterized by reversible airflow obstruction, airway hyperresponsiveness and hyperreactivity, chronic inflammation characterized by a predominant infusion of lungs with eosinophils, and the influx and activation of inflammatory cells such as macrophages, neutrophils, lymphocytes, and mast cells. Airway smooth muscle contraction, increased airway reactivity and secretions, increased vascular permeability, and increased generation of chemoattractants are the major features of an asthmatic response.

In COPD, the major site of attack is the alveolar spaces. Inflammatory cells become compartmentalized depending on the cell type. For example, neutrophils are mainly located in the airspaces of the lung, and macrophages accumulate in the tissue matrix in COPD. Progression of COPD has been strongly associated with the accumulation of inflammatory mucus exudates in the lumen of the small airways. In other phenotypes of COPD, oxidative stress occurs in the small airways, lung parenchyma, and alveolar regions. Hence the compartmentalization of different inflammatory cells in the lungs may help distinguish the oxidative stress response in asthma and COPD.

## OXIDATIVE STRESS IN ASTHMA

It has been shown that inflammation driven by increased oxidative stress occurs in the airways of patients with asthma [8]. Recent evidence indicates that increased oxidative stress occurs in the airways of patients with asthma [8]. Inflammatory and immune cells in the airways, such as macrophages, neutrophils, and eosinophils, release increased amounts of ROS [42–45]. ROS can result in lung injury as a result of direct oxidative damage to epithelial cells and cell shedding [46, 47].

ROS have been shown to be associated with the pathogenesis of asthma by evoking bronchial hyperreactivity [48, 49]. Viral infections, ozone, and cigarette smoke, potential triggers for asthma, may serve as sources of ROS which enhance inflammation and asthmatic symptoms. Animal studies suggest that ROS may contribute to airway hyperresponsiveness by increasing vagal tone due to inhibition of β-adrenergic receptors and by decreasing mucociliary clearance [50, 51]. The actions of ROS can produce many of the pathophysiological features of asthma [51], including changes in the biochemical microenvironment with enhanced arachidonic acid release, increased synthesis of chemoattractants, glucocorticoid resistance, and impaired β-adrenergic responsiveness. These and other effects lead to the physiological changes of airway smooth muscle contraction, increased airway reactivity and secretions, and increased vascular permeability.

ROS-mediated injury to the airway epithelium produces hyperresponsiveness of human peripheral airways, suggesting that ROS may play a role in the pathogenesis of asthma [47]. Much of the evidence for this is indirect, since there are no specific and reliable methods to assess oxidative stress *in vivo*. Neutrophils isolated from peripheral blood of asthmatic patients generate greater amounts of $O_2^{\bullet-}$ and $H_2O_2$ than do cells from normal subjects, and their ability to produce $O_2^{\bullet-}$ is related directly to the degree of airway hyperresponsiveness to inhaled methacholine [52, 53]. Inflammatory cells obtained from asthmatic patients, particularly eosinophils derived from peripheral blood, produce increased amounts of ROS and RNS such as NO spontaneously and after stimulation *ex vivo* [42–46, 54]. This observation suggests that the inflammatory milieu in asthma contains factors that may prime ROS generation. Other studies have shown that impaired SOD activity is associated with airflow obstruction, airway hyperresponsiveness, and remodeling [55, 56]. This inactivation of SOD in asthmatics, which has been reported in other studies [57, 58], was as a result of increased ROS causing tyrosine nitration of SOD.

Eosinophils are thought to play a critical role in the inflammation of asthma. They are present in large numbers in bronchoalveolar lavage (BAL) fluid and blood, and the number of cells correlates with bronchial hyperresponsiveness [59, 60]. BAL fluid eosinophils, alveolar macrophages, and neutrophils from asthmatic patients produce more ROS ($O_2^{\bullet-}$, $H_2O_2$, hypohalites) than do those from normal subjects [61, 62]. ROS cause direct contraction of airway smooth muscle preparations, and this effect is enhanced

when the epithelium is injured or removed. This observation might provide a mechanistic link between epithelial injury arising from a variety of causes and airway hyperresponsiveness [47]. ROS also stimulate histamine release from mast cells and mucus secretion from airway epithelial cells [63].

ROS generation is thought to be a nonspecific process initiated by the concurrent action of numerous inflammatory mediators that have been shown to be present in increased amounts in asthmatics. Several mediators, including lipid mediators, chemokines, adhesion molecules, and eosinophil granule proteins (EPO), are potential stimuli or promoters of ROS production in the airways of asthmatic patients [64, 65].

Numerous surrogate markers of oxidative stress have been measured in exhaled air or breath condensate. The concentration of $H_2O_2$ in exhaled air condensate is increased in asthmatics [66], and it has been suggested that airway inflammation increases exhaled peroxides. The increased levels of exhaled $H_2O_2$ may be due to decreased dismutation of $O_2^{\bullet-}$ since SOD activity is reduced in lung cells of patients with asthma [57]. The significance of elevated levels of various ROS markers to the disease pathogenesis has not been studied.

### The role of EPO-derived ROS

A specific role for EPO in the generation of oxidants by the phagocytes and in protein oxidation has been described [67]. Eosinophil activation (peroxidase – $H_2O_2$ system + halides) *in vivo* results in oxidative damage to proteins through bromination of tyrosine residues, as shown by the formation of 3-bromotyrosine in BAL fluid of patients with asthma [16]. The formation of 3-bromotyrosine is a specific response to the release of oxidants from eosinophils. Neutrophil- and monocyte-derived MPO, which are increased in smokers and patients with COPD, produce 3-chlorotyrosine [16]. Thus, distinction between these "footprints" might be useful in assessing the ROS burden in patients with asthma and COPD. A specific marker of protein modification by reactive brominating species 3-bromotyrosine has been shown to be markedly increased in BAL proteins obtained from asthmatics [16]. EPO-generated oxidants can interact with RNS present in asthmatics and promote protein nitration [15]. Thus, oxidative modification of critical biological targets in asthmatic airways may contribute to the pathophysiological features of asthma, such as epithelial cell damage, airway hyperreactivity, bronchoconstriction, β-adrenergic receptor dysfunction, mucus hypersecretion, microvascular leak, and airway edema [68, 69].

### Interaction between ROS and RNS

The levels of nitric oxide are elevated in the exhaled air of patients with asthma [70–73]. Increased levels of exhaled NO, together with increased exhaled $H_2O_2$ in asthmatic patients, are associated with a pro-oxidant activity in airway walls resulting in lipid peroxidation and nitration of

proteins [15, 16, 70, 74, 75]. The finding that NO reduces the potency of β-adrenergic signaling pathways may be an important deleterious effect of elevated RNS in asthma [50]. The presence of allergic inflammation, involving the recruitment and activation of eosinophils, may be a contributing factor in these pro-oxidant effects. Eosinophil granule proteins may participate in the formation of nitrating oxidants as well as unique molecules such as brominated products, which have been shown to be elevated in patients with asthma [15, 16]. However, the significance of these inflammatory ROS in the etiology of asthma is not established.

A reaction between NO and $O_2^{\bullet-}$ results in the formation of peroxynitrite anions ($ONOO^-$), a highly reactive oxidant species. $ONOO^-$ adds a nitro group to the 3-position adjacent to the hydroxyl group of tyrosine to produce the stable product nitrotyrosine. $ONOO^-$ induces hyperresponsiveness in airways of guinea pigs, inhibits pulmonary surfactant function, induces membrane lipid peroxidation, results in tyrosine/MAP kinase activation, and damages pulmonary epithelial cells [73, 75–78]. The levels of 3-nitrotyrosine are elevated in the exhaled breath of asthmatic patients [79]. Furthermore, there is strong immunoreactivity for nitrotyrosine in the airway epithelium, lung parenchyma, and inflammatory cells in the airways of patients with asthma [79, 80].

It has been postulated that increased levels of HOBr production as a result of EPO release from eosinophils result in increased peroxynitrite formation by interaction of HOBr with NO. NO itself can be stored in cells as s-nitrosothiols [81], and this may regulate cellular apoptosis through inactivation of caspases by s-nitrosylation of critical cysteine residues [82]. Consequently, increased $ONOO^-$ formation could deplete intracellular stores of NO, liberating active caspases that can then induce epithelial cell apoptosis. This is supported by the evidence showing that s-nitrosothiol levels in asthmatics are significantly depressed [83, 84]. However, there are other data, which show that levels of NO in exhaled breath condensate (EBC) are increased in asthmatics, that appear to conflict with this supposition [71]. This may simply reflect a compartmentalization effect in that different mechanisms are operating in an intracellular versus extracellular environment. The precise mechanistic role that SOD inactivation by $ONOO^-$ plays in asthma is as yet unclear. However, it is postulated that SOD inactivation by $ONOO^-$ could increase the overall redox state by allowing higher levels of $H_2O_2$ to persist thereby depleting intracellular NO stores through increased $ONOO^-$ formation and lowering s-nitrosothiol levels [85]. Overall, this clearly shows that oxidant stress occurs in asthma which can be reflected/detected in the lungs both systemically and locally.

## Generation of ROS-mediated lipid peroxidation products

The measurement of aldehydes in exhaled breath has been proposed as a means to assess lipid peroxidation *in vivo*. The levels of lipid peroxidation products (8-isoprostanes), hydrocarbons (ethane and pentane), and nonspecific products of lipid peroxidation (thiobarbituric acid reactive substances,

TBARS) are increased in EBC of patients with asthma [86–89]. The levels of 8-isoprostane are also increased in BAL fluid of patients with asthma [90]. Urinary excretion of 15-$F_{2t}$-isoprostane (8-isoprostaglandin$_{2\alpha}$, family of $F_2$-isoprostanes) was increased in mild atopic asthmatics following inhaled allergen provocation, whereas no increase in the urinary excretion of 15-$F_{2t}$-isoprostane was observed after inhalation of methacholine [91]. The presence of various markers of oxidative stress provide evidence that oxidative stress is present in the airspaces in asthma, but do not provide definitive evidence for a role for oxidative stress in the pathogenesis of asthma.

Measurement of systemic or exhaled isoprostane 8-iso-$PGF_{2\alpha}$ levels may provide a useful tool in monitoring clinical status in asthma [92]. The level of plasma $F_2$-isoprostanes (an 8-iso$PGF_{2\alpha}$ isomer) is significantly increased in asthmatics and is related to disease severity [92]. Similarly, arachidonic acid is increased in airway inflammatory cells of patients with bronchial asthma [93]. Arachidonic acid may undergo oxidation to produce an end-product of lipid peroxidation such as 4-HNE [24, 25]. The levels of plasma lipid peroxides TBARS have been shown to be elevated in asthma, and are negatively correlated with the Forced Expiratory Volume in one sec ($FEV_1$), suggesting a role for increased oxidative stress in the pathogenesis of the airway obstruction of asthma [94, 95]. Further studies are needed to define the source, significance, and specificity of these peroxidation products.

## OXIDATIVE STRESS IN COPD

More than 90% of patients with COPD are smokers, but not all smokers develop COPD [96–98]. However, 15–20% of cigarette smokers show a rapid decline in $FEV_1$ over time and develop COPD. An increased oxidant burden in smokers derives from the fact that cigarette smoke contains an estimated $10^{14}$ oxidants per puff, and many of these are relatively long-lived – such as tar-semiquinone that can generate $^{\bullet}OH$ and $H_2O_2$ by the Fenton reaction [20–23]. Other factors that may exacerbate COPD, such as air pollutants, infections, and occupational dusts, also have the potential to produce oxidative stress [5, 99]. These include oxidative stress, which has important consequences on lung physiology and for the pathogenesis of COPD including increased sequestration of neutrophils in the pulmonary microvasculature, increased oxidative inactivation of antiproteases, mucus hypersecretion, alteration in mitochondrial respiration, alveolar epithelial injury or permeability, breakdown and remodeling of extracellular matrix, apoptosis of epithelial and endothelial cells, skeletal muscle dysfunction fatigue and exercise limitation, and glucocorticoid resistance.

## ROS in the alveolar space

The oxidant burden in the lungs is enhanced in smokers by the release of ROS from macrophages and neutrophils [5]. Oxidants present in cigarette smoke can stimulate alveolar macrophages to produce ROS and to release a host of

mediators, some of which attract neutrophils and other inflammatory cells into the lungs. Both neutrophils and macrophages, which are known to migrate in increased numbers into the lungs of cigarette smokers compared with nonsmokers [5], can generate ROS via the NADPH oxidase system. Moreover, the lungs of smokers with airway obstruction have more neutrophils than smokers without airway obstruction [100]. Circulating neutrophils from cigarette smokers and patients with exacerbations of COPD release more $O_2^{\bullet-}$ [95]. Cigarette smoking is associated with increased content of MPO in neutrophils, which correlates with the degree of pulmonary dysfunction [101, 102]. MPO activity is negatively correlated with $FEV_1$ in patients with COPD, suggesting that neutrophil MPO-mediated oxidative stress may play a role in the pathogenesis of the airway obstruction in COPD [103].

Alveolar macrophages obtained by BAL fluid from the lungs of smokers release increased amounts of ROS such as $O_2^{\bullet-}$ and $H_2O_2$ in response to stimulation [5, 104, 105]. Exposure to cigarette smoke *in vitro* has also been shown to increase the oxidative metabolism of alveolar macrophages [106]. Subpopulations of alveolar macrophages with a higher granular density appear to be more prevalent in the lungs of smokers and are responsible for the increased $O_2^{\bullet-}$ production of smoker's macrophages [106, 107].

Hydrogen peroxide, measured in exhaled breath, is thought to be a direct measurement of oxidant burden in the airspaces. Smokers and patients with COPD have higher levels of exhaled $H_2O_2$ than nonsmokers [108–110], and levels are even higher during exacerbations of COPD [110]. The source of the increased $H_2O_2$ is unknown but may in part derive from increased release of $O_2^{\bullet-}$ from alveolar macrophages in smokers [110], However, in one study smoking did not appear to influence the levels of exhaled $H_2O_2$ [108]; the levels of exhaled $H_2O_2$ in this study correlated with the degree of airflow obstruction as measured by the $FEV_1$. However, the variability of the measurement of exhaled $H_2O_2$, along with the presence of other confounding factors, such as cigarette smoking and caffeine intake, has led to concerns over the reproducibility of the use of exhaled $H_2O_2$ as a marker for oxidative stress in smokers and in patients with COPD. The generation of ROS in ELF may be further enhanced by the presence of increased amounts of free iron in the airspaces in smokers [111, 112]. This is relevant to COPD since the intracellular iron content of alveolar macrophages is increased in cigarette smokers and is increased further in those who develop chronic bronchitis, compared with nonsmokers [113]. In addition, macrophages obtained from smokers release more free iron *in vitro* than those from nonsmokers [114].

In some studies, in both stable bronchitis [12] and mild exacerbations [10], eosinophils have been shown to be prominent in the airways. BAL fluid from patients with COPD has also been shown to contain increased eosinophilic cationic protein [102]. Furthermore, peripheral blood eosinophilia is also considered to be a risk factor for the development of airway obstruction in patients with chronic bronchitis and is an adverse prognostic sign [115, 116]. However, despite the presence of an increased number of eosinophils, EPO-mediated generation of 3-bromotyrosine has not been detected in COPD patients [16]. This does not provide support for a role

of brominating oxidant in eosinophil-mediated ROS damage in COPD.

Superoxide anion and $H_2O_2$ can be generated by the xanthine/XO reaction. XO activity has been shown to be increased in cell-free BAL fluid and plasma from COPD patients, compared with normal subjects; and this has been associated with increased $O_2^{\bullet-}$ and lipid peroxide levels [117–119].

## ROS in blood

The neutrophil appears to be a critical cell in the pathogenesis of COPD [120]. Previous epidemiological studies have shown a relationship between circulating neutrophil numbers and $FEV_1$ [121, 122]. A relationship has also been shown between the changes in peripheral blood neutrophil count and in airflow limitation over time [122]. Similarly, a correlation between $O_2^{\bullet-}$ release by peripheral blood neutrophils and bronchial hyperreactivity in patients with COPD has been shown, suggesting a role for systemic ROS in the pathogenesis of the airway abnormalities in COPD [123]. Another study has shown a relationship between peripheral blood neutrophil luminol-enhanced chemiluminescence, as a measure of the release of ROS, and measurements of airflow limitation in young cigarette smokers [124].

Various studies have demonstrated increased production of $O_2^{\bullet-}$ from peripheral blood neutrophils obtained from patients during acute exacerbations of COPD; these levels returned to normal when the patients were clinically stable [95, 125, 126]. Other studies have shown that circulating neutrophils from patients with COPD show upregulation of their surface adhesion molecules, which may also be an oxidant-mediated effect [95, 127]. Activation may be even more pronounced in neutrophils that are sequestered in the pulmonary microcirculation in smokers and in patients with COPD, since neutrophils sequestered in the pulmonary microcirculation in animal models of lung inflammation release more ROS than circulating neutrophils [128]. Thus, neutrophils sequestered in the pulmonary microcirculation may be a source of ROS and may have a role in inducing endothelial adhesion molecule expression in COPD.

## Interaction between ROS and RNS

Nitric oxide has been used as a marker of airway inflammation and indirectly as a measure of oxidative stress. There have been reports of increased levels of NO in exhaled breath in patients with COPD, but not so high as the levels reported in asthmatics [129–131]. One study failed to confirm this result [132]. Smoking cessation increases NO levels in exhaled air [133], and the reaction of NO with $O_2^{\bullet-}$ limits the usefulness of this marker in COPD, except perhaps to differentiate from patients with COPD from those with asthma (Table 25.1).

Cigarette smoking increases the formation of RNS and results in nitration and oxidation of plasma proteins. The levels of nitrated proteins (fibrinogen, transferrin, plasminogen, and ceruloplasmin) were higher in smokers than in nonsmokers [142]. Evidence of enhanced NO and

$ONOO^-$ activity in plasma has been shown in cigarette smokers [143]. *In vitro*, exposure to gas-phase cigarette smoke results in increased lipid peroxidation and protein carbonyl formation in plasma [140]. It is likely that alpha, beta-unsaturated aldehydes (acrolein, acetaldehyde, and crotonaldehyde) that are abundantly present in cigarette smoke may react with protein-SH and -$NH_2$ groups leading to the formation of a protein-bound aldehyde functional group and are capable of converting tyrosine to 3-nitrotyrosine and dityrosine [140]. Nitric oxide and $ONOO^-$-mediated formation of 3-nitrotyrosine in plasma and free catalytic iron ($Fe^{2+}$) levels in ELF are elevated in chronic smokers [144]. Nitration of tyrosine residues or proteins in plasma leads to the production of 3-nitrotyrosine [145]. The levels of nitrotyrosine and inducible NO synthase (iNOS) were higher in airway inflammatory cells obtained by induced sputum from patients with COPD, compared to those with asthma [144]. The levels of nitrotyrosine were negatively correlated with the percentage predicted $FEV_1$ in patients with COPD. These direct and indirect studies indicate that increased RNS- and ROS-mediated protein nitration and lipid peroxidation respectively may play a role in the pathogenesis of COPD.

## Generation of ROS-mediated lipid peroxidation products: Carbonyl stress

Formation of protein carbonyls (aldehyde protein adducts) in response to cigarette smoke-derived lipid peroxides (aldehydes) has been implicated in pathogenesis of COPD. The levels of lipid peroxides, such as 8-isoprostane, and

hydrocarbons, such as ethane and pentane, are increased in exhaled air condensate in smokers and in patients with COPD [134–136]. Furthermore, the levels of these lipid peroxidation products have been correlated with airway obstruction [136]. Urinary levels of isoprostane $F_{2\alpha}$-III have been shown to be elevated in patients with COPD compared with control subjects and are even more elevated during exacerbations of COPD [30]. These studies indicate that there is increased lipid peroxidation in patients with COPD. However, it is not known whether the increased level of lipid peroxidation products found in these diseases is the result of primary lung-associated processes such as alveolar macrophage activation, neutrophil activity, or the ongoing lipid peroxidative chain reaction in the alveoli, parenchyma, or airways, which are induced by inhaled oxidants/cigarette smoke [141].

Indirect and nonspecific measurements of lipid peroxidation products, such as TBARS, have also been shown to be elevated in breath condensate and in lungs of patients with stable COPD [112, 137, 138]. The levels of plasma lipid peroxides have been shown to be elevated in COPD and negatively correlated with the $FEV_1$ [94]. Oxidative stress, measured as lipid peroxidation products in plasma, has also been shown to correlate inversely with the percentage predicted $FEV_1$ in a population study [146], suggesting that in patients with COPD lipid peroxidation may play a role in the progression of the disease.

4-HNE is a highly reactive and specific diffusible end-product of lipid peroxidation. Increased 4-HNE-modified protein levels (protein carbonyls) are present in airway and alveolar epithelial cells and endothelial cells, and in neutrophils in smokers with airway obstruction compared to subjects without airway obstruction [139]. This demonstrates

not only the presence of 4-HNE but that 4-HNE modifies proteins in lung cells to a greater extent in patients with COPD. The increased level of 4-HNE adducts in alveolar epithelium, airway endothelium, and neutrophils was inversely correlated with $FEV_1$, suggesting a role for 4-HNE in the pathogenesis of COPD. The formation of 4-HNE may have detrimental effect on a variety of signaling molecules, such as Nrf2, HDAC2, and IκB kinase (NF-κB activation). Hence, the carbonyl stress that predominantly occurs in response to cigarette smoke may be a differentiating factor in distinguishing the oxidative stress response in the airways of asthma and COPD.

## ALTERATION IN ENDOGENOUS ANTIOXIDANT DEFENSES WITHIN THE LUNG

To combat and neutralize the deleterious effects of ROS, various endogenous antioxidant strategies have evolved which employ both enzymatic and nonenzymatic mechanisms. Within the lung lining fluid, several nonenzymatic antioxidant species exist which include, glutathione, ascorbic acid (vitamin C), uric acid, α-tocopherol (vitamin E), and albumin. The relative abundance of these antioxidants can differ from that observed in blood plasma [147]. Nevertheless, ROS-induced lung injury can increase lung epithelial permeability [148] allowing leakage of plasma constituents, which will also contain antioxidants, into the lung lining fluid providing additional antioxidant protection. Similarly, enzymatic antioxidant defenses can also differ in both anatomical and subcellular localization based on expression. This includes enzymes such as SOD, catalase, thioredoxin, glutathione peroxidase (GPx), and glutathione-S-transferase. Of these, enzymes such as SOD can be found as different isoforms expressed either intracellularly or extracellularly. Moreover, extracellular-SOD is highly expressed in the lungs mainly around blood vessels and airways [149].

Table 25.2 highlights the level of different nonenzymatic antioxidants found in the ELF compared to that in plasma. While differences are clearly evident, both enzymatic and nonenzymatic antioxidant strategies are employed within the lung.

**TABLE 25.2** Antioxidant constituents of plasma and lung epithelial lining fluid (ELF).

| Antioxidant | Plasma (μM) | ELF (μM) |
| --- | --- | --- |
| Ascorbic acid | 40 | 100 |
| Glutathione | 1.5 | 100 |
| Uric acid | 300 | 90 |
| Albumin-SH | 500 | 70 |
| α-tocopherol | 25 | 2.5 |
| β-carotene | 0.4 | – |

## Depletion of antioxidant enzymes in asthma and COPD

An important effect of oxidative stress and inflammation is the upregulation of protective antioxidant genes. Amongst antioxidants, glutathione (GSH), and its redox enzymes have an important protective role in the airspaces and intracellularly in lung epithelial cells. Indeed, GSH levels are increased in the ELF of both asthmatics and chronic cigarette smokers [150, 151]. GSH is a tripeptide (L-γ-glutamyl-L-cysteinyl-glycine) that contains a thiol group. It functions as an antioxidant by acting as a sacrificial target for ROS and other products of lipid peroxidation, such as reactive carbonyls. In so doing, GSH becomes oxidized to its dimeric form (glutathione disulfide, GSSG) or forms adducts with reactive carbonyls and other reactive xenobiotics (GS-X). Furthermore, enzymes such as GPx and glutathione transferase can facilitate this process. GSSG can itself be reduced back to GSH by glutathione reductase using NADPH generated from the pentose phosphate pathway. Oxidative stress causes upregulation of glutamate cysteine ligase, GCL (formerly known as γ-glutamylcysteine synthetase) [3, 152], an important enzyme involved in the synthesis of GSH, as an adaptive mechanism against subsequent oxidative stress. We have shown the increased expression of GCL mRNA in lungs of smokers which is even more pronounced in smokers with COPD [153]. This implies that GSH synthesis is upregulated in lungs of smokers with and without COPD. Similarly, bronchial epithelial cells of rats exposed to cigarette smoke have shown increased expression of the antioxidant genes such as manganese superoxide dismutase (MnSOD), metallothionein, and GPx [154]. This would suggest the importance of an adaptive antioxidant gene response against the injurious effects of cigarette smoke [154]. However, Harju and colleagues have found that GCL immunoreactivity was decreased (possibly leading to decreased GSH levels) in the airways of smokers compared to nonsmokers, suggesting that cigarette smoke predisposes lung cells to ongoing oxidant stress [155]. In addition, Neurohr and colleagues showed that decreased GSH levels in BAL fluid cells of chronic smokers were associated with a decreased expression of GCL-light subunit without a change in GCL-heavy subunit expression [156].

Important protective antioxidant genes such as MnSOD, GCL, heme oxygenase-1 (HO-1), GPx, thioredoxin reductase, and metallothionein are similarly induced by various oxidative stresses including hyperoxia and inflammatory mediators, such as TNF-α and LPS in lung cells [37–40]. Indeed, the transcription factor, Nrf2, is redox sensitive (contains –SH groups) and binds to the antioxidant response element (ARE) within DNA regulating a variety of antioxidant genes. The importance of Nrf2 can be gauged from a report by Rangasamy *et al.*, where they have shown that disruption of the Nrf2 gene in mice lead to an early and a more intense emphysema in response to cigarette smoke compared to mice with an intact Nrf2 gene [157]. In the same study they have shown that the expression of nearly 50 antioxidant and cytoprotective genes in the lungs may

be transcriptionally controlled by Nrf2 and all genes may work in concert to overcome the effects of cigarette smoke. Moreover, studies examining polymorphisms in these protective antioxidant genes, such as glutathione transferase and HO-1, have suggested a link to onset of COPD and emphysema [158, 159]. Interestingly, Rangasamy and colleagues have recently showed that disruption of Nrf2 also leads to susceptibility to severe allergen-induced asthma in mice. These findings indicate that though Nrf2 is important for the control of antioxidant genes, it is not specific to one inflammatory disease [160]. Recent studies showed depletion of various Nrf-2 dependent Phase II antioxidant genes in lungs of patients with COPD [161]. The compartmentalization and localization of various antioxidant enzymes and their functions/alterations in asthma and COPD are described in Table 25.3.

## Depletion of antioxidant small molecules in asthma and COPD

Apart from GSH, several other antioxidants, such as ascorbic acid (vitamin C), uric acid, α-tocopherol (vitamin E), and albumin, are present in the lung. Of these, the major antioxidants in lung lining fluid are GSH, ascorbic acid, and uric acid [147]. Like GSH, uric acid can also be found intracellularly, although at lower concentrations than that seen in plasma. It is a powerful scavenger of both ROS and RNS and can protect proteins against nitration [162] particularly from the nitrogen dioxide radical, nitrous oxide, found in cigarette smoke [163]. Oxidation of uric acid by ROS or RNS results in the formation of allantoin that

can then be measured in various body fluids as a marker of oxidative stress [164]. The antioxidant properties of albumin, as well as mucins, come from the presence of exposed −SH groups. Their protective effects are solely extracellular. However, albumin exists in a high concentration and acts as a sacrificial substrate able to react quickly with the very damaging and potent oxidizing $ONOO^-$ and $HOCl$ [165].

The remaining two protective antioxidant molecules, ascorbic acid and α-tocopherol, are derived from the diet. Both antioxidants are decreased in chronic cigarette smokers [5]. Furthermore, the total antioxidant capacity of plasma is decreased in smokers, and in patients with asthma and COPD [95]. It is interesting to note that the decrease in antioxidant capacity in smokers occurs transiently during smoking and resolves rapidly after smoking cessation. Depletion of total antioxidant capacity in smokers is associated with decreased levels of major plasma antioxidants (e.g. ascorbic acid, vitamin E, β-carotene, and selenium). The depletion of antioxidants may thus be a reflection of ongoing oxidative stress due to underlying inflammation in these diseases. There is, however, a limitation of oxidative stress and antioxidant biomarkers at present due to the lack of longitudinal studies, correlation with disease severity or outcome, and the variations observed in the control subjects.

Ascorbic acid, otherwise known as vitamin C, is water soluble. It functions as an antioxidant by accepting free radical electrons, thus forming the ascorbyl radical which is relatively unreactive. However, the ascorbyl radical will undergo a disproportionation reaction to regenerate ascorbate and dehydroascorbate, the latter rapidly breaking down

**TABLE 25.3** Antioxidant enzymes of the lungs, their localization, and functions in asthma and COPD.

| Enzyme | Lung localization | Function | Expression/Activity |
|---|---|---|---|
| Cu, ZnSOD | Bronchial, alveolar epithelium, macrophages, fibroblasts, pneumocytes | Scavenges $O_2^{\bullet-}$ | Decreased in COPD |
| EC-SOD | Bronchial epithelium, macrophages, neutrophils, vascular walls, pneumocytes | Scavenges $O_2^{\bullet-}$ | Decreased in COPD |
| MnSOD | Bronchial epithelium, macrophages, neutrophils, vascular walls, pneumocytes | Scavenges $O_2^{\bullet-}$ | Decreased in Asthma Decreased in Smokers |
| Catalase | macrophages, fibroblasts, pneumocytes | Hydrogen peroxide to water | Decreased in Asthma |
| Glutathione peroxidase | ELF cells, epithelium, macrophages, other lung cells | Organic hydroperoxides to organic hydroxides | Decreased in COPD Decreased in Asthma |
| Heme oxygenase-1 | Alveolar, bronchial epithelium, macrophages, inflammatory cells of lungs | Heme to CO and biliverdin | Decreased in Emphysema Decreased in COPD |
| Thioredoxin | bronchial epithelium, macrophages | Transcriptional modulation, thiol–dithiol exchange, Prot-S-S-Prot to Prot-SH | Decreased in COPD |
| GCL (catalytic subunit) | Alveolar, bronchial epithelium, macrophages | Synthesis of glutathione (first rate limiting step) | Decreased in COPD Decreased in Smokers |

to form oxalic acid and L-threonine [166]. Ascorbic acid has been shown to possess a whole array of antioxidant properties *in vitro*, from scavenging ROS and RNS, preventing lipid peroxidation to regenerating other antioxidants, such as uric acid and α-tocopherol. Like uric acid, ascorbic acid is also a powerful scavenger of nitrous oxide which is a potent promoter of both protein nitration and lipid peroxidation [167, 168]. Indeed, increases in $F_2$-isoprostane lipid peroxidation products are decreased in smokers who consume more ascorbate [169]. Further evidence of asorbate's antioxidant properties *in vivo* is provided by the evidence highlighting its depletion in clinical conditions associated with a high oxidative stress burden [170]. Intriguingly, there is also a dark side to ascorbic acid in that *in vitro* it can reduce $Fe^{3+}$ to $Fe^{2+}$ thereby facilitating $OH^•$ radical formation through Fenton chemistry. However, the relevance of this *in vivo* is still a subject of investigation.

