Preface

The first edition of this book volume was published in 1992, and the second edition in 1999 by Marcel Dekker, Inc., New York. Since then, volumes of new information on the fatty acids in various foods and food products, as well as their biological health effects have become available. In addition to quantity, the type of fatty acids consumed plays an important role in the etiology of a variety of degenerative diseases, including cardiovascular disease, cancer, immunity and inflammatory disease, renal disease, diabetes, neuromuscular disorders, liver disease, visual dysfunction, psychiatric disorders, and aging. Understanding the mechanisms by which fatty acids exert their biological effects is important in unraveling the pathogenesis of these disorders, and may help providing effective preventive measures.

Both animal- and plant-derived food products contain fat. Food fat provides taste, consistency, and helps us feel full. Fat is a major source of energy for the body, and aids in the absorption of lipid soluble substances including vitamins A, D, E, and K. Dietary fat is essential for normal growth, development, and maintenance, and serves a number of important functions. Increasing evidence indicates that fatty acids and their derived substances may mediate critical cellular events, including activation and expression of genes, and regulation of cellular signaling.

New reports or findings dealing with the health effects of various fatty acids have always commanded a strong public interest. In recent years, omega-3 and *trans* fatty acids have received more attention than others. On September 8, 2004, the Food and Drug Administration announced the availability of a qualified health claim for reduced risk of coronary heart disease on conventional foods that contain omega-3 fatty acids, eicosapentaenoic acid, and docosahexaenoic acid. While these fatty acids are not essential to the diet, scientific evidence indicates that these fatty acids may be beneficial in reducing coronary heart disease. On the other hand, recent scientific reports, expert panels, and studies concluded that consumption of *trans* fatty acids contributes to increased low-density lipoprotein cholesterol levels, which increase the risk of coronary heart disease. The Food and Drug Administration's final rule on *trans* fatty acids (or *trans* fat) requires manufacturers to list the amount of *trans* fat per serving on a separate line under saturated fat on the Nutrition Facts panel. As of January 1, 2006, food manufacturers must list the content of *trans* fat on the nutrition label. The health effects of α-linolenic acids and conjugated linoleic acid have also received considerable recent attention.

In recent decades, the prevalence of obesity or overweight has increased steadily in the United States and elsewhere. Currently over 40% of the adult population in the United States are considered as overweight or obese. Obesity is an important risk factor contributing to the development of the three leading causes of death—cardiovascular disease, cancer, and diabetes—and other disorders in the United States. As fat has much higher energy density than that of protein and carbohydrate, dietary fat is often blamed as the source of excess energy, although it is difficult to differentiate the effects of dietary fat and other energy nutrients independent of total energy intake. Evaluating trends in energy nutrient intake is useful in understanding the role of individual energy nutrients in the development of obesity and obesity-related illness over time. Also, investigation of the role of fatty acids in satiating effect and energy homeostasis is important in understanding food intake and energy balance issues.

Partly owing to the high-energy density, concerns over health problems associated with obesity and overweight have led to the development of several fat substitutes. The rapid advance in molecular biology and biotechnology has allowed for selective alteration of fatty acid composition in oil crops. It is now possible to commercially produce oil crops that contain a desirable proportion of specific fatty acids. Owing to distinct biological and health effects of various fatty acids, manipulation of the lipid composition in oil crops is likely to impact our well-being and economy enormously.

In addition to updating original chapters on the basis of available recent information, the following new chapters are added to cover the subject areas that were not covered or not adequately

covered in the second edition: Fatty Acids in Fermented Food Products (Chapter 13), Effect of Heating and Frying on Oil and Food Fatty Acids (Chapter 20), Consumption of Fatty Acids (Chapter 21), Significance of Dietary γ-Linolenate in Biological Systems: Alternation of Inflammation and Proliferative Process (Chapter 32), Biological Effects of α-Linolenic Acid (Chapter 33), Biological Effects of Conjugated Linoleic Acid (Chapter 34), The Role of Omega-3 Polyunsaturated Fatty Acids in Food Intake and Energy Homeostasis (Chapter 35), and Fatty Acid and Cognition, Behavior and Brain Development, and Mood Disease (Chapter 39). Also, the following chapters were completely rewritten: Fatty Acids in Meat and Meat Products (Chapter 5), Fatty Acids in Milk Fat (Chapter 6), The Effects of Dietary Fatty Acids in Fatty Acid Metabolism (Chapter 23), Dietary Fatty Acids and Eicosanoids (Chapter 28), Fatty Acids and Aging (Chapter 40), and Essential Fatty Acids and Visual Dysfunction (Chapter 43). At the same time, several chapters that appeared in the second edition were not included in the third edition.

This updated and expanded book volume presents the current status of fatty acids in common foods and food products. It also aims to provide readers with state-of-the-art information on the widely diversified health implications of fatty acids. However, as the precise role of fatty acids in the etiology of various degenerative disorders is yet to be delineated, it is not the intention of this book volume to present a unified view on the health implications of fatty acids or to provide guidelines for fatty acid consumption.

I would like to express my sincere appreciation to all the authors of this book volume for their cooperation and excellent contributions. Without their participation and efforts this project would not be a reality. Also, I would like to thank Susan Lee and Amber Donley of Taylor & Francis for their assistance and support during the course of the project. Finally I wish to thank my wife Shukwei for her understanding and patience over the past many years.

1 Fatty Acid Classification and Nomenclature

Kelly Lobb and Ching Kuang Chow

CONTENTS

I. INTRODUCTION

Fats or lipids consist of numerous chemical compounds, including monoglycerides, diglycerides, triglycerides, phosphatides, cerebrosides, sterols, terpenes, fatty alcohols, and fatty acids. Fatty acids constitute the main component of phospholipids, triglycerides, diglycerides, monoglycerides, and sterol esters. Fatty acids consist of elements, such as carbon, hydrogen, and oxygen, that are arranged as a linear carbon chain skeleton of variable length with a carboxyl group at one end. Fatty acids can be saturated (no double bond), monounsaturated (one double bond), or polyunsaturated (two or more double bonds), and are essential for energetic, metabolic, and structural activities.

Food scientists, nutritionists, biochemists, chemists, and biomedical scientists alike recognize the need for a coherent nomenclature for fatty acids. There are a number of nomenclature systems for fatty acids, and some researchers continue to name fatty acids traditionally on the basis of the names of the botanical or zoological species from which they are isolated. Such naming system provides no clue as to the structure of fatty acids. The International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Biochemistry (IUB) attempted to deal with this problem by setting up two nomenclature committees, the IUB-IUPAC Joint Commission of Biochemical Nomenclature (JCBN) and the Nomenclature Committee of IUB (NC-IUB). IUPAC states definitive rules of nomenclature for organic chemistry (1960) and lipids (1978), Markely (1960) presents a historical review of chemical nomenclature, and Fletcher et al. (1974) discuss the origin and evolution of organic nomenclature. Other excellent reference sources for fatty acid classifications and nomenclatures include Fahy et al. (2005), Fasman (1989), Gunstone (1996, 1999), Gunstone et al. (1992), Gunstone and Herslof (1992), Hopkins (1972), and Robinson (1982).

II. NOMENCLATURE

According to the strictest rules of nomenclature, a chemical name must identify and describe its chemical structure unambiguously. This is done by using systematic nomenclature, and there is no

possibility of mistaken identity when this system is used. The systematic method names fatty acids solely on the basis of the number of carbon atoms and the number and position of unsaturated bonds relative to the carboxyl group(s). Substituted groups and their positions are identified. Optical activity and geometric configuration at double bonds are also designated. Systematic nomenclature will be described generally for the saturated fatty acids and then for other types of fatty acids as necessary thereafter.

It is also important to note that there are modifications to this naming system that bring novel naming systems into existence. Trivial (common) nomenclature, which includes circumstantially assigned names, for example, source names, is widely used. The English system of trivial name arose from the practice of adding the suffix "-ic" to a root indicative of the natural source or some property of the acid; for example, acetic (ethanoic) acid from the Latin word *acetum*, meaning vinegar; stearic (octadecanoic) acid from the Greek word *stear*, meaning tallow; palmitic (hexadecanoic) acid from palm oil; and oleic (octadecenoic) acid from the Latin word *oleum*, meaning oil.

Semisystematic nomenclature is often found in verbal communication and as an abbreviation in written communication. This system tries to preserve some of the structural features of systematic nomenclature, yet does so using trivial names, illustrating features that seem important for a particular purpose at the time. For example, the systematic name 2-hydroxy-*cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid might become abbreviated to 2-hydroxylinolenic acid.

Also widely used is the structural system in which fatty acids are identified solely by carbon number and number of unsaturated double bonds. Morris (1961) has proposed that chain length be designated as C10, C20, and so forth, and the unsaturated double bonds be serialized. That is, either methylene-interrupted or conjugated, only the number of the carbon where the series begins will be indicated. For example, linolenic acid, or *cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid, becomes C18:3Δ9c.

The Greek letters omega (ω) and delta (Δ) are sometimes used with special significance in naming fatty acids. Omega is often used to indicate how far a double bond is from the terminal methyl carbon irrespective of the chain length. Delta, followed by a numeral or numerals, is used to designate the presence and position of one or more double or triple bonds in the hydrocarbon chain counting from the carboxyl carbon. Thus, ordinary oleic acid is also named Δ9-octadecenoic acid.

Another system of nomenclature in use for unsaturated fatty acids is the "ω" or "n" classification, and the "n" system is analogous to the "ω" naming system. This system is often used by biochemists to designate sites of enzyme reactivity or specificity. The terms "ω" and "n" refer to the position of the first double bond in the carbon backbone of the fatty acid, counting from the end opposite to the carboxy group or closest to the methyl end of the molecule. Thus, oleic acid, which has its double bond nine carbons from the methyl end, is an ω-9 (or n-9) fatty acid, and linoleic acid is an ω-6 (or n-6) fatty acid because its second double bond is six carbons from the methyl end of the molecule (or between carbons 12 and 13 from the carboxyl end). Eicosapentaenoic acid, found in many fish oils, and alpha-linolenic acid, found in certain vegetable oils, are both ω-3 (or n-3) fatty acids, which have the first double bond that exists as the third carbon–carbon bond from the terminal methyl end (ω) of the carbon chain. Also, both ω- and n-naming methods give a clear indication of the stereoisomeric species concerned; for example, *cis* C20:4n-6 and *cis* C20:4ω-6. The first number indicates the number of carbon units, the second number refers to the number of double bonds, and the n-6 or ωω-6 designation refers to the position of the last double bond. Both the "ω" and "n" nomenclature methods used to designate the position of the last terminal double bond are interchangeably used, however, the "n-3" designation is the proper IUPAC abbreviation. See Davidson and Contrill (1985) for a comparison of the "n" and "ω" naming systems.

The nomenclature of some common fatty acids using the four common naming systems is shown in Table 1.1. Of which, three systems employ the chain length and the number and position of any double bond. The first two columns show systems based on complete names and the last two columns show systems for denoting fatty acids with abbreviations.

Although the IUPAC system is unambiguous, some authors still select a nomenclature system according to their audience. Also, criteria for a suitable abbreviated terminology have been proposed but have yet to be universally adapted. Questions of which abbreviated terms are most appropriate

TABLE 1.1
Nomenclature of Some Common Fatty Acids

Names		Abbreviation	
Trivial	**IUPAC**	**Carboxyl-Reference**	**n- or ω-Reference**
Palmitic acid	Hexadecanoic acid	16:0	16:0
Stearic acid	Octadecanoic acid	18:0	18:0
Oleic acid	9-Octadecenoic acid	18:1Δ9	18:1n-9 or 18:1–9
Linoleic acid	9,12-Octadecadienoic acid	18:2Δ9,12	18:2n-6 or 18:2–6
Linolenic acid	9,12,15-Octadecatrienoic acid	18:3Δ9,12,15	18:3n-3 or 18:3–3

for representing the long and complicated chemical names will continue until an accepted system of nomenclature for individual fatty acids is agreed upon.

III. SATURATED FATTY ACIDS

The naturally occurring fatty acids can be grouped on the basis of the presence of double or triple bonds into two broad classes termed *saturated* and *unsaturated*. Most of the saturated fatty acids occurring in nature have unbranched structures with an even number of carbon atoms. They are referred to as normal alkanoic acids and may bear the prefix "*n*-," such as in *n*-hexanoic or *n*-octadecanoic. They have the general formula R–COOH, in which the R group is a straight-chain hydrocarbon of the form $CH_3(CH_2)_x$ or C_nH_{2n+1}. These acids range from short-chain-length volatile liquids to waxy solids having chain lengths of ten or more carbon atoms. Fatty acids from 2 to 30 carbons (or longer) do occur, but the most common and important acids contain between 12 and 22 carbons and are found in many different plant and animal fats. Under the systematic rules of nomenclature, the aliphatic acids are regarded as derivatives of hydrocarbons of the same number of carbon atoms ($–CH_3$ is replaced by –COOH). The final "e" of the corresponding hydrocarbon (alkane) is replaced by the suffix "-oic"; for example, alkane becomes alkanoic. The unsaturated fatty acids are named in a similar manner, with alkene becoming alkenoic and alkyne becoming alkynoic. The presently accepted names for the hydrocarbons are given in Table 1.2. The tables in this and the following sections are representative only, not complete. Except for the first four members of the series (meth-, eth-, prop-, but-), which have trivial names, the prefix of the name cites the number of carbon atoms.

Saturated fatty acids are also functionally divided into short- and long-chain acids and are most widely known by their trivial names. Table 1.3 lists some of the most important saturated fatty acids. Also included is a system of abbreviated nomenclature that designates chain length and degree of unsaturation; for example, 18:0 designates an 18-carbon saturated fatty acid, whereas 18:2 indicates two double bonds. The location of unsaturations as well as conformation of double bonds can also be designated; 18:2Δ9c, 12c designates *cis* double bonds at the 9 and 12 carbons from the carboxyl group. Similar designations will be described for hydroxy, keto, and so on.

The short-chain saturated acids (4:0–10:0) are known to occur in milk fats and in a few seed fats. Bovine milk contains butanoic acid as well as smaller amounts of 6:0, 8:0, 10:0, and 12:0 acids. Milk from the sheep and goat also contain these, but decanoic is present in larger amounts. Lauric acid (12:0) and myristic acid (14:0) are major components of seed fats of the Lauraceae and Myristiceae families, which accounts for their trivial names. Palmitic acid is the most prominent saturated fatty acid occurring in fish oils, in the milk and storage fat of many mammals, and in vegetable fats. Stearic acid (18:0) is a minor component in most vegetable fats, and its trivial name derives from the fact that it is a major component in the tallow of ruminants.

The long-chain saturated acids (19:0 and greater) are major components in only a few uncommon seed oils. Although many types of fatty-acid-containing oils are present in natural sources, only

about two dozens are the sources for most of the fatty acids. The fatty acid composition of a variety of fats and oils in foods can be found from the chapters of this volume and other sources (Brignoli et al., 1976; Pryde, 1979; Smith, 1979).

Although the majority of natural saturated fatty acids have a straight chain, there are many that have a branched chain. The branched-chain saturated fatty acids have systematic names consisting of two parts; the terminal portion is the name of the longest straight chain present in the compound, that is, the parent chain, and preceding this are the names of side chains. Arabic numbers indicate the locations of the branching. Such prefixes, called *locants*, are listed in numerical sequence from the carboxyl carbon and are separated from each other by commas and from the remainder of the name by a hyphen. The entire name is written as one word; for example, 2,3-dimethyloctadecanoic acid. Branched-chain fatty acids can be further divided into the iso acids, in which the methyl group is in the penultimate, referred to as ω-1, position from the carboxyl group, and the anteiso acids, in which the methyl group is in the ω-2 position. The anteiso isomers are optically active. (*R*) and (*S*) are absolute-configuration labels assigned to any asymmetrical carbon atoms and are preferred to the L and D labels. (*R*) is derived from the Latin word *rectus*, meaning right, and (*S*) from the Latin word *sinister*, meaning left. It is to describe the spatial relationship among the groups around the

asymmetrical carbon (Cahn et al., 1956). The most common type of branch is a single methyl group, but sometimes there are longer branches or more than one branching methyl.

Iso and anteiso acids occur frequently but in small amounts in animal fats, waxes, and marine oils. For example, phytanic acid (3,7,11,15-tetramethylhexdecanoic acid) is an isoprenoid acid derived from the corresponding alcohol (phytol), and it is found in most land and marine fats. Also, phytenic acid is the corresponding C_{20} branched-chain acid with a double bond adjacent to the carboxyl group resulting from the corresponding alcohol phytol (Gunstone and Herslof, 1992). Although rare in plant lipids, branched-chain acids are major components of the lipids of gram-positive bacteria. More elaborate reviews of the branched-chain fatty acids are available (Shorland, 1956; Gensler, 1957; Hartman, 1957; Abrahamsson et al., 1964). Lipids of mycobacteria have also been found to contain a very complex mixture of branched-chain acids (Asselineau, 1966).

If a fatty acid contains two carboxyl groups, the suffix becomes -dioic; three carboxyls, -trioic; and so forth. The saturated dicarboxylic acids conform to the general formula $(CH_2)_x(COOH)_2$. This series of acids is frequently referred to as the oxalic acid series. Like the members of most other acid series, the various dioic fatty acids are best known by their trivial (common) names. In the present accepted method of nomenclature, the carbon atom of the carboxyl group is considered part of the chain, and the acids are named according to the number of carbon atoms in the hydrocarbon chain, that is, alkanedioic. Table 1.4 lists the chemical names, formulas, and common names for some of the more important saturated dicarboxylic acids. The lower molecular weight dioic acids are easily recognizable as fatty acid and tricarboxylic acid cycle intermediates involved in many of the biochemical pathways in metabolism. Of somewhat less frequent occurrence are the higher molecular weight dioic acids.

IV. UNSATURATED FATTY ACIDS

The unsaturated fatty acids may contain one or more double or triple bonds and so can be separated into monounsaturated, polyunsaturated, and acetylenic fatty acids. If an unsaturated fatty acid contains only double bonds, it is called an alkenoic, ethenoic, or olefinic acid. If it contains only triple bonds, it is called an alkynoic, ethynoic, or acetylenic acid. If the unsaturated fatty acid contains a number of double bonds in the hydrocarbon chain, the prefix di-, tri-, tetra-, and so forth, is inserted before "-enoic" to indicate the number of such double bonds (Table 1.1). An unsaturated fatty acid

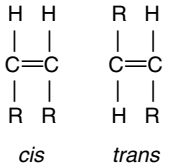
Heneicosanedioic	$(CH_2)_{19}(COOH)_2$	Japanic

with a double bond can have two possible configurations, either *cis* or *trans*, depending on the relative positions of the alkyl groups:



Most naturally occurring unsaturated fatty acids have the *cis* orientation. With systematic nomenclature, the prefix *cis*- or *trans*- precedes the unsaturation position. Some naturally occurring acids have trivial names that are sufficiently specific. For example, oleic and elaidic refer to the *cis* and *trans* forms, respectively, of 9-octadecenoic acid. In other trivial names containing "-oleic" and "-elaidic," the former denotes a *cis* form and the latter a *trans* form. Thus, myristoleic refers to *cis*-9-tetradecenoic acid and by convention myristelaidic to *trans*-9-tetradecenoic acid.

More than 100 naturally occurring monounsaturated fatty acids have been identified, but most of these are very rare compounds. In general, these fatty acids have an even number of carbon atoms and the double bond has the *cis* conformation. Table 1.5 lists some of the more important monounsaturated fatty acids. Petroselinic acid (18:1Δ6c) is a positional isomer of oleic acid and occurs widely in seed oils of the order Umbellifere, usually along with oleic acid and other saturated and unsaturated fatty acids. Oleic acid is one of the most widely distributed fatty acids. It is a major component of safflower, pecan, pistachio, and macadamia nut oils and occurs in fish oils and animal fats (Holman, 1966). Some important oils containing erucic acid (22:1Δ13c) are rape, mustard, and *Crambe abyssinica*.

TABLE 1.5
Some Important Monounsaturated Acids

Systematic Name	Abbreviation	Trivial Name
9-Decenoic	10:1Δ9 (9-10:1)	Caproleic

cis-13-Docosenoic	22:1Δ13c (13c-22:1)	Erucic
trans-13-Docosenoic	22:1Δ13t (13t-22:1)	Brassidic
cis-15-Tetracosenoic	24:1Δ15c (15c-24:1)	Selacholeic or nervonic
cis-17-Hexacosenoic	26:1Δ17c (17c-26:1)	Ximenic
cis-21-Triacosenoic	30:1Δ21c (21c-30:1)	Lumequic

Although most natural sources of unsaturated fats are of the *cis* configuration, *trans* fatty acids do occur in foods. Unsaturated fats are hydrogenated to produce solid fats for margarine and shortening product. Hydrogenation also improves the oxidative and flavor stability of the oils. However, this process can move double bonds from their naturally occurring positions and convert configurations from *cis* to *trans*, creating both positional and geometrical isomers. See Emken (1984) and Emken and Dutton (1979) for a review of geometrical and positional fatty acid isomers.

Polyunsaturated fatty acids, sometimes referred to as PUFAs or polyalkenoic acids, can be divided into a number of categories depending on the relative positions of the double bonds. When double-bonded carbon atoms alternate with single bonds, that is, (–C=C–C=C–), the acid is referred to as *conjugated*. If the double bonds are separated by one or more carbon atoms with only single bonds (–C=C–C, –C=C–), the acid is said to be *unconjugated*. Unconjugated fatty acids usually occur in a methylene-interrupted arrangement. A third group, frequently described as nonmethylene-interrupted dienes, has double bonds that are not entirely in a methylene-interrupted arrangement. If a single carbon atom has two double bonds, that is, (–C=C=C–), then it is called *allenic*. These acids are chiral by virtue of their allenic group. Examples are laballenic acid [$H_3C(CH_2)_{10}CH{=}C{=}CH(CH_2)_3COOH$] and lamenallenic acid [$H_3CCH{=}CH(CH_2)_8CH{=}C{=}CH(CH_2)_3COOH$] (Gunstone and Herslof, 1992).

The most common conjugated polyunsaturated acids are trienes such as octadecatrienoic acids, of which seven isomers occur naturally. Conjugated dienes do exist—for example, 2,4-hexadienoic or sorbic acid and *trans*-2-*cis*-4-decadeinoic, which is a known flavor component in the Bartlett pear (Jennings et al., 1964)—but do not occur extensively. Seven conjugated octadecatrienoic acids have been identified as natural compounds, including three 8,10,12-trienes and four 9,11,13-trienes. Systematic and trivial names and some indication of occurrence are given in Table 1.6. These acids are all believed to arise from linoleic acid (18:2Δ9,12) by oxidation and dehydration mechanisms. Reviews have been published by Smith (1971, 1979), Pohl and Wagner (1972), Hopkins (1972), Pryde (1979), and Badami and Patil (1980). Conjugated PUFAs are in limited abundance in animal fats and occur extensively in only a few seed oils.

The unconjugated and methylene-interrupted PUFAs are probably the most important PUFAs in terms of extent of occurrence. These acids have been arranged into families based on the number of carbons on which the methylene-interrupted double bonds begin. The acids are categorized into n-1 through n-12 families. These symbols indicate the carbon number counting from the methyl end. Formerly, the terms ω1 to ω12 were used. The most important families are the n-3, n-6, and n-9 acids. Monounsaturated acids can be included in this family system, with oleic being an important

member of the n-9 family. Table 1.7 lists some of the more important natural fatty acids arranged by families. The acids within each family are biosynthetically related, being interconverted by enzymatic processes of desaturation, chain elongation, and chain shortening. One of the most familiar and widespread fatty acids is linoleic, which is also nutritionally essential. Natural linoleic acid is predominately the *cis–cis* isomer. It occurs in almost every vegetable fat, with rich amounts in corn, cottonseed, safflower, sunflower, and soybean oils. It is present in animal fats and fish oils at much lower levels. An important n-3 fatty acid is α-linolenic. This fatty acid is a major component of linseed oil and is valuable in paints because of its drying properties. Linolenic acid is the major fatty acid of plant leaves, stems, and roots, and is also a significant component of many photosynthetic organisms (Hilditch and Williams, 1964). The other two important n-3 acids are eicosapentaenoic acid and docosa-hexaenoic acid, which are primarily found in fish oils and marine algae. The C_{20} acid is also a precursor of some prostaglandins and thromboxanes. Arachidonic acid, an n-6 acid, is best known as a precursor to the prostaglandins, thromboxanes, and leukotrienes. It is present in animal fats and at lower levels in many fish oils.

There are also a number of PUFAs in which the unsaturation is not completely methylene interrupted. These acids are thought to occur by insertion of an additional double bond into the more common poly- and monounsaturated compounds. These fatty acids are seen in some seed oils, certain microorganisms, and marine lipids. Table 1.8 lists natural nonmethylene-interrupted PUFAs.

The acetylenic acids are composed of a series of straight-chain carboxylic acids characterized by the presence of one or more triple carbon–carbon bonds (–C≡C–) in the hydrocarbon chain. They are therefore conveniently divided into those with only one triple bond and those with more than one. In the former group of acids, one or more double bonds can occur, and unsaturation frequently appears in the conventional methylene-interrupted pattern. Alkenoic acids containing a triple bond must be named with the positions of the double and triple bonds in mind; for example, 11-octadecene-9-ynoic is an 18-carbon fatty acid with the double bond at position 11 and the triple bond at position 9. In general, most natural acetylenic acids are C_{18} compounds with conjugated unsaturation involving one or more acetylenic groups along with olefinic unsaturation (usually at C-9), which may be *cis* or *trans*. Table 1.9 lists some of the more common acetylenic acids. Acetylenic acids are rarely found in naturally occurring fats and oils; they are seen only in a number of rare seed oils and in some mosses. The first acetylenic compound identified in nature was the 18-carbon tariric acid found by

Arnaud in a fatty oil in 1892. Compounds up to the pentyne stage have been isolated, but from triyne onwards some of the fatty acids become increasingly unstable and even explosive. Bohlmann et al. (1973) described crepenynic (18:2Δ9c12a), isolated from the seed oil of *Crepis foetida*, as one of the most important monoacetylenic acids. See Meade (1957) for a review on the naturally occurring acetylenic acids.

V. OXYGENATED FATTY ACIDS

The naturally occurring oxygenated fatty acids include the hydroxyl, keto, and epoxy groups, of which the hydroxy-substituted acids are most common. As mentioned previously, if one or more hydrogen atoms of the hydrocarbon chain are replaced with some other atom or group, such as a hydroxyl or keto, the acid may retain its specific name and be prefixed by the name and position of the substituent atom or group, such as 2-hydroxybutanoic acid and 9,10-dihydroxyoctadecanoic acid.

The hydroxy fatty acids are composed of a series of straight-chain carboxylic acids that contain one or more hydroxyl groups substituted on the hydrocarbon portion of the molecule. Since the hydroxy fatty acids possess at least one asymmetrical carbon atom, they are capable of being resolved into their optical isomers. Most of the naturally occurring hydroxy acids are optically active. The hydroxy fatty acids may be saturated, or they may contain one or more unsaturated bonds in the hydrocarbon chain. Those hydroxy acids that contain an ethylenic bond exhibit geometrical isomerism and can be obtained in either the *cis* or *trans* form. Natural monohydroxy acids that are either saturated or contain unconjugated unsaturation are listed in Table 1.10. The hydroxy position precedes the name of the substituted hydrocarbon chain and is followed with any stereochemical designations. Ricinoleic acid (12-hydroxyoleic) is the best known, being the major acid in castor oil. In all of these 18- and 20-carbon acids, the hydroxy groups are in the 3 and/or 4 positions from the methyl end. Hydroxy acids with conjugated unsaturation (*cis* and/or *trans* olefinic and/or acetylenic) are listed in Table 1.11.

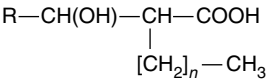
The polyhydroxy fatty acids are also a distinctive group that range in chain length from C_{14} to C_{24}. The acids with 2–5 hydroxy groups are usually saturated, and the C_{16} and C_{18} acids are the most common. Several long-chain polyhydroxy acids that contain adjacent hydroxy groups produce asymmetrical centers and have been isolated from natural sources (Hilditch and Williams, 1964). The prefixes *cis*- and *trans*- used by many investigations in naming these open-chain compounds should be replaced by *threo*- and *erythro*-. By definition, *threo* compounds result by *trans* addition to a *cis*-ethylenic compound or by *cis* addition to a *trans*-ethylenic compound, and the *erythro* isomers are the products of *cis* addition to a *cis*-ethylenic or *trans* addition to a *trans*-ethylenic compound. Table 1.12 lists some of the most common polyhydroxy fatty acids.

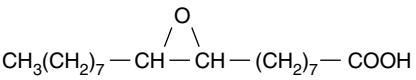
Natural hydroxy acids do not occur extensively, although they are very important industrial sources of synthetic oils. They occur in sphingolipids, stillingia oil, leaf waxes, and fungal and bacterial lipids. Unsaturated oils often contain small amounts of hydroxy and epoxy acids after prolonged storage, probably as a result of oxidation. See Downing (1961) for a review of the naturally occurring aliphatic hydroxy acids found in animals, plants, and microorganisms.

Mycolic acids are a series of very complex hydroxy fatty acids with high molecular weights. These acids occur in a wide range of microorganisms. They are generally 2-alkyl-3-hydroxy acids with the structure shown below.



These fatty acids may contain up to 80 carbons and may even contain one or more cyclopropane units (Polgar, 1971).

The epoxy fatty acids are characterized by the presence of a cyclic bond between two carbons in the chain and one oxygen atom. The epoxy carbons are counted in the longest hydrocarbon chain, and the acids are named accordingly. The name of the acid is prefixed by the two positions of the epoxy carbons attached to the prefix "epoxy." Epoxy carbons also allow *cis* or *trans* conformations to occur, and this is also designated; for example, *cis*-9,10-epoxyoctadecanoic acid describes an 18-carbon acid with an epoxy group at positions 9 and 10 of the *cis* configuration.

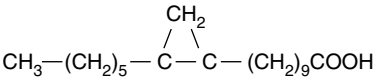


The epoxy fatty acids are another group of acids known to develop in some seed oils after prolonged storage (Gunstone et al., 1986). Natural epoxy acids occur in seed oils as triacylglycerols and in cutins as polymers of hydroxy acids. The best known and most widely occurring of the natural epoxy acids is vernolic acid (*cis*-12,13-epoxy-*cis*-9-octadecenoic), which was first investigated as the characteristic epoxy acid of *Vernonia anthelmintica*. Coronaric acid (*cis*-9,10-epoxy-*cis*-12-octadecenoic), a positional isomer of vernolic acids, is the second most common epoxy acid, and sometimes the two acids occur together.

The keto fatty acids comprise a group of straight-chain carboxylic acids that contain one or more carbonyl groups in the hydrocarbon portion of the molecule. The hydrocarbon chain may be either saturated or unsaturated. The naming of keto acids is similar to that of the hydroxy acids, with the keto position prefixing the fatty acid; for example, licanic acid or 4-keto-9,11,13-octadecatrienoic (18:3Δ4-oxo-9c, 11t, 13t) and lactarinic acid (6-oxo-octadecanoic acid). The properties of specific keto acids depend on the position of the keto group relative to the carboxyl group. Keto acids are rarely found in naturally occurring fats and oils.

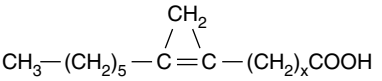
TABLE 1.13
Cyclic Fatty Acids

1. The cyclopropanes



10-(2-Hexyl-cyclopropanyl)decanoic, 11,12-methyleneoctadecanoic (lactobacillic or phytomonic)

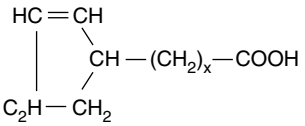
2. The cyclopropenes



x	Cyclopropene	Trivial Name
7	8-(2-Octyl-cyclopropenyl)octanoic	Sterculic
6	7-(2-Octyl-cyclopropenyl)heptanoic	Malvalic

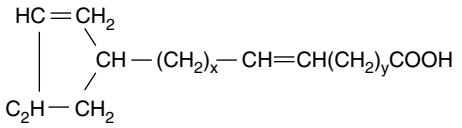
3. The cyclopentenes

a. Monoene acid



x	Cyclopropene	Trivial Name
0	3-(2-Cyclopentenyl)methanoic	Aleprolic
2	3-(2-Cyclopentenyl)propanoic	Alepramic
4	5-(2-Cyclopentenyl)pentanoic	Aleprestic
6	7-(2-Cyclopentenyl)heptanoic	Aleprylic
8	9-(2-Cyclopentenyl)nonanoic	Alepric
10	11-(2-Cyclopentenyl)undecanoic	Hydnocarpic
12	13-(2-Cyclopentenyl)tridecanoic	Chaulmoogric
14	15-(2-Cyclopentenyl)pentadecanoic	Hormelic

b. Diene acids



x	*y*	Cyclopentene	Trivial Name
4	4	11-(2-Cyclpentenyl)-4-undecenoic	Manaoic
6	4	13(2-Cyclopentenyl)-6-tridecenoic	Gorlic
6	6	15-(2-Cyclopentenyl)-6-pentadecenoic	Oncobic

VI. CYCLIC FATTY ACIDS

The cyclic fatty acids may contain a cyclic unit with three (cyclopropane and cyclopropene acids), five (prostaglandins and cyclopentene acids), or even six carbon atoms (cyclohexane acids). Most of these acids are known by their trivial names. The systematic name is derived again from the hydrocarbon chain including the carboxyl but not the cyclic structure. The cyclic structure and any R groups prefix the fatty acid name, with their position designated; for example, 8(-2octyl-cyclopropenyl) octanoic describes an eight-carbon fatty acid attached with a terminal cyclopropene that contains an eight-carbon alkyl group. Table 1.13 lists some of the more common cyclic fatty acids with their structures.

The cyclopropane fatty acids occur frequently in bacterial membrane phospholipids. They also generally accompany the cyclopropene acids in seed oils. Although other chain lengths have been reported, the most common cyclopropane acids are the *cis* 17-carbon and *cis* 19-carbon (lactobacillic acid) compounds. The cyclopropene acids have been identified in seed oil triacylglycerols. They are found mainly among Malvales, especially Sterculiaceae, Malvalaceae, Bombaceae, and Tiliaceae. In addition to the seeds, the cyclic acids are found in leaves, stems, and roots and are present mainly as glycerides. See Badami and Patil (1980), Christie (1970), and Lie Ken Jie (1979) for information with respect to these fatty acids.

VII. CONCLUSION

This chapter describes a number of naming systems, some of which are more popular than others. The IUPAC system for naming chemical compounds is the most comprehensive for naming fatty acids. This system permits the unambiguous naming of all the fatty acids. The abbreviated nomenclature, with carboxyl-reference or n-/ω-reference, found in the tables is aimed to provide a coherent way to substitute the trivial names or chemical names. The abbreviated terminology for naming fatty acids, when standardized, will be of great value in presentation and written formats for both laymen and professionals.

2 Chemical and Physical Properties of Fatty Acids

John M. deMan

CONTENTS

I. INTRODUCTION

Fatty acids in foods occur mainly in the form of esters with the alcohol glycerol. The predominant esters are triacylglycerols accompanied by minor amounts of mono- and diacylglycerols and free fatty acids. In fact, most fats and oils can be classified as mixtures of mixed glycerides. To understand the chemical and physical properties of these food fats and oils, we have to go back to the properties of the component fatty acids. However, many of the properties of food fats and oils are not simply a reflection of the properties of the component fatty acids but are also influenced by the nature of their incorporation into the acylglycerols. In this chapter, therefore, both the properties of fatty acids and their behavior in the form of acylglycerols will be covered.

II. REACTIVITY OF SATURATED AND UNSATURATED FATTY ACIDS

Saturated fatty acids, being composed of paraffinic hydrocarbon chains, are generally considered to have a very low reactivity. Introduction of one or more double bonds into a fatty acid provides an active center that can be the site of a variety of reactions—undesirable, as in the case of oxidation, or desirable for industrial purposes, such as hydrogenation, or for analytical purposes, such as reactions with halogens or mercuric compounds.

The relative stability of oxidation at 100°C has been given by Pardun (1976) as follows: saturated fatty acids 0.8, oleic acid 1.1, linoleic acid 13.7, and linolenic acid 25.5. Since fatty acids occur in food fats and oils as mixtures of mixed glycerides, the interactions between these different fatty acids must be taken into account. Raghuveer and Hammond (1967) studied the rate of autoxidation of mixtures of triunsaturated glycerides and tridecanoin and found that randomization with sodium methoxide decreased the rate of autoxidation. They suggested that the concentration of unsaturated fatty acids in the 2-position of the glycerides stabilizes a fat toward autoxidation.

Autoxidation of unsaturated fatty acids involves attack on the α-methylene group, resulting initially in a number of unsaturated hydroperoxides. Saturated fatty acid oxidation occurs at high temperatures (100°C–120°C) and is mainly a β-oxidation. Stearic acid yields lower fatty acids with an even number of carbon atoms and in addition small amounts of oxalic acid and methyl ketones with odd carbon numbers. The latter results from decarboxylation of β-keto acids. Even the position of double bonds in a polyunsaturated fatty acid may affect its oxidation rate. Zhang and Chen (1998) found that conjugated linoleic acid oxidized considerably faster than linoleic acid.

III. AUTOXIDATION

The unsaturated bonds present in all fats and oils represent active sites that can react with oxygen. This reaction leads to the formation of primary, secondary, and tertiary oxidation products that may make the fat or fat-containing food unsuitable for consumption.

The process of autoxidation and the resulting determination in the flavor of fats and fatty foods are often described by the term *rancidity*. Lundberg (1961) distinguishes several types of rancidity. Common oxidative rancidity can be seen in fats such as lard and is characterized by sweet but undesirable odor and flavor that progressively become more intense and unpleasant as the reaction progresses. *Flavor reversion* is the term used for the objectionable flavors that develop in oils containing linolenic acid such as soybean oil. This type of oxidation is produced with considerably less oxygen than common oxidation.

Among the factors that affect the rate of autoxidation are the amount of oxygen present, degree of unsaturation, presence of antioxidants, presence of prooxidants (especially copper and some organic compounds such as heme-containing molecules and lipoxidase), storage temperature, and exposure to light. The autoxidation reaction can be divided into three stages: initiation, propagation, and termination. In the initiation part, hydrogen is abstracted from an olefinic compound to yield a free radical:

$$RH \rightarrow R^{\bullet} + H^{\bullet}$$

The removal of hydrogen takes place at the carbon atom next to the double bond and can be brought about by the action of, for instance, light or metals. The dissociation energy of hydrogen in various olefinic compounds has been given by Ohloff (1973) and is listed in Table 2.1. Once a free radical has been formed, it will combine with oxygen to form a peroxy free radical, which can in turn abstract hydrogen from another unsaturated molecule to yield a peroxide and a new free radical,

TABLE 2.1

thus starting the propagation reaction. This reaction may be repeated up to several thousand times and has the nature of a chain reaction.

$$R^{\bullet} + O_2 \rightarrow RO_2^{g}$$
$$RO_2^{g} + RH \rightarrow ROOH + R$$

The propagation can be followed by termination if the free radicals react with themselves to yield nonactive products, as shown here:

$$R^{\bullet} + R^{\bullet} \rightarrow R{-}R$$
$$R^{\bullet} + RO_2^{\bullet} \rightarrow RO_2R$$
$$nRO_2^{\bullet} \rightarrow (RO_2)n$$

The hydroperoxides formed in the propagation part of the reaction are the primary oxidation products. The hydroperoxide mechanism of autoxidation was first proposed by Farmer (1946). These oxidation products are generally unstable and decompose into the secondary oxidation products, which comprise a variety of compounds, including carbonyls, which are the most important. The peroxides have no importance to flavor deterioration, which is wholly caused by the secondary oxidation products. The nature of the process can be represented by the curves of Figure 2.1 (Pokorny, 1971). In the initial stages of the reaction, the amount of hydroperoxides increases slowly; this stage is termed the *induction period*. At the end of the induction period, there is a sudden increase in peroxide content. As peroxides are easily determined in fats, the peroxide value is frequently used to measure the progress of oxidation. Organoleptic changes are more closely related to the secondary oxidation products, which can be measured by various means, including the benzidine value, which is related to aldehyde decomposition products. As the aldehydes are themselves oxidized, fatty acids are formed; these free fatty acids can be considered tertiary oxidation products. The length of the induction period, therefore, depends on the method used to determine oxidation products.

Although even saturated fatty acids can be oxidized, the rate of oxidation greatly depends on the degree of unsaturation. In the series of 18-carbon-atom fatty acids—18:0, 18:1, 18:2, 18:3—the relative rate of oxidation has been reported to be in the ratio of 1:100:1200:2500. The reaction of

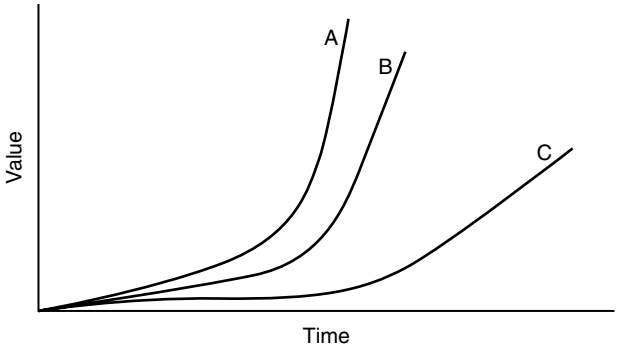

FIGURE 2.1 Autoxidation of lard. A, peroxide value; B, benzidine value; and C, acid value. (From Pokorny, J. (1971). *Can. Inst. Food Sci. Technol. J. 4*: 68–74.)

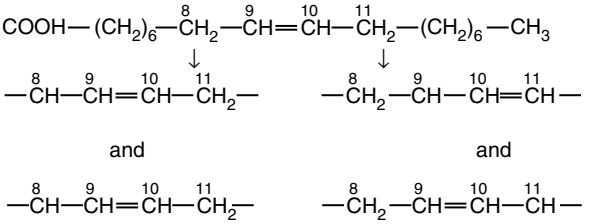
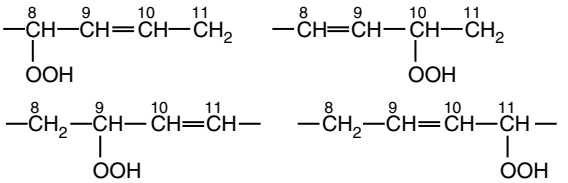
unsaturated compounds proceeds by the abstraction of hydrogen from the α-carbon, and the resulting free radical is stabilized by resonance as follows:

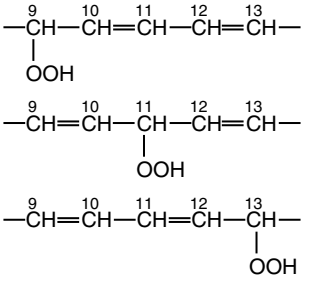
If oleic acid is taken as an example of monoethenoid compound (*cis*-9-octadecenoic acid), the reaction will proceed by abstraction of hydrogen from carbons 8 or 11, resulting in two pairs of resonance hybrids.



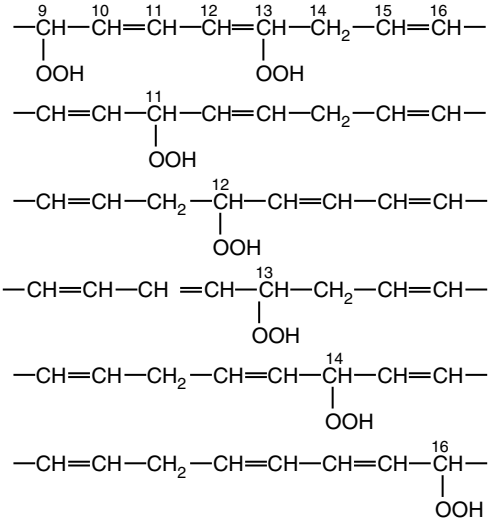
This leads to the formation of four isomeric hydroperoxides:



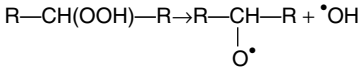
In addition to the changes in double-bond position, there is isomerization from *cis* to *trans*, and 90% of the peroxides formed may be in the *trans* configuration (Lundberg, 1961). From linoleic acid (*cis–cis*-9,12-octadeadienoic acid), three isomeric hydroperoxides can be formed:



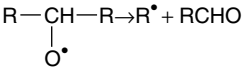
In this mixture of 9-, 11-, and 13-hydroperoxides, the conjugated ones occur in greater quantity because they are the more stable forms. The hydroperoxides occur in the *cis–trans* and *trans–trans* configurations, the content of the latter being greater with higher temperature and greater extent of oxidation. From the oxidation of linolenic acid (*cis–cis–cis*-9,12,15-octadecatrienoic acid), six isomeric hydroperoxides can be expected according to theory:



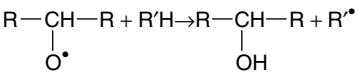
Hydroperoxides of linolenate decompose more readily than those of oleate and linoleate, because active methylene groups are present. The active methylene groups are the ones located between a single double bond and a conjugated diene group. The hydrogen at this methylene group could readily be abstracted to form dihydroperoxides. The possibilities here for decomposition products are obviously more abundant than with oleate oxidation. The decomposition of hydroperoxides has been outlined by Keeney (1962). The first step involves decomposition to the alkoxy and hydroxy free radicals:



The alkoxy radical can react to form aldehydes:



This reaction involves fission of the chain and can occur on either side of the free radical. The aldehyde that is formed can be a short-chain volatile compound, or it can be attached to the glyceride part of the molecule; in the latter case, the compound is nonvolatile. The volatile aldehydes are in great part responsible for the oxidized flavor of fats. The alkoxy radical may also abstract a hydrogen atom from another molecule to yield an alcohol and a new free radical:



The new free radicals formed may participate in propagation of the chain reaction. Some of the free radicals may interact with themselves to terminate the chain, and this could lead to the formation of ketones as follows:

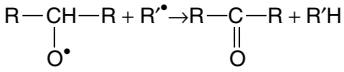


TABLE 2.2
Hydroperoxides and Aldehydes (with Single Oxygen Function) That May Be Formed in Autoxidation of Some Unsaturated Fatty Acids[a]

Fatty Acid	Methylene Group Involved	Isomeric Hydroperoxides Formed from the Structures Contributing to the Intermediate Free Radical Resonance Hybrid	Aldehydes Formed by Decomposition of the Hydroperoxides
Oleic	11	11-Hydroperoxy-9-ene	Octanal
		9-Hydroperoxy-10-ene	2-Decenal
	8	8-Hydroperoxy-9-ene	2-Undecenal
		10-Hydroperoxy-8-ene	Nonanal
Linoleic	11	13-Hydroperoxy-9,11-diene	Hexanal
		11-Hydroperoxy-9,12-diene	2-Octenal
		9-Hydroperoxy-10,12-diene	2,4-Decadienal
Linolenic	14	16-Hydroperoxy-9,12,14-triene	Propanal
		14-Hydroperoxy-9,12,15-triene	2-Pentenal
		12-Hydroperoxy-9,13,15-triene	2,4-Heptadienal
	11	13-Hydroperoxy-9,11,15-triene	3-Hexenal
		11-Hydroperoxy-9,12,15-triene	2,5-Octadienal
		9-Hydroperoxy-10,12,15-triene	2,4,7-Decatrienal
Arachidonic	13	15-Hydroperoxy-5,8,11,13-tetraene	Hexanal
		13-Hydroperoxy-5,8,11,14-tetraene	2-Octenal
		11-Hydroperoxy-5,8,12,14-tetraene	2,4-Decadienal
	10	12-Hydroperoxy-5,8,10,14-tetraene	3-Nonenal
		10-Hydroperoxy-5,8,11,14-tetraene	2,5-Undecadienal
		8-Hydroperoxy-5,9,11,14-tetraene	2,4,7-Tridecatrienal
	7	9-Hydroperoxy-5,7,11,14-tetraene	3,6-Dodecadienal
		7-Hydroperoxy-5,8,11,14-tetraene	2,5,8-Tetradecatrienal
		5-Hydroperoxy-6,8,11,14-tetraene	2,4,7,10-Hexadecatetraenal

[a] Only the most active methylene groups in each acid are considered.

Source: Keeney, M. (1962). Secondary degradation products, in *Lipids and Their Oxidation* (H.W. Schultz, E.A. Day, and R.O. Sinnhuber, eds.), AVI Publishing, Westport, CT.

As indicated, a variety of aldehydes have been demonstrated in oxidized fats. Alcohols have also been identified, but the presence of ketones is not identified. Keeney (1962) listed the aldehydes that may be formed from breakdown of hydroperoxides of oxidized oleic, linoleic, linolenic, and arachidonic acids (Table 2.2). The aldehydes are powerful flavor compounds and have very low flavor thresholds; for example, 2,4-decadienal has a flavor threshold of less than 1 ppb. The presence of a double bond in an aldehyde generally lowers the flavor threshold considerably. The aldehydes can be further oxidized to carboxylic acids or other tertiary oxidation products.

When chain fission of the alkoxy radical occurs on the other side of the free radical group, the reaction will not yield volatile aldehydes but will instead form nonvolatile aldehydoglycerides. Volatile oxidation products can be removed in the refining process during deodorization, but the nonvolatile products remain, and this could result in lower oxidative stability of oils that were already oxidized before refining.

IV. PHOTOOXIDATION

In addition to the free radical process of autoxidation of lipids, oxidation may be brought about by photooxidation. Light-induced oxidation, or photooxidation, results from the reactivity of an excited state of oxygen, known as singlet oxygen ($^1O_2$). Normal or ground-state oxygen is triplet

oxygen ($^3O_2$). The activation energy for the reaction of normal oxygen with an unsaturated fatty acid is very high: in the range of 146–273 kJ/mol. When normal oxygen converts to the singlet state, energy is taken up amounting to 92 kJ/mol. This conversion makes the oxygen much more reactive. Production of singlet oxygen requires the presence of a sensitizer. The sensitizer is activated by light and can react directly with the substrate (type I sensitizer) or activate oxygen to the singlet state (type II sensitizer). The wavelength of the light can be from the visible or ultraviolet (UV) spectrum. With both type I and type II sensitizers, unsaturated fatty acids are converted into hydroperoxides according to the following equations:

$$^3\text{Sens}^* + {}^3O_2 \rightarrow {}^1O_2 + {}^1\text{Sen}$$

$$^3O_2 + \text{RH} \rightarrow \text{ROOH}$$

Singlet oxygen is short-lived and reverts back to the ground state with the emission of light. This light is fluorescent, meaning its wavelength is higher than that of the light originally absorbed. The reactivity of single oxygen is 1500 times greater than that of normal oxygen. Compounds that can act as sensitizers are widely occurring food components, including chlorophyll, myoglobin, riboflavin, and heavy metals. These sensitizers are activated by light and then produce singlet oxygen. The singlet oxygen reacts directly with the double bond by addition and causes the double bond to shift away by one carbon atom. Singlet oxygen attack on linoleate produces four hydroperoxides. Photooxidation has no induction period, but the reaction can be stopped by compounds known as quenchers. These quenchers compete for the singlet oxygen and return it to the ground state. Carotenoids are widely occurring quenchers. Rahmani and Saari Csallany (1998) reported that in the photooxidation of virgin olive oil, pheophytin A functioned as sensitizer while β-carotene acted as quencher. Ascorbyl palmitate has been described as a quencher in the photosensitized oxidation of oils (Lee et al., 1997).

Food containing sensitizers should be protected from light exposure during storage and handling. One of the important characteristics of singlet oxygen oxidation is that phenolic antioxidants do not provide protection against this reaction (Yasaei et al., 1996).

V. THERMAL OXIDATION

The fatty acids in food lipids are exposed to heat during processing and also during cooking, baking, frying, and other treatments of foods. Great care is taken to minimize thermal oxidation of fats and oils during processing; for example, by applying vacuum to remove oxygen. Heating during processing mainly involves hydrogenation, physical refining, and deodorization. The temperatures used in these processes may range from 120°C to 270°C. At the high temperatures used in physical refining and deodorization, several chemical changes may take place. These include randomization of the glyceride structure, dimer formation, *cis–trans* isomerization, and formation of conjugated fatty acids (Hoffmann, 1989). The *trans*-isomer formation during high temperature deodorization has been described by Ackman (1994).

Conditions favoring breakdown of oils or fats exist during frying, whether practiced in the home, in food service, or in commercial frying operations. Frying temperatures are in the range of 160°C–195°C. Deep frying is a complex process involving both the oil and the food to be fried. Steam is given off and this removes volatile antioxidants, free fatty acids, and other volatiles. Contact with air leads to autoxidation and the formation of a large number of degradation products. The presence of steam results in hydrolysis with the production of free fatty acids and partial glycerides. Oxidation can result in the formation of oxidized monomeric, dimeric, and oligomeric triglycerides, as well as volatile compounds, including aldehydes, ketones, alcohols, and hydrocarbons. In addition, oxidized sterols may be formed. The polymerization reaction may take place by conversion of part of the *cis–cis*-1,4-diene system of linoleates to the *trans–trans* conjugated 1,3-diene. The 1,4- and

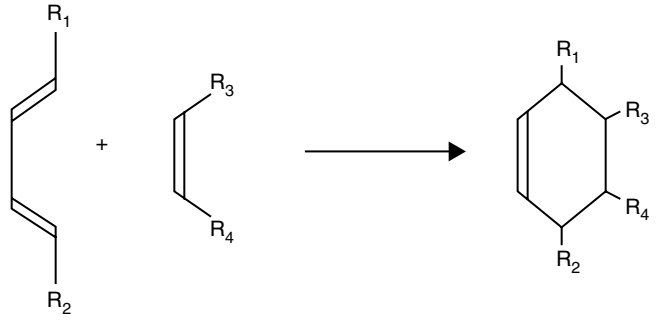

FIGURE 2.2 Dimer production of 1,4- and 1,3-dienes.

1,3-dienes can combine in a Diels–Alder-type addition reaction to produce a dimer (Figure 2.2). From these dimers, higher oligomers can be produced, the structure of which is relatively unknown.

Another class of compounds formed during frying is that of cyclic monomers of fatty acids. Linolenic acid can react at either the C9 or the C12 double bonds to give rings between carbons 5 and 9, 5 and 10, 8 and 12, 12 and 17, and 13 and 17. Cyclic monomers with a cyclopentenyl ring have been isolated from heated sunflower oil (Le Quéré and Sébédio, 1996). The loss of polyunsaturated fatty aids during deep frying has been reported by Tyagi and Vasishtha (1996).