## IS THERE A CO-RELATIONSHIP BETWEEN OXIDATIVE STRESS, ANTIOXIDANT DEPLETION AND DECLINE IN LUNG FUNCTION IN ASTHMA AND COPD?

Emerging evidence suggests that oxidative stress is directly correlated with the decline in lung function in asthma and COPD. Epidemiological studies have shown a relationship between circulating increase in neutrophil numbers and decline in $FEV_1$. Oxidative stress, measured as lipid peroxidation products in plasma, has also been shown to correlate inversely with the $FEV_1$ percentage in a population study [171].

There is an association between dietary intake of antioxidant vitamins and polyphenols and lung function in the general population as well as in obstructive airway disease, supporting the hypothesis that oxidative stress may have a role in decline in lung function, and chronic cough and breathlessness (but not chronic phlegm) in COPD [146, 172–174]. This is substantiated by a study highlighting the beneficial protective effect of fruit containing polyphenols and vitamin E intake against COPD symptoms in 20-year COPD mortality from three European countries consisting of Finnish, Italian, and Dutch cohorts [175]. It has been shown that there is a correlation between increased dietary antioxidant intake and improved lung function [146]. Moreover, increased dietary antioxidant status, particularly vitamin E (α-tocopherol), correlated with lower levels of lipid peroxidation [176]. α-Tocopherol is a lipid soluble antioxidant and as such is probably one of the most important scavengers and inhibitors of lipid peroxidation. It largely achieves this by reacting faster with the lipid peroxyl radicals than these radicals can react with other lipid molecules. Similarly, another study reported that increased dietary intake of ascorbic acid led to an improvement in lung function in both smokers and asthmatics [177]. These studies support the concept that oxidative stress plays an important role in decline in lung function in smokers, and possibly in asthma patients with COPD.

## THERAPEUTIC INTERVENTION WITH ANTIOXIDANTS IN ASTHMA AND COPD

In view of the evidence implicating oxidative stress in the pathogenesis of chronic airway diseases, one rational approach would be to consider antioxidant intervention to neutralize the increased oxidative stress, and the subsequent inflammatory response. Several small molecular weight compounds that target oxidant signaling, or quench oxidants/aldehydes/carbonyls derived from cigarette smoke or boost antioxidant potential in the lung are currently being tested clinically [178]. Antioxidant agents such as thiol molecules (GSH/cysteine and mucolytic drugs, such as *N*-acetyl-L-cysteine (NAC) and nacystelyn (NAL)), dietary polyphenols (curcumin, resveratrol, green tea, and quercetin), erdosteine, fudosteine, and carbocysteine lysine salt, all have been reported to increase intracellular thiol antioxidant levels and induction of GSH biosynthesis genes. The various antioxidant strategies used have been divided into six categories; dietary, thiols, spin traps, enzyme mimetics, and polyphenols as shown in Table 25.4.

### Dietary

Reports of clinical benefit in asthma and COPD for increased vitamin C, E, and other dietary antioxidants have been varied. Nevertheless, epidemiological studies have shown that there are decreased vitamin C, E, β-carotene, and selenium levels in cigarette smokers [179–181]. Similarly, other studies have reported a link with decreased lung function [182] and the presence and severity of asthma to dietary antioxidant intake, such as vitamins C and E, β-carotene and selenium [183, 184]. One small trial has shown that there was a clinical improvement in asthmatic symptoms after being given selenium supplementation compared to placebo [185]. In addition, one very early study incorporating selenium supplementation in smokers demonstrated that this resulted in reduced superoxide release from leukocytes [186]. Moreover, two studies by the same group have shown no clinical benefit of supplemental intake of vitamin C or E when compared to current standard therapies for mild-to-moderate asthma [187, 188]. This is in contrast with earlier studies, showing decreased lipid peroxidation and a corresponding improvement in lung function with increased vitamin C intake in smokers [177, 189]. Supplementation with either vitamin E or β-carotene alone resulted in no clinical benefit in COPD [190]. Moreover, β-carotene supplementation may have a detrimental side

effect in that it may accelerate the onset of lung cancer in cigarette smokers [189]. Hence, dietary antioxidants intake/supplementation may not be so effective as therapeutic option to control the declining lung function in airway diseases.

## Thiols

In the lung, thiols in the form of GSH constitute one of the main antioxidant defenses in both intracellular and extracellular compartments. Attempts to raise GSH levels in the lung through administration of GSH itself have been tried [191]. Unfortunately, aerosolization of GSH into the lung was characterized by a poor half life [192] and led to induction of bronchial hyperreactivity [193]. Intracellular antioxidant protection after GSH oral administration was also limited, due to its inefficient cellular uptake [194]. Alternative methods of raising GSH levels have involved supplementing the GSH precursor cysteine, through the use of NAC. This approach has met with varying success in the past [195]. A Cochrane systematic review and other systematic reviews demonstrated that NAC treatment was associated with a significant reduction of 0.79 exacerbations/patient/year compared with placebo, and a 29% decrease in COPD patients [196–200]. Similarly, randomized, double-blind, placebo-controlled Phase II trials of a 6-12 month oral dose (of 600 mg, twice a day) showed reduction in various plasma and BAL fluid oxidative biomarkers in smokers [201, 202]. Similarly, two further studies showed a clear benefit of NAC in reducing oxidant burden [203, 204]. While there is a body of evidence that the administration of NAC provides a potential benefit for COPD patients, this evidence is not clinically directive. For example, in a recently conducted Phase III multicenter Bronchitis Randomized on NAC Cost-Utility Study (BRONCUS) [205], NAC (600 mg oral, daily) was ineffective in halting the decline in lung function, but did lead to a reduction in hyperinflation in patients with severe COPD and decreased the exacerbation rate in patients who were not treated with inhaled glucocorticoids [205] (Table 25.5). The variability in all the current studies using NAC at 600 mg, oral, daily may simply reflect the fact that the dose was not high enough. Indeed the pharmacokinetics support this explanation. Given orally, 600 mg of NAC is rapidly absorbed by the gut but has a bioavailability of only 10% with a plasma half life of 6.3 h; this led to a transient increase in lung GSH levels after daily dosing for 2 weeks [206, 207]. Though oral intake of NAC (600 mg daily) led to decreased markers of oxidative stress in smokers and patients with COPD, perhaps higher doses of NAC (1200–1800 mg/day) are needed to observe any clinical benefit on lung function.

An alternative to NAC is the lysine salt of NAC, nacystelyn (NAL). It has been used as a mucolytic for cystic fibrosis. However, it also possesses antioxidant properties and can reduce both ROS levels and ROS-mediated inflammatory events *in vitro* [213] and *in vivo* [214]. NAL has several advantages over NAC, firstly it can enhance GSH levels twice as effectively as NAC and secondly it forms a neutral pH when in solution, unlike NAC which is acidic [215]. This has meant that when delivered directly into the lung by aerosol in healthy volunteers, it did not cause any irritation or other side effects [216]. Therefore NAL may be more promising than NAC in reducing the oxidant burden in the lung in chronic airways disease.

The potential of other thiols as antioxidants are also being explored. These include erdosteine, fudosteine, and carbocysteine, which have mucoactive properties as well as reduce bacterial adhesiveness. In the "Equalife" randomized placebo controlled trial, erdosteine was dosed orally 300 mg b.i.d. for a period of 8 months [217]. Patients receiving erdosteine had significantly fewer exacerbations and spent few days in hospital than the placebo group. Moreover, patients receiving erdosteine showed no reduction in lung function over this period and showed a significant improvement in health-related quality of life. Similarly, fudosteine has shown to possess promising potential in treatment of patients with COPD. A clinical trial on the combination of steroids and erdosteine/fudosteine/carbosyteine in patients with COPD is needed. A recent study has shown that long-term use of carbocysteine reduced the rate of exacerbations in patients with COPD, but there was no difference in exacerbation rate between the carbocysteine group and placebo group at an early treatment (3 months) [218]. However, 1-year treatment of carbocysteine (1,500 mg/day) was effective in COPD patients in terms of reductions in numbers of exacerbations and improvements in quality of life. Hence, it was suggested that longer use of carbocisteine is more effective for preventing exacerbations of COPD.

## Spin traps

Spin traps are based around a nitrone or nitroxide containing molecule such as isoindole-based nitrones [219] and azulenyl-based nitrones [220]. One such azulenyl nitrone, STANZ, may prove promising for *in vivo* use as it exhibits very potent antioxidant activity. Surprisingly, no studies have been performed in asthma and COPD, looking at the impact of spin traps on clinical endpoints, such as $FEV_1$. A phenyl-based nitrone spin trap developed by AstraZeneca, NXY-059, is due to enter Phase III clinical trials for use in acute ischemic stroke. The utility of this compound in SAINTII trial was unsuccessul though the drug was safe. Nevertheless, it remains to be seen whether such compounds could be developed for more long-term use in asthma and COPD.

## Enzyme mimetics

Enzyme mimetics are generally small compounds that possess catalytic activity that mimics the activity of larger enzyme-based molecules. In the case of antioxidants, this includes the SOD, catalase, and GPx-like activities. A number of SOD mimetics based around organo–manganese complexes have been developed which retain their antioxidant properties *in vivo*. These include a series of manganese-based macrocyclic ligands, such as M40401, M40403, and M40419 [221–223]. The second class of SOD mimetics are the manganese–metalloporphyrin based compounds as exemplified by AEOL-10113 and AEOL-10150 [224, 225]. The third class of manganese-based SOD mimetic are the "Salens." These are generally aromatic substituted ethylene–diamine metal complexes [226], such as EUK134 [227, 228]. The "Salens" also possess some catalytic activity and can therefore

**TABLE 25.5** Clinical trials conducted for the efficacy of antioxidants in asthma and COPD.

| Trial name | Antioxidant used | Aim of study | Disease/Condition | Outcome | References |
|---|---|---|---|---|---|
| BRONCUS | $N$-acetyl-L-cysteine | Effect of NAC on $FEV_1$ | COPD | 30% reduction in COPD hospitalization obtained without change on decline in $FEV_1$. | [205] |
| Systematic Cochrane review of 23 randomized controlled trails | $N$-acetyl-L-cysteine (2 months of oral NAC therapy) | Effect of NAC and antibiotics on number of days of disability | COPD | Significant reduction in days of disability (0.65 day/patient/month) and 29% reduction in exacerbations. No difference in lung function | [197, 198] |
| A Cochrane systematic review of randomized, controlled trials of 11 of 39 retrieved trials | $N$-acetyl-L-cysteine | Used a validated score to evaluate the quality of each study | COPD | 9 trials showed prevention of exacerbation and 5 of which addressed improvement of symptoms compared with 34.6% of patients receiving placebo | [199] |
| A meta-analysis of published trials | $N$-acetyl-L-cysteine | To assess the possible prophylactic benefit of prolonged treatment | COPD | 23% decrease in number of acute exacerbations | [200] |
| | $N$-acetyl-L-cysteine (600 mg once a day for 12 months) | Effect of NAC on $H_2O_2$ and TBARS in EBC | COPD | No change in TBARS reduce $H_2O_2$ levels | [202–204] |
| | $\beta$-carotene (20 mg/day) and $\alpha$-tocopherol (50 mg/day) | Effect on the symptoms (chronic cough, phlegm, or dyspnea) | COPD | No benefit on symptoms | [208] |
| | $\beta$-carotene (20 mg daily for 4 weeks) | Effect on lipid peroxides Levels in exhaled breath | Smokers | Reduce lipid peroxidation (pentane levels) in exhaled breath | [190, 209, 210] |
| The MORGEN study | Diet rich in polyphenols/bioflavonoids (catechin, flavonol, and flavone) (58 mg/day) | Effect on $FEV_1$, chronic cough, breathlessness, and chronic phlegm | COPD | Positively associated with decline in $FEV_1$ and inversely associated with chronic cough and breathlessness, but not chronic phlegm | [174] |
| European countries (Finnish, Italian, and Dutch cohorts) | Diet rich in fruits, vegetables and fish intake | Effect on 20-year COPD mortality | COPD | A 24% lower COPD mortality risk | [175] |
| | Vitamin C (500 mg daily for 4 weeks) | Effect on lipid peroxides Levels in breath and plasma | Smokers | No change in lung function No change in lipid peroxidation (breath pentane and plasma MDA levels) | [209] |
| | Vitamin C (600 mg) Vitamin E (400 IU) $\beta$-carotene (30 mg) | Effect on lipid peroxidation | Smokers | Reduced lipid peroxidation | [211, 212] |
| | Vitamin E (400 IU b.i.d. For 3 weeks) | Effect on breath ethane levels | Smokers | No effect on breath ethane levels | [208] |
| | Vitamin C and E, $\beta$-carotene, selenium | Effect on lung function and oxidative stress biomarkers | Asthmatics | 50% reduction in asthma prevalence and clinical improvement whereas other studies showed no clinical improvement | [185–188] |
| Peace study | Carbocysteine (Carbocisteine) | Effect on rate of exacerbations in COPD | COPD | Long-term (one year) use of carbocysteine (1,500 mg/day) produced reduction in numbers of exacerbations in patients with COPD | [218] |

BONCUS: Bronchitis randomized on NAC cost utility study.

also scavenge hydrogen peroxide, a product of SOD activity. Moreover, they are also able to decompose peroxynitrite [229].

Within the various classes of SOD mimetic, only the metalloporphyrin-based compounds AEOL-10150 and AEOL-10113 (iron-containing porphyrin complexes that decomposes $ONOO^-$ into innocuous nitrate) have been studied in models of airway inflammation [230]. In one study, AEOL-10113 was shown to inhibit both airway inflammation and bronchial hyperreactivity in an ovalbumin challenge model of airway inflammation [224]. This highlighted an important therapeutic benefit in asthma. In another study, AEOL-10150 was demonstrated to inhibit cigarette smoke-induced lung inflammation [225] suggesting a potential therapeutic benefit in COPD.

Another type of catalytic antioxidant is the GPx mimetic ebselen. This is a selenium-based organic complex and has been shown to be a very powerful antioxidant against the highly reactive and destructive $ONOO^-$ [231]. It is able to prevent both NF-κB/AP-1 activation and pro-inflammatory gene expression in human leukocytes exposed to $ONOO^-$. Other studies have shown that ebselen is also active *in vivo* in preventing LPS-induced airway inflammation [23, 232]. However, no studies have been reported so far on the protective effects of ebselen in cigarette smoke-induced lung inflammation. In contrast, the GPx mimetic BXT-51072 (Oxis, USA) and the lipid peroxidation inhibitor BO-653 (Chugai Pharma, Japan) are either currently in Phase I or pre-clinical trials in patients with COPD. A more detailed review of the development and properties of these catalytic antioxidants is described elsewhere [233].

### Polyphenols

Several epidemiological studies have been undertaken, which have established a beneficial link between polyphenol intake and lower disease risk with many of the clinical benefits being attributed to both the antioxidant and anti-inflammatory properties of polyphenols [234]. In one Finnish study with over 10,000 participants, a significant inverse correlation was observed between polyphenol intake and the incidence of asthma [235]. Similar beneficial associations were also observed for COPD in a study encompassing over 13,000 adults. This study reported that increased polyphenol intake correlated with improved symptoms, as assessed by cough, phlegm production, and breathlessness and improved lung function as measured by $FEV_1$ [174]. Two further studies appeared to corroborate these findings. The first study showed a beneficial protective effect against COPD symptoms for increased fruit intake, high in polyphenol and vitamin E content [175]. In the second more recent study, a standardized polyphenol extract administered orally was shown to be effective in reducing oxidant stress and increasing $PaO_2$, as well as improvements in $FEV_1$ between the enrollment and the end of the study [236].

While the above studies would appear to demonstrate an epidemiological link between polyphenol intake and clinical benefit in asthma and COPD, other studies have tried to show a direct impact of specific polyphenolic compounds on inflammation *in vitro* and *in vivo*. For example, the flavonoid resveratrol, a constituent of red wine, inhibits inflammatory cytokine release from macrophages isolated from COPD patients [237]. Moreover, Birrell and colleagues have showed that *in vivo*, resveratrol can inhibit inflammatory cytokine expression in response to LPS challenge in rat lungs [238]. Furthermore, in both monocytic U937 and alveolar epithelial A549 cells, resveratrol inhibits NF-κB and AP-1 activation [239, 240]. However, the clinical utility of resveratrol in patients with asthma and COPD is not known.

Another well-studied polyphenol is curcumin. It is the active constituent of *Curcuma longa*, commonly known as turmeric. Like resveratrol, it has also been reported to inhibit NF-κB activation, along with IL-8 release, Cyclooxygenase-2 expression, and neutrophil recruitment in the lungs [241]. Interestingly, one study postulates that curcumin prevents cigarette smoke-induced NF-κB activation through the inhibition of IκBα kinase in human lung epithelial cells [242]. Recently, we have observed that curcumin can inhibit inflammation and restore glucocorticoid efficacy in response to oxidative stress, through the upregulation/restoration of HDAC2 activity in macrophages (U937 and MonoMac6 cells) [243]. This would facilitate steroid-mediated HDAC2 recruitment in attenuating NF-κB-mediated chromatin acetylation and subsequent pro-inflammatory gene expression. As glucocorticoids are the main thrust of anti-inflammatory treatment, any therapeutics that can be used as an add-on to improve steroid responsiveness in COPD and severe asthma would be of significant clinical benefit. Clearly clinical trials by using a combination approach of a steroid with polyphenols are warranted.

### SUMMARY

There is now increasing evidence that ROS generation plays a major pathophysiological role in asthma and COPD, and it is important for the severity of these conditions. ROS generation through endogenous mechanisms or exogenous cigarette smoke/environmental oxidants is critical to the inflammatory response through activation of redox-sensitive transcription factors and pro-inflammatory signaling pathways. At the same time, endogenous antioxidant mechanisms are present to attenuate this redox-mediated inflammatory response. It is when these two opposing mechanisms are out of balance that a chronic and more severe inflammatory state becomes apparent. The use of antioxidants or other pharmacological agents to boost the endogenous antioxidant system could be used to redress this imbalance. In so doing, this would provide therapeutic benefit in damping down and curtailing the severity and chronicity of the inflammatory response in asthma and COPD patients.

A variety of oxidants, free radicals, and aldehydes are implicated in the pathogenesis of COPD, therefore it is possible that the therapeutic administration of multiple antioxidants will be effective in the treatment of COPD. An effective wide spectrum antioxidant therapy that has good bioavailability and potency is needed to control the localized oxidative and inflammatory processes that occur in the pathogenesis of asthma and COPD. Furthermore, human clinical trials of newly developed small molecular antioxidants (alone or in combination with anti-inflammatory agents), or higher doses

of NAC, are urgently needed to validate these compounds as clinical therapies and to provide the proof of concept that oxidative stress is involved in the pathogenesis of COPD.

Clearly, further studies are required to understand the effect of ROS on basic cellular functions and the differential responses seen in different cell types and how this in turn impacts on the pathology of different inflammatory disease states. At the same time, endeavors into identifying new and more efficacious antioxidants, radical quenchers, inhibitors of lipid peroxidation, and agents that can reverse protein carbonyl protein damage as a therapeutic strategy should continue. Indeed, elucidating the mechanism of action for some of the naturally occurring antioxidants, such as the potent enzyme mimetics and polyphenols, may lead to new therapeutic targets that can be antagonized/agonized through more conventional pharmacological approaches.

Tissue infection or injury induces a local inflammatory response in which the accumulation of white blood cells from the blood is an essential feature. The type of infection or injury determines the types of leukocyte which are recruited as appropriate for the necessary local host defense and repair response. Inflammatory diseases can result from an inappropriate or overzealous inflammatory response. Such inflammation, when it occurs in the lung, can seriously compromise the normal function of the organ and can be life-threatening. Thus, there is considerable interest in the mechanisms underlying leukocyte recruitment and the endogenous molecules regulating the process, with an ultimate aim of designing targeted therapy to attenuate the trafficking of specific cell types. Leukocyte recruitment represents a refinement of a fundamental property of a motile cell to detect a chemical gradient, orient itself, and move along the gradient.

This process, known as chemotaxis, has been elegantly described and analyzed in primitive single-celled organisms and is an essential property of cells at different stages of their life history in multicellular organisms. In higher animals, this property has been adapted to trap specific leukocyte types on the inner surface of small blood vessels and induce migration through the vessel wall into the tissues. Pivotal to the process of chemoattraction of leukocytes are the chemokines, a large family of chemotactic proteins, typically of 10 kDa; see Rot and Von Andrian [1] for a review. These proteins act upon specific G-protein-coupled receptors (GPCRs) found on the surface of cells and have a prominent role in the immune system, where they are essential for both the localization of different types of leukocytes in tissue compartments under basal conditions and the rapid recruitment of these cells to sites of injury or infection.

The chemokine gradient, which the cells follow, is produced constitutively in specialized locations, or upregulated at sites of inflammation, such as in asthma or chronic obstructive pulmonary disease (COPD). The chemokines produced locally stimulate integrins on the leukocyte to attach to complementary receptors on the microvascular endothelium and cytoskeletal changes necessary for attachment and migration through the barrier. Similar processes mediate the movement of the cell in the tissue toward the inflammatory focus and elsewhere if appropriate (e.g. to lymph nodes).

Until recently, little was known about how the immune system organizes its geography under basal conditions or how specific cell types can be recruited to sites of inflammation. Chemoattractants, such as complement-derived C5a, leukotriene B4, and platelet activity factor, had been discovered to be chemotactic *in vitro* in Boyden chamber chemotaxis assays, but none had the specificity necessary for many of the migratory responses seen in the body. This situation changed dramatically with the discovery of the first chemokines in the late 1980s and the growing number of family members that have been discovered over the last decade.

## CHEMOKINES

Chemokines have multiple roles in the organization of the immune system under basal conditions and during infection, and are also involved in angiogenesis. A crucial role of chemokines is the recruitment of different types of leukocytes

from the blood to the sites of inflammation. Selective cell recruitment is achieved by means of locally produced chemokines, the particular chemokine secreted depends on the type of stimulus and the tissue involved. Specificity is provided by the expression of different types of receptor on different leukocyte types.

Most of the known chemokines (Table 26.1) belong to two major families defined by the position of four conserved cysteine residues (Fig. 26.1). The largest family is the CC chemokine family (28 in number) which possess two adjacent cysteines in the vicinity of the N-terminus of the mature peptide. The CXC family (16 members) have two cysteine residues in this same region, but with an interposed amino acid. In both families, the first cysteine forms a disulfide bond with the third, and the second with the fourth cysteine. CXC chemokines are characteristically chemotactic for neutrophils and lymphocytes, whereas CC chemokines act upon the majority of leukocytes, but generally have little activity on neutrophils. CXC chemokines can be further subdivided into those possessing a glutamate–leucine–arginine (ELR) motif immediately before the first cysteine, and those lacking the ELR motif. Members of the former, such as CXCL1, CXCL8, and CXCL7, are associated with angiogenic properties, while those lacking the ELR motif are typically inducible by IFN-$\gamma$ and are angiostatic, such as CXCL9, CXCL10, and CXCL11 [2]. There are some nonconforming chemokines: lymphotactin

has only one pair of cysteines and a single disulfide bond [3] and fractalkine has a CXXXC motif at the N-terminus [4]. Fractalkine is also unusual in that it is produced attached to a cell-bound mucin stalk, a property shared by the CXC chemokine CXCL16 [5]. This allows them to also function as adhesion molecules, tethering cells expressing the cognate receptor.

Chemokines are thought to bind to presenting molecules on the luminal surface of the venular endothelium, such as glycosaminoglycans, where the chemokines engage their receptors on the leukocyte surface. Leukocytes typically roll on the endothelium through low affinity intermolecular interactions mediated by selectins. Stimulation of chemokine receptors induces the upregulation of adhesion molecules on the leukocyte surface and cytoskeletal changes necessary for firm attachment, followed by emigration.

Chemokines bind to and transduce their actions via specific GPCRs [7, 8]. To date, 6 CXC and 10 CC chemokine receptors have been characterized, with single receptors identified for fractalkine and for lymphotactin. The majority of receptors bind and signal in response to several chemokine ligands, but such promiscuity is generally class-restricted, with CC chemokines binding only to CC chemokine receptors. One exception to this is the Duffy antigen receptor for chemokines (DARC) which can bind chemokines of both classes and has a role in clearance of chemokines. This receptor is present on erythrocytes and endothelial

**TABLE 26.1** CXC Chemokines, and their receptors.

| Chemokine | Original name | Chemokine receptor(s) | Chemokine | Original name | Chemokine receptor(s) |
|---|---|---|---|---|---|
| CXCL1 | GRO-$\alpha$/MGSA-$\alpha$ | CXCR2 > CXCR1 | CCL8 | MCP-2 | CCR3 |
| CXCL2 | GRO-$\beta$/MGSA-$\beta$ | CXCR2 | (CCL9/10) | Unknown | Unknown |
| CXCL3 | GRO-$\gamma$/MGSA-$\gamma$ | CXCR2 | CCL11 | Eotaxin | CCR3 |
| CXCL4 | PF4 | Unknown | (CCL12) | Unknown | Unknown |
| CXCL5 | ENA-78 | CXCR2 | CCL13 | MCP-4 | CCR2, CCR3 |
| CXCL6 | GCP-2 | CXCR1, CXCR2 | CCL14 | HCC-1 | CCR1 |
| CXCL7 | NAP-2 | CXCR2 | CCL15 | HCC-2/Lkn-1/MIP-1$\delta$ | CCR1, CCR3 |
| CXCL8 | IL-8 | CXCR1, CXCR2 | CCL16 | HCC-4/LEC | CCR1 |
| CXCL9 | Mig | CXCR3 | CCL17 | TARC | CCR4 |
| CXCL10 | IP-10 | CXCR3 | CCL18 | DC-CK1/PARC AMAC-1 | Unknown |
| CXCL11 | I-TAC | CXCR3 | CCL19 | MIP-3$\beta$/ELC/exodus-3 | CCL7 |
| CXCL12 | SDF-1$\alpha$/$\beta$ | CXCR4 | CCL20 | MIP-3$\alpha$/LARC/exodus-1 | CCR6 |
| CXCL13 | BLC/BCA-1 | CXCR5 | CCL21 | 6Ckine/SLC/exodus-2 | CCR7 |
| CXCL14 | BRAK/bolekine | Unknown | CCL22 | MDC/STCP-1 | CCR4 |
| (CXCL15) | Unknown | Unknown | CCL23 | MPIF-1 | CCR1 |
| CXCL16 | SexCkine | CXCR6 | CCL24 | MPIF-2/eotaxin-2 | CCR3 |

The systematic names, together with the colloquial names and agoinst activity of known receptors ae shown. Some chemokines appear to be missing from the list, e.g. CCL6. In these cases please note that whilst a chemokinase of that name has been identified in the mouse, no human orthologue has been documented.

cells, whereas a second receptor, D6 is located primarily on the lymphatic endothelium and is involved in the selective uptake of inflammatory chemokines [9].

The chemokines and their receptors have now been given a nomenclature to alleviate some of the problems associated with multiple colloquial names for the same ligands. Chemokine receptors are designated as CXCRn, CCRn, CX3CR1, and XCR1 with the chemokine ligands that stimulate these receptors now designated CXCLn, CCLn, CX3CLn, and XCLn, respectively (Table 26.1).

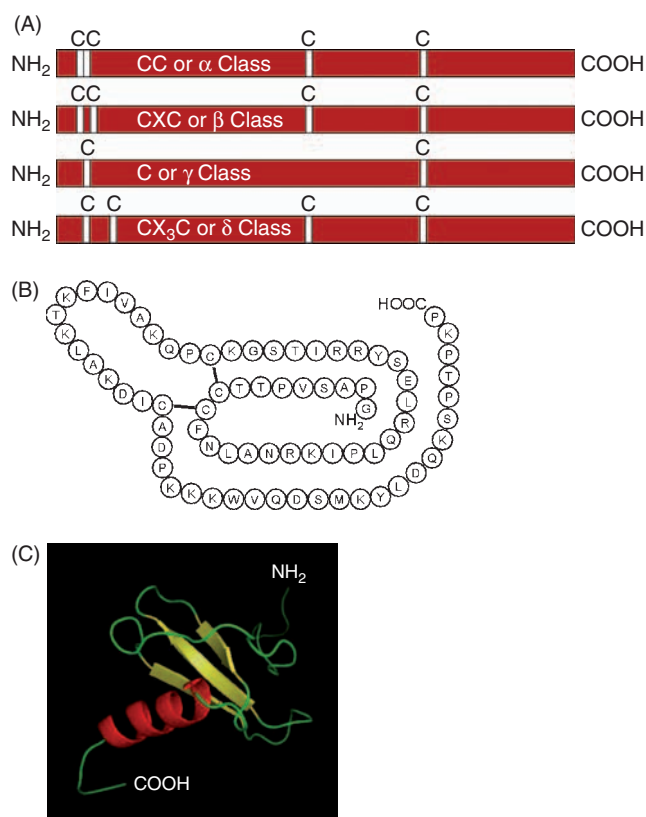

**FIG. 26.1** (A) Linear representations of the major chemokine classes. (B) Primary structure of the human homolog of CCL11/Eotaxin showing disulfide bridges. (C) The secondary structure of human CCL11 is represented as a ribbon model, modeled from the coordinates given in Crump *et al.* using the Pymol software [6].