VI. ENZYMATIC OXIDATION

Enzymatic oxidation reactions are important in both animal and plant systems. In animal systems, they involve mainly the oxidative transformation of arachidonic acid to prostaglandins, thromboxanes, and leukotrienes. These compounds are formed in all mammalian tissues and have a broad range of biological activities. The first product formed from arachidonic acid is prostaglandin G_2 (PGG_2), which contains hydroperoxide and cyclic peroxide functions. The enzyme involved in this reaction is cyclooxygenase. The 5-hydroperoxide reacts further to form leukotrienes. PGG_2 is the precursor of prostaglandins and thromboxanes. The 5-hydroperoxide and the 5,6-epxide are precursors of the leukotrienes (Gunstone, 1986).

Enzymatic oxidation in plant systems is mediated by a widely occurring group of enzymes that use molecular oxygen to catalyze the oxidation of lipids containing a *cis–cis*-1,4-pentadiene group. This reaction leads to the formation of conjugated hydroperoxides. The best known of these enzymes is soy lipoxygenase (linoleate:oxygen oxidoreductase, EC 1.13.11.12).

The major source of lipoxygenase is in legumes, soybeans, other beans, and peas. It is present in lesser amounts in peanuts, wheat, potatoes, and radishes. Lipoxygenase is a metalloprotein with an iron atom in its active center. Two types of lipoxygenase occur in plants: type I lipoxygenase peroxidizes only free fatty acids with a high stero- and regioselectivity; and type II, which is less specific for free linoleic acid, acts as a general autoxidation catalyst. Type I reacts only on free fatty acids after they have been released from triacylglycerols by lipase. Type II will act directly on triacylglycerols.

The mechanism of lipoxygenase activity has been reviewed by Gardener (1996). The enzyme has been reported (Georgalaki et al., 1998) as a component in virgin olive oil. The reaction is highly specific for the *cis–cis* methylene-interrupted group and forms the basis for an analytical method for measuring essential fatty acids. The reaction is shown in Figure 2.3 (Chism, 1985).

VII. HYDROGENATION

Hydrogenation of fats is a chemical reaction consisting of the addition of hydrogen at double bonds of unsaturated acyl groups. This reaction is of great importance to industry, because it permits the

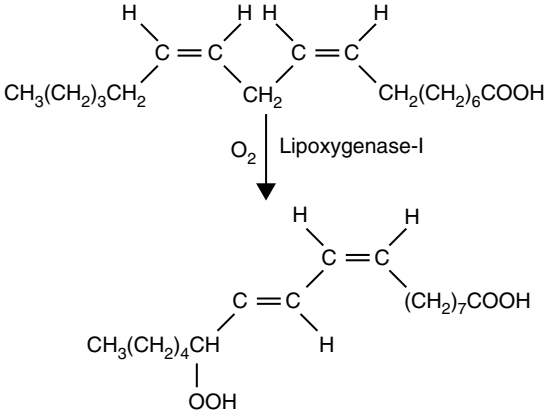

FIGURE 2.3 Lipoxygenase-catalyzed reaction of *cis–cis* methylene-interrupted compounds.

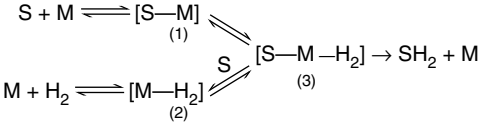
conversion of liquid oils into plastic fats for the production of margarine and shortening. For some oils, the process also results in a decreased susceptibility to oxidative deterioration. In the hydrogenation reaction, gaseous hydrogen, liquid oil, and solid catalyst participate under agitation in a closed vessel. Although most industrial processes use solid nickel catalysts, interest in organometallic compounds that serve as homogeneous catalysts has increased greatly. Frankel and Dutton (1970) represented catalytic hydrogenation by the following scheme, in which the reaching species are the olefinic substrate (S), the metal catalyst (M), and H_2:



Intermediates 1, 2, and 3 are organometallic species. If the reaction involves heterogeneous catalysis, the olefins and hydrogen are bound to the metal by chemisorption. If homogeneous catalysis takes place, the intermediates are organometallic complexes. The intermediates are liable and short-lived and cannot usually be isolated. In heterogeneous catalysis, the surface of the metal performs the function of catalyst, and the preparation of the catalyst is of major importance. When hydrogen is added to double bonds in a natural fat consisting of many component glycerides and component unsaturated fatty acids, the result depends on many factors if the reaction is not carried to completion. Generally, hydrogenation of fats is not carried to completion, and fats are hydrogenated only partially. Under these conditions, hydrogenation may be selective or nonselective. "Selective" means that hydrogen is added first to the most unsaturated fatty acids. Selectivity is increased by increasing the hydrogenation temperature and decreased by increasing pressure and agitation. Table 2.3 shows the effect of selectivity on the properties of soybean oil. The selectively hydrogenated oil is more resistant to oxidation because of the preferential hydrogenation of the linolenic acid. The influence of selectivity conditions on the fatty acids of hydrogenated cottonseed and peanut oils is demonstrated by the data presented in Table 2.4.

Another important factor in hydrogenation is the formation of positional and geometrical isomers. Formation of *trans*-isomers is rapid and extensive. The isomerization can be understood by the reversible character of chemisorption. When the olefinic bond reacts, two carbon-metal bonds are formed as an intermediate stage (represented by an asterisk in Figure 2.4). The intermediate may react with an atom of adsorbed hydrogen to yield "half-hydrogenated" compound, which remains attached by only one bond. Additional reaction with hydrogen results in the formation of the

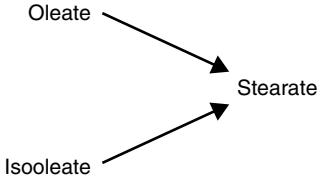
TABLE 2.4
Fatty Acid Composition of Cottonseed and Peanut Oils Hydrogenated Under Different Conditions of Selectivity to Iodine Value 65

Oil	Hydrogenation Conditions	Fatty Acids		
		Saturated (%)	Oleic (%)	Linoleic (%)
Cottonseed	Moderately selective	31.5	64.5	4.0
Peanut	Moderately selective	27.5	72.5	—
Cottonseed	Nonselective	36.0	56.0	8.0
Peanut	Nonselective	30.0	67.0	3.0
Cottonseed	Very nonselective	39.5	48.5	12.0
Peanut	Very nonselective	33.0	61.0	6.0

saturated compound. There is also the possibility that the half-hydrogenated olefin may again attach itself to the catalyst surface at a carbon on either side of the existing bond, with simultaneous loss of hydrogen. Upon desorption of this species, a positional or geometrical isomer may result. The proportion of *trans* acids is high, because this is the more stable configuration. Double-bond migration occurs in both directions but probably more extensively in the direction away from the ester group. The hydrogenation of oleate can be represented as follows:



The change from oleate to isooleate involves no change in unsaturation but does result in a considerably higher melting point. Hydrogenation of linoleate first produces some conjugated

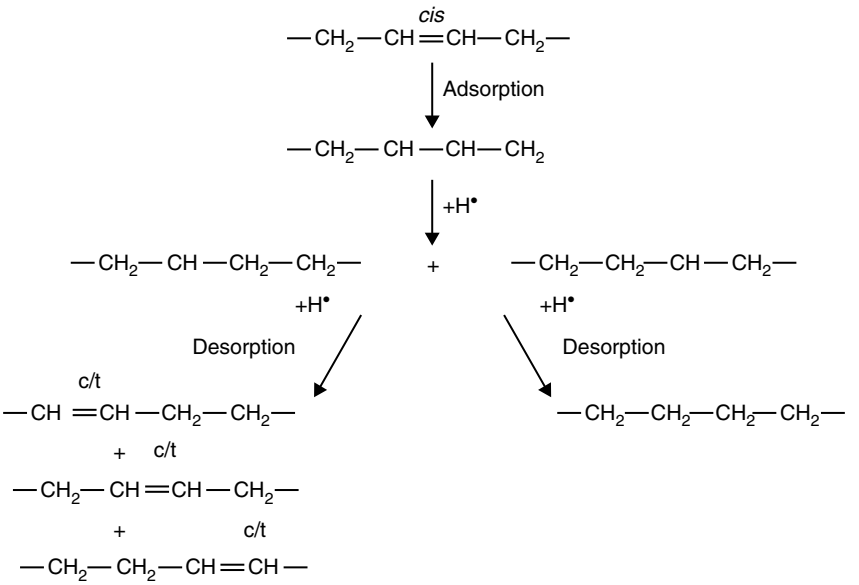


FIGURE 2.4 Hydrogenation of an olefinic compound.

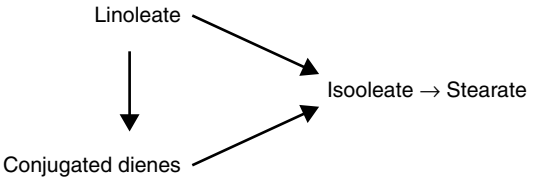
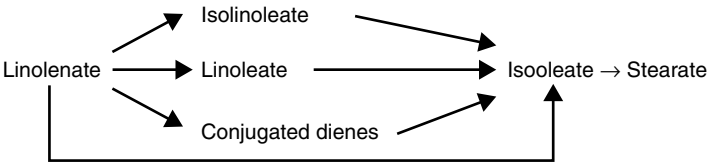
dienes, followed by the formation of positional and geometrical isomers of oleic acid and finally stearate.



Hydrogenation of linolenate is more complex and is greatly dependent on reaction conditions. The reactions can be summarized as follows:



During hydrogenation, solid isomers of oleic acids are formed by partial hydrogenation of polyunsaturated acid groups or by isomerization of oleic acid. This has an important effect on the consistency of partially hydrogenated oils. For example, compare olive oil, which has an iodine value of 80 and is liquid at room temperature, with soybean hydrogenated to the same iodine value, which is a fat with a consistency similar to that of lard.

It is difficult to eliminate oxidation-sensitive polyunsaturated fatty acids by partial hydrogenation of fish oils. This has been demonstrated by Ackman (1973) in the progressive hydrogenation of anchovetta oil. The original eicosapentaenoic acid (20:5ω3) is not completely removed until an iodine value of 107.5 is reached. Even at this point, there are other polyunsaturated fatty acids present that may be susceptible to flavor reversion. In the nonselective hydrogenation of typical seed oils, polyunsaturated fatty acids are rapidly reduced and *trans*-isomer levels increase to high values; Figure 2.5 shows the hydrogenation of canola oil (deMan et al., 1982).

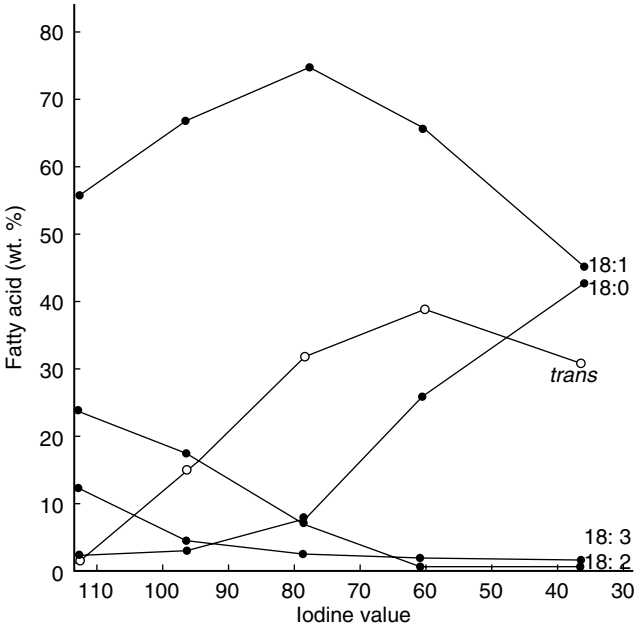


FIGURE 2.5 Change in fatty acid composition during hydrogenation of canola oil. (From deMan, J.M. et al. (1982). *Chem. Microbiol. Technol. Lebensm. 7*: 117–124.)

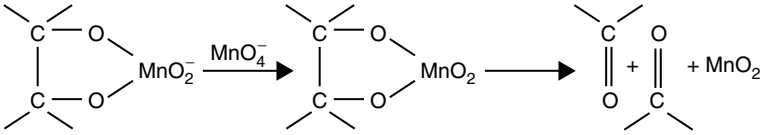
VIII. HALOGENATION

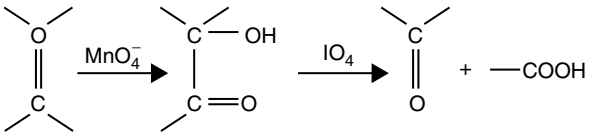
The reaction of halogens with unsaturated fatty acids is important, because it forms the basis for the measurement of the iodine value of fats and oils. This has traditionally served as a measure of total unsaturation. In part, this has been superseded by the gas–liquid chromatographic analysis of fatty acid composition. Chlorine, bromine, iodine monochloride, and iodine monobromide add to the double bonds of unsaturated fatty acids. The most widely used method, known as the Wijs method, employs iodine monochloride. The Hanus method employs iodine monobromide. The addition reaction can be speeded up greatly by using mercuric acetate as a catalyst. Conjugated fatty acids react only incompletely with halogens. Bromination of polyunsaturated fatty acids yields 9,10,12,13-tetrabromostearic acid (mp 116°C) from linoleic acid and 9,10,12,13,15,16-hexabromostearic acid (mp 186°C) from linolenic acid. These tetra- and hexabromides are insoluble in cold ether and petroleum ether. Brominated vegetable oils are used as clouding agents in soft drinks. Other uses for halogenated fatty compounds are as intermediates in the preparation of other industrial chemicals.

IX. OXIDATIVE FISSION

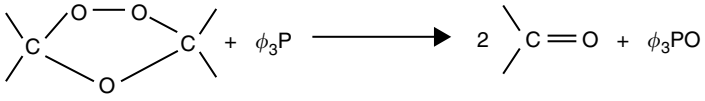
Fatty acid chains can be cleaved at the location of a double bond by two procedures: permanganate oxidation or ozonolysis. Both methods are used to determine the structure of unsaturated fatty acids.The reaction of olefinic compounds with $KMnO_4$ under neutral conditions results in carbon–carbon bond cleavage. The first product formed is a cyclic ester intermediate, which is oxidized to a neutral ester, that in turn is cleaved to two aldehydes. This is followed by oxidation to the corresponding acids.



An improvement to this procedure was suggested by von Rudloff (1956). In this reaction, a catalytic amount of permanganate is used with an excess of periodate. The permanganate oxidizes the olefin to a glycol or ketol. The periodate affects both the cleavage of the intermediate and the regeneration of the permanganate.



The yield of the expected dicarboxylic acid from the oxidation of unsaturated acids has been reported to be within 2% of the expected value. Ozone can add to the double bond to form a primary ozonide. On oxidation, the ozonolysis products give carboxylic acids and/or ketones. Mild reduction yields aldehydes and/or ketones. Reduction can result in clean oxidation products that can be used directly for analysis by gas–liquid chromatography. In the usual procedure, the ozonized sample is reacted with triphenylphosphine. The phosphine reduces the ozonide and is itself oxidized to triphenylphosphine oxide.



X. ESTER INTERCHANGE

It is possible to change the position of fatty acid radicals on the glycerides in a fat by the process known as interesterification, randomization, or ester interchange. This is because, in the presence of certain catalysts, the fatty acid radicals can be made to move between hydroxyl positions so that an essentially random fatty acid distribution results, according to the reaction pattern (Formo, 1954).

The reaction is used in industry to modify the crystallization behavior and physical properties of fats. The catalysts are usually alkaline and consist of sodium methoxide or alloys of sodium and potassium. Several procedures are available. A fat may be randomized by carrying out the reaction at temperatures above its melting point, several raw materials may be interesterified together so that a new product results, or a fat may be interesterified below its melting point so that only the liquid fraction reacts (this is called *directed interesterification*). The effect of randomization can be shown, for example, by considering the simple mixture of equal quantities of triolein and tristearin. After randomization, six possible triglycerides are formed in quantities that can be calculated (Figure 2.6). Industrially, interesterification is applied to lard. Lard has some undesirable physical properties: It has a narrow plastic range, creams poorly, and gives poor cake volume. Interesterification results in considerable improvement in these properties so that interesterified lard can be used as a shortening. Natural fats can be interesterified with simple glyceryl esters such as acetates and butyrates to give new mixed glycerides. Acetoglycerides prepared in this manner are translucent, waxy materials that can be used as edible protective coatings and plasticizers.

Interesterification may provide an alternative to hydrogenation for the production of margarine and shortening fats. Hydrogenation has the disadvantages of forming *trans*-isomers and losing essential fatty acids. Interesterification of liquid oils with highly saturated fats (obtained by complete

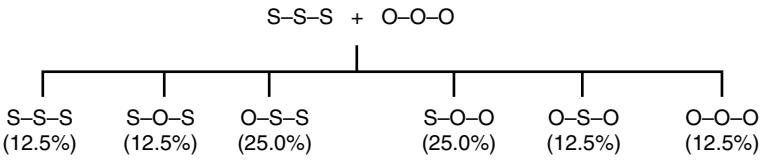


FIGURE 2.6 Interesterification of a mixture of equal quantities of triolein and tristearin.

hydrogenation or fractionation) may yield suitable fats with little or no *trans*-isomers and high levels of essential fatty acids.

Ester interchange of fats with a large excess of glycerol at high temperature, under vacuum, and in the presence of a catalyst results in an equilibrium mixture of mono-, di-, and triglycerides. After removal of excess glycerol, the mixture is called technical monoglyceride and contains about 40% 1-monoglyceride. Technical monoglycerides are used as emulsifying agents in foods. Molecular distillation yields products with well over 90% 1-monoglycerides; the distilled monoglycerides are also widely used in foods.

Interesterification is being adopted as an alternative to hydrogenation for the production of low-*trans* or *trans*-free margarines and shortenings. The physical and chemical properties of *trans*-free fats produced by chemical interesterification of vegetable oil blends have been described by Petrauskaite et al. (1998). Interesterification is used for producing commercial margarines and shortenings (Allen, 1998) and also for preparing structured lipids. These materials are triglycerides that contain mixtures of either short- or medium-chain fatty acids and long-chain fatty acids in the same glyceride molecule (Fomuso and Akoh, 1997). They can be tailor-made for specific disease or metabolic conditions and also serve as reduced- or low-calorie fats. To produce structured lipids, position-specific lipase catalysts are used to obtain the desired glyceride structure. Rodriguez et al. (2001) have manufactured a shortening using chemical interesterification of tallow-sunflower oil blends to replace fish oil in the formulation.

XI. HYDROLYSIS

In the presence of water, fatty acid esters can be hydrolyzed to free acids and alcohol. In industrial fat splitting, this reaction is carried out under conditions of high temperature and high pressure. Hydrolysis is catalyzed by acids. Lipolytic enzymes rapidly break down triglycerides under appropriate conditions. This occurs frequently in oilseeds and palm fruit during processing. Limiting the action of lipases is important, because removal of free fatty acids reduces the yield of neutral oil.

It is known that the lipases will promote the reverse of lipolysis, that is, esterification, under conditions of limited availability of water. These reactions include both esterification and transesterification (Lazar, 1985).

The catalytic activity of lipases is reversible and depends on the water content in the reaction mixture. At high water content, the hydrolytic reaction prevails, whereas at low water content, the synthetic reaction is favored. The lipases that have received attention for their ability to synthesize ester bonds have been obtained from yeasts, bacteria, and fungi. Lipases can be classified into three groups based on their specificity (Macrae, 1983). The first group contains nonspecific lipases; these show no specificity regarding the position of the ester bond in the glycerol molecule or the nature of the fatty acid. Examples of enzymes in this group are lipases of *Candida cylindracea*, *Corynebacterium acnes*, and *Staphylococcus aureus*. The second group contains lipases with position specificity for the 1- and 3-positions of the glycerides. 1,3 Specificity is common among microbial lipases. This positional specificity is the result of the inability of the sterically hindered ester bond of the 2-positon of glycerol to enter the active site of the enzyme. Examples of lipases in this group are obtained from *Aspergillus niger*, *Mucor javanicus*, and *Rhizopus arrhizus*. The third group of lipases shows specificity for particular fatty acids. As an example, the lipase from *Geotrichum candidum* has a marked specificity for long-chain fatty acids containing a *cis* double bond in the 9-position.

XII. MELTING AND CRYSTALLIZATION

The economic importance of the distinctive melting and solidification behavior of fatty acids and their esters was well described by Bailey (1950). Fatty acids and their derivatives constitute an almost infinite variety of long-chain compounds differing in carbon chain length, unsaturation, and isomerism, resulting in a complex and fascinating gamut of physical properties.

The transformation from the liquid to the solid state is accompanied by release of heat (latent heat of crystallization signifying an exothermic reaction); the reverse, transformation from solid to liquid, is accompanied by a negative heat effect (endothermic reaction). This forms the basis for the widely used technique of differential scanning calorimetry (DSC).

Another important phenomenon is melting expansion. Conversion from the solid state to the liquid state results in a melting expansion that is added to the normal thermal expansion. This phenomenon constitutes the basis for the determination of the solid fat index by dilatometry. Protons in the solid state of a fat behave differently from those in the liquid state when subjected to radiofrequency energy when the sample is contained in a magnetic field. This serves as the basis for the determination of the solid fat content in a product by wide-line or pulsed-nuclear magnetic resonance.

The internal structure of solid fats in the crystalline state is fairly well-known. Crystals are closely packed systems of molecules or atoms with a regular three-dimensional repeating order. The molecules or atoms are held together by strong forces, and crystals have well-defined spacings between repeating groups. These short and long spacings are characteristic of different fat crystals.

Although it can be assumed that the internal structure of liquids is represented by molecules in complete disorder, there is evidence that a limited degree of order does exist in liquids. According to Bailey (1950), long-chain compounds in the liquid state contain limited areas of orderly packing. However, these regions of orderly packing extend only over a very limited number of molecules, whereas in a crystal the lattice arrangement extends throughout the crystal. Bailey speaks of the quasicrystalline character of liquids as "short range order" and of crystals as "long range order."

Studies by Hernqvist (1984) shed light on the structure of triglycerides in the liquid state and how this affects crystallization. On the basis of x-ray diffraction and Raman spectroscopy studies, he suggested a gradual decrease in size with increasing temperature of the melt (Figure 2.7). The order in the melt is constant even at 40°C above the melting point. The order is related to chain length; a long chain is more disordered at the methyl end-group plane than a short one. When the temperature is decreased, the lamellar units increase in size until crystallization occurs (Figure 2.8).

Substances consisting of identical molecules have a well-defined sharp melting point. Complications arise in long-chain compounds such as fatty acids and their esters because of polymorphism and because fats and oils are mixtures of mixed glycerides. The molecules in these compounds, although of the same chemical structure, differ in chain length, unsaturation, and isomerism. Each component in these products has its own melting point. Fats, therefore, have a melting range. What is commonly known as the melting point of a fat is in reality the end of the melting range (deMan et al., 1983). There are a variety of methods for determining the melting points of fats, and the results may differ depending on the method chosen. Some of the better known methods are the capillary tube, slip point, Wiley melting point, and Mettler dropping point methods. It is also possible to determine the end of the melting range from a DSC heating curve.

Melting of a fat is an instantaneous reaction, whereas crystallization is usually a slow process. The driving force in crystallization is the degree of supercooling. Crystallization consists of two

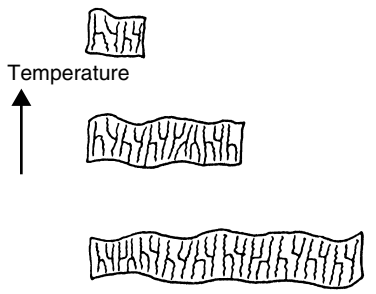

FIGURE 2.7 Reduced size of lamellar units with temperature. (From Hernqvist, L. (1984). *Fette Seifen Anstrichm. 86:* 297–300.)

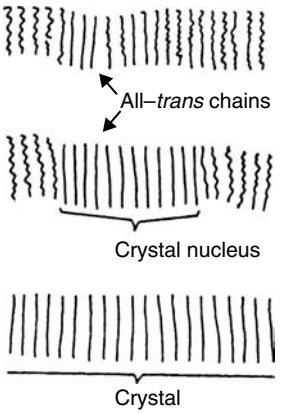

FIGURE 2.8 Proposed mechanism for the crystallization of a triglyceride melt. (From Hernqvist, L. (1984). *Fette Seifen Anstrichm*. *86*: 297–300.)

phases: nucleation and crystal growth. A high degree of supercooling will be conducive to nucleation, and many small crystals will be formed. At temperatures closer to the crystallization point, crystal growth will be favored and large crystals will be formed. Another result of a high degree of supercooling is the formation of mixed crystals, also known as solid solutions. Molecules with a range of melting points may crystallize together. As a result, rapidly cooled fats may have higher solid fat content than the same fats that cooled more gradually. These mixed crystals will partially melt when the fat is subjected to temperature variations below its melting point, a phenomenon known as tempering (Moziar et al., 1989).

Svenstrup et al. (2005) have shown that the number of melting points and the melting temperature are correlated with the cooling rate for pork fat, lard, and leaf fat in three different products: extracted fat, raw fat, and fat as an ingredient in liver pate, a rapid cooling leads to lowering of the melting point, assigned to the presence of unstable β' crystals, and that the melting points vary with the treatment of the fat. The findings suggest that the fraction of unsaturated fatty acids present in the fat is important for both crystallization rate and melting points of α and β' crystals in extracted lard, and is less pronounced in liver pate because of the presence of diverse components such as proteins. The identification of the various levels of structure present in fat crystal networks, and the development of analytical techniques to quantify these levels have been reviewed by Narine and Marangoni (1999, 2002). The types, formulations, functionality, and processing required for the production of lipid-shortening systems, as well as their crystallization, structural elucidation, and mechanical modeling of fat crystal networks have been reviewed by Ghotra et al. (2002). Also, Humphrey and Narine (2004) have compared the lipid-shortening functionality as a function of molecular ensemble and shear: crystallization and melting.

XIII. FRACTIONATION

Fats can be separated into fractions with different physical characteristics by fractional crystallization from a solvent or by fractionation from the melt. The former process gives sharply defined fractions but is only used for the production of high-value fats, and the latter process is much simpler and cost effective. Fractionation from the melt or dry fractionation is carried out on a very large scale with palm oil and also other fats, including beef tallow, lard, and milk fat.

There are several reasons for employing fractional crystallization (Hamm, 1995):

1. To remove small quantities of high-melting components that might result in cloudiness of oil. This can be either a triacylglycerol fraction or nontriacylglycerol compound. The

former happens when soybean oil is lightly hydrogenated to convert it to higher stability oil. The resulting solid triglycerides have to be removed to yield a clear oil. The latter occurs when waxes crystallize from oils such as sunflower oil. This type of fractionation is known as winterization.

2. To change a fat or oil into two or more fractions with different melting characteristics. In simple dry fractionation, a hard fraction, or stearin, and a liquid fraction, or olein, is obtained. This is by far the most common application of fraction.
3. To produce well-defined fractions with special physical properties that can be used as specialty fats or confectionery fats, often done by solvent fractionation.

The process of fractionation involves the controlled and limited crystallization of a melted fat. By careful management of the rate of cooling and the intensity of agitation, it is possible to produce a slurry of relatively large crystals that can be separated from the remaining liquid oil by filtration. By far the major application of fractionation is with palm oil.

The fractionation of palm oil can be carried out in a number of ways to yield a variety of products. In a multistage process, a palm mid fraction is obtained, which can be further fractionated to yield a cocoa butter equivalent (Kellens, 1994). Palm oil can be double fractionated to yield a so-called super olein with an iodine value of 65.

Milk fat fractionation has been described by Deffense (1993). By combining multistep fractionation and blending, it is possible to produce modified milk fats with improved functional properties. The use of anhydrous milk fat fractions in milk chocolate formulations has been described by Full et al. (1996). Dimick et al. (1996) reported the chemical and thermal characteristics of milk fat fractions isolated by a melt crystallization. Methods for determining thermal fat crystal properties for the fractionation of milk fat were developed by Breitschuh and Windhab (1996).

XIV. POLYMORPHISM

Polymorphism is the ability of long-chain compounds such as fatty acids and their esters to exist in more than one crystal form, and this results from different patterns of molecular packing in the crystals. Triglycerides may occur in three main forms, namely, α, β′, and β in order of increasing stability and melting point. When fats are cooled, crystals of a lower melting form may be produced. These may change slowly or rapidly into a more stable form. The change is monotropic, that is, it always proceeds from lower to higher stability. Polymorphism results in the phenomenon of multiple melting points. When a fat is crystallized in an unstable form and heated to a temperature slightly above its melting point, it may resolidify into a more stable form. This is demonstrated by the melting points of the polymorphic forms of triglycerides containing palmitic and stearic acids (Table 2.5).

TABLE 2.5
Melting Points of the Polymorphic Forms of Tristearin (SSS), 2-Palmitoyldistearin (SPS), and 2-Stearoyldipalmitin (PSP)

	Melting Point (°C)		
Form	**SSS**	**SPS**	**PSP**

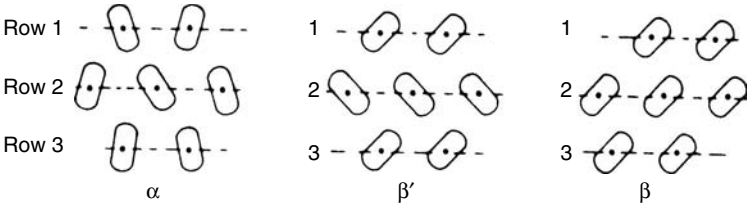

FIGURE 2.9 Cross-sectional structures of long-chain compounds. (From Lutton, 1972.)

The cross-sectional structures of long-chain compounds in the different polymorphic forms are shown in Figure 2.9. In the α-form, the chain axes are randomly oriented—the crystal is of the hexagonal type. In the β′-form, alternate rows are oriented in opposite directions and the crystal type is orthorhombic. In the β-form, the rows are oriented in the same direction and the crystal type is triclinic. The polymorphic forms are also distinguished by differences in the angle of tilt of the unit cell in the crystal. X-ray diffraction analysis enables measurement of the short spacings and long spacings of the unit cell.

The short spacing measured by x-ray diffraction can be used to characterize the polymorphic forms. Principal short spacings are as follows: α, 0.415 nm; β′, 0.42 and 0.38 nm; β, 0.46, 0.385, and 0.37 nm. Forms with identical x-ray patterns but with different melting points are described by a letter subscript, for example, α_1 and α_2.

The polymorphic behavior of cocoa butter is more complex than that of most other fats. There are six distinct polymorphic modifications that are usually designated by roman numerals as forms I to VI in the order of increasing melting point. The desirable form in chocolate is form V, which is a β modification. The polymorphism of cocoa butter has been studied by van Malssen et al. (1996) and Loisel et al. (1998). Narine and Humphrey (2004) have compared lipid-shortening functionality, including microstructure, polymorphism, solid fat content, and texture, as a function of molecular ensemble and shear.

XV. THERMAL PROPERTIES

The specific heat of a substance is the amount of heat required to increase the temperature of 1 g of material by 1°C. The specific heats of the solid and liquid states of fatty compounds are different. The specific heat of the liquid state is always higher. The transformation of solid to liquid releases the latent heat of crystallization. Transformation of a lower to a higher polymorphic form is also an exothermic reaction. The heat content curve of a fat covering the solid, melting, and liquid states is given in a schematic form in Figure 2.10 (Bailey, 1950). The specific heat and latent heat of fusion of saturated fatty acids are given in Table 2.6.

There is a similarity between heat effects and volume changes, as was pointed out by Bailey (1950). Calorimetric curves such as the one in Figure 2.10 represent heat content plotted against temperature. Dilatometric curves are plots of specific volume against temperature. Both methods can be used to establish the relative amounts of solid and liquid in a plastic fat. Newer methods have superseded the calorimetric and dilatometric procedures. DSC is now a widely used thermal method. A sample is subjected to a linear temperature program, either heating or cooling, and the heat flow rate is measured as a function of temperature (O'Neill, 1966). DSC has many advantages including the use of small samples; only a few milligrams are needed. In addition to the latent heat of crystallization, it is possible to measure crystallization rate constants (Yap et al., 1989), polymorphic changes (Kawamura, 1980), and melting points (deMan et al., 1989). Examples of DSC cooling curves and heating curves are given in Figures 2.11 and 2.12, respectively.

There are many methods available to test the physical properties and chemical changes of frying fats. Physical methods include density, viscosity, smoke point, color, refractive index, UV

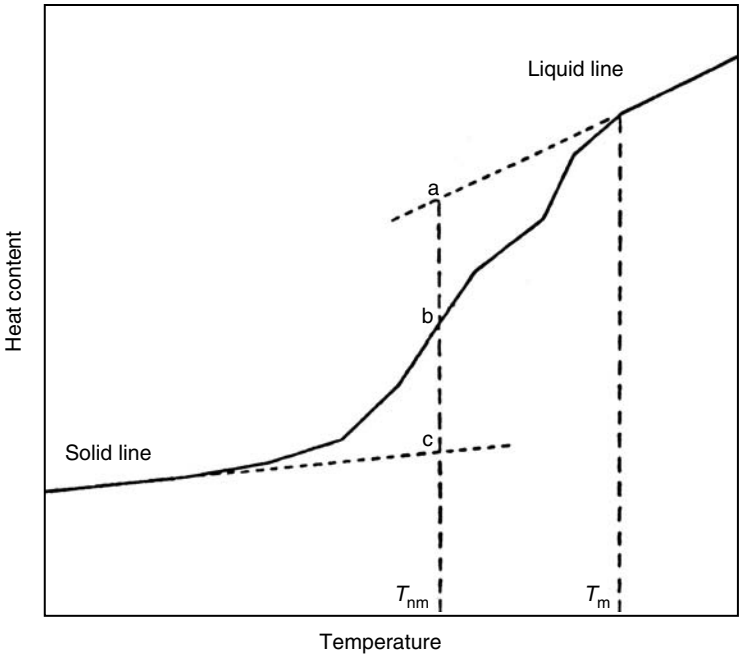

FIGURE 2.10 Schematic representation of the heat content curve of a plastic fat showing calculation of the heat of fusion at the point of half-fusion. (From Bailey, A.E. (1950). *Melting and Solidification of Fats*. Interscience, New York.)

TABLE 2.6
Specific Heat and Latent Heat of Fusion of Some Saturated Fatty Acids

Acid	Latent Heat of Fusion (cal/g)	Specific Heat (cal/g) (Temperature, °C)	
		Solid	Liquid
Caproic	31.2	0.4495 (–33 to –10)	0.5105 (0–23)
Caprylic	35.4	0.4650 (0–12)	0.5050 (18–46)
Capric	38.9	0.5009 (0–24)	0.4989 (35–65)
Lauric	43.7	0.5116 (19–39)	0.5146 (48–78)
Myristic	47.1	0.5209 (24–43)	0.5157 (to 84)
Palmitic	50.6	0.4920 (22–53)	0.5416 (to 68)
Arachidic	54.2	0.4597 (20–56)	0.5663 (to 100)
Behenic	55.1	0.4854 (18–71)	0.5556 (to 109)
Lignoceric	57.3	0.4656 (18–78)	0.5855 (to 109)

absorption, infrared spectroscopy, and dielectric constant, and chemical tests include free fatty acids (acid value), iodine value, anisidine index, saponification value, nonoxidized monomer fatty acids, polymerized triglycerides, fatty acids insoluble in petroleum ether, and total polar compounds can be utilized as quality indicators of frying oils (Gertz, 2000). The mechanical and thermal properties of a fat crystal network are determined by chemical composition, solid fat content, crystal habit (polymorphism and microstructure), and other factors. Campos et al. (2002) have shown that

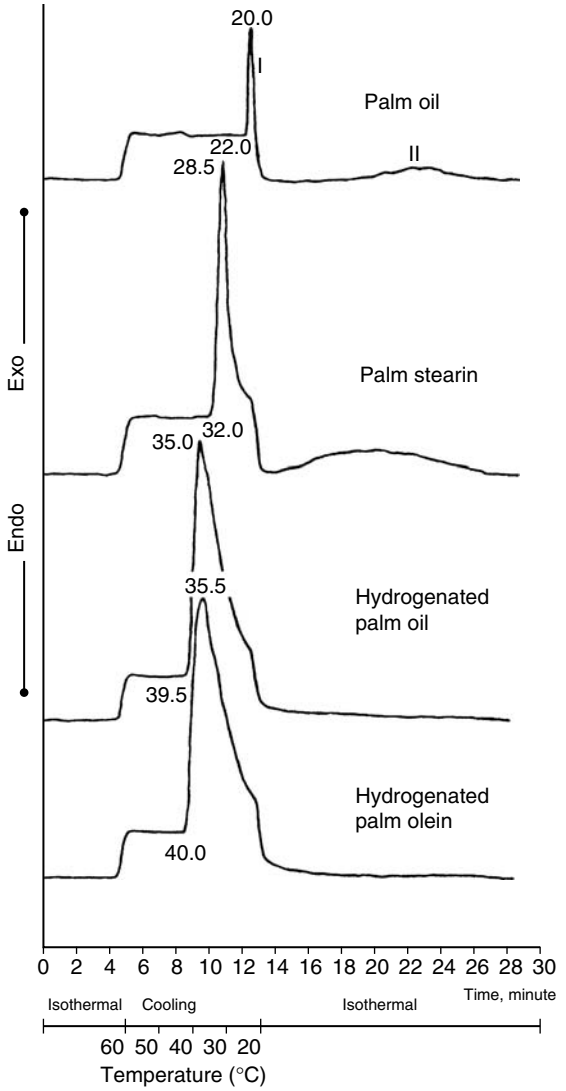

FIGURE 2.11 DSC crystallization curves of palm oil and hydrogenated palm oil IV 27.5. (From Yap, P.H. et al. (1989). *J. Am. Oil Chem. Soc*. *66*: 1792–1795.)

cooling rates affect the structure and mechanical properties of milk fat and lard. When crystallized rapidly, crystals are numerous and small, and when crystallized slowly, a smaller number of large crystals are found.

Tyagi and Vasishtha (1996) have shown that refractive index, specific gravity, color, viscosity, saponification value, and free fatty acids of soybean oil increased with frying temperature, whereas the iodine value decreased. The same trend was observed in vanaspati, a partially hydrogenated vegetable blend, but less markedly than in soybean oil, indicating a lesser degree of deterioration. Also, iodine values of soybean oil and vanaspati are decreased after frying, and polyunsaturated fatty acids are decreased in direct proportion to frying time and temperature.

XVI. OPTICAL PROPERTIES

Fatty acids and their esters crystallize in any one or several polymorphic forms in the hexagonal, orthorhombic, or triclinic crystal systems. Since all of these crystal systems are anisotropic, the

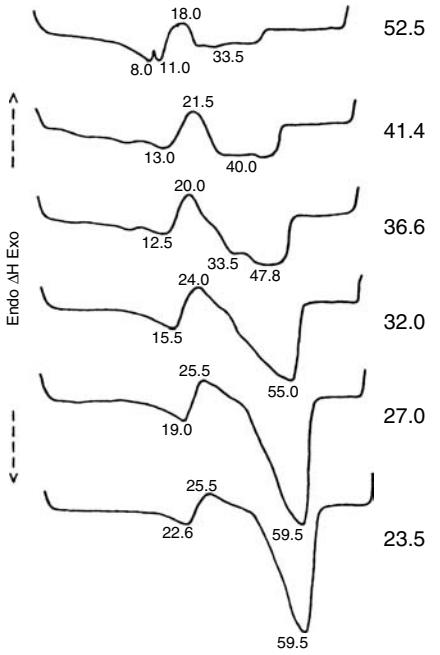

FIGURE 2.12 DSC heating curves of palm oil at various stages of hydrogenation. (Numbers at right indicate iodine values.)

crystals will rotate the plane of polarized light. This will make it possible for these crystals to be viewed in the polarizing microscope. A typical sample of shortening examined in the polarizing microscope shows a multitude of elongated crystal particles (Figure 2.13).

XVII. REFRACTIVE INDEX

The refractive index of a fat or fatty acid is a measure of the relative velocities of light in air, ν, and of the material being tested, ν′. If the angle of incidence of the light striking the surface of the material is *i* and the angle of the refracted beam in the oil is *r*, the refractive index *n* is expressed as

$$n = \frac{\nu}{\nu'} = \frac{\sin i}{\sin r}.$$

The refractive index of the fat or fatty acid is influenced by wavelength, temperature, density, and constitution. The measurement is usually carried out at the wavelength of 589 nm of monochromatic sodium light. As the temperature increases, the refractive index for an oil drops by 0.00035 per °C. Measurement of the refractive index is important in following the change in unsaturation during hydrogenation. This is possible because the refractive index and iodine value show a linear relationship. As an example of this relationship for the hydrogenation of canola oil, according to Patterson (1983), a drop of 10 units in the iodine value parallels a decrease in the refractive index of 0.00116, as shown in Figure 2.14.

XVIII. SPECTRAL PROPERTIES

UV spectroscopy has been used primarily to detect the presence of and type of conjugated double bonds in fatty acids. As conjugated double bonds are rarely found in fatty acids, the procedure is used after the treatment of polyunsaturated fatty acids with strong alkali (alkali isomerization). As the conjugation in a compound increases, the absorption changes to a higher wavelength. Chapman (1965) listed the absorption maxima for various conjugated chromophores (Table 2.7).

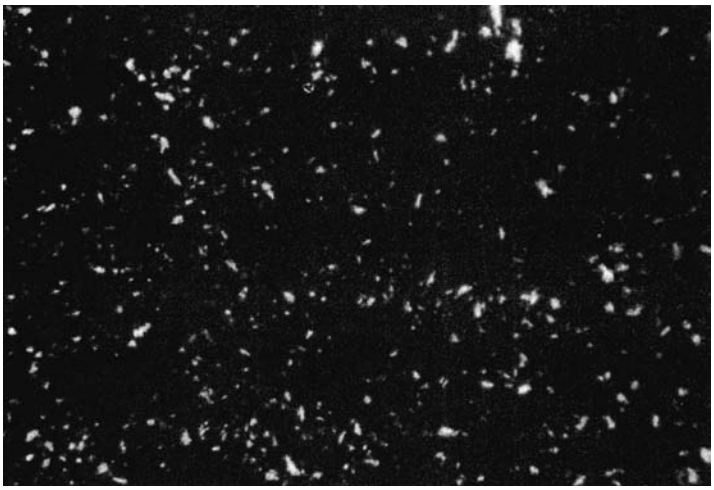

FIGURE 2.13 Crystal particles in a plastic fat as seen by using the polarizing microscope.

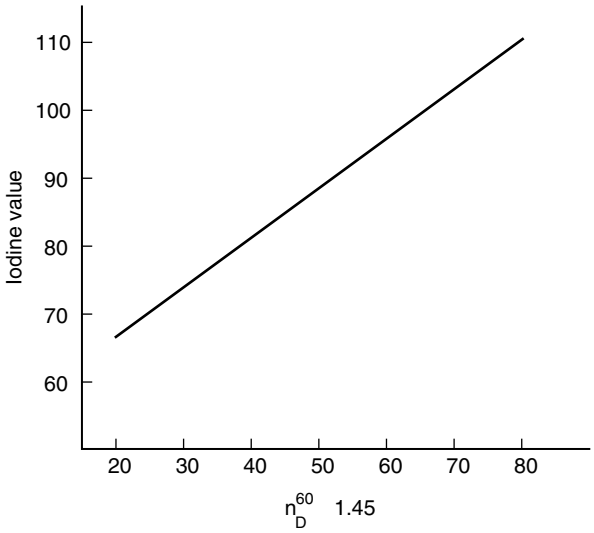

FIGURE 2.14 Relationship between refractive index and iodine value in the hydrogenation of canola oil.

Infrared spectroscopy has found important uses in the identification and quantitative analysis of isolated *trans* double bonds and conjugated systems with one or more *trans* double bonds. The *trans* group exhibits a characteristic maximum in the 10- to 11-μm range. The most widely used method of analysis for isolated *trans* double bonds is based on the absorption maximum at 10.35 μm. The absorption maxima for various *trans* compounds are shown in Figure 2.15 (Wolff and Miwa, 1965).

Recently, this technique has been improved by using attenuated total reflectance and Fourier transform principles. The resulting rapid methods have been used to determine *trans* fatty acids (Adam et al., 1998; de Greyt et al., 1998; Sedman et al., 1998). Other procedures include the determination of iodine value (Sedman et al., 1998) and free fatty acids (Che Man and Moh, 1998).

XIX. SOLUBILITY AND INTERFACIAL PROPERTIES

Fats and fatty acids are completely miscible with mot organic solvents at temperatures above their melting points. The solubility of fats in organic solvents decreases with increasing mean molecular

TABLE 2.7
Absorption Maxima of Various Chromophores in the UV Range

Chromophore	Type	Compound	λ max (nm)
—C=C—	Ethylenic	Octene-3	185
—C=C—C=O	Conjugated ene-al	Croton aldehyde	217
$(—C=C—)_2$	Conjugated diene	9,11-Linoleic acid	232
—C=C—C=C—C=O	Conjugated diene-al	Sorbaldehyde	263
$(—C=C—)_3$	Conjugated triene	α-Elaeostearic acid	270
$(—C=C—)_4$	Conjugated tetraene	Parinaric acid	302

weight and increases with increasing unsaturation. This is the basis for fractional crystallization of fats into a number of fractions based on molecular weight and unsaturation. Alcohols from methanol to octanol have the interesting property of being miscible with the liquid portion of plastic fats but not the solid. This has been used as a method for the separation of solid fat (Chawla and deMan, 1990).

Water is slightly soluble in oil at 0°C, with solubility amounting to about 0.07% and 0.14% at 32°C. Surface tension increases with increasing chain length and decreases with temperature. Surface and interfacial tensions against water for different oils are similar; Table 2.8 contains data reported by Feuge (1947).

Surface and interfacial tensions are greatly reduced when surfactants such as monoglycerides and phosphatides are added. The adhesion of edible oils to food contact surfaces is of importance in the cleaning of food-processing equipment and in product–package interactions. Theoretical models for oil adhesion to food contact surfaces have been presented by Michalski et al. (1998). This is of importance in deep frying. The effect of surfactants on the interfacial tension of frying fat has been described by Gil and Handel (1995).

TABLE 2.8
Surface and Interfacial Tension of Some Vegetable Oils

	Surface Tension (dyne/cm)		Interfacial Tension (dyne/cm)		
Temperature (°C)	Cottonseed	Coconut	Peanut	Cottonseed	Soybean
20	35.4	33.4	—	—	—
70	—	—	29.9	29.8	30.6
80	31.3	28.4	—	—	—
130	27.5	24.0	—	—	—

TABLE 2.9
Viscosity of Some Oils

	Viscosity (cP)	
Oil	37.8°C	98.9°C
Olive	42.75	8.32
Rapeseed	46.15	9.41
Cottonseed	32.96	7.71
Soybean	26.29	7.01
Sunflower	30.67	7.07
Castor	282.22	19.31
Coconut	27.48	5.59
Palm kernel	28.42	5.97

XX. VISCOSITY

Viscosity or internal friction of fatty acids and their esters is relatively high because of the attraction between the long hydrocarbon chains. Viscosity increases with chain length and decreases slightly with unsaturation. The relatively high viscosity of high-erucic acid rapeseed oil can be related directly to its level of 22-carbon fatty acids. This is illustrated by the increasing viscosity of triglycerides of increasing fatty acid chain length (Table 2.9). Castor oil, because of its high content of ricinoleic acid, is a special case; its viscosity is exceptionally high. The other common oils range in viscosity from 20 to 50 cP at ambient temperature (Table 2.10). Except under conditions of high shear stress, oils behave as true Newtonian liquids. The viscosity of a fatty acid is higher than that of the corresponding methyl or ethyl ester because of hydrogen bonding between carboxyl groups.

Viscosity is an important parameter in the process of melt crystallization. The dry fractionation of oils to produce a solid (stearin) and a liquid (olein) fraction is greatly influenced by the viscosity of the oil at the fractionation temperature. Toro-Vazquez and Gallegos-Infante (1996) have described the relationship between viscosity and crystallization in a system-containing saturated triacylglycerols and liquid oil. The viscosities of fatty acids, triglycerides, and their binary mixtures are reported by Valeri and Meirelles (1997).

XXI. DENSITY

Apparent density equals mass per unit volume at the measurement temperature. Relative density or specific gravity is the ratio of the weight in air of a given volume to the weight of an equal volume of water. These measurements can be made at the same or different temperatures. In the American

TABLE 2.10
Viscosity of Triglycerides of Different Chain Lengths, Measured at 85°C

Triglyceride	Viscosity (cP)
Tricaprin	5.51
Trilaurin	7.22
Trimyristin	9.20
Tripalmitin	11.44
Tristearin	14.31

TABLE 2.11
Density of Some Commercial Fats and Oils

	Density (g/mL)		
Product	**20°C**	**40°C**	**60°C**
Cottonseed oil (IV = 110)	0.934	0.927	0.920
Soybean oil (IV = 130)	0.938	0.931	0.924
Hydrogenated vegetable oil, a lard (IV = 70)	0.928	0.821	0.914
Highly hydrogenated vegetable oil (IV = 10)	0.924	0.917	0.910

IV = iodine value.

Oil Chemists' Society (AOCS) official method, a water temperature of 25°C is specified. For liquid oils, density can be determined as d_{25}^{25}. For fats, the usual temperature of measurement is 60°C, giving d_{25}^{60}. The density of fatty acids and their esters increases with decreasing molecular weight and increasing unsaturation. The densities of some commercial fats and oils are given in Table 2.11. A compilation of literature values for density of liquid oils as well as of other physical properties is given by Coupland and McClements (1997). They present a series of empirical equations to calculate the temperature dependency of these physical properties.

XXII. SMOKE, FLASH, AND FIRE POINTS

The smoke, flash, and fire points are important properties when oils and fats are heated in contact with air, as in frying operation.

The *smoke point* is the temperature at which smoke is first detected in a standardized test. The *flash point* is the temperature at which volatile substances are produced at a rate that permits them to be ignited but not to support combustion. When the latter point is reached, we speak of the *fire point*.

The smoke and flash points of fats and oils are greatly dependent on the content of free fatty acids and to a lesser degree on partial glycerides. The influence of the degree of unsaturation is minimal, but chain length has an important effect. Oils containing short-chain fatty acids (e.g., the lauric oils) have lower smoke and flash points than oils with predominantly longer-chain fatty acids. According to Bailey (1979), the smoke points of corn, cottonseed, and peanut oils vary from about 232°C at a free fatty acid content of 0.01% to about 94°C at 100% free fatty acid content. The flash points correspondingly decrease from about 329°C to 193°C and the fire points from 362°C to 221°C.

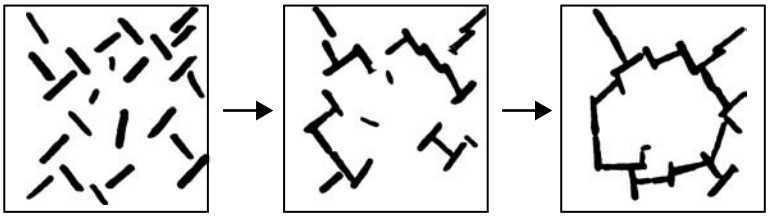

FIGURE 2.16 Schematic representation of network formation by crystals in a plastic fat.

XXIII. RHEOLOGICAL PROPERTIES

Partly solidified fats, also known as plastic fats, combine the physical properties of both solid and liquid. This is caused by the presence of a three-dimensional network of crystals in which a considerable amount of liquid oil is immobilized. A plastic fat is usually workable at room temperature when the solid fat content lies between 20% and 40%. Under the influence of weak attractive forces between crystals, mostly due to van der Waals forces, a three-dimensional structure is formed that lends the product a good deal of resistance to deformation. A schematic representation of such network formation is given in Figure 2.16.

As a result of the presence of a fat crystal network, plastic fats exhibit a yield value. The product behaves similar to a rigid solid until the deforming stress exceeds the yield value and the fat starts flowing like a viscous liquid. The application of a shear stress to such a product is accompanied by structural breakdown and a decrease in strength. This is also known as work softening.

The consistency of plastic fats is determined by a number of factors, including solid fat content, crystal size and shape, and polymorphic form. Rheological properties of fats can be measured by penetration and compression tests and by creep analysis. The latter method permits the separation of viscous and elastic components of the deforming force (deMan and Beers, 1987). The nature of the relationship between rheological properties and the crystal network has traditionally been explained by the postulated existence of weak attractive forces between crystal particles. In plastic fats, however, the crystals are present in such large numbers that a more likely hypothesis (deMan, 1997) is that the mechanical properties are the result of entanglement of mostly rod shaped crystals. Humphrey et al. (2004) have reviewed the phase behavior, from molecular to rheology, of a binary lipid shortening system.

3 Application of Gas–Liquid Chromatography to Lipid Separation and Analysis: Qualitative and Quantitative Analysis

Robert G. Ackman

CONTENTS

I. ISOLATION AND ANALYSIS OF FATTY ACIDS

Almost all foods contain "fat," which is very loosely defined as material that is soluble in any of several organic solvents such as hexane, diethyl ether, or chloroform. The major lipid classes commonly encountered in foods are shown in Figure 3.1. For this discussion, pigments, sterols, hydrocarbons, tocopherols, waxes, and so on will be ignored, although they are coextracted along with the major classes of lipids. The distinguishing feature of lipids in foods is the universal occurrence of medium- and long-chain (C_{14}–C_{22}) fatty acids. The hydrocarbon chains of these fatty acids are the main factor in the solubility already mentioned. As emphasized by the adjectives, the nomenclature is rather confused. Most nutritionists distinguish the C_8, C_{10}, and C_{12} fatty acids from the common C_{16} and C_{18} fatty acids by calling the former "short chain" and the latter "long chain." The former are readily digested, and on absorption they pass directly to the liver via the portal vein, whereas the latter tend to transfer into the lymph in chylomicrons (Nelson and Ackman, 1988). For most foods, C_{22} fatty acids are the longest chain length present in any quantity, and in this chapter, "long chain" will mean C_{20} and C_{22}.

A further group of fatty acids of very short chain lengths (C_1–C_6) were historically called the volatile fatty acids (VFAs), primarily because they can be steam distilled at atmospheric pressure.

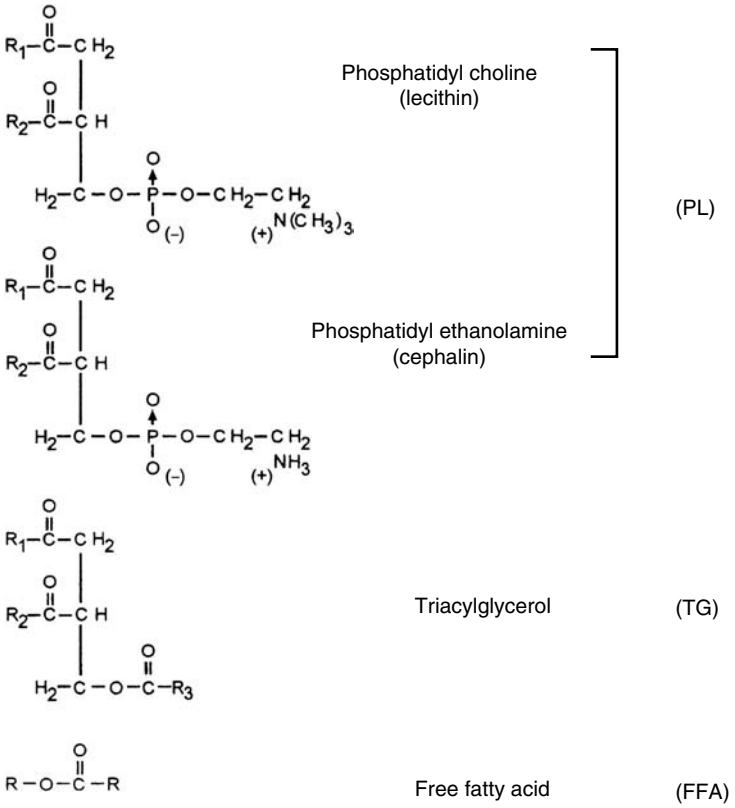

FIGURE 3.1 Principal classes of acyl lipids found in fish and shellfish. Free fatty acids are not initially important but develop postmortem.

Basically, these fatty acids are also quite water soluble, whereas fatty acids of C_8 and longer chains become progressively less water soluble. The VFAs will be considered separately from the longer-chain fatty acids, although it is intriguing to recollect that gas–liquid chromatography (GLC) was in fact invented expressly to determine low levels of VFAs (James and Martin, 1952).

II. DRAWBACKS OF SAMPLE ABUSE

Unless one is handed a bottle of salad oil, it is usually necessary to consider that the lipid classes of Figure 3.1 are dispersed in some sort of food matrix. At one time, a sausage was considered one of the toughest food items on which to perform an extraction, although a chicken pot pie is a close second (Sheppard et al., 1974; Hubbard et al., 1977). Historically, analysts regarded oven drying as an essential first step in sample "proximate analysis," because moisture content was needed in any event and a dry sample could be conveniently ground and homogenized. Unfortunately, the oven drying created two problems. One was that the fats or lipids might be encased in dry protein or some similar matrix that solvent could penetrate only with difficulty (Happich et al., 1984; de Koning and Mol, 1989). The second difficulty created was the potential for oxidation of polyunsaturated fatty acids. Until modern chromatographic methods were introduced, it was not appreciated that not only did oxidation create polar compounds of relatively low solubility in many organic solvents (Sebedio et al., 1987; Hara et al., 1989) but also these compounds could react with other fatty acids to produce relatively insoluble polymers or with amino acids or carbohydrates to give a more permanent and insoluble binding of fat or lipid (Allen and Hamilton, 1983).

Yet another form of sample abuse is freeze drying. This is often used by biologists and some biochemists, but more rarely by food scientists. The opportunity for oxygen damage is obvious. Solvent extraction of freeze-dried fatty tissues can be done with chloroform alone (Firth et al., 1985), because water is no longer a problem.

The rules for avoiding sample abuse in lipid analyses are simple. Leave the sample in the original matrix as long as possible, but store it frozen at the lowest possible temperature, preferably at –30°C or lower, to avoid enzymatic lipolysis (Hardy et al., 1979). An oxygen-impermeable wrap or a container flushed with nitrogen should be considered. The next best thing is to do a *total* extraction immediately and then store the extract in solution, or partially dried by solvent removal with nitrogen, at –30°C or lower.

With larger samples or packages of foods, it may be necessary to use a Hobart silent cutter or equivalent equipment to produce a uniform homogenate for subsampling and analysis of an economic or otherwise rational portion. The same technique would apply to "averaging" several units for one determination of lipid content. These critical points are basic to good practice in laboratory quality control plans (Malanoski, 1990).

III. TOTAL LIPID RECOVERY

Most of the organic solvents already mentioned will dissolve the triacylglycerols and free the fatty acids of Figure 3.1. The difficulty in total lipid extraction is twofold: (1) Some of the solvents are immiscible with water and (2) some are poor solvents for the polar lipids (mostly phospholipids). The triglycerides may be obvious in fatty streaks or layers, or they may exist in the form of adipocytes (fat cells) scattered within muscle tissue. A very small fraction will be found in the cell membrane bilayers, which are mostly phospholipids. It is likely that the latter do not exist in the neat arrangements usually shown but are instead hydrated to some extent because of the affinity for water of both the phosphoric acid and amino acid molecules on the 3-position of the glycerol.

Methanol is a poor solvent for triacylglycerols but is fully miscible with water in all proportions. It can thus serve to strip away the hydrating water and allow chloroform; for example, to dissolve the phospholipids. This was the basis of the famous Folch et al. (1957) 2:1 chloroform–methanol solvent system, which became the basic lipid extraction unit for biochemists. The water in the system caused the chloroform to separate cleanly, with the methanol component retaining the water and suppressing emulsions. The original method included extensive procedures for the removal of nonlipid components that are probably ignored by most people citing the method.

Similarly, the utilization of a monophase based on exact proportions of chloroform, methanol, and water as developed by Bligh and Dyer (1959) tends to be bypassed for expediency, and there are thousands of scientific papers published annually in which the extraction of various samples is executed with "chloroform:methanol:2:1" with little attention paid to proportions, ratios, and water content variables. The key role of methanol has been emphasized by Areas (1985).

The Bligh and Dyer system can yield more lipid than most other methods, and Table 3.1 compares the recovery of lipid by three methods in the difficult case of oxidizing fishmeal, which is in essence cooked and dried fish muscle (de Koning and Mol, 1989). Food applications of solvent systems are reviewed by Sheppard et al. (1974), Hubbard et al. (1977), and Sahasrabudhe and Smallbone (1983). Particular cases, such as recovery of all the free fatty acids formed in frozen stored fish, may require modification of "standard" techniques such as the Bligh and Dyer chloroform–methanol system (Hardy et al., 1979). Incomplete lipid recovery is sometimes not a problem if the material recovered is a representative sample but can be misleading if food fatty acid composition data are needed. Fish phospholipids include substantial proportions of polyunsaturated fatty acids (Table 3.2), and in lean fish samples, failure to recover phospholipids can give low values of 20:5n-3 and 22:6n-3. In red meat, 18:2n-6, 18:3n-3, and 20:4n-6 would be affected. (This shorthand notation is based on chain length, number of ethylenic *cis*-methylene-interrupted bonds [if more than one], and position counted from the terminal methyl group.)

IV. TOTAL FATTY ACID RECOVERY

The objective of lipid extraction is varied. Increasingly, it develops from requests for specific information on cholesterol and fatty acids. There is thus very little reason to bother with lipid extraction. Instead, total lipid recovery may be bypassed, and the sample may be digested under nitrogen to destroy the protein food matrix. Traditionally, as in the Association of Official Analytical Chemists' (AOAC) method 18.043 (Williams, 1984), concentrated HCI was used to digest carbohydrates and so on, but in practice alcoholic alkali will do this job more efficiently (Kovacs et al., 1979).

A problem with the concentrated HCI, in addition to the obnoxious fumes, is that the glyceride lipids of Figure 3.1 are only partially hydrolyzed. Thus the free fatty acids will be increased, but the proportions of these are unpredictable. With alcoholic alkali digestion there is another problem that may be overlooked. The saponification reaction in the presence of ethanol and water will produce the free acids as alkali salts but may also produce a small proportion of ethyl esters of fatty acids, because alkali-catalyzed transesterification is a very fast equilibrium-type reaction. If separate recovery of sterols and fatty acids is an objective, some small part of the fatty acids bound as ethyl esters may be lost if the sterols are removed as "unsaponifiables" from the water–alcohol solution of soaps. Usually these esters are a representative part of the whole fatty acid mixtures, but on occasion they may be specific to some part of the lipid. Similarly, the addition of a fatty acid as an internal standard may require that formation of esters be avoided at this stage of fatty acid recovery (Ackman et al., 1990) unless acid–ester equilibrium is attained.

Digestion is accelerated by providing a high proportion of ethanol to the matrix, but in view of the ethyl ester formation, additional water may be added as the reaction proceeds. This is usually required in any event to promote recovery of the unsaponifiable material from the alkaline solution and of the free acids after subsequent acidification with HCI. For these extractions, the use of diethyl ether usually reduces emulsion formation but may contribute damaging peroxides if the ether is not freshly distilled. *n*-Hexane or light petroleum ether is an acceptable alternative. Usually one extraction of free acids is about 90% efficient, and thus two extractions are required to complete adequate (99%) recovery of the free acids. If shorter chain (C_8–C_{12}) fatty acids are present, a third extraction is recommended. Christie (1982) covers some of the above problems. If a total lipid extract is to be later saponified and the fatty acids recovered, much the same principles apply.

The U.S. Food and Drug Administration has now defined total fat in a food as the sum of all fatty acids, expressed as triacylglycerols. A compendium issued by the AOAC (Sullivan and Carpenter, 1993) explains all the steps for gas chromatography-fatty acid methyl ester (GC–FAME) analysis clearly and it has been recently confirmed for ground beef and oilseeds that the GC–FAME method provides equivalent lipid recovery to supercritical fluid extraction with ethanol-modified CO_2 (Taylor et al., 1997). However, gravimetric results were less satisfactory. It should be noted that supercritical fluid chromatography itself may not be ideal as a replacement for gas–liquid or high-performance liquid chromatography (HPLC) in analytical separations for all classes of lipids (Borch-Jensen and Mollerup, 1996).

V. ANALYSIS OF FATTY ACIDS BY GAS–LIQUID CHROMATOGRAPHY

The objectives of fatty acid recovery having been met, it is usual to convert the fatty acids to derivatives for analysis. Although HPLC can be used, appropriate derivatives are required, usually those absorbing strongly in the ultraviolet (Ratnayake and Ackman, 1989). If that is the case, an advantage is that the only thing measured is the derivative molecule itself; this will give the composition in moles of fatty acid and not in weight units of fatty acids unless converted.

Probably 99% of the analyses of fatty acid compositions in foods are executed by GLC with the methyl esters. In principle, any ester can be used; for example, the isopropyl esters used for combined extraction and esterification by Peuchant et al. (1989). The reason for preferring esters to

free acids is twofold. The acids may "associate" in pairs in the vapor phase, a long-known phenomenon adversely affecting distillation of free acids, but they will also absorb on any convenient surface, resulting in tailing and/or "ghosting" (Ackman, 1972a; Cochrane, 1975). This problem can be reduced with flexible fused silica wall-coated open-tubular (WCOT) columns (Hordjik et al., 1990). Generally much higher temperatures are required for the GLC of free acids than for methyl esters, which is an advantage for the latter. The decade 1980–1990 marked a major shift in GLC technology. The packed GLC column became obsolete with the introduction of the flexible fused silica column (FFSC). Packed columns will therefore be omitted from further discussion, but the principles and column packings are well described elsewhere (Ackman, 1969, 1984; Lie Ken Jie, 1980).

The FFSC is a modern version of the WCOT column introduced in a practical commercial form about 1965 and the subject of a major review two decades ago (Ackman, 1972b). Glass WCOT columns were also available but were more widely used in Europe than in North America (Ackman, 1986). The modern GLC unit remains an assembly of the three basic parts and one essential auxiliary. These are as follows:

1. *Injection port*. This should be of the split type, because there are usually plenty of samples available to food scientists. Biochemists and environmentalists are the main users of on-column injection. An autosampler is a very useful, if rather expensive, accessory. A split ratio of 30:1 to 50:1 is compatible with 1- to 2-μL injections of 1%–5% solutions of methyl esters.
2. *Column.* Quality control departments may be able to standardize on a short (10 m) FFSC for the minimal separations required with numerous samples of common vegetable oil fatty acids. Times of 5 min or less are feasible. However, with "bonded" liquid phases (see below), the 30 m × 0.32 (or 0.25) mm i.d. FFSC may as well be used, because a small elevation in temperature will bring the sample off in the same time frame but with superior peak resolution. Fatigue or accidents usually break the FFSC near the end. With the longer column, the end can usually be reinstalled and the column continues in use. Sometimes with dirty samples a 1-m length of inert silica forecolumn may be useful to prolong column life.
3. *Detector*. This is universally the flame ionization detector (FID). The FFSC is usually fed through the base of the FID into the hydrogen gas stream, and often through the flame jet, with the tip almost in the flame itself. This elimination of postcolumn connectors is a major benefit of FFSC technology. The FID is tolerant of a wide range of sample sizes and column gas flows, but operating gas (air and hydrogen) flows should be checked regularly and follow the manufacturer's recommendation.
4. *Electronic integrator.* This indispensable auxiliary unit is now offered as an integral part of modern GLC equipment. A variety of options on data recording and processing are usually available, but generally peaks are identified by time printouts in a digitally regenerated chromatographic chart and then a matching area percent table is printed out.

VI. OPERATIONS—IDENTIFICATION AND QUANTIFICATION

For most analyses of food fatty acids, a polar column will be selected. The exception could be for gas chromatography–mass spectrometry (GC–MS) use, for which a methyl silicone liquid phase might be used, or for *cis–trans* analyses requiring a cyanosilicone column (see below). The term bonded column is not strictly accurate. The liquid phase contains a cross-linking agent so that the whole of the liquid phase layer becomes one supermolecule. Consequently, column bleed is minimal, with the advantages that the baseline is stable during temperature programming (compare Figures 3.2 and 3.3) and GC–MS operations are readily performed. The first successful polar bonded columns were based on Carbowax-20M (Union Carbide Corp., Danbury, CT) as the liquid phase, and they have excellent

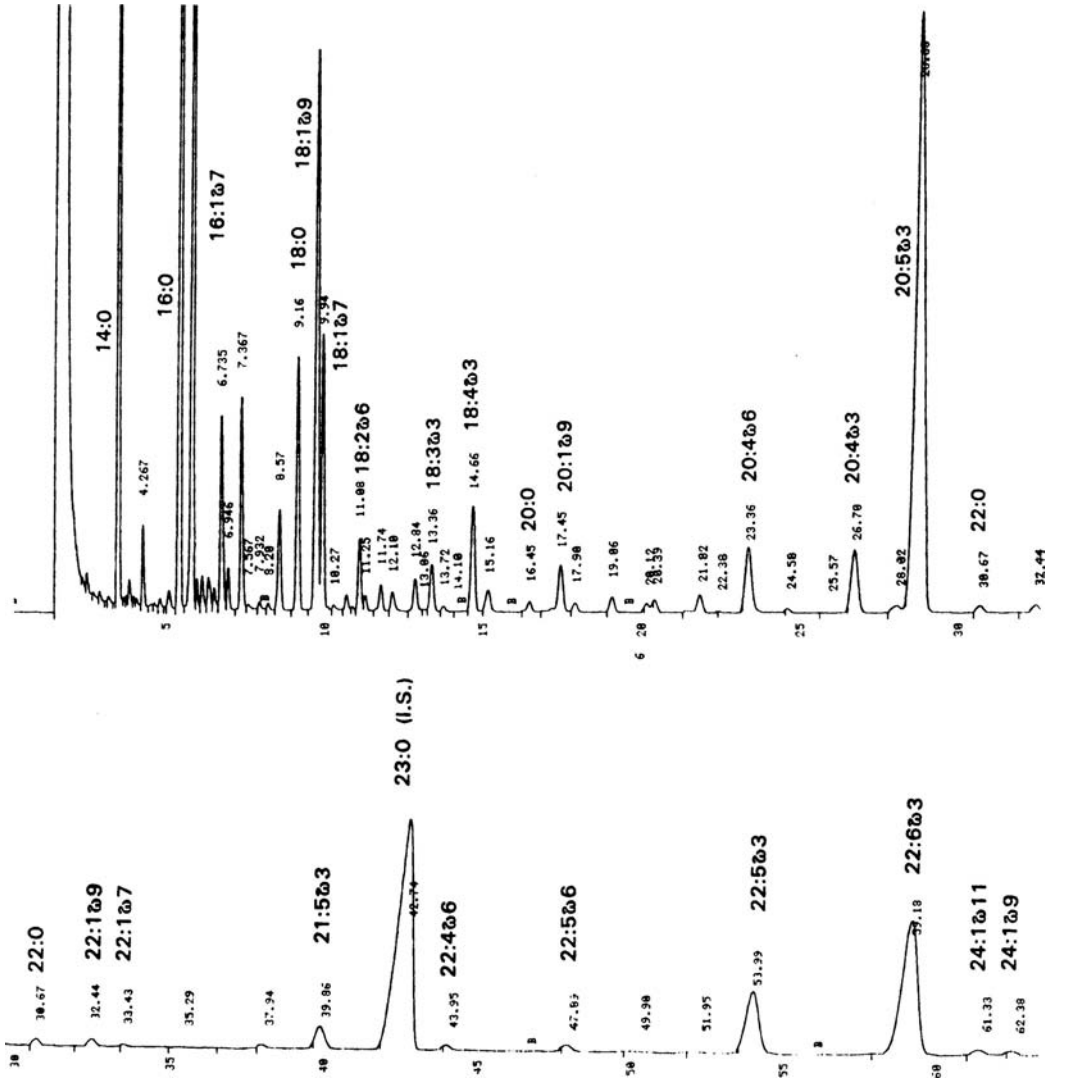

FIGURE 3.2 Isothermal analysis of methyl esters of fatty acids of menhaden oil, a fish oil produced in quantity in the United States, with added 23:0 internal standard. Column, Omegawax-320 (Supelco Inc., Bellefonte, PA), 30 m × 0.32 mm i.d., operated at 190°C with helium carrier gas at 12 psig. Print numbers at baseline are minutes from injection, so 22:6n-3 emerges at close to 60 min elapsed time.

stability up to 260°C or 280°C. Originally, this polyethylene glycol was an industrial chemical with a formula weight of approximately 20,000 produced by Union Carbide Corp. (Danbury, CT). Several companies coat FFSC with this or similar polymers. The Supelco (Bellefonte, PA) 1999 catalogue offers their bonded columns prepared from Carbowax-20m as SUPELCO-Wax, or Omegawax-250 or Omegawax-320, and lists the names of similar liquid phases offered by other companies. Their use greatly facilitates interlaboratory comparisons of fatty acid methylester retention data (Ackman and Ratanayake, 1989). The retention characteristics for methylesters of fatty acids are also less temperature sensitive than those of the more polar cyanosilicone liquid phases (Sidisky and Ridley, 1991). Several cyanosilicone liquid phases (Sidisky et al., 1988; Cumbers et al., 1990) are at least partially stabilized, and all benefit from having a deoxygenation cartridge installed in the carrier gas line. Either hydrogen or helium is necessary as the carrier gas.

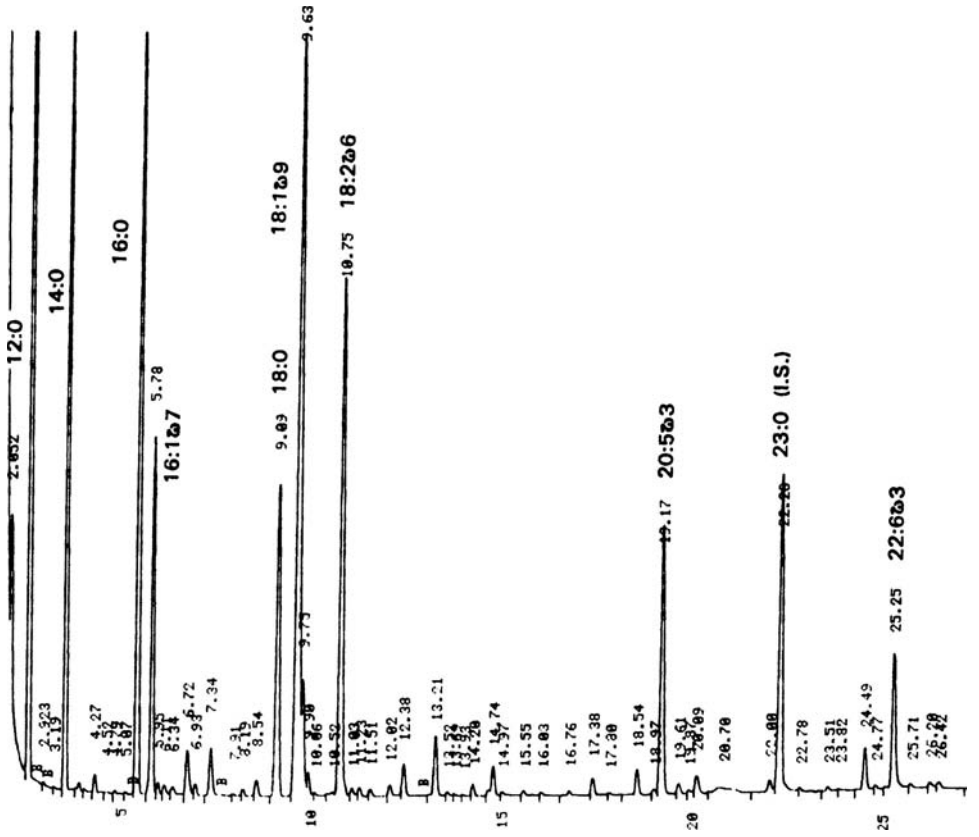

FIGURE 3.3 Temperature-programmed analysis of methyl esters of a mixture of menhaden oil (cf. Figure 3.2) and vegetable oils. Column and equipment as in Figure 3.2. Oven temperature: Hold at 190° for 8 min, program at 3°/min to 240°, hold. Note that elapsed time is reduced to 25 min. Features not observed in fish oils include the 12:0 and the high proportion of linoleic acid (18:2) relative to oleic acid (18:1). The presence of 12:0 and increases in 14:0, 16:0, and 18:0 suggest addition of a tropical oil or oil fraction.

A frequent injection problem is the failure to use a solvent flush (~1 μL) in a typical syringe. Drawn into the syringe prior to the actual solution of methyl esters, this small extra amount of solvent will help ensure complete injection of the sample (Berg, 1988). All of the solvent should be drawn back just out of the needle, the needle inserted through the septum quickly to its full length, and the syringe plunger smartly depressed. There is then no point in leaving the syringe needle in for more than one-tenth of a second.

The main problem in identification of peaks for fatty acids is the increased use of both programming and high-polarity columns. The GLC analysis of fish oils has long been recognized as being difficult (Ackman, 1969, 1972b), and for isothermal analyses tabulations of equivalent chain lengths (ECL values) are available (Ackman, 1984, 1986; Christie, 1988). One inexpensive standard solution of even-chain saturated fatty acids provides a series of reference points (14:0–24:0) from which most other fatty acids can be readily identified with ECL values. A virtue of the Carbowax-20M type of polyglycol FFSC is that the elution order will hardly change on going from isothermal operations to temperature programming. Figure 3.2 is an excellent example of the analysis of fish oil fatty acid methyl esters on columns of this type operated isothermally. With programming, the same analyses can be executed in a run time of about 20 min. Note that the only case of chain-length overlap is that 24:0 falls before and 24:1 after 22:6n-3. The liquid-phase DB-225 (J. & W. Scientific, Folsom, CA) is slightly less polar. With more polar liquid phases, chain-length overlap will appear in different chain lengths, for example, with possible coincidence of 20:1 and 18:3n-3, or of 22:1 with 20:4n-6 or 20:5n-3.

TABLE 3.3
Theoretical (Relative) Response Factors (TRF) for Fatty Acid Methyl Ester (FAME)

Atomic weights: carbon, 12.011; hydrogen, 1.0079; oxygen, 15.994 (*Handbook of Chemistry and Physics,* 64th ed., 1983–1984), (Chemical Rubber Publishing Co., Cleveland, OH). Factors are relative to 18:0, which has a factor of 1.0000 by definition. Factors for the following FAME have been verified experimentally: 4:0; 6:0; 8:0; 10:0; 12:0; 14:0; 16:0; 17:0; 20:0; c9–18:1; c9, c12–18:2; c9, c12, c15–18:3; c5, c8, c11, c14–20:4; c4, c7, c10, c13, c16, c19–22:6. Only one factor is given for all positional and geometrical isomers and for branced-chain FAME, as the factors are dependent only on the content of carbon to which hydrogen is bonded. Calculation by Craske, J.D., and Bannon, C.D. (1998). *J. Am. Oil. Chem.. Soc. 65*: 1190–1191.

The area percentage from the FID response represents a close approximation of weight percentage for simple C_{18} vegetable oils but is still only an approximation. To convert to true weight percentage for these VFAs, appropriate response factors (Table 3.3) must be employed, especially if coconut or similar oils are involved. It should be noted that these peaks may not be representative of the weight content of fatty acids in the sample. For example, a fish oil deodorized under very severe conditions contained 12% dimeric acid and 17% trimeric acid (Change, 1988). These would not appear in the chromatogram, and the analyst could report that the fatty acids of the sample contained, for example, 25% 22:6n-3, whereas in fact the true figure would be less. For this reason, in critical cases or if lipid or fat samples contain nonvolatile or inert material, an internal standard should be used to give the sample content of a particular fatty acid in milligrams per gram of sample. The procedure was outlined by Einig and Ackman (1987) and is now an Official Method (Ce-lb-89) of the American Oil Chemists' Society if fish oils or concentrates are involved (Ackman et al., 1990). This could become important to the food industry, because fish oils are receiving serious consideration as food additives (Garcia, 1998). An interlaboratory trial of this technology was also successful in satisfying the requirements of the AOAC (Joseph and Ackman, 1992). If the sample consists of shorter chain lengths, other appropriate internal standards such as 13:0, 15:0, and 17:0 may be used with suitable FID correction factors applied (Ackman, 1986; Craske and Bannon, 1988).

In the oils and fats industries, it is common to specify iodine values, and computer methods for converting GLC area percentages to weight percent fatty acids can be extended and adapted to calculate iodine values. This provides an excellent check on quantification if the calculated and Wijs iodine values are compared (Ackman and Eaton, 1978).

VII. *TRANS* FATTY ACIDS

A special problem in fatty acid analysis is that some labels require accurate figures for the content of saturated, polyunsaturated, and *trans* fatty acids. The analysis of saturated fatty acids by GLC is easy and accurate, and the total *trans* bonds in fatty acids have always been feasible using infrared spectroscopy.

The problems created by label requirements some years ago are also factors in the analysis of the polyunsaturated fatty acids. The soybean lipoxidase assay (Beare-Rogers and Ackman, 1969; Firestone, 1984) is specific for fatty acids with polyethylenic *cis* bonds in the n-6 and n-9 positions. An excessively narrow nutrition viewpoint that only the ω6 *cis–cis*-18:2n-6 was "essential" meant that *cis–cis–cis*-18:3n-3, which reacts equally well, could not be included. The C_{20} and C_{22} fish oil fatty acids have ω3 structures (n-3, n-6, n-9), and would also react (Beare-Rogers and Ackman, 1969). More recently, the ω3 fatty acids have been "rehabilitated" (Lands, 1986; Bjerve et al., 1987; Hunter, 1990) as "essential," a belated and long-overdue recognition (Holman, 1998).

For a decade or more, packed-column GLC (Conacher and Iyengar, 1978) was poorly suited for the specific C_{18} fatty acid types, with *trans*-isomers resulting from partial hydrogenation even with the cyanosilicone liquid phases (Ackman, 1986; Lercker et al., 1987; Ackman and Ratnayake, 1989), but more recently, the introduction of the FFSC has stimulated the use of capillary GCL (Lercker et al., 1987; Ackman and Ratnayake, 1989). The presence of simple geometrical isomers of all-*cis*-18:3n-3 (and of all-*cis*-18:2n-6) in deodorized vegetable oils was documented with capillary GLC over a decade ago (Ackman et al., 1974). These may have hitherto unforeseen biochemical

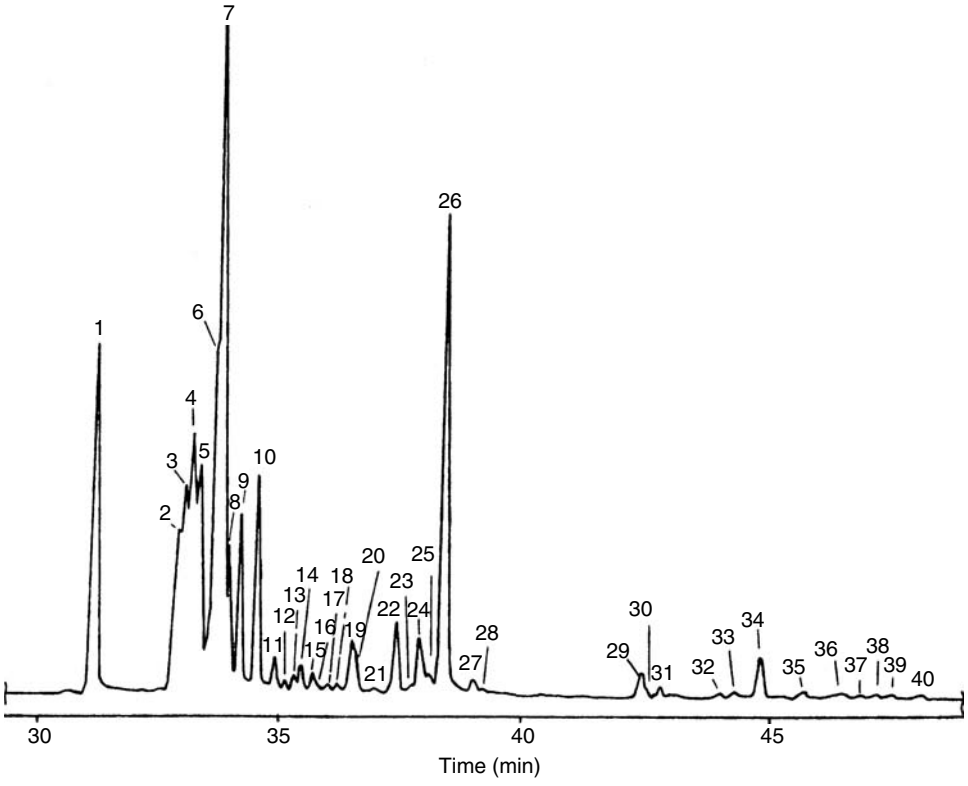

FIGURE 3.4 The C_{18} region of the gas chromatogram of the fatty acid methyl esters of soybean oil margarine. Analysis on an SP-2560 FFSC column (100 m × 0.25 mm i.d.). Numbers correspond to 1, 18:0; *2*, 18:1Δ6–8t; *3*, 18:1Δ9t; *4*, 18:1Δ10t; *5*, 18:1Δ11t; *6*, 18:1Δ12t; *7*, 18:1Δ9c + 18:1Δ13t + 18:1Δ14t; *8*, 18:1Δ10c; *9*, 18:1Δ11c; *10*, 18:1Δ12c + 18:1Δ15t; *11*, 18:1Δ13c; *12*, 18:2tt; *13*, 18:1Δ14c; *14*, 18:2tt; *15*, 18:1Δ15c; *16*, 18:2tt; *17*, *18*, *20*, *21*, 18:2tc/ct; *19*, 18:2Δ9t, 12t; *22*, 18:2Δ9c, 12t; *23*, ?; *24*, 18:2Δ9t, 12c; *25*, ?; *26*, 18:2Δ9c, 12c; *27*, 18:2Δ9c, 15c; *28*, ?; *29*, 20:0; *30*, 18:3?; *31*, 18:3Δ9c, 12c, 15t; *32*, 18:3Δ9t, 12c, 15c; *33*, 18:3Δ9c, 12t, 15c; *34*, 18:3Δ9c, 12c, 15c; *35*, 20:1; *36*–40, 18:2 conjugated? (Reproduced from Ratnayake, W.M.N., et al. (1990). *J. Am. Oil. Chem. Soc*. *67*: 804–810. With permission.)

properties when extended to the C_{20} and C_{22} chain lengths (O'Keefe et al., 1990). An appropriate AOAC interlaboratory collaborative study of margarine materials has now been executed by de Palma (Firestone, 1990). Two papers by Ratnayake and Beare-Rogers (1990) and Ratnayake et al. (1990) provide in-depth reviews of all facets of the particular problems caused by the overlap of certain *cis*- and *trans*-isomers. Other comprehensive material on margarine analyses is provided by Mossoba et al. (1990, 1993).

The total analysis of methyl esters of fatty acids from partially hydrogenated fat samples by GLC requires a column of special polarity (Figure 3.4), usually a cyanosilicone such as a Supelco SP-2560 (Ratnayake et al., 1997) or chrompack CP-Sil-88 (Chrompack, Middleburg, the Netherlands) (Wolff et al., 1995). It is the length that often deters analysts, since 60 m is good but 100 m is even better (Wolff and Bayard, 1995). Unfortunately very detailed analyses then run to 2 h. Although much useful information on the sample can be extracted, a significant portion of late-eluting 18:1 fatty acid isomers will be hidden under early-eluting *cis*-isomers (Figure 3.5). Auxiliary fractionation is then required (Ratnayake, 1995; Wolff et al., 1995). Curiously, among the *trans* 18:1 isomers, the butyl esters of *trans*-14-18:1 and *trans*-15-18:1 coincide on a polyglycol-based column (Figure 3.6), but when the isopropyl or methyl esters are used, *trans*-13-18:1 and *trans*-14-18:1 coincide on the cyanosilicone CP-Sil 88 column (Figure 3.7).

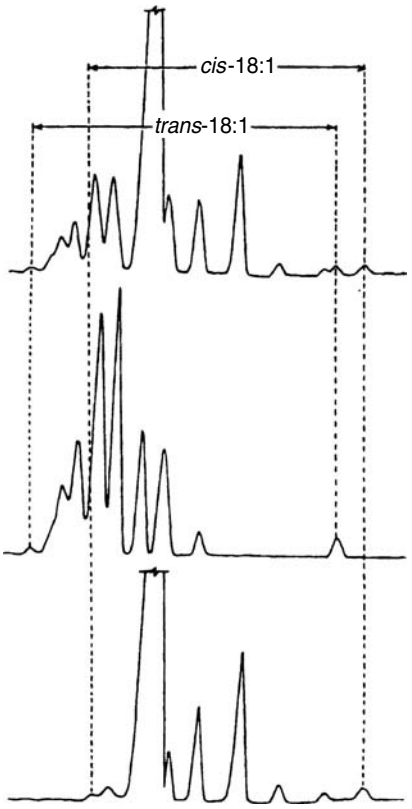

FIGURE 3.5 Partial chromatograms of the isopropyl esters of fatty acids of partially hydrogenated soybean oil (top). Included are the same esters after fractionation on silver nitrate TLC plates to give the *trans*-18:1 acids (center) and *cis*-18:1 acids (bottom), illustrating the extent of overlap. Column, 100 m × 0.25 mm, CP-Sil 88 coated, at 160°C. (Reproduced from Wolff, R.L., and Bayard, C.C. (1995). *J. Am. Oil Chem. Soc. 72*: 1197–1201. With permission.)

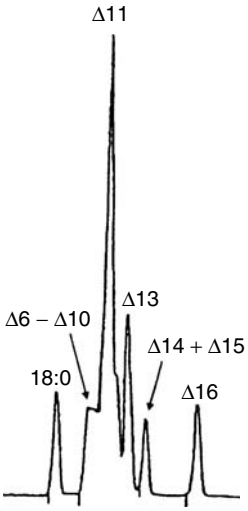

FIGURE 3.6 Partial gas–liquid chromatogram of butyl esters of *trans* monoethylenic fatty acids of butter fat as isolated by $AgNO_3$-TLC. Column 30 m × 0.25 mm, Omegawax-320; note coincidence of Δ14 and Δ15. (Adapted from Ackman, R.G., and Macpherson, E.J. (1994). *Food Chem. 50*: 45–52.)

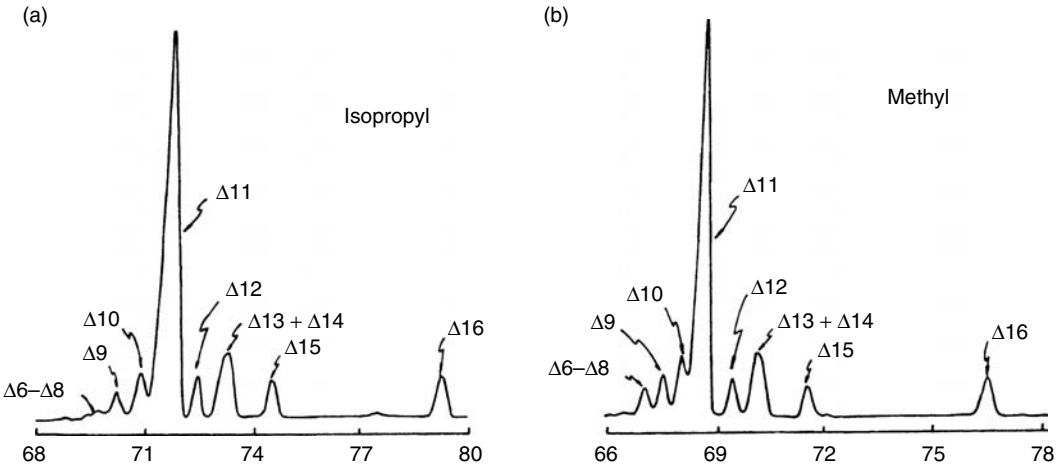

FIGURE 3.7 Comparison of chromatograms of isopropyl and methyl esters of *trans*-18:1 acids isolated from beef tallow (a and b, respectively). Analyses were done on a CP-Sil 88 fused-silica capillary column 100 M × 0.25 mm; note similarity of profiles. (Reproduced from Wolff, R.L., and Bayard, C.C. (1995). *J. Am. Oil Chem. Soc. 72*: 1197–1201. With permission.)

VIII. CONJUGATED LINOLEIC ACID

Recently, a spate of papers on conjugated linoleic acid (CLA) has appeared. One of the interesting aspects is that there are two major isomers (Figure 3.8) if CLA is produced chemically from linoleic acid, respectively, *cis*-9, *trans*-11- and *trans*-10, *cis*-12-octadecadienoic acids (Christie et al., 1997). However, with *in vivo* biosynthesis, in ruminants the *cis*-9, *trans*-11-octadecadienoic isomer dominates and is that commonly reported for the human body (Fritsche et al., 1998) because of our consumption of beef and dairy products. Synthetic and biological samples need to be distinguished (Ackman, 1997; Christie et al., 1997). CLA is not increased in the human body by adding a ready

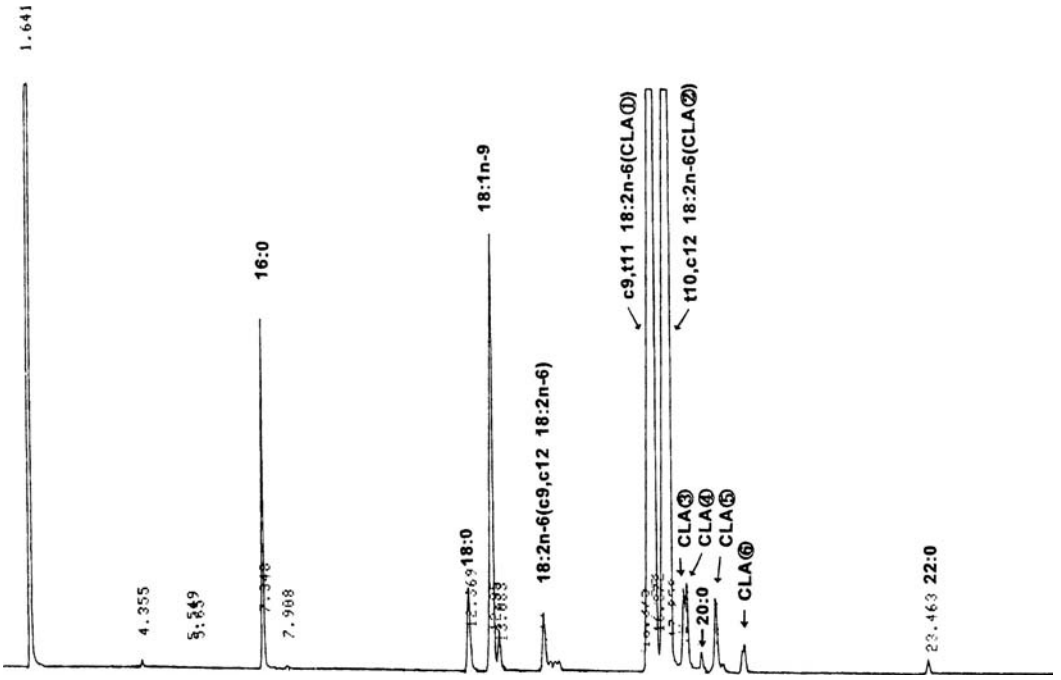

FIGURE 3.8 Gas–liquid chromatographic analysis of methyl esters of fatty acids of safflower oil after alkali isomerization to produce CLA from linoleic acid. Column, Omegawax-320. (Courtesy of S.J. Kang, Gyeongsang University, Korea.)

source of *cis*-9, *cis*-12 linoleic acid such as safflower oil to the diet (Herbel et al., 1998). Therefore, foods appear to be the principal sources of CLA. On GLC, they elute a little later than other C_{18} fatty acid esters (Figure 3.8). Overheating of homemade standards in alkali can produce many additional isomers (Mounts et al., 1970; Christie et al., 1997; Ackman, 1998), and careless saponification of lipids can also produce extra peaks of CLA (Ast, 1963). Special care is needed for methyl ester preparation from lipid samples if CLAs are suspected (Shantha et al., 1993; Kramer et al., 1997). In general, the analysis of CLA is difficult and should not be taken lightly (Sehat et al., 1998). This almost automatically includes all dairy products and human milks (McGuire et al., 1997; Jensen et al., 1998; Lavillonnière et al., 1998; Lin et al., 1998).

IX. OTHER LIPIDS

Food scientists may occasionally have a need to examine minor food ingredients—for example, mono- and diglycerides or even triglycerides—by using GLC. The modern FFSC is very well suited to these requirements, but because higher temperatures are involved, only "bonded" liquid phases should be considered. Many examples of this type of analysis have been published (Ackman, 1986), and it is only necessary to select an appropriate commercially available column because the GLC units manufactured in the past decade should already meet requirements. It is probable that thick liquid-phase column coatings should be avoided to keep temperatures as low as possible. In particular, peak asymmetry can indicate either too low a temperature or column overload.

The basic requirement for GLC analyses is that the analyte be volatile. Alternatives may have to be sought for materials of low volatility; an example of the combination of the sensitivity of the FID of GLC with the efficiency of thin-layer chromatography (TLC) is the Iatroscan-Chromarod combination (Ackman, 1981; Ackman and Ratnayake, 1989; Hara et al., 1989; Walton et al., 1989).

A recent development now widely used in this type of work is Fourier transform infrared (FT-IR) as an attachment to a gas chromatograph (Mossoba et al., 1993; Wolff and Sébédio, 1994). It can classify methyl esters of fatty acids as *cis* or *trans* (Mossoba et al., 1993), including those geometrical isomers of the *cis* bonds of polyunsaturated ethylenic fatty acids such as α-linolenic (Chardigny et al., 1996). The biochemical consequences of elongation products of such acids are almost unknown (O'Keefe et al., 1990; Grandgirard et al., 1994; Chardigny et al., 1995). The technology is of course in wider use with other types of samples (Mossoba et al., 1995).

To resolve problems of positional ethylenic bond identification, many laboratories can now benefit from quadrupole mass spectrometers fitted directly on the gas chromatograph. Nitrogen compounds at the carboxyl group such as picolinyl or pyrrolidide derivatives stabilize the bond so that the position can be identified (Harvey, 1992), and they were initially popular. The latter derivative has been applied to several foods, with preparation being accelerated by microwave irradiation (Dasgupta et al., 1992). Another nitrogen base, 4,4-dimethyloxazoline (DMOX), may give better gas chromatographic patterns, similar to that of the methyl esters, and is easy to work with (Lamberto and Ackman, 1994). As shown in Figure 3.9, a "gap" of 12 amu that usually fixes the bond position is *not* observed for fatty acids with an ethylenic bond in the 3-position of *cis* or *trans* esters. *Trans*-3-16:1 is found in photosynthetic parts of green vegetables and could be present in ruminant fats. Figure 3.10, of a *trans*-2-16:1 DMOX derivative, an artifact of the DMOX derivative preparation (Lamberto and Ackman, 1995), shows the expected 12 amu gap between fragments 98 and 110. This has been successfully applied with DMOX derivatives of polyunsaturated fatty acids and other structures in heated fats and oils (Mossoba et al., 1995).

Some lipid-type materials such as vitamins may be better analyzed by TLC or HPLC than by GLC. Progress in all such methods is erratic, but research on methods often gradually becomes commercial practice (Poole and Poole, 1989), much as the early flexible-fused silica GLC column held great promise but had "teething" problems (Ackman, 1981). Progress is inevitable, and food science has lagged behind some other fields in applying modern technology. There is no excuse for this in the application of GLC to fatty acids.

The preponderance of omega-3 fatty acids is going to be influenced slightly in the case of farmed fish. There is an apparent growing problem in the overfishing of the oceans, which creates some shortages in the feeds needed by the aquaculture industry. The GC in Figure 3.3 specified that it

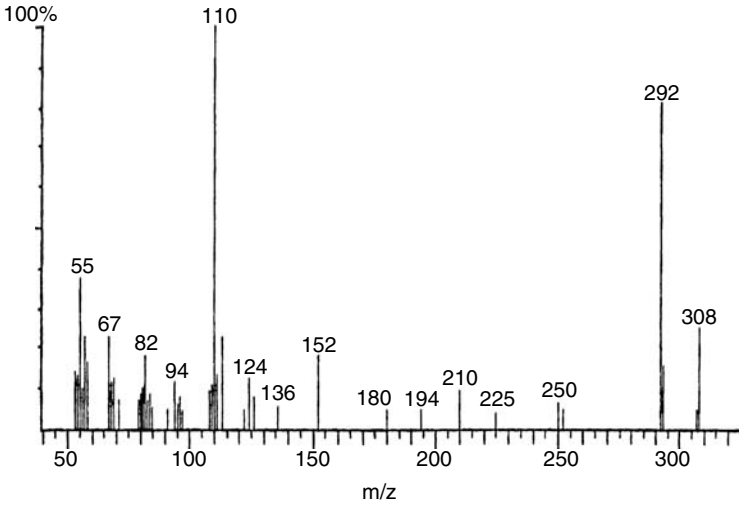

FIGURE 3.9 Electron impact mass spectrum of the GC peak of the 4,4-dimethyloxazoline derivative of natural *trans*-3-hexadecenoic acid. (Reproduced from Lamberto, M., and Ackman, R.G. (1995). *Anal. Biochem. 230*: 224–228. With permission.)

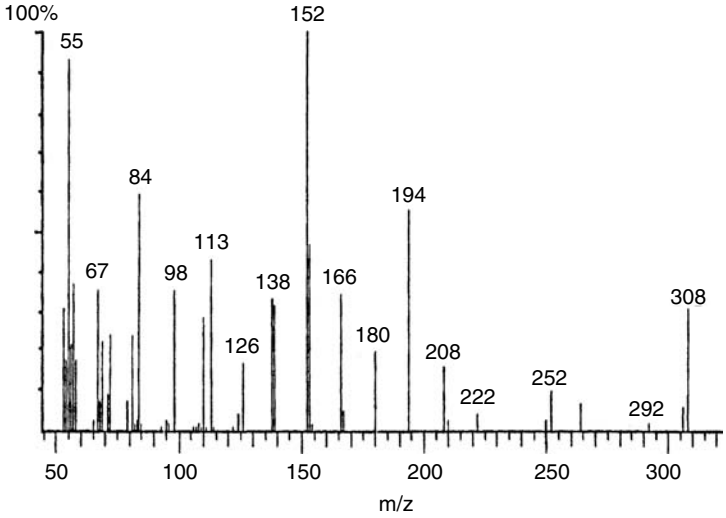

FIGURE 3.10 Electron impact mass spectrum of the GC peak of the 4,4-dimethyloxazoline derivative of an artifact 2-hexadecenoic acid. Fragments of 98 and 110 amu indicated the ethylenic bond position. (Reproduced from Lamberto, M., and Ackman, R.G. (1995). *Anal. Biochem. 230*: 224–228. With permission.)

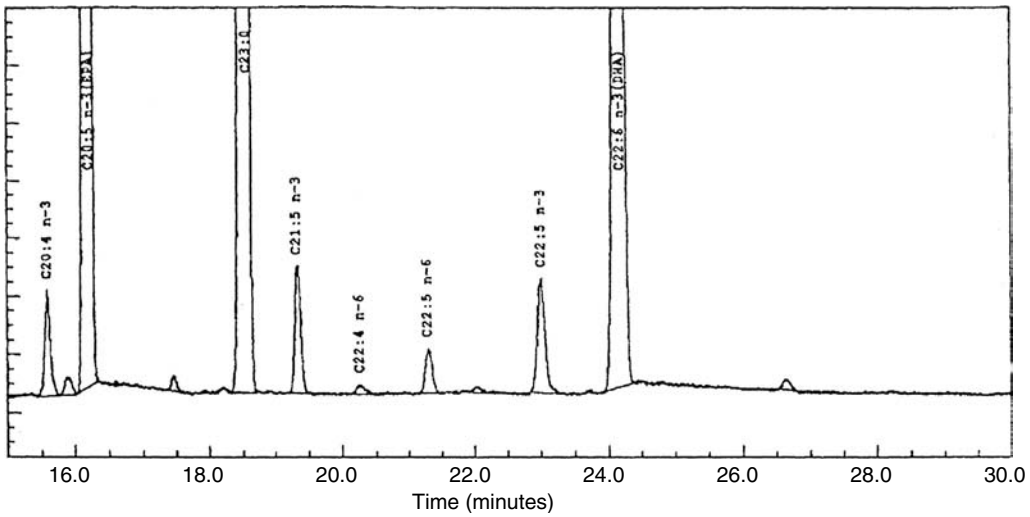

FIGURE 3.11 A contemporary gas–liquid chromatogram of the separations possible in a short time-frame of the methyl esters of typical fish oil of the anchovy or sardine type. The peak numbers identify specific fatty acids. The small peak marked 26 has been identified by the author as 24:1n-11, followed by the isomer 24:1n-9. In the explanation of the numbers EPA is 20:5n-3 and DHA is 22:6n-3. Adapted from European Pharmacopoeia 5.4 (2005).

was an analysis of (European) farmed salmon, presumably Atlantic salmon *Salmo salar*. Peaks in Figure 3.3 represent the fatty acids of an oil, but in fact salmon as a food may have a body rich in triacylglycerols, as it has always been ranked as an "oily" fish and therefore a desirable food source of omega-3 fatty acids. Unfortunately the high price of fish meal and scarcity of crude fish oil have led to increasing amounts of vegetable feed stuffs being added to the rations of farmed salmon (Pickova, 2006). Depending on the type of vegetable material fed, peaks 8 (18:2n-6) and 9 (18:3n-3) may be somewhat increased in farmed salmon lipids. Since these fatty acids are common in our diets

anyway, the effect may be only a slight dilution of the long chain fatty acids omega-3 present in wild salmon. There are at least five types of salmon to be considered (Ackman, 1996), but the general pattern for all fatty acids of edible fish should conform to that in Figure 3.11.

4 Isotopic Methods for Assessing Lipid Metabolism

Joanne K. Kelleher, Carolina B. Cabral, and Jennifer M.K. Cheong

CONTENTS

I. INTRODUCTION

In recent years, new stable isotopic methods have been developed that enhance our capabilities to assess metabolism (Brunengraber et al., 1997). These newer methods complement and, in some cases, exceed the capabilities of more traditional radioisotopic methods. The major advantage of the new methods is the improved ability to estimate the enrichment of a precursor during biosynthesis leading to more accurate estimates of metabolic rates. To put this new information in perspective, this chapter presents a tutorial describing the underlying basis of isotopic methods for the analysis of lipid metabolism. We show how the new stable isotopic methods differ from radioisotopic methods and explain the rationale for choosing among various types of isotopic tracers in specific situations. The goal of this presentation is not limited to the fate of fatty acids in foods. We also include a discussion of methods for assessing the endogenous production of lipids *in vivo*. The literature citations offer examples of interesting applications but are not meant as an exhaustive

survey of all the noteworthy work in this field. We bring to this discussion the viewpoint of metabolic physiologists who think in terms of pathways. To deal with the complexities of dietary lipid metabolism, the classic definition of a pathway is expanded to include all processes from ingestion of food to oxidation. Thus, the major metabolic pathways of a dietary triglyceride involve many steps—oral ingestion, digestion, hydrolysis of the triglyceride, intestinal transport, chylomicron synthesis, export to plasma, flux through various lipoproteins, uptake by cells, recirculation through the liver, and ultimately oxidation. To lay the groundwork for the tutorial, we begin with a review of the key concepts underlying the isotopic methodology used in metabolic studies.