## CHEMOKINES IN COPD

Neutrophils have been strongly implicated in the pathogenesis of COPD and are found in high numbers in lung tissue and sputum [10]. It is believed that activation of these cells to release activated oxygen species and proteases, such as elastase, is important in the specific pattern of lung damage and chronic dysfunction that characterize COPD. Consequently, there is considerable interest in the mechanisms involved in the recruitment of these cells to the lung with the aim of identifying opportunities for potential therapeutic intervention (Fig. 26.2).

CXCL8/IL-8 is a CXC chemokine that is a potent chemoattractant for neutrophils and was amongst the first of the chemokines to be discovered and characterized [11–13]. Early studies showed that this chemokine was present in the inflammatory exudate induced in a model of microbial infection *in vivo* [14, 15] and its production was often preceded by a phase of appearance of the complement fragment, C5a, which is also a potent neutrophil attractant but is generated in tissue fluid rather than as a secretory product of a cell [16]. Neutrophils themselves have been shown to produce CXCL8 during phagocytosis [17, 18], these effects can be blocked by antibodies to integrins and platelet-activating factor antagonists [19]. A similar pattern of chemoattractant production, C5a followed by CXCL8, has also been observed in response to myocardial ischemia, and interestingly the CXCL8 production is dependent on the presence of neutrophils in the heart – implying that neutrophils are the source of the chemokine [20]. In a lung model of ischemia, neutralization of CXCL8 by an antibody

**FIG. 26.2** Mechanisms underlying leukocyte recruitment in COPD. The roles of CXC chemokines in recruiting neutrophils, monocytes and T-cells to the COPD lung are illustrated.

suppresses tissue damage, thus providing a link between neutrophils and injury to lung tissues [21].

CXCL8 was first discovered as a secretory product of stimulated macrophages and other cells [11]. It stimulates neutrophils via two different receptors namely CXCR1 and CXCR2 [22, 23]; another related chemokine, CXCL6/GCP-2 can stimulate both receptors [24, 25]. There are several other chemokines that can stimulate CXCR2 only (e.g. CXCL1/GRO-$\alpha$, CXCL2/GRO-$\beta$, CXCL3/GRO-$\gamma$, and CXCL7/NAP-2). CXCL8 appears to be an important mediator of neutrophil accumulation in COPD. Elevated levels of CXCL8 have been detected in the bronchoalveolar lavage (BAL) fluid, induced sputum, and in the circulation of patients with the disease compared with smoking and nonsmoking controls [26–29] with the levels of CXCL8 correlating with neutrophil accumulation [30–32]. Increases in CXCL8 levels in the sputum from COPD patients have also been documented during disease exacerbation [33, 34] although there appears to be some debate as to whether there is correlation with acute inflammation and viral/bacterial airway infections. Likewise, elevated levels of CXCL1 [35] and CXCL5 [36] have been detected in the sputum and BAL fluid of COPD patients compared with smoking and nonsmoking controls, although levels of the latter chemokine were not significantly different in normal smokers versus patients with emphysema [36]. The source of CXCL1 in COPD patients appears to be predominantly bronchial epithelial cells under the influence of TNF-$\alpha$ [37]. The chemotactic activity of CXCL1 for monocytes in addition to neutrophils, may explain in part the marked increase in alveolar macrophage numbers observed in COPD patients compared with normal controls [38]. The upregulation of MCP-1/CCL2 in the sputum and BAL of patients with COPD [35, 39] may also play a role in this process as it too is a potent recruiter of monocytes [40]. Since the engagement of chemokines with their cognate receptor usually leads to receptor endocytosis, this is the likely explanation for the finding that, compared with control subjects, the cell surface expression of CXCR2 on peripheral blood neutrophils is lower in patients with COPD than healthy controls [41]. Enhanced chemotaxis of monocytes from COPD patients in response to the CXC chemokines CXCL1/GRO-$\alpha$ and NAP-2/CXCL7, compared with monocytes from smoking and nonsmoking control subjects has also been reported, although this was apparently not due to differences in expression of either CXCR1 or CXCR2 on the cell surface [42].

In addition to the neutrophil influx observed in the lungs of COPD patients, increased numbers of CD8$^+$ T-cells have also been reported [43]. These cells are a major source of IFN-$\gamma$ which itself, when expressed as a lung-targeted transgene in mice, can induce emphysema with classical symptoms of alveolar enlargement, enhanced lung volumes, enhanced pulmonary compliance, and an inflammatory infiltrate rich in both macrophages and neutrophils [44]. This suggests a primary role for CD8$^+$ T-cells in the orchestration of leukocyte recruitment and subsequent pathology. Supportive of this, a recent study showed that CD8$^+$ T-cell-deficient mice had a blunted inflammatory response and did not develop emphysema when exposed to long-term cigarette smoke [45]. Increased expression

of CXCR3 by peripheral blood CD8$^+$ T-cells has been reported to be increased in smokers with COPD compared to controls [46]. Similarly, increased numbers of CXCR3$^+$ CD8$^+$ T-cells have been reported within the epithelium and submucosa of lung biopsies from smokers with COPD, compared with nonsmoking control subjects [47]. This suggests that this receptor and its ligands may play a role in their recruitment to the lung. Since the CXCR3 ligands CXCL9, CXCL10, and CXCL11 are all induced by IFN-$\gamma$ and CD8$^+$ T-cells are themselves a source of IFN-$\gamma$, there is a great potential for positive feedback. A more recent study examining 11 different chemokine receptors, found that in addition to CXCR3, CCR5, and CXCR6 expression by lung CD8$^+$ T-cells was also increased in COPD patients and the levels of expression correlated with COPD severity [48], the cells displaying a Tc1, CD45RA$^+$ effector memory phenotype. Since the LTB4 receptor BLT1 has also been shown to be expressed by this subset [49], an additional role for leukotrienes in cell recruitment may be likely.

## CHEMOKINES IN ASTHMA

Considerable evidence underpins the link between the infiltration of inflammatory cells in the lung and the progressive changes in lung pathophysiology that characterize asthma. For example, the late asthmatic response to allergen exposure is associated with activation of Th2-lymphocytes that are believed to regulate the massive eosinophil influx that occurs. Eosinophils are thought to make an important contribution to lung damage and dysfunction by releasing their toxic granular contents which directly induce tissue damage and also by the release of cytokines, such as TGF-$\beta$, which plays an important role in tissue remodeling [50]. The recent generation of mice deficient in eosinophils has allowed the role of the cell to be probed. Data from allergen-challenge models with these mice implicate the eosinophil in both airways remodeling and airway hyperresposiveness [51–53], although this is the subject of controversy [54]. For this reason, there is considerable interest in the endogenous chemoattractants involved in the recruitment of eosinophils to the lung. Since eosinophils are believed to have evolved in host defense to parasitic worms, these cells are an attractive therapeutic target in the Western world. In contrast, neutrophils present difficulties as a target, as they are essential for survival against microbial infection.

## EOSINOPHIL CHEMOATTRACTION

The selective recruitment of eosinophils during the late response to allergen in sensitized individuals implies the existence of endogenous selective eosinophil chemoattractants (Fig. 26.3). A protein was purified from BAL fluid of allergen-challenged, sensitized guinea pigs that had this property [55]. This protein was sequenced and named "Eotaxin" as it was found to exhibit high specifically in recruiting eosinophils when intradermally injected into naïve recipients [55].
**FIG. 26.3** Mechanisms underlying eosinophil recruitment in asthma. An example of the links between the cytokine, chemokine and cellular adhesion systems mediating the recruitment of eosinophils to sites of allergic inflammation .

Eotaxin/CCL11 is expressed by many cells [56–66] and its generation within the lung appears to be dependent upon the presence of T-cells [67]. CCL11 orthologs have been discovered in several species, including human, mouse, rat, and macaque [68–72]. CCL11 is a highly potent chemoattractant for eosinophils acting via a single chemokine receptor, CCR3, that is highly expressed on eosinophils [72], but also on Th2 cells [73], basophils [74], and mast cells [75, 76], supportive of a critical role for this molecule in the process of allergic inflammation. Two additional functional homologs, with low sequence similarity but closely related biological properties, have been described in the human and are named CCL24/Eotaxin-2 and CCL26/Eotaxin-3 [77–81]. Despite sharing the same colloquial name, both CCL24 and CCL26 are only distantly related to CCL11, being encoded in different chromosomal locations and sharing only low identity at the amino acid level. In terms of their ability to recruit eosinophils in assays of chemotaxis *in vitro*, CCL11 and CCL24 exhibit similar potencies, whilst CCL26 has been reported to be an order of magnitude less potent [77]. All three signal specifically via CCR3. Animal studies have highlighted the production of both CCL11 mRNA and CCL11 protein in the lung during the early response to allergen exposure [55, 82–84]. In humans, increased expression of CCL11 and CCL24 at both the mRNA and the protein level has been observed in the allergic lung of both atopic and nonatopic asthmatics [56, 59, 60, 85] and the proteins are also found in induced sputum [60, 86]. In both animal and human studies of allergic airways disease, airway epithelium, microvascular endothelium, tissue macrophages, and infiltrating inflammatory cells have been shown to express eotaxins [56, 57, 59, 60]. CCL11 has also been shown to act in concert with the important eosinophil survival factor IL-5, promoting eosinophil recruitment from the microcirculation [87] and eosinophil mobilization from the bone marrow [84, 88, 89]. Thus, CCL11 along with other cytokines may further contribute to eosinophilia. Indeed, the number of eosinophils in the blood appears to be an important determinant of the number

that can be recruited to a site of allergic inflammation [87]. In addition to the eotaxins, an increasing number of CC chemokines, have been found to activate CCR3 with varying potency, including CCL5/RANTES and members of the monocyte chemotactic proteins such as CCL2, CCL7, and CCL13, but as these chemokines also activate other chemokine receptors, they are relatively nonselective (Table 26.2).

Different approaches have been made to determine the role of particular chemokines in eosinophil recruitment *in vivo,* including the use of neutralizing antibodies against both CCR3 and CCL11 which inhibited the migration of eosinophils *in vivo* [90, 91]. Studies with mice harboring a disrupted gene for CCL11 have shown conflicting results; BALB/c mice deficient in CCL11 showed a reduction in ovalbumin-induced lung eosinophilia [92] whilst, in contrast, CCL11-deficient mice of the outbred ICR strain exhibited no difference in allergen-induced eosinophil recruitment.

Use of CCR3-deficient mice has also been informative. Reduced eosinophil numbers in the airways of intraperitoneal-sensitized, aerosol-challenged CCR3-deficient mice have been reported by Humbles *et al.*, with the eosinophils trapped within the vasculature, unable to migrate into the lung parenchyma [93]. Intriguingly, CCR3-deficient mice also exhibited elevated airway hyperresponsiveness (AHR) to methacholine upon ovalbumin challenge which was attributed to increased numbers of intraepithelial mast cells within the trachea. The routes of immunization used for allergen sensitization appear to make an important contribution, as intradermal sensitization of mice with ovalbumin led to reduced AHR responses in CCR3-deficient mice following methacholine and ovalbumin challenge [94]. More recently, a study using *Aspergillus* as the challenge, rather than ovalbumin, found reduced numbers of perivascular and peribronchial eosinophils in both CCR3-deficient mice and double knockout CCL11/CCL24-deficient mice [52]. Deletion of the genes for CCL11 and the Th2 cytokine IL-5 in double knockout mice appears to be particularly effective in suppressing

**TABLE 26.2** Cellular specificity of chemokines.

airway eosinophilia and hyperresponsiveness [95]; interestingly, IL-13 levels were markedly reduced in these animals.

## CHEMOATTRACTION OF DENDRITIC CELLS

Dendritic cells (DCs) are important sentinels of the immune system, and their migration to lymph nodes following activation and encounter with antigens is crucial to the adaptive immune response. In the context of allergic lung inflammation, CCR6 has been shown to be expressed by lung-derived DCs [96] allowing them to be recruited by the chemokine CCL20, produced by lymphocytes and monocytes and markedly upregulated by tumor necrosis factor or lipopolysaccharide [97, 98]. This receptor is downregulated during maturation and is replaced by CCR7, allowing the cells to respond to the chemokines CCL19 [99, 100] and CCL21 produced in the lymphatic system [101]. This maturation is accompanied by the production of chemokines, such as CCL22, which can recruit activated T-cells expressing CCR4 [102]. The importance of CCR7 in animal models of allergy has been demonstrated by the finding that mAb-mediated neutralization of CCR7 in a Severe Combined Immunodeficiency

mouse reconstituted with Peripheral blood mononuclear cells from allergic humans, impaired DC homing to lymph nodes following antigen challenge, accompanied by a decrease in both Th2 cytokine production and T-cell recruitment [103]. Likewise, mice deficient in the transcription factor Runx3, which have enhanced expression of CCR7 on alveolar DCs, have an accumulation of activated DCs within the lymph nodes which is associated with features characteristic of allergic asthma, such as increased serum IgE levels and AHR to methacholine [104].

## CHEMOATTRACTION OF T-LYMPHOCYTES

T-cell depletion has been shown to prevent allergen-induced CCL11 generation and eosinophil accumulation in the lungs of sensitized mice, emphasizing the pivotal role for T-cells in allergic disease [67]. A link between Th2 cells and eosinophil recruitment is well established, with the Th2 cytokines, IL-4, and IL-13 stimulating CCL11 and CCL26 production by other cells *in vitro* [58, 63, 105–107]. In addition, expression of CXCR4 [108] by naïve T-cells can be upregulated by IL-4 [109]. In murine models of allergic airway disease, neutralizing mAbs to CXCR4 and its with ligand CXCL12 were reported to reduce lung eosinophilia and airway hyperresponsiveness [110]. Likewise, treatment of allergic mice with the CXCR4 antagonist AMD3100 resulted in significant reduction in airway hyperresponsiveness, eosinophilia, and the production of Th2 associated cytokines such as IL-4, IL-5, CCL17, and CCL22 [111] supportive of a role for the CXCR4:CXCL12 axis in allergic airways disease. Th2 cells polarized *in vitro* express the chemokine receptors CCR3, CCR4, and CCR8 [73, 112, 113]. Such polarization has also been observed *in vivo*, with T-cells recovered from the allergic airways of humans shown to preferentially express CCR3, CCR4, and CCR8 [114–116]. Consistent with this, the CCR4 ligands CCL22 and CCL17 are upregulated in the human lung following allergen challenge [117, 118].

In mice, mAb-mediated neutralization of CCL11 and CCL22 has been shown to impede the early recruitment of Th2 cells to the allergic lung with CCL22 responsible for Th2 cell recruitment following repeated antigen stimulation [119]. Studies using mice deficient in CCR4 and CCR8 have failed to conclusively prove a requirement for either receptor in allergic airways disease [120–122] and likewise, mAb-mediated neutralization of CCR4 in guinea pigs or CCL1 in mice had little effect upon T helper cell recruitment following allergen challenge [123, 124].

### Regulatory T-cells

An inbalance or defect in the activity of regulatory $CD4^+CD25^+$ T-cells may result in allergic disease [125, 126]. CCR4 and CCR8 are also reported to be co-expressed by $CD4^+CD25^+$ regulatory T-cells, in both murine and human systems. In the former, these cells have been reported to suppress the differentiation of murine $CD4^+$ T-cells toward Th2 cells via a contact-dependent mechanism [127]. Similarly in the human, $CD4^+CD25^+$ regulatory T-cells purified from peripheral blood have been reported to express CCR4 and CCR8 which is likely to facilitate their migration toward antigen-presenting cells (APCs) and activated T-cells, enabling them to inhibit APC function or suppress responding T-cells respectively [128]. T-cell polarization may also be amplified by chemokines acting as antagonists for example, CXCL9, CXCL10, and CXCL11, ligands for the Th1 associated receptor CXCR3, can also act as antagonists of CCR3 both *in vitro* [129] and *in vivo* [130].

## CHEMOATTRACTION OF BASOPHILS

Basophils are the least common granulocyte in peripheral blood, but they accumulate in significant numbers in certain types of inflammatory responses [131]. Basophils contribute to the cellular infiltrate in asthmatic lung and are prominent in late-phase cutaneous allergic reactions. Although, relative to eosinophils and neutrophils, basophils contain small amounts of cytotoxic proteins and proteases, they are able to release mediators, such as histamine, in response to cross-linking of their FcεR1 receptors by allergens. Further, basophils are thought to contribute large amounts of the Th2 cytokines, IL-4 and IL-13 [132].

A major observation was that basophils express the CCR3 receptor and CCL11 is highly chemotactic for these cells [74, 133]. However, the preferential recruitment of basophils in certain types of inflammatory response (e.g. the cutaneous response to ectoparasitic ticks) suggests that more selective basophil chemoattractant molecules exist. Despite this, no such molecule has been identified. One possibility is that two or more chemokines acting in combination control basophil recruitment *in vivo*. Using a system for measuring shape change in basophils with flow cytometry, some evidence has been provided for this [134]. Combinations of ligands acting via CCR2 and CCR3 were the most effective in this system. Alternatively, nonchemokine molecules may have potent stimulatory effects on basophils. In this context, an extract of nasal polyps was found to have potent stimulatory effects on basophils. This activity was found to be due to insulin-like growth factor-1 and -2 (IGF-1 and -2) [135]. The IGFs induce increase random migration (i.e. chemokinesis). This action, not observed with eosinophils, had a marked potentiating effect on chemotaxis along a gradient induced by CCL11.

## CHEMOATTRACTION OF MAST CELLS

Mast cells pose a particular challenge in the identification of chemoattractant mechanisms as recruitment is from a small circulating pool of progenitors in the blood. Recently, it has been found that mast cell progenitors express the high affinity BLT1 receptor [136]. As the ligand for this receptor, LTB4, is secreted by activated mature mast cells,

this may explain part of the mechanism underlying local mast cell hyperplasia associated with allergic reactions. The cells mature and proliferate in the tissue under the influence of local factors, such as stem cell factor. During maturation, the BTL1 receptor is downregulated [136], and it is likely that other chemoattractants and their receptors are involved in moving the cells along local tissue gradients to mediate the localization of the long-lived tissue-resident mature cells. Several chemokine receptors have been identified on mast cells [76, 137, 138], and their ligands may be important in this localization in the tissues. Of particular interest is the finding that mast cells move into airway smooth muscle layers in asthmatic patients [139]. These mast cells have been found to express CXCR3 and one of its ligands, CCL10, is produced by asthmatic smooth muscle cells [140]. These observations may indicate an important mechanism underlying lung dysfunction in asthmatic patients.

## CHEMOKINES AND THEIR RECEPTORS AS THERAPEUTIC TARGETS

The observations outlined above provide the basis for the development of low-molecular-weight compounds aimed at selectively preventing the recruitment of a particular leukocyte type to a site of inflammation and thus suppressing the pathogenesis associated with that cell type. High throughput screening of vast libraries comprising several millions of small molecules have identified many molecules that can modify the interaction between GPCRs and their ligands; such compounds, either agonists or antagonists, provide a large proportion of the drugs currently prescribed [141].

A selection of prototypic chemokine receptor antagonists of relevance to this chapter are shown in Fig. 26.4.

The first low-molecular-weight compound to be developed against a chemokine receptor was a CXCR2 antagonist [142]. This compound, SB225002, is a potent antagonist that blocks CXCL8 binding and inhibits neutrophil chemotaxis *in vitro* and neutrophil accumulation *in vivo* . It is therefore plausible that CXCR2 antagonists could be developed to prevent neutrophil accumulation as observed in the lung of COPD patients. However, such effects would have to be monitored carefully because neutrophils are essential for host defense against microbial pathogens, as previously discussed. The SB225002 compound has shown efficacy in several animal models of disease including bronchopulmonary dysplasia [143] and arthritis [144] although some of this efficacy may be due to "off-target" effects as recent profiling of the compound suggests it has potency at several additional targets, including histamine and prostanoid receptors [145].

Because of its prominence on cells associated with Th2 cell-driven allergic reactions, CCR3 has become a prime target for the development of antagonists. The first publication of such an antagonist described the effects of a low-molecular-weight compound (UCB 35625, a structure based on a compound produced by Banyu, Japan) that antagonizes CCR3 [146]. This compound also antagonizes CCR1, a receptor for CCL3 and CCL5. Such a bispecific compound may be advantageous as around 15–20% of individuals also express CCR1 at high levels on their eosinophils [147, 148]. UCB 35625 is unusual amongst chemokine receptor antagonists as, although it blocks the activation of chemokine receptors at nanomolar concentrations, it does not readily displace chemokine from the receptor. It appears that the antagonist binding site is located within the transmembrane helices of the receptor [149], whilst

**FIG. 26.4** Chemical structures of the CXCR2 antagonist (A) the bispecific CCR1 and CCR3 antagonist UCB 35625 (B), and the CCR3 antagonists A-122058 (C) and GW-701897B (D).

the ligand binding sites are located extracellularly [150]. Despite several publications describing the *in vitro* efficacy of CCR3 specific antagonists [151–154], descriptions of their efficacy *in vivo* lag well behind, as the molecules generally have poor cross-reactivity with the rodent ortholog receptors. The small molecule CCR3 antagonist A-122058 (Abbott Laboratories) has been reported to be efficacious in reducing the number of eosinophils in a mouse peritoneal model of eosinophil recruitment following injection with CCL11 [155]. Likewise, the Yamanouchi Pharmaceutical Company have recently described compounds with efficacy in a murine model of cutaneous inflammation [156] and in a macaque model of eosinophil recruitment to the lung following bronchoprovocation with CCL11 [151].

To date, the only small molecule antagonist reported to have entered Phase II trails is the compound GW-766994 from GlaxoSmithKline, with little apparent efficacy in an allergic rhinitis study [157]. This follows on from the recent reports of the efficacy of the GlaxoSmithKline compound GW-701897B in reducing vagally mediated bronchoconstriction in antigen-challenged guinea pigs [158]. In an alternative approach, neutralization of CCL11 has been achieved by the generation of a human single-chain fragment variable antibody named CAT-213, isolated by phage display methodologies [159]. CAT-213 is selective for CCL11 over closely related chemokines, such as CCL2, with sub-nanomolar $IC_{50}$ values. In a Phase I single-dose clinical study, CAT-213 was reported to be well tolerated, and long-lived, remaining in an active form in serum for over 2 months, following intravenous administration [160]. In subsequent Phase II studies, administration of CAT-213 prior to the allergen challenge of rhinitic subjects was observed to reduce the mucosal eosinophil infiltration [161, 162].

## CONCLUSION

A combination of clinical observations, *in vitro* cell biology and *in vivo* animal modeling has delineated potentially important mechanisms underlying lung inflammation in COPD and asthma. These extensive studies support the hypothesis that chemokines have a fundamental role in regulating leukocyte trafficking in inflammatory disease. The chemokine receptors represent novel targets for treatment and therapeutic compounds have been described with efficacy *in vitro* and *in vivo*. Clinical trials will ultimately provide the crucial information that will define the chemokine receptors that can be blocked to provide future therapy in these diseases.

# Cytokines

**Kian Fan Chung**

**Department of Thoracic Medicine,
National Heart and Lung Institute,
Imperial College, London, UK**

## INTRODUCTION

Cytokines are signaling proteins, usually less than 80 kDa in size, which regulate a wide range of biological functions including innate and acquired immunity, hematopoiesis, inflammation and repair, and proliferation through mostly extracellular signaling. They are secreted by many cell types at local high concentrations and are involved in cell-to-cell interactions, have an effect on closely adjacent cells, and therefore function in a predominantly paracrine fashion. They may also act at a distance by secretion of soluble products into the circulation (endocrine or systemic effect) and may have effects on the cell of origin itself (autocrine effect). The first group of cytokines described was immune-response factors, labeled as lymphokines that were soluble products released from activated lymphocytes in response to specific or polyclonal antigen. Other groups of cytokines were named according to their actions such as the colony stimulating factors (e.g., granulocyte colony stimulating factor, G-CSF or granulocyte-macrophage colony stimulating factor, GM-CSF), the chemoattractants now grouped under chemokines with a special nomenclature (e.g., CCL11/eotaxin or CXCL1/MIP-1$\alpha$), or the growth factors that mediate proliferation, differentiation, and survival of cells (e.g. transforming growth factor-$\beta$, TGF-$\beta$). However, the effect of a particular cytokine is not restricted to only one set of biological functions but often has more than one function extending beyond the function that may be implied in its name. The wide pleiotropy and element of redundancy in the cytokine family, with each cytokine having many overlapping functions, and with each function potentially mediated by more than one cytokine make the classification of cytokines a difficult task. In the context of airways disease, nevertheless, a broad functional classification remains helpful (Table 27.1). The major classes of cytokines include: pro- and anti-inflammatory cytokines, cytokines of neutrophil and eosinophil recruitment and activation, cytokines derived from T-helper (Th) and T-regulatory (Tregs) cells, and cytokines of T-cell recruitment and growth factors.

The receptors for many cytokines have been grouped into superfamilies based on the presence of common homology regions (Table 27.2). Cytokine receptors are linked to multiple signaling pathways in the cytoplasm and nucleus, leading to transcriptional and post-transcriptional activation of many factors including cytokines. Some cytokines may stimulate their own production in an autocrine manner while others stimulate the synthesis of different cytokines that have a stimulatory feedback effect on the first cytokine. Cytokines may also induce the expression of receptors which may change the responsiveness of both source and target cells. This complexity of cytokine interactions is referred to as the "cytokine network", the overall effect of which will depend on the type of cytokines and cytokine receptors involved and the general milieu and context of the response.

The potential contribution of cytokines to disease has been explored in studies using cytokines as agonists (mainly in cell-based studies), by blocking the effects of specific cytokines mainly in animal models, by conditional overexpression and deletion of cytokines in transgenic mice, and by genetic studies. In humans, implication for particular cytokines in disease has rested on the ability to detect their expression in the tissue of interest, and rarely on the effect of selective inhibition of specific cytokines. The sources and effects of cytokines are summarized in Table 27.2. In this chapter, the cytokines will

**TABLE 27.1** Classification of cytokines and cytokine receptors.

| | |
|---|---|
| *Cytokines* | |
| Proinflammatory cytokines | IL-1α/β, TNF-α/β, IL-6, IL-11, IL-18, IFN-γ |
| Anti-inflammatory cytokines | IL-10, TGFβ, IL-1ra |
| Cytokines of neutrophil recruitment and activation | CXCL8/IL-8, IL-1α/β, TNF-α/β, G-CSF, IL-17A, IL-17F |
| Cytokines of eosinophil recruitment and activation | IL-2, IL-3, IL-4, IL-5, GM-CSF, CCL5/RANTES, CCL11/eotaxin, CCL7/MCP-3, CCL13/MCP-4 |
| Cytokines from T-helper (Th) cells | *Th1*: IFN-γ, IL-2, IL-12, GM-CSF, TNF-α, TNF-β, IL-18 |
| | *Th2*: IL-4, IL-5, IL-6, IL-9, IL-10, IL-13, IL-25 (IL-17E) |
| Cytokines from T-regulatory cells (Tregs) | IL-10, TGFβ |
| Cytokines of T-cell recruitment | IL-16, CCL5/RANTES, CCL3/MIP-1α, CCL4/MIP-1β, TSLP, CCL17/TARC, CCL22/MDC |
| Growth factors | PDGF, VEGF, TGF-β, FGF, EGF, SCF |
| *Cytokine receptor superfamilies* | |
| Cytokine receptor superfamily | IL-2R β and γ chains, IL-4R, IL-3R α and β chains, IL-5 α and β chains, IL-6R, gp130, IL-12R, GM-CSFR Soluble forms by alternative splicing (e.g. IL-4R) |
| Immunoglobulin superfamily | IL-1R, IL-6R, PDGFR, M-CSFR |
| Protein kinase receptor superfamily | PDGFR, EGFR, FGFR |
| Interferon receptor superfamily | IFN-α/β receptor, IFN-γ receptor, IL-10 receptor |
| Nerve growth factor superfamily | NGFR, TNFR-I (p55), TNFR-II (p75) |
| Seven-transmembrane G-protein-coupled receptor superfamily | Chemokine receptors: CXCR1 to CXCR7, CCR1 to CCR10, $CX_3CR1$ |

EGF = epidermal growth factor; FGF = fibroblast growth factor; GM-CSF = granulocyte–macrophage colony stimulating factor; IFN = interferon; IL = interleukin; MCP = monocyte chemotactic protein; MDC = macrophage-derived chemokine; MIP = macrophage inflammatory protein; NGFR = nerve growth factor receptor; PDGF = platelet-derived growth factor; R = receptor; RANTES = regulated on activation, normal T-cell expressed, and secreted; SCF = stem cell factor; TARC = thymus and activation regulated chemokine; TGF = transforming growth factor; TNF = tumor necrosis factor; TSLP = thymic stromal lymphopoietin; VEGF = vascular endothelial growth factor.

**TABLE 27.2** Sources and effects of cytokines.

| Cytokine | Sources | Important cellular and mediator effects |
|---|---|---|
| *Th2 cytokines* | | |
| IL-3 | Th2 cell<br>Mast cells<br>Eosinophils | ● Eosinophilia *in vivo*<br>● Pluripotential hematopoietic factor |
| IL-4 | Th2 cell<br>Mast cells<br>Basophils<br>Eosinophils | ● ↑ Eosinophil growth<br>● ↑ Th2; ↓ Th1<br>● ↑ IgE<br>● ↑ Mucin expression and goblet cells |
| IL-5 | Th2 cell<br>Mast cells<br>Eosinophils | ● Eosinophil maturation<br>● ↓ Apoptosis<br>● ↓ Th2 cells<br>● BHR |
| IL-9 | Th2 cells<br>Eosinophils | ● ↑ Activated T-cells and IgE from B-cells<br>● ↑ Mast cell growth and differentiation<br>● ↑ Mucin expression and goblet cells<br>● Causes eosinophilic inflammation and BHR |

ASM = airway smooth muscle; BHR = bronchial hyperresponsiveness; GM-CSF = granulocyte–macrophage colony stimulating factor; IgE = immunoglobulin E; IFN = interferon; IL = interleukin; IL-1ra = interleukin-1 receptor antagonist; MCP = monocyte chemoattractant protein; MIP = macrophage inflammatory factor; NK = natural killer; TNF = tumor necrosis factor; Treg = CD4$^+$CD25$^+$ regulatory T-cells; VCAM = vascular adhesion molecule.

be considered separately in terms of asthma and chronic obstructive pulmonary disease (COPD), although there is often a clear overlap in the role of many cytokines in the context of these two airway diseases.