A. Compartments and Pathways

What is a pathway? A pathway is a set of fluxes related by precursor product relationships and regulated as a unit. A diagram, often called a metabolic network, defines the scope of the pathway under study (Figure 4.1). Note that a flux is simply the rate molecules travel along the routes designated by the arrows (mol/time). The metabolic network is important as the arrows represent allowable fluxes and the metabolites, shown enclosed, represent compartments. The classic discipline of compartmental analysis (Jacquez, 1985) provides a rigorous framework for analyzing a metabolic pathway. In this approach, a compartment is defined as a population of molecules that behave kinetically in a homogeneous manner. Each molecule in a compartment has the identical probability of participating in each of the reactions leading from the compartment. It is useful to contrast the definitions of compartment and the more commonly used term, *pool*. The definition of compartment is more precise than the definition of a pool. For example, we may speak of the total body triglyceride pool. However, this pool comprises a number of compartments, including, for example, plasma very low density lipoprotein (VLDL) triglyceride and hepatic intracellular triglyceride. Compartments may comprise more than one metabolite. For example, if lactate and pyruvate are rapidly interconverted because of high lactate dehydrogenase activity, lactate and pyruvate molecules may be equally likely to flow to lipid synthesis, and thus only one compartment may be needed for the lactate–pyruvate compartment. The key to defining a compartment is that all molecules in the compartment must be equally likely to leave by any of the paths permitted. By designating compartments and setting up the metabolic map, a hypothesis is provided for how the system interacts. This hypothesis may be then investigated experimentally. An important feature of compartmental models is that the fluxes in and out of the compartments describe the probability of a molecule from each compartment reaching any other compartment. For example, from Figure 4.1, it is clear that a molecule of A has a probability of 1.0 of reaching compartment B, a probability of 0.5 of reaching compartment C, and a probability of 0.25 of reaching compartment D. The use of probabilities in describing compartmental models is a powerful asset for obtaining information from the model. To obtain this information, all terms used to

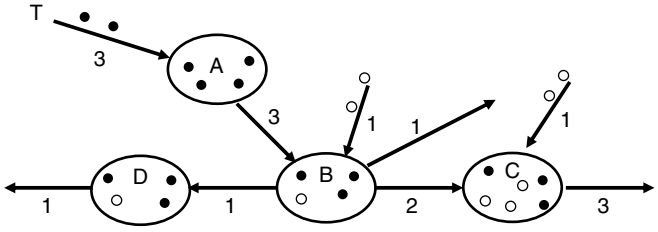

FIGURE 4.1 A metabolic network displaying essential features of compartmental model for tracer metabolism. Tracer atoms (filled circles) enter the pathway at compartment A. Natural molecules, not enriched with isotope (open circles), the tracee, enter the pathway at various points. Arrows indicate permitted fluxes and numbers indicate fluxes in moles/time. The isotopic distribution shown reflects metabolic and isotopic steady state, fluxes in equal fluxes out, and amount of tracer and tracee in each compartment is constant.

quantify the behavior of the model must be consistent with probability theory. Thus, throughout this chapter, we use fractions rather than percentages. Fractions sum to 1 and reflect probabilities.

Compartmental models may be used to examine metabolism in various kinetic states. The simplest kinetic state is that of the metabolic and isotopic steady state. In the metabolic steady state, the fluxes and amounts of each metabolite in each compartment are constant. End products may accumulate linearly. In the metabolic steady state, each arrow can be assessed a relative flux rate that does not change over the course of the time period we are studying. In the isotopic steady state, the amount of isotope and the amount of metabolite in each compartment are constant (see Figure 4.1). If the system reaches both the metabolic and isotopic steady state, the model is linear and the equations describing the behavior of isotopic tracers are algebraic, making the analysis relatively straightforward. This ideal may contrast with the real experience of researchers determining the fate of dietary lipids which rapidly flow into a system altering fluxes and concentrations and depart. A model describing these complex, more realistic, processes may be nonlinear and require differential equations to characterize the system. Thus, in designing isotopic tracer experiments, the investigator is faced with the dilemma of determining to what extent a real experiment may be depicted by a relatively simple steady state model. Additionally, it should be noted that compartmental models are most useful when pathways can be described by a series of discrete steps. Complications may arise when the composition of a metabolic pool changes gradually, as when a metabolite is removed from plasma across an organ to create a gradient. These more complicated situations require more sophisticated models that are beyond the scope of this chapter.

II. ISOTOPIC TRACERS

A. General Properties

By way of review it is useful to recall a few fundamental facts about isotopes as tracers. The word *trace* may have two meanings: to track a pathway or to be present in very small amounts. Both meanings are involved in the application of tracers to analyze metabolism. Tracers, stable or radioisotopes of specific compounds, offer an enticing approach to the quantitative metabolic pathways. They provide a simplified way to study complicated pathways and may replace the considerable effort of mass balance analysis. Tracers are normally assumed to behave identically to their naturally occurring counterpart, the "tracee." A tracer is a molecule containing isotopes of specific elements, which differ in atomic mass but not in the number of orbiting electrons. Isotopes may be stable at this higher mass (^{2}H, ^{15}N, and ^{13}C) or radioactive beta and gamma emitters (^{14}C, ^{131}I, and ^{3}H) decaying with a characteristic half-life. Radioactive compounds such as ^{11}C, ^{13}N, and ^{15}O (positron emitters) offer the advantage that they can be used for imaging studies. Offsetting this advantage is their short half-lives, less than 20 min, which necessitates specialized facilities for preparation and analysis. For lipid metabolism it is notable that metabolic tracers are available in either of two major elements, hydrogen and carbon, both as stable isotopes (^{2}H and ^{13}C) or as long-lived beta emitting radioisotopes (^{3}H and ^{14}C). Additional stable isotopes, including ^{18}O, and radioisotopes, such as ^{31}P, are also useful in assessing lipid metabolism. Metabolic tracers are assumed to be ideal, that is, to behave identically to the naturally occurring tracee in metabolic reactions. An ideal tracer then has the following characteristics. First, the amount of the tracer administered must not perturb the metabolic pathway such that the rates are changed. Thus, either the concentration of the tracer entering the metabolic pathway is low relative to the tracee concentration or the tracer substitutes for tracee. An example of this second situation is when tracer lipid is placed in a diet or total parenteral nutrition (TPN) solution and equivalent tracee removed. Second, the metabolic properties of the tracer molecules must be identical to those of the tracee. Thus, isotope effects must be insignificant. Many useful experiments are performed with tracers that are not ideal; however, the best experiments are those designed by investigators conscious of the shortcomings of the chosen tracer.

The very first isotopic studies of lipid metabolism illustrated the question of whether the tracer is ideal. In 1949, Stanely and Thannhauser investigated fat malabsorption using ^{131}I-labeled olive oil, chiefly triolein. The principle behind the isotopic approach was that absorbed ^{131}I from the radiolabeled lipid would be detected in urine and blood. Thus, a low level of ^{131}I in urine and blood indicated fat malabsorption. This isotopic procedure was, in principle, much simpler than the standard nonisotopic method of the day, which required a 3-day diet, quantitative stool collection, and fat analysis of these samples. However, this simple concept for the isotopic assay did not easily translate into a true quantitative method for detecting fat malabsorption in human subjects. The tracer atom, ^{131}I, is of course not a natural component of triolein. The fate of absorbed iodine as a component of iodinate lipids and the biochemical properties of iodinate lipids were not clearly understood at the time. Furthermore, the handling of iodine absorbed in this manner by the kidney was later found to be variable (Oddie et al., 1966). Clearly, iodinated fatty acids did not represent an ideal tracer. Despite the problems with the iodine tracer, this early method established the principle of using isotopes to evaluate fat absorption. In this chapter, we will assume that isotopic effects, such as the substitution of ^{2}H or ^{3}H for H, are negligible in determining fluxes.

B. Tracer Activity

To perform a tracer metabolic study, the investigator needs a method in hand for quantifying the amount of the tracer molecule in one or more key compartments. Consider as an example the fate of labeled palmitate triglyceride infused intravenously. By measuring the appearance of the tracer in various compartments and the total concentration (tracer + tracee), the investigator obtains a record of the fate not only of the labeled molecules given orally but also of the tracee traveling in parallel through the pathway. Tracee molecules generated endogenously may enter the pathway at various points, as shown in Figure 4.1. The relationship between the tracer and tracee molecules in a compartment is referred to as the *specific activity* (SA) in radioisotopic studies. Stable isotopic studies sometimes use the term *enrichment*, but we wish to define here the term *tracer mole fraction* (TMF), which may be more useful for metabolic studies using stable isotopes. In the past, relationship between the tracer and tracee has focused on the tracer to tracee ratio. Because our goal is to build a probability-based system for the analysis of metabolism, this ratio is not employed. Instead, we define for stable isotopes the TMF

$$\text{TMF} = \frac{\text{Tracer molecules}}{(\text{Tracer molecules} + \text{Tracee molecules})}$$

and for radioisotopes the SA

$$\text{SA} = \frac{k * \text{Tracer molecules}}{(\text{Tracer molecules} + \text{Tracee molecules})}$$

where k is a constant expressing the inherent activity of the tracer in either curies, becquerels, or disintegrations per minute (dpm)/per mole. For simplicity, we use dpm; 1 μCi = 2.22×10^6 dpm. The term TMF is used to indicate the relative amount of stable isotopic tracer molecules, independent of the amount of labeled atoms. We use these two terms to describe molecular equivalents for comparing radioisotopes and stable isotopes. At first glance, the two expression may not appear to be equivalent. The numerator of the SA relationship is dpm, a convenient measure of radioactivity, but not equivalent to tracer molecules, the numerator of the TMF equation. However, dpm can be converted to tracer molecules by dividing the SA of the tracer used. The SA of the infused tracer, in dpm/(mole tracer), is the link that relates SA to a true measure of tracer/(tracer + tracee). Thus, it is always important to perform this operation and present radioisotopic tracer data in terms of molecules in specific compartments. TMF or SA provides important insight into the rates of the

reactions in the pathway. Clearly, if tracee is present, the SA or TMF of the tracer will decrease as it travels through a pathway (see Figure 4.1). If no tracee is present, the SA or TMF at the exits from the pathway will equal that of the infusion.

The above definitions illustrate important properties of tracers as used in metabolic studies. First, the definitions are consistent with probability theory. TMF is the probability that a molecule selected randomly from a compartment is a tracer. SA is directly proportional to this probability. In contrast, the tracer-to-tracee ratio approaches the probability only if the tracer amount is very small relative to the tracee. Often in stable isotope studies, the tracer is of significant mass and tracer/tracee is not equivalent to probability. Second, the proposed definitions emphasize the fact that we are concerned with labeled molecules. An individual tracer molecule may contain one or more isotopically labeled atoms, but metabolic pathways concern the flow of molecules. Thus, definitions of tracer activity in terms of molecules are essential. Finally, before moving to specific types of tracers, we underscore that, in theory, either stable isotopes or radioisotopes may be used to trace metabolic pathways. The underlying tracer theory is equivalent. Yet, in practice, each type of tracer has distinct properties that are best for particular applications. To choose an appropriate tracer for a metabolic study, an investigator needs to understand these issues. To explain this to students approaching this subject for the first time, we stress that the differences between stable isotopes and radioisotopes arise on account of the way isotopically labeled molecules are detected. To continue this tutorial, we review the aspects of detection of radioisotopes and stable isotopes that lead to these differences.

C. Radioisotopes

Radioisotopes were the commonly used type of tracer in the growth of biomedical research in the 1950s and 1960s. Radioisotopes emit radiation in spontaneous nuclear reactions decreasing mass. Emitted radiation provides a powerful signal from each decaying atom. This signal provides a sensitive method for the detection of radiolabeled molecules and provides a major reason why radioisotopes have been preferred for many studies. For example, a liquid scintillation counter can detect 20 dpm above background for ^{14}C. Molecules with one ^{14}C-labeled atom are routinely available at 50 Ci/mol or 100×100^{12} dpm per mole. This means that an investigator can easily detect the presence of 0.02 pmol (100 dpm) of this ^{14}C-labeled compound. The purchaser of radioisotopes notices this sensitivity when calculating the amount of compound purchased. If 50 μCi of [1-^{14}C]palmitic acid is purchased at an SA of 50 Ci/mol, the amount of palmitic acid obtained is only 1 μmol. Thus, ^{14}C-labeled tracer lipids are often diluted in SA with natural compounds to perform studies at physiological concentrations without consuming large amounts of isotope. Table 4.1 illustrates a simple example, where an investigator wishes to expose cells to palmitic acid tracer and follow it into triglycerides. An important advantage of radioisotopes is that the detection of radioisotope tracers, using liquid scintillation counting or gamma counting, is not affected by the presence of unlabeled trace molecules. The natural abundance of radioisotopes is negligible; there is no background signal to consider, and thus the tracer can be detected even if the SA is very low. However, the offsetting disadvantage is that detection of radioisotope dpm does not confirm the identity of the labeled molecule. A second assay is required to obtain (tracer + tracee), the denominator in the SA equation. The accuracy of the resulting SA measurement is a function of the error in both methods.

When radioisotopes are used, ^{14}C-labeled lipids are often chosen over ^{3}H-labeled ones for metabolic studies, because ^{14}C is less likely to be lost in isotopic exchange reactions not related to the metabolic pathway. Also, ^{14}C is a stronger β-emitter and is less likely to be quenched, complicating the measurement of the dpm. On the other hand, an advantage of ^{3}H isotopes for some studies is that the maximum SA is higher for ^{3}H than for ^{14}C. The upper limit for SA is determined by the rate of decay or half-life. An interesting student exercise is to compare the maximum SA possible for a ^{14}C atom with a half-life of 5730 years to that of ^{3}H with a half-life of 12.3 years. The result for ^{14}C is that the maximum SA, with each atom ^{14}C labeled, corresponds to an SA of about 62 Ci/mol carbon. Thus, when [U-^{14}C]palmitate is purchased at 800 Ci/mol, about 80% of the palmitate C atoms are ^{14}C

TABLE 4.1
Calculation of ^{13}C and ^{14}C Palmitate Requirements for Isotopic Study

	^{14}C Study	^{13}C Study
Isotope	[U-^{14}C]palmitate	[1,2,3,4-^{13}C]palmitate
Activity	800 Ci/mol	99% ^{13}C
Amount of isotope	^{14}C 1 μCi = 1.25 nmol	150 nmol
Amount of natural palmitate	298.75 nmol	150 nmol
Total nanomoles palmitate/mL	300	300
Final SA or TFM of tracer	2.22×10^6 dpm/300 nmol	50%
Expected result in TG palmitate	444,000 dpm [U-^{14}C]palmitate	15% [1,2,3,4-^{13}C]palmitate
TG palmitate from tracer	4.44×10^5 dpm/(2.2×10^6 dpm/300 nmol)	30% TG palmitate from tracer * 200 moles
Amount of new TG palmitate from tracer	60 nmol TG palmitate	60 nmol TG palmitate

Conditions: Isolated cells to be suspended in 1 mL of medium containing isotopically labeled palmitate to determine incorporation into triglycerides (TG) over a 24-h period. Tracer concentration 0.3 mM fatty acid bound to albumin. Estimated incorporation: approximately 20% of label accounting for 30% of TG palmitate in the cells, since the cells contain 200 nmol of TG palmitate.

^{14}C *experiment:* Using 1 μCi [U-^{14}C]palmitate as tracer. Tracer is obtained at SA = 800 Ci/mol. Since 20% may be incorporated, adequate results should be obtained using 1 μCi; expected triglyceride incorporation will be $0.2^* 2.22 \times 10^6$ dpm = 444,000 dpm. However, 1 μCi of this tracer is only 1.25 nmol. For a 1 mL incubation, 300 nmol is required. Thus, add 298 nmol unlabeled palmitate for each milliliter of ^{14}C medium.

^{13}C *experiment:* Using [1,2,3,4-^{13}C]palmitate as tracer. Tracer is 99% ^{13}C at each labeled position. If incorporation labels 30% of TG palmitate in cells, tracer could be diluted 50% with natural palmitate to conserve isotope and still provide accurate detection of labeling.

rather than ^{12}C. It is easy to lose track of this fact, because the measurement of radioisotopes detects only those few atoms that decay in the scintillation counter. The shorter half-life of ^{3}H, greater dpm per labeled atom, is the key to understanding why ^{3}H-labeled compounds are available at SAs 100 times or more greater than ^{14}C. Thus, ^{3}H rather than ^{14}C-labeled tracers are often selected for radioimmunoassays and other sensitive assays that detect femtomoles or less of a compound.

D. Stable Isotopes

In the past decade, the use of stable isotopes as metabolic tracers has increased dramatically. Availability of specific stable isotopic tracers for metabolic studies now rivals that of radioisotopes. As with ^{14}C isotopes, ^{13}C-labeled tracer molecules are commercially available with high enrichments; routinely 99% of the specified carbon atoms of a molecule will be labeled. An advantage of stable isotopes in clinical studies is the absence of a radiation hazard and disposal issues. Although radioisotopes are detected only by decay of atoms, stable isotope may be detected by methods that report either the labeled atoms or labeled molecules. Stable isotopically labeled molecules may be combusted to atoms such as a mixture of $^{13}CO_2$ and $^{12}CO_2$. However, more information is available when stable isotopes are detected in organic mass spectrometry as molecules. Organic mass spectrometry for metabolic studies is typically accomplished by gas chromatography/mass spectrometry (GC/MS) or high-performance liquid chromatography/mass spectrometry (HPLC/MS). Organic mass spectrometry yields both the number of labeled molecules and the number of labeled atoms in each labeled molecule. To characterize this increased information, the term *isotopomer*, isotope isomer, is used to denote the number of labeled atoms in a molecule. In metabolic research, molecules with ^{12}C, ^{16}O, and ^{1}H at each position are represented by the term *mass + zero*, $m + 0$, or M_0. A molecule

with n heavy isotopes is designated mass + n, or M_n. Continuing with the example of palmitic acid as the tracer, mass + 0 corresponds to mass 270, the molecular weight of palmitate methyl ester. As the user of GC is aware, fatty acids are commonly derivatized to their methyl esters for GC. To simplify the mass distributions shown below, the methyl ester is omitted. Although 16 positional $m + 1$ isotopomers of palmitate may occur, mass spectrometry of the palmitate molecule detects each of them as M_1. In general, the detection of mass isotopomers by organic mass spectrometry does not directly report positional information. The exception to this generalization occurs when molecules are fragmented in the ionization process. Isotopomer patterns of these fragments may be used to provide positional information. An important advantage of organic mass spectrometry is the information indicating the number of labeled atoms in each molecule detected, the mass isotopomer distribution (MID) pattern.

A complication in interpreting the MID is the natural abundance of ^{13}C. Unlike ^{14}C and other radioisotopes, which are not present naturally, ^{13}C is both a useful tracer and a naturally occurring isotope. Approximately 1.1% of atmospheric carbon is ^{13}C rather than ^{12}C. Other stable isotopes appearing in lipids (^{17}O, ^{18}O, and ^{2}H) are much less abundant in nature, and thus the probability of isotopomers greater than M_0 in naturally occurring fatty acids is approximated by 0.011 times the number of carbon atoms. Natural palmitate produces a fractional MID of $M_0 = 0.84$, $M_1 = 0.15$, and $M_2 = 0.01$, all due to natural ^{13}C abundance. A comparison of the MID for natural palmitate (containing the 1.1% natural abundance of ^{13}C) and a mixture containing ^{13}C-enriched palmitate is shown in Figure 4.2. In describing the MID an important distinction is between "enrichment" and "abundance." Enrichment indicates an amount above the natural background, whereas abundance usually includes the natural background.

Investigators using enrichment subtract the natural abundance from the raw GC/MS data and then proceed to calculate. Although this process may simplify the appearance of the MID, we advocate retaining the natural abundance of molecules as part of the MID. In this way, the data may be fitted to models that have different assumptions about the natural abundance effect. Hence, to indicate the amount of each isotopomer, we prefer the term *fractional abundance*, the amount of a specific isotopomer over the sum of all isotopomers. Fractional abundance is directly obtained from the specific ion monitoring mass spectrometry data by dividing the signal intensity for each isotopomer by the sum. More formally, the fractional abundance of an isotopomer mass + i of a molecule M with a maximum number of heavy isotope positions of n is defined as the relative amount of M_1 detected by organic mass spectrometry over the sum of all isotopomers or,

$$\text{Fractional abundance} = \frac{M_i}{\sum_{i=0}^{n} M_i}$$

Again, it is important to note that this definition requires that the sum of the fractional abundances of all isotopomers equals 1 so that fractional abundance is equivalent to the probability of the occurrence of each mass isotopomer. This relationship with probability is not present when isotopomer amounts are expressed as atom or mole percent excess, a common terminology used in the past. Also, it should be noted that some investigators use the term *molar enrichment,* defined as the sum of the fractional abundances for each isotopomer multiplied by the number of labeled carbons or

$$\text{Molar enrichment} = \sum_{i=0}^{n} M_i * i$$

Molar enrichment is useful to predict the relationship between radioisotopes and stable isotopes.

The MID for the stable isotope tracer described in Table 4.1 is shown (Figure 4.2b) to indicate the fact that a stable isotope tracer is really a population of isotopomers with a specific MID that is not identical to that of the naturally occurring tracee. In other words, the simple depiction of the tracer as molecules designated by the filled circles in Figure 4.1 omits the important point that

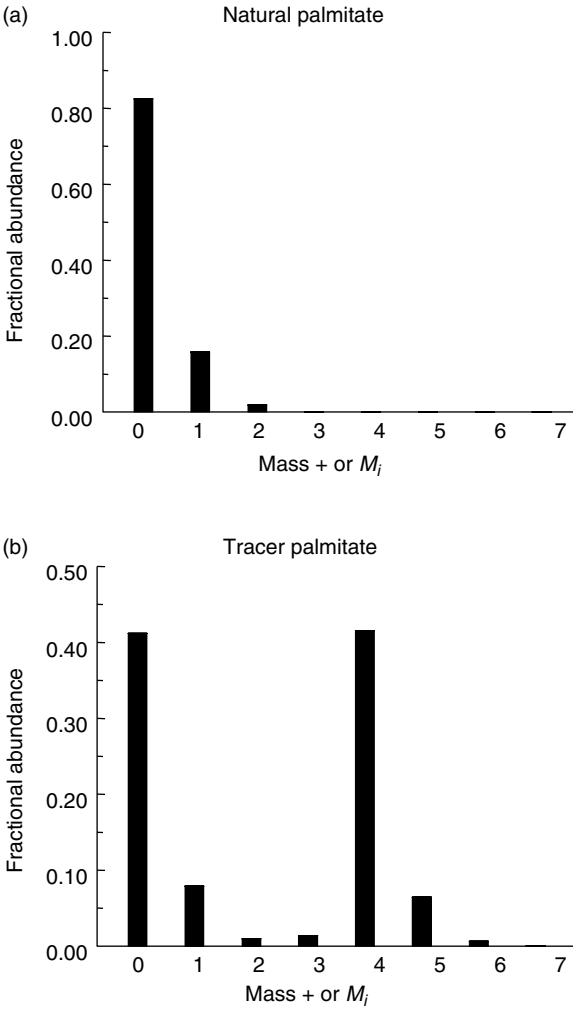

FIGURE 4.2 Mass isotopomer distribution profile for natural palmitate (a) and tracer formed as mixture of 50% [1,2,3,4-^{13}C]palmitate and 50% natural palmitate (b). Amounts are shown as fractional abundance and sum to 1.

individual tracer molecules are not identical because they may be in one of several isotopomers as indicated in Figure 4.3. The important point is that the population distribution of the isotopomers of the tracer is distinctly different from the population distribution of the tracee, which is characterized by natural abundance.

E. Selecting the Tracer

The MID profiles in Figure 4.2 represent only natural compound (a) and a specific tracer (b). In an experiment, it is expected that the tracer may be diluted by the flow of tracee into the pathway lowering the TMF, as shown in Figure 4.1. We now address this situation and consider the fractional abundance profile of a mixture of tracer and tracee. We consider two mixtures using ^{13}C palmitate as tracer. The examples representing palmitate sampled from a compartment illustrate the process of estimating the fraction of the total palmitate derived from the tracer (Figure 4.3). Both examples here are 25% tracer and 75% tracee, thus TMF = 0.25. If the tracer used is [1-^{13}C]palmitate, the

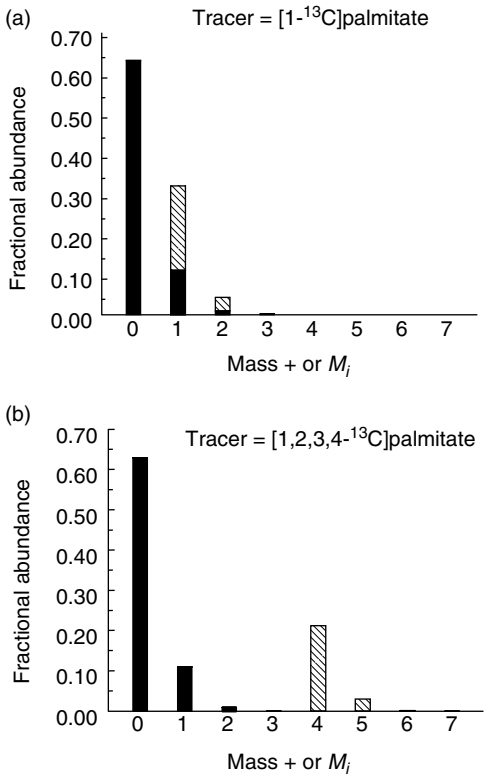

FIGURE 4.3 Mass isotopomer distribution profile for mixture of 25% [1-^{13}C]palmitate tracer and 75% natural palmitate (a). Profile of 25% [1,2,3,4-^{13}C]palmitate and 75% natural palmitate (b).

dominant mass will be M_1; however, higher masses will occur owing to the fact that the other 15 carbon atoms have a probability of 0.0108 of being ^{13}C rather than ^{12}C owing to natural abundance. In addition, the tracee will have significant abundance at M_1 for the same reason. The profile (Figure 4.3a) clearly indicates that the calculation of the TMF is not straightforward. The TMF cannot be determined without considering the contribution of the natural abundance to M_1. Alternatively, if [1,2,3,4-^{13}C]palmitic acid is the tracer (Figure 4.3b) used this time without any natural palmitate as part of the tracer, the entire MID of the tracer will be separated from the natural tracee compound so that:

$$\text{Tracer mole fraction (TMF)} = \frac{(M_3 + M_4 + M_5 + M_6)}{\sum M}$$

The process of identifying the contribution of the tracer to the total MID is straightforward when the tracer is sufficiently labeled to separate it from the isotopomers contributed by the natural form of palmitate, as in Figure 4.3b. For both examples shown, the TMF is 0.25 indicating that 25% of palmitate is derived from the tracer, but the ease of calculating the TMF for heavily labeled stable isotope tracer is clearly a convenience. Accordingly, researchers often consider it desirable to select a tracer three or more mass units greater than the base M_0 molecular weight of the tracee. The inconvenience of dealing with the overlap of tracer and tracee in the MID must be weighed against the usually increased expense of the heavily labeled tracer. If the singly labeled tracer is chosen, it is of course possible to account for the contribution of the tracee at M_1 from the natural abundance profile of the tracee alone. A linear regression least squares approach may be required for the most

precise estimates of TMF from the MID shown in Figure 4.2a. However, even when the presence of isotopomers greater than M_0 from the tracee is correctly considered, the signal from the natural abundance of ^{13}C decreases the precision of detection of the tracer. Thus, Figure 4.3 provides a view of the choices of the investigator when choosing a ^{13}C-labeled lipid for a metabolic study. For *in vivo* experiments, the activity of the tracer detected in plasma compartments will not be high and the investigator will have to determine whether the advantage of increased precision conferred by [1,2,3,4-^{13}C]palmitic acid outweighs its increased cost. Because organic mass spectrometry does not discriminate between increased mass due to ^{2}H vs. ^{13}C or other heavy isotopes, the effect of natural abundance of ^{13}C will also complicate the interpretation of experiments using ^{2}H as tracer.

III. PRACTICAL APPLICATIONS OF TRACERS IN LIPID METABOLISM

As indicated above, tracer can be used to trace the steps in a metabolic pathway if the pathway is not known. However, simple tracing experiments with tracers are rarely informative today. We know reasonably well the actual steps in most pathways but are lacking sorely in quantitative measurements of the true rates of pathways. Here we review a few simple types of tracer experiments to evaluate metabolic pathways of lipids.

A. Flux Ratios Determined in Isotopic and Metabolic Steady State

Returning to Figure 4.1, we now consider how tracers would be used to evaluate this metabolic pathway. We assume the system as shown has reached isotopic and metabolic steady state and that the compartments A, B, C, and D may be sampled. The fluxes indicated in the diagram are unknown and are to be investigated by the analysis of the TMF or SA of the tracer in various compartments. To make this more relevant, we may imagine that Figure 4.1 is a simplified diagram of dietary lipid metabolism. The tracer is a specific fatty acid and the compartments are the triglyceride of this fatty acid as chylomicrons (A), lipoprotein (B), adipocyte tissue (C), and endothelial cell (D). In this model, the chemical composition of the fatty acids is not altered by the metabolic pathway; that is, the structure of the fatty acid is not changed. Thus, the SA or TMF of the fatty acid in each compartment will be measured and the data used to estimate the relative fluxes of other sources of this fatty acid into the pathway. The major limitation of this type of steady state protocol is that SA or TMF alone at steady state cannot yield true flux rates, mol/(kg-min). They provide relative fluxes into each compartment. For example, from the fact that SA or TMF of B is 0.75 relative to A, the flux of tracer to tracee into this compartment must be 3:1. Likewise with compartment C, we can deduce that the flux ratio is 2:1, and we can deduce that no tracee flux enters D. For the steady state model to determine actual fluxes, some reference fluxes must be determined independently.

B. Flux Rates Relative to Pool Size: Metabolic Steady State with Isotope Filling Pools

From this simple model, more complex ones can be developed. For example, a model in metabolic but not isotopic steady state provides a method to estimate the size of each compartment relative to the fluxes through it. Imagine beginning with metabolic steady state but no tracer in the system. We may use the pathway described in Figure 4.1. Perhaps a natural source of the tracee feeds the system with initial flux into compartment A so that the size of each compartment is not altered when the tracer infusion is begun. Thus, the experiment begins with each pool with the same number of molecules as shown in Figure 4.1, except that tracer flux through the compartments has not yet begun.

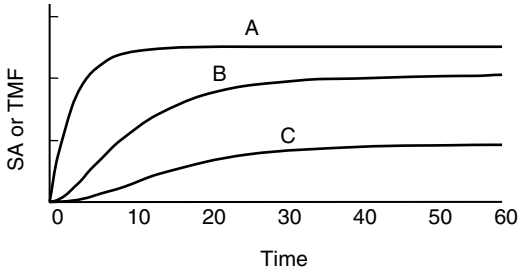

FIGURE 4.4 Tracer labeling profiles for hypothetical compartments from Figure 4.1 in an experimental protocol where tracer infusion was initiated in a system already in metabolic steady state.

With the start of tracer infusion, the size of the pools remains constant but each pool increases in SA or TMF until the steady state is attained. The equation describing the SA or TMF of the first pool A is

$$\mathrm{SA} = k\left[1 - \mathrm{e}^{-(F/N)\mathrm{time}}\right] \tag{4.1}$$

where F is the flux rate of the tracer into the pool and N is the pool size in moles. The equation for each of the successive pools is more complex, but the basic relationship holds that the filling of each pool is determined by the pool size and the rate of flux of tracer into the pool. The pools tend to reach steady state in the order they receive tracer, as indicated in Figure 4.4. These profiles can be used to estimate *F/N*, and if the pool size is determined independently, flux may then be estimated. Thus, the type of tracer experiment can be varied from the very simple isotopic and metabolic steady state to more complex situations to obtain additional information about the system. This equation for the filling of a pool with label will return as the equation for the fractional synthesis rate (FSR) in the analysis of de novo synthesis below.

C. Rate of Appearance

In metabolism of lipids, a primary measurement is the rate of appearance of a substance in plasma or Ra. Isotope dilution is the standard method for measuring Ra. The Ra for a specific compound is measured with a constant infusion of a tracer for that compound (Figure 4.5). The tracer is infused until the enrichment in plasma reaches a constant value, a steady state, and this value of the tracer enrichment is used in the following equations. Analogous equations are provided for both stable and radioisotopes. Using radioisotope terminology:

$$\mathrm{Ra} = \text{tracer infusion (moles/time)} \times [(\text{infused tracer SA/plasma tracer SA}) - 1].$$

Using stable isotope terminology:

$$\mathrm{Ra} = \text{tracer infusion (moles/time)} \times [(\text{infused tracer TMF/plasma tracer TMF}) - 1].$$

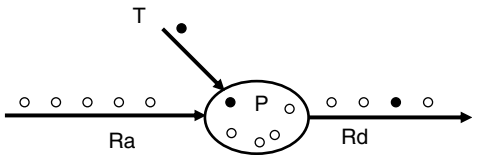

FIGURE 4.5 Rate of appearance of endogenous metabolite determined by tracer dilution. In steady state, rate of appearance into plasma (Ra) plus tracer infusion (T) equals rate of disappearance (Rd). Ra in this simple model is equivalent to endogenous production.

Both equations result in an estimate of Ra in moles/time where TMF and SA are as defined above. This equation simply indicates that the appearance of tracee in the plasma is detected by the finding that the SA of the tracer in the plasma at steady state is less than the SA of the injected material. Usually the tracer infusion (T) is a small percentage of the Ra to avoid perturbing metabolism. In a steady state system, the Ra will equal the rate of disappearance, Rd minus the trace infusion (Figure 4.5). Thus, the Ra of compounds in plasma will be measured to determine the rate at which a dietary or endogenous lipid enters the plasma. Another example is to determine the rate at which a lipid in the plasma is taken up by cells. These definitions of Ra and Rd assume that the distribution of the compound of interest in plasma is that expected of a substance in a homogeneous compartment.

One of the first isotopic studies of Ra using fatty acids was performed by Armstrong and coworkers (Watkins et al., 1982) using ^{14}C palmitate. To measure the plasma Ra of free fatty acids, the protocol required a constant intravenous infusion of ^{14}C palmitate followed by sampling of blood to measure the SA. A review of issues raised in the analysis of isotopic data from this study illustrates concerns that apply to investigations conducted today. The first issue is how far one can extend the behavior of a single fatty acid such as palmitate to represent the behavior of other related compounds. The answer depends on the situation and the level of accuracy required. The Ra of a single common fatty acid such as palmitate may be useful as an indicator of the behavior of plasma fatty acids. However, when examined in detail, individual fatty acids each have properties not identical to that of palmitate. Another issue raised by investigations of plasma Ra is the effect of the site of injection and sampling on the values determined. In theory, the Ra calculations above require that plasma behave like a single well-mixed compartment for tracer and tracee equilibration, as shown in Figure 4.1. Analysis of free fatty acid kinetics indicated differences in the values obtained depending on the sites of tracer injection and sampling. These differences indicate that plasma does not equilibrate fast enough to be a perfect single compartment for free fatty acid kinetics. It appears that the most physiological results are obtained with venous infusion of free fatty acids and arterial sampling (Jensen et al., 1988).

IV. ESTIMATING DE NOVO BIOSYNTHESIS OF LIPIDS

In the previous section, the discussion focused on "isotope dilution" methods for estimating Ra. A key feature of isotope dilution is that the tracer is identical to the tracee, except for the isotopic substitutions (Figure 4.5). Although the Ra measures the endogenous rate of flux of a tracee molecule into the plasma it does not discriminate between de novo synthesis and flux of preexisting molecules into the plasma. To quantify de novo biosynthesis, "isotope incorporation" methods are used. When more than one precursor tracer molecule is incorporated into a product, stable isotopes have distinct advantages over radioisotopes for estimating biosynthesis. The reason is that the incorporation of multiple labeled precursor molecules into a product can be used to estimate the precursor enrichment when measured by mass spectrometry. Precursor enrichment is required for estimating biosynthesis by isotope incorporation. The procedure for calculating precursor enrichment from the product isotopomer distribution is the basis of the MIDA (Hellerstein and Neese, 1992) and ISA methods (Kelleher and Masterson, 1992). A common application of this technique for lipid biosynthesis utilized ^{13}C acetate as the tracer. When products such as cholesterol and fatty acids are analyzed as polymers of acetate, the precursor enrichment can be estimated (Kharroubi et al., 1992; Neese et al., 1993). The development of MIDA and ISA demonstrated the power of stable isotope studies for estimating biosynthesis. The use of ^{13}C acetate and other acetyl CoA generating tracers to estimating de novo lipogenesis was valuable but had the drawback of requiring constant infusions of tracer. Recently, an increasing number of studies have replaced ^{13}C acetate as discussed in the following section.

A. Deuterium Incorporation Approach

H atoms from water are incorporated into lipids during biosynthesis. The incorporation may be directly as H^+ ions or from the H of NADPH, which has exchanged with water. The theoretical

basis for the use of labeled water as deuterium, ^{2}H, to estimate lipid biosynthesis follows from classic studies using tritium, ^{3}H (Wadke et al., 1973; Lowenstein et al., 1975; Dietschy and Spady, 1984). Most investigators now choose ^{2}H over ^{3}H, to eliminate the use of radioactivity. This is especially important because the precursor, H_2O is present at 55M resulting in a large requirement for ^{3}H isotope (Curies) to attain sufficient SA (Curies/mole) for detecting the label when incorporated into lipids. $^{2}H_2O$ may be preferred over other stable isotopes such as ^{13}C acetate because the isotope can be administered orally, is low cost, and can be used for multiple simultaneous assays (Hellerstein, 2004; McCabe and Previs, 2004). However, it should be noted that $^{3}H_2O$ continues to be used and has one advantage over $^{2}H_2O$ in terms of the signal-to-noise. When mass spectrometry of multicarbon lipid molecules is performed, a large signal is observed at M_1 is due to the natural abundance of ^{13}C (Figure 4.2a). In basic mass spectrometry protocols ^{13}C and ^{2}H provide identical signals at M_1. Thus, if only a small fraction of a specific lipid is newly synthesized, most of the M_1 signal will be due to the natural abundance of ^{13}C. The deuterium incorporated from water must be detected above the natural abundance ^{13}C. This may limit the ability of $^{2}H_2O$ to detect lipogenesis when the water enrichment is low as in most *in vivo* studies. In contrast, there is no comparable endogenous signal for radioisotopes. Therefore, $^{3}H_2O$ may be the tracer of choice when an experiment is designed to measure the synthesis of a small fraction of a large depot. Newer mass spectrometry methods may overcome some of these obstacles and are discussed below. Overall, the use of $^{2}H_2O$ to estimate lipid biosynthesis is a technique with great promise for enhancing our understanding of lipid synthesis and interconversions. The section that follows provides an overview of the use of $^{2}H_2O$ for estimating the biosynthesis of lipids using palmitic acid as an example.

An important difference between the two commonly used stable isotope tracers for lipid biosynthesis, ^{13}C acetate and $^{2}H_2O$, relates to the precursor enrichment. To determine the rate of biosynthesis, the following must be known, the precursor enrichment and the number of precursor units incorporated into the product during biosynthesis. Considering the first requirement, the precursor for biosynthesis from ^{13}C acetate is the cytosolic lipogenic acetyl CoA pool. The precursor for biosynthesis from $^{2}H_2O$ is cytosolic water and the NADPH equilibrated with water. Lipogenic acetyl CoA enrichment is unknown, and difficult to measure. This limitation also applies to ^{14}C acetate (Dietschy and Brown, 1974). As discussed above in reference to MIDA and ISA, with ^{13}C acetate, the precursor enrichment must then be calculated from the isotopomer distribution of the product. Alternatively, when the tracer is $^{2}H_2O$, the isotopic enrichment of all compartments is assumed to be equal. Water enrichment is estimated from a sample from an accessible compartment such as plasma. Thus, an advantage of $^{2}H_2O$ over ^{13}C acetate is the availability of the enrichment of the precursor for biosynthesis. However, the second requirement, the number of precursor units incorporated into product, is straightforward for ^{13}C acetate and problematic for $^{2}H_2O$. When ^{13}C acetate is used as the tracer for palmitic acid biosynthesis, it is well known that 8-acetyl CoA or malonyl CoA subunits are incorporated per molecule of the 16-carbon palmitic acid synthesized. However, when $^{2}H_2O$ is the tracer, the equilibration of water with NADPH may not be complete. Additionally, some ^{2}H may be incorporated into the acetyl units prior to biosynthesis. Consequently, the number of H atoms that may be exchanged with the labeled water may not be constant for all situations. For example, *in vivo* studies have found that n is approximately 21 for palmitate and 27 for cholesterol, but lower values are found *in vitro* (Diraison et al., 1996). In many cases, the small differences due to different values of n may not be significant. However, for novel biosyntheses it would be valuable to carry out initial studies to estimate n. When it is feasible to follow the labeling of a product molecule until 100% of the molecules are newly synthesized, the value of n may be calculated from the isotopic enrichment of the product at the plateau (Figure 4.6).

The actual estimation of n involves mathematical models for each isotopomer detected. The models predict the plateau values for each isotopomer at each successive value of n. The best-fit model is found, which most accurately predicts the various isotopomers of the product at each of several values for the water enrichment. Once the value of n is determined for a $^{2}H_2O$ experiment, the FSR may be determined without following the experiment to the plateau level using the assumption

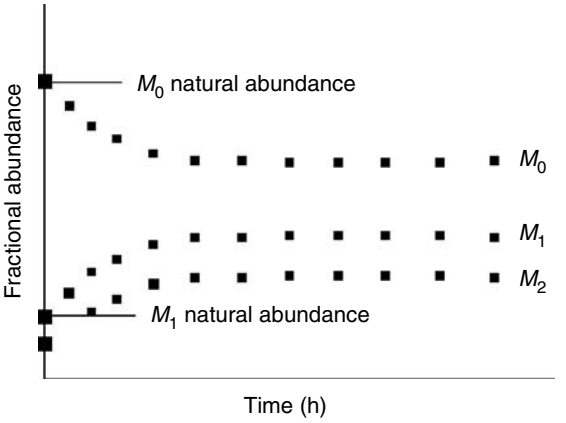

FIGURE 4.6 Tracer labeling profiles for isotopomers of palmitic acid incubated in 5% ^2H_2O. Data were collected over time until 100% labeling occurs and a plateau value is reached. Note that the incorporation of ^2H_2O leads to a decline in the M_0 isotopomer and an increase in M_1 and M_2.

that the product is behaving as a single pool labeled from the tracer. This situation is comparable to that described in Equation 4.1. Except that this time the label is reaching the product by isotope incorporation. To calculate the fractional synthesis, the concept of a single pool filling with a labeled metabolite is rewritten so that *F/N* is fractional synthesis (FSR). The result estimates the FSR from the fractional abundance of the M_1 isotopomer with Ap representing the plateau value of the isotopic enrichment.

$$M_1 = \mathrm{Ap}\left[1 - e^{-(\mathrm{FSR})\mathrm{time}}\right]$$

and

$$\mathrm{FSR} = -\ln\left[(M_1/\mathrm{Ap}) - 1\right]/\mathrm{time}$$

Finally, to illustrate the dependence of the isotopomer fractional abundances on the enrichment of water used in the study, a mathematical model was used to calculate the values for the isotopomers 0 through 7 for palmitic acid synthesized in the presence of ^2H_2O at various enrichment values (Figure 4.7). This model assumed that $n = 21$. The distribution of isotopomer values can provide much information for testing the assumptions of the model. If the water enrichment is near the higher end of those used here, the abundance of additional isotopomers above M_0 and M_1 is observed. These additional isotopomers allow the model to be "overdetermined," that is, they provide the information that allows the model to be thoroughly tested. In summary, the theory and practice for the use of ^2H_2O for estimating biosyntheses are now mature and should be very accessible to investigators.

V. METHODS FOR DETECTING ^{13}C ATOMS RATHER THAN MOLECULES

One of the problems with the use of ^2H_2O for estimating the biosynthesis of lipids as described above is the large natural abundance of ^{13}C that creates a large background noise. ^2H enrichment in newly synthesized lipid must be detected above this background. This situation applies when the entire lipid molecule is detected as the parent mass ion. Below, we briefly review methods for avoiding this situation and increasing the sensitivity of isotopic detection.

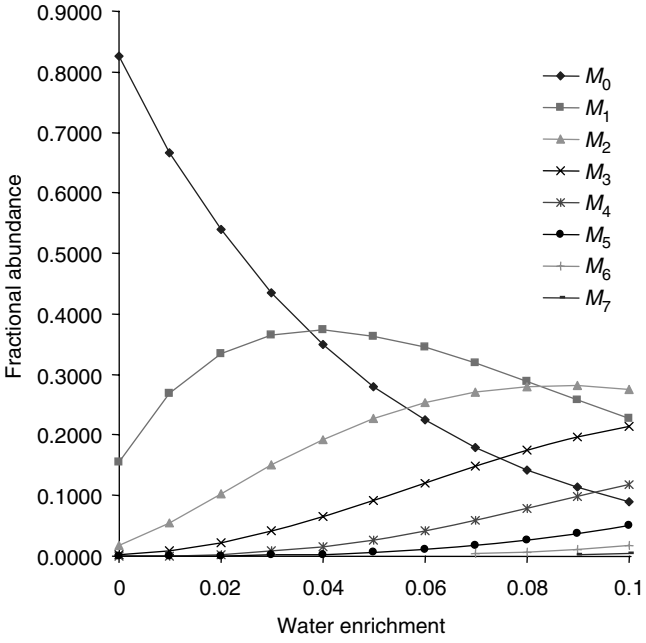

FIGURE 4.7 Calculated values of Ap for palmitate at different water enrichment levels. For each water enrichment value a mathematical model calculated each isotopomer value.

A. Gas Isotope Ratio Mass Spectrometry

Gas isotope ratio mass spectrometry (GIRMS) is theoretically akin to radioisotopic methods in that it detects labeled atoms. However, GIRMS instruments accept only pure gas as input and report the ratio of mass 45 (largely $^{13}C^{16}O_2$) to 44 ($^{12}C^{16}O_2$). If a ^{13}C-labeled lipid is combusted to CO_2, a signal proportional to the number of ^{13}C atoms will be reported by GIRMS. This is analogous to the dpm reported for a radioisotopic study. Both provide useful information, the number of labeled atoms recovered, but no details of the location of ^{13}C within the molecule.

Organic mass spectrometry provides the fractional abundance of various isotopomers of a molecule, but it does not provide the highest precision in the detection of ^{13}C or other stable isotopes. For highest precision, a method is required that detects labeled atoms rather than molecules and avoids the problems created by the natural abundance of multicarbon compounds. The best known of these is GIRMS first developed in the 1940s. Current instruments can detect very small amounts of $^{13}CO_2$: 10 parts per million or less. GIRMS is important for the analysis of the oxidation of dietary lipids. To detect fat absorption and metabolism, ^{13}C-enriched lipids is administered orally and breath samples are analyzed for $^{13}CO_2$. In detecting $^{13}CO_2$ enrichment resulting from the oxidation of ^{13}C-labeled lipids, GIRMS is much more precise than standard organic mass spectrometry. Typically, GC/MS may detect ^{13}C with a precision of about 1% relative standard deviation. In contrast, GIRMS machines are routinely available that detect ^{13}C at 10 parts/million. GIRMS data may be reported as atom percent excess, a percentile notation equivalent to percentage of enrichment or alternatively as the delta value, δ. The rationale behind the δ notation is that the ^{13}C:^{12}C ratio, $R_{(\text{sample})}$, is measured by GIRMS of CO_2 and compared to this ratio for standard, $R_{(\text{standard})}$, thus

$$\delta\ ^{13}C(\%) = [R_{(\text{sample})} - R_{(\text{standard})}]/R_{(\text{standard})} \times 1000.$$

By international convention, the standard is a specific calcium carbonate, which has a $^{13}C/^{12}C$ ratio of 0.012.

Two important applications of GIRMS in dietary lipid metabolism are the gastric emptying and fat malabsorption tests. Gastric emptying is measured indirectly by monitoring the appearance of $^{13}CO_2$ in breath using GIRMS following ingestion of a test meal containing ^{13}C-octanoic acid. The medium-chain free fatty acid is readily oxidized and its appearance as breath $^{13}CO_2$ correlates well with other measures of gastric emptying (Ghoos et al., 1993). This method was first developed using ^{14}C tracer, but with the advent of GIRMS, ^{13}C has become the method of choice. To measure fat malabsorption, ^{13}C-enriched triolein is administered orally and $^{13}CO_2$ enrichment in breath CO_2 is measured by GIRMS (Watkins et al., 1982). A more specific assay assessing pancreatic exocrine insufficiency focusing on cholesterol ester hydrolase deficiency has been developed recently (Ventrucci et al., 1998). This test analyzes the oxidation of cholesteryl[1-^{13}C]octanoate measuring breath $^{13}CO_2$ enrichment using GIRMS. This test clearly indicates severe pancreatic insufficiency but has not yet been proven effective in discriminating moderate pancreatic insufficiency from healthy controls. It serves, however, as an interesting example of a new variety of ^{13}C-labeled precursors that may be used to indicate very specific enzyme deficiencies.

B. Gas Chromatography Combustion Isotope Ratio Mass Spectrometry

To overcome the limitations of GIRMS due to its dependency on CO_2 and the large amount of sample required, new methods have been developed that first separate molecules using GC/MS and then perform combustion. Current versions of these GC combustion isotope ratio mass spectrometry (GCC-IRMS) instruments focusing on lipid metabolism have been pioneered by Brenna and coworkers (Goodman and Brenna, 1992, 1995). These investigators have been able to document the consistency of fatty acid $^{13}C/^{12}C$ ratios in human subjects (Rhee et al., 1997b). They developed methods for using tracer doses of dietary ^{13}C fatty acids (Rhee et al., 1997a) and found that an oral dose of only 30 mg of [U-^{13}C]palmitic or stearic acid is required to detect ^{13}C enrichment in the corresponding monounsaturated fatty acids in blood for 1 week. Other investigators using the GCC-IRMS methods have found that the minimum tracer dose of [U-^{13}C]palmitate to measure the palmitate Ra in human subjects was reduced to two orders of magnitude using GCC-IRMS compared with GC/MS (Demmelmair et al., 1997). This rapidly developing technique offers exciting possibilities for the analysis of the fate of fatty acids in foods without using large amounts of tracer.

An important carbon isotope effect with implications for the study of dietary fatty acids is fractionation of the natural abundance of ^{13}C in photosynthesis. The two major photosynthetic pathways discriminate against ^{13}C in carbohydrate synthesis. The preference for ^{12}C is greater for C3 plants (wheat) than for C4 plants (corn, sugarcane). This difference can be resolved by GIRMS techniques and has been the basis of interesting approaches to the analysis of dietary fatty acids. For example, a study of European infants switched from breast milk or formula to a corn oil diet detected a sufficient change in $^{13}C/^{12}C$ of plasma arachidonic acid and allowed researchers to estimate the ability of infants to synthesize arachidonic acid (Demmelmair et al., 1995). This study employed GCC-IRMS to obtain the $^{13}C/^{12}C$ of the lipids. The method is dependent on the fact that fats available in breast milk in Europe are derived largely from C3 plants such as wheat. These few examples of recent developments in the use of GCC-IRMS clearly indicate that the use of stable isotope tracers at concentrations that do not perturb metabolism is now becoming a reality.

VI. LOOKING TO THE FUTURE

A. Mass Spectrometry as a Key to New Lipid Methodologies

Mass spectrometry is widely used in the food industry to identify and quantify lipids. Stable isotopes are of value here as internal standards for quantification. In addition, the mass fragmentation of specifically labeled lipids provides detailed structural information. Most importantly, once techniques

have been validated for identifying novel lipids, the stage is set for future work quantifying fluxes. We highlight here a few interesting developments. In the fish industry, GC/MS has been used to identify chlorinated fatty acids (Zhuang et al., 2004), to clarify the structure, and to determine carbon chain length as well as the degree and position of double bonds in esterified fatty acids (Zhuang et al., 2004; Dayhuff and Wells, 2005). Mass fragmentation patterns confirmed the chemical structures of fatty acids. Based on these studies, it was found that all the polyunsaturated fatty acids in the fish that were examined had methylene-interrupted double bonds of *cis* geometry. The application of GC extends to other industries, including the infant formula industry where GC is used to determine lipid hydroperoxides and to study the stability of the lipid fraction in infant formula (Lagarda et al., 2003). The emerging biotechnology interests of the oil industry uses GC to identify the unique presence of unusual fatty acids such as ricinoleic, vernolic, and cyclopropenoid fatty acids in seed oils of oil-rich plants such as *Ochrocarpus africanus* (Hosamani and Ganjihal, 2003). The bakery products industry routinely utilizes GC for the identification and quantification of *trans* fatty acids and is now combining this technique with novel methods for isolating lipids (Ruiz-Jimenez et al., 2004). Liquid chromatography–mass spectrometry with atmospheric pressure chemical ionization has been used to identify unusual very long chain fatty acids up to C47, both saturated and unsaturated, with two positional isomers (omega-9 and omega-26) in green alga *Chlorella kessleri* (Rezanka, 2002). The ratio of saturated to unsaturated fatty acids changes with the number of carbons, with saturated fatty acids predominating in the C29 acids and the unsaturated acid predominating in the C30 acids. In yet another method, a combination of HPLC techniques was used to isolate and identify conjugated isomers of linolenic acid and arachidonic acid in cheese (Winkler and Steinhart, 2001). In summary, the wide use of mass spectrometry in industry provides a wealth of techniques for identifying and quantifying lipids in food. These techniques lay the groundwork for new era of tracer-based studies quantifying the biosynthesis and metabolism of novel lipid products.

B. Isotopic Flux Studies as a Tool in the Genomics Era

Isotopic tracers have played a fundamental role in developing our understanding of metabolism over the past half century. Both the actual steps in pathways and the rates of the pathways have been elucidated with the aid of tracers. Currently, the Human Genome Project and other molecular techniques are providing massive amounts of information not only about the genome but also the protein sequences coded by the genome, "the proteome" and more recently "the metabolome." Lipids are clearly an important component of the metabolome (German et al., 2003). A first metabolomic goal may be to quantify lipids both those endogenously produced and those supplied in food. Eventually, this will lead to questions about the rates of biosynthesis and flux of lipids into various compartments. A static view will not suffice for long. This brings us again to the use of isotopes and tracers to quantify and understand a new level of control of metabolism. Looking toward the future, it may be relevant to focus on more complete networks rather than on isolated biosynthesis. In the past, we have learned how to accurately estimate de novo lipogenesis and fluxes of food-derived lipids across the plasma. In the future, we hope to integrate entire metabolic networks that include many reactions such as those that supply the NADPH and other cofactors required for lipogenesis to gain a deeper understanding of metabolic control.

We may ask how isotopic tracer studies specifically may contribute to advances in metabolic studies in this new environment. In the field of metabolism, quantitative tools for evaluating metabolism such as "metabolic control analysis" (Fell, 1997) have already provided a framework for organizing this new information. Isotopic tracers may be key to quantifying how changes in gene expression alter metabolic pathways, because they provide a quantitative measure of changes in fluxes and flux ratios. Consider the hypothetical case based on the metabolic network shown in Figure 4.1, where an investigator wants to increase flux to compartment D rather than compartment C to prevent disease. The investigator may hypothesize that this desired change may be accomplished by increasing a specific

enzyme catalyzing a key step in the network or by adding to the system a molecule that is an effector stimulating a specific reaction. The ultimate test of whether the goal of increasing flux has been accomplished may best be determined by isotopic studies that actually measure the flux changes. To study the effect of genetic manipulations on a larger, more complex network, one may select key compounds in the network as reporters for the flux through specific branches. The isotopic enrichment in these molecules offers a quantitative tool for the understanding of the behavior of the network. Clearly, the variety of metabolic alterations that may be feasible with the developing molecular technologies will challenge metabolic researchers to bring the isotopic methods and analytical skills to this new arena. Hopefully, this tutorial has provided a framework for understanding the methodology underlying tracer analysis and will enable more researchers to utilize these powerful tools.

5 Fatty Acids in Meat and Meat Products

J.D. Wood, M. Enser, R.I. Richardson, and F.M. Whittington

CONTENTS

I. INTRODUCTION

Meat has an important place in a healthy diet, providing protein with a good balance of amino acids, iron in a readily available form, vitamins, especially of the B group and other essential minerals such as zinc (Williamson et al., 2005). Meat also contributes a significant amount of fat to the human diet and it is this component that has been most under the spotlight in recent years in relation to the healthiness of people consuming meat. Meat contains relatively high amounts of saturated fatty acids (SFA) and ruminant meats (beef and lamb) are low in polyunsaturated fatty acids. This balance, if replicated in the whole diet, predisposes people to a range of diseases including cardiovascular disease (CVD). However, research papers show that the fatty acid composition of meat can be greatly modified by production factors such as animal diet, age, weight, sex, and breed. Fatty acid composition also varies between species and tissue sites in the body. All these variations provide the meat industry with the tools to supply meat containing a healthy balance of fatty acids to the consumer, either in the form of fresh meat or meat products.

The fatty acids in meat are located mainly in adipose tissue, commonly termed "fat." This has a role in product quality, contributing toward texture (tenderness and mouthfeel) and juiciness in both fresh meat and meat products. The softness/hardness of fat, which is greatly influenced by fatty acid composition, affects various properties such as the sliceability of bacon and the stability of

sausage emulsions (Teye et al., 2006b). Fatty acids in adipose tissue and in muscle membranes also contribute to meat flavor, providing volatile degradation products during cooking. Changes in fatty acid composition can affect all these aspects of meat quality.

The aim of this chapter is therefore to review current research findings on the factors affecting the fatty acid composition of meat. Much of the information presented comes from research on cattle, sheep, and pigs conducted at the University of Bristol.

II. TYPES OF FATTY ACIDS IN MEAT

The fatty acids in meat are mainly of medium to long chain length, that is, they have 12- to 22-carbon atoms in the molecule, with a basic structure of CH_3–$(CH_2)_n$–COOH. Small amounts of shorter chain length fatty acids, C8–C10, are present in lamb fat.

About 40% of fatty acids are saturated (SFA), that is, each carbon has two hydrogen atoms attached, about 40% have one double bond (monounsaturated fatty acid, MUFA) where adjacent carbon atoms are attached to only one hydrogen atom each and a smaller proportion, about 2%–25% have more than one double bond (polyunsaturated fatty acid, PUFA). Fatty acids are commonly labeled according to carbon chain length and the number of double bonds, for example, linoleic acid is labeled as 18:2, being 18 carbons in length and containing two double bonds. Double bonds are either of the more common *cis*-type, in which the hydrogen atoms point in the same direction, or of the *trans*-type, in which they point in opposite directions resulting in a straighter molecular configuration (Figure 5.1). Oleic acid (18:1 *cis*-9) is the major fatty acid in all meats, contributing over 30% of total fatty acids.

The length, degree of unsaturation, and configuration of the fatty acid molecule influence physical properties such as melting point. The longer the chain length and the fewer the number of double bonds present in the molecule, the higher the melting point. Saturated and *trans* fatty acids have a higher melting point than unsaturated and *cis* fatty acids (Table 5.1). A high proportion of SFA therefore causes hard rather than soft fat tissue.

The fatty acids in ruminant tissues are more complex than those in nonruminants, containing higher proportions of *trans* fatty acids, fatty acids with an odd number of carbon atoms (arising from rumen-derived proprionic acid rather than acetate as a precursor for fatty acid synthesis, e.g., C15 and C17), fatty acids with branched chains (derived from the amino acids, leucine, valine, and isoleucine, i.e., 4-methyl octanoic acid, C8:0 and 4-methyl nonanoic acid, C9:0) and fatty acids with conjugated double bonds (i.e., the bonds are on adjacent carbon atoms rather than being separated by a CH_2 group). These variations are the result of the actions of enzymes present in microorganisms in the rumen that degrade plant structures and dietary fatty acids, producing a wide range of products, some of which are absorbed in the small intestine and incorporated into tissue lipids. An important group of fatty acids in ruminants are the conjugated linoleic acids (CLAs) with 18 carbons and 2 conjugated double bonds. These have been shown to have a range of physiological actions in the body of the animal and consumers of meat.

TABLE 5.2
Sources of Some Major Fatty Acids in Meat

Fatty Acid Type	Source
Saturated	Synthesis + diet + biohydrogenation
Monounsaturated-*cis*	Synthesis + diet
Monounsaturated-*trans*	Biohydrogenation
Polyunsaturated-18:2n-6	Diet (essential FA)
Polyunsaturated-18:3n-3	Diet (essential FA)
Conjugated linoleic acid	Synthesis + biohydrogenation
Polyunsaturated C*20*, C*22*	Synthesis + diet

The SFA in meat can be derived from the diet, produced in the rumen from unsaturated dietary fatty acids, or synthesized from glucose or acetate in liver or adipose tissue (Table 5.2). MUFA (e.g., 18:1*cis*-9) are mainly formed in adipose tissue from SFA by the action of desaturase enzymes, for example, delta-9-desaturase that forms oleic acid (18:1*cis*-9) from stearic acid (18:0) and palmitoleic acid (16:1*cis*-9) from palmitic acid (16:0). This same enzyme complex forms the main CLA isomer, *cis*-9, *trans*-11 CLA from 18:1 *trans*-11, which is produced in the rumen. Most CLA formation occurs in adipose tissue (the mammary gland in the case of lactating animals) but some occurs in the rumen.

PUFAs are of the n-6 or n-3 type that describes the position along the carbon chain from the methyl end where the first double bond is inserted. The n-6 fatty acid present in the largest amount is linoleic acid (18:2n-6), which is an essential fatty acid, that is, it is derived entirely from the diet (e.g., oilseeds and grains). The animal possesses desaturase and elongase enzymes that can convert 18:2 to longer-chain n-6 fatty acids such as arachidonic acid (20:4n-6). Similarly, the most common n-3 fatty acid is α-linolenic acid (18:3n-3), which is present in the leaves of plants and grasses. This fatty acid can be converted to long-chain n-3 fatty acids such as eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). There is competition between 18:2n-6 and 18:3n-3 for conversion to the long-chain PUFA because the enzymes are shared. Evidence suggests that 18:3n-3 is the preferred substrate but the presence of much more 18:2n-6 usually results in greater synthesis and deposition of long-chain PUFA derived from this fatty acid (Williams and Burdge, 2006). These long-chain n-6 and n-3 fatty acids have important physiological roles in the body through their conversion to eicosanoids, which among other actions, control thrombosis and tissue inflammation.

Ruminant and nonruminant species differ greatly in their proportions of PUFA in tissues and meat because, whereas these are hardly changed by digestion in pigs and poultry and are incorporated directly into adipose tissue, in ruminants they are extensively hydrogenated by microorganisms

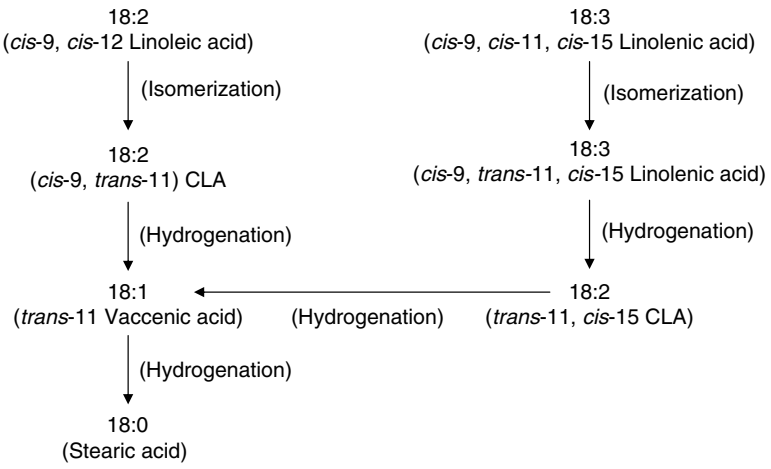

FIGURE 5.2 A simple representation of biohydrogenation pathways in the rumen.

in the rumen (Figure 5.2). This microbial action results in generally low levels (10% or less) of dietary PUFAs being available for absorption into body tissues after passing through the rumen and a wide range of modified fatty acids.

The fatty acids in meat are found in two main lipid classes, neutral triacylglycerol (storage role) and more polar glycerophospholipid (structural and metabolic role). The former is the main lipid component (>90%) of adipose tissue in mature animals (visible fat) and the latter, a constituent of cell membranes, contributes between 10% and 40% of the total fatty acids in muscle. Phospholipid has a much higher concentration of PUFA than triacylglycerol. For example, pig loin muscle neutral lipid (triacylglycerol) and phospholipid contained 12% and 34% 18:2n-6, respectively. in a pig study (Wood et al., 2004). Some average values for the fatty acid composition of adipose tissue triacylglycerol and muscle phospholipid are given in Table 5.3 and are derived from studies in which the different species were fed grain-based (concentrate) diets. As meat animals grow toward the point of slaughter they deposit increasing amounts of fat in the carcass including that within the muscle (marbling fat). This results in an increasing ratio of triacylglycerol to phospholipid, producing a lower concentration of PUFA in total lipids. A clear picture of the effects of production factors on fatty acid composition can therefore only be obtained by analyzing triacylglycerol and phospholipid separately.

III. MEASUREMENT OF FATTY ACID COMPOSITION

Analysis of the amount and type of fat present in meat can be carried out in a variety of ways depending on the requirements of the research project. Results should always be judged in relation to the procedures used.

The widely used Soxhlet method that involves continuous refluxing of ether or light petroleum spirit over a prepared ground and dried sample for several hours will readily extract neutral triacylglycerol but not the phospholipid component. If the amount of total fat (without subsequent fatty acid analysis) is required, then after the Soxhlet extraction, the sample can be hydrolyzed using 5 M hydrochloric acid, washed with distilled water and oven dried, and then reextracted with light petroleum spirit using the Soxhlet method once again.

In order to identify fatty acids present in the different lipid classes, the extraction mixture chloroform/methanol (2:1, v/v) proposed by Folch et al. (1957) is ideal for the initial total lipid extraction process since it will extract both the neutral triacylglycerol components as well as more polar phospholipid components of the tissue without damage to the fatty acids. An antioxidant such

as butylated hydroxy toluene (BHT) is added to prevent oxidation of the unsaturated fatty acids. The neutral and polar fractions can then be separated by applying this total lipid extract to silicic acid solid-phase extraction columns or by thin layer chromatography. Following this step, individual fatty acids can be isolated by saponification, extracted into organic solvents, prepared as fatty acid methyl esters, and then subsequently analyzed by gas–liquid chromatography (GLC).

The gas chromatograph (GC) is widely accepted as a valuable tool in the analysis of fatty acids, and with the introduction of 100-m silica narrow bore capillary columns, the development of liquid phases suitable for a variety of applications, and the appropriate use of temperature programming, separation of individual fatty acids from complex mixtures is possible. Identification is carried out by comparison with standards and, where necessary, by simultaneous mass spectrometry. Modern technology with automation and the use of sophisticated integration software means that routine measurement is possible.

For complex mixtures containing different isomers of particular fatty acids such as CLA, the use of multiple-column silver-ion high-performance liquid chromatography (HPLC) has proved very effective.

IV. MEAT FATTY ACIDS AND HUMAN HEALTH

Some SFA, that is, those with less than 18-carbon atoms chain length, raise blood levels of low-density lipoprotein (LDL) cholesterol, which increases the risk of atherosclerosis leading to CVD in man (Williamson et al., 2005). On the other hand, MUFA and PUFA lower blood levels of LDL-cholesterol. As a result of these findings, health bodies around the world have issued dietary guidelines for the fatty acid composition of the human diet. The World Health Organization (2003) has said that total fat should constitute not more than 15%–30% of total energy in the diet, SFA around 10%, n-6 PUFA around 5%–8%, and n-3 PUFA 1%–2%. The U.K. Department of Health (1994) recommended that ratios between these fatty acid groups should be >0.4 for PUFA:SFA and <4.0 for n-6:n-3 PUFA. Several studies agree that n-3 PUFA levels are too low in Western diets and that these fatty acids reduce the risk of CVD, are necessary for proper brain and visual development in the fetus, and have a role in reducing various cancers (Enser, 2001).

Trans fatty acids have potentially more potent effects on LDL-cholesterol than SFA, although *trans* fatty acids are generally low in meat and there is some evidence that the *trans* fatty acids in meat and milk are less damaging to human health than those in other processed fatty foods (Williamson et al., 2005). *Trans*-11 18:1 (*trans* vaccenic acid) is the precursor in tissues of the major CLA isomer, *cis*-9, *trans*-11 CLA, which is recognized to have several positive health benefits including inhibition of carcinogenesis and atherosclerosis and enhancement of the immune response.

V. SPECIES EFFECTS ON FATTY ACID COMPOSITION

The results in Table 5.3 show data for cattle, sheep, and pigs for specific lipid classes and dietary treatments. Results for the composition of the total fatty acids of muscle tissue from loin chops or steaks representing a wide range of production systems are shown in Table 5.4. The samples were purchased from four supermarkets in the town of Weston-Super-Mare, United Kingdom, in 1994 and therefore represent the meat on sale to the public.

The values for the weight of total fatty acids in muscle shown in Table 5.4 are high in comparison with other studies in which cores from the central part of the *longissimus* muscle have been examined. The results were intended to reflect muscle normally consumed so they include the epimysial connective tissue and some adhering subcutaneous and intermuscular fat that would be consumed by people separating fat from muscle on the plate.

The results in Table 5.4 show that beef and lamb have higher proportions of most SFA than pork. Conversely, pork is much higher than beef and lamb in the main PUFA, 18:2n-6. Values for 18:3n-3

[a] P:S is 18:2n-6 + 18:3n-3/12:0 + 14:0 + 16:0.

are more similar between the species, reflecting its presence at a high level in grass and forages. Although a high proportion (about 90%) of 18:3n-3 in the diet of ruminants is normally hydrogenated in the rumen (Scollan et al., 2001b), some does escape to the duodenum, to be absorbed and deposited in tissues as in pigs. The proportions of long-chain PUFA are also similar between the species, apart from 20:4n-6 that is high in pigs because of the high concentration of its precursor, 18:2n-6.

The study of Enser et al. (1996) also included analysis of subcutaneous adipose tissue removed from the steak. Values for the proportions of the C12–C18 fatty acids were similar to those for muscle but whereas small proportions of the C20–C22 PUFA were present in pork, these were not detected in beef and lamb, reflecting the lack of incorporation of the long-chain PUFA into ruminant triacylglycerols (Enser et al., 1996).

Values for the nutritional indices of fatty acid composition in muscle and adipose tissue, with explanations of how they were calculated, are shown in Table 5.5. The P:S ratio was much lower than advocated for the whole diet (>0.4) in beef and lamb tissues but was beneficially high in pork. This ratio was higher in pork adipose tissue (subcutaneous fat) than in muscle, whereas this was not the case in beef and lamb. The ratios of n-6 to n-3 PUFA were within the range advocated for the whole diet for beef and lamb (<4.0) but well above this (less desirable) for pork. These results mainly reflect the high level of 18:2n-6 in pig diets, coming from grains and oil seeds.

In a comparison of different species, Rossell (1992) found that broiler chicken meat fatty acid composition was similar to that of pork, although the proportion of 18:2n-6 was much higher, that is, 18.9% against 9.5% in that study. Rule et al. (2002) also found a high value for chicken 18:2n-6 in a comparative study, 17.0% of total fatty acids in breast muscle. Among other characteristic species differences is the very high value for 18:3n-3 in horse muscle and adipose tissue (Rossell, 1992; Robb et al., 1972).

VI. DIET EFFECTS ON FATTY ACID COMPOSITION

Compared with other production factors, diet has the largest effect on fatty acid composition in all species, particularly in the monogastrics.

A. Pigs

Studies conducted in the United States in the 1920s showed clearly the effects of different oil sources in the diet on the fatty acid composition of pork (Ellis and Isbell, 1926). Different diets produced different commercial grades of subcutaneous fat tissue, from brewer's rice that produced hard fat to soybeans grazed in the field, which produced oily fat. These effects were due to the incorporation of relatively saturated fat from brewer's rice into body fat to a large amount of highly unsaturated fat as in the case of grazed soybeans. The fatty acid most affected by diet was 18:2n-6, which was 1.9% and 30.6% of total fatty acids in subcutaneous fat of pigs fed brewer's rice and grazed soybeans, respectively.

A review by Wood (1984) showed that 18:2n-6 from oil sources such as soybean meal is incorporated into muscle and adipose tissue in direct proportion to its concentration in the diet. Similar results were found in other PUFA sources having characteristic fatty acid compositions; for example, linseed, which contains a high proportion of 18:3n-3 (Enser et al., 2000) and fish oil, which contains the long-chain n-3 PUFA EPA and DHA (Irie and Sakimoto, 1992).

Feeding SFA does not raise their proportions in muscle and adipose tissue as much as feeding PUFA. This is because of a lower incorporation into lipid and elongation and desaturation of these fatty acids into other SFA and MUFA. Results in Table 5.6 contrast the fatty acid composition of the diet and of the muscle tissue from pigs fed palm kernel oil, palm oil, or soybean oil when these supplied 2.8% of the diet (Teye et al., 2006a). The proportion of 18:0 was three times higher in the palm kernel oil diet than in the soybean oil diet but values in muscle were similar. On the other hand, a doubling of the proportion of 18:2n-6 in the soybean oil diet compared with the palm kernel oil diet produced a 33% increase in the proportion of this fatty acid in muscle.

Comparison of papers published in the 1970s and 1980s with more recent ones shows that the level of 18:2n-6 in pig muscle and adipose tissue has greatly increased during this time. This is partly not only because the oil content of diets has increased to promote faster growth but also due to lower carcass fat levels. When carcass fat deposition is reduced for reasons of genetics or a lower feed intake this decreases the fatty acids synthesized from carbohydrates (SFA and MUFA); therefore, the relative contribution of dietary PUFA to body fat deposition increases. One consequence is softer fat tissues in modern lean pigs compared with the fatter pigs of former years.

B. Cattle

Despite the hydrogenating effect of the conditions of the rumen on dietary PUFA, small but significant amounts enter the duodenum to be absorbed into blood and delivered to tissues as

in pigs. A recent study conducted by the University of Bristol and the Institute of Grassland and Environmental Research (IGER) has compared muscle fatty acid composition in cattle of two breeds (Holstein-Friesian and Aberdeen Angus cross) fed either a grain-based concentrate diet or a grass silage diet from 6 to 14, 19, or 24 months of age. Results for the Aberdeen Angus cross animals slaughtered at 24 months are shown in Table 5.7. The concentrate diet raised the proportion of 18:2n-6 and 20:4n-6, whereas the grass silage diet increased levels of the n-3 PUFA 18:3, 20:5, and 22:6. All these changes reflect the fatty acid composition of the diets. The increased concentration of 22:6n-3 in the grass silage group was significant since the provision of more 18:3n-3 does not always result in higher levels of 22:6n-3 in tissues (Scollan et al., 2003). The higher levels of SFA and MUFA in the grass silage groups can partly be explained by overall greater fatness resulting from de novo fatty acid synthesis in these cattle.

When cattle are fed concentrate alone, the rate of PUFA passage through the rumen is rapid, limiting the access to microorganism action, compared with a mixed forage/concentrate diet. This helps to explain the high values for muscle PUFA proportions seen in young bulls fed a "barley beef" diet (Enser et al., 1998), although a low carcass fat level in bulls will also be important, leading to a high proportion of phospholipid in total lipid.

The concentrate portion of beef cattle diets can be fortified with dietary oils with positive effects on muscle and adipose tissue fatty acid composition. Scollan et al. (2001a) fed linseed and fish oils to increase proportions of 18:3n-3 and the long-chain n-3 PUFA, respectively (Table 5.8). The concentrate portion of the diet contained 6% oil of which half was the test oil. These diets were fed for 120 days along with grass silage in a 60:40 forage/concentrate combination. The results

show that there was a limited effect of oil source on neutral lipid fatty acid composition (e.g., 18:3n-3 increased from 0.4% in the control diet to 0.6% in linseed) but a bigger effect on phospholipid (18:3n-3 increased from 2.1% in controls to 4.3% in the linseed diet; 20:5n-3 increased from 2.3% in controls to 4.8% in the fish oil diet). These results again emphasize the importance of the phospholipid fraction in muscle PUFA proportions.

The effects of dietary oils on meat fatty acid composition are enhanced if they are protected from biohydrogenation in the rumen. Chemical protection can be achieved if protein in the diet is treated with formaldehyde, which results in a matrix structure within which dietary fatty acids are "encapsulated." In a study where soybean (0.7), linseed (0.2), and sunflower (0.1) seed oils were combined and protected in this way, %18:3n-3 in neutral lipid was raised from 0.4% to 1.7% and in phospholipid from 2.5% to 3.3% (Scollan et al., 2003). Interestingly, there were no increases in proportions of 20:5n-3 and 22:6n-3 in phospholipid despite this increase in 18:3n-3. These results contrast with those in Table 5.7, which show that providing 18:3n-3 in grass increased all the long-chain n-3 PUFA, including 22:6n-3.

Several studies have shown that there is a linear relationship in muscle and adipose tissue between the proportions of 18:1 *trans*-11 (*trans* vaccenic acid) and the main CLA isomer, *cis*-9, *trans*-11 CLA, reflecting the synthesis of CLA from its precursor. In the study of Warren et al. (2007) described in Table 5.7, a group of steers was reared on fresh grazed grass from 14 to 19 months in addition to those steers fed concentrate and grass silage to the same ages. The results for adipose tissue (Figure 5.3) confirm the linear relationship between 18:1 *trans*-11 and CLA and show that both fatty acids are at higher proportions following the consumption of fresh grass compared with

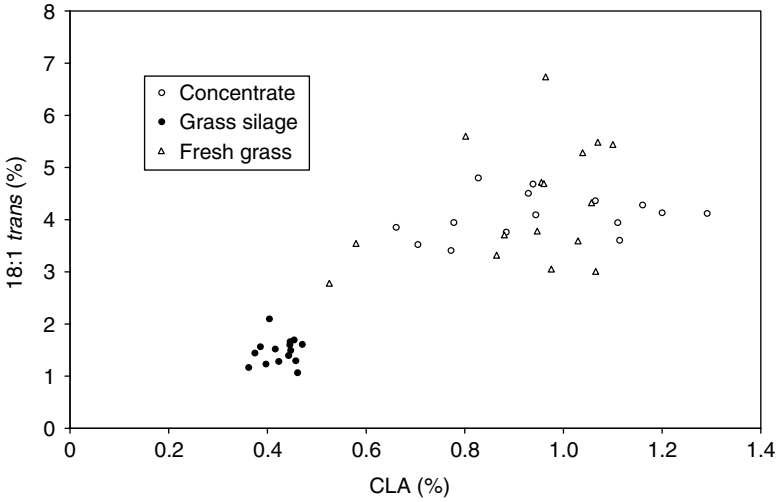

FIGURE 5.3 Relationship between proportions of 18:1 *trans*-11 and CLA in adipose tissue of steers given different diets. (Warren, H.E., et al. 2007a. *Meat Science*, in press.)

grass silage. Values for the group fed fresh grazed grass were similar to those fed concentrate, in contradiction to other findings showing higher values after consuming grass.

Wood et al. (2005) showed that there were three main CLA isomers in beef muscle and the levels were affected by dietary oil source. The *cis*-9, *trans*-11 isomer always exceeded 80% of the total, the other two isomers being *trans*-11, *cis*-13 and *trans*-11, *trans*-13.

The 18:3n-3 content of grass changes through the growing season in parallel with other nutrients such as nitrogen (Walker et al., 2004). Other factors that affect grass fatty acid composition and therefore meat fatty acid composition include the conservation process. Excessive drying of grass prior to producing hay or silage reduces PUFA proportions through the action of plant enzymes (Dewhurst et al., 2003) and fatty acid oxidation.

C. Sheep

The effects of grass-based diets compared with grain-based (concentrate) diets are similar in sheep to those in cattle. Results in Table 5.9 are from a study by Fisher et al. (2000) in which Suffolk cross sheep were grazed on lowland pasture or fed a standard concentrate diet for 3 months before slaughter. Values for the proportions of PUFA are high in comparison with the beef steers in Table 5.7 when those data are used to calculate proportions of total lipid. For example, 18:3n-3 was 0.6% of total lipid in the steers fed grass silage compared with 2.3% in the grazed lambs in Table 5.9. However, the much lower level of total muscle fatty acids is also a factor in these high values for lambs. As with the grass-fed steers, all the long-chain n-3 PUFA were higher in the grass-fed lambs than in those fed concentrate, including DHA.

Concentrate diets containing the same dietary oil sources as those used in the cattle study described in Table 5.8 were fed to three breeds of ram lambs in a study by Wachira et al. (2002). The diets contained 6% oil from different sources and were fed between 24 and 44 kg live weight. Results for the fatty acid composition of *longissimus* muscle total lipid (containing both neutral lipid and phospholipid) for Suffolk cross lambs are shown in Table 5.10. The proportion of 18:3n-3 in the group fed linseed was higher than for the grazed lambs in Table 5.9 and yet proportions of 20:5n-3, 22:5n-3, and 22:6n-3 were lower. These results confirm the effect of grass diets in raising levels of long-chain n-3 PUFA.

VII. GENETIC EFFECTS ON MEAT FATTY ACID COMPOSITION

A. Pigs

Several authors have shown effects of breeds and genetic lines on muscle and adipose tissue fatty acid composition. In pigs, Wood et al. (2004) compared four pure breeds reared from 9 weeks of age for 12 weeks on two different concentrate diets. Results for the standard (control) diet are shown in Table 5.11. The two traditional breeds, Berkshire and Tamworth, were fatter than the two modern breeds, Duroc and Large White, at slaughter. Values for P_2 fat thickness (fat thickness at the last rib position, 6.5 cm from the midline) were 15.1, 9.1, 7.8, and 14.7 mm in Berkshire, Duroc, Large White, and Tamworth, respectively. In general, differences in fatty acid composition between the breeds were restricted to neutral lipid and were quite small, reflecting differences in carcass fatness. Thus the two modern lean breeds, Duroc and Large White, had higher proportions of 18:2n-6 (12.0% and 12.8%) than the two traditional breeds, Berkshire and Tamworth (7.8% and 8.8%). The main product of de novo synthesis (16:0) was higher in the two traditional breeds. Many of the other differences between the breeds were statistically significant but numerically small. The content of total muscle fatty acids (neutral lipid plus phospholipid) did not reflect the differences in carcass fat, Durocs having a higher value for muscle lipid than Large Whites but a similar P_2 fat thickness. Similarly, Tamworth pigs had a lower muscle fat value than Berkshires but similar subcutaneous fat thickness (Figure 5.4). These results show that partition of fat in the body is under genetic control.

B. Cattle

Results in Table 5.12 show the fatty acid composition of *longissimus* muscle in steers reared from 6 to 24 months of age on a grass silage diet. There were two breeds, a beef crossbreed (Aberdeen

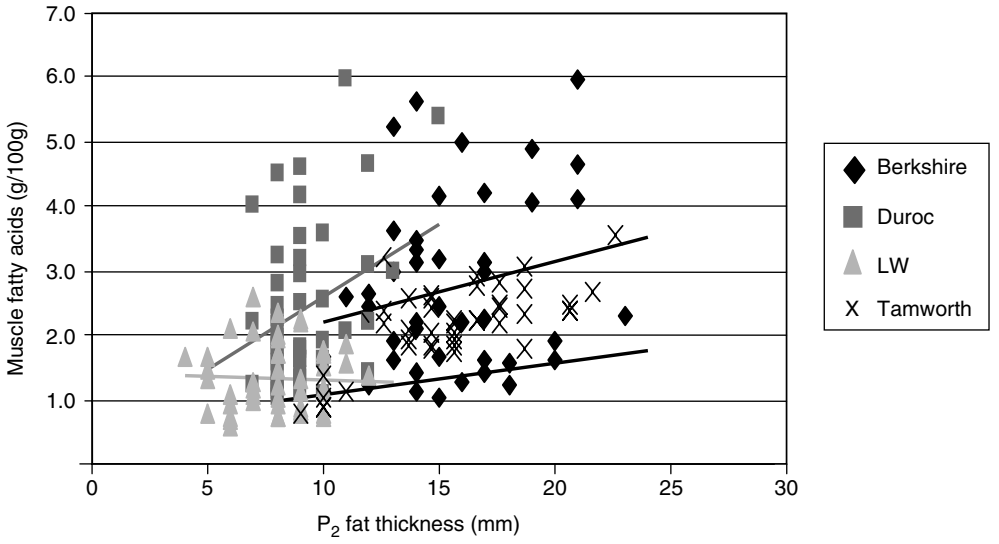

FIGURE 5.4 Relationship between total muscle fatty acids in *longissimus* muscle and thickness of subcutaneous fat (P_2, mm) in four pig breeds. (Wood, J.D., et al. 2004. *Meat Science*, **67**, 651–667.)

Angus × Holstein-Friesian) and a dairy breed (Holstein-Friesian). The Aberdeen Angus steers were considerably fatter, judged by the carcass fat score, which is a visual estimation of subcutaneous fat deposition. Values approximate to percentage subcutaneous fat in the carcass 10 times. Aberdeen Angus also had more neutral lipid and more phospholipid fatty acids in muscle. Values for the main fatty acid proportions follow a pattern similar to those for pig breeds differing in carcass fat content (Table 5.11). Thus, the fatter Aberdeen Angus steers had higher proportions of 16:0 in neutral lipid and lower proportions of PUFA. However, the differences in proportions of n-6 and n-3 PUFA in phospholipid, with Holstein-Friesians having much higher values than Aberdeen Angus, are an indication of a genetic effect that is independent of fatness. Differences are much bigger than seen in the pig study (Table 5.11) despite similarly large differences in fatness. We hypothesize that these differences are due to breed differences in the expression of enzymes forming long-chain n-3 PUFA from 18:3n-3.

Studies in Belgium have shown that the Belgian Blue breed has very high proportions of PUFA in muscle tissue linked directly to a low fat content. In a study by Raes et al. (2004), values for 18:2n-6 in *longissimus* muscle of Belgian Blue cattle fed different diets were above 10% of total lipid (almost as high as in pigs) and the P:S ratio was above 0.3. Contrast this with 0.11 in United Kingdom beef in Table 5.5. The authors concluded that a low concentration of muscle lipid (<1% of muscle weight) resulted in a high ratio of phospholipid to total lipid and this caused the high-PUFA proportions.

C. Sheep

Considerable variations in body size and shape exist between sheep breeds, explained by the wide range of environments inhabited by sheep and selection of breeding animals for different production characteristics. Wachira et al. (2002) compared Suffolk cross, Friesland cross, and Soay breeds representing extremes of breed types in the United Kingdom (i.e., a meat type, a milk type, and a primitive/traditional type). Ram lambs were fed a concentrate diet containing different oil sources to about 50% of the breed mature weight. Results for the groups fed megalac, a relatively saturated oil source, are shown in Table 5.13. Suffolks were slightly fatter than Soays and Frieslands, although the total fatty acid content of muscle (neutral lipid plus phospholipid) was higher in Soays. The differences in total lipid fatty acid composition were small when compared with the results for cattle (Table 5.12). Although the proportions of 18:2n-6 and 18:3n-3 were highest in the lean Soay breed, long-chain n-3 fatty acid proportions were similar. Fisher et al. (2000) found that PUFA proportions were higher in grass-fed Soays than in Welsh Mountain and Suffolk cross animals fed on grass.

Recent results from Bishop et al. (2006) show high heritabilities for fatty acid composition in sheep and evidences that genetic differences in fatty acid composition can be detected using genetic markers (QTLs).

VIII. FATTY ACID COMPOSITION OF DIFFERENT MUSCLES, TISSUES, AND MEAT PRODUCTS

Muscles in the carcass differ in fiber type, with muscles involved in rapid movement having predominantly white glycolytic type II fibers and those involved in posture retention having predominantly red oxidative type I fibers. All muscles contain a mixed population of fiber types, including intermediate types between these two extremes.

Red oxidative fibers contain more mitochondria and a higher proportion of phospholipid than white glycolytic fibers and as a result contain a higher proportion of PUFA. Results in Table 5.14 show the fatty acid composition of the predominantly "white" *longissimus* and the "red" *psoas* muscle in Duroc pigs fed the control diet in the study of Wood et al. (2004). The proportion of 18:2n-6

was higher in phospholipid from *psoas* but the main difference between the two muscles was the higher proportion of phospholipid in total lipid of *psoas* (41.5% vs. 23.7%).

Liver is also a metabolically active tissue with a high proportion of phospholipid in total lipid. Results in Table 5.15 for lambs show that total lipid was 2.4% and 5.4% of tissue weight in muscle and liver, respectively, phospholipid being 24.1% and 56.9% of total lipid. The phospholipid in liver was less unsaturated than that in muscle. For example, 18:2n-6 was 12.4% and 5.8% of phospholipid fatty acids in muscle and liver, respectively.

The fatty acid composition of various tissues in pigs fed a control diet is shown in Table 5.16. The range in values for 18:2n-6 was from 10.9% in muscle neutral lipid to 29.0% in muscle phospholipid. Values for 18:2n-6 and 20:4n-6 were higher in pig liver than lamb liver (Table 5.15), whereas 18:3n-3 and 20:5n-3 were higher in lamb liver. These differences again reflect the different diets consumed. The presence of long-chain PUFA in pig subcutaneous fat albeit at low levels, contributes to a high nutritional value in pigmeat.

IX. EFFECTS OF FATTY ACIDS ON MEAT QUALITY

The total amount of fat in meat and its fatty acid composition affect many aspects of meat quality and only a few examples will be given here. More information is in Wood et al. (2003).

In pigs, the fatty acid composition of subcutaneous fat affects its firmness, which is a factor in product quality. High concentrations of PUFA in fat tissue, caused by a high level in the diet, produce soft, oily fat with low visual and handling quality as shown in the early studies of pigs fed soybeans by Ellis and Isbell (1926). The two fatty acids having the biggest effect on firmness are 18:0 and 18:2n-6, and Whittington et al. (1986) found that the ratio between these provided the best prediction of firmness measured by using a penetrometer. The reduced "fat quality" of pigs with thin

as opposed to thick subcutaneous fat, which includes separation between fat layers and a dull color as well as softness, was found by Wood et al. (1986, 1989) to be closely related to changes in the proportions of these two fatty acids as well as water and lipid. An increase in fat thickness indicates a more mature tissue with larger fat cells, a higher proportion of lipid, and a corresponding reduction in the proportion of water.

Fatty acid composition plays an indirect role in the color of meat in retail display. Vatansever et al. (2000) examined the beef produced using different dietary oil sources reported by Scollan et al. (2001a) (Table 5.8). The sources were megalac (relatively saturated), linseed (high in 18:3n-3), and fish oil (high in 20:5n-3 and 22:6n-3). Sirloin steaks were displayed under simulated retail display conditions and lipid oxidation and surface color were measured over 11 days. As the display period progressed, lipid oxidation increased, more so in the steaks produced using fish oil, which had the highest concentration of PUFA. These are relatively unstable, oxidation leading to production of many compounds, including aldehydes, ketones, and alcohols. There was a parallel decline in the color saturation of the steaks during the display period, this being a measure of the intensity of the red color. Saturation declined fastest in the steaks produced using fish oil and slowest in the megalac controls. The implication is that lipid oxidation products catalyze the oxidation of the muscle pigment myoglobin leading to accelerated production of the oxidized form, metmyoglobin.

A difference in the color of beef sirloin steaks develops during retail display in grass- and concentrate-fed cattle. In the study of Warren et al. (2007b), color saturation declined more quickly in the concentrate-fed steers than in those fed grass silage (Figure 5.5). This was associated with higher lipid oxidation in the steaks from animals fed concentrate. This was partly related to higher proportions of PUFA in these steers (Table 5.7) although a much lower concentration of vitamin E in muscle tissue compared with that from steers fed grass silage was probably a more important factor.

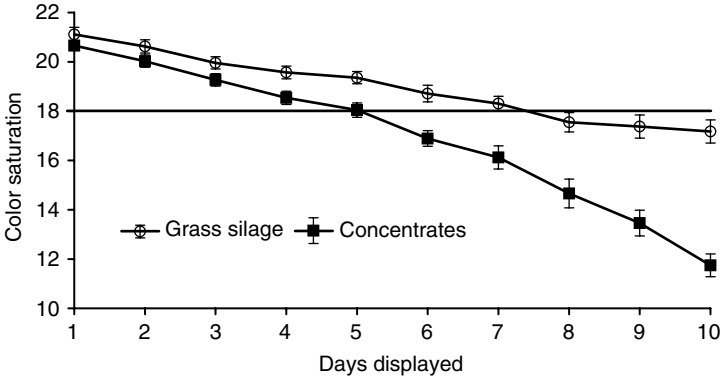

FIGURE 5.5 Color of beef sirloin steaks from steers fed concentrate or grass silage diets to 14 months of age. (Warren, H.E., et al. 2007b. *Meat Science*, in press.)

Vitamin E is present at high concentrations in leafy grass when n-3 PUFA proportions are also high, protecting the PUFA from oxidation, both in the grass and in the animal tissues.

Fatty acids contribute to the meat flavors generated during cooking, either directly through the lipid oxidation products, some of which are odorous, or indirectly by reactions between lipid oxidation products and proteins and carbohydrates present in the meat. High levels of 20:5n-3 and 22:6n-3 in lamb, created by feeding fish oils or marine algae, produced high taste panel scores for "rancid" and "fishy" and low scores for "overall liking" in recent research by Nute et al. (2007). On the other hand, an increased concentration of 18:3n-3 from linseed elicited the highest scores for "lamb flavor" and "overall liking." In a companion paper, Elmore et al. (2005) identified high concentrations of compounds generated from the thermal oxidation of n-3 PUFA in headspace volatiles from the samples produced from marine algae.

Campo et al. (2006) observed that beef sirloin steaks displayed in "modified atmosphere" packs containing a high concentration of oxygen showed increased lipid oxidation as the display period progressed. Samples with high concentrations of PUFA had the highest oxidation and they received the lowest taste panel scores for "beef flavor." They scored highest for "abnormal flavor" and "rancid" and there were strong negative correlations between TBARS (thiobarbituric acid reactive substances, the standard test for meat lipid oxidation) and "beef flavor" and between "beef flavor" and "rancid." These results show that fatty acid composition is a major factor in beef flavor.

X. CONCLUSIONS

This chapter shows that the fatty acid composition of meat in pigs, cattle, and sheep is affected by diet and breed, and differs between tissues. The levels of fat tissue in the carcass and meat are important underlying factors because fatty acid composition changes as fat is deposited. One important consequence of increasing fat deposition is that the proportion of phospholipid is reduced, leading to a decrease in the proportion of the major PUFA, 18:2n-6.

The fatty acid composition of pork can be readily modified by diet since fatty acids are deposited unchanged by digestion. In ruminants, the rumen is a barrier to the incorporation of PUFAs into meat although the effect of grass diets in increasing proportions of n-3 PUFA and possibly CLA is an interesting area of current research, leading to more desirable meat products for the consumer.

The fatty acid composition of meat is important for human health reasons and also has crucial effects on meat quality, for example, fat tissue firmness, color, shelf life, and flavor. Changes in production that affect fatty acid composition should therefore only be introduced after examining the impact on meat quality.

ACKNOWLEDGMENTS

The research at Bristol University is supported mainly by the Department for Environment, Food and Rural Affairs and the British meat industry. We thank our colleagues for their contributions to the research reported (i.e., A. Fisher, G. Nute, P. Sheard, K. Hallett, K. Gibson, R. Ball, A. Baker, and S. Hughes).

6 Fatty Acids in Milk Fat

Donald L. Palmquist and Robert G. Jensen

CONTENTS

I. INTRODUCTION

The bulk of the lipids in milk, 97%–98%, are triacylglycerols (TG), with sterols (mostly cholesterol) and phospholipids next in quantity (Table 6.1). The di- and monacylglycerols (DG and MG, respectively) and nonesterified fatty acids (FA) in quantities greater than traces are the products of postharvest lipolysis. Freshly drawn milk that is promptly pasteurized or frozen and stored at –70°C contains little of these lipolytic compounds. However, increased milking frequency, a practice that is increasing in the dairy industry, increases lipolysis in fresh milk (Wiking et al., 2006). The FA of commercial milk do not vary greatly in proportion because of the averaging effect of pooling by milk processors; many FA that are found in milk in low or minute quantities may have important nonnutritive roles as nutriceuticals (Milner, 1999; Parodi, 2006).

Most of the lipids in milk and dairy products exist as globules 1–4 μm in diameter as oil in water emulsion (Jensen and Newburg, 1995; Huppertz and Kelly, 2006). The emulsion is stabilized by a bipolar membrane of phospholipids and proteins existing as a loose layer at the oil–water interface. In making butter, the membrane is removed, causing reversal of the emulsion to a water–oil type.

Numerous reviews on lipid composition of milk fat are available (Jensen and Newburg, 1995; Jensen, 2002; MacGibbon and Taylor, 2006). This chapter complements a thorough review on bovine milk lipids published by Jensen (2002). Readers who need more historical information are referred to the chapter in the first edition of this monograph (Jensen, 1992); and for those desiring detailed discussions of all milk lipids see the recent volume *Advanced Dairy Chemistry. Volume 2. Lipids, 3rd edition* (Fox and McSweeney, 2006).

II. ANALYSIS OF MILK FATTY ACIDS

Extraction of milk fat in preparation for gas–liquid chromatography (GLC) analysis is discussed by Jensen et al. (1997). For GLC analysis, milk FA are usually transesterified to FA methyl esters (FAME) with sodium methoxide or acids (H_2SO_4, HCl, or BF_3) as catalysts. Kramer et al. (1997) evaluated the applicability of catalysts for converting milk FA to FAME. They recommended that sodium methoxide be used even though FA in sphingomyelin were not esterified. The amount of FA excluded (approximately 0.1% of total FA) is so low that there would be little or no effect on the amounts or proportions of FA measured. Acid catalysts were reported to cause isomerization of conjugated bonds, resulting in decreased recovery, whereas sodium methoxide did not lower the quantities of these. It is important to determine FA by appropriate methods; if referencing Kramer et al. (1997), one must take care to specify which procedure was used, as these authors describe numerous combinations of methods for FAME preparation and analysis. If lipolysis has occurred (not common in commercial samples), then acid-catalyzed transesterification should be employed so that the Ca-FA salts (soaps) will be cleaved, allowing complete derivative formation. Modern technologies employ both mild acid and alkaline transesterification for milk fat samples (Kramer et al., 1997). See the discussion on acid transesterification by Kramer et al. (1997) and Carrapiso and García (2000), and on using internal standards for quantifying FA (Palmquist and Jenkins, 2003). Up-to-date literature and discussion of advances in lipid analysis can be found at http://www.lipidlibrary.co.uk.

Butyric acid (4:0) as the methyl ester is difficult to measure because of its extreme volatility and water solubility; repeated extraction of methyl butyrate from the aqueous reaction mixture with organic solvent is required to achieve complete recovery and to prevent biased estimates of FA proportions. If the measured content of 4:0 is less than 3% by weight, probability is that some of the butyrate has been lost. Molkentin and Precht (1997) reported 3.42% ± 0.144 (range 3.07–3.75) in 136 samples. Butyl (Iverson and Sheppard, 1986; Ulberth et al., 1999) and isopropyl (Wolff and Fabien, 1989) esters, rather than methyl esters, have been utilized to minimize loss of 4:0–10:0. Butyl and isopropyl esters can be prepared by substituting butanol or isopropanol for methanol in the esterification reaction. Temperature programming is applied to separate the esters of the short-chain FA from the solvent peak and from each other.

Proper identification of isomers is critical; this is particularly difficult in the 16:1 to 18:2 region of GLC chromatograms, where the numerous C18 monoenoic isomers elute. Comparison of retention

times with authentic standards is a minimum requirement, though not conclusive. Use of authentic standards, aided by comparison with published profiles such as those by Kramer et al. (1997) or Precht and Molkentin (1996, 1997b,c) may have greater reliability, whereas greatest certainty for the identification of isomers is by combined gas chromatography–mass spectrometry (GC–MS). Use of a certified butter oil reference standard, such as CRM 164 (Commission of the European Community, Bureau of References, Brussels, Belgium; Precht et al., 1998), is encouraged.

FA compositions are usually reported as relative weight percentages based on the peak areas from the GLC chart, though for some investigations, calculation of mole percentages is more informative. For fluid products, weights of FA/dL should be reported, so that the actual yields (in the case of production studies) or intake (for nutrition studies) of FA can be calculated. The amounts of FA can be determined by use of an internal standard with GLC analysis (Carpenter et al., 1993; Palmquist and Jenkins, 2003).

In the United States, the Food and Drug Administration and the Department of Agriculture (USDA) require that fats and FA contents be reported on food labels as the sum of TG equivalents (Carpenter et al., 1993). For example, if the weight of 16:0 taken from the GLC chart is 1 g then it is reported as 1.044946 g of tripalmitin, that is, the molecular weight (MW) of tripalmitin divided by the 3 × MW of palmitic acid. The factors for milk FA range from 1.074 for 10:0 to 1.037 for 22:0; most are close to 1.05, which may be utilized. Although not stated by Carpenter et al. (1993), the glyceride fragments of CH_3O and CH_2O and the methyl portion CH_3O esterified to FA have nearly equal MWs: 30 and 31; thus, the equivalent weights of FAME and TG FA are nearly identical, and the FAME units summed equals the sample TG weight. Although the weights of FA calculated from the areas on a GLC chart in relation to a FFA internal standard will not be equal to the weight of the extracted lipid, because the glyceride fragment is not included, the FA weight can be converted to TG by using the conversion factors, usually 1.05, as described above. The calculations described here allow one to report FA analysis as TG, according to package labeling requirements for commercial products. However, for computing energy values, it is more appropriate to consider FA and glycerol separately, because glycerol is metabolized and has the energy value of carbohydrate.

III. MILK FATTY ACIDS

Hilditch and Williams (1964) described early efforts to analyze milk FA when separations were attained by distillation of FAME, which were then characterized by determination of fat constants. Some of their data are presented in Table 6.2 and compared with results from GLC analyses of methyl esters from Posati et al. (1975) and Precht and Molkentin (1997a). The results described by Hilditch and Williams (1964) compare well with modern GLC analyses, remarkable when the differences in time, location, and methods are considered. Differences could be attributed to changes in feeding practices alone (Palmquist et al., 1993). Note that Precht and Molkentin (1997a) resolved 18:1c from 18:1t, a separation not possible with most packed GLC columns. Nevertheless, unless isomers of FAME coeluted, as with 18:1c and 18:1t, the weight percentages reported before use of capillary GLC columns were precise. However, the older procedures for measuring the areas of peaks on the GLC charts lacked sensitivity and thus are less reliable and report fewer FA than current analyses that utilize long capillary columns. Vaccenic acid is the predominant *trans* FA in milk fat (Wolff, 1995), and may comprise more than half of the 18:1 isomers in milk under some feeding conditions. Vaccenic acid was first described in milk fat by Bertram (1928); the name is derived from the latin word for cow and is the trivial name for the naturally occurring t11 18:1. Use of the term *trans* to describe this isomer is redundant and unnecessary.

The improved sensitivity and greater resolving power of capillary GLC have increased the number of FA detected and identified in milk. For example, 11 FA were listed in a 1929 publication (Hilditch and Williams, 1964). The number increased from 11 in 1929 to 167 in 1967 (Jensen et al., 1967) and

406 in 1995 (Jensen and Newburg, 1995). Jensen (2002) lists 416 FA and explains corrections made to some earlier accountings of the number of identified milk FA. Many of these FA were not identified by GLC alone. Other techniques were utilized to obtain fractions enriched in certain types of FA, such as separation of classes of unsaturated FA with $AgNO_3$-thin-layer chromatography (TLC) before GLC analysis. Identifications have been confirmed with GLC–MS. A typical milk FA profile with modern analysis is in Table 6.3.

The variety of FA found in milk fat is accounted for mainly by the ruminal biohydrogenation (BH) process (see below). Under most feeding conditions, 18:0 is the predominant FA absorbed from the intestine of ruminants. This is desaturated variably to c9-18:1 by Δ-9 desaturase (stearoyl-CoA desaturase; SCD; EC 1.14.99.5); activity is minimal in the intestinal tissue and most active in mammary gland and adipose tissue (Palmquist et al., 2005). Because absorbed FA in ruminants are highly saturated, unique adaptations have evolved to accommodate the requirement that milk fat must be liquid at body temperature. In addition to Δ-9 desaturase activity, ruminant milk fat is unique in its content of short chain and branched FA; these, together with oleic acid, primarily are responsible for maintaining milk fat fluidity. Among bovine breeds, the contents of oleic acid and short chain FA tend to be reciprocal; also, breeds that secrete milk of higher fat content tend to have lower c9-18:1 and higher content of the short chain de novo-synthesized FA.

The TG structure of milk fat contributes to its unique rheological properties. If the 400 + FA of milk fat were randomly distributed in the TG, the total number of TG species would exceed 64×10^6. Clearly, arrangement is not random, but very few specific TG species exceed 1 mol. % of the total. The *sn*-1 position is dominated by 16:0 and 18:1 (34 and 30 mol. %, respectively), *sn*-2 by 14:0, 16:0, and 18:1 (18, 32, and 19 mol. %, respectively), and *sn*-3 by 4:0 and 18:1 (35 and 23 mol. %, respectively). All of the 4:0 and most of the 6:0 occur at *sn*-3, where they are readily released by lipases, thus contributing importantly to the characteristic flavor of milk fat.

Ruminant milk fat contains glycerides with TG number (the total number of FA carbon atoms in the glyceride) ranging from 24 to 54, with modes at 36–40 and 48–50. Feeding high-fat diets to

cows shifts the modes to higher TG numbers. The plasticity of milk fat most notable in butter is caused by suspension of the mostly liquid unsaturated TG in a crystalline matrix of a small amount of long-chain fully saturated TG (German et al., 1997).

IV. VARIABILITY OF MILK FAT COMPOSITION

The greatest sources of variation in bovine milk fat composition are attributable to feeding management of the cow (especially the proportion of forage and the amount and type of fat in the ration), stage of lactation and breed. Numerous reviews on factors affecting the FA contents of milk

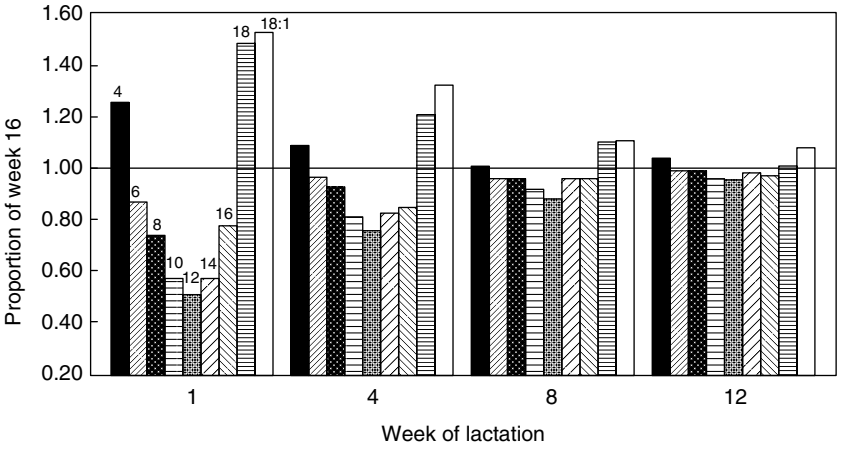

FIGURE 6.1 Concentrations of individual milk fatty acids at weeks 1, 4, 8, and 12 of lactation as proportions of their concentrations at week 16. (From Palmquist, D.L., et al. (1993). *J. Dairy Sci.* 76:1753–1771. With permission.)

are available; for example, see Grummer (1991), Palmquist et al. (1993), Mansbridge and Blake (1997), Bauman and Griinari (2001, 2003), and Chilliard and Ferlay (2004).

A. Animal Effects on Milk Fat Composition

Differences in milk fat composition occur among animals due to physiological effects (stage of lactation, disease) and to genetics (species, breed, individual animal). Breed differences among bovines tend to be less than the individual differences. In early lactation, relatively higher proportions of long-chain FAs with lower proportions of the short chain, de novo-synthesized FA are observed (Palmquist et al., 1993; Figure 6.1), caused primarily by mobilization of long-chain FA from adipose tissue and their subsequent deposition in milk fat. Differences among breeds in the activity of SCD are evidenced by differences in ratios of desaturase pairs (14:1/14:0; 16:1/16:0; *c*-9 18:1/18:0; *c*-9, *t*-11-18:2/*t*-11-18:1) and in relative abundance of rumenic acid (DePeters et al., 1995; Kelsey et al., 2003). Proportions of short-chain de novo-synthesized FA in milk fat are higher in breeds with higher milk fat percent, and the proportions of de novo-synthesized FA and long-chain unsaturated FA tend to be reciprocal (Karijord et al., 1982).

B. Seasonal (Feed) Influence on Fatty Acid Composition

Seasons as such do not influence milk fat composition; however, in traditional dairy systems the feeding program changes with changing seasons, and in some management systems, calving (the lactation cycle) is seasonal; both of these factors will influence the composition of the milk fat in the market. Jahreis et al. (1999) reviewed species, seasonal, dietary, and management f actors influencing CLA in milk, concluding that the strong seasonal effects are attributable to the relatively high content of unsaturated FA in fresh forages from cows grazing pasture. Lock and Garnsworthy (2003) measured changes in CLA concentration of milk during a full year in which cows were fed in a winter barn feeding/summer pasture regimen. During the winter months, a total mixed ration was fed, whereas through the summer fresh grass was fed with increasing levels of rumen buffer to maintain optimal ruminal pH as the summer progressed. The CLA content of milk in May, June, and July was higher than all other months, averaging 1.50 g CLA/100 g FAME compared with a mean of 0.77 g/100 g for other months. Milk fat produced during the summer contained greater amounts of short chain FA at the expense of medium chain FA, indicating that fresh grass may alter the pattern of FA synthesis

in the mammary gland. Fat composition of milk produced from "ecological" or "organic" systems have higher concentrations of n-3 FA (Ellis et al., 2006). Couvreur et al. (2006) reported a linear relationship between the proportion of fresh grass in the diet and unsaturated FA of milk fat; these changes were, in turn, responsible for linear decreases in final melting temperature and solid fat content of butter and the sensation of butter firmness in the mouth. See Dewhurst et al. (2006) for more discussion on the effects of forages on milk FA unsaturation. Only a relatively small proportion of the U.S. milk supply is from cows grazing pasture, so that seasonal effects on milk composition in the United States is minor, as shown in Table 6.4 (Palmquist et al., 1993). These samples were collected from 50 cheese plants in 10 areas in the United States and were analyzed by packed GLC columns. Though the contents of 18:1 and 18:2 were higher during May and August than in the period of November through February, differences were not attributed to any specific feeding systems.