## INFLAMMATION AND CYTOKINES IN ASTHMA

### T-cell-derived cytokine expression

The chronic airway inflammation of asthma is characterized by an infiltration of T-cells, eosinophils, macrophages/monocytes, and mast cells, and sometimes neutrophils; the latter are a possible marker of severity. Acute-on-chronic inflammation may be observed with acute exacerbations of the disease, with an increase in eosinophils and neutrophils in the airway submucosa and release of mediators such as histamine and cysteinyl leukotrienes from eosinophils and mast cells to induce bronchoconstriction, airway edema, and mucus secretion. Airway wall remodeling changes include increase in the thickness of the airway smooth muscle (ASM) layer result from both hypertrophy and hyperplasia and thickening of the lamina reticularis with increased collagen and tenascin deposition, in blood vessels and goblet cell numbers in the airway epithelium [1].

Cytokines play an integral role in the coordination and persistence of the chronic allergic inflammatory process in asthma (Fig. 27.1). Particular subsets of CD4$^+$ T-cells may be induced as a result of microenvironmental events resulting the preferential secretion of defined patterns of cytokines, leading to initiation and propagation of distinct immune effector mechanisms. Studies in mouse CD4$^+$ T-cell clones,
**FIG. 27.1** Interactions of cells and cytokines in airway inflammation of asthma. Antigen presentation by dendritic cells to T-cells with the subsequent polarization to Th2 cells appears to be important initial process. The roles of other cells are also crucial, such as airway epithelium, eosinophils, neutrophils, macrophages, and ASM cells. Arrows shown in red with dashed lines indicate potential interactions of allergens through high-affinity IgE receptors with macrophages and mast cells. GM-CSF: granulocyte-macrophage colony stimulating factors; IFN = interferon; IgE = immunoglobulin E; IL = interleukin; MCP-1= monocyte chemoattractant protein-1; PDGF = platelet-derived growth factor; RANTES = regulated on activation, normal T-cell expressed, and secreted; TCR = T-cell receptor; Th2 = T-cell helper type 2; Th17 = T-cell helper producing IL-17; Treg = CD4$^+$ regulatory T-cell; TGF = transforming growth factor; TNF = tumor necrosis factor.

and later in human CD4$^+$ T-cells, indicate the presence of two basic functional polarized subsets, termed T-helpers (Th1 and Th2). The Th2-associated cytokines are one of the more important classes of cytokines identified in the airway mucosa of patients with asthma. By using *in situ* hybridization techniques, increased proportions of cells in bronchial biopsies and in bronchoalveolar lavage (BAL) fluid from patients with atopic asthma express mRNA for IL-3, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF) that is the Th2 gene cluster, when compared with those of nonatopic control subjects [2–4]. In a model of inhalational allergen challenge, an increase in mRNA for these Th2 cytokines, but not for IFN-γ, has been demonstrated in bronchial biopsies and BAL cells of atopic

asthmatics [5]. Thus, lung T-cells are activated and express and release high levels of Th2-type cytokines.

A subset of CD4$^+$ T-cells expressing CD25, termed T-regulatory cells (Tregs), are capable of suppressing both Th1 and Th2-mediated adaptive immune responses, and these cells may mediate their suppressive actions through release of TGF-β or IL-10 [6]. An imbalance between allergen-specific Tregs and effector Th2 cells has been shown in allergic diseases [7].

Recruitment of Th2 cells to the airways may occur through certain chemokines such as CCL17/TARC and CCL22/MDC which are ligands for CCR4 expressed on Th2 T-cells. Increased expression of these chemokines in the bronchial mucosa of asthma patients has been reported, together

with the expression of thymic stromal lymphopoietin that can increase the expression of these Th2 chemoattractants [8].

Although CD4$^+$ T-cells appear to be the main cell expressing these Th2 cytokine transcripts, mast cells and eosinophils also express IL-4 and IL-5 mRNA [9–11]. Mast cells in mucosal biopsies from atopic asthmatics were positive for IL-3, IL-4, IL-5, IL-6, and tumor necrosis factor-α (TNF-α) by immunohistochemistry, while immunoreactive IL-5 and GM-CSF in eosinophils have been detected after endobronchial allergen challenge in asthmatics [10]. Alveolar macrophages from patients with asthma release more proinflammatory cytokines (i.e. IL-1β, TNF-α, GM-CSF, and MIP-1α) than do macrophages from normal subjects [12, 13].

## Antigen presentation and release of cytokines

The primary signals that activate Th2 cells are related to the presentation of a restricted panel of antigens in the presence of appropriate cytokines. Allergens are taken up and processed by specialized cells within the mucosa, such as dendritic cells (antigen presenting cells, APC), followed by presentation of peptide fragments to naive T-cells. The activation of naive T-cells occurs firstly via the T-cell receptor on CD4$^+$ cells through the APC-bound antigen to major histocompatibility complex (MHC)-II complex and, secondly, via the costimulatory pathway linked by the B7 family and T-cell-bound CD28 [14]. CD28 itself has two major ligands: B7.1 that inhibits Th2 cell activation and development, and B7.2 which induces T-cell activation and Th2 cell proliferation. Under the influence of IL-12 and IFN-γ, Th cells are polarised toward Th1 which predominantly secrete interleukin (IL-2), interferon (IFN-γ), and tumor necrosis factor (TNF), triggering both cell-mediated immunity and production of opsonizing antibodies. Th2 cells secrete IL-4, IL-5, IL-10, and IL-13, responsible for IgE and IgG$_4$ antibody production, and activation of mast cells and eosinophils [15]. A third subset of T-helper cells, Th0, shows a composite profile producing both Th1- and Th2-associated cytokines. These soluble factors can also be expressed by macrophages, epithelial cells, and mast cells and may take part in more general inflammatory processes.

Cytokines may play an important role in antigen presentation. Airway macrophages are usually poor at antigen presentation and suppress T-cell proliferative responses (possibly via release of cytokines such as IL-1 receptor antagonist), but in asthma there is reduced suppression after exposure to allergen [16]. Both GM-CSF and IFN-γ increase the ability of macrophages to present allergen and express HLA-DR [17]. IL-1 is important in activating T lymphocytes and is an important costimulator of the expansion of Th2 cells after antigen presentation [18].

Airway macrophages may also be an important source of "first wave" cytokines, such as IL-1, TNF-α, and IL-6, which may be released on exposure to inhaled allergens via transduction mediated by FcεRI receptors. These cytokines may then act on epithelial cells to cause release of a "second wave" of cytokines, including GM-CSF, CCL11/eotaxin, and CCL5/RANTES, which then leads to influx of secondary cells, such as eosinophils, which themselves may release multiple cytokines.

## The immunoglobulin-E response and mast cells

IL-4 is the most important cytokine mediating IgE synthesis through isotype switching by B-cells, but IL-13 is also capable of a similar action on B-cells [19]. IL-4 also activates B-cells through increasing the expression of class II MHC molecules, as well as enhancing the expression of CD23, the low-affinity IgE (FcεRII) receptor. CD40 antigen is expressed on B-cells after antigen recognition. IL-4 together with the engagement of CD40 antigen with its ligand, CD40-L on activated T-cells, promotes IgE class switching and B-cell growth. Because IL-4 can also be produced by basophils, mast cells, and eosinophils and also have surface CD40-L, these cells may contribute to the amplification of IgE responses. IL-4 and IL-13 share the α-chain of the IL-4 receptor (IL-4Rα). On engagement of the ligand with IL-4Rα, signal transducer and activator of transcription 6 (STAT 6) translocates to the nucleus, and germline ε mRNA transcription is initiated together with ε-class switching of immunoglobulin genes. Individuals with gain of function mutations in both the extracytoplasmic and intracellular domains of IL-4Rα show an enhanced IgE response and predisposition to atopic disease [20].

IgE produced in asthmatic airways binds to FcεRI receptors ("high affinity" IgE receptors) on mast cells and basophils, priming them for activation by antigen. Cross-linking of FcεRI receptors upregulates its own expression and leads to mast cell degranulation, with the release of mediators such as histamine and cysteinyl leukotrienes. The importance of IgE in asthmatic inflammation has been emphasized by the demonstration that a humanized monoclonal antibody to IgE inhibits eosinophilic inflammation and reduced CD4$^+$ T-cells, IL-4$^+$ staining cells and B-cells in the airway mucosa of asthmatic patients [21].

The maturation and expansion of mast cells from bone marrow cells involves growth factors and cytokines such as stem cell factor (SCF) and IL-3 derived from structural cells. Bronchoalveolar mast cells from asthmatics show enhanced release of mediators such as histamine. Mast cells also elaborate IL-4 and IL-5 [9]. IL-4 also increases the expression of an inducible form of the low-affinity receptor for IgE (FcεRII or CD23) on B lymphocytes and macrophages [22]. IL-4 drives the differentiation of CD4$^+$ T-helper precursors into Th2-like cells.

## Eosinophil-associated cytokines

The differentiation, migration, and pathobiological effects of eosinophils may occur through the actions of GM-CSF, IL-3, IL-5, and certain chemokines such as CCL11/eotaxin [23–25]. IL-5 influences the production, maturation, and activation of eosinophils, acting predominantly at the later stages of eosinophil maturation and activation, and can also prolong the survival of eosinophils. IL-5 causes eosinophils to be released from the bone marrow, while the local release of an eosinophil chemoattractant such as eotaxin may be necessary for the tissue localization of eosinophils [26]. Mature eosinophils may show increased survival in bronchial tissue, secondary to the effects of GM-CSF, IL-3, and

IL-5 [27]. Eosinophils themselves may also generate other cytokines such as IL-3, IL-5, and GM-CSF [11].

Cytokines such as IL-4 may also exert an important regulatory effect on the expression of adhesion molecules such as VCAM-1, both on endothelial cells of bronchial blood vessels and on airway epithelial cells. IL-1 and TNF-$\alpha$ increase the expression of intercellular adhesion molecule 1 (ICAM-1) in both vascular endothelium and airway epithelium [28]. An anti-IL5 monoclonal antibody administered to mild allergic asthmatics has been shown to suppress allergen-induced blood and sputum eosinophilia, without affecting the degree of the late-phase response [29], indicating that IL-5 may not be the only cytokine involved in allergen-induced late-phase responses. Eotaxin is a chemoattractant cytokine (chemokine) selective for eosinophils and acts through the chemokine receptor CCR3 present on eosinophils, basophils, and T-cells. Cooperation between IL-5 and eotaxin appears necessary for the mobilization of eosinophils from the bone marrow during allergic reactions and for the local release of chemokines to induce homing and migration into tissues.

## Th17 cytokines: IL-17 family

A separate lineage of effector T-helper cells termed Th-17 cells produced by the action of IL-15 or IL-23 on CD4 or CD8$^+$ memory T-cells has been described. Several members of the IL-17 family have been described, with the founder member, IL-17 or IL-17A, originally reported from CD4$^+$ memory T-cells. Together with IL-17F, these two members are the most studied and have overlapping functions particularly mediating neutrophil mobilization through activation of T-cells (Th17). IL-17A activates neutrophils to cause release of neutrophil elastase and myeloperoxidase activity and regulate the recruitment of neutrophils in response to allergen, while attenuating allergen-induced increase in IL-5 and eosinophils [30]. IL-17A may be necessary for the proliferation of CD4$^+$ T-cells for the production of IL4 and IL5 and for bronchial hyperresponsiveness [31]. IL-17A induces the release of CXCL1/GRO$\alpha$, CXCL8/IL-8 and G-CSF, and GM-CSF from the airway epithelium, which may be a mechanism for neutrophilic chemotaxis and activation, as is found in patients with severe asthma. IL-17A induces the expression of the mucins, MUC-5AC and MUC-5B, in bronchial epithelial cells. An increase in the expression of IL-17A in eosinophils has been shown in patients with asthma [32].

Unlike IL-17A and IL-17F, IL-17E, also known as IL-25, is a Th2-like cytokine produced by Th2 cells and mast cells. IL-17E induces overproduction of Th2 cytokines, IL-4 and IL-13, production of IgA and IgE, mucus, epithelial cell hyperplasia, and eosinophilia. IL-17E$^+$ cells, probably eosinophils, were detected in the bronchial submucosa of patients with asthma [33].

## Airway wall remodeling cytokines

Experimental approaches made possible by genetically modified mice have highlighted the potential role of various T-cell-derived cytokines in aspects of airway wall remodeling.

Overexpression of these cytokines in the airway epithelium causes various features of airway wall remodeling. A CC10-driven overexpression of IL-13 in the lungs caused eosinophilic and mononuclear inflammation with goblet cell hyperplasia, subepithelial fibrosis, airway obstruction, and airway hyperresponsiveness [34]. IL-4, IL-5, and IL-9 overexpression lead to substantial mucus metaplasia, while IL-9 and IL-5 overexpression also caused subepithelial fibrosis and airways hyperresponsiveness [35–37]. ASM hyperplasia occurs following IL-11 overexpression [38]. IL-5 and IL-13 have been associated with the production of TGF-$\beta$ in asthma [39, 40].

Proliferation of myofibroblasts and the hyperplasia of ASM may also occur through the action of several growth factors, such as platelet-derived growth factor (PDGF) and TGF-$\beta$. They may be released from inflammatory cells in the airways, such as macrophages and eosinophils, but also by structural cells such as airway epithelium, endothelial cells, and fibroblasts. These growth factors may stimulate fibrogenesis by recruiting and activating fibroblasts or transforming myofibroblasts [41]. Epithelial cells may release growth factors, since collagen deposition occurs underneath the basement membrane of the airway epithelium [42].

Growth factors may also stimulate the proliferation and growth of ASM cells. PDGF, TGF-$\beta$, and epidermal growth factor (EGF) are potent stimulants of human ASM proliferation [43, 44]. Pro-angiogenic factors such as angiogenin, vascular endothelial growth factor (VEGF), and CCL2/MCP-1 may be involved in angiogenesis of chronic asthma [45]. There is greater expression of airway mucosal eosinophils expressing TGF-$\beta$ mRNA and protein, correlating with the severity of asthma and the degree of subepithelial fibrosis [46]. Increased expression of TGF-$\beta$ is also observed in epithelial cells and airway smooth cells of patients with asthma [47]. EGF expression is increased in bronchial epithelium, smooth muscle, and the bronchial submucosa of asthmatic patients [48, 49].

## Airway smooth muscle-associated cytokines

Airway smooth muscle (ASM) cells have the capacity to elaborate a range of cytokines, including IL-4, IL-5, GM-CSF, CXCL8/IL-8, CCL5/RANTES, CCL11/eotaxin, CCL2/MCP-1, and TGF-$\beta$ and therefore may play a role in the induction of local inflammatory and remodeling responses [50]. In addition, these cytokines may provide the mechanisms for interacting with cells within the ASM bundle of asthmatic patients, such as mast cells [51]. Thus, increased production of CXCL10/IP-10 from ASM cells of asthmatics could be the cause for enhanced chemotactic activity of lung mast cells toward ASM cells in asthma [52].

## INFLAMMATION AND CYTOKINES IN COPD

## Cytokine profile in COPD

The characteristic pathology of stable COPD includes chronic inflammation of the small bronchi and bronchioles less than

2 mm diameter, together with structural changes to all the airways and lungs with alveolar wall destruction or emphysema. The inflammation is characterized by an accumulation of neutrophils, macrophages, B-cells, lymphoid aggregates, and CD8$^+$ T-cells particularly in the small airways and is proportionate to the severity of disease [53]. Chronic bronchitis characterized by glandular hypertrophy and hyperplasia with dilated ducts of 2–4 mm internal diameter may be present with mucus plugging, goblet cell hyperplasia, increased ASM mass, and distortion due to fibrosis of bronchioles. Neutrophils are localized particularly to the bronchial epithelium, the bronchial glands [54], and also in close apposition to ASM bundles [55]. Some patients with COPD have a preponderance of eosinophils in sputum, which has been associated with improvement of FEV$_1$ with corticosteroid therapy [56]. CD8+ T-cells expressing IFN-$\gamma$ and CXCR3, probably of the type 1 cytotoxic (Tc1) T-cells [57], are increased throughout the airways and in lung parenchyma [58].

In COPD the basic abnormality is thought to be the response of airway cells, particularly epithelial cells and macrophages to toxic gases and particulates in cigarette smoke, which generate an inflammatory and immune response with the release of proinflammatory cytokines, chemokines, growth factors, cathepsins, and serine and matrix metalloproteinase

(MMP) proteases. In COPD, as contrasted to healthy smokers also exposed to cigarette smoke, the release of cytokines may be amplified by the effect of oxidative stress, perhaps viruses and by unknown genetic factors (Fig. 27.2).

Cytokines in COPD may be classified as (i) proinflammatory cytokines including chemokines involved in the recruitment of neutrophils, macrophages, T-cells, and B-cells (ii) cytokines of airway wall remodeling, including goblet cell, ASM hyperplasia (iii) cyokines of emphysema (iv) systemic cytokines, that is extrapulmonary source of cytokines involved in systemic inflammatory responses.

## Proinflammatory cytokines and chemokines

Increased levels of IL-6, IL-1$\beta$, TNF-$\alpha$, CXCL8/IL-8, and CCL2/MCP-1 have been observed in induced sputum of patients with stable COPD [59, 60]. Increased release of proinflammatory cytokines CXCL8/IL-8, CCL1/GRO$\alpha$, CXCL5/ENA-78, IL-1, TNF-$\alpha$ and of the anti-inflammatory cytokine, IL-10 from alveolar macrophages of cigarette smokers and of COPD patients have been reported [61, 62]. Levels of TNF-$\alpha$, IL-1$\beta$, IL-6, CXCL8/IL-8, and

**FIG. 27.2** Interaction of cells and cytokines in airway inflammation of COPD. The initiating factors include cigarette smoke with macrophages and airway epithelium, inducing the release of chemotactic factors for neutrophils, which in turn are important effector cells for inflammation, tissue damage, and repair. Potential amplification factors include viruses, oxidative stress, and genetic factors. EGF = epidermal growth factor; IL = interleukin; IP-10 = IFN-$\gamma$-induced protein 10; LTB$_4$ = leukotriene B4; MCP = monocyte chemotactic protein; MMP = matrix metalloproteinase; TGF = transforming growth factor; TIMP = tissue inhibitor of matrix metalloproteinase; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor. Black arrows indicate interactions with inflammatory cells leading to release of cytokines and mediators; red arrows indicate interactions of bacteria with macrophages and epithelial cells that could amplify the inflammatory process.

CCL2/MCP-1 were increased in BAL fluid of chronic smokers compared to non-smokers [63], and of CXCL8/IL-8 and GM-CSF levels in COPD patients [64, 65]. In general, the expression of cytokines from COPD patients is higher than of asymptomatic smokers. Sputum neutrophil counts and level of CXCL8/IL-8 and circulating levels of TNF-α and C-reactive protein (CRP) have been reported to be the best markers for distinguishing the various levels of severity of COPD [66].

Cigarette smoke increases CXCL8/IL-8 gene expression and release by bronchial epithelial cells, and TNF-α and IL-6 by alveolar macrophages [67, 68], through oxidant mechanisms that include activation of the transcription factor, nuclear factor-κB (NF-κB) [69]. Exposure of lung epithelial cells to smoke extract causes the release of neutrophil and monocytic chemotactic activities with CXCL8/IL-8 and G-CSF accounting for the neutrophilic activity and CCL-2/MCP-1 for the monocytic activity [70].

A higher expression of CCL2/MCP-1, TGF-β1 and CXCL8/IL-8 mRNA and protein has been observed in bronchiolar epithelium in macrophages of smokers with COPD compared with those smokers without COPD [71]; a similar difference has been found for CCR2. Since CCL2/MCP-1 binds to CCR2 and can induce T-cell and monocytic migration, CCL2 [72] may contribute to the recruitment of these cells in COPD.

Different chemokines in induced sputum from COPD patients have been found to be involved in the chemotaxis of monocytes. Thus, there is increased chemotaxis of monocytes in COPD for CCL1/GROα or CXCL7/NAP2 but not for CXCL8/IL-8 or CXCL5/ENA-78, possibly due to differential regulation of CXCR2 receptors in COPD [73]. CD8 T-cells expressing IFN-γ infiltrate the peripheral airways of smokers with COPD and have an increased expression of the chemokine receptor, CXCR3, which is paralleled by a strong epithelial expression of its ligand, CXCL10/IP-10 [57], a chemoattractant for Th1 cells. The chemokine ligand 20, CCL20, is the most potent known chemoattractant for dendritic cells and is upregulated in lung and in induced sputum of patients with COPD [74]. This could account for increased number of dendritic cells observed in the small airways of COPD as these cells express CCR6 which is the receptor for CCL20. Microarray analysis of lung tissues from COPD patients revealed the expression of CX3CL1/fractalkine [75].

## Th2 cytokines

Expression of Th2 cytokines is less prominent in COPD as compared to asthma. IL-5 expression is absent in COPD airways associated with eosinophilia, but other eosinophil chemoattractants such as eotaxin or RANTES may be implicated, particularly during exacerbations [76]. Increased IL-4+ cells in mucus secreting cells and associated plasma cells of the airway mucosa of chronic bronchitis patients have been reported [77].

Overexpression of the Th2 cytokine, IL-13, in lungs of adult mice induces emphysema, mucus goblet cell hyperplasia, and airway inflammation with macrophages, lymphocytes, and eosinophils, and increased MMPs, which are many of the features associated with COPD [78]. The induction of

emphysema in these mice was related to the release of metallo- and cysteine-proteases [78]. Interestingly, the proinflammatory cytokine, IL-18, can induce lung inflammation and emphysema through the production of IL-13 but not through IFN-γ [79], despite IFN-γ's capability of inducing emphysema [80]. Although IL-18 expression appears to be increased in pulmonary macrophages of COPD patients, IL-13 expression is decreased in emphysema lung [81]. IL-9-mRNA is overexpressed in CD3+ T-cells in patients with COPD [82].

## Systemic cytokines

Evidence of systemic inflammatory processes in COPD can be judged from increased circulating levels of cytokines such as IL-6, CXCL8/IL-8, TNF-α, and TNF receptors 55 and 75, together with CRP levels [83]. The source of these circulating cytokines may represent a spill-over from pulmonary sources but may also originate from other sources such as circulating blood monocytes [84], striated muscle or from concomitant atherosclerotic lesions. In stable COPD patients with respiratory muscle impairment, increased TNF-α and IL-6 gene and protein expression in muscle has been reported [85].

## Exacerbations of COPD

Increases in plasma levels of IL-6, CXCL8/IL-8, and LTB4 but not of TNF-α have been reported during COPD exacerbations severe enough to require the patient to be hospitalized [86]. During exacerbations of COPD associated with neutrophilia requiring mechanical ventilatory support, gene expression for CXCL5/ENA78, CXCL8/IL-8, and the receptor CXCR2 is increased in tissue, particularly in the bronchiolar epithelium [87]. Both CXCL5/ENA-78 and CXCL8/IL-8 bind to CXCR2 and are neutrophil chemoattractants.

In acute exacerbations of COPD, eosinophils may be prominent among the cells recovered in sputum or in bronchial biopsies, but there is no increased expression of IL-5 protein in tissues [88]. Higher levels of IL-6 and CXCL8/IL-8 in induced sputum of patients with recurrent exacerbations of COPD (>3 per year) have been reported [89]. In patients with stable COPD, lymphomononuclear cells expressing eotaxin mRNA was increased compared to healthy non-smokers. In patients with an exacerbation of chronic bronchitis, RANTES mRNA expression was upregulated and strongly expressed on the surface epithelium and subepithelial lympho-mononuclear cells, together with increased number of eosinophils [76]. CCL11/eotaxin and its receptor, CCR3, are upregulated during exacerbations of chronic bronchitis, with CCR3 colocalized mainly to eosinophils [90]. The increased expression of CCL11/eotaxin and CCL5/RANTES may underlie the eosinophilia sometimes observed during exacerbations of COPD.

## Properties of some specific cytokines in COPD

### TNF-α

TNF-α is produced by many cells including macrophages, T-cells, mast cells, and epithelial cells, but the principal

source is the macrophage. The secretion of TNF-α by monocytes/macrophages is greatly enhanced by other cytokines such as IL-1, GM-CSF, and IFN-γ. TNF-α activates NFκB that switches on the transcription of the CXCL8/IL-8 gene and increases CXCL8/IL-8 release from the airway epithelium and neutrophils. Bacteria and bacterial products such as lipopolysaccharide can induce CXCL8/IL-8 expression, probably as a result of initial TNF-α production [91, 92]. TNF-α may be important in inducing the expression of CXCL2/MIP-2 and CCL2/MCP-1, and in connective tissue breakdown following cigarette smoke exposure [93]. TNF-α through the activation of EGF receptor leads to the expression of mucin genes, in particular MUC5AC [94].

TNF-α increases the expression of ICAM-1, which is increased in serum of COPD patients [95]. TNF-α may activate macrophages to produce MMPs. This effect is inhibited by the anti-inflammatory cytokine, IL-10, which also enhances the release of tissue inhibitor of metalloproteinases (TIMP) in macrophages from normal volunteers. In smokers IL-10 increases TIMP-1 release, without modifying MMP-9 release, from alveolar macrophages [61]. TNF-α also stimulates bronchial epithelial cells to produce tenascin, an extracellular matrix glycoprotein that may contribute to airway remodeling. In animal models, MMP-12 induces the release of TNF-α from lung macrophages exposed to cigarette smoke, causing endothelial activation and neutrophil influx [96].

Increased serum concentrations of TNF-α have been measured in patients with COPD with weight loss [97, 98], and increased TNF-α production has been noted by peripheral blood monocytes from COPD patients during the catabolic phase of their illness leading to weight loss [99]. TNF-α has direct effects on skeletal muscle cells and reduces adult myosin heavy chain content and induces apoptosis of skeletal muscle via several signaling pathways [100, 101]. Given the potential role for TNF-α in the inflammation of COPD, the effect of TNF-α blockers in this disease is of therapeutic interest. However, a multicenter randomized trial of an anti-TNF-α antibody, infliximab, found no treatment benefit in terms of quality of life, lung function, and the 6-min walking test [102].

## IL-1β

IL-1β induces leukocytosis by the release of neutrophils from the bone marrow and induces the release of many other cytokines such as IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, CXCL8/IL-8, CCL5/RANTES, GM-CSF, IFN-γ, TNF, and PDGF from a variety of cells. It induces fibroblasts to proliferate, and increases prostaglandin secretion, and the synthesis of fibronectin and collagen. Together with TNF-α, IL-1β induces ICAM-1 expression on endothelial cells. IL-1β can induce attenuation of β-adrenergic receptor-induced airway relaxation through reduction of β-adrenoreceptors, an increase in the G-protein, Giα subunit, and a defect in adenylate cyclase activity [103].

## CXCL8/IL-8

CXCL8/IL-8 is a neutrophil chemoattractant and activator that induces a transient shape change, rise in intracellular calcium, exocytosis with release of enzymes and proteins from intracellular storage organelles, and respiratory burst. It also upregulates the expression of two integrins (CD11b/CD18 and CD11c/CD18) during exocytosis of specific granules. CXCL8/IL-8 activates neutrophil 5-lipoxygenase with the formation of LTB$_4$ and 5-hydroxy-eicosanotetraenoic acid (5-HETE) and together with LTB$_4$ contributes to the neutrophil chemotactic activity of sputum from COPD patients [104, 105]. CXCL8/IL-8 also has chemoattractant properties for T-cells. Bacteria for example due to a soluble cytoplasmic factor of nontypeable Haemophilus Influenzae can induce CXCL8/IL-8 expression in epithelial cells [106]. The increased levels of CXCL8/IL-8 found in sputum samples of COPD patients correlate with airway bacterial load and with myeloperoxidase released from activated neutrophils. Elastase released from neutrophils may also stimulate epithelial cells to produce more CXCL8/IL-8 [107]. A study of a blocking anti-IL-8 antibody in moderate COPD patients showed a small effect in improving dyspnea [108].

## TGF-β

TGF-β is a multifunctional growth factor with biological effects on fibroblast proliferation, deposition of extracellular matrix, epithelial repair, chemotactic activities, and also as an immune suppressor. TGF-β is secreted as latent TGF-β that is sequestered by many binding proteins including decorin, biglycan, fibronectin, and elastin. TGF-β can be activated *in vivo* by mechanisms including thrombospondin, acid pH, reactive oxygen species, and nitric oxide nitrosylation. TGF-β regulates epithelial repair by inhibiting proliferation but increasing epithelial cell migration [109]. TGF-β1 is involved in the transformation of fibroblasts to myofibroblasts, and enhancing myofibroblast survival. In addition, TGF-β1 and TGF-β2 can convert myofibroblasts into smooth muscle cells [110]. TGF-β induces hypertrophy and hyperplasia of ASM cells [47, 111]. TGF-β induces collagen production in human lung fibroblasts [112] and ASM cells [113]. Therefore, TGF-β is involved in remodeling of the airway wall in both asthma and COPD.

Increased expression of a number of related growth factors, CTGF, TGF-β1, and PDGFRA in the lungs using gene microarray analysis of lungs from smoking COPD patients compared to healthy smokers has been reported [75]. Expression of TGF-β in the bronchiolar and alveolar epithelium and submucosal cells of patients with COPD has been reported [114–116]. In addition, increased release of TGF-β and of fibronectin from alveolar macrophages from patients with chronic bronchitis has been observed [117].

## VEGF

Increased levels of VEGF have been observed in sputum of patients with COPD [118], and its augmented expression appears to be localized to pulmonary arteries [119]. Inhibition of VEGF receptor activation in mice led to the induction of enlargement of air spaces, and induced alveolar septal cell apoptosis, indicating that VEGF receptor signaling is required for maintenance of alveolar structures [120]. Oxidative stress and apoptosis may be the down-stream effects of VEGF receptor activation [121]. The finding that VEGF levels are increased in patients with COPD reinforces a potential non-proteolytic mechanism for emphysema through VEGF.

## CONCLUSION

Because there has been little direct comparison of tissues between asthma and COPD patients, it is not possible to state categorically the degree of overlap of cytokine profiles or networks that exist between the two diseases. However, analysis of cytokine expression in asthma and COPD from the published literature reveals many similarities in terms of increased expression of many cytokines (Table 27.3)

**TABLE 27.3** Expression of cytokines in asthma and COPD[a].

|  | Asthma | COPD |
| --- | --- | --- |
| IL-3 | + | ? |
| IL-4 | + + | + |
| IL-5 | + + | – |
| IL-9 | + | + |
| IL-10 | + or – | + |
| IL-13 | + | + |
| IL-17A | + | ? |
| IL-25 (IL-17E) | + | ? |
| IFNγ | – | + |
| CCL2/MCP-1 | + | + |
| CCL5/RANTES | + | +* |
| CCL11/Eotaxin | + | +* |
| CCL17/TARC | + | ? |
| CCL20 | ? | + |
| CCL22/MDC | + | ? |
| CXCL1/GROα | ? | + |
| CXCL8/IL-8 | + | + + |
| CXCL10/IP10 | + | + |
| IL-1β | + | + |
| TNF-α | + | + |
| TGF-β1 | + | + |
| CTGF | ? | + |
| GM-CSF | + | + |
| EGF | + | + |
| VEGF | + | + |

[a]From review of literature: expression is reported as gene or protein in airway cells or tissues, in addition to measurement of protein release in airway fluids. The degree of expression has been arbitrarily assessed as: – = reduced; + or + + = increased; ? = not known or uncertain; * = associated with exacerbations.

that may reflect similarities in established disease but not necessarily during the initial phase of these diseases. For example, severe asthma may resemble more closely COPD with a neutrophilic inflammatory response, and remodeling aspects of the airways may be similar despite being differently localized in the airways in terms of the cytokines and growth factors involved. Further analysis of cytokine expression in asthma and COPD may help determine whether these conditions have common mechanisms or similar predisposing factors. Analysis of cytokine expression may help determine which ones may be useful to target for therapeutic effects, although the limited experience so far has been disappointing.

# Matrix Degrading Proteinases in COPD and Asthma

**Steven D. Shapiro**

**Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA**

## INTRODUCTION

In chronic obstructive pulmonary disease (COPD), we now appreciate that cigarette smoke sets into motion a complex inflammatory network leading to inflammation, destruction, and when coupled with abnormal repair results in COPD. Elastolytic proteinases are well established in the destructive phase. Recent studies have focused on the roles of proteinases in control of inflammation and repair. With respect to asthma, proteinases are prominently expressed on many airway cells and also appear be involved in controlling inflammation as well as participating in other aspects of remodeling such as subepithelial fibrosis, mucus metaplasia, and smooth muscle hypertophy. This discussion will be limited to host proteinases with potential extracellular matrix degrading capacity, excluding intracellular cysteine proteinases, such as caspases, that regulate cell death, and non-host serine proteinases of dust mites and other allergens that may also play a role in asthma.

## PROTEINASES

### Serine proteinases

Serine proteinases have diverged evolutionarily from a single gene product; as a result of duplications and mutations, enzymes with diverse biological functions including digestive enzymes of exocrine glands, clotting factors, and leukocyte granule associated proteinases some of which degrade extracellular matrix proteins and are of relevance to emphysema have

been derived (Table 28.1). Host serine proteinases associated with COPD and asthma largely belong to the SA clan, S1(trypsin/chymotrypsin) family. S1 serine proteinases are characterized by conserved His, Asp, and Ser residues that form a charge-relay system that functions by transfer of electrons from the carboxyl group of Asp to the oxygen of Ser which then becomes a powerful nucleophile able to attack the carbonyl carbon atom of the peptide bond of the substrate. These enzymes are synthesized as pre-proenzymes in the endoplasmic reticulum and processed by cleavage of the signal peptide (pre-) and removal of a dipeptide (pro-) by cathepsin C, and stored in granules as active packaged proteins. Distinct subsets of serine proteinases are expressed in a lineage-restricted manner in immune and inflammatory cells. Serine proteinases are also expressed in a developmentally specific manner. For example, neutrophil elastase (NE), proteinase 3, and cathepsin G are major components of primary or azurophil granules that are formed during a very specific stage during the development of myeloid cells.

*Neutrophil elastase (NE), cathepsin G,* and *proteinase 3* are ~30 kDa glycoprotein containing ~20% neutral sugars. NE is a more potent elastase than the other serine proteinases and has received the most attention in COPD. NE's tertiary structure is similar to other chymotrypsin-like serine proteinases with two interacting antiparallel β-barrel cylindrical domains that form a crevice encompassing the catalytic triad [1]. NE prefers substrates with Val > Ala > Ser, Cys at the P1 position. NE has activity against a broad range of extracellular matrix proteins including the highly resistant elastin. NE expression is localized to primary or azurophil granules of neutrophils and a subset of proinflammatory monocytes (Fig. 28.1) [2].
**FIG. 28.1** Interactions between neutrophil and macrophage proteinases in emphysema. Neutrophil elastase (NE) originating from azurophil granules directly degrades elastin and indirectly augments elastolysis via degradation of TIMP(s). Macrophage MMP-12 also directly degrades elastin and also indirectly augments NE activity by degrading its inhibitor $\alpha$1-AT. Extracellular matrix (ECM) fragments released during proteolysis play a role in perpetuating inflammatory cell recruitment.

Studies from several laboratories have shown that NE is responsible for most of the degradative activity of neutrophils toward extracellular matrix structures. However, when optimally primed and stimulated by biologically relevant agonists, neutrophils release less than 2% of their content of NE freely into the extracellular space, and that they are able to translocate as much as 12% of their total NE to the cell membrane, where it is catalytically active and resistant to inhibitors [3]. The high concentration of NE ($\sim$5 mM) within azurophil granules transiently overwhelm local NE inhibitors, resulting in a quantum burst of obligate catalytic activity near the cell surface when each granule is released [4]. These mechanisms allow NE to proteolyze extracellular matrix (ECM) in a focused and protected manner while limiting widespread tissue destruction. NE might also be freely released during "frustrated phagocytosis," or by necrotic or apoptotic neutrophils if the latter are not cleared efficiently by macrophages. Regardless of the mechanisms by which active NE reaches ECM, it is relatively protected from inhibitors following binding to insoluble macromolecules, and NE is intimately associated with elastic fibers in emphysematous tissue [5]. During bacterial exacerbations of COPD, overwhelming (micromolar) concentrations of active NE can be found as a result of brisk neutrophil influx, and active NE can often be found within the airways of patients with alpha-1-antitrypsin ($\alpha_1$-AT) deficiency. NE is also a potent secretagogue and induces mucin gene expression [6], which might aggravate airflow obstruction in COPD. Neutrophil influx and NE is also believed to be important in severe, steroid-resistant asthma.

NE deficient mice have demonstrated a role for NE in killing gram-negative bacteria [7]. NE-mediated bacterial killing is related to proteolytic degradation of Omp proteins on the outer wall of gram-negative bacteria [8]. Application of NE$^{-/-}$ mice to cigarette smoke also demonstrates a role for NE in the development of emphysema as discussed below [9].

## Serine proteinase inhibitors

Serine proteinase inhibitors are abundant in the plasma. *Alpha-2 macroglobulin*, a large protein usually restricted to the bloodstream because of its mass, 725,000 kDa, inhibits proteinases of several classes by "entrapping" proteinases following cleavage of susceptible regions of the molecule. At a concentration of 150–350 mg/dl, $\alpha_1$-AT has the highest concentration of the plasma inhibitors. $\alpha_1$-AT belongs to a family of serine proteinase inhibitors called the *serpins*. Serpins have considerable sequence homology, particularly around their reactive sites. They are important for homeostasis, since they exert some control over such major proteolytic cascades as the complement system and coagulation. $\alpha_1$-AT is a 52 kDa glycoprotein synthesized primarily by the liver, consisting of a single polypeptide chain of 394 amino acids. Proteolytic inhibition by $\alpha_1$-AT involves cleavage of the "strained" reactive open center of $\alpha_1$-AT between Met$^{358}$ and Ser$^{359}$, resulting in an altered, "relaxed" $\alpha_1$-AT conformation in complex with the proteinase. Formation of the complex renders the proteinase inactive and, because the complex is quite stable, inactivation is essentially permanent. The association and inhibition of NE by $\alpha_1$-AT is much faster than with other serine proteinases including trypsin, yet the name "$\alpha_1$-antitrypsin" is retained for historical respect. $\alpha_1$-AT is the major inhibitor of serine proteinases in the lower airspace. As discussed below, inherited deficiency of $\alpha_1$-AT represents the only genetic abnormality to date associated with COPD.

Additional low molecular weight serine proteinase inhibitors are abundant in airway fluid and hence thought to represent the primary defense against proteinase-mediated airway damage. *Secretory leukoprotease inhibitor (SLPI)* is a 12 kDa protein produced by mucus-secreting and epithelial cells in the airway as well as type 2 pneumocytes [10]. SLPI inhibits NE and cathepsin G and many other serine proteinases, but not proteinase 3. *Elafin*, also produced by airway secretory and epithelial cells is released as a 12 kDa precursor which is processed to a 6 kDa form that specifically inhibits NE and proteinase 3 [11]. These inhibitors are able to inhibit NE bound to substrate giving them an added dimension that $\alpha_1$-AT lacks. An additional serpin, serpin B1 or monocyte/neutrophil elastase inhibitor, also has considerable activity against NE [12]. Airway mucus contains several other substances that partially inhibit NE including polyanionic molecules such as mucins, other glycosaminoglycans, and fatty acids. DNA, released from inflammatory leukocytes, binds to SLPI greatly enhancing its rate of association with NE. The relative contribution of each of these molecules to proteinase inhibition is unknown.

## Matrix metalloproteinases

Matrix metalloproteinases (MMPs) [13] comprise a family of 23 human matrix degrading enzymes believed to be essential for development and physiologic tissue remodeling and repair (Table 28.1). Abnormal expression of MMPs has been implicated in many destructive processes, including tumor cell invasion and angiogenesis, arthritis, atherosclerosis, arterial aneurysms, and pulmonary emphysema [14]. MMPs are secreted as inactive proenzymes that are activated

at the cell membrane surface or within the extracellular space by proteolytic cleavage of the N-terminal domain. Catalytic activity is dependent upon binding of a zinc ion at the active site and is specifically inhibited by members of another gene family, called tissue inhibitor of metalloproteinases (TIMPs) for tissue inhibitors of MMPs. Currently, four TIMPs have been described. Optimal activity of MMPs is around pH 7.4. MMP family members share 40–50% identity at the amino acid level, and they possess common structural domains. Domains include a proenzyme domain that maintains the enzyme in its latent form, an active domain that coordinates binding of the catalytic zinc molecule, and (except for MMP-7) a C-terminal domain involved in substrate, cell and TIMP binding. The gelatinases A and B (MMP-2 and MMP-9, respectively) have an additional fibronectin-like domain which mediates their high binding affinity to gelatins and elastin. MMP-9 has one more domain with homology to type V collagen. Membrane-type MMPs (MT1-6-MMP or MMP-14 to -19) have an additional C-terminal membrane-spanning domain.

Individual members of the MMP family can be loosely divided into groups based on their matrix degrading capacity. As a whole, they are able to cleave all extracellular matrix components. Those MMPs implicated in COPD and asthma include the *collagenases* (MMPs − -1, -8, -13) that have the unique capacity to cleave native triple helical interstitial collagens but not elastin. MMP-1 is prominently expressed in epithelial cells in patients with asthma and COPD [15]. However, mice do not have MMP-1 but only MMP-8 and -13. Gene targeting of MMP-8 has shown that this neutrophil-derived proteinase is involved in turning off neutrophil recruitment, likely via degradation of neutrophil chemokines [16]. MMP-13$^{-/-}$ mice have developmental bone defects [17].

*Gelatinases of 72 kDa (gelatinase A, MMP-2) and 92 kDa (gelatinase B, MMP-9)* differ in their cellular origin and regulation, but share the capacity to degrade gelatins (denatured collagens), type IV collagen, elastin, and other matrix proteins. The gelatinases are by far the most thoroughly studied members of the MMP family and MMP-9 clearly the most thoroughly investigated in COPD and asthma. Research focus to gelatinases is in part due to their importance in biology, but also reflects the ease of detecting them by the exquisitely sensitive technique of gelatin zymography in which the active moiety is detected by virtue of its cleavage of an artificial substrate.

In both COPD [18] and asthma [19, 20] many studies have found increased expression of MMP-9, often in association with decrease in its inhibitor TIMP-1, in sputum, bronchoalveolar lavage (BAL), lung tissue, and cells obtained from asthmatic patients. For example, airway epithelial cells produce MMP-9 upon injury and proportional to the severity of asthma [21]. Inflammatory and immune cells are a rich source of MMP-9 particularly eosinophils, neutrophils, macrophages [22,23], *and DCs* [24,25].

MMP-9$^{-/-}$ mice are protected from airway subepithelial fibrosis in models of asthma [26]. Yet, they have no role in cigarette smoke-induced airspace enlargement (Shapiro unpublished). Other phenotypes of MMP-9$^{-/-}$ mice include abnormal long bone development (through failed activation of vascular endothelial growth factor, VEGF) [27], and

many interesting vascular phenotypes, such as a requirement for MMP-9, for abdominal aortic aneurysms [28].

*Macrophage elastase (MMP-12)* is characterized by macrophage-specific expression and broad potent matrix degrading capacity for an MMP [29]. MMP-12, like many MMPs also has important non-matrix substrates. MMP-12 is required for TNF-α shedding following smoke exposure [30], and MMP-12 to a greater degree than other MMPs degrades and inactivates α$_1$-AT [29], thus indirectly enhancing the activity of NE.

MMP-12 is predominantly a macrophage product and it has been found in macrophages in association with cigarette smoke exposure and COPD. In fact, it was the most highly upregulated gene by expression profiling in macrophages obtained from both murine and human smokers [31]. MMP-12 has also been found in asthmatic lungs, and has even been detected in airway epithelial cells [32] and smooth muscle cells as well [33].

Macrophages of MMP-12$^{-/-}$ mice have a markedly diminished capacity to degrade extracellular matrix components and are essentially unable to penetrate reconstituted basement membranes both *in vitro* and *in vivo* [34]. As discussed below unlike wild-type (WT) mice, MMP-12-deficient mice were protected from macrophage accumulation and the development of emphysema despite heavy long-term smoke exposure [35]. MMP-12 appears to be important in inflammatory cell recruitment in several murine models of asthma described below as well (Fig. 28.2).

*Membrane-type metalloproteinases (MT-MMPs)* represent six MMPs that are localized at the cell surface and at least one MT-MMP, MT1-MMP, activates MMP-2. MT-MMPs also appear to directly degrade ECM proteins, but their catalytic capacities is not well defined at present. MT1-MMP is among the MMPs associated with COPD [36].

*ADAMs (a disintegrin and metalloprotease domain)* represents a family of related metalloproteases that are bound to the cell surface. ADAM-33 was described as an asthma gene in humans following an extensive genetic linkage analysis [37]. Subsequently, ADAM-33 has been replicated in some but not all asthma populations, as well as in COPD. The role of ADAM-33 is not clear, in fact it does not appear to be catalytically active due to splicing. Expressed by fibroblasts and smooth muscle cells, it might be involved in airway remodeling and hyperresponsiveness [38].

## Tissue inhibitors of metalloproteinases

*Tissue inhibitors of metalloproteinases (TIMPS)* comprise a family of four with molecular masses ranging between 21 (TIMP-2, nonglycosylated) and 27.5 (TIMP-1, glycosylated). Each TIMP inhibits MMPs via tight, non-covalent binding with 1:1 stoichiometry. TIMP-1 binds to the C-terminal domain of MMPs, but how this leads to inhibition of catalysis is unknown. Those MMPs that lack the C-terminal domain, including MMP-7 and fully processed form of MMP-12 are still susceptible to TIMP inhibition although with a lower Ki. TIMP-2 is secreted complexed to MMP-2 in fibroblasts. TIMP-2, not only inhibits MMP-2, but also is involved in docking pro-MMP-2 to the cell surface where the enzyme is activated by MT1-MMP.
**FIG. 28.2** Potential functions of proteinases in asthma. Tryptase mediates bronchoconstriction and fibroblast proliferation, most likely via proteolytic activation of protease activated receptor-2. MMPs have been linked to both fibroblast proliferation (MMP-2) and collagenolysis (MMP-1). MMP-9 might promote eosinophil transvascular migration. MMPs and related ADAMs (a disintegrin and metalloproteinase domain) might regulate cell survival via shedding of surface molecules such as Fas, TNF/TNF receptor.

TIMPs are secreted from many cell types and are abundant in tissues. For example, alveolar macrophages secrete both a variety of metalloproteinases and TIMP-1 and TIMP-2. TIMP-3 is expressed predominantly by epithelial cells and binds to extracellular matrix and thus may be important in preventing emphysema and in allowing excess matrix accumulation in asthmatic airways. Expression of MMPs and TIMPs may depend on the inflammatory stimulus, MMPs, and TIMPs may be coordinately regulated, perhaps to limit tissue injury during normal remodeling associated with inflammation, or regulation may be discoordinate, potentially leading to tissue injury.

## Cysteine proteinases

Cysteine proteinases utilize the sulfhydryl group of Cys as a nucleophile. Similar to serine proteinases a proton donor from His form a catalytic dyad (and in some cases triads) required for endopeptidase activity (Table 28.1). Cysteine proteinase represent a large, diverse group of plant and animal enzymes with amino acid homology at the active site only [39]. Human alveolar macrophages produce the lysosomal thiol proteinases, cathepsins B, H, L, and S that have been implicated in COPD [40]. CD4$^+$ cells express cathepsin S which functions in antigen processing [41] and thus might prove to play a role in asthma . These enzymes share similar sizes of 24–32 kDa and high mannose side chains (typical of proteins targeted for lysosomal accumulation). *Cathepsins B and H* have little endopeptidase activity and may function to activate other proteins similar to a distant relative; interleukin converting enzyme. *Cathepsin C* or dipeptidyl peptidase I has limited extracellular matrix degrading activity but is required for activation of nearly all matrix degrading serine proteinase proenzymes to their active form. *Cathepsins L and S* have large active pockets with relatively indiscriminate substrate specificities that include elastin and other matrix components. These enzymes have an acidic pH optima but cathepsin S retains ~25% of its elastolytic capacity at neutral pH (making it approximately equal to NE). *Cathepsin K* is a potent elastase predominantly expressed in osteoclasts but also by macrophages in the vasculature and perhaps other tissues. These enzymes clearly have the capacity to cause lung destruction if targeted to the cell surface or extracellular space particularly in acidic microenvironments.

The role of cysteine proteinases in COPD and asthma remains speculative. However, cathepsin S was shown to be involved in the emphysematous process associated with IFN-γ transgenic mice [42].

### Cysteine proteinase inhibitors

Cysteine proteinases are inhibited by *cystatins*. Some cystatins are strictly intracellular, while others, such as cystatin C, possess a signal peptide and are secreted by a variety of cells into the extracellular fluid. Cystatin C, comprised of a single nonglycosylated 120 amino acid peptide chain (13 kDa) forms reversible 1:1 complexes with enzymes in competition with substrates. Cystatin C, the most ubiquitous cystatin, is found in all human tissues and body fluids tested, providing general protection against tissue destruction by intracellular cathepsin enzymes leaking from dying cells. Lack of cystatin C has been associated with destructive lesions in the vasculature [43].

## COPD

*COPD* is currently defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as a disease state characterized by exposure to a noxious agent resulting in airflow limitation that is not fully reversible (http://www.goldcopd.com/) [44]. Airflow limitation may be secondary to airway obstruction or alveolar destruction with loss of elastic recoil. In fact, most patients have an admixture of large airway changes (accounting for symptoms of chronic bronchitis), small airway changes, and parenchymal lung involvement.

### Small airway disease

The small airways (diameter <2 mm) are the major sites of airway obstruction in COPD. Characteristic cellular changes leading to luminal narrowing include goblet cell

**TABLE 28.1** Main inflammatory cell matrix degrading proteinases in the lung.

| Cell (major source) | Proteinase | Class | Molecular mass*(kDa) | Matrix substrates | Other cells expressing proteinase |
|---|---|---|---|---|---|

*denotes (pre)proenzyme forms. basement membrane (bm) components include fibronectin, laminin, entactin, vitronectin, and type IV collagen (non-helical domains). #Pro, molecular mass of proenzyme form.

*Note:* parentheses denote minor cellular sources.

metaplasia with excess mucus production, smooth muscle hypertrophy, infiltrating mononuclear inflammatory cells, and submucosal fibrosis. Surrounding lung parenchymal elastin provides radial traction on bronchioles at points where alveolar septa attach. Hence, elastolysis may lead to loss of alveolar attachments with airway distortion and narrowing in COPD. Destruction of small airways may directly contribute to an increase in flow resistance through destruction of parallel conducting pathways.

The role of proteinases in small airways disease in COPD is less well appreciated than in the lung parenchyma. Proteinase expression has been well studied in asthma (see below) where there may be some common mechanisms of airway remodeling. One distinction is that neutrophil influx is a hallmark of COPD, while prominent only in severe asthma. Neutrophil influx in COPD is likely related directly to both cigarette smoke exposure and colonization by pathogens later in the disease process. In addition to its elastolytic activity, NE is a potent secretagogue. As in asthma, MMP-9 is expressed by several cell types in the airway might paradoxically lead to increased, rather than decreased, collagen accumulation in the airway. Similarly, despite collagenase-1 (MMP-1) expression by airway epithelial cells [15], collagen accumulates in the airways, highlighting the complexity of matrix turnover.

## Emphysema

Emphysema is characterized by abnormal, permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of their walls with coalescence into larger airspaces. The explanation for this pathology stems from the elastase:antielastase hypothesis, the

foundation of which was built upon two seminal observations made over 35 years, one experimental and the other clinical. First, in 1963 Gross instilled papain into the lungs of rodents which resulted in emphysema [45]. Subsequently, investigators have instilled a variety of proteinases into animal lungs, yet only elastases result in emphysema. Second, in 1964 Laurel and Eriksson described five patients with deficiency of $\alpha_1$-AT, the physiologic inhibitor of NE. Three of these initial subjects had emphysema [46].

Over time, there have been revisions to the elastase: antielastase hypothesis, but the basic concept has stood the test of time remarkably well [47]. A current rendition of the pathogenesis of emphysema includes the following steps. First, cigarette smoke causes inflammatory cell recruitment. Next, these inflammatory cells release matrix degrading proteinases that locally overwhelm or evade inhibitors, causing destruction of lung elastin and other extracellular matrix (ECM) proteins. In addition to loss of ECM, alveolar cells die by apoptosis. Whether this is a primary or secondary event remains a point of controversy. Finally, lung destruction coupled with failure to repair abnormal structures leads to airspace enlargement characteristic of emphysema.

## Inflammation and proteinases in human COPD

A major achievement in our understanding of emphysema has been our appreciation of the complex inflammatory milieu and the interrelationships between inflammatory/immune cells leading to lung destruction [48]. Macrophages patrol the lower airspace under normal conditions. Acutely following cigarette smoke exposure, macrophages may become activated

and neutrophils quickly arrive. Subacutely, macrophages accumulate in respiratory bronchioles. Chronically, macrophages, neutrophils, and $CD8^+ > CD4^+$ T-cells as well as B-cells accumulate in the lung. Moreover, loss of cilia predisposes to airway infection with a prominent neutrophilic response.

While cigarette smoke initiates the inflammation and destruction in emphysema, in severe disease inflammation is sustained by factors other than cigarette smoke. Indeed intense inflammation with many cell types was observed in lung tissue taken from patients with end-stage lung COPD undergoing volume reduction surgery, who had discontinued smoking on average 9 years earlier [49].

A more careful examination of inflammatory cell interrelationships demonstrates that proteinases are not only involved in lung destruction, but also in regulation of inflammation. Upon initial exposure to cigarette smoke, constitutive macrophages secrete MMP-12 which is responsible for "shedding" of active TNF-$\alpha$ from the cell surface and subsequent recruitment of neutrophils in response to cigarette smoke in mice [50]. In addition, cigarette smoke related oxidant activity, inactivates macrophage histone deacetylase-2 promoting transcription of MMPs and neutrophil chemokines including IL-8 [51]. Both MMP-12 and neutrophil NE contribute to lung destruction in murine models of cigarette smoke-induced emphysema with MMP-12$^{-/-}$ mice being fully protected and NE$^{-/-}$ mice being two-third protected from airspace enlargement [9]. These two proteolytic systems interact to achieve maximal lung damage. NE degrades TIMP-1 augmenting MMP activity [52] and MMPs degrade $\alpha_1$-AT, indirectly augmenting NE activity [53].

Elastin degradation products generated by these enzymes themselves appear to be a critical chemokine in further macrophage accumulation in COPD [54]. Hence, a positive feedback loop is established between elastolysis, macrophage accumulation, and neutrophil recruitment. Most recently, elastin fragments have also been implicated an auto-immune target in COPD [55]. Interest in B-cells in COPD has grown with the appreciation that the amount of BALT (bronchial associated lymphoid tissue) correlates with the severity of COPD [56]. BALT could simply be associated with airway remodeling and bacterial colonization. However, patients with COPD have been show to develop antibodies to elastin and this might be involved in disease progression [55]. Hence, these new wrinkles continue to strengthen the elastase:antielastase hypothesis demonstrating that not only elastin is critical to the structure and function of the lung, but by-products of its dissolution are both proinflammatory and may induce auto-immune disease.

Currently, focus has shifted to understanding the role of adaptive immunity in COPD, particularly the CD8$^+$ T-cell. CD8$^+$ T-cells, are known to be increased in lungs of patients with COPD [57]. Transgenic mice overexpressing IFN-$\gamma$ develop inflammation, apoptosis, and consequent emphysema [58]. Humans with COPD have increased amounts of IP-10 and its receptor CXCR3 [59]. Induction of IP-10 in CD8$^+$ T-cells and bronchiolar epithelium signals through CXCR3 expressed on alveolar macrophages to produce MMP-12 [60]. As discussed above, MMP-12 production leads to elastolysis and sets in motion a cycle of further

lung destruction. These concepts were confirmed in a mouse model where cigarette exposure to mice deficient in CD8$^+$ T-cells fails to produce IP-10, activate/recruit macrophages, produce MMP-12, or develop airspace enlargement [61].

## Emphysema associated with $\alpha_1$-AT deficiency

The clearest example of the association of proteinase–antiproteinase imbalance and emphysema occurs with inherited deficiency of $\alpha_1$-AT. Several abnormal $\alpha$1-AT alleles are associated with very low serum concentrations of $\alpha_1$-AT and enhanced risk for emphysema. Of these, the Pi Z variant is by far the most common, and greater than 95% of $\alpha_1$-AT deficient individuals have only the Z variant detectable. A variety of rare deficiency variants, including non-expressing alleles that do not result in detectable $\alpha_1$-AT in plasma, comprise the remaining individuals. Pi Z individuals have about 15% of the normal serum concentration of $\alpha_1$-AT. The abnormality leading to the Pi Z variant is a point mutation involving a single nucleotide at codon 342 that results in coding for Lys instead of Glx. This amino acid substitution changes the charge attraction between the amino acids at positions 342 and 290 present in the normal form of $\alpha_1$-AT and prevents the formation of a fold in the molecule. With this change in tertiary structure, the molecule is susceptible to loop sheet polymerization of $\alpha_1$-AT in the endoplasmic reticulum that impedes secretion of the protein from the hepatocyte [62]. In addition, its rate of association with NE is slightly but significantly slower than the association rate of normal $\alpha_1$-AT with NE. The prevalence of the Pi Z phenotype in the United States is about one in 2800 people [63]. The Z allele is not found in Asians and African populations at measurable frequencies.

Most Pi Z individuals eventually become symptomatic with COPD, but there is considerable variation and some individuals reach advanced age with minimal symptoms. Smoking has a marked effect on the age at which shortness of breath appears. On the average Pi Z smokers have symptoms by age 40, about 15 years earlier than Pi Z nonsmokers [63]. Additional genetic modifiers, such as polymorphisms in IL-10 [64], also help explain differences in the clinical course of patients with $\alpha_1$-AT deficiency.

## ASTHMA

Human asthma is characterized by persistent airway hyper-responsiveness (AHR) and episodic airflow obstruction. Asthma is also associated with an immune/inflammatory response characterized by activated T-cells with Th2 cytokines (IL-4, -5, -9, -13), eosinophils, and mast cells that infiltrate the mucosa and submucosa. The AHR may be a distinct trait, separate and preceding the inflammation. While several proteinases, particularly MMPs have been associated with asthma, their role in disease pathogenesis is still emerging. Proteinases might be particularly important in controlling inflammatory cell migration and airway remodeling.

## Initiation of asthma

The initiation of asthma is driven, in large part, by stimulation of allergen-specific CD4[+] T helper cells by professional antigen presenting cells (APCs), most notably lung dendritic cells (DCs). DCs play a prominent role in the pathogenesis of asthma because they are able to efficiently present major histocompatibility complex (MHC) class II-restricted antigenic determinants to naïve T-cells to direct CD4[+] T-cell polarization to promote a Th2-type immune response within the lung.

MMP-9 is expressed in DCs and has been shown to be promote DC trafficking [24] lending support for its potential importance in the initiation of asthma. Cathepsin S, a potent matrix degrading cysteine proteinase in its own right, has been shown to be required for normal MHC class II trafficking and function within DCs [65]. Pharmacological inhibition of cathepsin S attenuated lung eosinophilia and IgE generation in a mouse model of asthma [41].

## Asthma progression

Chronic asthma is characterized by airway remodeling, a term that incorporates chronic airway inflammation, marked smooth muscle hyperplasia (with mast cell infiltration), mucus gland and goblet cell hyperplasia, myofibroblast accumulation with subepithelial fibrosis, and angiogenesis.

## Inflammation

Although MMP-9 is expressed in a variety of inflammatory cells including eosinophils, macrophages, and neutrophils, the role of MMP-9 deficiency in asthma pathogenesis has been confusing to date. Application of MMP-9[−/−] mice to acute allergic/inflammatory models have reported both proinflammatory [66] and anti-inflammatory roles [67,68]. It is likely that depending upon the protocol, amount of lipopolysaccharide (LPS) and other conditions, one might suppress or exacerbate inflammation in asthma. Future studies will require control for these factors. Moreover, the role of MMPs in newer models of chronic asthma with repetitive antigen stimulation in susceptible strains will allow us to establish roles for MMPs in models of chronic asthma, with potential human applicability.