C. Effects of Feeding Fat to the Cow on Milk Fat Composition

The ruminant diet typically provides less than 3% of feed dry matter as FA; however, these are highly unsaturated, being predominantly 18:3n-3 derived from forages and 18:2n-6 from cereals. Feeding management of dairy cows has changed as genetic progress has increased yield potential; it is now common to feed supplemental fat to increase energy intake by the animal. Supplemental fat increases the proportion of long-chain (mainly 18-carbon) FA in milk fat, thus decreasing the relative contribution of short-chain de novo-synthesized FA. Rumen microbial BH of dietary unsaturated fat causes very little dietary unsaturated fat to appear in milk. Only a brief summary of BH will be presented here; for more in-depth treatment, refer to Harfoot and Hazlewood (1997) and Palmquist et al. (2005).

Optimal feeding (adequate fiber intake from forages) of dairy cattle causes the rumen pH to remain near or above 6.0; in this environment unsaturated FA are BH predominantly to 18:0. Intermediate steps involve isomerization of the c9, c12 double bonds to c9, *t*11conjugated dienes or trienes, followed by hydrogenation of the c9 and c15 bonds to yield t11-18:1 (vaccenic acid), which is then hydrogenated to 18:0. More detailed discussion of the BH of 18:3 and the formation of its various isomers is presented by Destaillats et al. (2005), who have proposed the trivial names of *rumelenic acid* for c9, t11, c15-18:3 and *isorumelenic acid* for c9, t13, c15-18:3. High amounts of unsaturated FA in the diet inhibit the final BH step, causing the accumulation of vaccenic acid. The long-chain unsaturated FA of fish oil seem to be especially potent in this regard. When feeding conditions (decreased forage, highly fermentable carbohydrates) allow rumen pH to remain below 6.0 for extended periods of the day, the microbial population is altered, accompanied by the accumulation of numerous *trans* monoenoic isomers, especially t10-18:1. Some of these isomers have been implicated as causal in the inhibition of milk fat synthesis (Bauman and Griinari, 2003). The diversity of *cis* and *trans* monoenes and dienes formed during BH contribute to the large number of different FA identified in milk fat.

The conjugated diene, c9, t11-18:2 (trivial name, *rumenic acid*), formed transiently during the BH of linoleic acid, accounts for only a part of this isomer found in milk fat; 60%–90% of rumenic acid in milk fat arises from Δ-9 desaturation of vaccenic acid in the mammary gland by SCD (Griinari et al., 2000; Palmquist et al., 2005). This discovery has stimulated research to develop feeding systems that maximize ruminal synthesis of vaccenic acid as a means to increase concentration of rumenic acid in milk fat. Generally, supplementing free oils increases vaccenic acid and other unsaturated isomers in the rumen and milk FA, whereas feeding whole oil seeds is less effective. Slow release of FA from the matrix of whole oilseeds minimizes the accumulation of free unsaturated FA in ruminal content, allowing more complete BH of unsaturated FA to 18:0 (Morales et al., 2000).

A very detailed analysis of the isomers of milk fat as influenced by type and amount of forage in the diet and a sunflower/fish oil supplement is in Tables 6.5 through 6.7 (Shingfield et al., 2003, 2005). To achieve this analysis, the milk fat FAME were separated with a high-performance liquid chromatography system, using dual heated columns impregnated with $AgNO_3$. Separation of *cis*/*trans* isomers was improved by use of a manually operated switching valve that allowed fractions to be recycled between columns.

In the studies reported in Tables 6.5 through 6.7, the control diet dry matter (DM) was grass silage/concentrate (60:40), containing 377 g/day of FA, of which 60% was polyunsaturated FA. The control milk 18:0 content (Table 6.5), 19.54%, is unusually high, about double the usual concentration. This has been reported recently to be caused by the addition of transition metals as digesta flow markers to the diet. Inhibition of SCD activity by transition metals, especially Cu, has been documented; although identification of the specific inhibitor of SCD was not determined by Shingfield et al. (2006), Co was implicated. Addition of oil (30 g/kg of diet DM) as a mixture of fish oil and sunflower oil (2:3) reduced 18:0 content to only 5%–8% of the milk FA. The reduction was greater when corn silage was fed than when grass silage was fed, indicating differential effects of the forage on the ability of fish oil to inhibit ruminal BH. Note the low accumulation of the eicosanoic FA in milk fat when fish oil was fed. Transfer of these to milk fat varies and is invariably low, ranging from 1% for 22:6n-3 to 11% for 22:5n-3 (Palmquist and Griinari, 2006). The fish oil/sunflower oil mixture modified BH end products dramatically, as seen in the diversity of monoenoic (Table 6.6) and dienoic (Table 6.7) isomers measured in the milk fat. During recycling of the *trans* unsaturated region of the chromatograms by Shingfield et al. (2005), an unidentified isomer was found to elute immediately after the *c*9, *t*11-18:2 peak. Extensive purification of this isomer and comparison with chemically synthesized compounds confirmed the identity as t9, c11-18:2 (“reverse CLA”), previously unidentified in milk fat.

D. Fat Supplements

Because free oils or unsaturated FA in ruminant diets tend to decrease diet fiber digestion and milk fat percent (Palmquist and Jenkins, 1980; Bauman and Griinari, 2003), the dairy feed industry has developed alternate fat sources as energy supplements for high-milk producing cows. Although tallow and whole oilseeds are widely used as fat supplements, feeding saturated FA and calcium salts of FA has become standard practice. Whereas oilseeds contain high amounts of 18-carbon FA and increase the proportion of these in milk fat, most commercial fat supplements are based mainly on palm oil by-products, containing about 50% of 16:0. These increase the proportion of 16:0 in milk fat; thus, the FA profile of the commercial milk supply is influenced by the sources of fat used as energy supplements. The extent to which feeding supplemental oils or oilseeds modify contents of c9-18:1 and 18:2n-6 in milk FA was summarized by Jenkins and McGuire (2006).

E. Protected Lipids

Since 1970, there has been concerted effort by many research groups to develop fat supplements that are not susceptible to ruminal BH (i.e., they are "protected"). The first of these, drawing much research attention, was a process developed by CSIRO in Australia whereby vegetable oils were incorporated into a protein matrix, followed by treatment with formaldehyde and heat. Under ideal conditions, the fat was not subjected to BH; the low pH of the ruminant stomach and intestine then broke the formaldehyde linkages, releasing the fat for absorption. Depending on the extent of treatment, variable protection and availability of the FA occurred. Using this process, milk fat containing as much as 35% 18:2 was produced (McDonald and Scott, 1977). However, such milks, even at 10%–20% 18:2, are readily susceptible to the development of oxidized flavor (McDonald and Scott, 1977; Timmons et al., 2001). For this and other reasons, the process has not gained wide acceptance. Later applications by CSIRO (Ashes et al., 1992) have shown that significant decreases in 14:0 and 16:0 of milk fat can be achieved by feeding protected canola oil, with only modest increases in 18:2 content. A recent development (Carroll et al., 2006) has shown significant protection of unsaturated FA from BH by using a processed whey complex that avoids the negative aspects of using products with added formaldehyde. Because BH requires the presence of a free carboxyl group in the substrate, providing dietary unsaturated FA as amides is also effective to protect FA from BH; *c*9-18:1 content greater than 40% of total milk FA has been achieved by feeding amide derivatives of canola oil (Jenkins, 1999). Although Ca salts of FA dissociate in ruminal content with subsequent BH of the unsaturated FA, BH of 18:1 and 18:2 in the Ca salts of palm oil is less than complete, being usually about one-half the extent of BH observed with FA in oils and oilseeds. Increased unsaturation improves FA digestibility by the animal, but has minimal effects on milk FA composition (Wu et al., 1991).

F. Fatty Acid Composition of Other Dairy Products

FA composition of dairy products has long been available as USDA Agriculture Handbook 8-1, but modern summaries are no longer available in the USDA database. However, FA composition of dairy products reflects closely the composition of the parent milk fat. Although changes in feeding practice and newer analytical methods lead to changes in reported milk FA profiles, very few manufacturing practices cause the FA profiles of products to differ from those of the raw source. Because of this and widespread availability of product data in the literature, these are not duplicated in this chapter.

V. HEALTH CONCERNS

Some FA in milk, chiefly lauric (12:0), myristic (14:0), and palmitic (16:0), may be atherogenic (Jensen, 1992); therefore, the FA composition of milk is of interest. Newer research suggests that palmitic acid is not atherogenic if consumed with adequate linoleic acid intake (Clandinin, 2000); Mensink et al. (2003), in a meta analysis of 60 controlled studies, showed that lauric acid increases the HDL cholesterol/LDL cholesterol ratio, whereas myristic and palmitic acids had little effect on this ratio in plasma. Although widely regarded as a high-cholesterol food, whole milk contains only about 15 mg of cholesterol/dL and cannot be considered a major contributor to dietary cholesterol levels. However, the fat and cholesterol contents of dairy products increase roughly in parallel, so that butter, for example, with minimum 80% fat, contains about 200 mg of cholesterol per 100 g. Cardiovascular and other public health problems are discussed elsewhere in this volume and by Miller et al. (1995); Parodi (1999, 2006) has addressed the nutritional significance of milk lipids, focusing on anticarcinogenic properties. Readers are referred to Patton (2004) for a comprehensive overview of the qualities of milk as a food.

The major health concern has been that the 12:0, 14:0, and 16:0 and cholesterol in milk fat contribute to the risk of coronary heart disease (CHD) by increasing plasma cholesterol and low-density lipoprotein (LDL). These FA comprise 45%–50% of milk fat; thus, the often-stated "milk fat is 70% saturated fat" is inappropriate because the 4:0–10:0 and 18:0 are neutral with respect to

atherogenic properties. The *trans* FA content of milk (1.9%–6.3% of milk fat or 63–208 mg/dL of milk containing 3.3% fat) is low compared with some food fats, and is below 0.5 g/serving, the level required for declaration by food labeling laws. The role of *trans* FA in nutrition, metabolism, and health has been a subject of research for many years (Gurr, 1996). Research became more focused with publication of studies by Mensink and coworkers (Katan et al., 1995) that linked *trans* FA in the diet to increased lipoprotein Lp(a), LDL-cholesterol and decreased HDL cholesterol; higher Lp(a) and an increase in the ratio of LDL/HDL-cholesterol are believed to increase the risk of atherosclerosis and cardiovascular disease (CHD). Interesting effects of *trans* FA were reported by Willett et al. (1993), summarizing data from the Nurses' Health Study that included dietary and health questionnaires over an 8-year period from 1970 to 1980 for over 69,000 female registered nurses. They found that persons in the highest quintile of *trans* FA intake (mean *trans* FA intake as percentage of energy ranged from 1% to 3.5%) had a 67% greater risk of CHD than those in the lowest quintile of intake ($p < .002$). When *trans* isomers from only vegetable fats (60% of total *trans* FA intake) were considered, the highest quintile risk was 78% higher than the lowest ($p < .009$). However, when *trans* isomers from only animal fat (40% of *trans* FA intake, mainly vaccenic acid) were considered, there was no significant relationship ($p = .23$), and the mean risk actually tended to decrease as *trans* FA intake increased. Updated analysis of data from a 14-year period of the study (Hu et al., 1997) was consistent with the conclusion of no effect of *trans* FA from animal fats on relative risk of CHD. These studies show that all *trans* FA are not the same in their biological effects; it is presumed that the differences are attributable to vaccenic acid that constitutes >80% of the *trans* FA in ruminant fats (Lock et al., 2004).

A. Conjugated Linoleic Acid and Other FA with Biological Effects

Because conjugated linoleic acid (CLA) is a product of ruminal BH, ruminant foods are the most important source of this highly biologically active FA (Pariza, 1999). Rumenic acid, the predominant CLA isomer found in ruminant foods, is reported in Table 6.8 (Lin et al., 1995), and is presented in detail elsewhere by Parodi (2003). Concentration of CLA in milk fat from countries where grazing is a major component of dairy management (e.g., Ireland, New Zealand) is about double that where intensive feedlot dairy production is practiced (Parodi, 2003). Estimates of intake of CLA in the human diet range from 80–120 mg/day in the United States to 300–450 mg/day in Germany (McGuire et al., 1999). CLA is synthesized in the body by desaturation of vaccenic acid (Turpeinen et al., 2002), essentially doubling the dietary supply of CLA to the tissues (Parodi, 2006).

In addition to CLA, the branched chain FA of milk fat have been shown to have cell regulatory properties. Phytanic and pristanic acids, metabolites of chlorophyll metabolism, and 13-methyl

TABLE 6.8
Amounts of Rumenic Acid in Dairy Products[a]

Sample	c9, t11-18:2 mg/100 g Sample	mg/g Fat
Sharp cheddar cheese	161.20	4.59
Cottage cheese	19.60	4.80
Mozzarella cheese	91.40	4.31
American processed cheese	91.10	3.64
Homogenized milk	14.20	4.49
Yogurt	7.40	3.82

[a] Data from Lin, H., et al. (1995). *J. Dairy Sci*. 78:2358–2365.

tetradecanoic acid, a product of rumen microbial metabolism, or their CoA esters, strongly bind the nuclear receptor peroxisome proliferator-activated receptor α (PPARα), inducing β-oxidation of FA (Hostetler et al., 2006), which may result in decreased blood lipids (Bremer, 2001). Concentration of the branched chain FA of milk is less variable and less subject to manipulation than is CLA.

It is becoming an increasing practice to report "atherogenic index" (AI) values in studies on milk fat composition, to suggest that certain modified fats are more "healthy." This is an inaccurate and misleading exercise; inaccurate because milk fat provides only a part of the daily intake of fat and misleading because it reinforces a concept that milk fat is an "unhealthy" food. Only diets, not individual foods, are unhealthy; similarly, if AI has any merit as to measuring healthfulness, it applies only to diets, not individual foods.

VI. CONCLUSION

There continues to be too few publications that take care to report in detail the minor milk FA. As has been found with CLA isomers and the branched chain FA, many of these may have important biological activities. More analyses are needed to report the minor FA. We have published pleas to take more care in reporting the minor FA (Jensen, 1999), and continue to do so in this monograph. More than 400 FA have been characterized in milk fat; a few have been found to have powerful biological effects. How many others with biological activity remain to be discovered?

ACKNOWLEDGMENTS

This chapter is dedicated to the memory of R.G. 'Bob' Jensen, a pioneer in analysis and composition of milk fat. Dr Jensen died 9 July 2006.

7 Fatty Acids in Poultry and Egg Products

Austin H. Cantor, Eric A. Decker, and Victoria P. Collins

CONTENTS

I. FATTY ACID COMPOSITION OF POULTRY MEATS

This section deals with the differences in fatty acid composition of several species of poultry meats including chicken, turkey, duck, goose, and game birds. The fatty acid composition of variety meats, mechanically deboned meat, and separable fat and the effect of cooking methods and other processing techniques are also discussed.

A. Fatty Acid Composition of Chicken Muscle

The total lipid concentration of raw skinless chicken (broiler) light muscle is approximately 1.7% (Table 7.1). Light muscle lipids are composed of 36.6% saturated, 32.5% monounsaturated, and 30.8% polyunsaturated fatty acids. The primary saturated fatty acids are palmitic acid followed by stearic acid. The major monounsaturated fatty acids are oleic and palmitoleic acids; linoleic acid, arachidonic acid (AA), and docosahexaenoic acid (DHA) are the primary polyunsaturated acids (PUFAs). All other fatty acids account for less than 1% of the total fatty acid concentration.

In raw chicken (broiler) light muscle with skin, the concentrations of saturated and polyunsaturated fatty acids are 14% and 24%, respectively, less and the concentration of monounsaturated fatty acids is 39% more than in skinless light muscle (see Table 7.1). The predominant fatty acids in each of these classifications are the same as in light muscle without skin; however, light muscle with skin contains a higher proportion of palmitoleic, oleic, gondoic (20:1), and linoleic acids and a lower proportion of palmitic, stearic, arachidonic, and docosahexaenoic acids. This increase in monounsaturated fatty acids and the decrease in saturated and polyunsaturated fatty acids are due to the presence of triacylglycerols associated with the skin (see Table 7.13, separable chicken fat). Whereas the percentages of fatty acids are similar in light muscle with and without skin, the fat content is 6.7-fold as higher in muscle with skin (11.07 g/100 g of muscle). Therefore, the amounts of individual fatty acids in muscle with skin are higher than in muscle without skin for the same serving size.

The fatty acid composition of raw chicken (broiler) dark muscle without skin (4.3 g fat/100 g muscle) is 31.3% saturated, 38.3% monounsaturated, and 30.5% polyunsaturated fatty acids (see Table 7.1). The fatty acid profile is similar to that of light muscle, with the predominant fatty acids being palmitic, stearic, palmitoleic, oleic, linoleic, linolenic, arachidonic, and docosahexaenoic acids. Raw chicken dark muscle with skin contains 4.3-fold more total fat and 18% more monounsaturated, 23% less polyunsaturated, and equal proportions of saturated fatty acids compared with skinless dark muscle. Chicken dark muscle with skin has a fatty acid profile similar to that of skinless dark muscle except that it contains a higher proportion of oleic and gondoic acids and lower percentages of linoleic acid, AA, and DHA owing to an increase in the triacylglycerol content from the skin.

B. Fatty Acid Composition of Turkey Muscle

The lipid content of raw turkey (all classes) light muscle with and without skin is 7.36% and 1.56%, respectively (Table 7.2). Lipids from skinless turkey light muscle are composed of 42.0% saturated, 22.7% monounsaturated, and 35.3% polyunsaturated fatty acids. The fatty acid profile is similar to that of chicken light muscle, with the major fatty acids being palmitic, stearic, oleic, palmitoleic, linoleic, and arachidonic acids. Turkey light muscle with skin contains less saturated (30.6%) and polyunsaturated (26.5%) fatty acids and more monounsaturated (43.0%) fatty acids than skinless light muscle (Table 7.2). Turkey light muscle with skin contains lower proportions of stearic acid, AA, and DHA but higher proportions of palmitoleic and oleic acids.

Turkey dark raw muscle (all classes) with and without skin contains 8.8% and 4.38% fat, respectively (see Table 7.2). Dark muscle without skin is composed of 39.0% saturated, 26.3% monounsaturated, and 34.7% polyunsaturated fatty acids. The predominant fatty acids within this classification are the same as in skinless light muscle except that they are found in higher concentrations, because dark muscle contains 2.8 times more lipid. As in turkey light muscle, turkey dark muscle with skin contains a lower proportion of saturated (32.8%) and polyunsaturated (29.0%) fatty acids but a higher percentage of monounsaturated fatty acids (38.2%) than skinless muscle, which is primarily due to an increase in palmitic and oleic acids (see Table 7.2).

C. Fatty Acid Composition of Duck, Goose, and Other Game Birds

Duck and goose muscle are predominantly dark muscle throughout the carcass. Duck muscle contains 5.95% lipid without skin and 39.34% with skin (Table 7.3). Muscle alone contains 50.3%

Total polyunsaturated	0.75 (16.3)	5.08 (13.7)	1.43 (15.4)	3.65 (12.8)
Total fat (g/100 g edible portion)	5.95	39.34	11.20	28.35

[a]Fatty acid concentrations expressed as g/100 g edible portion. Numbers in parentheses are the percentage of total fatty acid content.

Source: Adapted from USDA Nutrient Database for Standard Reference, Release 19 (Nutrient Data Laboratory Home Page, http://www.ars.usda.gov/nutrientdata).

saturated, 33.4% monounsaturated, and 16.3% polyunsaturated fatty acids, whereas duck with skin contains 35.7% saturates, 50.5% monounsaturates, and 13.7% polyunsaturates. As with chicken and turkey, the addition of the skin increases the proportion of monounsaturated fatty acids in the lipid from duck. The major fatty acids in duck fat are similar to those in chicken and turkey except for the absence of long-chain PUFAs and a higher proportion of linolenic acid.

Goose contains 7.13% fat in the muscle and 33.6% fat in muscle with skin (Table 7.4). Skinless goose muscle lipids are composed of 50.3% saturated, 33.4% monounsaturated, and 16.3% polyunsaturated fatty acids, whereas goose muscle with skin contains less saturated (31.2%) and polyunsaturated (12.0%) fatty acids and more monounsaturated fatty acids (52.7%). The fatty acid profiles of goose and duck muscle are very similar.

The fatty acid content of pheasant muscle (3.64% fat) is 40.9% saturated, 38.6% monounsaturated, and 20.5% polyunsaturated fatty acids; pleasant muscle with skin (9.29% fat) is 32.9%, 52.7%, and 14.4% saturated, monounsaturated, and polyunsaturated fatty acids, respectively (Table 7.5). The fatty acid profile of pheasant muscle is similar to those of duck and goose muscle; however, pheasant muscle generally contains less saturated and more monounsaturated fatty acids.

Quail meat without skin contains 3.7% fat, and the fatty acids are 35.0% saturated, 34.0% monounsaturated, and 31.0% polyunsaturated (see Table 7.5). Quail with skin contains 2.8-fold more total fat, 8% less saturated, 17% more monounsaturated, and 9% less polyunsaturated fatty acids than skinless quail muscle. The fatty acid profile of quail muscle is very similar to that of chicken light muscle except for the absence of DHA and the presence of a higher proportion of linoleic acid.

D. Fatty Acid Composition of Cooked Poultry Muscle

The total fat composition of cooked muscle foods is affected by the cooking method. In general, cooking will cause a loss of water from skinless poultry meat, resulting in an increase in total lipid concentration when 100 g of cooked muscle is compared with 100 g of raw muscle. Dry cooking methods such as roasting will cause more moisture loss from skinless muscle and result in a greater increase in total fat content (compared with raw muscle) than moist cooking methods such as stewing. Cooking meat with skin decreases the amount of water lost and causes subcutaneous fat associated with the skin to be removed from the meat. Therefore, cooking meat with skin causes an overall decrease in the lipid concentration when expressed on a 100-g portion. Roasting meat with the skin on results in smaller fat losses than stewing. The greater loss of fat in stewed meat could be due to longer cooking times and/or the direct contact of the cooking medium with the meat, which could facilitate the removal of adipose fat.

Total fat content of skinless light muscle (broiler) increases from 1.65 to 4.51 g/100 g when the meat is roasted (Table 7.6) and 3.99 g/100 g when it is stewed (Table 7.7). The fatty acid compositions of roasted and stewed light muscle without skin are similar; however, when compared with raw muscle, the saturated and polyunsaturated fatty acid concentrations decrease and the monounsaturated fatty acid concentration increases. The increase in monounsaturated fatty acids is mainly due to increases in palmitoleic and oleic acids. Decreases in PUFAs are due to the loss of 20- and 22-carbon PUFAs, which could reflect a change in membrane lipids during cooking.

The total fat content of chicken (broiler) light muscle with skin will decrease from 11.07 g/100 g meat to 10.85 g/100 g meat when the meat is roasted (see Table 7.6) and 9.97 g/100 g meat when

it is stewed (see Table 7.7). The fatty acid profiles of roasted and stewed light muscle with skin are essentially identical, and the fatty acid composition changes only slightly compared with raw muscle because of a slight decrease in monounsaturated fatty acids and an increase in PUFAs. This change is most likely due to a loss of triacylglycerols from the subcutaneous fat.

Dark chicken muscle without skin contains 4.3%, 9.7%, and 9.0% fat in raw (see Table 7.1), roasted (see Table 7.6), and stewed meat (see Table 7.7), respectively. The fatty acid profiles are similar for roasted and stewed skinless dark muscle but lower in monounsaturated fatty acids and higher in PUFAs than for raw skinless dark muscle. Changes in total fat content in cooked chicken (broiler) dark muscle with skin decrease in a trend similar to that of light muscle. Dark muscle with skin contains 18.3% (see Table 7.1), 15.8% (see Table 7.6), and 14.7% (see Table 7.7) fat when raw, roasted, and stewed, respectively. Roasted and stewed dark muscle with skin have similar fatty acid compositions; however, they differ from that of raw muscle in that they contain slightly less monounsaturated fatty acids and more PUFAs.

Turkey increases in fat content when roasted with or without skin (Table 7.8). This increase in fat content is greater in turkey without skin (2.1-fold for light and 1.6-fold for dark muscle) than with skin (1.1-fold for light and 1.3-fold for dark muscle). The increase in fat content in roasted turkey is primarily due to the loss of water. Roasting turkey has little effect on the fatty acid profile of skinless meat; however, in both light and dark roasted turkey muscle with skin, the percentages of saturated and polyunsaturated fatty acids increase, whereas monounsaturated fatty acids decrease owing to loss of triacylglycerol. These changes are due to increases in stearic and linoleic acids and decreases in palmitoleic and oleic acids.

Duck (see Table 7.3) and goose (see Table 7.4) lose fat when roasted with skin (35% and 52% decrease for goose and duck, respectively), but the fat content increases when roasted without skin

(78% and 88% increase for goose and duck, respectively). Loss of fat in roasted waterfowl with skin is due to the loss of subcutaneous fat associated with the skin. Increases in fat content for birds roasted without skin is due to loss of water from the muscle. Fatty acid compositional changes in roasted goose and duck with skin are due to increases in saturated and polyunsaturated fatty acids and decreases in monounsaturated fatty acids, with the proportions of palmitic (goose only), stearic, and linoleic acids increasing and that of oleic acid decreasing. Roasting goose and duck without skin has the opposite effect, causing an overall decrease in saturated and polyunsaturated fatty acids and an increase in monounsaturated fatty acids. The effects of roasting without skin on fatty acid content include decreases in palmitic, stearic, palmitoleic, and linoleic acids, and increases in oleic acid.

E. Poultry Variety Meats

The fat content of raw liver is similar for chicken (3.86%), turkey (4.64%), duck (4.64%), and goose (4.28%). The content of specific fatty acids in raw liver is quite variable among species; however, liver generally contains more saturated and less polyunsaturated fatty acids than muscle (Tables 7.9 and 7.10). The major fatty acids in raw liver from poultry species are palmitic, stearic, oleic, and linoleic acids. Cooking (simmering) chicken and turkey livers has little effect on their fatty acid composition but does increase the total fat content (Table 7.9).

Raw chicken and turkey heart muscle contain 9.33% and 6.99% fat, respectively (Table 7.11). The major fatty acids in heart muscle are similar for turkey and chicken, with palmitic, stearic, oleic, linoleic, and arachidonic acids predominating. Simmering the heart decreases the fat content by 15% for chicken and 13% for turkey but has little effect on the fatty acid profile (Table 7.11). Raw and

cooked chicken gizzards contain 2.06% and 2.68% fat, respectively, while the respective values for raw and cooked turkey gizzards are 4.58% and 3.87% (Table 7.12). Cooking has little effect on the fatty acid composition of gizzards, and the predominating fatty acids are the same as for heart muscle.

F. Separable Fat and Mechanically Deboned Muscle

Poultry fat and mechanically deboned muscle are commonly used in processed poultry products. Chicken fat contains primarily triacylglycerols and therefore would have less PUFAs than muscle, which contains more membrane lipids. Overall, the predominant fatty acids in separable fat are similar to those in chicken muscle, with palmitic, oleic, and linoleic acids predominating; however, separable fat has an absence or lower proportion of 20-carbon PUFAs (Table 7.13) compared with muscle lipids. The amount of monounsaturated fatty acids is higher in separable fat than in muscle fat (46.8% vs. 32.5% for light and 38.2% for dark muscle without skin). This increase is due to increases in palmitoleic and oleic acids.

Mechanical deboning processes are used to increase the utilization of poultry meat by removing meat from necks, backs, or whole carcasses. This process involves crushing the bones and separating the meat from the bones by extruding it through a sieve. Mechanically deboned meat has a high amount of triacylglycerols, some of which are derived from adipose fat and bone marrow (Dawson and Gartner, 1983). Therefore, the total fat content (15.48%–24.73% for chicken backs and necks with and without skin; Table 7.14) is higher than in raw muscle (4.31% and 18.34% for dark muscle with and without skin; see Table 7.1). The fatty acid composition of mechanically deboned turkey frames (Table 7.14) is similar to that of turkey light and dark muscle, but, as in mechanically

deboned chicken muscle, the proportion of monounsaturated fatty acids (especially oleic acid) is higher than in hand-deboned chicken muscle. The increase in oleic acid is most likely due to the increase in triacylglycerol concentration.

G. Processed Poultry Products

In recent years, an increasing number of processed poultry products have become available to consumers. The purpose of this section is not to cover all processed poultry products but to give examples of products that represent the processing techniques used on a variety of poultry meats.

Canned poultry meats are cooked at high temperature in broth. Therefore, both total fat concentration and fatty acid composition (see Table 7.1) are similar to those of stewed meats. Canned chicken is slightly higher in monounsaturated fatty acids than stewed chicken owing to the retention of triacylglycerols in the broth of these products. Poultry meat is also marketed as boneless rolls that are produced by restructuring processes that use a combination of sodium chloride and phosphate salts to bind together whole or coarsely cutup meat pieces (Addis, 1986). These products are often marketed as ready-to-cook roasts and luncheon meats. The total fat concentration of chicken and turkey rolls made from light meat is higher than in cooked muscle without skin but lower than in cooked muscle with skin (Table 7.15). This is because skin or separable fat is included in these products and/or less fat is lost during the cooking process. The fatty acid compositions of chicken and turkey rolls are similar to those of cooked chicken and turkey light muscle with skin.

Numerous cured poultry products are available to consumers, including frankfurters and luncheon meats. The fat and fatty acid contents of these products are dependent on the type of meat used in the formulation. Chicken frankfurters contain 19.48% fat and have a fatty acid profile that contains more monounsaturated and less saturated and polyunsaturated fatty acids than either chicken light or dark muscle (Table 7.16). The increase in the proportion of monounsaturated fatty

acids in frankfurters is due to the presence of mechanically deboned chicken and/or separable fat, which are high in monounsaturated fatty acids (Addis, 1986). Turkey ham is another example of a cured poultry product available to consumers. Turkey ham is made primarily from dark muscle (Addis, 1986), and, as one would expect, its fatty acid composition (see Table 7.16) is similar to that of cooked turkey dark muscle without skin.

H. Influence of the Fatty Acid Composition of Feeds on the Fatty Acid Composition of Chicken

Like that of most monogastrics, the fatty acid composition of chicken is influenced by the type of fat in the diet (Miller et al., 1967; Edwards et al., 1973; Phetteplace and Watkins, 1989, 1990). Changes in fatty acid composition due to diet are seen in all tissues, including muscle, liver, heart, and adipose fat (Phetteplace and Watkins, 1990). Edwards and coworkers (1973) reported that the adipose lipids of 8- to 9-week-old broilers had different fatty acid compositions depending on the source of fat in the diet (Table 7.17). The adipose fat of broilers fed a basal diet with no added fat contained 30.7% saturated, 34.7% monounsaturated, and 34.5% polyunsaturated fatty acids. Adipose fat from chickens fed the basal diet plus cottonseed oil contained 29% less monounsaturated, 29% more polyunsaturated, and about the same proportion of saturated fatty acids as chickens fed the basal diet. The fatty acid changes were due to a decrease in the amount of palmitoleic and oleic acids and an increase in linoleic acid. Feeding beef tallow in addition to the basal diet both increased monounsaturated and decreased polyunsaturated fatty acids 25% while having little influence on saturated fatty acid content compared with the basal diet. The change in the fatty acid profile of adipose fat

from chickens fed beef tallow was due to increases in oleic acid and decreases in linoleic acid. These changes in the chicken fat directly reflected the fatty acid composition of the beef tallow used in the feeding studies.

Although n-3 fatty acid levels in poultry meat can be increased by inclusion of fish oil or fish meal in the diet, there is relatively little use of fish products in poultry diets in the United States due to the cost. In contrast, in other geographic areas (e.g., South America), there is considerable use of fish meal. Valenzuela (1999) indicated that pork, poultry meat, and eggs were important sources of n-3 fatty acids for people in Chile due to the use of fish products in animal diets.

Phetteplace and Watkins (1990) fed chickens fish (menhaden) oil to increase the proportion of n-3 fatty acids in chicken. Abdominal fat from chickens fed menhaden oil contained 14% more saturated, 47% more polyunsaturated, and 32% less monounsaturated fatty acids than chickens fed chicken fat (Table 7.18). The increase in n-3 fatty acids in chicken fed menhaden oil was more than eightfold that of chickens fed chicken fat. The increase in the n-3 fatty acid content was primarily due to increases in eicosapentaenoic, docosapentaenoic, and docosahexaenoic acids.

In recent years, there has been increasing concern regarding consumption of *trans* fatty acids in the human diet. Intake of *trans* fatty acids has been associated with negative effects on lipid profiles (increased low-density lipoprotein cholesterol and decreased high-density lipoprotein cholesterol). However, there is evidence that suggests the intake of certain *trans* fatty acids (*trans* 18:1) may have beneficial health effects (Lemaitre et al., 2006). One major source of *trans* fatty acids is hydrogenated vegetable oil (shortening), which is extensively used in baking and other food manufacturing. Another source is animal products derived from ruminants, as a consequence of biohydrogenation in the rumen by microorganisms. As discussed previously, the fatty acid profile in poultry meat can be altered by the type of fat used in the animals' diet. Very little *trans* fatty acids would be expected

to contained in the major grain and protein sources in the United States (corn and soybean meal, respectively). However, some *trans* fatty acids could enter the bird's diet by the inclusion of ingredients such as animal fats (derived from ruminants), restaurant grease, or bakery by-product. A major decline in the content of *trans* fatty acids in the latter two ingredients would be expected as a result of the recent efforts of the baking and restaurant industries to minimize *trans* fatty acid levels in their products. Thus, a consequent reduction in levels of *trans* fatty acids in poultry meat products would also be expected.

Conjugated linoleic acids (CLA) is another group of fatty acids receiving considerable attention due to potential health benefits. A number of studies (e.g., Crespo and Esteve-Garcia, 2001; Badinga et al., 2003; Sirri et al., 2003) have shown that content of CLA in broiler meat and fat can be increased by including CLA in the chickens' diet. Most of these studies have also shown that dietary CLA changes fatty acid levels in tissues by increasing saturated fatty acids and decreasing monounsaturated fatty acids, while usually not altering PUFAs.

I. Summary

The skin of poultry meat is associated with triacylglycerols, which have a higher proportion of monounsaturated fatty acid than muscle lipids. Therefore, poultry meats with skin not only contain more total fat but also have a greater proportion of monounsaturated fatty acids (primarily oleic acid) and lower proportions of saturated and polyunsaturated fatty acids than muscle alone. Poultry light muscle without skin contains more saturated and less monounsaturated fatty acids but about the same amount of PUFAs as dark muscle.

Chicken light and dark muscle generally contain less saturated and polyunsaturated fatty acids but more monounsaturated fatty acids than turkey light and dark muscle. Skinless duck and goose muscle contain the highest proportion of saturated fatty acids and lowest proportion of PUFAs of all the poultry species. Duck and goose also contain the greatest amount of total fat in muscle with and without skin. Pheasant meat contains the same fatty acids as duck and goose; however, it contains a smaller proportion of saturated fatty acids, a greater proportion of monounsaturated fatty acids, and less total fat. The total fat and fatty acid content of quail are similar to that of chicken and turkey muscle.

The total fat content and the fatty acid profile of poultry variety meats are similar among species; however, they differ from organ to organ. Heart muscle contains the greatest amount of fat of all the organ meats. Hearts and gizzards contain a higher proportion of PUFAs (primarily AA) than liver or muscle. Liver contains the greatest amount of saturated fatty acids of all the organ meats.

Separable chicken fat and mechanically deboned poultry contain a high proportion of monounsaturated fatty acids compared with muscle lipids owing to the presence of high concentrations of triacylglycerols. Therefore, any processed poultry products that contain mechanically deboned meat or separable fat, such as frankfurters, would contain a higher proportion of monounsaturated fats than muscle. Processed poultry products that do not contain mechanically deboned muscle or separable fat can be expected to have a fatty acid composition similar to that of the muscle from which they are produced.

Poultry represents a muscle food in which diet can be used to increase the concentration of bioactive fatty acids in the final product. Increasing n-3 fatty acids in poultry products by dietary supplementation of marine lipids is possible; however, such practices will change the physical and chemical properties of the skeletal muscle. Muscle containing high concentrations of PUFAs will

have lipids with lower melting points leading to muscle with soft and even liquid fat. Reduction of fat hardness will cause problems during the processing of poultry products due to fat smearing and can lead to consumer rejection if fat softness is severe. In addition, high concentrations of unsaturated fatty acids will decrease the oxidative stability of poultry products leading to consumer rejection due to the development of rancidity and associated fishy odors. Reduction of oxidative stability in poultry products containing high concentrations of unsaturated fatty acids can be partially overcome by dietary supplementation of α-tocopherol and by vacuum or modified-atmosphere packaging technologies.

II. FATTY ACID COMPOSITION OF EGGS AND EGG PRODUCTS

The fatty acid composition of eggs and various cooked and uncooked egg products varies greatly owing to a number of factors. This section will discuss the variations in the fatty acid composition of raw and cooked chicken eggs, egg yolks, dried egg products, and egg substitutes. Factors affecting the fatty acid composition of eggs will also be discussed. Unless otherwise noted, mention of eggs and egg products will refer to chicken eggs. The composition of eggs and egg products has been reviewed by several authors (Cotterill et al., 1977; Naber, 1979; Cook and Briggs, 1986; Burley and Vadehra, 1989; Stadelman and Pratt, 1989).

A. Fatty Acid Composition of Chicken Eggs

The fatty acid composition of the edible portion of whole eggs, egg yolks, cooked eggs, egg products, and egg substitutes is shown in Tables 7.19–7.25. Two chicken eggs constitute a typical serving, with

each egg providing roughly 50 g of edible material. Thus, the values in tables showing the fatty acid concentration in g/100g edible portion can be used to approximate the fatty acid content of a serving of two chicken eggs. The values can be halved to obtain the amounts of fatty acids from a serving of one egg.

The fatty acid composition of chicken eggs is shown in Table 7.19. These values apply to raw eggs, fresh or frozen, as well as to whole eggs hard cooked in the shell. A 100 g edible portion of whole egg contains 3.35 g saturated fatty acids, 4.46 g monounsaturated fatty acids, and 1.45 g PUFAs. The predominant saturated fatty acid is palmitic acid (16:0), whereas oleic acid (18:1) and linoleic acid (18:2) are the major monounsaturated and polyunsaturated fatty acids, respectively. Almost one-half of the total fatty acids are monounsaturated, whereas a little more than one-third are saturated.

The reported values for the fatty acid content of whole eggs taken from several reports in the literature are shown in Table 7.20. In general, there is fair agreement on the amounts of saturated and unsaturated fatty acids in whole eggs. However, there is some variation among the various reports. The values of Cotterill et al. (1977) are higher than others shown in Table 7.20. The values reported

by the U.S. Department of Agriculture (1988) are approximately the same as those reported earlier by that organization (USDA, 1979).

The fatty acid composition of fresh chicken egg yolk and several other yolk products is shown in Table 7.21. The values for fresh yolk are for the yolk with a small amount of adhering albumen. The albumen is essentially fat free. Therefore, the effect of its inclusion is to dilute slightly the fatty acid concentration in the yolk. The frozen raw yolk listed in Table 7.21 is a product with approximately 17% albumin. Thus, the fatty acid content is appreciably diluted compared with fresh yolk. In the case of dried yolk, the moisture content is reduced and, therefore, the levels of fatty acids are considerably higher than the other yolk products. The relative amounts of fatty acids (% of total fatty acids) in all of the products shown in Table 7.21 are similar. The proportions of the various fatty acids for the fresh yolk reported in Table 7.21 are similar to the ratios for the whole egg. The levels of fatty acids for the yolk are higher than those of the whole egg, as all of the lipid in the yolk fraction. The values in Table 7.21 are expressed as g/100 g of edible portion. The yolk of an average large egg (60 g) weighs approximately 17 g. Thus, the amount of various fatty acids provided per yolk can be readily calculated. However, it should be noted that the percentage of yolk is not constant for eggs of various weight classes (Washburn, 1979). Smaller eggs tend to have a larger ratio of yolk to albumin, and they would therefore have relatively higher fatty acid levels.

B. Fatty Acid Composition of Cooked Eggs

Values for the fatty acid composition of whole eggs cooked in several ways are shown in Table 7.22. The amounts of fatty acids in whole eggs hard cooked in the shell are essentially the same as those for the whole fresh egg. In addition, similar values are noted for poached eggs. On the other hand, the values for fried and scrambled eggs and for omelets are different from those of fresh eggs owing to the use of butter and milk in the preparation. Fried eggs prepared with butter contain approximately 1.9 g more saturated fatty acids and 0.8 g more monounsaturated fatty acids per 100 g than raw, hard-cooked, and poached eggs. In addition to higher concentrations of myristic, palmitic, stearic, and oleic acids, fried eggs also contain small amounts of the shorter chain saturated fatty acids. These values would be higher in PUFAs and lower in saturated fatty acids if margarine and vegetable oil are used in place of butter. Omelets and scrambled eggs prepared with milk and butter have 1.19 more saturated fatty acids and 0.4 g less monounsaturated fatty acids per 100 g than raw eggs. However, owing to the dilution of the egg in omelets and scrambled eggs with milk, the total fat concentration is approximately the same as that of raw, poached, and hard-cooked eggs. Nevertheless, it should be recognized that a serving of scrambled eggs made from two eggs would contain more fat than two hard-cooked eggs.

C. Fatty Acid Composition of Dried Whole Eggs

The fatty acid composition of dried whole eggs is shown in Table 7.23. The proportions of the fatty acids, expressed as percentages of the total fatty acids, are the same as those of raw fresh whole eggs. However, the fatty acid concentrations are almost fourfold that of the fresh whole egg owing to the removal of water from the product. The amount of total fat per 100 g of dried eggs is approximately 42–44 g, whereas the respective value for fresh whole egg is 11 g. The concentration of total fat in dried eggs is also higher than that of fresh yolk (33 g/100 g) and lower than that of dried yolk (61 g/100 g) (see Table 7.21). The concentrations of fatty acids in stabilized, dried whole egg are slightly higher than those of dried whole egg due to differences in the moisture content of the products.

D. Fatty Acid Composition of Raw Whole Eggs of Several Avian Species

Most eggs used for human consumption are obtained from chickens. However, eggs from a number of other avian species are also consumed. The fatty acid composition of eggs from ducks, geese,

quail, and turkeys is shown in Table 7.24. Total fat concentrations are higher in duck eggs and goose eggs than in quail eggs and turkey eggs. The fat concentration of the latter two types of eggs is similar to that of chicken eggs (see Table 7.19). Compared with goose eggs, duck eggs have a similar percentage of total saturated fatty acids, a higher percentage of total monounsaturated fatty acids (mainly due to a higher level of oleic acid), and a lower percentage of PUFAs. Quail and turkey eggs have a higher percentage of saturated fatty acids and a lower percentage of monounsaturated fatty acids compared with duck and goose eggs. These percentages of the three classes of fatty acids in quail and turkey eggs are similar to those of chicken eggs.

Another avian species that is used for egg production is the guinea fowl. Oguntona and Hughes (1988) observed that guinea fowl eggs contain approximately 12% total fat; that is, about 1% more fat than chicken eggs. These authors found that the guinea fowl eggs contain 49% saturated, 30% monounsaturated, and 21% polyunsaturated fatty acids (expressed as a percentage of the total fatty acid content). The respective values for chicken eggs are 36%, 48%, and 16% (see Table 7.19). Thus, the guinea fowl eggs are higher in saturated fatty acids, lower in monounsaturated fatty acids, and higher in PUFAs.

The composition of eggs from a number of wild birds were compared with that of several domesticated species by Bitman and Wood (1980). These authors observed that egg yolks of several aquatic carnivorous birds have much lower total fat levels than those of chickens. In addition, the aquatic birds had appreciable levels of 20:5, 22:5, and 22:6 fatty acids.

E. Fatty Acid Composition of Egg Substitutes

The fatty acid composition of several egg substitutes is shown in Table 7.25. Two of these products, the liquid and the frozen products, are made with vegetable oils and without egg yolk. The percentage of total saturated and monounsaturated fatty acids is low and the value for PUFAs is high compared with respective values for chicken eggs. Although the frozen product shown in Table 7.25 has a total fat value similar to that of fresh whole eggs, the total fat content of the liquid product is quite low. The powdered product illustrated in Table 7.25 contains whole egg solids. It contains a blend of

saturated, monounsaturated, and polyunsaturated fatty acids similar to that of fresh whole eggs and has a higher total fat concentration.

F. Factors Affecting the Fatty Acid Composition of Eggs

There are a number factors that can influence the fatty acid composition of eggs. The differences among various species of birds were discussed earlier. There are indications that variations can exist within a species. Washburn (1979) reviewed a number of studies that showed a difference in the relative proportions of yolk and albumen among various genetic strains of chickens. Increasing the proportion of yolk increases the total amount of fatty acids per egg. Washburn (1979) suggested that the variation in the proportion of yolk may be a secondary effect of changes in egg size. Studies in our laboratory (A.H.C., unpublished data) and elsewhere have indicated that although the yolk weight increases with the total egg weight, it is not proportional to the total egg weight. Smaller eggs tend to have a larger percentage of yolk. Consequently, the concentration of fatty acids would tend to be higher in smaller eggs. Another factor reviewed by Washburn (1979) is the genetic variation in the percentage egg solids. Variations in egg dry matter would alter the concentration of fatty acids without affecting the relative proportions of different fatty acids. The nature of the hen's diet is another important factor affecting the fatty acid composition of egg yolks. This topic is discussed in the next section.

Another possible source of differences in values reported for fatty acid composition of eggs and egg products is the analytical procedure that is employed. Fletcher et al. (1984) compared several methods for determining total yolk lipid content. They observed values ranging from 30.3% to 35.2% using three extraction procedures. This suggests that incomplete extractions can affect fatty acid determinations and calculated values derived from these assays.

G. Influence of the Hen's Diet on Fatty Acid Composition of Egg Yolks

The composition of the diet fed to hens has been shown to alter the fatty acid composition of eggs. Although most studies have dealt with the influence of altering the fatty acid composition of the diet, there are other dietary factors that may affect the composition of yolk lipids. For example, Shadad et al. (1985) studied the effect of administering oxytetracycline to hens upon egg lipid composition. These authors observed a decrease in the concentration of palmitic acid (as a percentage of total fatty acids in egg yolk) and increases in the concentrations of stearic, oleic, and linoleic acids.

As early as 1934, Cruikshank demonstrated that the fatty acid composition of eggs could be altered by the hen's diet. Linoleic and linolenic acid levels in the yolk were markedly increased, whereas oleic acid decreased upon feeding high levels of unsaturated fat. Many studies have confirmed this observation over the decades. The earlier studies focused on the use of oilseeds and animal fat sources (Cruikshank, 1941; Sell et al., 1968; Naber, 1979). Sim and Bragg (1978) observed that the substitution of 8% safflower oil for 8% hydrogenated coconut oil in the diet increased the concentrations of palmitic and linoleic acids and decreased the concentrations of palmitoleic and oleic acids without affecting the total lipid concentration of the yolk. Sell et al. (1987) observed increased yolk weights with no change in albumin weight following the addition of animal–vegetable fat to the diet of laying hens.

In recent years, especially following recommendations for the increased intake of n-3 fatty acids in human diets (Health and Welfare Canada, 1989), there has been considerable interest in providing consumers with eggs containing elevated levels of n-3 fatty acids. Most studies have shown that the egg composition could be altered within 2 weeks of dietary changes. Because much of the development of the egg yolk occurs within the 10 days before ovulation (Austic and Nesheim, 1990), a change in yolk fatty acid composition within a few weeks would be expected.

In some studies (Cruikshank, 1941; Navarro et al., 1972), fish oils were fed to laying hens, and the long-chain n-3 fatty acids in these oils appeared in eggs. In a typical study, 5% menhaden oil increased the egg DHA content from 2.9% to 11.8% of total yolk fatty acids (Couch and Saloma, 1973). Huang et al. (1990) found long-chain n-3 fatty acids increased from 0.78% to 4.42% of total fatty acids when 4% menhaden oil was fed. Adams et al. (1989) increased long-chain n-3 from 56 to 622 mg/100 g yolk by substituting menhaden oil for corn oil at 3% of the diet. Upon feeding 3% menhaden oil, Hargis et al. (1991) observed that the long-chain n-3 fatty acid concentration increased from 35 to 210 mg/100 g yolk, whereas the concentration of n-6 fatty acids, especially AA, decreased from about 100 to approximately 30 mg/100 g yolk. High levels of long-chain n-3 fatty acids might have suppressed the hepatic production of AA from dietary linolenic acid. Maurice (1994) added 4% menhaden oil to layer feed and increased eicosapentaenoic acid plus DHA from 1.67 to 18 mg/g. Most studies showed roughly a fivefold increase in the long-chain n-3 percentage when fish oils were fed, but Adams et al. (1989) and Maurice (1994) found approximately 11-fold increases.

Several researchers have addressed the possibility that feeding fish oils might produce fishy off-flavors in the eggs or tissue, and several observers reported significantly poorer organoleptic evaluations when fish oils were fed at levels as low as 1.5% of diet (Miller et al., 1967; Koehler and Bearse, 1975; Van Elswyk et al., 1992). Others have reported minimal flavor problems. Holdas and May (1966) found no effect on organoleptic scores when good-quality fish oil was fed at 2.5% of the diet. Huang et al. (1990) found an acceptable egg flavor when 3% fish oil, stabilized with ethoxyquin, was fed. Maurice (1994) reported that panelists were unable to detect off-flavors in eggs from hens fed deodorized menhaden oil at 8% of the diet. Minimizing oxidation of dietary fats by proper storage and antioxidant addition seems to be beneficial in preventing flavor problems and maximizing incorporation of long-chain n-3 into eggs (Huang et al., 1990; Hargis et al., 1991).

Herber and Van Elswyk (1996) reported a novel source of long-chain n-3 PUFAs: a marine alga that has approximately the same percentage (11%) of long-chain n-3 PUFAs as menhaden oil.

When fed at 2.4% of the diet, marine alga did not affect egg production or weight when compared with corn, although feeding 4.8% of marine alga depressed both egg production and weight. Feeding 2.4% alga and 1.5% menhaden oil gave very similar egg fatty acid compositions. In studies reported by Abril et al. (1999), use of a commercial marine algae product at 4.8% of the diet (providing 825 mg DHA per day) did not depress egg production, but decreased egg weight slightly. In addition to the high content of n-3 fatty acids, the algal products are also rich in β-carotene and canthaxanthin, which can enhance the pigmentation of the egg yolk.

Flax seed is another feed ingredient that has been reported to increase n-3 fatty acid levels in eggs. Freshly ground whole flax seed, rather than flax (linseed) oil, is used to minimize oxidation problems. Linolenic acid represents approximately 55% of total fatty acids in flax seed. Naber (1979) reviewed several studies showing large increases in the linolenic acid concentration in eggs due to high dietary levels of linseed oil and large increases in linoleic acid concentrations due to feeding vegetable oils. Aymond et al. (1994) increased egg linolenic acid from 0.95 to 16.08 mg/g yolk and long-chain n-3 PUFAs from 4 to 8.3 mg/g by feeding 15% flax seed. Using six different strains of laying hens, Ahn et al. (1995) found egg linolenic acid increased from about 0.5% to about 5% and long-chain n-3 PUFAs increased from about 1% to 3% of total fatty acids when a proprietary blend of "high linolenic acid ingredients" was fed at 17% of the diet. Cherian and Sim (1991) and Ajuyah et al. (1992) reported similar results—a ninefold increase in egg or tissue linolenic acid and only a twofold increase in long-chain n-3 PUFAs—when they fed 16% flax seed. Caston and Leeson (1990) reported that feeding graded levels of ground flax seed (up to 30% of the diet) increased the linolenic acid content from 0.4% to 11.5% of yolk fatty acids. The content of DHA was elevated from 0.04% to 0.22% by feeding 20% flax seed in the diet. Feeding a higher level of flax seed did not lead to a further increase in the concentration of DHA. This suggests that the hen's capacity for elongation of linolenic acid is limited.

Canola, a form of rapeseed which is low in erucic acid ($C_{22:1n9}$) and glucosinolates, has a fairly high level of linolenic acid, typically 9%–10% of total fatty acids, and a low level of saturated fatty acids (<10%). Nwokolo and Sim (1989) fed full-fat canola seed to layers at 10% of diet and increased egg linolenic acid by 50% and DHA by 26% compared with control treatment. By feeding 16% canola seed to laying hens, Cherian and Sim (1991) increased egg linolenic acid from 0.6% to 2.4% of total fatty acids and long-chain n-3 PUFAs from 1% to 1.7%. Increases in the n-3 PUFA percentage were accompanied by corresponding decreases in the saturated fatty acid content.

Studies by Collins et al. (1997) examined the effect of substituting pearl millet (*Pennisetum americanum*) for corn in laying hen diets on egg yolk fatty acids. Typical concentrations of linoleic and linolenic acids in these grains are 45% and 4% for pearl millet and 57% and 0.9% for corn, respectively. Replacing all of the corn in the diet with millet significantly decreased the linoleic acid content and increased the content of linolenic acid and DHA (Table 7.26). In addition, the ratio of n-6:n-3 fatty acids decreased from 13.1 to 8.3. A subsequent study by Collins (1997) examined egg fatty acid composition due to feeding diets that included corn, canola oil, pearl millet, menhaden fish oil, or flax seed. Substituting millet for corn or adding canola oil, menhaden oil, or flax seed to the diets significantly decreased the concentrations of linoleic and arachidonic acids and significantly increased concentrations of linolenic acids and long-chain n-3 fatty acids (Table 7.27). Feeding canola oil, pearl millet, or pearl millet plus canola oil greatly reduced the ratio of n-6:n-3 fatty acids compared with feeding corn. Greater reductions were observed when menhaden oil or flax seed were fed.

Farrell (1999) also examined the effects of several dietary several sources of n-3 fatty acids on egg fatty acid profiles. Cod liver oil was much more effective in elevating long-chain PUFAs in the yolk, compared with canola oil or flaxseed oil. Because the long-chain PUFAs are the ones associated with health benefits, Farrell indicated that all sources of n-3 fatty acids for enriching eggs should not be considered interchangeable with respect to expected health benefits.

As noted previously, there is increasing concern about levels of *trans* fatty acids in the human diet. Use of feed ingredients, such as restaurant grease and bakery products, two potential sources

of *trans* fatty acids, is typically much lower in diets for laying hens than for broilers or turkeys. Thus, very low levels of *trans* fatty acids would be expected in eggs. Levels of *trans* fat have been estimated to be 0.11 g per 100 g of whole liquid egg and 0.28 g per 100 g of liquid egg yolk (Egg Nutrition Center).

Because of potential health benefits of CLA in human nutrition, there have been a number of studies aimed at enriching egg yolk with CLA. Watkins and coworkers (1999) showed that supplementing hens with a human grade dietary supplement of CLA could effectively increase yolk CLA, without negative effects on production. Du et al. (2000) also noted that egg yolks could be enriched with CLA by adding CLA to the laying hen diet. They observed that using dietary CLA also resulted

in decreased monounsaturated fatty acids and increased PUFAs in both egg yolks and liver. Similar results on egg yolk fatty acid profiles due to CLA supplementation of the laying hen diet were also noted by Cherian et al. (2002). In these studies levels of PUFAs were not altered by CLA. In a study in which graded levels of CLA was substituted for soybean oil in the diet, Suksombat et al. (2006) observed increasing levels of saturated fatty acids and decreasing levels of both monounsaturated and polyunsaturated fatty acids in egg yolk.

Typical feeds used for laying hens in the United States contain corn and soybean meal as the major ingredients with very little added fat. Some of the alternative ingredients for laying hen diets mentioned above are used in various geographical areas owing to their lower costs and availability. In other cases, some of the ingredients discussed previously are specifically included in the diet for the purpose of producing nutritionally enhanced or "designer" eggs. Thus, the eggs that consumers eat may vary considerably in fatty composition from the values published for "normal" eggs (e.g., see Table 7.19).

III. SUMMARY

Raw chicken eggs contain a blend of fatty acids consisting of 36% saturated, 48% monounsaturated, and 16% polyunsaturated fatty acids. The fat in the edible portion of eggs is entirely in the yolk. Therefore, egg yolk and yolk products contain similar proportions of the three classes of fatty acids but have higher concentrations. This is also true for dried egg products. The fatty acid composition of cooked eggs is influenced by the ingredients used in the particular method of preparation. There are differences in fatty acid composition of eggs from different avian species. Eggs from quail and turkeys are similar in composition to chicken eggs. The composition of egg substitutes will vary with the ingredients used in their preparation. The use of vegetable oils in these products results in higher levels of PUFAs compared with chicken eggs.

There are a number of factors that influence the fatty acid composition of the chicken egg. These include genetic strain, egg size, and the nutrient composition of the hen's diet. Feeding high levels of vegetable oils increases the levels of unsaturated fatty acids in the egg. Inclusion of fish oil, canola oil, flax seed, marine alga, and pearl millet are some of the ingredients that have been used to enhance the content of n-3 fatty acids in egg yolks.

8 Fatty Acids in Fish and Shellfish

Robert G. Ackman

CONTENTS

I. INTRODUCTION

"Fish is a brain food" is an old admonition given to children who decline to eat fish. It originated in the roughly similar appearance of white fish muscle lipids and those extracted from the human brain, and even the chemists of the nineteenth century found similarities in the phosphorus content, not realizing that this indicated that both tissues were rich in phospholipids. The fatty acids of fish were even more mysterious and the polyunsaturated ones were easily destroyed in the inexact analyses of the time. Fish was usually sold just as fish, a food to be eaten because it was Friday in Catholic countries, or because it was cheap. At about the turn of the century, a few organic chemists began to sort out the structures of two highly unsaturated fatty acids, known as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3). By the 1950–1960 era, much patient work in Germany, Japan, Britain, and the United States had identified most of the fish fatty acids and Stansby (1967) could write an excellent book on fish oils, including early work on their hypercholesterolemic effects. However, the nutritional and biochemical aspects of these two particular fatty acids had to wait nearly two more decades for proper documentation of the role of "omega-3" fatty acids (Holman, 1998).

II. WHY THERE ARE SO MANY FISH FATTY ACID COMPOSITIONS

The author realised rather late in his career that he had developed one table of fatty acids of fish and fish oils and just kept changing the numbers (Ackman et al., 1988). This was almost independent of whether the analysis was of edible muscle, or the whole fish or bodies of molluscs, or whether of freshwater or marine species. The qualitative uniformity of the tables was a consequence of the

continuous recycling of fatty acids though different food webs in the ocean. The composition tables were also independent of whether the data were prepared for nutritionists and food scientists in g/100 g (Tables 8.1 and 8.2) or in weight % fatty acids (Table 8.3), but total lipid was also frequently requested (Table 8.4). Subtle differences among different diets or with animal life stage, or in the proportions of triacylglycerols and phospholipids of some species, made up most of the differences tabulated.

A. Coldwater Fish

Much of the work on fish lipids and fatty acids was, for decades, focused on North Atlantic and North Pacific species. Even the first tabulation from New Zealand included many products imported from Great Britain. Table 8.1 is an excellent presentation of marine fish fatty acids with the weights given in g/100 g. These units appeal to dieticians, who agreed on 100 g (or 3½ oz) as a "serving." The number of fish sampled is stated, with their size and proximate composition data. The scientific names are given in Table 8.2, because this is a regional survey and common names of fish can change from place to place.

There are 16 fatty acids listed (excluding 15:0). This is two more than are really needed to describe the fatty acids of fish, as 18:1n-7 (*cis*-vaccenic acid) is usually included with 18:1n-9 (oleic acid). These two isomeric octadecenoic acids illustrate the shorthand nomenclature system now in use, which facilitates the understanding of fatty acid interconversions. By computing *n* carbons from the terminal methyl group, it is easy to see that 16:1n-7 plus one acetate unit becomes 18:1n-7 (the hyphen is often omitted for brevity). Both 16:1n-7 and 18:1n-9 arise by action of one Δ9,10 desaturase on the corresponding saturated acid. Similarly, the two polyunsaturated fatty acids (PUFAs; 20:5n-3 and 22:6n-3) most often identified with fish oils and lipids are related to 18:3n-3 (α-linolenic acid), as shown in Figure 8.1. The 22:5n-3 is also related to 20:5n-3, and the very minor 22:5n-6 is clearly associated by the nomenclature system to 20:4n-6 (arachidonic acid) and ultimately to the common 18:2n-6 (linoleic acid) of plant origin (Figure 8.2).

North Atlantic fish depot fats are set apart from many fish fats by the presence of 5% or more of 22:1n-11 (cetoleic acid). This is usually accompanied by minor proportions of 22:1n-9 (Ackman et al., 1980). The latter isomer is erucic acid, the source of much concern in the past in health and nutrition circles but now recognized as probably harmless in humans (Sauer and Kramer, 1983; Sauer et al., 1989). Table 8.3 illustrates several points of interests with respect to marine fish lipids and fatty acids. The first is that phospholipids have high proportions of 22:6n-3, less 20:5n-3, and very little 22:1. Triglycerides have more 20:5n-3 than 22:6n-3. In some older analyses on highly polar gas chromatography columns, 20:4n-6 and 22:1 coincided (Ackman, 1987). The other fat details include the extraordinary distribution of fat possible in some species, the nape tissue of Canadian redfish being very fatty indeed, although the fillet of the same fish has only 1.5% fat. In larger fish of this species, pure fat deposits also infiltrate the flanks, and this probably leads to the higher percentage of fat in the German samples. In the United States, the Canadian species is sold as "ocean perch" (Table 8.4).

The fats of the ever-popular salmon are somewhat confusing, because farmed fish tend to have more fat (10%–16%) than wild fish (5%–8%) (see also Suzuki et al., 1986; Roch et al., 1988; Hardy and King, 1989; van Vliet and Katan, 1990), but basically (Table 8.5) salmon fillets have modest levels of 20:1 and 22:1, and 22:6n-3 exceeds 20:5n-3. This table also makes the point that in herring fillet, 22:1 usually exceeds 20:1, and because of the higher level of these two acids, the 20:5n-3 and 22:6n-3 are relatively low. The fatty acids of canned salmon (pink, *Oncorhynchus gorbuscha*) closely resemble those of the fillet in this case except for the detailed proportions among the 18:1, 20:1, and 22:1, which in both cases total over one-quarter of all fatty acids. These fatty acids are nutritionally "neutral" in terms of serum cholesterol. The levels of presumably functional 20:5n-3 and 22:6n-3 are virtually identical. The wild salmon are migratory, and actual fat levels vary with date and location of capture. Additional data on other salmon samples have been published

TABLE 8.2.
Scientific Names of Fish Listed in Table 8.1

Species (Common Name)	Scientific Name
Bass, Black Sea	*Centropristis striata*
Bluefish	*Pomatomus saltatrix*
Butterfish, Gulf	*Peprilus burti*
Catfish, channel	*Ictalurus punctatus*
Croaker, Atlantic	*Micropogonias undulatus*
Dolphin	*Coryphaena hippurus*
Flounder, southern	*Paralichthys lethostigma*
Goosefish (monkfish)	*Lophius americanus*
Grouper, gag	*Mycteroperca microlepis*
Grouper, yellowedge	*Epinephelus flavolimbatus*
Grunt, white	*Haemulon plumieri*
Harvestfish	*Peprilus alepidotus*
Hind, speckled	*Epinephelus drummondhayi*
Jack, Crevalle	*Caranx hippos*
Kingfish, southern (whiting)	*Menticirrhus americanus*
Ladyfish	*Elops saurus*
Mackerel, chub	*Scomber japonicus*
Mackerel, king	*Scomberomorus cavalla*
Mullet, striped	*Mugil cephalus*
Porgy, red	*Pagrus pagrus*
Rag, Silver	*Ariomma bondi*
Runner, blue	*Caranx crysos*
Scad, rough	*Trachurus lathami*
Seatrout, spotted	*Cynoscion nebulosus*
Shad, American	*Alosa sapidissima*
Shark, Atlantic sharpnose	*Rhizoprionodon terraenovae*
Shark, lemon	*Negaprion brevirostris*
Shark, scalloped hammerhead	*Sphyrna lewini*
Shark, tiger	*Galeocerdo cuvieri*
Sheepshead	*Archosargus probatocephalus*
Snapper, red	*Lutjanus campechanus*
Snapper, vermilion	*Rhomboplites aurorubens*
Spot	*Leiostomus xanthurus*
Tilefish	*Lopholatilus chamaeleonticeps*
Tilefish, blueline	*Caulolatilus microps*
Triggerfish, gray	*Balistes capriscus*
Weakfish	*Cynoscion regalis*

(Ackman, 1989; Vanderstoep et al., 1990). The tuna (albacore, *Thunnus alalunga*) canned in oil is included to make the point that the vegetable oil components dominate the fatty acids in such products, whereas water-packed products have fish fatty acids only. For this reason, Table 8.6 presents data for a variety of canned retail fish products in summary form with 20:5n-3 and 22:6n-3 given in g/100 g. This, of course, has to be defined in terms of "can contents" or "drained weight of solids."

It is necessary to note that trade in fish products is international. For this reason, fatty acids of many Southern European species of fish and shellfish are included in Tables 8.7 and 8.8. Others from Northern Europe (e.g., Sweden; Ackman, 1989) will be found elsewhere (Paul et al., 1980).

B. Freshwater Fish

Freshwater fish represent a major part of aquaculture production across the globe. Their fatty acids are in some cases similar to those of marine fish, with 20:5n-3 and 22:6n-3 as reasonably important lipid components (Kinsella et al., 1977; Henderson and Tocher, 1987; Ackman, 1989). In other species such as the popular carp (see Table 8.8), there is more emphasis on the C_{18} fatty acids, although the fish diet has an important influence (Pigott, 1989).

The U.S. channel catfish *Ictalurus punctatus* accounts for 45% of all U.S. aquaculture production. Data from a recent thorough analysis (Nettleton et al., 1990) are included in Table 8.9. The mean fat content of the samples was 6.9%, and that for the U.S. Department of Agriculture (USDA) samples was 4.3%. On or above 2% or 3% fat, it is not unreasonable to convert this directly from g/100 g to weight percent fatty acid data, although more accurate conversions are possible (Exler et al., 1975). The species peculiarity of the high 18:1 is confirmed by the wild catfish sample of Table 8.1, but the 20:5n-3 and 22:6n-3 may reflect the fish meal component in the diet of the farmed fish. The carp from Italy (Table 8.8) is a noncarnivorous species with similar flesh characteristics. Coldwater fish such as the chub (*Coregonus zenithicus*) and whitefish (*Coregonus clupeaformis*), with 13.2% and 7.2% lipid, respectively, are more apt to be better sources of the 20:5n-3 and 22:6n-3 (Wang et al., 1990).

TABLE 8.4
Lipid Analysis: Amount of Total Lipid, EPA, DHA, and Total n-3 Acids in Seafood Available from Nova Scotia Sources

Seafood	Total Lipid (g/100 g)	EPA (20:5n-3) (g/100 g)	DHA (22:6n-3) (g/100 g)	Total n-3 (g/100 g)

Squid	2.00	0.27	0.64	0.93

C. Shellfish and Crustacea

Shellfish (Table 8.10) include both molluscs and crustaceans. Although phospholipids and triglycerides are included in Table 8.10, these are highly variable in proportions as the molluscs store glycogen for energy, not triglycerides. It is better to take the total animals in such cases, and the lipid contents are in the 0.5%–2.5% range. In crustaceans (lobster, crab, and shrimp), the edible parts are low in fat, 0.5%–1.5%, but in both types, a distinguishing feature is that 20:5n-3 ≥ 22:6n-3. It is worth recording that the shrimp has approximately 150 mg of cholesterol per 100 g (Krzynowek and Panunzio, 1989) but crab and lobster have only about 75 mg, and in edible muscle, the bivalves

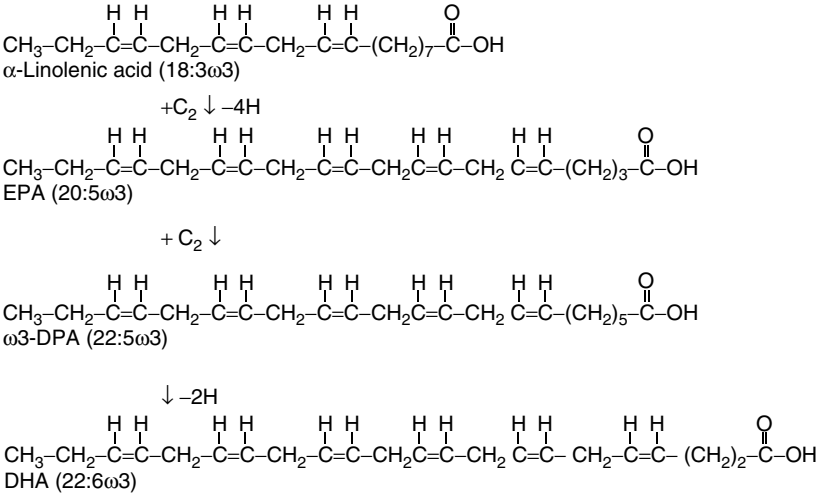

FIGURE 8.1 Principal fatty acids of the n-3 or linolenic acid (18:3n-3) family. Linolenic acid itself is a minor acid in marine animal fats, but the successor acids with five and six ethylenic bonds are two of the fatty acids most characteristic of marine animal fats and lipids. They have acquired considerable popular status as the "omega-3" fatty acids EPA and DHA.

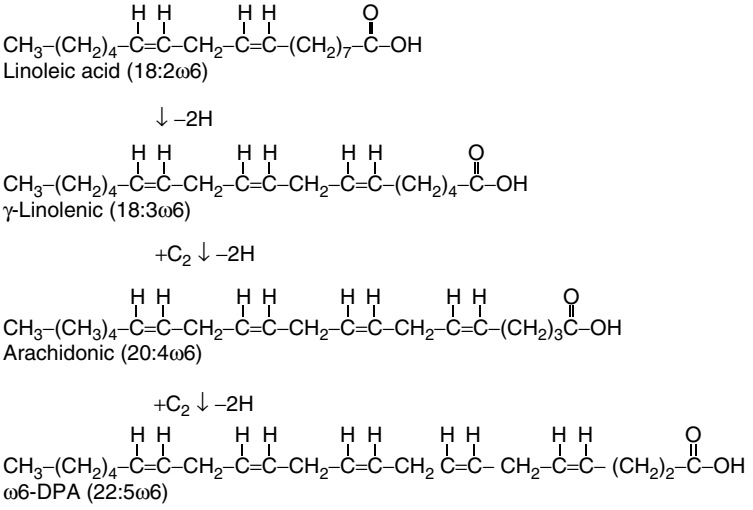

FIGURE 8.2 Condensed scheme of the elongation of linoleic acid (18:2n-6) to arachidonic acid (20:4n-6) and then to a DPA (22:5n-6). Note the retention of the basic n-6 ethylenic bonds, which establishes the "omega-6" relationship among these fatty acids.

usually have only about 35–45 mg (i.e., 40%–50% of total sterols). The most recent paper on this topic is that of King et al. (1990), but some other data are included in Ackman (1989). Northwest Pacific species are reviewed in some detail by Gordon (1982).

D. Australasia and the Tropics

The 1989 review of Ackman focuses on Australasian semitropical and tropical species, which have more 20:4n-6 than is common in coldwater marine species (Table 8.11). This extra 20:4n-6 in the diet may be of minor importance in most cases, but the view of Weber (1989) that the blood level of

Source: Adapted in part from Ackman, R.G. (1976). Fish oil composition. In *Objective Methods for Food Evaluation*, National Academy of Science, Washington, DC, pp. 103–131; and Polvi, S.M. (1989). Diet and availability of omega-3 fatty acids in salmonids. MSc Dissertation, Technical University of Nova Scotia, Halifax, pp. 1–221.

selected acids such as 20:4n-6 and 20:5n-3 correlates with cardiovascular mortality requires that it be considered. Fortunately, these fish, by and large, are very lean (Evans et al., 1986; Brown et al., 1989; Childress et al., 1990) and contribute little fat to the diet.

Nevertheless, in view of the brief report that Japanese heavy fish eaters in Hawaii did not show a reduction in cardiac mortality compared to those who ate less fish (Curb and Reed, 1985), this imbalance in preformed long-chain n-6 vs. long-chain n-3 fatty acids may be important in total fish consumption. The most recent data for Queensland, Australia, is given in Table 8.12. In the totals for long-chain n-6 fatty acids, arachidonic acid (20:4n-6) is one-half to two-thirds of the figure presented for n-6. Linoleic acid was in the 1%–2% range of the total fatty acids, and 20:3n-6 was even less, so attention should focus on the three long-chain n-6 fatty acids in Table 18.2. The latitude in Australia is approximately the same as for Table 8.11; the data shows that it is the important factor in this brief comparison of fatty acids of warm water marine fish.

III. OILY FISH AND HEALTH CONSIDERATIONS

Among the numerous books dispensing advice, recipes, and fish composition data are those of Kinsella (1987) and Nettleton (1985, 1987). Although other information is available, it is indisputable that fish is in all respects a healthy food. Many people do not eat *any* fish (Must et al., 1988), and the consumer does not always understand quality considerations (Hadlett and Raab, 1990). Despite this, the evidence associating increased fish consumption with good circulatory health increased steadily (Leaf and Weber, 1988; Burr et al., 1989; Kinsella et al., 1990) after the results of the 20-year study in Zutphen were published (Kromhout et al., 1985). Biomedical citations on the topic regularly number more than 500 per year (Patrias, 1990).

Source: Adapted from Belling, G.B., et al. (1997). *Lipids 32*: 621–625.

In the past decade, there have been several papers published in the medical literature stating even more clearly that fish consumption reduces the risk of *sudden* cardiac death (Shekelle and Stamler, 1993; Ascherio et al., 1995; Siscovick et al., 1995; Norday, 1996; Daviglus et al., 1997; Albert et al., 1998), and this term has been debated because of the impact of cardiac arrhythmia (Kang and Leaf, 1996) as a significant part of the mortality problem (Albert et al., 1998).

In addition, a diet rich in fish seems to prevent stroke (Keli et al., 1994). There is not enough space here to consider the other pathological conditions that may be influenced by dietary fish fats (Simopoulos, 1991, 1997), but papers continue to consider matters as diverse as asthma (Broughton et al., 1997) and perinatal neural development (Crawford, 1993). The concern here is the availability in our diets of the necessary long-chain fatty acids EPA, docosapentaenoic acid (DPA), and DHA shown in Figure 8.1. In an official report of the U.K. Cardiovascular Review Group Committee on

Medical Aspects of Food Policy (United Kingdom Department of Health, 1994) several recommendations stand out:

R.2.2 We recommend no further increase in average intakes of n-6 PUFA, and we recommend that the proportion of the population consuming n-6 PUFA in excess of about 10% of energy should not increase.

R.2.3 We recommend an increase in the population average consumption of long-chain n-3 PUFA from about 0.1 g/day to about 0.2 g/day (1.5 g/week).

R.3.1 We recommend that people eat at least two portions of fish, of which one should be oily fish, weekly.

This committee considered the competitive effects of plant n-6 and n-3 fatty acids. Here it is sufficient to say that there has been a severe imbalance in our intake of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3). Holman (1997, 1998) has coined the term *omega-6-induced omega-3 deficiency* to describe the resulting lack of conversion of 18:3n-3 to the fish oil type of long-chain n-3 fatty acids. The now excessive Japanese intake of 18:2n-6 is discussed in detail by Okuyama et al. (1997) and in condensed form by Sugano (1996), who recommended that the plant (C_{18}) essential fatty acid dietary supply be in the proportion of 4:1 for n-6:n-3. A problem among the Japanese is that the traditional diet rich in fish and shellfish has now shifted to the Western diet and EPA, DPA, and DHA are now less common. The traditional Japanese diet was highly diversified in terms of seafood, but what about our Western diets? What oily fish were available and acceptable? Part of that question can be answered by Table 8.13. In 1848, fresh, salted, or smoked herring was a cheap food in the United Kingdom. Pilchards, mackerel, and salmon were also part of this diet. The much leaner "whitefish" such as cod, haddock, and pollack were less plentiful than later when steam trawlers were developed and sailed out as far as Iceland.

Burr et al. (1989) were responsible for introducing the term and recommending the consumption of *oily* fish and have expanded on that concept and the results. Salmon has a history of being thoroughly evaluated in a clinical context; for example, by Connor et al. (1983), by Nelson et al. (1991), and by Wander and Patton (1991). Gerhard et al. (1991) compared biochemical effects in humans of diets high in three Pacific fish species: Dover (*sic*) sole (lean), chincook salmon (mid range for fat), and sablefish (a fish high in fat but relatively lower in EPA and DHA). As expected the two "oily" fish produced more improvement in cardiovascular risk factors than the leaner sole. However, the latter showed improvement over the regular diet of the subjects. Even in Central Africa the availability of freshwater fish to one population group compared to a different diet group has produced similar results, illustrating that any fish is better than no fish (Pauletto et al., 1996).

The question usually asked by well-informed consumers interested in changing their diets is whether aquaculture (farmed) fish are as "good" as naturally harvested fish. Bell et al. (1998) have

TABLE 8.13
Estimates of Changes between 1848 and 1978 in *per capita* Consumption of Fish in the U.K. and of EPA and DHA in Grams/Week

	1848	1978
Oily fish	137	22
White fish	44	100
EPA	1.7	0.2
DHA	1.2	0.2

Source: Adapted from Ackman, R.G. (1988).

examined the muscle from stocks of Atlantic salmon farmed in Scotland. Doubling the dietary fat content from 16% to 30% in diets fed to these salmon increased the flesh lipid from about 8% to about 11% depending on the edible part examined. The percentages of EPA and DHA in the total fatty acids of the muscle lipid averaged between 5.6% and 11.3%, respectively, which is similar to their analysis of wild Atlantic salmon (3.5% lipid, EPA 5.9%, DHA 12.9%). This comparison shows the fallacy of merely looking at the percentage of fatty acids, and in this species, at least, the farmed salmon is the better source of omega-3 fatty acids. Some vegetable products such as canola oil can give the lipids of farmed salmon increased linoleic acid (18:2n-6) in the total fatty acids, but the wild salmon examined by Bell et al. (1998) had only 1.2% of this fatty acid, a figure common in muscle lipids of coldwater marine fish. A new technology, x-ray tomography, has been applied to determine the fat in Atlantic salmon flesh (Bjerkeng et al., 1997). High-energy (i.e., high fat) diets with 32% and 39% fat gave only marginal differences in whole body fat (15.6 vs. 17.7%), suggesting that the fish diet is overloaded if maximizing fat were an objective of the dietary difference. Recently, Aursand et al. (1997) could also give the n-3 fatty acid content through quantitative nuclear magnetic resonance (NMR) technology. Some consumers worry about quality or contamination, but the North Atlantic salmon aquaculture industry is constantly improving quality control (Sigurgisladottir et al., 1997). Lipids are less likely to be part of the quality image than bacterial or protein-related changes in unfrozen fresh fish. For example, the gilthead seabream *Sparus aurata* had 7.69 g of fat/100 g flesh, and 5%–10% of this fat was hydrolyzed to free fatty acids in 24 days on ice. The thiobarbituric acid (TBA) index increased only slightly in this period, from 0.67 to 1.07, so rancidity was not a problem in the shelf life of this species (Kyrana et al., 1997). The free fatty acids, probably from phospholipids, would also be completely available and digestible. In frozen storage, similar processes are very slow in lean fish such as cod (Hardy et al., 1979) and are less obvious in oily fish (Polvi et al., 1991), although some oily fish such as Atlantic mackerel (*Scomber scombrus*) eventually can go rancid if tocopherol is depleted (Ackman and Gunnlaugsdottir, 1992; Bhuiyan et al., 1993; Ackman and Timmins, 1995). Only fish such as Atlantic salmon show to some degree changes in muscle fatty acids with changes in diet. Table 8.14 shows that most phopholipids in farmed fish muscle resist changes from dietary fatty acids, and that the depot fat triacylglycerols are only moderately responsive to extreme changes in dietary fats. This is because each species of fish has some typical composition factors affecting triacylglycerols that could be called "species specific." In the United States, menhaden oil (from *Brevoortia tyrannus*) EPA usually exceeds DHA, and menhaden oil or meal are extensively used in farmed fish product diets as well as for, for example, fowl and pigs. However, the U.S. channel catfish (*I. punctatus*) does not respond with increased EPA in the depot fat (see Table 8.9). It is unfortunate that this freshwater species may be included in U.S. fish consumption statistics, since conclusions drawn for fish are often thought to be for marine species. Despite a fat content of 6%–7%, the amount of n-3 fatty acids is very low (i.e., roughly 100 mg/100 g fish). The term *oily* fish must therefore be used with care.

Seals are omnivores, eating fish or invertebrates, and they accumulate fish oil fatty acids in their depot fat. Even seal oil tends to be species specific in fatty acid composition, possibly reflecting diet, but seal oil can be regarded as a high-quality "biofiltered" fish oil safe for human consumption (Ackman, 1997), and it has joined other encapsulated oils rich in omega-3 fatty acids for those who do not like fish but wish to partake of the benefits of fish as a healthy food. The n-3 DPA (22:5n-3) of seal oil may be unexpectedly potent and beneficial in the biochemistry of the blood vessel wall (Kanayasu-Toyoda et al., 1996). Seal oil is richer in this DPA than are most fish oils.

There is increasingly some confusion over "omega-3" fatty acids because of aggressive health claims in the marketing of flaxseed (linseed, *Linum usitatissimum* L.) oil and its products. The oil contains more than 50% of 18:3n-3 or α-linolenic acid. This has only recently been accepted as truly an "essential" fatty acid in C_{18} terminology (Holman, 1998). Even by 1992 (see British Nutrition Foundation Report, 1992), it was not considered as important as linoleic acid (18:2n-6). Although both are important in our diets (Ackman and Cunnane, 1991), public awareness of the benefits of consuming fish and shellfish for preformed and preferred EPA and DHA suffers from this public relation problem. Only recently (Leaf et al., 1995; Garland et al., 1998) has there been research

directed to assessing body depot fat acid status and the relationship to longer-chain dietary fatty acids of the n-6 and n-3 types, as well as to those circulating throughout the body (Bjerve et al., 1993).

Even greater confusion is created by the increasing sale and restaurant use of surimi products. Although the protein is still nutritionally valuable, the lipids may be reduced by processing. Analyses of finfish surimi in USDA Handbook 8-15 (now found under USDA Nutrient Database for Standard Reference, Release No. 12, at http://www.nal.usda.gov/fnic/foodcomp/) do not indicate the content of EPA + DHA. Imitation Alaska king crab, on the other hand, had 1.3% lipid and a total of 0.6% EPA + DHA. Excellent reference sources for most considerations of fish handling, composition, and quality will be found in Martin and Flick (1990), Burt et al. (1992), and Ruiter (1995).

IV. FISH AS FOOD

The seminal research reported by Dyerberg and Bang (1979) caused a sensation in the fatty acid world, and reports by Dyerberg (1981) and Dyerberg et al. (1981) enhanced the acceptability of longer-chain omega-3 fatty acids of marine origin. Later in an international meeting in London, United Kingdom, Ackman (1988b) reviewed "The Year of the Fish Oils" in 1987, suggesting the maturation stage of a new science. The enormously productive research in medicine in the next decade prompts an update mainly of 1990 and on as a decade of progress, and the controversy that has sprung up about fish as food during this decade. Owing to wider implications, some revision in the viewpoints is needed as being solely concerned with public acceptance of fish as food.

A. Omega-3 Fatty Acids and Health

It has to be recognized that the originator of "lies, damned lies, and statistics," Benjamin Franklin, was a far-sighted person. In a recent review article, Hooper et al. (2006) concluded that "Long-chain and shorter-chain omega-3 fats do not have a clear effect on total mortality, combined cardiovascular events, or cancer."

The media did not miss this opportunity for publicity, especially when furnished with the reactions of other scientists. Among the torrents of objections some pointed out that simply removing one study from the multiplicity included would reverse most of the negative conclusions on the basis of statistical analyses. Today, many of the problems, including some negative results for omega-3 and certain ailments or clinical conditions, are genuine, but apply to small groups. An example is provided by ventricular tachycardia and fibrillation patients, as a study (Raitt et al., 2005) showed that fish oil may "act in a proarrhythmic way in some patients." More or less the same conclusions were reached by Brouwer et al. (2006). Also, Iso et al. (2006) followed 41,578 middle-aged men and women free of prior diagnoses and habitual fish consumers, ranging from 20 g/day to the highest with a median consumption of 180 g/day for 5 years and found that strong inverse associations existed between dietary intake of n-3 fatty acids and risk of definite myocardial infarction and nonfatal coronary events (Figure 8.3). Compared with a modest fish intake of once per week or ≈20 g/day, a higher intake was associated with a substantially reduced risk of coronary heart disease, primarily nonfatal cardiac events, among middle-aged persons.

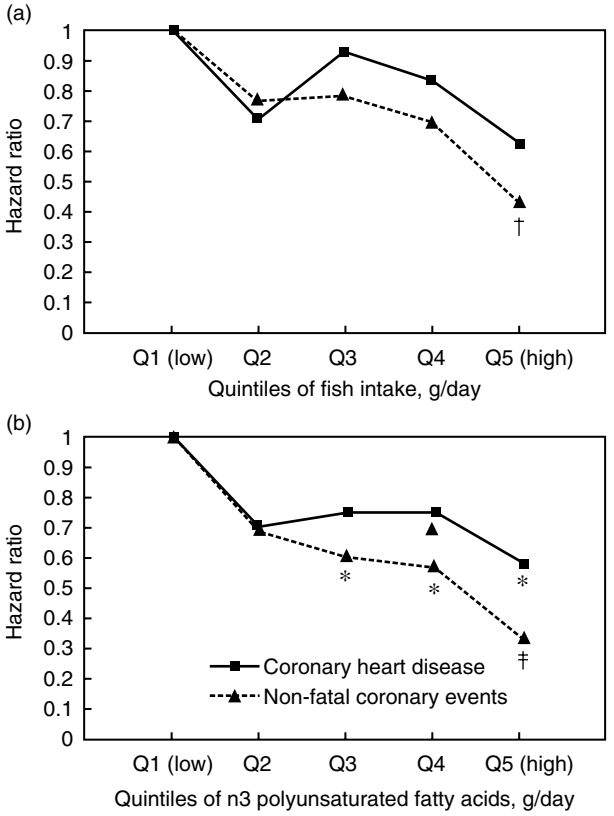

FIGURE 8.3 Comparison of hazard ratio for quintiles of fish consumed (a) and n-3 PUFAs (b) for men and women. The term quintile refers to the five diet levels of habitual fish consumers, ranging from 20 g/day to the highest with a median consumption of 180 g/day. Subjects were middle-aged Japanese men and women. (From Iso, H., et al. (2006). Circulation 113: 195–202. With permission from the American Heart Association.)

This confirms other studies that discriminate between definite myocardial infarction and nonfatal coronary events. The most recent reviews, both in the form of a brief editorial (Deckelbaum and Akabas, 2006) and a lengthy review (Wang et al., 2006), are in favor of the longer-chain omega-3 fatty acids, but not α-linolenic acid. This is for reducing the "rates of all-cause mortality, cardiac and sudden death, and possibly stroke. The evidence for the benefits of fish oil is stronger in secondary—than in primary—prevention settings." Marine omega-3 fatty acids cannot prevent death, but do reduce the probability. Obviously fish as a healthy food is generally supported by these recent findings, including the low C-reactive protein concentrations found in Japanese with a diet rich in marine products (Niu et al., 2006).

B. New Market Exploitation

The aging populations in North America and Europe are often made up of persons who have survived cardiovascular disease or will never develop it. Instead their interest, when they or their relatives recognize it, is "cognitive decline with age," typified by diagnosis of Alzheimer's disease. This is even harder to recognize and control than cardiovascular disease, but is unlikely to convert nonfish consumers to a new diet, so they will follow supplement or nutraceutical routes to omega-3

treatment. In a large community study of over 65 population of Chicago, Morris et al. (2005) compared different rates of fish consumption, and found that higher fish intake correlated with slower cognitive decline.

What does the average consumer really know about fish as food? Table 8.15 presents the case for Atlantic salmon. The U.S. Government did not bother to state whether it was a steak or a fillet, tissues with quite different lipid compositions (Zhou et al., 1995). Among the fatty acids, "undifferentiated" means that two or more isomers were lumped together. The three critical longer-chain omega-3 fatty acids, EPA (20:5n-3), DPA (22:5n-3), and DHA (22:6n-3) are differentiated and correspond to those expected. The lipid content (6.34%) is about right for most wild Atlantic salmon returning to a river to spawn. Since the sample tissue is not known it could be estimated that about 5.5 g will be triacylglycerides (oil) and the balance, about 1%, phospholipids. Roughly, the fatty acids correspond to those of the farmed Atlantic salmon (see Figure 3.3 in Chapter 3 of this book). It is presumed to be all muscle with at worst a few pinbones. Note that no man-made organic compounds, persistent pesticides, or dangerous metals are included. Salmon acquire environmental chemicals associated with health risks from both their diets and the ocean waters in which they live. Geography, however, can be a factor in eating fish.

A particularly appropriate paper on the subject of benefits vs. risks is that of Foran et al. (2005). This paper provides a U.S. Government data table of 16 contaminants and salmon was provided for analyses from Northern Europe, South America (Chile), Eastern and Western Canada, and finally all five wild Pacific species were included. Their opinion is that benefit–risk ratio can be optimized by selective shopping on the basis of geographical origins. The inevitable conclusion provided suggests that the risk from exposure to contaminants in farmed and wild salmon is at least partially offset by the associated fatty acid health benefits.Those persons not at significant risk for sudden cardiac death associated with coronary heart disease but concerned with health impairments such as reduction in IQ and other cognitive and behavioral effects, can minimize contaminant exposure by choosing the least contaminated wild salmon or by selecting other sources of longer-chain n-3 fatty acids. However, young children, women of child-bearing age, pregnant women, and nursing mothers, receive the usual cautions with respect to consuming fish. This period of pregnancy and lactation has long been recognized as unique and requiring special dietary considerations (Lichtenstein et al., 2006). The new factor of DHA requirement in early childhood, even into school years, has been considered by Genuis and Schwalfenberg (2006), who carried their overview of the problem into the time of pediatric health problems. They were careful to suggest that only refined fish oil materials be considered, even in the postnatal period, as an alternative to fish.

A rhetorical question (see title in references) asked by J.-M. Bourre (2005) clarifies some of the French viewpoints on fats in foods. That country was for decades held to be the stronghold of gourmands who put desirable flavors above nutritional value. Now a majority of the population has access to new foods strong in either principle, and this paper evaluates their position on fish fed different diets, as well as other matters such as eggs, ducks, and dairy products.

The current levels of recommended intakes of longer-chain omega-3 fatty acids will need to be adjusted in most western countries to cope with the neurological changes in an aging population. Alzheimer is in fact now better known than many other medical pioneers. Research is very difficult but omega-3 fatty acids, particularly DHA, have been obvious candidates. Recent progress by Florent et al. (2006) at the cellular level is able to explain how DHA might function by interacting with protein processes, rather than on a purely lipid basis. "Animal fats" otherwise remain out of the picture, but Colombani (2006) is worth reading in view of the statistical comments above, if only to find out that the U.S. Government made an enormous error (tenfold) in calculating a recommendation suggesting limits on cholesterol consumption. A valuable lesson! An animal fat that is being ignored is the "EGG, Chicken, whole, hard cooked." Thus, the description in USDA Agriculture Handbook No. 8-1 says that 50 g, edible portion, contains 0.019 g of DHA. In view of the low mass of children a steady diet of at least one egg at breakfast may have provided past generations with enough DHA for normal child development. The contemporary cereal breakfasts of today do not,

possibly, account for the attention deficit disorder and other problems in an age group that often formerly also received cod liver oil supplementation for vitamins A and D, unwittingly consuming EPA and DHA in large amounts.

In 2002, Burdge et al. upset the essentiality of α-linolenic acid by showing that 33% of a labeled dose given to a human was exhaled as CO_2 in the first 24 h. More recently "Long-Chain n-3 PUFA: Plant v Marine-Sources" (William and Burdge, 2006) really focuses sharply on whether the well-fed human can benefit much from supplemental α-linolenic acid when only 8% of a label reaches the EPA stage of elongation, and only 0.1% reaches the DHA stage. Women do better, producing 9% DHA, in keeping with the demands that can be made by the fetus and neonate lactation (Burdge and Calder, 2005). These very recent presentations should be compared with the view of Sinclair et al., as recently as 2002. Minor roles for α-linolenic acid in the body are given by this group, but progress with it since then has not been rapid. The conversion of α-linolenic acid to EPA is good in humans, but as continued by a recent study conversion to DHA would add only minimal new DHA (Goyens et al., 2006).

The "plant" title quoted above adds a modest element of confusion to these topics since Martek Biosciences Corporation and other firms are now successfully marketing DHA produced by culturing algae, and so could more legitimately make a vegetarian claim. Martek has gone as far as advertising DHA with a trade mark sign on the Martek DHA Omega-3 but then some fish may also accumulate most of their DHA from algae. More commonly, marine plants biosynthesize EPA and not DHA. Another example of scientific findings being exploited in a dubious manner would be a health claim for tuna, a popular food in the United States, if marketing of albacore and other popular species were to use results from a pelagic tuna species *Thunnus tonggol* (Bleeker). Saito (2006) of Japan has published comprehensive analyses on it recently, showing that the neutral body lipids (oils) may have 20% DHA. Similarly, there are extravagant claims for products made from Antarctic krill *Euphausia superba*. There are enormous populations of this quite large species that happens to store energy in the form of phosphatidyl choline (Lee et al., 2006). Unlike the muscle phospholipids of fish, rich in DHA, and because there is a direct link to feeding on algae, these lipids have an excess of EPA over DHA (Stubing et al., 2003). The menhaden fish of the U.S. east coast has a similar algal diet but uses oil for its energy store, resulting in the initially famous 180:120 ratio for EPA/DHA in fish oil supplements. The *E. superba* has however been merchandized as more digestible than competing omega-3 supplements on the basis of triacylglyceride fish oils. Canada-based Neptune Technologies has also announced results from a clinical trial that reports a daily dose of its krill oil can lower bad cholesterol levels by 34% and boost good cholesterol by 44%.

C. Short-Chain or Long-Chain

The controversy over "n-3" or "omega-3" fatty acids needed for good health falls into place in many articles debating whether the C18 α-linolenic acid has some merit in itself, or functions mainly as a precursor of the C20 EPA and the C22 DHA, or whether the latter two are always needed preformed. An excellent article on this has just appeared in the *American Journal of the Clinical Nutrition* (Gebauer et al., 2006). This takes a broad viewpoint, even admitting that fish oil supplements are a valuable alternative to eating fish and shellfish only.

a. Alternate Sources and Delivery Systems

Medical people have sometimes narrow viewpoints. At the same time as some emphasize the long-chain omega-3 PUFA of (mostly) marine origin, other dedicated scientists are working to persuade oilseed plants to undergo genetic modifications to become pharmacologically active sources of long-chain PUFAs. An overview of the changes in dietary fats possible and considered desirable includes the current human targets of several national and international bodies and makes thoughtful reading (Griffiths and Morse, 2006).

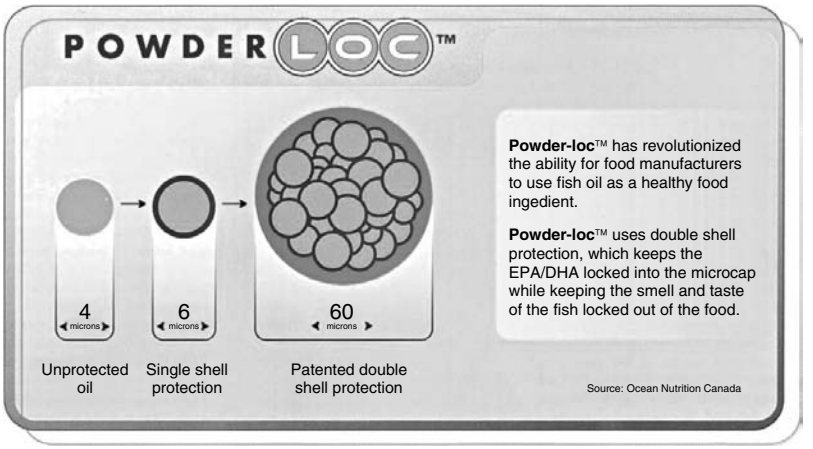

FIGURE 8.4 Microencapsulation can protect the long-chain omega-3 fatty acids of marine oils and concentrates from oxidation and production of off-flavors. A particularly strong microcapsule is the POWDER LOC™ of Ocean Nutrition Canada.

"Fortification" of foods is not new (Muggli, 2006). In fact the addition of DHA produced by Martek Biosciences Corporation to infant formulas, thus copying mother's milk, has been standard for some years. Extravagant claims of health benefits from fatty acids have been the norm for many years but may now become less common as regulations get tighter (D'Innocenzo, 2006). "Nutraceuticals" can include a variety of fats and oils. These are considered by Shahidi and Senanayzke (2006) in a new book edited by F. Shahidi (2006), who also contributed other material to the book *Nutraceuticals and Specialty Lipids and Their Co-Products*.

A new type of fish oil supplement that may be unnoticed for health reasons unless eaten regularly is now on the market, in foods and baked goods enriched with fish oil in microcapsules. It is important that no trace of oil or oil concentrate rich in omega-3 fatty acids be left on the outside to oxidize. Moreover, the encapsulating shell must be strong enough to stand up to handling and mixing as well as any baking process. The patented POWDER-LOC of Ocean Nutrition Canada (Figure 8.4) illustrates how a double shell achieves these objectives. The type of enrichment of food fortification is featured in articles in many trade publications (Wade, 2006; Zegler, 2006), but more sober reflection reveals the problems (Williams, 2005). The health claims allowed in Canada for functional foods and nutraceuticals are discussed in a recent trade publication (D'Innocenzo, 2006). They are very strict compared to those allowed in the United States. So far Health Canada has only permitted five generic health claims (sodium, potassium, and hypertension; calcium, vitamin D, and osteoporosis; saturated fat, *trans* fat, and heart disease; vegetables and fruits and some types of cancer; and sugar alcohol and dental caries) that may be used to communicate the benefits of functional foods and nutraceuticals. Examples of health claims would be "A diet low in saturated and *trans* fat reduces risk of heart disease. Product is low in saturated and *trans* fat," or "A diet with adequate calcium and vitamin D, and regular physical activity reduces risk of osteoporosis."

D. The Safety Factor

A recent advertisement in a daily newspaper merchandizing insert displayed two bottles side-by-side, containing capsules of fish oil supplements. One label read "Salmon and Fish Oils, 1000 mg, 180:120" (180 Softgel Capsules). The other, of identical size and from the same company, read "*Wild* Salmon & Fish Oils, 1000 mg, EPA 180.DHA 120" (150 softgels) and carried a small symbol in the lower left corner of a fish followed by "MEG-3." The latter is part of a licensed trademark of

the firm Ocean Nutrition Canada, and indicates a highly refined and purified fish oil product meeting the standards of the Council for Responsible Nutrition. That the unspecified salmon oil, and for that matter both salmon oils, may not be of good quality is a paradox. Yet both products contain marine long-chain omega-3 fatty acids that are esteemed by the public and most scientists as healthy nutritional supplements.

Unfortunately an activist minority have taken it on themselves to claim that farmed salmon, as distinct from the same species caught in the wild, are dangerous sources of man-made organic chemical of the pesticide, herbicide, and flame retardant type (DeMont and Nicklen, 2004). Mercury is another favorite threat in their activities, mostly as methylmercury, naturally present in ocean water, and the authorities do frown on it in the diet of pregnant women (Smith and Sahyoun, 2005; Wilson, 2004).

Unfortunately, public information on foods is often no better, for example, than a newspaper article "Is it safe to eat salmon?" Calamai (2006). Citing several scientific publications did not really clarify the issues because the authors cited were themselves often at odds. One effort to control and resolve these issues with omega-3 fatty acid supplements has been successful in North America. The Council for Responsible Nutrition was a typical response of U.S. industries to voluntarily control a problem faster than the U.S. Government could take action. The voluntary specifications for long-chain omega-3 EPA and DHA products published by the Council for Responsible Nutrition are shown in Table 8.16.

It should be understood that there are hundreds of isomers of chlorinated hydrocarbons involved. They can be distinguished often in tiny amounts only by specialized laboratories. To facilitate rapid understanding of results certain "congeners" are selected as representative, important, and widely distributed. They may also be found in familiar terrestrial foodstuffs. Jacobs et al. (2004) explore these factors for the whole regional food chains, and not just for fish. Other sources of information that may be useful include the U.S. Pharmacopoeia and the corresponding pharmaceutical bodies in other countries, including the one for the whole of Europe. Measuring toxic chemicals by chemical analysis is an exact science. Deciding on how toxic they are in the normal human adult body is biochemistry hardly ever exposed to the public. Some are very fat soluble and from a meal may be mostly deposited at once in our depot fat, then being very slowly released. How does this compare humans with rats, mice, and rabbits? One of the few efforts to expose this aspect of mercury toxicity is that of Flores (2005) in a REUTERS (know.now) release. In this document Dr William E. M. Lands, a retired professor of biochemistry, pointed out that mammals, including humans, are protected by variable levels of the desirable element selenium, and concluded that the benefits of eating seafood far outweighs the risks of the little bit of mercury that are found in the seafood.

TABLE 8.16
The Voluntary Specifications for Long-Chain Omega-3 EPA and DHA Products[a]

Arsenic: Maximum 0.1 ppm
Cadmium: Maximum 0.1 ppm
Lead: Maximum 0.1 ppm
Mercury: Maximum 0.1 ppm (ONC's specification is maximum 0.01 ppm)
Dioxins and Furans: Maximum 2 pg WHO-PCDD/F-TEQ/g
Dioxin-like PCBs: Maximum 3 pg WHO-PCB-TEQ/g
PCBs: Maximum 0.09 ppm (Sum of IUPAC congeners 28, 52, 101, 118, 138, 153, and 180)

[a] Information courtesy of Ocean Nutrition Canada. WHO, World Health Organization; PCDD, polychlorinated dibenzo-*p*-dioxides; PCDF, polychlorinated dibenzofurans; TEQ, toxic equivalents; PCB, polychlorinated biphenyls; IUPAC, International Union of Pure and Applied Chemistry.

In 1994, the U.K. Committee on Medical Aspects of Food Policy, Department of Health issued a special report on dealing with omega-3 fatty acids and cardiovascular disease. The report includes the now famous recommendation to eat two servings of fish a week, one being an oily fish. Those who are currently pondering whether they should eat fish for good cardiovascular health, at a time when toxic contents receive wide publicity, will find two publications extremely useful. U.K. Scientific Advisory Committee on Nutrition, Committee on Toxicology (2004) issued science-based advice on the benefits and risks of fish consumption. This document brings together the nutritional considerations from the U.K. Scientific Advisory Committee on Nutrition (SACN) on fish consumption with the toxicological considerations from a Toxicology Committee on the contamination in fish. In May, 2004, the Joint Health Claims Initiative (JHCI) released a final draft of a health claim submission along with the paper "Metabolism and Functions of Lipids and Fatty Acids in Teleost Fish" by Tocher (2003). This document was later approved on November 2, 2005 as a final report (U.K. Joint Health Claims Initiative, 2005). The JHCI is a U.K. body joining consumer organizations, enforcement authorities, and industry trade associations. In some aspects, it acts like the Council for Responsible Nutrition in North America.

9 Fatty Acids in Vegetables and Vegetable Products

Geza Bruckner and Andrew C. Peng

CONTENTS

I. INTRODUCTION

Consuming a diet high in fruits and vegetables is associated with lower risks for numerous chronic diseases, including cancer and cardiovascular disease (Block et al., 1992; Ness and Fowle, 1997). In 1990, the Dietary Guidelines Committee recommended three or more servings of vegetables each day (Report of the Dietary Guidelines Advisory, 1990), and the National Cancer Institute in 1991 and the Produce for Better Health Foundation jointly established the 5 A Day for Better Health Program (Heimendinger et al., 1996). Per capita consumption of fresh and frozen vegetables has increased steadily over the past two decades (data for 1970–1988). Consumption of fresh vegetables increased by 40% (from 64.1 to 89.8 lb per capita), and that of frozen vegetables, more than 32%

(from 13.5 to 17.9 lb) (Institute of Food Technologists, 1990; Putnam, 1990). However, since 1990 the level of vegetable consumption has increased at a much slower rate. The proportion of adults who consumed fruits and vegetables at least five times per day increased from 19.0% in 1990 to 22.1% in 1994 and to 22.7% in 1996. The geometric mean intake of fruits and vegetables increased from 3.3 times per day in 1990 to 3.4 times per day in both 1994 and 1996, whereas the arithmetic mean increased from 3.7 times a day in 1990 to 3.9 times per day in both 1994 and 1996. Although the trend toward increased consumption of fruits and vegetables is apparent, the overall frequency of fruit and vegetable consumption changed little from 1994 to 2000, if the true goal is to achieve five per day. If increases are to be achieved, additional efforts and new strategies will be needed.

Although we know the overall health benefits of increased vegetable consumption, we know very little about the specific components responsible for these health effects. It is known that increased consumption of mono- and polyunsaturated fatty acids and decreased consumption of *trans* and saturated fats are linked to positive health outcomes (Lemaitre et al., 2006). The fatty acid composition of vegetables is generally accepted as "healthful," containing more mono- and polyunsaturated fatty acids than saturated fatty acids.

Vegetable is defined in Webster's dictionary as "an herbaceous plant cultivated for food, and the edible part or parts of such plants as prepared for market or table." In other words, vegetables form one of the legs of MyPyramid (http://www.mypyramid.gov/) and the USDA recommends increased consumption of vegetables with an emphasis on dark green and colored vegetables.

Vegetables are a good source of lipids, simple and complex carbohydrates (especially soluble and insoluble fiber), proteins (beans, peas, and sweet corn), minerals (leafy vegetables and root crops), and secondary metabolites for human nutrition. Additionally, a great deal of attention has recently been focused on the health benefits of phytochemicals (Heber, 2004). Lipids are a major constituent of foods; fresh vegetables may contain 0.1%–1.0% lipids on fresh weight basis (Haytowitz and Matthews, 1984). Their presence, quantity, and composition are important not only for organoleptic satisfaction but also for nutrition and keeping quality. A small amount of lipid present in a food system makes it more palatable and satisfying, facilitates the utilization of proteins and fat-soluble vitamins, provides the essential fatty acids for body needs, and serves as the structural material of cell membranes in all tissues (Gurr and James, 1975). Each fatty acid plays a significant role in normal biological functions and in relation to major problems in health and agriculture (King, 1970; Hansen, 1990).

The type and quantity of fatty acids in the lipid molecule and the position and distribution of these fatty acids in the lipids determine the chemical, physical, and functional properties (Dugan, 1976). Knowing fatty acid composition may help to facilitate new food product development. Some medium-chain fatty acids (C_{12}–C_{18}) have antimicrobial properties (Jay, 1986; Beuchat and Golden, 1989). The major fatty acids of commercial vegetable crops are lauric (12:0), myristic (14:0), palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2), and linolenic (18:3) acids, with palmitic, oleic, and linoleic acids predominating. Generally, lipids from vegetable sources are liquid (oil) at room temperature and less saturated than animal fats (Hitchcock and Nichols, 1971).

The analysis and evaluation of vegetable lipids and fatty acid composition are influenced by production conditions, cultivar, maturity, season, cultural practices, processing, storage, packaging, and analytical procedures (Kinsella et al., 1975). The fatty acid composition is generally analyzed by gas–liquid chromatography and mass spectrometry. As with any analytical technique there are problems and limitations (Ackman et al., 1967); however, these are the most widely used analytical tool. For vegetables not cited in this chapter, information on their fatty acid composition may be found at the following USDA website: http://www.nal.usda.gov/fnic/foodcomp/search/.

II. SOLANACEOUS CROPS

The vegetables in this group belong to the Solanaceae family.

A. Potatoes (*Solanum tuberosum*)

The tuber-bearing species are herbaceous dicotyledonous annual plants and reproduce asexually by seed tubers. The total lipid content of potatoes is relatively low, approximately 0.1%–0.13% of the fresh weight (Galliard, 1968, 1973; Haytowitz and Matthews, 1984) or about 0.21%–0.81% of the dry weight (Mondy et al., 1963; Cotrufo and Lunsetter, 1964; Lepage, 1968). Galliard (1973) found no varietal difference in total lipid content. Potato tubers are composed of 16.5% neutral lipids, 38.0% glycolipids, and 45.5% phospholipids (Lepage, 1968). The potato microsomes contain 15.6%–19.0% neutral lipids, 35.1%–42.7% glycolipids, and 41.7%–45.9% phospholipids, whereas potato mitochondria have 8.1%–9.0% neutral lipids, 6.4%–11.8% glycolipids, and 79.2%–85.5% phospholipids (Lepage, 1968; Pun et al., 1980). The polar structural lipids are the major lipid components.