Application of MMP-12[−/−] mice to several models of asthma has established the importance of the enzyme in inflammatory cell migration in asthma. For example, IL-13 inducible transgenic mice, described above, develop both inflammation and emphysema. Inflammation and emphysema were dependent upon MMP-12 [69]. In addition, in mice sensitized and challenged with cockroach antigen (CRA) [70], MMP-12 deficiency resulted in fewer peribronchial leukocytes and correspondingly less protein and fewer cells in BAL compared to WT mice. Eosinophils were reduced to the greatest degree (80% reduction). In addition, there were marked decreases in IL-5, MIP-1$\alpha$, MCP-1, and TNF-$\alpha$ in MMP-12[−/−] BAL. AHR did not differ between groups. Another model of acute allergic airway inflammation that involved sensitization by aerosolized OVA ×10 days in the context of adenovirus-mediated GMCSF [71], resulted in a Th2 cytokine profile, OVA-specific IgE, and airway eosinophilia. In WT mice, MMP-12 mRNA and protein were upregulated 70-fold in OVA treated versus saline controls. MMP-12[−/−] mice had an 80% reduction in eosinophil accumulation in BAL compared to WT mice. It is noteworthy that, MMP-12 production was IL-13 dependent, since it was abrogated in similar experiments using IL-13[−/−] mice.

## Airway remodeling

*Inflammation* is generally thought to drive other aspects of airway remodeling. For example, eosinophils were shown to be required for fibrosis and smooth muscle hypertrophy, but not AHR or mucus production [72]. In turn, smooth muscle changes might also regulate inflammation [73]. Alternatively, many changes related to airway remodeling have been replicated by pathological stretch applied purely to airway epithelial cells (i.e. in the absence of inflammation) [74]. Expression profiling, followed by confirmative studies demonstrated that mechanical deformation of airway epithelial cells induces production of MMP-9 as well as its activator plasmin(ogen) [75].

MMP-9 has been implicated in *subepithelial airway fibrosis*. The IL-13 transgenic mice described above also have features of airway remodeling including *mucus cell hyperplasia* and subepithelial fibrosis [76]. The airway changes were attenuated upon back-crossing to MMP-9[−/−] mice [26]. This appears to work through the capacity of MMP-9 to activate TGF-$\beta$ promoting collagen production. NE also has been shown to activate latent TGF-$\beta$ in a model of bleomycin-induced lung fibrosis. It is noteworthy that, NE also induces epithelial cell production of MUC5 [77] and mucus cell metaplasia in mouse lungs [78]. Hence, in addition to the local concentration of proteinases and their inhibitors, additional non-matrix substrates will influence the effect of a proteinase is turnover.

## INTRODUCTION

It has long been recognized that after acute injury to the lung, the tissue repair process is engaged to return the organ to normal function. In chronic tissue injury, it appears the process of repair loses many of the control mechanisms, and continued repair results in remodeling of the tissue with alteration of normal structure and compromise of normal lung function. The remodeling process involves excess matrix synthesis along with distorted deposition of that matrix; in addition there is the appearance of altered tissue cell phenotypes, most notably that of the myofibroblast. These cells are derived from existing fibroblasts under the influence of cytokines and growth factors, such as transforming growth factor-$\beta$ (TGF-$\beta$), or possibly from circulating (stem cell like) precursors that have migrated into the tissue injury site. Given the morphology seen in lung disorders, asthma is mostly associated with minor, primarily peribronchial, matrix deposition, while chronic obstructive pulmonary disease (COPD) has wide evidence of remodeling, primarily at the alveolar level and fibrosis of the small airways [1].

Many cytokines and growth factors can be found at the site of tissue remodeling using immunohistochemistry, *in situ* hybridization, and gene expression assessments, so much so, that it is difficult to determine causative versus secondary presence. However, some, in comparison to others, have recently been shown to play a primary role in induction, and thus represent more likely targets for developing therapeutic interventions. Transgenic and gene knockout models in mice point to possible primary targets in growth factors such as TGF-$\beta$, IL-13, or hepatocyte growth factor (HGF), while others implicate factors such as IL-1$\beta$ or TNF-$\alpha$. The presence of acute inflammation, such as in ARDS, or more chronic inflammation states such as COPD and usual interstitial pneumonia (UIP) are usually associated with the sequelae of tissue remodeling. However, there may be situations involving structural cell phenotype or extra cellular matrix alterations that can propagate the remodeling process through autocrine and paracrine pathways independent of the state of inflammation that may have preceded the alteration. Thus, identification of growth factors known to modulate the synthesis and deposition of matrix or influence the make-up of the cell phenotype in the tissue may be crucial in defining the therapy that halts remodeling and progression and/or induces the tissue to return to normal structure and function.

## GROWTH FACTORS IN HUMAN LUNG AND AIRWAY DISEASE

A large number of studies have investigated the role of growth factors in human lung disease in which tissue remodeling is a prominent feature. Most of these studies are based on immuno-histochemical analysis of bronchial and pulmonary tissue, obtained by biopsy, and on analysis of bronchoalveolar lavage (BAL) fluid and cells. Unfortunately there is minimal information available about growth factors in airway disease, but the presence of fibrotic responses and mesenchymal cell proliferation would suggest factors that are prevalent in fibrogenesis. Three different factors are considered to play a prominent role: epidermal growth factor (EGF), GM-CSF, and TGF-$\beta$ [2, 3]. Increased EGF and EGF receptor are present in the submucosa of asthmatic airways

[4, 5] and it is suggested that the epithelium does not respond adequately to EGF after damage in asthma [3]. GM-CSF expression is increased in asthmatic epithelium and lymphocytes after allergen challenge [4] and GM-CSF can mediate airway remodeling through its survival effect on eosinophils [2] and release of profibrotic cytokines [6]. TGF-β has received particular interest. In one study TGF-β expression in airways is shown to correlate with the degree of subepithelial fibrosis in asthma, although the data are controversial [4, 7]. More telling is the presence of TGF-β in BAL fluid after segmental allergen challenge [5]. Moreover, neutralization of TGF-β in an animal model of repeat allergen exposure showed decreased bronchial fibrotic sequelae [8] and TNF-α and IL-1 are found at elevated levels in acutely inflamed asthmatic airways [4]. Since both acute inflammatory cytokines are able to trigger profibrotic tissue reactions [9–11], this strongly suggests a role in airway remodeling. Other growth factors detected, such as platelet-derived growth factor (PDGF) [2], insulin growth factor-I (IGF-I), and basic fibroblast growth factors (bFGF) [3], could also participate in the repair process in airways.

Most knowledge about growth factors in lung tissue remodeling has been accumulated through studies of parenchymal lung disease, such as asbestosis, sarcoidosis, or idiopathic pulmonary fibrosis (IPF). We include these disorders in our discussion to provide the reader perspective on the potential biological actions of these factors and thus to provide a better perspective on asthma and COPD. The presence of two key profibrotic growth factors, TGF-β and PDGF, has been demonstrated in various fibrosing disorders. In IPF, TGF-β was shown to be elevated in BAL fluid [12, 13] and can be expressed by bronchial and alveolar epithelial cells, alveolar macrophages and fibroblast foci [14–17]. PDGF-mRNA was shown to be upregulated in BAL cells retrieved from patients with IPF and in fibrotic areas of the lung, while lungs affected by asbestosis and silicosis express increased TGF-β mRNA [18]. In human fibrotic disorders TNF-α and IL-1 are present in BAL fluid or BAL cell supernatants [19]. In lungs of patients with progressive pulmonary fibrosis, TNF-α and G-CSF are expressed at higher than normal levels [19, 20], while similar tissue expresses lower than normal levels of HGF [21]. An important consideration is the relationship between growth factors and extracellular matrix (ECM). Many growth factors can induce ECM synthesis, but many are also associated with the matrix through adherence via RGD or related sequences to proteoglycans, collagens, and fibronectins [22] and require activation (release) through interaction with cell integrins and ECM components [23–25] or via proteolysis, as seen with plasminogen-mediated activation and release of HGF from ECM [26]. (Table 29.1 and Fig. 29.1)

## SPECIFIC GROWTH FACTORS

### Tumor necrosis factor-α

Tumor necrosis factor-α (TNF-α) is a peptide secreted as membrane bound form and released after cleavage by TNF-α-converting enzyme [27]. The cytokine is not constitutively present in the lung but is secreted rapidly upon a variety of stimuli, mainly by alveolar macrophages and type II epithelial cells [18]. TNF-α can bind to two different types of receptors, which are expressed on most cells and signals through various intracellular pathways [27]. It is a potent proinflammatory cytokine and exerts a variety of effects, which may contribute to the process of remodeling and fibrosis: TNF-α induces inflammatory cell migration and adhesion, initiates a cytokine cascade, and regulates apoptosis [27]. Further, it is mitogenic for mesenchymal cells and influences collagen metabolism, being either pro- or antifibrotic [18, 28]. Numerous studies have demonstrated that TNF-α is involved in acute and chronic tissue changes seen after bleomycin, asbestos, silica, and irradiation damage. Animal strains that do not develop fibrosis following exposure to these agents show less TNF-α upregulation. Transient overexpression of TNF-α in the lung induces a limited fibrosis, likely by upregulation of TGF-β [29]. Others have shown that TNF-α can act also through PDGF pathways [18]. TNF-α was detected in BAL fluid and biopsies of patients with IPF, BOOP, and asbestosis, and likely plays a role in many pulmonary diseases [18, 30].

In asthma, TNF-α can amplify the inflammatory process and have indirect influence on airway remodeling through induction of other growth factors [4]. It has been detected in BAL fluid of asthmatics, in alveolar macrophages after allergen challenge and in bronchial mucosa of asthma patients [4] and can be rapidly released from mast cells on degranulation [31].

### Interleukin-1β

Two forms of IL-1 (α and β) are known with almost identical biological properties. In the lung, many parenchymal and epithelial cell types are able to produce IL-1β; however, the major sources are activated macrophages [4]. IL-1 is a pleiotropic proinflammatory cytokine, often acting synergistically with TNF-α [32]. In remodeling and fibrosis, several actions of IL-1 are important. IL-1 stimulates fibroblasts to secrete other cytokines including IL-1β, IL-8, MCP-1, PDGF, and TGF-β [33, 34], while the direct effect on fibroblast proliferation and ECM synthesis is controversial [28, 32, 35, 36]. *In vivo*, IL-1 is elevated in BAL fluid and alveolar macrophages of patients with ARDS, but not in IPF [19, 33], while in animal studies IL-1 is involved in the early stage of pulmonary bleomycin injury [33], and IL-1 receptor antagonist ameliorates the fibrotic response following silica and bleomycin administration [37]. Recent studies show that transient transgene expression of IL-1 in the lung causes marked alveolar damage, induction of TGF-β and fibroblast foci with progressive fibrosis [38], and similar findings are seen in mice with inducible IL-1β transgene [11]. Moreover, IL-1β is a potent stimulator of osteopontin expression in lung fibroblasts, one of the most highly expressed genes found in IPF tissues [39, 40] and a cytokine that recently has been shown to play a critical role in allergic airway disease [41].

In asthma, IL-1β was found in BAL fluid and macrophages of asthma patients [4]. Its role in airway disease is probably similar to TNF-α, perpetuating primarily acute

inflammatory processes and affecting remodeling directly, through modification of the matrix microenvironment, or indirectly via induction of growth factors, such as PDGF and TGF-β.

## Granulocyte macrophage-colony stimulating factor

GM-CSF is a colony-stimulating factor that regulates growth and differentiation of hematopoietic cells. The lung is a major source of GM-CSF and most pulmonary cells are able to synthesize this cytokine in response to various stimuli [4]. In the context of tissue remodeling and fibrosis, the effects of GM-CSF in the local environment of the lung depend on dose and time of expression and on concomitant epithelial cell damage. In the model of transient transgene overexpression, low levels of GM-CSF induce little peribronchial inflammation and facilitate allergic reactions to exogenous allergen [42]. At higher levels, GM-CSF in the airways results in sustained eosinophilia and macrophage accumulation with moderate development of tissue fibrosis mediated by induction of TGF-β[43] and may represent a target for manipulation in diseases such as COPD [44]. In the bleomycin model, early upregulation of GM-CSF in pulmonary cells is present and followed by enhanced TGF-β expression [45], while other studies imply a protective effect of GM-CSF on the development of fibrosis in rats [46] and mice [47]. The profibrotic response may be due to stimulation and enhanced survival of macrophages and eosinophils, both cells major sources for TGF-β[4, 43, 45]. In the setting of damaged bronchial and alveolar epithelium, the proliferative response of epithelium to GM-CSF stimulation might result in a more protective effect [46].

GM-CSF is present in asthmatic airways of humans; there are increased levels in BAL after allergen challenge; significant levels of GM-CSF are found in plasma of patients with severe asthma [4]. These observations indicate that GM-CSF likely contributes to airway remodeling and plays a major role in the pathogenesis of asthma [2].

## Platelet-derived growth factor

PDGF is a glycoprotein homo- and heterodimer composed of A and B chains, and is secreted by epithelial and endothelial cells, macrophages, and fibroblasts. PDGF-A chains can bind to both PDGF-receptors α and β, whereas PDGF-B bind only

PDGF-receptor β[48]. Signal transduction proceeds through tyrosine kinases, a major pharmacologic target [49, 50]. PDGF isoforms are chemoattractive not only for fibroblasts, but also for neutrophils and macrophages and they upregulate fibronectin and procollagen gene expression and synthesis. PDGF can induce TGF-β expression, suggesting that some of the long-term effects are partly mediated through this cytokine. However, PDGF and PDGF-receptor expression is stimulated by TGF-β, IL-1β, TNF-α, and bFGF, indicating that parts of the profibrotic activities of these molecules are due to PDGF-dependent pathways [18]. In animals that are exposed to asbestos, both PDGF and its receptors are upregulated in bronchial bifurcations with developing fibroproliferative lesions [51]. PDGF-A knockout mice die from pulmonary emphysema apparently because of impaired alveolar development and lack of myofibroblasts [52]. Interference with PDGF activity, either through transgene overexpression of a truncated receptor or through inhibition of tyrosine kinase results in amelioration of the fibrotic response in the bleomycin model and in the bronchiolitis obliterans model [18]. In human fibrotic disorders of the lung, such as IPF, scleroderma and bronchiolitis obliterans, PDGF genes were shown to be upregulated in BAL cells or in affected tissues [18].

In asthma and airway remodeling, a contribution of PDGF to the pathogenesis is likely, but available data are controversial. Eosinophils in biopsies of asthmatic airways have been shown to produce PDGF-B chain [4]. Bronchial fibroblasts from asthma patients show enhanced responsiveness to the mitogenic effects of PDGF, but increased levels of PDGF in BAL are either not present or do not correlate with airway fibrosis [2].

## Insulin-like growth factor

IGF-I and II are single chain peptides with structural homology to pro-insulin [53]. In the lung, the major sources of IGFs are macrophages, but mesenchymal and bronchial epithelial cells are also able to produce IGF [4, 54]. IGFs can bind to two receptors, type I and II, and biological activity is mainly determined by IGF-binding protein that releases IGF [55]. IGFs regulate proliferation and differentiation of a variety of cells [53], being strong mitogens for fibroblasts and causing enhanced collagen synthesis [54]. IGFs are also found in tissue and BAL fluids of various fibroproliferative diseases [12, 56]. However, little information is available about the role of IGF's in asthma or COPD, but IGF's can stimulate the proliferation of airway smooth muscle cells and may be involved in airway fibrosis [4].

## Fibroblast growth factors

FGFs are a group of nine heparin-binding peptides, amongst them acidic and basic FGF (now FGF-1 and 2) and keratinocyte growth factor (KGF or FGF-7) [53, 57]. FGF-1 and 2 have been shown to accelerate granulation tissue formation, fibroblast proliferation and collagen synthesis [53]. They are strong mitogens for angiogenesis and endothelial cell migration [4]. FGF-1 and 2 are not present at significant levels in normal lungs but are produced after tissue injury by alveolar macrophages, epithelial cells, and fibroblasts [58]. Major sources for FGF-2 in the lung are mast cells [59]. In humans, FGF-2 was found in BAL and serum of patients with IPF and scleroderma [60] and in human airway smooth muscle cells; FGF-2 increases the expression of PDGF-receptor α and therefore indirectly stimulates proliferation [4].

KGF (FGF-7) is primarily produced by fibroblasts and is mitogenic mainly for alveolar type II epithelial cells through the FGFR2-IIIb receptor, essentially expressed only by epithelial cells [57, 61]. IL-1β appears to be the most potent inducer of KGF from fibroblasts [35] and in the context of epithelial-mesenchymal cell interaction, IL-1β from epithelial cells stimulates the release of KGF from fibroblasts and results in the stimulation of the epithelium in a positive paracrine system [62]. In the bleomycin model of fibrosis instillation of KGF prevented the progression to fibrogenesis [63] and KGF was able to limit tissue damage and enhance epithelial repair in a syngeneic tracheal transplant model in rats [64]. In humans with ARDS, KGF in BAL fluid was taken as a marker of the severity of tissue injury and correlated with poor prognosis [57], while KGF administration limited the decreased lung permeability and inflammation seen on allergen challenge in an OVA-sensitized rat model [65].

## Epidermal growth factor

The EGF family is an enlarging group of related proteins and includes EGF and transforming growth factor-α (TGF-α). Both factors have potential roles in wound healing and remodeling. They share 42% homology and signal through the EGF receptor that activates tyrosine kinase [49, 66].

EGFs are important in the repair of epithelial injury. It has been shown in damaged bronchial epithelial cells that EGF receptors become phosphorylated and consequently the defect is repaired and supplementation with exogenous EGF further enhances this process [3]. In asthma, EGF receptor is highly expressed in airway epithelium, but epithelial cell proliferation is still impaired [3], and impaired re-epithelialization induces the formation of granulation tissue [67]. This suggests that an abnormal response of the epithelium to growth factors could be a central factor in the pathogenesis of asthma and airway remodeling. In humans, EGF and EGF receptor are present in the submucosa of asthmatic airways [3, 4].

Similar to EGF, TGF-α is able to promote wound epithelialization [53], while tissue specific overexpression of TGF-α in the lung of mice leads to alveolar enlargement and interstitial and pleural fibrosis. Conversely, elimination of the TGF-α gene significantly decreases the fibrogenic tissue response to bleomycin [66]. In humans, TGF-α protein is elevated in BAL fluid of patients with ARDS and IPF [68], and TGF-α and EGF receptor expression is seen in biopsy material in IPF [69].

## Hepatocyte growth factor

HGF was originally identified as a potent stimulator of mature hepatocytes, but more recently is recognized as

a participant in many tissue responses to injury and is a potentially important stimulator of alveolar epithelial cells and vascular endothelial cells [70, 71]. In lung development, HGF is shown to be required for alveologenesis in the rodent [72], and recent studies indicate this growth factor may play a role in airway sensitization through modulation of dendritic cell activation [73]. Importantly, there are defects in HGF production from fibroblasts in tissue samples from both emphysema and IPF patients [21, 74]. Most impressive is the experimental attenuation of both elastase-induced emphysema and bleomycin-induced fibrosis by administration of either recombinant HGF or by gene transfer to the lung [71, 75, 76]. These data suggest that HGF has activities that could balance the profibrotic activities of factors such as TGF-β and establishes an interplay between these powerful factors that could distinguish correct tissue repair from disordered pathology (Fig. 29.2).

## Transforming growth factor-β

The TGF-β family includes 5 isoforms, of which mammalian cells express three. The isoforms TGF-β 1 to 3 reveal considerable sequence homology, and their biological properties in wound healing and tissue remodeling are similar. Most studies have been performed with TGF-β1, which is the most abundant and best-characterized isoform [77]. TGF-β is profibrotic by various effects on ECM turnover and stromal cell biology. The immunomodulatory activities of TGF-β are crucial and aim mainly at the limitation of inflammatory processes. Many different cells secrete TGF-β, in the lung mainly macrophages, epithelial cells, and fibroblasts. The secreted molecule is inactive and has to be activated by cleavage of the latency associated peptide (LAP) through oxygen radicals or proteases (e.g. thrombospondin or plasmin) [78] or through interaction with cell integrins, most notably αVβ6 and αVβ8 on epithelial cells or fibroblasts [24, 79]. TGF-β binds to two receptors, type I and II, and signals are transduced by serine/threonine kinases to different intracellular pathways [80, 81]. In the context of tissue remodeling, the *Smad*-signaling pathway is the most prominent and a potential target for pharmacologic intervention in fibrotic disorders [82, 83]. TGF-β stimulates ECM production, predominantly collagen and fibronectin, and reduces matrix degradation by changing the balance of collagenases and collagenase inhibitors (TIMP-1) [78]. It is anti-proliferative for epithelial cells, inducing apoptosis and subsequent fibrotic responses in the lung [84, 85]. The mitogenic effect on fibroblasts is not uniform, but it is apparent that TGF-β induces the transformation of fibroblasts into myofibroblasts [86]. Myofibroblasts are contractile cells and synthesize most matrix proteins, both important factors in the final step of wound healing, but potentially a pathogenic process in fibrosis. In the remodeling process, TGF-β acts in concert with many other cytokines and growth factors. On the afferent, it can be upregulated by TNF-α, IL-1, GM-CSF, PDGF, and TGF-β itself. On the effector, TGF-β not only acts through direct interference with collagen metabolism but may induce the expression and secretion of FGF, PDGF, and connective tissue growth factor (CTGF), as well as its own upregulation [9, 18, 86].

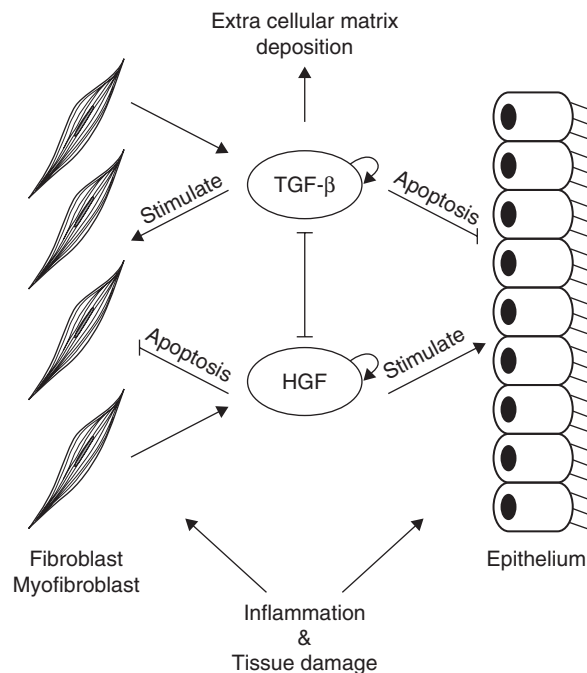

**FIG. 29.2** Two main growth factors balance cell survival and tissue remodeling. TGF-β, released from the matrix in the parenchyma during tissue injury, is a major stimulator of myofibroblast and fibroblast survival and ECM production. TGF-β also induces apoptosis in pulmonary epithelial cells. HGF, released from fibroblasts in the parenchyma by molecules such as IL-1β, balance the pro-fibrotic effects of TGF-β by stimulating the survival of epithelial cells and inducing the apoptosis of myofibroblasts, as well as dampening the inflammatory response that accompanies tissue injury. Both are autocrine and paracrine in function, and have an apparent inhibition effect on release of the counterpart.

The role of TGF-β in pulmonary remodeling and fibrosis has been investigated mainly in interstitial lung disease, where the key role of this growth factor is widely accepted, with evidence from a large number of animal models and human studies [18, 53, 83, 85]. In models using chemical agents such as bleomycin, asbestos or silica, or irradiation to induce progressive tissue damage, TGF-β was shown to be upregulated at the sites of developing fibrosis. In our own studies, in which transient overexpression of active TGF-β1 is achieved by adenoviral gene transfer, severe and diffuse pulmonary fibrosis developed in rats and mice [78], mediated through the Smad3-signaling pathway [83]. The importance of TGF-β in tissue remodeling after pulmonary injury is highlighted by several experimental settings that demonstrate the beneficial effect of anti-TGF-β agents on the course of fibrosis. Neutralizing antibodies, dominant negative TGF-β-receptors or natural antagonists such as the proteoglycan decorin have all been able to reduce fibrotic reactions in the lung [87, 88] and TGF-β was shown to be present in a variety of human lung diseases, including asthma and IPF. Also, as COPD could be considered a disorder with inadequate tissue repair [89], the genetic association of the TGF gene with COPD disease is a positive indication of involvement [90].

The importance of TGF-β in pulmonary remodeling is not only restricted to the interstitium, but is also present in airways. TGF-β genes are upregulated in bronchial walls

in a model of chronic airway disease [91], and anti-TGF-β is shown to modulate the subepithelial fibrotic response seen in a chronic allergen challenge model in the mouse [8]. Interestingly, TGF-β1 and TGF-β3 may have opposite effects on connective tissue synthesis in cultured airway smooth muscle cells, suggesting a protective role for TGF-β3 in airway remodeling [92]. In asthma patients, TGF-β was found in airway walls and correlated with the degree of subepithelial fibrosis [7], but others have failed to find a correlation to disease severity [93], while TGF-β is released into BAL fluid after endobronchial allergen challenge [3]. There are findings that link the pathogenesis of fibrogenesis to that of emphysema; interference with either the activation of TGF-β (αVβ6 null mouse) or signaling through the receptor (Smad3 null mouse) leads to spontaneous airspace enlargement and aspects of emphysema [89, 94]. These changes are accompanied by enhanced expression of MMP12 by macrophages, normally controlled by exposure of these cells to TGF-β [89], implying tissue repair abnormalities lie at the center of both disorders.

## Connective tissue growth factor

Connective tissue growth factor is a growth factor with similar activities on collagen metabolism as TGF-β. It is a cysteine-rich peptide produced by fibroblasts and endothelial cells, but not by leukocytes or epithelial cells [18, 95]. CTGF is constitutively expressed in human lung fibroblasts and is stimulated by TGF-β, but not TNF-α or IL-1β [96] In mouse lungs, TGF-β and CTGF are upregulated following bleomycin injury. It has been suggested that TGF-β exerts its profibrotic effects in part through PDGF pathways and through a PDGF-independent pathway using CTGF [18].

Less information is known about CTGF in airway remodeling. However, the association with TGF-β makes it likely that CTGF might have similar effects in the airway as TGF-β. Indeed, it has been recently shown that TGF-β stimulates expression of CTGF in cultured airway smooth muscle cells [97].

## ANIMAL MODELS

### Chronic airway challenge

Airway remodeling in human chronic airway disease is a concept not yet clearly defined [2]. The principal morphologic features are subepithelial fibrosis, myofibroblast hyperplasia, airway smooth muscle hypertrophy, mucus gland and goblet cell hyperplasia, and epithelial disruption [98]. The mechanisms leading to persistent airway changes are poorly characterized because of a lack of simple and suitable animal models. An impaired response of asthmatic bronchi to EGF after epithelial injury seems to be important to initiate the process, while other growth factors, such as TGF-β isoforms, PDGF, and bFGF might be responsible for the proliferative response [3]. Recently described animal models resemble certain aspects of human asthma induced by repeat allergen exposure with *Aspergillus*, ovalbumin or house dust mite antigens. These models produce in mice changes similar to human asthmatic airway remodeling, and airway fibrosis, accompanied by upregulation of TGF-β and GM-CSF [8, 17, 91, 99, 100].

## Transgene animal models

In transgenic animal models certain genes are deleted, overexpressed, or mutated. Transgenic animals, either developed by gene insertion (or deletion) in embryonic stem cells or developed by transient transgene expression in adult animals by gene transfer (e.g. adenoviral vectors) have proven useful to answer questions about the role of specific growth factors in the pathogenesis of pulmonary disease. Animals transiently overexpressing IL-1 or TGF-β develop progressive fibrotic lesions in the lung, IL-1, likely through induction of TGF-β [10, 29, 43, 78]. Conversely, TNF-α-receptor and TGF-α knockout mice are resistant to bleomycin-induced pulmonary fibrosis [18, 66]. Also implicated by transgenic studies are IL-11 and IL-13; these molecules were not previously known to be factors involved in tissue remodeling and repair, but showing evidence of fibrotic changes, emphysematous lesions, and deranged mucus production [101, 102].

## SUMMARY

Of the many cytokines and growth factors that are found within the tissue or surrounding fluids in COPD and asthma, only a few can be shown to have direct impact on the process of tissue remodeling. *In vitro* and *in vivo* studies outlined above indicate that factors such as TGF-β, which induces chronic repair without accompanying tissue injury, and IL-1β, which induces tissue injury and chronic repair, likely through induction of TGF-β, may be considered the most critical targets for intervention. The fact that these growth factors act mainly at a local site in association with matrix helps explain the progressive and tissue-restricted nature of remodeling. Development of potent inhibitors of these growth factors or of genes activated downstream of them could prove beneficial in modifying the altered tissue in asthma and COPD allowing conjoint therapy with anti-inflammatory drugs, preferably delivered to the local remodeled site, to halt the destructive process and return the lung to normal function.

# Nitric Oxide

CHAPTER

Sergei A. Kharitonov and Kazuhiro Ito

Section of Airway Disease, National Heart and Lung Institute, Imperial College, London, UK

## INTRODUCTION

Nitric oxide (NO) in human biology was mostly considered to be a by-product of the combustion of fossil fuels and therefore as an air pollutant, until the mid- to late 1980s when it was discovered that this free radical was the previously uncharacterized endothelial-derived relaxing factor [1].

NO is now known to play a central role in the physiology and the pathophysiology of many human organ systems. Within the respiratory system, NO promotes vascular and bronchial dilation, is a key mediator of the coordinated beating of ciliated epithelial cells, promotes mucus secretion, and is an important neurotransmitter for nonadrenergic, noncholinergic neurons in the bronchial wall [2, 3]. Additionally, NO is a mediator of inflammatory phenomena within the lung by virtue of its ability to influence the phenotype of inflammatory cells and its contribution to the formation of reactive nitrogen products. Given its wide distribution within the lung and airway, it is not surprising that NO can be detected in exhaled gas in levels that we now know vary in health and disease.

This chapter reviews the formation of NO, novel approaches of its measurements, and its role in the pathobiology and the management of asthma and chronic obstructive pulmonary disease (COPD).

## SOURCE OF NO IN ASTHMA AND COPD

The enzyme system responsible for producing NO is NO synthase (NOS), consists of at least three isoforms: (1) constitutive neuronal NOS (NOS I or nNOS); (2) inducible NOS (NOS II or iNOS); and (3) constitutive endothelial NOS (NOS III or eNOS). The existence of a genetic association between a polymorphism in the nNOS gene and the diagnosis of asthma has led to the speculation that nNOS is a candidate gene for asthma [4].

Functionally, constitutive (or c) NOSs (nNOS and eNOS) are $Ca^{2+}$- and calmodulin-dependent enzymes and rapidly release low concentrations of NO upon receptor stimulation by selective agonists. The activity of iNOS is largely regulated at a pretranslational level and can be induced by proinflammatory cytokines, such as tumor necrosis factor-$\alpha$ (TNF-$\alpha$), interferon-$\gamma$ (IFN-$\gamma$), and interleukin (IL)-1$\beta$ [5]. Several hours after exposure to these inflammatory stimuli, iNOS action releases large quantities of NO, which may continue in a sustained manner (hours or days).

All the three NOS isoforms are found in the respiratory system and may co-operatively regulate various functions in the respiratory tract from bronchomotor tone to immunologic/inflammatory responses:

a. eNOS is expressed in human bronchial epithelium [6] and in type II human alveolar epithelial cells [7, 8].

b. nNOS is localized in the airway nerves and in the airway smooth muscle where NO is the major mediator for the neuronal smooth muscle relaxation [9], mediated by the inhibitory nonadrenergic, noncholinergic (iNANC) system [10]. In the human lung nNOS is expressed in capillary endothelial cells of alveolar septa and plays a role as an endothelium-derived regulator of capillary permeability, a modulator of cholinergic neuronal transmission, or an inhibitor of

platelet aggregation [11]. These low NO concentrations produced by nNOS are detectable in exhaled air [12], and contributes to bronchial responsiveness [13]. We recently found that nNOS is upregulated with increased disease severity and dominant isoform as a source of NO in COPD (Ito et al., in preparation).

**c.** iNOS is expressed in alveolar type II endothelial cells, lung fibroblasts, airway and vascular smooth muscle cells, airway epithelial cells, mast cells, endothelial cells, neutrophils, and chondrocytes.

- The increased levels of exhaled NO in asthma, for example, have a predominant lower airway origin and are most likely due to activation of NOS2 in airway epithelial and inflammatory cells [14–18], with a small contribution from NOS [14].

- Exhaled NO levels in stable COPD [19, 20] are lower than in either smoking or nonsmoking asthmatics [21] and are not different from normal subjects. This reduction in exhaled NO is due to the effect of tobacco smoking, which downregulates eNOS [22] and reduces exhaled NO [23], suggesting that this may contribute to the high risk of pulmonary and cardiovascular disease in cigarette smokers. In addition to the effects of cigarette smoking, a relatively low value of exhaled NO in COPD may reflect more peripheral inflammation than in asthma, low NOS2 expression [24], and increased oxidative stress that may consume NO in the formation of peroxynitrite [25].

## POTENTIAL MECHANISMS OF NO-RELATED DYSFUNCTION IN ASTHMA AND COPD

### Nitration of proteins

NO production and release are directly linked to the formation of reactive nitrogen species (RNS) that modify proteins in asthma and COPD. The magnitude of this modification correlates with the degree of oxidative and nitrosative stresses.

Protein nitration is unique among posttranslational modifications in its dependency on reactivity of tyrosine residues in the protein target that may be achieved:

**a.** by peroxynitrite (formed from the reaction between NO and $O_2^{\cdot-}$),

**b.** through the reaction of NO with protein tyrosyl radicals,

**c.** by the reaction of nitrite with peroxidases [26, 27] including myeloperoxidase and eosinophil peroxidase [28],

**d.** by combination of all the above pathways.

Nitration of proteins by peroxynitrite is a concentration-dependent process related to formation of two distinctive forms of nitrated proteins: stable 3-nitrotyrosine (nitration) and labile *S*-nitrosocysteine (*S*-nitrosation) [29]. Both of these nitrated proteins can be further enzymatically

modified by glutathione *S*-transferase or glutathione peroxidase *via* either of the following:

**a.** converting $NO_2^-$ to $NH_2^-$ in tyrosine residues

**b.** denitrating $NO_2^-$ directly/indirectly in tyrosine residues

**c.** changing SNO to $SH^-$ in cysteine residues, or denitrosation.

Nitration of tyrosine residues by lipopolysaccharide (LPS) [30], for example, induces the formation of hydrophilic negatively charged nitrotyrosine residue which alters the function [31], catalytic activity, structure, susceptibility to proteolytic degradation, and reduces the kinase substrate efficiency of proteins [32–34]. Nitration of mitochondrial proteins may change the activity of several enzymes involved in energy production (glutamate dehydrogenase), or in the electron transport chain (cytochrome oxidase and ATPase), or in energy production (creatine kinase) [30] (Fig. 30.1).

Interestingly, both energy production and apoptosis are affected by NO and related oxides [35] and are different in asthma and COPD.

Nonasthmatic lungs showed little or no nitrotyrosine staining, whereas lungs of patients even with mild asthma [15] and especially who died of status asthmaticus [36] have high presence of nitrotyrosine in both the airways and the lung parenchyma. Nevertheless, nitrotyrosine formation in airway epithelial and inflammatory cells is significantly higher in COPD than in asthma [37] and is related to COPD severity [38]. This exaggerated level of nitration may explain low protective properties of antioxidant enzymes [30] in the central bronchial epithelium in COPD [39].

On the other hand, protein nitration may be also beneficial:

**a.** Surfactant protein A (SP-A), a product of tyrosine nitration of human pulmonary surfactant, downregulates T-cell-dependent alveolar inflammation and protect against idiopathic pneumonia injury [40].

**b.** Tyrosine nitration in proteins is also sufficient to induce an accelerated degradation of the modified proteins by the proteasome, which may be critical for the removal of nitrated proteins *in vivo* [41].

**c.** Nitration of tyrosine residues in tyrosine kinase substrates may prevent phosphorylation and, therefore, inhibit tyrosine kinase function in cellular signaling [27]; this mechanism remains highly speculative.

**d.** Despite the discovery of enzymatic "nitrotyrosine dinitrase" activity in lung homogenates [42], suggesting the potential role of nitration (and dinitration) as a signaling mechanism, it remains to be established whether nitrotyrosine is merely a biomarker of increased nitrosative stress or whether it actively contributes to cellular dysfunction and development of the airway inflammatory processes in asthma or COPD.

### Tyrosine hydroxylase

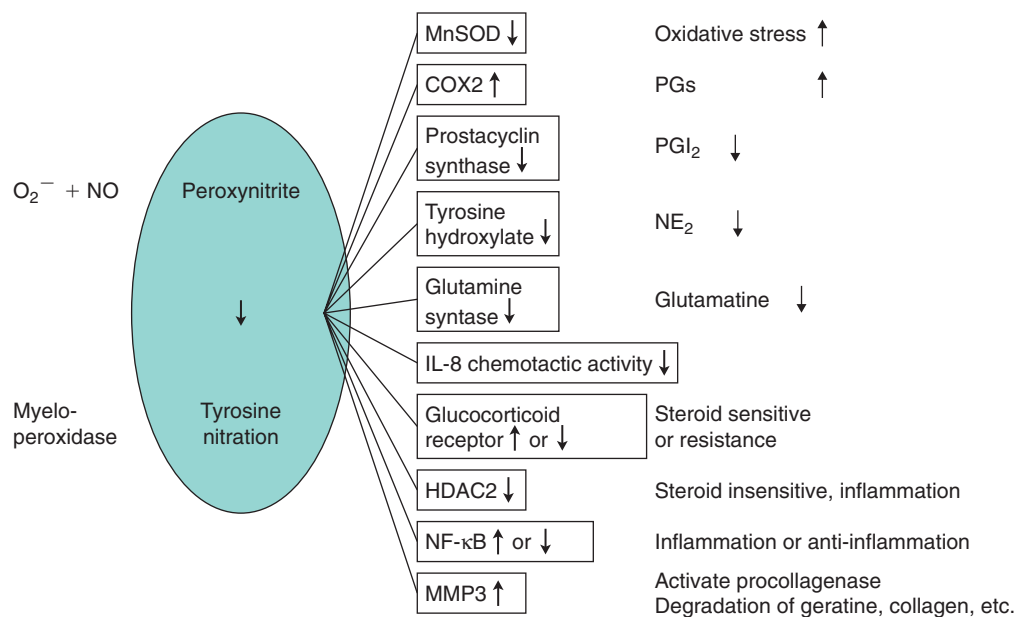
Tyrosine hydroxylase (TH), the enzyme which catalyses the production of L-dihydroxyphenylalanine (L-DOPA) is also


**FIG. 30.1** Effect of peroxynitrite or impact of tyrosine nitration on various molecules. PG: prostaglandin, NE: norepinephrine.

reported to be inactivated following tyrosine nitration [43]. The loss in TH activity and expression is thought to contribute to the L-DOPA deficiency observed in certain neurological disorders such as Parkinson's disease [43, 44].

Repeated exposures to cigarette smoke cause a variety of molecular neuroadaptations in the cAMP signaling pathway in postmortem tissue from the brains of human smokers and former smokers [45]. Activity levels of two major components of cAMP signaling, cAMP-dependent protein kinase A (PKA), and adenylate cyclase, have been found abnormally elevated in nucleus accumbens of smokers and in ventral midbrain dopaminergic region of both smokers and former smokers. Although protein levels of other candidate neuroadaptations, including glutamate receptor subunits, TH, and other protein kinases, were within normal range, protein levels of the catalytic subunit of PKA were correspondingly higher in the ventral midbrain dopaminergic region of both smokers and former smokers [45]. These findings suggest that smoking-induced brain neuroadaptations can persist for significant periods in former smokers.

## Histones

Histones are appreciably more stable than most cellular proteins and their slower turnover may permit them to accumulate 3-nitrotyrosine more than high turnover proteins [46]. Since nitrotyrosine can readily be detected immunohistochemically, nitrated histones may prove to be useful as a marker of extended exposure of cells or tissues to reactive nitrogen oxygen species.

The fact that only a limited number of the tyrosine residues were nitrated in histones [46] allows us to consider nitrotyrosine as one of the posttranslational modifications of histones that can occur *in vivo*. Nitration of histones using Mutatect cells (contain a relatively low level of nitrated proteins) cultured under standard conditions was not apparent until 3 days of sodium nitroprusside exposure, reaching a

maximum at about 6 days [46]. This suggests that presence of nitrated histones in tissues may reflect the long-term exposure to RNS [47].

## Histone deacetylase

Inducible NOS and other NF-κB-dependent genes involved in inflammation may be regulated by the specific recruitment of histone deacetylases (HDAC) [48], that may further enhance cytokine induction of both the iNOS and the NF-κB. HDAC activity/expression is reduced in airways of mild asthmatics [49] compared with normal subjects, but may be restored by steroids that activate histone acetyltransferases [49]. It has been shown that in subjects with severe asthma and COPD with reduced HDAC activity, the ability of inhaled steroids to control inflammation may be lost [49].

Molecular mechanisms underlying this reduction in HDAC2 activity is currently believed to be linked to nitrative stress. Peroxynitrite has been reported to alter HDAC2 function and stability via nitration of tyrosine residues on proteins *in vitro* and *in vivo* [50, 51].

## Fate of nitrated protein

Protein nitration is reported to be more sensitive to trypsinization, and TH, once nitrated by peroxynitrite, is eliminated by proteasomal degradation [41, 52]. An increase in free nitrotyrosine is also an evidence of nitrated protein degradation. Oxidative/nitrative stress may delay the degradation of nitrated proteins due to the inactivation of the proteasome [53].

Interestingly, protein tyrosine nitration is a reversible process catalysed by an unknown enzyme [54] that removes the nitro ($NO_2$) group on nitrated proteins and has been referred to as a "denitrase" [42, 55].

We have found that denitrase activity in human cells and lung tissue is reduced in COPD (Ito and Osoata, unpublished), suggesting that reduced denitration activity could be involved in accumulation of *n*-tyrosine in the lung as well as elevated NO production.

## MEASUREMENT OF NO IN EXHALED AIR

Several techniques are currently used to measure the fraction of NO in the exhaled air (Fig. 30.2); these are published in internationally recognized guidelines [56, 57]. The major issues are to control the expiratory flow rate [58] and to use an orapharnygeal pressure that prevents contamination of the expirate with high NO gas derived from the nasopharynx [59].

Measurement of exhaled NO from a single expiration at a fixed flow are simple, highly reproducible [60], have been used to monitor $FE_{NO}$ in asthma research [61] and are now moving into clinical practice [62].

Methods for measuring exhaled NO at multiple expiratory flows (ME $FE_{NO}$) [63, 64] have been used to detect elevated levels of alveolar NO in asthma [65, 66] leading to the refinement of analytical methods to potentially discriminate exhaled NO sources in the lung [67] (Fig. 30.2).

Until recently, no day-to-day and home $FE_{NO}$ monitoring was possible, as portable and simple NO analysers were not available. The arrival of the first hand-held portable NO analyser (NIOX MINO, Aerocrine, Sweden)

(Fig. 30.2) that allows $FE_{NO}$ measurements with sufficient accuracy and reproducibility in both children and adults [68, 69], may considerably change current management of asthma, as $FE_{NO}$ can be measured on a daily basis by patients at home and frequently during their regular visits to their general practitioner [62].

## Asthma

Increased levels of exhaled NO of a predominant lower airway origin [70], have been widely documented in patients with asthma [17, 71], and are likely related to activation of NOS2 in airway epithelial and inflammatory cells [14–18], with a small contribution from NOS1 [4].

## Diagnosis

The diagnostic value of exhaled NO measurements (with 90% specificity and 95% positive predictive value) to differentiate between healthy subjects with or without respiratory symptoms and patients with confirmed asthma has been reported by several groups [72, 73]. This suggests that the simple measurement of exhaled NO can be used as an additional diagnostic tool for the screening of patients with a suspected diagnosis of asthma. Importantly, normal values of $FE_{NO}$ for adults have been established and can be predicted on the basis of age and height [74].

It has been confirmed that the diagnostic utility of exhaled NO and induced sputum are superior to the conventional tests (peak flow measurements, spirometry, and changes in these parameters after a trial of steroid) [75],

with exhaled NO being most advantageous because the test is quick and easy to perform.

## Asthma control

Monitoring of asthma may be much more conclusive [76] when repetitive $FE_{NO}$ measurements, especially made at home by a portable NO analyzer, instead of single assessment were used, *changes* in $FE_{NO}$ correlates significantly not only with changes in sputum eosinophils and hyperresponsiveness, but also with lung function and asthma symptoms.

Jones *et al*. [77] have demonstrated that repetitive exhaled NO measurements have a positive predictive value between 80% and 90% for predicting and diagnosing loss of control in asthma and are as useful as induced sputum eosinophils and airway hyperresponsiveness to hypertonic saline, but with the enormous advantage that they are easy to perform.

An advantage of $FE_{NO}$ as a "loss-of-control-marker" [78] is that increase in $FE_{NO}$ and asthma symptoms may be seen before any significant deterioration in airway hyperresponsiveness, sputum eosinophils, or lung function during asthma exacerbation induced by steroid reduction [18, 79]. Exhaled NO levels were (median, interquartile range) 11 ppb (9–21) in children who had good asthma control, 15 ppb (11–26) acceptable asthma control, and 28 ppb (19–33) with insufficiently controlled asthma [80], suggesting NO measurements may be useful for monitoring pediatric asthma in clinic.

## Inhaled corticosteroids

### Onset and cessation of action

Exhaled NO behaves as a "rapid response" marker that is extremely sensitive to steroid treatment, because it may be significantly reduced even 6 h after a single dose of nebulized budesonide [81], or within 2–3 days [16, 82] after treatment with inhaled corticosteroids (ICS) from a metered-dose or dry-powder inhaler.

We observed that the onset of action of inhaled budesonide on exhaled NO was dose dependent, both within the initial phase (first 3–5 days of treatment) and during treatment weeks 1, 2, and 3 [82]. Cessation of the actions of ICS is a rapid process too and can also be monitored by repetitive NO during the first 3–5 days in patients who stopped inhaling budesonide [82].

### Dose dependency

We have shown that the acute reduction in exhaled NO (within the first 3–5 days of treatment) and the chronic reduction (days 7–21) are dose dependent in patients with mild asthma who are treated with low doses of budesonide [82]. Serial exhaled NO measurements, as we recently suggested [61], may therefore be useful in studying the onset and duration of action of ICS, as well as in monitoring patient compliance.

It is unclear, however, whether exhaled NO can guide an asthma treatment strategy. Thus, recent study based on the measurement of exhaled NO did not result in a large reduction in asthma exacerbations, but resulted in more patients on lower doses of ICS over 12 months, when compared with management by current asthma guidelines and no measure of $FE_{NO}$ [83].

## iNOS inhibitors

The flux of NO through the airways can be decreased by a single dose of inhaled NOS inhibitors in both asthma and healthy controls subjects with a greater reduction in patients with asthma (80 versus 61%) [84] (Fig. 30.3). This finding supports the hypothesis that iNOS induction may be

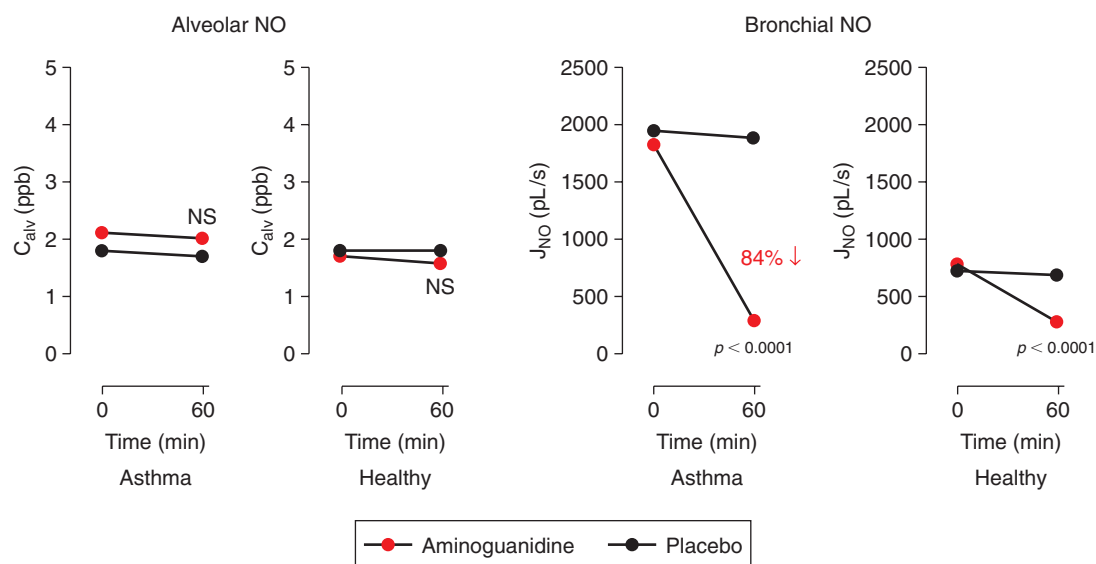

**FIG. 30.3** Fast and "differential" effect of inhaled aminoguanidine versus placebo on bronchial NO and alveolar NO in asthma and healthy. From Ref. [84].
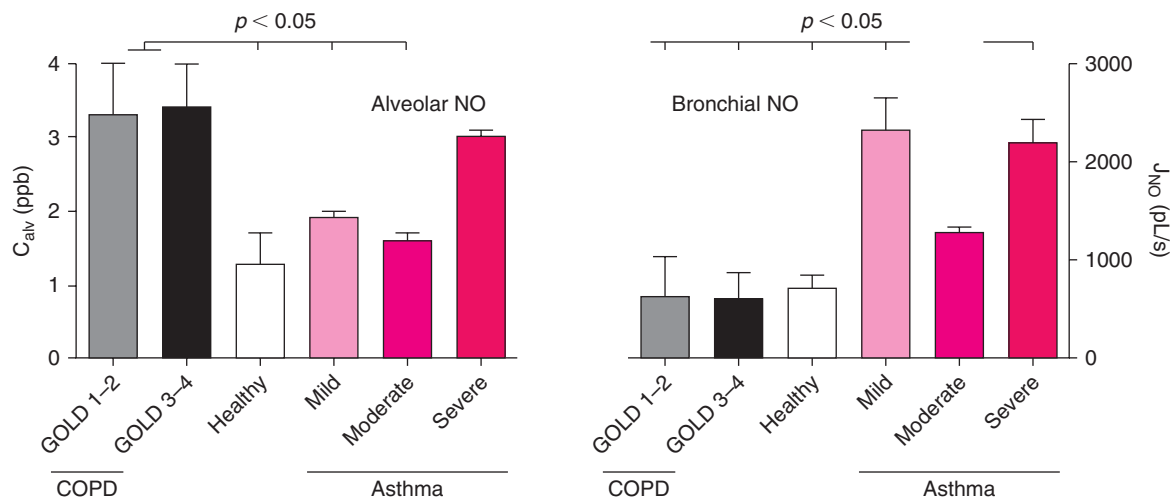

**FIG. 30.4** Exhaled NO measured with the MEF technique: Alveolar versus bronchial inflammation is asthma and COPD of different stage and severity. From Ref. [84, 90].

responsible for the raised levels of NO in asthma, whereas the levels seen in normal subjects seem due to cNOS and a low level of iNOS activity.

## COPD

Exhaled NO levels in stable COPD [19, 20] are lower than in either smoking or nonsmoking asthmatics [21] and are not different from normal subjects. Patients with unstable COPD, however, have high NO levels compared with stable smokers or ex-smokers with COPD [19], which are still lower than expired NO in nonsteroid-treated asthmatic subjects [85].

Data from experiments using multiple expiratory flows have demonstrated that the peripheral airways/alveolar region is the predominant source of elevated exhaled NO in COPD. In contrast, increased exhaled NO levels in asthma (Fig. 30.4) are mainly of larger airways/bronchial origin [86]. Prevalence of alveolar-derived NO in COPD is possibly related to the iNOS in macrophages, alveolar walls, and bronchial epithelium of COPD patients [87].

### Disease severity and progression

Severity-related increase of the inferred concentration of NO in the alveolar zone, $C_{alv}$, may be due to higher presence of iNOS-positive cells in alveolar walls in more severe COPD patients [88], but not with severe emphysema that shows a lower percentage of iNOS-positive alveolar macrophages than patients with milder disease [89]. Patient with COPD rated as stage Global Initiative for Chronic Obstructive Lung Disease II (GOLD II) have $C_{alv}$ levels [90] similar to those of more severe asthma patients

[91] (Fig. 30.4) suggesting similar mechanisms may be responsible.

## MONITORING OF SMALL AIRWAY INFLAMMATION IN BOTH COPD AND SEVERE ASTHMA

MEFT $FE_{NO}$ measurements are highly reproducible, free of diurnal variation, unaffected by smoking, bronchodilator, or ICS [90] and therefore could be useful for COPD monitoring (Fig. 30.5).

Interestingly, the elevated levels of alveolar NO are similar in COPD [90] and severe asthma [91], supporting our previous finding of elevated exhaled $FE_{NO}$ levels in patients with severe [92] and difficult steroid-resistant asthma [93].

Therefore, differential flow analysis of exhaled NO provides additional information about the sites of inflammation in asthma and COPD which are clearly different (Figs. 30.3, 30.4, 30.6), may be useful in assessing the response of peripheral inflammation to therapy, including its combination with iNOS inhibitors [94].

### iNOS inhibitors

Under conditions of inflammation and oxidative stress, superoxide anion will preferentially react with available NO rather than its endogenous neutralizer superoxide dismutase, thus increasing the formation of peroxynitrite in tissues [95].

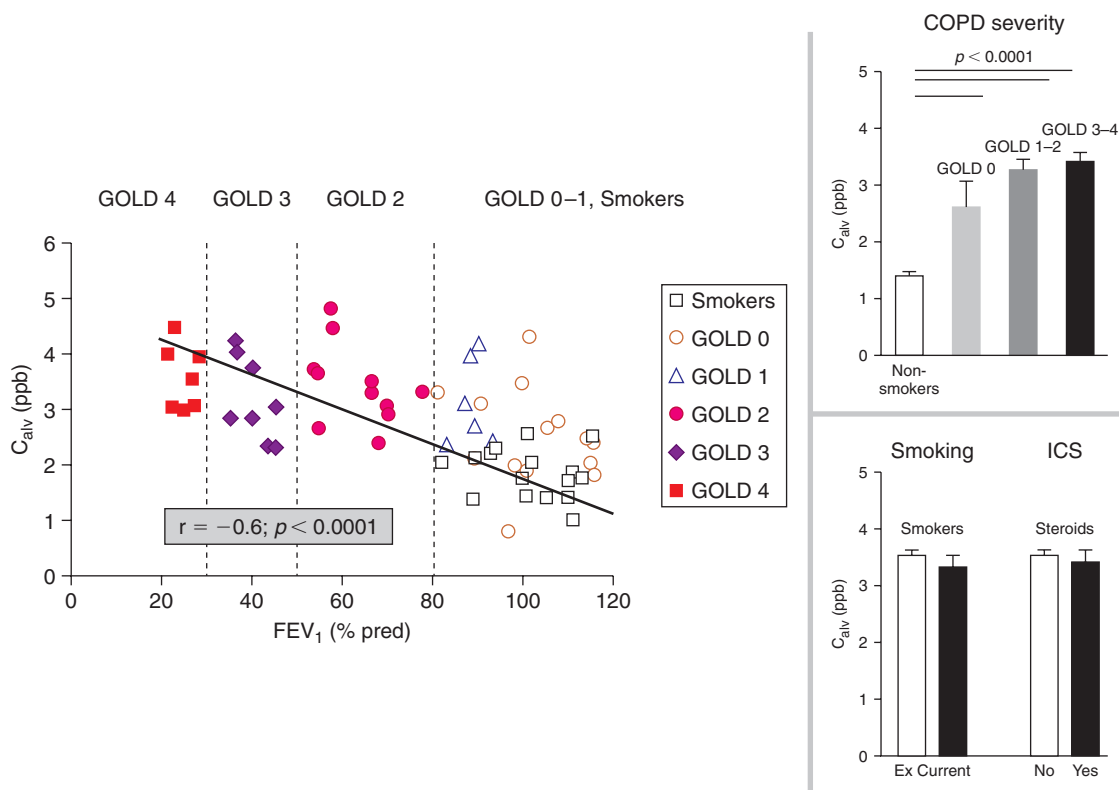
Diffusion of peroxynitrite through biomembranes can cause oxidative damage at one to two cell diameters from its site of formation [96] that may be of importance in COPD


FIG. 30.5 Alveolar NO in COPD: relationship to the disease stage and severity, smoking and treatment with inhaled corticosteroids. ICS: inhaled corticosteroids. From Ref. [90].

FIG. 30.6 Fast and "differential" effect of inhaled aminoguanidine versus placebo on bronchial and alveolar NO in COPD and healthy smokers. From Ref. [97].

with its high local NO production [90]. Therefore, the use of iNOS inhibitors by reducing "available" NO may restore the preferred pathway of superoxide radicals detoxification, *via* superoxide dismutase.

We have reported this "selective inhibition" by aminoguanidine versus placebo of bronchial NO flux ($J_{NO}$) in COPD patients but not in smokers or normal volunteers [97] (Fig. 30.6). Aminoguanidine also caused a decrease in alveolar NO ($C_{alv}$) in smokers and in COPD but not in healthy controls. These findings give potential new insights into the differences between asthma (Fig. 30.3) and COPD (Fig. 30.6).

## SUMMARY

The precise inflammatory pathways and cells, NOS enzyme isoforms, and anatomical compartments responsible for production of the NO captured in the expirate are areas of active investigation (Fig. 30.7).

There are two interlinked and equally important future areas of NO research: exploring further potential and prevalent sources of NO and its role in different diseases and the use of NO in clinical medicine, including home measurements and routine asthma monitoring.

## INTRODUCTION

Inflammation is a central feature of asthma and chronic obstructive pulmonary disease (COPD). The specific characteristics of the inflammatory response in each disease and the site of inflammation differ, but both involve the recruitment and activation of inflammatory cells and changes in the structural cells of the lung [1]. Asthma and COPD are characterized by an increased expression of components of the inflammatory cascade. These inflammatory proteins include cytokines, chemokines, growth factors, enzymes, receptors, and adhesion molecules [2]. The increased expression of these proteins seen in asthma and COPD is the result of enhanced gene transcription since many of the genes are not expressed in normal cells but are induced in a cell-specific manner during the inflammatory process [2].

Changes in gene transcription are regulated by transcription factors, which are proteins that bind to DNA and modulate the transcriptional apparatus. Transcription factors regulate the expression of many genes, including inflammatory genes, and may play a key role in the pathogenesis of asthma and COPD since they regulate the increased gene expression that may underlie the acute and chronic inflammatory mechanisms that characterize these diseases [1, 3]. Transcription factors may amplify and perpetuate the inflammatory process, so it is possible that abnormal functioning of transcription factors may determine disease severity and response to treatment. The increased understanding of the role of transcription factors in the pathogenesis of asthma and COPD has also opened an opportunity for the development of new potential anti-inflammatory drugs [4].

Several new compounds based on interacting with specific transcription factors or their activation pathways are now in development for the treatment of asthma and COPD, and some drugs already in clinical use (such as glucocorticoids) are thought to work via transcription factors. Glucocorticoids are effective therapy in the long-term control of asthma. One of their mechanisms of action in asthmatic airways is by inhibiting the action of transcription factors that regulate inflammatory gene expression [5]. Glucocorticoids may also have a beneficial effect in COPD during exacerbations, although this is less marked than in asthma, indicating that different genes and transcription factors are involved and emphasizing the importance of cell-specific transcription factors.

One concern about this approach is the specificity of such drugs, but it is clear that transcription factors have selective effects on the expression of certain genes and this may make it possible to be more selective. In addition, there are cell-specific transcription factors that may be targeted for inhibition, which could provide selectivity of drug action. One such example is GATA3, which has been reported to have a restricted cellular distribution [6]. In asthma and COPD it may be possible to target drugs to the airways by inhalation, as is currently performed for inhaled glucocorticoids, to systemic effects.

Despite the fact that many transcription factors have now been discovered there is still a paucity of data concerning the regulation of transcription factors in the human lungs. This chapter briefly reviews the physiological function of the transcription factors in the normal cells and the role of some transcription factors that may be relevant in the pathogenesis of asthma and COPD.

# TRANSCRIPTION FACTORS

Transcription factors are proteins that bind to DNA-regulatory sequences (enhancers and silencers), usually localized in the 5′-upstream region of target genes, to modulate the rate of gene transcription. This may result in increased or decreased gene transcription, protein synthesis, and subsequent altered cellular function. Many transcription factors have now been identified and a large proportion of the human genome appears to code for these proteins.

Several families of transcription factors exist and members of each family may share structural characteristics. These families include

- helix-turn-helix (e.g. Oct-1),
- helix-loop-helix (e.g. E2A),
- zinc finger (e.g. glucocorticoid receptors, GATA proteins),
- basic protein-leucine zipper [cyclic AMP response element-binding factor (CREB), activator protein-1 (AP-1)],
- β-sheet motifs [e.g. nuclear factor-κB (NF-κB)] [4, 7] (Table 31.1).

Many transcription factors are common to several cell types (ubiquitous), such as AP-1 and NF-κB, and may play a general role in the regulation of inflammatory genes, whereas others are cell-specific and may determine the phenotypic characteristics of a cell. Transcription factor activation is complex and may involve multiple intracellular signal transduction pathways, including the kinases PKA, MAPKs, JAKs, and PKCs, stimulated by cell-surface receptors [8, 9]. Transcription factors may also be directly activated by ligands such as glucocorticoids and vitamins A and D [5]. Transcription factors may therefore convert transient environmental signals at the cell surface into long-term changes in gene transcription, thus acting as "nuclear messengers." Transcription factors may be activated within the nucleus, often with the transcription factor already bound to DNA, or within the cytoplasm, resulting in exposure of nuclear localization signals and targeting to the nucleus [5]. It is becoming clear that post-translational modifications of transcription factors by phosphorylation, acetylation, and nitration can have profound effects on either the DNA-binding capacity or the transcriptional activity of a transcription factor [10]. This is exemplified by changes in p65 NF-κB phosphorylation and acetylation which alter its association with transcriptional coactivator and repressor complexes resulting in changes in gene expression profile [11–13].

## Cross-talk

One of the most important concepts to have emerged is the demonstration that transcription factors may physically interact with each other to form homodimers or heterodimers, resulting in inhibition or enhancement of transcriptional activity at a site distinct from the consensus target for a particular transcription factor (Fig. 31.1). This then allows cross-talk between different signal transduction pathways at the level of gene expression. Generally it is necessary to have coincident activation of several transcription factors in order to have maximal gene expression. This may explain how transcription factors that are ubiquitous may regulate particular genes in certain types of cells [4, 10].

The complexity of the activation pathways and their ability to engage in cross-talk enables cells to overcome inhibition of one pathway and retain a capacity to activate specific transcription factors. This cross-talk and redundancy may also hinder the search for novel anti-inflammatory agents targeted toward transcription factor activation. Binding of transcription factors to their specific binding motifs in the promoter region may alter transcription by interacting directly with components of the basal transcription apparatus or via cofactors that link the transcription factor to the basal transcription apparatus [14]. Large proteins that bind to the basal transcription apparatus bind many transcription factors and thus act as integrators of gene transcription. These coactivator molecules include CREB-binding protein (CBP), and the related p300, thus allowing complex interactions between different signaling pathways [14].

## Histone acetylation

DNA is wound around histone proteins to form nucleosomes and the chromatin fiber in chromosomes [15]. It has long been recognized at a microscopic level that chromatin may become dense or opaque owing to the winding or unwinding of DNA around the histone core [16]. CBP, p300, and other coactivators have histone acetylase activity (HAT) which is activated by the binding of transcription factors, such as AP-1, NF-κB, and STATs (Fig. 31.2) [14, 15]. Acetylation of histone residues results in unwinding of DNA coiled around the histone core, thus opening up the chromatin structure, allowing increased transcription. Histone deacetylation by specific histone deacetylases (HDACs) reverses this process, leading to gene repression [17].

**TABLE 31.1** Transcription factor families involved in the pathogenesis of asthma and COPD.

| GR | NFATs |
|---|---|
| NF-κB | GATA |
| AP-1 | HIF-1 |
| CREB | C/EBP |
| STATs | SP1 |

GR: glucocorticoids receptor; NF-κB: nuclear factor-kappa B; AP-1: activator protein 1; CREB: cyclic AMP response element binding protein; STATs: signal transducers and activators of transcription; NFATs: nuclear factors of activated T cells; GATA: GATA binding proteins; HIF-1: hypoxia-inducible factor-1; C/EBP: CAAT/enhancer-binding protein; SP1: specificity protein 1.

**FIG. 31.1** Multiple pathways mediating transcription factor modulation of inflammatory genes, (A) Inflammatory mediator signal transduction activation. The binding of cytokines, growth factors, or chemokines to their respective receptors sets in train the activation of a number of signal transduction pathways, including the receptor tyrosine kinases, mitogen-activated protein kinases (MAPKs including MEKK1 and JNK), Janus kinases (JAKs), and other kinase pathways involved in NF-κB activation. Activation of nuclear factor-κB involves phosphorylation of the inhibitory protein IκB by specific kinase(s), with subsequent ubiquitination and proteolytic degradation by the proteasome. The free NF-κB then translocates to the nucleus, where it binds to κB sites in the promoter regions of inflammatory genes. Activation of the IκB gene results in increased synthesis of IκB to terminate the activation NF-κB. (B) JAK-STAT pathways. Cytokine binding to its receptor results in activation of JAK which phosphorylate intracellular domains of the receptor, resulting in phosphorylation of signal transduction-activated transcription factors (STATs). Activated STATs dimerize and translocate to the nucleus where they bind to recognition elements on certain genes. (C and D) Nuclear factor of activated T-cells (NF-AT) is activated via dephosphorylation by calcineurin (CaN) and translocates to the nucleus where it interacts with AP-1 to induce gene transcription. (E) Classical mechanism of steroid action. Glucocorticoids are lipophilic molecules which diffuse readily through cell membranes to interact with cytoplasmic receptors. Upon ligand binding receptors are activated and translocate into the nucleus where they bind to specific DNA elements. The foregoing pathways can interact so that the final signal may be amplified or altered depending upon the exact combination of stimuli. The final response to each stimulus or combination of stimuli by a particular cell depends upon the receptors present in a particular cell along with the exact intracellular transduction pathway activated.

**FIG. 31.2** Histone acetylation by proinflammatory transcription factors. In response to stress and other stimuli, such as cytokines, various second messenger systems are upregulated, leading to activation of signal-dependent transcription factors such as CREB, NF-κB, AP-1, and STAT proteins. Binding of these factors leads to recruitment of CBP and/or other coactivators to signal-dependent promoters and acetylation of histones by an intrinsic acetylase activity (HAT). Induction of histone acetylation allows the formation of a more loosely packed nucleosome structure which enables access to TATA box-binding protein (TBP) and associated factors (TAFs) and the recruitment of further remodeling factors including switch/sucrose nonfermentable (SWI/SNF). Remodeling thereby allows RNA polymerase II recruitment and the activation of inflammatory gene transcription.

## TRANSCRIPTION FACTORS IN ASTHMA

Asthma is a complex chronic inflammatory disease of the airways that involves the activation of many inflammatory and structural cells, all of which release inflammatory mediators that result in the typical clinicopathological changes of asthma. The chronic airway inflammation of asthma is unique in that the airway wall is infiltrated by T-lymphocytes of the T-helper (Th) type 2 phenotype, eosinophils, macrophages/monocytes, and mast cells. In addition, an "acute-on-chronic" inflammation may be observed during exacerbations, with an increase in eosinophils and sometimes also neutrophils [5].

### The role of transcription factors in differentiation of Th1/Th2 cells

CD4$^+$ T-helper (Th) cells can be divided into three major subsets, termed Th1, Th2, and Th0 based on the pattern of cytokines they produce [18]. Th1 cells produce predominantly IL-2 and interferon gamma (IFN-γ) and predominantly promote cell-mediated immune responses. Th2 cells, which
**FIG. 31.3** Differentiation of T-cell subtypes depends upon the action of a number of transcription factors. Th0 cells can differentiate into Th1 and Th2 cells following IL-12 or IL-4 stimulation. Stimulation through the IL-12 receptor (IL-12) activates the transcription factor STAT4 and the MAPK pathways JNK2 and p38 and drives Th1 cell differentiation, leading to cells capable of releasing IFN-γ. In contrast, activation of the IL-4R in concert with T-cell receptor (TCR) stimulation leads to activation of the transcription factors STAT6, GATA3, c-Maf, and NFATc1, and drives Th2 cell differentiation. Th2 cells can release a number of cytokines including interleukins 4, 5, 6, 9, 10, and 13. In addition, activation of JNK1, NFATc2, and NFATc3 can prevent Th2 cell differentiation.

produce mainly interleukins (IL-4, IL-5, and IL-13), augment certain B-cell responses. IL-4 in particular is the major inducer of B-cell switching to immunoglobulin E (IgE) production, and therefore plays a crucial role in allergic reactions involving IgE and mast cells. Th cells producing cytokines typical of both Th1 and Th2 clones have also been described and they have been named Th0 [1].

Evidence indicates that Th1 and Th2 cells differentiate from a common precursor, naive T-cells. This appears to be a multistep process, in which naive T-cells pass through an intermediate stage (Th0) at which both Th1 and Th2 cytokines are produced (Fig. 31.3). Transcription factors, including GATA3, T-bet, c-maf, and STAT6, are involved in the molecular mechanisms by which Th1 and Th2 cells differentially express the Th1 and Th2 cytokines [19, 20] and that this may have differing consequences on subepithelial fibrosis, airway smooth muscle hyperplasia and mucus hyperplasia as a consequence of effects on TGF-β and CCL11 expression [21]. However, most of these studies were conducted on murine T-cells, and the situation in human T-cells, in physiological and pathological conditions (e.g. bronchial asthma) remain largely unknown. A key role for regulatory T-cells (e.g. Treg and Th-17) has also been proposed in asthma, particularly in those patients with severe disease [22, 23]. Production of the Treg phenotype is associated with the transcription factor Foxp3 whose DNA binding to gene promoters has recently been mapped [24] and whose activity is also dependent upon NF-AT [25].

## Determination of asthma severity

Activation of NF-κB leads to the coordinated induction of multiple genes that are expressed in inflammatory and immune responses. Many of these genes are induced in inflammatory and structural cells and play an important role in the inflammatory process.

### NF-κB

While NF-κB is not the only transcription factor involved in regulation of the expression of these genes, it often appears to have a decisive regulatory role. NF-κB often functions in cooperation with other transcription factors, such as AP-1 and C/EBP, which are also involved in regulation of inflammatory and immune genes [10, 26]. Genes induced by NF-κB include those for the proinflammatory cytokines IL-1β, TNF-α, and GM-CSF and the chemokines IL-8, macrophage inflammatory protein-1α (MIP-1α), macrophage chemotactic protein-1 (MCP-1), RANTES, and eotaxins, that are largely responsible for attracting inflammatory cells into sites of inflammation [4, 7]. NF-κB also regulates the expression of inflammatory enzymes, including the inducible form of nitric oxide synthase ($NOS_2$) that produces large amounts of nitric oxide (NO). NF-κB also plays an important role in regulating expression of adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1), that are expressed on endothelial and epithelial cells at inflammatory sites and play a key role in the initial recruitment of inflammatory cells [4, 7].

Data also suggest that NF-κB may be activated by many of the stimuli that exacerbate asthmatic inflammation (e.g. rhinovirus infection, allergen exposure, proinflammatory cytokines, and oxidants) [27–29]. There is also evidence for activation of NF-κB in bronchial epithelial and sputum cells of patients with asthma [30]. NF-κB is an amplifying and perpetuating mechanism that exaggerates the disease-specific inflammatory process through the coordinated activation of multiple inflammatory genes. The degree of NF-κB phosphorylation and acetylation in asthma is unknown as is the specific transcriptome associated with each modified NF-κB [10]. Inhibitors of the controlling kinase (Inhibitor of κB kinase 2, IKK2) are in clinical development for asthma and other inflammatory diseases with the hope of achieving as good an anti-inflammatory effect as glucocorticoids without the side effects [31].

### AP-1

AP-1 is a collection of related transcription factors belonging to the Fos (c-Fos, FosB) and Jun (c-Jun, JunB, JunD) families which dimerize in various combinations through their leucine zipper region. Fos/Jun form heterodimers with high affinity and are the predominant form of AP-1 in most cells, whereas Jun/Jun homodimers bind with low affinity and are less abundant [32]. AP-1 may be activated by various cytokines, including TNF-α and IL-1β, via several types of protein tyrosine kinase (PTK) and mitogen-activated protein (MAP) kinases in particular JUN-N-terminal kinase (JNK), which themselves activate a cascade of intracellular kinases [9]. AP-1, like NF-κB, regulates

many of the inflammatory and immune genes that are over-expressed in asthma. Indeed many of these genes require the simultaneous activation of both transcription factors that work together cooperatively. There is evidence for increased expression of c-Fos in bronchial epithelial cells in asthmatic airways [33] and an even greater expression in patients with severe, treatment-insensitive asthma [34, 35], and many of the stimuli relevant to asthma that activate NF-κB will also activate AP-1. Inhibitors of JNK are being developed [32] and these show good effectiveness against bronchial hyper-responsiveness, bronchoalveolar lavage (BAL) inflammatory cells, and airway remodeling in animal models of asthma [36]. Interestingly, JNKs are also involved in T-cell class switching and their inhibitors may also have a profound immunomodulatory role [32].

### STATs and other transcription factors

Signal transduction-activated transcription factor-6 (STAT6) also provides a target as a potential treatment for allergic asthma. STAT6 knockout mice have no response to IL-4, do not develop Th2 cells in response to IL-4, and fail to produce IgE, bronchial hyperresponsiveness, or BAL eosinophilia after allergen sensitization indicating the critical role of STAT6 in allergic responses [37]. STAT6 has been reported to be overexpressed in bronchial biopsies from asthmatic patients [38]. In addition, evidence exists for enhanced expression of STAT1 in the airways of asthmatic, but not of COPD subjects [39]. Indeed, decoy oligonucleotides against STAT1 are in early clinical development for asthma [40].

Cyclosporin has been used as an immunomodulator for many years although its side effect profile limits its utility in asthma [1]. Its target is cyclophilin which controls the dephosphorylation of NF-AT (nuclear factor of activated T-cells) and thereby the expression of key Th2 cytokines including IL-13 [4, 7].

Sp1 is a ubiquitous transcription factor that binds to GC-boxes and related motifs, which are frequently occurring DNA elements present in many promoters and enhancers. Modification of these sites within the IL-10 and IL-4 and the 5-lipoxygenase promoters has been associated with altered expression of these genes in distinct patient groups [41, 42].

### Transcription factors and glucocorticoid action

Glucocorticoids belong to the family of nuclear steroid hormone receptors and are important anti-inflammatory agents used in the treatment of chronic inflammatory diseases such as asthma [5]. Functionally they act by suppressing airway hyperresponsiveness, reducing airway edema and the infiltration of inflammatory cells from the blood to the airway and thereby reducing the airway inflammatory response [5]. Glucocorticoid receptors (GR) are predominantly localized to the airway epithelium, alveolar macrophages and endothelium [5], which are, therefore, probably important sites for the anti-inflammatory action of steroids, especially those delivered by the inhaled route. Airway epithelial cells

**FIG. 31.4** The actions of the dexamethasone/GR complex on inhibition of IL-1β-stimulated histone acetylation. DNA-bound p65 induces histone acetylation via activation of CBP and a CBP-associated HAT complex to occur. This causes local unwinding of DNA and increased gene transcription. GR, acting as a monomer, interacts with CBP causing an inhibition of CBP-mediated HAT activity. In addition, GR also recruits HDAC2 to the p65/CBP complex, further reducing local HAT activity, leading to enhanced nucleosome compaction and repression of transcription.

act as important regulators of the inflammatory reaction, responding to various inflammatory mediators, such as cytokines, by the production of a wide range of cytokines, chemokines, and other inflammatory mediators [5].

Glucocorticoids bind to and activate a cytosolic receptor (GR) which then translocates to the nucleus. Within the nucleus two GR subunits form a dimer and bind to specific DNA elements (glucocorticoid response elements or GREs) in the promoter regions of glucocorticoid-responsive genes, resulting in modulation of transcription [5]. Several genes are upregulated by glucocorticoids, including the $\beta_2$-receptor, MAPK phosphatase (MKP1), and serum leukoprotease inhibitor (SLPI). However, in inflammation the major role of glucocorticoids appears to be gene repression. Evidence accumulated over the past few years has suggested that a major mechanism of glucocorticoids is repression of the actions of AP-1 and NF-κB [5].

The major effect of glucocorticoids is on gene transcription although actions on mRNA stability do occur with specific genes under the control of MKP-1 [43]. Several molecular mechanisms for the suppressive actions of the activated GR on NF-κB-mediated gene transcription have been proposed, but it is likely that a combination of inhibition of histone H4 acetylation on lysines 8 and 12 induced by inflammatory mediators, such as IL-1β and TNF-α, lead to changes in the ability of RNA polymerase II to transcribe mRNA [5, 44–46]. This effect on histone acetylation is achieved by a direct inhibition of CBP-associated histone acetylation and by recruitment of HDAC2 to the activated DNA-bound NF-κB complex [44] (Fig. 31.4). Of interest is that oxidative stress that modulates HDAC activity is able to markedly alter the expression of some inflammatory mediators and reduce glucocorticoid responsiveness [47]. We have recently reported that the expression of HDAC2 is reduced in the lung of patients with COPD [48] and that overexpression of HDAC2 restores glucocorticoid sensitivity in BAL macrophages from these patients [49]. The failure of glucocorticoids to regulate proopiomelanocortin (POMC)

expression in Cushing's disease has also been related to a lack of HDAC2 [46] and targeting of these enzymes may provide another novel target for future drug discovery.

Glucocorticoids are able to activate the expression of a number of anti-inflammatory genes due to GR binding to specific GREs in the promoter regions of responsive genes [5]. This is often in conjunction with other transcription factors and activation of CAAT/enhancer-binding protein (C/EBP$\alpha$) by long-acting $\beta_2$-agonists in airway smooth muscle cells has been proposed to account, at least in part, for the enhanced effect of combination treatment in asthmatic patients [50]. Loss of C/EBP$\alpha$ expression in some asthmatic patients may account for steroid effectiveness in these subjects [50].

A very small number of asthmatic patients are steroid-resistant and fail to respond to even high doses of oral glucocorticoids (so called steroid-resistant asthma). This defect is also present in their peripheral blood mononuclear cells (PBMCs) and T-lymphocytes [35]. Although ligand binding data show no change in GR number in these patients, immunocytochemistry indicates a reduced GR nuclear translocation which may account for the reduced binding to DNA seen in these patients [51]. Altered nuclear translocation is affected by GR phosphorylation status [52], which may also be a target for long-acting $\beta$-agonists [5]. In the same patients there is a reduced inhibitory effect of glucocorticoids on AP-1 activation, but not on NF-$\kappa$B. Furthermore, there is an increase in the baseline activity of AP-1 which appears to be due to excessive activation of JNK [53, 54]. This resistance will be seen at the site of inflammation where AP-1 is activated but not at uninflamed sites. This may explain why patients with steroid-resistant asthma are not resistant to the endocrine and metabolic effects of glucocorticoids, and thus develop the drug's systemic side effects.

## TRANSCRIPTION FACTORS IN COPD

In contrast to the enormous increase in our understanding of the pathogenesis of asthma, less is known about the molecular pathogenesis of COPD [55].

## Transcription factors and disease susceptibility

The etiology of COPD appears to be due to interactions between environmental factors (particularly cigarette smoking) and genetic factors. Chronic heavy cigarette smoking is currently the cause of more than 90% of cases of COPD in Westernized countries, so environmental factors are clearly very important. However, it is important to identify the factors that determine why only 15–20% of chronic heavy cigarette smokers develop symptomatic COPD [55]. So far, this is little understood, although it is likely that genetic factors are important. There is convincing evidence that several genes influence the development of COPD. In a complex polygene disease such as COPD, it is likely

that multiple genes are operating and that the influence of each gene in isolation may be relatively weak. The susceptibility to develop COPD with smoking is likely to depend on the coincidence of several gene polymorphisms that act together [55].

The only clearly established, but rare, genetic risk factor for COPD is $\alpha_1$-antitrypsin deficiency ($\alpha_1$-AT) [56]. Approximately 95% of cases of clinical $\alpha_1$-AT deficiency are caused by a single amino acid substitution at position 342 (lysine for glutamic acid) in the coding region of the $\alpha_1$-AT gene (Z allele). This genotype is uncommon, but a Taq1 polymorphism in the 3'-flanking region of the $\alpha_1$-AT gene has been reported to be present in 18% of COPD patients but in only 5% of the general population in the United Kingdom [56]. Although this mutation is not associated with an abnormal $\alpha_1$-AT protein expression, this genetic variant is within an enhancer sequence (which contains C/EBP-binding sites) and may impair the acute-phase increase in $\alpha_1$-AT gene expression in response to IL-6 [57].

## Transcription factors and clinical manifestations of COPD

The chronic airflow obstruction in tobacco smoking-related COPD results from a combination of airway disease, which particularly affects small airways, and loss of lung elasticity because of destruction of the lung parenchyma. The modulation of the inflammatory response in COPD by genetic factors associated with transcription factors may, in part, cause of the different clinical phenotypes of patients with COPD [4]; however, it is clear that COPD patients have marked inflammation, which increases with disease stage [58]. Patients with COPD are reported to have increased activation of NF-$\kappa$B in sputum and lung tissue macrophages and bronchial epithelial cells [59–61]. The activation status of NF-$\kappa$B and its repression by glucocorticoids may also be affected by altered expression of HDAC2 [48, 49] and of the protein deacetylase sirtuin (SIRT1) [62].

Hogg and colleagues [58] were able to show that the mRNA expression of the transcription factors early growth response (Egr)-1 and c-Fos were increased in bronchial biopsies and that exposure of fibroblasts to cigarette smoke enhanced Egr-1 expression [63]. This results in subsequent induction of MMP2 expression *in vitro* and *in vivo* [64]. In contrast to the tissue destruction seen in the alveoli in COPD patients, the small airways are characterized by fibrosis and increased smooth muscle. Activation of Smad factors by growth factors, such as TGF$\beta$, may be important in this process and Smad3 knockout mice develop emphysema [65]. In addition, expression of the inhibitory Smad7 is reduced in epithelial cells of COPD (Global Initiative for Chronic Obstructive Lung Disease, GOLD stage II) patients [66].

In contrast to asthma, where C/EBP$\alpha$ is abnormally expressed, Borger and colleagues have reported a reduction of C/EBP$\delta$ in patients with COPD [67]. Activation of STAT4 is critical for the differentiation of Th1/Tc1 cells T-cells and the production of IFN-$\gamma$ [68]. We have reported increased expression of activated phospho-STAT4 in bronchial biopsies and BAL lymphocytes of COPD patients and

that this correlated with the degree of airflow obstruction and the number of IFN-$\gamma^+$ cells. In contrast, T-bet expression was not altered [68].

Recently it has been suggested that in patients with COPD and symptoms of chronic bronchitis there is an increased prevalence of a common polymorphism in the 5'-flanking region of the TNF-$\alpha$ gene, which was previously found to be associated with high baseline and induced TNF-$\alpha$ expression [69]. Unfortunately, recent results indicate that anti-TNF$\alpha$ therapy is ineffective in COPD [70].

## CONCLUSION

In the future the role of transcription factors and the genetic regulation of their expression in asthma and COPD may be an increasingly important aspect of research, as this may be one of the critical mechanisms regulating the expression of clinical phenotypes and their responsiveness to therapy. Despite recent advances in the knowledge of the pathogenesis of asthma and COPD, much more research on the molecular mechanisms of asthma and COPD are needed to aid the logical development of new therapies for these common and important diseases, particularly in COPD where no effective treatments currently exist.

## INTRODUCTION

Airway nerves and circulating hormones regulate the caliber of the airways and have an influence on airway smooth muscle tone, airway blood flow, and mucus secretion. They may also influence the inflammatory process and play an integral role in host defense. There is increasing evidence that neural and humoral mechanisms may play a role in the pathophysiology of asthma and COPD, and several of the treatments used interact with neural or humoral control.

## NEURAL CONTROL

### Overview of airway innervation

Neural control of airway function is complex and many neurotransmitters are autonomic receptors are involved. Three types of airway nerve are recognized:

1. parasympathetic nerves which primarily release acetylcholine (ACh)
2. sympathetic nerves which primarily release norepinephrine (noradrenaline)
3. afferent (sensory nerves) whose primary transmitter is glutamate.

In addition to these classical transmitters, multiple neuropeptides have now been localized to airway nerves and may have potent effects on airway function [1]. All of these neurotransmitters act on autonomic receptors that are expressed on the surface of target cells in the airway. It is increasingly recognized that a single transmitter may act on several subtypes of receptor, which may lead to different cellular effects mediated via different second messenger systems.

Several neural mechanisms are involved in the regulation of airway caliber and abnormalities in neural control may contribute to airway narrowing in disease (Fig. 32.1). Neural

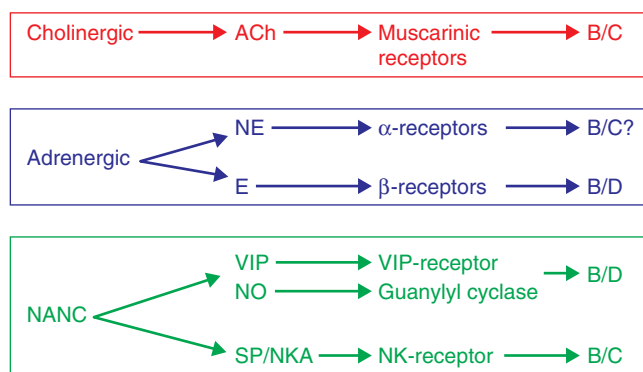

**FIG. 32.1** Autonomic control of airway smooth muscle tone. Neural mechanisms resulting in bronchoconstriction (B/C) and bronchodilatation (B/D). Ach: acetylcholine; NE: norepinephrine; E: epinephrine; VIP: vasoactive intestinal peptide; NO: nitric oxide; i-NANC: inhibitory non-adrenergic non-cholinergic nerves; e-NANC: excitatory non-adrenergic non-cholinergic nerves; NK: neurokinin.

mechanisms are involved in the pathophysiology of asthma and COPD, contributing to the symptoms, and possibly to the inflammatory response [2]. There is a close interrelationship between inflammation and neural responses in the airways, since inflammatory mediators may influence the release of neurotransmitters via activation of sensory nerves leading to reflex effects and via stimulation of pre-junctional receptors that influence the release of neurotransmitters [3]. In turn, neural mechanisms may influence the nature of the inflammatory response, either reducing inflammation or exaggerating the inflammatory response. Neuroimmune interactions in asthma are increasingly recognized, particularly the role of neurotrophins released from inflammatory and immune cells in the airways [4].

## Neural interactions

Complex interactions between various components of the autonomic nervous system are now recognized. Adrenergic nerves may modulate cholinergic neurotransmission in the airways and sensory nerves may influence neurotransmission in parasympathetic ganglia and at post-ganglionic nerves. This means that changes in the function of one neural pathway may have effects on other pathways.

## Co-transmission

Almost every nerve contains multiple transmitters. Thus airway parasympathetic nerves, in which the primary transmitter is ACh, also contain the neuropeptides vasoactive intestinal polypeptide (VIP), peptide histidine isoleucine/methionine (PHI/M), pituitary adenylyl cyclase activating peptide (PACAP), helodermin, galanin, and neuronal nitric oxide synthase (Fig. 32.2). These co-transmitters may have

**FIG. 32.2** Neurotransmitters and co-transmitters in airway nerves. SP: substance P, NKA: neurokinin A, CGRP: calcitonin gene-related peptide, VIP: vasoactive intestinal peptide, PHI/PHM/PHV: peptide histidine isoleucine/methionine/valine, PACAP: pituitary adenylate cyclase activating peptide, NPY: neuropeptide Y.

either facilitatory effects or antagonistic effects on target cells, or may influence the release of the primary transmitter via pre-junctional receptors. Thus VIP modulates the release of ACh from airway cholinergic nerves. Sympathetic nerves, which release noradrenaline, may also release neuropeptide Y (NPY) and enkephalins, whereas afferent nerves may contain a variety of peptides including substance P (SP), neurokinin A (NKA), calcitonin gene-related peptide (CGRP), galanin, VIP, and cholecystokinin.

The physiological role of neurotransmission may be in "fine tuning" of neural control. Neuropeptides may be preferentially released by high frequency firing of nerves, and their effects may therefore only become manifest under condition of excessive nerve stimulation. Neuropeptide neurotransmitters may also act on target cells different from the primary transmitter, resulting in different physiological effects. Thus in airways ACh causes bronchoconstriction, but VIP which is co-released may have its major effect on bronchial vessels, thus increasing blood flow to the airways. In chronic inflammation the role of co-transmitters may be increased by alterations in the expression of their receptors or by increased synthesis of transmitters via increased gene transcription.

## SENSORY NERVES

The sensory innervation of the respiratory tract is mainly carried in the vagus nerve. The neuronal cell bodies are localized to the nodose and jugular ganglia and input to the solitary tract nucleus in the brain stem. A few sensory fibers supplying the lower airways enter the spinal cord in the upper thoracic sympathetic trunks, but their contribution to respiratory reflexes is minor and it is uncertain whether they are represented in humans. There is a tonic discharge of sensory nerves that has a regulatory effect on respiratory function and also triggers powerful protective reflex mechanisms in response to inhaled noxious agents, physical stimuli, or certain inflammatory mediators.

At least three types of afferent fiber have been identified in the lower airways [5] (Fig. 32.3). Most of the information on their function has been obtained from studies in anesthetized animals, so it is difficult to know how much of the information obtained in anesthetized animals can be extrapolated to human airways.

## Slowly adapting receptors

Myelinated fibers associated with smooth muscle of proximal airways are probably slowly adapting (pulmonary stretch) receptors (SARs) that are involved in reflex control of breathing. Activation of SARs reduces efferent vagal discharge and mediates bronchodilatation. During tracheal constriction the activity of SARs may serve to limit the bronchoconstrictor response. SARs may play a role in the cough reflex since when these receptors are destroyed by high concentration of $SO_2$ the cough response to mechanical stimulation is lost.