The fatty acid composition varies with cultivar, growth, maturity, storage and temperature, and lipid class (Mondy et al., 1963; Cotrufo and Lunsetter, 1964; Galliard, 1968, 1972, 1973; Lepage, 1968; Schwartz et al., 1968; Berkeley and Galliard, 1974; Galliard et al., 1975), as well as with

subcellular particles (Schwertner and Biale, 1973; Pun et al., 1980). Table 9.1 shows the fatty acid composition as affected by storage time and cultivar for potatoes stored at 4.4°C (Mondy et al., 1963). The Pontiac cultivar decreased in linoleic acid and increased in palmitic acid, whereas the Ontario cultivar decreased in palmitic and linolenic acids. The potato fatty acids are highly unsaturated. The unsaturation ratio (18:1 18:2 18:3)/(16:0 18:0) for Pontiac stored at 4.4°C was 2.4 after 2 weeks and 1.0 after 16 weeks; for Ontario, it was 2.6 and 2.7, respectively.

Pun et al. (1980) reported that potato microsomal and mitochondrial lipids consisted of palmitic (24.7% and 19.4%), stearic (6.8% and 4.7%), oleic (2.0% and 2.4%), linoleic (49.6% and 59.6%), and linolenic (15.4% and 12.1%) acids, and the unsaturation ratio was 2.1 and 3.1, respectively.

In raw and processed potatoes, phospholipids are the major lipid component, and palmitic and linoleic acids are the most common fatty acids, as shown in Table 9.2 (Pun and Hadziyev, 1978; Lilja and Lingnert, 1989).

The total lipid content of deep-fat-fried foods is greatly increased relative to the unfried products; for example, the average lipid content of potato chips is 40.4% and that of French fries is 13.5% (Smith et al., 1985) as compared with 0.1%–0.13% for raw potatoes. The fatty acid composition of potato chips is primarily reflective of the oil used for frying. Sheppard et al. (1978) investigated 12 brands of potato chips in the Washington, DC, and Davis, CA, areas and found a wide range of fatty acid content (Table 9.2); the chips were high in palmitic, oleic, and linoleic acids. The amount of unsaturated fatty acids was much lower than those reported by Smith et al. (1985) (Table 9.3), who studied nine brands of potato chips in the Davis and Sacramento areas of California. The storage of Norchip potato chips at 24°C for 10 weeks showed no significant changes in fatty acids (Robertson et al., 1972). However, the fatty acid composition of potato chips is altered by the use of different frying oils (Tables 9.4 through 9.6).

B. Tomatoes (*Lycopersicon esculentum*)

Tomato is an herbaceous perennial in the tropics and an annual plant in the Temperate Zone. Per capita consumption in America is 15.2 lb for fresh tomatoes and 61.0 lb for processed tomatoes (Putnam, 1990). The total lipids of red fresh tomatoes are 0.06%–0.21% (Ueda et al., 1970a; Haytowitz and Matthews, 1984; Peng, 1990).

Fatty acid composition of neutral lipids (Ueda et al., 1970a, b), glycolipids (Minamide and Ogata, 1972a), and phospholipids (Minamide et al., 1970a; Minamide and Ogata, 1972b) of

field tomatoes is primarily palmitic, stearic, oleic, linoleic, and linolenic acids. The unsaturated fatty acids in phospholipids are increased during ripening on the plant and decreased in the after-ripening stage (Minamide and Ogata, 1972b). Ueda et al. (1970a) investigated ten cultivars of tomatoes for processing; the main fatty acids of average-weight tomatoes are listed in Tables 9.7 and 9.8. The neutral lipids contained more unsaturated acids with a higher unsaturation ratio than the polar lipids (glycolipids and phospholipids), but polar lipids had higher palmitic and linolenic acids.

Minamide et al. (1970b) studied the fatty acid composition of greenhouse tomato phospholipids and found a higher fatty acid content and higher unsaturation ratios. The unsaturated fatty acids are increased during ripening after harvest. Three greenhouse tomato cultivars—GS244, MR13, and Jumbo—were examined (Peng, 1990). Except for GS244, glycolipids are generally higher in concentration (40.4%–43.9%) than the other two lipids. Fatty acids showed a typical composition of plant lipids, palmitic, stearic, oleic, linoleic, and linolenic acids (Table 9.9). There appears to be higher unsaturation in polar lipids than in neutral lipids.

Tomato processing waste consists of skins, seeds, and pulp. The seeds contain 22%–30% crude fat, 16%–22% crude fiber, and 23%–34% crude proteins (Lazos and Kalathenos, 1988), which could be used as essential raw material sources (Al-Wandawi et al., 1985). The fatty acids of tomato seed oil from processed tomato waste are found to be higher in unsaturated fatty acids (Peng, 1983), as presented in Table 9.10.

C. Pepper (*Capsicum annuum*)

The pepper, similar to the tomato, is a perennial in the tropics and an herbaceous annual in the Temperate Zone. The total lipid content is 0.40%–0.45% of fresh weight (Kinsella, 1971; Haytowitz and Matthews, 1984). Wang and Baker (1979) studied chilling injury on pepper fruits and found

that the degree of unsaturation of 18-carbon fatty acids in the polar lipids increased. The fatty acid composition is quite typical of plant lipids and consisted mainly of palmitic, stearic, oleic, linoleic, and linolenic acids (Kinsella, 1971). The neutral lipids and phospholipids are very high in linoleic acid, and glycolipids are rich in linolenic acids (Tables 9.11 and 9.12).

D. Eggplant (*Solanum melongena*)

The eggplant, a member of the deadly nightshade family, is a vegetable of dubious origin. Some say it originated in China some 4000 years ago, and then it was introduced into the Mideast by Arab traders in the eighth century. Others say it originated and was domesticated in India, and then brought home by members of Arab armies in the seventh century. Others yet say it has been grown and eaten as a vegetable in Iran since 1500 BC. The fatty acid composition of eggplant in various preparations is shown in Table 9.13.

III. CRUCIFERS

All vegetable crops in this group belong to the Cruciferae family.

A. Cabbage (*Brassica oleracea*)

The cabbage is a dicotyledonous biennial plant. It is the most important member of the cole crops in our daily diet. It has significant nutritional value and is valuable as a fresh or processed vegetable. The lipid content of cabbage is very low, 0.10%–0.21% (Wheeldon, 1960; Pederson and Albury, 1969; Peng, 1974a, b, 1975, 1982a; Salunkhe et al., 1974), but it is significant to keeping quality. Cabbage lipid composition has been studied (Wheeldon, 1960; Laseter et al., 1968; Komaitis and Melissari-Panagiotou, 1990). In our laboratory, we have investigated cabbage lipid components and their fatty acid composition (Table 9.14). The lipids isolated from the cabbage leaves are predominantly neutral lipids (51.0%), followed by glycolipids (40.8%) and phospholipids (8.2%). It is apparent that cabbage lipids contain more unsaturated fatty acids than saturated. Neutral lipids have a greater degree of unsaturation than polar lipids. The distribution of the fatty acids is mainly

palmitic, stearic, oleic, linoleic, and linolenic acids (Peng, 1974b). The varietal influence on the total lipid content and fatty acids examined by our laboratory (Table 9.15) indicates that the distribution of fatty acids varies but follows a typical plant lipid pattern (Hitchcock and Nichols, 1971; Peng, 1982b).

Leafy vegetables are perishable. Storage is the only means to extend the supply the year round. Cabbage is usually stored after harvest before it reaches the consumer's table. However, it is still physiologically active, with enzymatic and respiratory processes continuing; the storage temperature is crucial, for higher temperatures induce greater physiological activity, requiring more energy. In our laboratory, we found that total lipids decreased more rapidly when cabbage was stored at 7°C than when it was stored at 1°C (Peng, 1979). Fatty acids vary considerably in their quantitative distribution at different storage temperatures (Table 9.16). Total unsaturated fatty acids appear to change more than the saturated acids during storage, and the rate of change is higher at 7°C than at 1°C.

Dickson and Stamer (1975) developed several new high-solid cabbage inbreds that had higher dry matter than the standard cultivars, and a kraut made from such hybrids resulted in less juice. Our laboratory analyzed two of the hybrids, "364 × 326" and "364 × 328." Each high-solid cabbage

contains a different composition and distribution of lipid components. Neutral lipids are the predominant class—63.3% in "364 × 326" and 41.6% in "364 × 328"; phospholipids content is 22.6% and 39.0%; and glycolipids content is 14.1% and 19.4%, respectively (Peng, 1982a). The fatty acid composition of each class is reported in Table 9.17, in which palmitic, palmitoleic (16:1), stearic, oleic, linoleic, and linolenic acids constitute the major fatty acids. Among three lipid classes, phospholipids are higher in unsaturated fatty acids.

Lactic acid fermentation of cabbage has long been a traditional Chinese household skill for preserving this vegetable for off-season use. It produces a palatable, microbiologically safe, economical, and appetizing food that has been enjoyed by Asians for centuries. Vorbeck et al. (1963) reported lipid alterations during the fermentation of cabbage. Peng (1975, 1979) studied lipid changes of cabbage fermented to sauerkraut. Cabbage was fermented, canned, heat-processed, and stored at room temperature, and the total lipids, lipid classes, and fatty acids were analyzed at each stage of storage. Total lipids increased from 0.16 in the fresh cabbage to 0.22% in the sauerkraut after fermentation and then decreased to 0.17% after 8 months of storage (Table 9.18). It was found that the loss of 10.3% in neutral lipids from the original concentration was equal to the combined gains of 0.2% in glycolipids and 10.1% in phospholipids. The overall total lipid content was not altered.

The relative quantitative changes of fatty acids in total lipids are shown in Table 9.19. During fermentation and processing, palmitic, linoleic, and linolenic acids increased slightly, and a further

increase in these acids occurred in storage. On the other hand, stearic and oleic acids declined after 2 months but reappeared after 8 and 12 months of storage. High levels of lignoceric (24:0) and nervonic (24:1) acids could be an artifact during fermentation and storage that certainly affected the percentage of distribution of fatty acids (Peng, 1973, 1974a, 1975). A higher unsaturation ratio indicates the presence of higher unsaturated fatty acids.

Table 9.20 records the relative gross changes in fatty acids in the neutral lipid fraction. Except for palmitic, stearic, oleic, linoleic, and linolenic acids, fatty acids are found in smaller amounts after fermentation and processing. As storage time increases, palmitic and oleic acids are maintained at about the same level, whereas the relative changes of stearic, linoleic, and linolenic acids are varied. Higher unsaturated fatty acids are observed.

The glycolipid fraction is the second most predominant lipid component of cabbage and sauerkraut. It has the same pattern of fatty acid distribution as other fractions, as shown in Table 9.21

(Peng, 1975). Fermentation and subsequent processing cause a considerable decrease of most fatty acids; only linolenic acid is increased markedly with storage. The unsaturation ratio also increases with storage. Phospholipids constitute the smallest lipid fraction in cabbage and sauerkraut (Table 9.22). In contrast to the other classes, most fatty acid concentrations increase during fermentation and processing; however, palmitic, linoleic, and linolenic acids exhibit significant losses. When storage time is increased, the palmitic acid concentration increases steadily, whereas levels of stearic, oleic, linoleic, and linolenic acids decrease noticeably. The phospholipids contain a higher proportion of saturated fatty acids. The unsaturated fatty acids decrease with storage.

B. Cauliflower (*Brassica oleracea* cv. Botrytis)

The total lipid content of cauliflower is quite low, 0.18% (Haytowitz and Matthews, 1984). The fatty acid composition of mitochondrial lipid classes isolated from cauliflower buds shows large amounts of short-chain fatty acids, linolenic, palmitic, linoleic acids (Schwertner and Biale, 1973), and hexadecatrienoic acid (16:3) in glycolipids, as illustrated in Tables 9.23 and 9.24.

Source: From Peng, A.C. (1975). *J. Sci. Food Agric. 26*: 1325–1332.

C. Turnip (*Brassica rapa*)

The turnip is an herbaceous dicotyledonous biennial plant. Its total lipid content is 0.10% (Haytowitz and Matthews, 1984). Different cultivars may have different percentage distributions of fatty acids, but the pattern of distribution is similar (Lima et al., 1965; Lepage, 1967). The main fatty acids are palmitic, oleic, linoleic, and linolenic acids, of which linolenic acid is the most abundant (Table 9.25). Turnip lipids have higher unsaturated fatty acids. The fatty acid composition of turnip, broccoli, Brussel sprout, Kohlrab, and Mustard Greens in various preparations are shown in Tables 9.26 through 9.30, respectively.

IV. CUCURBITS

All vegetable crops in this group belong to the Cucurbitaceae family.

A. Cucumber (*Cucumis sativus*)

The cucumber is an herbaceous annual vine trailing plant. The total lipid content is 0.10%–0.14% (Kinsella, 1971; Peng, 1976a,b; Peng and Geisman, 1976a; Haytowitz and Matthews, 1984; Geduspan

and Peng, 1987). The distribution of cucumber lipids is neutral lipids 29.6%, glycolipids 60.0%, and phospholipids 10.4% (Peng and Geisman, 1976a). This is in contrast to Fishwick et al. (1977), who reported that phospholipids accounted for nearly half the weight of total lipids. Linolenic acid is recorded as the major fatty acid in total lipids (Draper, 1969; Galliard et al., 1976; Peng and Geismann, 1976a) and in neutral lipids, glycolipids, and phospholipids (Peng and Geisman, 1976a; Fishwick et al., 1977; Keppler and Novacky, 1989), which is in contrast to the lower concentration reported by Kinsella (1971). Chilling induced an increase in linolenic acid, and intermittent warming increased fatty acid unsaturation (Wang and Baker, 1979; Parkin and Kuo, 1989). The major fatty acids of fresh cucumber are listed in Table 9.31 (Peng, 1976a). The predominant fatty acids are palmitic, stearic, linoleic, and linolenic acids. Polar lipids have lower unsaturated fatty acids.

Mature green European cucumber fruits, grown in the greenhouse, were treated with butylated hydroxytoluene (BHT) and calcium chloride, stored at 4°C for 7 days, and transferred to 20°C for another 7 days (Geduspan and Peng, 1987). The total lipid content is not affected by chilling or chemical treatment, but changes in the lipid classes are observed. Neutral lipids are increased, and phospholipids are decreased. The predominant fatty acids are palmitic, stearic, oleic, linoleic, and linolenic acids (Table 9.32). Lauric (12:0) and myristic (14:0) acids are decreased by chilling and

chemical treatment. Palmitic acid is the major fatty acid and increases in each lipid class, especially in glycolipids, which increase to more than half the total acids after chemical treatment and chilling. Linoleic acid is increased by calcium chloride treatment in each fraction. However, the linolenic acid response is varied with chilling and chemical treatment. Calcium chloride treatment improves unsaturation slightly.

B. Pickles

Pederson et al. (1964) found marked changes in all lipid fractions during fermentation from both good and bloated dill pickles. Changes in lipid composition and fatty acid distribution of raw cucumbers and fresh-packed pickles during storage were studied by Peng and Geisman (1976a). Total lipids, neutral lipids, and phospholipids increased, and glycolipids decreased throughout the

entire experiment. Table 9.33 compares the distribution of three lipid classes of cucumber and dill pickles (Peng, 1976b). The distribution of fatty acids from the total lipids (Table 9.34) is representative of fresh-packed pickle composition. Alternation may occur through the use of different spice oils. Considerable differences in fatty acids are observed in their quantitative distribution at different storage times among different lipid classes. During storage, total unsaturated fatty acids change more than the saturated acids. The gross changes of fatty acids in the neutral lipid fraction (Table 9.35) illustrate that the major fatty acids in fresh cucumber are palmitic, linoleic, linolenic, and lignoceric (24:0) acids. After packing, most of the fatty acids increased except linoleic and lignoceric acids. After 12 months of storage, all major fatty acids generally increased in quantity. An increase in glycolipid content is typical of a photosynthesizing green plant. The fatty acid distribution of the glycolipid fraction (Table 9.36) is dominated by palmitic, linolenic, and tricosanoic (23:0) acids, followed by lauric, tridecenoic (13:1), stearic, and tricosenoic (23:1) acids. Packing and storage cause a considerable decrease of most fatty acids; however, unsaturation increases with packing and storage. The concentration of all fatty acids in the phospholipid fraction is increased after packing (Table 9.37) except linolenic acid. During storage, the concentration of palmitic, oleic, and linoleic acids decrease consistently, whereas that of lauric, myristic, stearic, and linolenic acids vary. Unsaturation decreases consistently.

Throughout the entire period of storage, palmitic and linolenic acids are the two predominant fatty acids distributed among all four lipid fractions and found in higher concentrations with random alterations. It is also interesting to note that the shorter-chain fatty acids (8:0–10:0) do not appear in the raw cucumber except for a small amount of capric (10:0) acid in the neutral lipids (Table 9.35). The presence of these shorter-chain fatty acids in pickles may indicate degradation of long-chain fatty acids and could influence the flavor of the product during storage.

To better understand brine changes, the fatty acid composition of fresh and recycled brine was analyzed (Peng and Geisman, 1976b). Table 9.38 shows that the predominant fatty acid is linolenic acid followed by caprylic (8:0) and palmitic acids. These three acids are in highest concentration in the fresh brine, then decrease during the first and second recycles, and increase in the third recycle. Lauric acid concentration increases as the brine is recycled. The fatty acids, especially the short-chain fatty acids, could be responsible for the characteristic odor associated with recycled brine.

C. Pumpkin (*Cucurbita* spp.)

Pumpkin is an annual plant. It contains 0.10% total lipids (Haytowitz and Matthews, 1984). The main fatty acids of pumpkin's glycolipids are linolenic and linoleic acids, followed by palmitic acid (Ito et al., 1974). The fatty acid composition of pumpkin and squash/zuccini in various preparations is shown in Tables 9.39 and 9.40, respectively.

V. PULSE CROPS

All vegetable crops in this group belong to the family Leguminosae. They are also referred to as legumes or pulse vegetables, and most of them are consumed in the immature stages of pod and/or seed.

A. Peas (*Pisum sativum*)

Peas are herbaceous annual plants. The total lipid content ranges from 1.2% to 6.0% depending on cultivar (Wagenknecht, 1957; Lee and Mattick, 1961; Haydar and Hadziyev, 1973; Reichert

is high in saturated fatty acids, whereas the cotyledons and embryo contain higher unsaturated acids (Tables 9.41 and 9.42).

B. Soybeans (*Glycine max*)

Immature soybeans (*mao tou*) are soybeans picked green when the pods are greenish yellow and the beans are large and tender. The green soybeans are usually cooked in the pod with some salt and then served. The pod is removed before eating, and the beans are plump and tender. They are considered a delicate hors d'oeuvre (Wang et al., 1979).

The total lipid content of soybeans increases with maturity (Rackis, 1981). There is 1.2% total lipids 9 days after flowering (DAF), which increases to 20.8% at 97 DAF. Neutral lipids increase fivefold at the expense of polar lipids (Privett et al., 1973). Changes in fatty acids are observed in the early stages of seed development. The palmitic, stearic, and linolenic acid concentrations are

reduced, whereas oleic and linoleic acids increase (Table 9.43) from 24 DAF to 72 DAF (Rubel et al., 1972). The unsaturation ratio indicates that the percentage of saturated fatty acids decreases rapidly in the early stages.

VI. SPINACH (*Spinacia oleracea*)

Spinach is an herbaceous annual plant. It belongs to the family Chenopodiaceae (goosefoot) and has 0.35% total lipids (Haytowitz and Matthews, 1984). Linolenic acid is 54.0%–60.0%, palmitic acid

VII. SWEET POTATOES (*Ipomoea batatas*)

The sweet potato is an herbaceous dicotyledonous perennial plant that is grown in tropical and subtropical zones. The total lipid content ranges from 0.6% to 2.7% and varies with cultivar, curing, and storage (Boggess et al., 1967, 1970; Walter et al., 1971; Alexandridis and Lopez, 1979; Charoenpong and Peng, 1990). The Centennial cultivar is composed of 42.1%–48.1% neutral lipids, 30.8%–31.2% glycolipids, and 20.7%–27.1% phospholipids (Walter et al., 1971; Alexandridis and Lopez, 1979); however, processing and storage may alter their distribution. Charoenpong and Peng (1990) found changes in the Georgia Jet cultivar lipid composition under atmospheric and low oxygen (7%) storage at 15.5°C and 85% relative humidity, as shown in Table 9.45. The total lipid content of fresh samples is 0.6%, lower than that of Centennial sweet potatoes when expressed on a dry weight basis (Boggess et al., 1967, 1970; Walter et al., 1971; Alexandridis and Lopez, 1979). Total lipids from both treatments are significantly increased after the first month of storage and then decrease thereafter; this is, probably due to lipid compositional changes during storage or synthesis from nonlipid components (Boggess et al., 1967). Neutral lipids in stored roots are markedly increased under two storage conditions at the expense of polar lipids. Although treatment does not affect the levels of total lipids and lipid fractions, storage time does affect their distributions.

The major fatty acids are palmitic, stearic, oleic, linoleic, and linolenic acids in all lipid fractions, but there are cultivar differences (Boggess et al., 1970) and storage influences (Boggess et al., 1967;

Charoenpong and Peng, 1990). Linoleic acid is the predominant acid, followed by palmitic acid. Storage time and conditions also affect fatty acid distribution (Table 9.46) (Charoenpong and Peng, 1990). Changes in fatty acid composition of each lipid class are shown in Tables 9.47 through 9.49. Linoleic and palmitic acids decreased significantly from the original concentration in all samples of

both treatments but increased at the end of the storage period. Stearic acid increased consistently, and linolenic acid varied with storage time. The unsaturated fatty acids decrease and saturated acids increase during storage. However, phospholipids did not show any change.

Heat processing of sweet potatoes into flakes and subsequent storage alters total lipids, lipid classes, and their fatty acid composition (Walter and Purcell, 1974; Alexandridis and Lopez, 1979). Total lipids decrease significantly, and some glycolipids and phospholipids also decrease after processing and storage. All lipid classes are composed mainly of palmitic and linoleic acids and appreciable amounts of stearic, oleic, linolenic, arachidic (20:0), and heneicosanoic (21:0) acids. Lauric (12:0) acid is found in glycolipids. Although sweet potato is high in unsaturated fatty acids (more than 50%), the unsaturation ratio is decreased upon heat processing and storage. The authors speculated that this could be due to lipids progressively becoming more difficult to extract and/or to volatilizing subsequent to lipid oxidation.

VIII. SWEET CORN (*Zea mays*)

Sweet corn is an annual herbaceous monocotyledonous plant. It belongs to the family Gramineae (grass). It is consumed fresh (e.g., corn on the cob), canned, or frozen. The total lipid content varies with cultivars and strains and ranges from 0.4% to 18.4% (Weber, 1969; Flora and Wiley, 1972; Dudley et al., 1974; Weber and Alexander, 1975; Haytowitz and Matthews, 1984). During kernel development, the total lipids, neutral lipids, glycolipids, and phospholipids reach a maximum concentration 45 days after pollination (DAP), then either decrease or level off thereafter (Leng, 1967; Weber, 1969, 1970; Pascual and Wiley, 1974). The major fatty acids are typical plant lipids containing palmitic, stearic, oleic, linoleic, and linolenic acids (Weber, 1969; Flora and Wiley, 1972; Weber and Alexander, 1975; Leibovitz and Ruckenstein, 1983). The positional distribution of those fatty acids was stereochemically analyzed, and unsaturated fatty acids were found to predominantly occupy the C-2 (middle, or β) position of corn oil triglyceride molecules (Brockerhoff and Yurkowski, 1966; Weber and Alexander, 1975; Ohnishi et al., 1989); 97%–98% of them at this position accounted for unsaturation. Saturated fatty acids were found at the C-1 and C-3 (outer, or α and α′) positions. The fatty acid composition also changes during kernel development from immature to mature (Curtis et al., 1968; Weber, 1969; Jellum, 1970; Poneleit and Davis, 1972), as indicated in Tables 9.50 and 9.51. In the triglyceride fraction, there are large changes in the fatty acid composition from 10 to 30 DAP; the percentages of palmitic, stearic, linoleic, and linolenic acids decrease and oleic acid increases, and the unsaturation ratio reaches its maximum and then remains

nearly constant throughout. The fatty acids of the polar lipids are more saturated, and their unsaturation ratio is much lower than that of the triglycerides. Palmitic, stearic, and linolenic acids decrease, whereas oleic and linoleic acids increase from 10 to 45 DAP; then linoleic acid and the unsaturation ratio start to fall (Weber, 1970).

Corn chips are as popular as potato chips. They are deep-fat fried, and the total lipid content is greatly increased, from 0.4%–18.4% in raw corn to 32.8%–37.6% after frying (Smith et al., 1985). The fatty acid composition of frying oil may have a great influence on the fatty acid profiles of the fried products. Smith et al. (1985) analyzed seven corn snacks purchased from market; the fatty acid contents are shown in Table 9.52. Because the source of frying oil is not known, the variation

TABLE 9.53
Yam Fatty Acid Composition in Various Preparations

Fatty Acids (g/100 g)	16:0	18:0	18:1	18:2	18:3	Fatty Acids, Total Polyunsaturated	Fatty Acids, Total Saturated	Fatty Acids, Total Monounsaturated
Cooked	0.027	0.003	0.005	0.050	0.009	0.060	0.029	0.005
Raw	0.034	0.004	0.006	0.064	0.012	0.076	0.037	0.006

in the main fatty acids is noticed, especially palmitic (9.0%–24.8%), oleic (17.9%–39.0%), elaidic (0%–16.2%), and linoleic (20.7%–51.6%) acids.

IX. YAM (*Dioscorea* spp.)

Yam is a monocotyledonous plant. It belongs to the family Dioscoreaceae. The tuber contains 0.17%–1.5% total lipid content depending on the cultivar (Osagie and Opute, 1982; Coursey, 1983; Haytowitz and Matthews, 1984). Palmitic and linoleic acids are the predominant fatty acids (Opute and Osagie, 1978; Osagie and Opute, 1982; Kouassi et al., 1988). The glycolipids exhibit a relatively higher concentration of linolenic acid (Osagie and Opute, 1982). Yam fatty acid composition in various preparations is shown in Table 9.53.

X. CASSAVA (*Manihot esculenta*)

Cassava is a basic food in the tropics. It is a dicotyledonous perennial bushy shrub and belongs to the family Euphorbiaceae. The total lipid content ranges from 0.30% to 0.48% (Odigboh, 1983; Haytowitz and Matthews, 1984; Ezeala, 1985). The major fatty acids of cassava tubers are oleic (37.5%–43.7%), palmitic (28.8%–35.1%), linoleic (14.5%–23.0%), and linolenic (5.5%–11.0%) acids (Harris, 1970; Hudson and Ogunsua, 1974; Opute and Osagie, 1978; Ezeala, 1985).

XI. AMARANTH (*Amaranthus* spp.)

Edible amaranth is an annual monocotyledonous plant, also called Chinese spinach or tampala, and belongs to the family Amaranthaceae. The total lipid content is 0.33% (Haytowitz and Matthews, 1984), and linolenic, palmitic, linoleic, and oleic acids are the major fatty acids (Fernando and Bean, 1984; Lakshminarayana et al., 1984).

SUMMARY

It is important when consuming a "healthy diet" to include fresh, frozen, or canned vegetables, and as the data presented in this chapter illustrate the consumption of vegetables, in general, give a favorable polyunsaturated to saturated fatty acid ratio and in many vegetables a favorable omega 3 to omega 6 ratio.

10 Fatty Acids in Oilseeds (Vegetable Oils)

Pamela J. White

CONTENTS

I. INTRODUCTION

Oilseeds are, by definition, those seeds or crops grown mainly for their oil. This chapter presents data on the fatty acid composition of selected vegetable oils, factors affecting fatty acid composition, general stability of the oil, factors affecting its stability, and any special features that make the oil or its production unique. Other chapters deal specifically with fatty acids in fruits and fruit products, in vegetables and vegetable products, and in grains and grain products; therefore, oils not discussed in this chapter will be covered there. There may also be some overlap among chapters. A comprehensive reference regarding all aspects of industrial and edible oil and fat products can be found elsewhere (Shahidi, 2005).

Table 10.1 presents detailed data on the typical fatty acid composition of all oils, as traditional sources, discussed in this chapter plus some animal fats and other unique fats and oils for comparison Panford and deMan (1990). Although the data are not discussed, the table also includes typical ranges for the iodine value and the saponification value for handy reference. The compositions listed are for conventional vegetable oils. As noted in this chapter and in Chapter 15, "Genetic Alteration of Food Fats and Oils," gene alternations have vastly expanded the available fatty acid compositions possible in most vegetable oil crops; thus, many additional modified crops with altered fatty acid compositions exist.

Although the fatty acid composition of many vegetable oils has been reported in the literature since the early 1900s, the accuracy of the reported data has improved dramatically since the introduction

TABLE 10.1
Typical Compositions and Chemical Constants of Common Edible Fats and Oils[a]

Butyric	Caproic	Caprylic	Caprie	Undecanoic	Lauric	Tridecanoic	Myristic	Myristoleic	Pentadecanoic	Pentadecenoic	Palmitic	Palmitoleic	Margaric	Margaroleic	Stearic	Oleic	Linoleic

[a] Fatty acid compositions were determined by GLC and are expressed as mean average weight percent composition on a fatty acid basis. Trace acids (less than 0.1%) are excluded.

[b] Low-erucic-acid rapeseed oil.

[c] Values from Panford and deMan (1990).

[d] Hammond et al. (1997) identified this fatty acid as *cis*-11-eicosenoate.

of gas–liquid chromatography (GLC) techniques in the 1950s. In fact, better separation columns and new techniques continue to provide more accurate and reliable data. Other modern procedures such as high-performance liquid chromatography (HPLC) are also good methods. The fatty acid data reported in this chapter are derived from papers published after 1960 and where modern methodology was used. Even so, the data are somewhat variable, because many GLC and HPLC techniques are available and data between laboratories are not always completely comparable.

In addition to variations in reported fatty acid composition that occur because of differences in measuring techniques, there are also natural variations in the fatty acids produced in an oilseed. The fatty acids produced in any one type of oilseed may vary with geographical location, soil type, climate, moisture, temperature, maturity of the seed, and agricultural practice (Chu and Sheldon, 1979). For example, sunflower oil grown in Minnesota contained about 70% linoleic acid (18:2), whereas that grown in Texas contained about 30% (18:2) (Purdy, 1986). In addition, damage by

Nezara veridula L. (a common species of stinkbug) was shown to increase the palmitic acid (16:0), stearic acid (18:0), and oleic acid (18:1) percentages and to decrease the 18:2 and linolenic acid (18:3) percentages of soybean oils (Todd et al., 1973). With soybeans, low temperatures were associated with a low oil content and increased unsaturation of oil under field conditions (Howell and Cartter, 1953; Howell and Collins, 1957) and controlled temperature conditions (Howell and Cartter, 1958). Finally, lower temperatures produced increased unsaturation in flax (linseed) oil but the oil content also increased (Sosulski and Gore, 1964; Canvin, 1965; Dybing and Zimmerman, 1965). Factors such as these, which influence the fatty acid composition of oils, are discussed.

Recent attempts to alter genetically the fatty acid composition of major vegetable oils (e.g., canola, soybean, and sunflower) have also resulted in changing patterns of fatty acids in the oilseeds. The variation in the fatty acid pattern of any one vegetable oilseed is expanding as the demand for specialty oils for specialty markets increases. A main driving force for changing fatty acid composition, either by plant breeding techniques or by transgenic means, for edible oil use of the oilseeds has been the increasing recognition of the health implications. For example, many nations around the world have banned the sales of foods containing *trans* fats arising from the process called hydrogenation, suggested a restricted amount of *trans* fats for consumption, or begun mandatory labeling of foods containing *trans* fatty acids. The process of hydrogenation results in a shift of some of the double bonds within a fatty acid from the *cis* position, which is naturally found in vegetable oils, to the *trans* position (King and White, 1999). *Trans* fatty acids are also found in fats from animal sources such as beef, milk, and cheese. Smallbone and Saharabudhe (1985) reported amounts of *trans*-isomers of 18:1 found in partially hydrogenated soybean, canola, and sunflower oils. The original oils contained no *trans*-18:1 isomers, whereas after partial hydrogenation canola oil contained 32.9%, soybean oil contained 26.8%, and sunflower oil contained 56.0% of the isomer. Strocchi (1981) reported *trans*-18:1 levels of 59.1% in hydrogenated corn oil and 26.6% in corn oil margarine. Levels of *cis–trans*-18:2 or of *trans–trans*-18:2 ranged from trace amounts to 0.2% in both products.

In March 2003, Denmark was the first country to officially suggest restricting *trans* fatty acids in the diet. They adopted legislation restricting *trans* fatty acids in oils and processed foodstuffs containing fats and oils as ingredients to <2%, but exempted naturally occurring *trans* fatty acids in animal fats. In the United Kingdom, a major retailer, Marks and Spencer, banned sales of processed foods containing hydrogenated fats on November 24, 2005. Canada began mandatory labeling of *trans* fatty acids for processed foods on December 12, 2005 (Health Canada, 2003), followed closely by the United States, who began mandatory labeling of *trans* fatty acids in foods on January 1, 2006 (Food and Drug Administration, 2003). The goals of oilseed modifications, then, have been to provide suitable fatty acid compositions in the extracted edible oils that allow for oxidative and frying stability, as well as provide good flavor without hydrogenation, the major cause of *trans* fatty acids in oils.

II. CANOLA OIL (LOW-ERUCIC-ACID RAPESEED OIL WITH LOW GLUCOSINOLATES)

Canola is the name used to identify rapeseed cultivars of *Brassica napus* and *Brassica campestris* that have been selectively bred to produce oil that contains less than 2% erucic acid (22:1) (Eskin et al., 1996). In addition, the seed must contain low levels of glucosinolates. Original rapeseed cultivars contained 25%–50% erucic acid in the oils and fairly high amounts (80 μM/g) of glucosinolates in the seed (Abraham and deMan, 1988). These cultivars have been grown in China and India for about 4000 years and, more recently, in Northern Europe. Concern about the cardiopathic potential of 22:1 in the diet has resulted in the development of new cultivars (Daun, 1986). The glucosinolates were reduced to improve the quality of both the meal and the oil. It is thought that the glucosinolates hydrolyze during the crushing of the seed, thus releasing sulfur compounds into the oil (Rutkowski et al., 1982; Abraham and deMan, 1987, 1988). The presence of sulfur in the oil

poisons hydrogenation catalysts (Klimmek, 1984; Abraham and deMan, 1986) produces unpleasant odors during heating (Moser et al., 1965; Dobbs et al., 1978), and adversely affects the processing of rapeseed (Rutkowski et al., 1982). It may also enhance the development of thyroid disease. The current level of sulfur found in refined oils processed from the new canola varieties is about 3–10 mg/kg (Abraham and deMan, 1988). Although this low level reduces the health risk and odor problems in the oil, the small amount of sulfur still can reduce the effectiveness of hydrogenation catalysts. Methods have been developed to remove sulfur compounds from canola oil (Abraham and deMan, 1988).

The adoption of canola oil for human consumption in Canada and the United States has been unique because of the health and safety effects of the original rapeseed oils just mentioned. In Canada, the characteristics of canola oil must conform to a standard established by the Canadian General Standards Board (CGSB, 1987), which makes canola oil comparable in quality to that of any other vegetable oil currently on the market. In 1985, the Food and Drug Administration of the United States granted the status of Generally Recognized as Safe (GRAS) to canola oil, and North American companies now refine to sell it. For 2005–2006, rapeseed/canola oil was projected to rank third among major oils in world production, at 16.59 million metric tons (Table 10.2) (USDA, 2006), a ranking it has held for many years.

The typical fatty acid composition of canola oil is shown in Table 10.1. Of particular interest are its high oleic acid (18:1) content, which is similar to that of olive oil, and its high level of linolenic acid (18:3). The only other major vegetable oil to have significant amounts of 18:3 is soybean oil. In addition, canola oil has the lowest level of saturated fatty acids of all the major vegetable oils. In general, canola oil is intermediate among vegetable oils in its level of polyunsaturated fatty acids (PUFAs; 30%–35%). This level is lower than soybean, sunflower, corn, and cottonseed but higher than peanut and palm oils (Sebastian, 1985; Kupranyez et al., 1986).

The odor or flavor of fully refined, deodorized canola oil is described as bland, slightly nutty, and buttery when it is fresh, but grassy, painty, or rancid off-flavors develop during storage (Warner et al., 1989). The stability problem of canola oil is attributed to its high level of 18:3. The role of 18:3 in the development of off-flavors in oils is well documented (Moser et al., 1965), and it is discussed in this chapter under soybean oil below. Some researchers have suggested that the presence of the

small amounts of erucic acid in canola oil may inhibit the enzyme lipoxygenase, which is known to enhance the oxidation of unsaturated fatty acids, especially 18:3 (Downey, 1976), thus improving the keeping quality of rapeseed oils (Moser et al., 1965). Comparison of eight different commercially processed vegetable oils after storage for 8 and 16 days at 60°C showed that canola oil had lower peroxide values (PVs) and total GLC volatiles than the other oils tested: corn, cottonseed, olive, peanut, safflower, soybean, and sunflower (Snyder et al., 1985). However, gas chromatography and mass spectrometry revealed the presence of butylated hydroxytoluene in the canola oil, thus enhancing its stability. Canola oil was also more stable in an active oxygen test than oils from sunflower, corn, soybean, and butterfat, but less stable than olive oil, peanut oil, and lard (deMan et al., 1987). In contrast, canola oil was less stable than several soybean lines, as measured by PVs and sensory tests, in a 60°C storage test in the dark (Liu and White, 1992a). Warner et al. (1989) compared the flavor stability of canola, soybean, and sunflower oils during accelerated storage at 60°C. Sensory panelists noted that sunflower and canola oils were less stable than soybean oil. In addition, oxidation induction periods, as assessed by PV, were 1 day for sunflower and canola oils and 5 days for soybean oil; thus, canola oil was much less flavor stable than the other oils. Malcolmson et al. (1994), however, noted that oils in the latter two studies were deodorized in the laboratory, where lower temperatures of 220°C–240°C were used. If higher deodorization temperatures generally associated with commercial processing of canola oil had been used, the results might have been different.

Dobbs et al. (1978) found that low-erucic-acid rapeseed oil (LEAR; the forerunner to current canola oil), when heated to 190°C and subsequently smelled, had a significantly stronger odor than did sunflower, corn, and safflower oils. Soybean oil was intermediate in strength. Canola and soybean solid and liquid fats were compared in frying studies (Stevenson et al., 1984), in which the solid fats have been hydrogenated and the liquid fats lightly hydrogenated. The properties of the canola and soybean products were quite similar. On the other hand, in a study by Liu and White (1992b), in which bread cubes were fried in the canola and soybean oils and then stored in the dark, canola was much less stable to oxidation than were the soybean oils.

The smoke point is a good indicator of the usefulness of an oil for frying. The higher the smoke point, the more stable the oil at frying temperatures. Canola solid and liquid fats have slightly lower smoke points than similar soybean fats. Sensory evaluation of French fried potatoes using canola and soybean oils at 1, 2, 4, 6, and 10 days of heating the fats indicated few differences in quality between the two oils (Stevenson et al., 1984).

Canola and other rapeseed oils have fewer natural tocopherols than oils such as corn and soybean. Ackman (1983) reported a total tocopherol content in canola oil of 660 mg/kg oil, with alpha, gamma, and delta homologues contributing 190, 430, and 40 mg/kg, respectively. Müller-Mulot (1976) reported a total tocopherol level in canola oil of 271.4 mg/kg, with alpha, beta, gamma, and delta homologues representing 70, 16, 178, and 7.4 mg/kg of oil, respectively. These relatively low levels of tocopherols may contribute to the oxidative instability of canola oil.

As with the other major vegetable oils, new types of canola oil continue to be developed with altered fatty acid patterns to improve the quality of the oil. For example, Scarth et al. (1988) reported the development of a *B. napus* L. (Stellar) summer rape line that produces seed oil with 3% 18:3 and 28% 18:2. This oil has a shorter hydrogenation time and better stability than standard canola oils. The Stellarline was created through a combination of mutation and breeding, and it is the first rapeseed cultivar having the quality standards required for canola oil (i.e., low erucic acid and low glucosinolate). In another study, two canola oils from similar genetic origin and having a high-18:3 (12.5%) or a low-18:3 (2.5%) composition were evaluated for odor acceptance (Vaisey-Genser et al., 1994). The 18:3 content of these oils was similar to that of the licensed varieties of Westar (high 18:3) and Stellar (low 18:3). The consumer-acceptance threshold was 12.5 days for the high-18:3 canola oil and 34.3 days for the low-18:3 canola oil, indicating substantially greater stability for oil from the genetically modified cultivar. Further chemical studies on oils from these canola cultivars confirmed that the low-18:3 canola oil produced significantly fewer volatiles and lower PVs than

the high-18:3 canola oil during accelerated storage at 60°C in the dark (Malcolmson et al., 1996). Earlier studies on these oils showed that the low-18:3 canola oil did not change significantly in odor intensity or odor pleasantness during 12-day storage, whereas Westar oil changed significantly during the same time (Przybylski et al., 1993).

In frying tests, canola oil obtained from seed modified by breeding to contain 1.7% 18:3 in the oil had significantly ($p < .05$) less room odor intensity after initial heating tests at 190°C than normal canola oil that contained 10.1% 18:3 (Warner and Mounts, 1993). Other chemical indices, such as free fatty acids, polar compounds, and foam heights, were significantly ($p < .05$) less in the low-18:3 oil than in the normal canola oil after 5 h of frying. The potatoes fried in normal canola oil were described by the sensory panel as being fishy. Three high-18:1 canola oils with different levels of 18:3, along with a partially hydrogenated canola, a medium-high-18:1 sunflower oil, and a commercial palm olein, were compared during frying of potato chips (Xu et al., 1999). The 18:3 concentration of the canola oils was inversely related to sensory ranking of the chips and to the oxidative stability of the oils. The low-18:3 canola and the sunflower oils ranked best among the oils tested in sensory evaluations. Partially hydrogenated canola oil received the lowest scores in sensory evaluations.

In response to the push by industry to reduce or eliminate *trans* fats in the diet to comply with *trans*-fat labeling, Dow AgroSciences LLC released specially bred NEXERA™ canola seeds that produce oil with high (>70%) oleic and low (<3%) linolenic acid concentrations (Anon., 2006). The oils were designed to replace partially hydrogenated oils in frying operations. Bunge Canada offers this oil under the brand name of Nutra-Clear®, and Canbra Foods sells it under the brand name of Canola Harvest HiLo™.

III. CORN OIL

Corn oil is a by-product of the corn wet-milling industries and is recovered from the corn germ. Corn generally is grown to be used as starch, sweeteners, alcohol, meal, and animal feed, so the amounts of corn available for oil production are derived from those markets. In general, corn oil has historically been in short supply, although increased demand for corn sweeteners (high-fructose corn syrup) and fuel alcohol (ethanol) from corn is increasing the amount of available corn oil. World production of corn oil does not generally rank among the top 10 major oils (Table 10.2) (USDA, 2006). United States' corn oil production for 2005–2006, however, was estimated to be over 2.45 billion pounds, ranking second behind soybean oil, at 20.04 billion pounds.

Crude corn oil is refined, bleached, and deodorized to produce a good-quality edible oil. The typical fatty acid composition of commercial corn oil in the United States is shown in Table 10.1. This corn oil is derived from "Corn Belt"-grown dent corn, which was shown to have a remarkably constant fatty acid distribution when 103 samples were grown over a 2.5-year period during the 1960s (Beadle et al., 1965). However, studies have shown that the oil content and composition of some corn lines are affected by the geographical locations in which the corn is grown (Genter et al., 1956; Jellum and Marion, 1966).

Thompson et al. (1973) found considerable differences in response to temperature among four corn genotypes. One inbred line, Pa36, which was high in 18:2, was quite stable for most of its fatty acids when grown at five different controlled temperatures. Inbred GE82, which was low in 18:2, was highly responsive to temperature difference for the fatty acids. In general, there was an increased unsaturation of the seed oil with decreased temperatures during seed maturation. Other researchers have also noted that corn oil from warmer regions had a higher proportion of saturated fatty acids than did corn oil from cooler areas (Leibovitz and Ruckenstein, 1983).

The application of herbicides has also been demonstrated to alter slightly the fatty acid composition of corn oil. Wilkinson and Hardcastle (1973, 1974) found that increased application rates of certain combinations of herbicides caused changes in the fatty acid composition of corn oil. However although statistically significant, the changes were not of major importance, representing alterations

of only a few percentage points. Southern corn leaf blight (Jellum, 1971) and nitrogen and boron (Jellum et al., 1973) did not influence fatty acid composition. In general, U.S. corn oil increased in polyunsaturation, mainly as 18:2, by about 5%–8% from 1974 to 1986 (White and Weber, 2003), likely because of the selection of parental lines with desirable agronomic traits. Although environmental factors have some effect on fatty acid composition, the principal cause of variation is genetic (Leibovitz and Ruckenstein, 1983).

Oils from different corn cultivars have different fatty acid compositions. Corn oils from Argentina, Russia, and Italy were reported to be more saturated than those produced in the United States (Sonntag, 1979). A wide range of fatty acid profiles was found in corn oil from elite, unadapted corn-breeding materials originating from the United States, Chile, Argentina, and Uruguay and grown in Ames, Iowa (Dunlap et al., 1995a). A total of 250 different lines (50 lines from each of five accessions) from each country were evaluated. The oil from corn of foreign origin was slightly more saturated than that of United States' origin (14.4%–15.1% vs. 13.4%). The United States' corn oil averaged 30.5% 18:1 and 53.7% 18:2. This fatty acid profile closely matched that of values obtained by Tan and Morrison (1979) for United States' corn oil. In other work, Dunlap et al. (1995b) reported fatty acid averages of 25.2% 18:1 and 59.7% 18:2 for 418 corn hybrids and 98 corn inbreds grown in Iowa. These values represent compositions typical of commercially available corn oils, since they were taken from adapted, elite materials. The compositions were similar to values reported by others for commercially refined oils from Corn Belt populations (Beadle et al., 1965; Leibovitz and Ruckenstein, 1983). Even so, Dunlap et al. (1995b) found relatively wide ranges of fatty acid profiles present in these adapted, elite corn-breeding materials with ranges for each fatty acid as follows: 16:0, 6.7%–16.5%; 16:1, 0.0%–1.2%; 18:0, 0.7%–6.6%; 18:1, 16.2%–43.8%; 18:2, 39.5%–69.5%; 18:3, 0.0%–3.1%; and arachidic acid (20:0, 0.0%–1.0%). Small amounts of myristic (14:0), margaric (17:0), and gadoleic (20:1) acids were also found. Oleic acid composition positively correlated with kernel oil concentration (Alrefai et al., 1995).

Elsewhere, Thompson et al. (1973) reported ranges in fatty acid compositions of three inbred lines and one variety of corn. The 16:0 ranged from 9.4% to 13.3%; 18:0, 1.2% to 11.5%; 18:1, 17.0% to 49.1%; 18:2, 36.4% to 70.8%; and 18:3, 0.6% to 1.5%. Jellum bred corn for fatty acid variability and achieved the following ranges for various fatty acids in corn cultivars: 16:0, 5%–24%; 18:0, 0.5%–20%; 18:1, 15%–65%; and 18:2, 15%–75%. After that, he released an inbred with 18% 18:0 (Jellum, 1984). P. J. White and E. G. Hammond (personal communication, 2006) surveyed over 500 lines of corn for variations in fatty acid composition. These composition values ranged as follows: 16:0, 7%–24%; unknown (16:1?), 0%–9%; 18:0, 0%–13%; 18:1, 15%–50%; 18:2, 5%–70%; 18:3, 0%–9%; and 20:0, 0%–11%. The results form these many studies give a starting point for future work of breeding corn designed to produce oils of specific fatty acid composition. The E. I. du Pont de Nemours & Company were issued United States' and world patents for a corn oil from seed genetically modified to contain 65% 18:1 (Leto and Ulrich, 1995, 2001). This oil was evaluated for its frying quality and oxidative stability, and was shown to have significantly ($p < .05$) lower total polar compound levels after 20 h of heating and frying at 190°C than normal corn oil (23.8% 18:1), hydrogenated corn oil, and high-oleic sunflower oils (80% and 90% 18:1) (Warner and Knowlton, 1997). The high-oleic corn oil was also significantly ($p < .05$) more stable than normal corn oil after accelerated storage at 60°C, as evaluated by sensory-panel flavor scores and PVs.

A patent was issued for a method to improve corn lines by altering fatty acid composition, as well as protein, total oil, and starch, by introgressing genes from the native corn relative, *Tripsacum dactyloides* L. through several cycles of selective breeding and evaluation (Duvick et al., 2003). Fatty acid alterations included elevated oleic acid, and/or elevated or lowered saturated fatty acid compositions. The progeny from these lines backcrossed with Corn Belt inbred lines were grown and evaluated (Duvick et al., 2006). The relative amounts of oleic acid and saturated fatty acids (palmitic and stearic acids) were greatly increased by selective breeding within the *Tripsacum* introgressed corn germplasm. The target was to create new corn oils with more healthful fatty acid compositions and products with reduced *trans* fats from these corn lines. To reduce the C:16 fatty acids

(palmitic) and make other alterations in the fatty acid profile of corn oil, genes encoding acyl–acyl carrier protein thioesterases were cloned from maize (Rubin-Wilson et al., 1998).

Corn oil generally is considered to be fairly stable to oxidation; thus, its flavor quality is very good. A study evaluating the flavor quality of oils stored in the dark at 60°C for 12 days (Shen et al., 2001) revealed that by day 6, corn oil had significantly ($p < .05$) less off-flavor than canola oil, and tended to have less off-flavor than soybean oil. There may be several reasons for this innate stability. As noted above, corn oil contains only a trace of 18:3, a fatty acid that oxidizes more than twice as quickly as 18:2 and 20 times as quickly as 18:1 (Fatemi and Hammond, 1980). Furthermore, the unsaturated fatty acids tend to occupy the 2-position of the triacylglycerol molecule, thus affording protection to some of the unsaturated acids (Weber, 1978; Strocchi, 1981; Lau et al., 1982). In addition, corn oil is the only oil containing a significant amount of ubiquinone (200 mg/kg; a benzoquinone with a side chain of 6–10 prenyl units), an excellent antioxidant that helps protect oils against oxidative rancidity (Folkers, 1974; Kamei et al., 1986). The oil contains relatively good amounts of tocopherols (also good antioxidants) with estimates ranging from 495 to 1071 mg/kg oil (Müller-Mulot, 1976; Carpenter, 1979; Slover et al., 1983; Van Niekerk and Burger, 1985; Tan, 1989; Warner and Mounts, 1990; Boki et al., 1992; Clough, 1992). Individual homologues ranged as follows: alpha, 121–281 mg/kg; beta, 0–94 mg/kg; gamma, 346–790 mg/kg; and delta, 10–42 mg/kg. Small amounts of tocotrienols, differing from tocopherols by their unsaturated side chain, were also reported. Corn oil also contains many other phenolic components, especially ferulic acid (5.79 mg/kg), a very active antioxidant, present as an ester of dihydro-beta-sitosterol, that likely contributes to the oil's excellent oxidative stability (Bernwieser and Sontag, 1992).

IV. COTTONSEED OIL

Cottonseed oil was the first edible vegetable oil produced in the United States, and its production dominated the world edible oil market until just before World War II. At that time, more sophisticated cultivation of soybeans resulted in good-quality soybean oil and its dominance in the world market. Cottonseed oil was projected to rank sixth for 2005–2006 in world production of major oils, at 4.67 million metric tons (Table 10.2) (USDA, 2006). Cottonseed oil is a by-product of cotton fiber production and is derived largely from the seeds of *Gossypium hirsutum*. A small portion (2% of the United States' crop and 8% worldwide) of cottonseed comes from the seeds of *Gossypium barbadense.*

Crude cottonseed oil is unusual in that it contains almost 2% of nonglyceride materials, most of which are removed during refining (Sonntag, 1979). These materials include gossypol, phospholipids, sterols, resins, carbohydrates, and related pigments. The most significant of these is gossypol, which is a complex phenolic substance that gives a strong red to brown color in crude cottonseed oil and that has been shown to have antioxidant properties (Sonntag, 1979). Gossypol is also toxic, so its removal from the oil is of concern. Many studies have reported the effects of gossypol on animal production and physiology (Berardi and Goldblatt, 1980). This subject will be discussed elsewhere in this book. In practical terms, all but a trace of the gossypol is removed during refining (Yabe et al., 1984), but enough is left to give cottonseed oil its characteristic yellow color.

The typical fatty acid composition of refined cottonseed oil is presented in Table 10.1. As with most vegetable oils, the actual fatty acid composition varies, depending on genetic and environmental factors. In a study by Cherry et al. (1978), the fatty acid composition and oil quantity varied significantly among cultivars and growing location within Texas. The range in contents of the major fatty acids was as follows: 16:0, 21.6%–26.2%; 16:1, 0.6%–0.8%; 18:0, 2.3%–2.9%; 18:1, 15.2%–19.9%; and 18:2, 49.1%–57.6%. Badami et al. (1978) studied the fatty acid composition of five varieties of cottonseed oils grown in India and found the following ranges: 14:0, 0.8%–1.1%; 16:0, 23.0%–23.9%; 18:0, 2.7%–4.2%; 18:1, 11.9%–22.8%; 18:2, 47.5%–58.1%; 20:0, 0.3%–0.7%; and 22:0, 0.3%–1.4%. Badami et al. (1977) reported similar fatty acid ranges for the oils from seven varieties of cottonseed grown in India. Yazicioglu and Wetherilt (1985) reported the effects of three

different growing locations in Turkey on the fatty acid compositions of 22 cottonseed varieties. The wetter the climate, the more unsaturated were the oils, but the total unsaturates varied only slightly, from 73.3% in the wettest climate to 71.7% in the driest climate. The triacylglycerol composition of cottonseed oil is unique in that almost 29% of the molecules contain two 18:2 and one saturated fatty acid (most likely, 16:0) (Bezard et al., 1990; Bland et al., 1991). The next most common type (16%–19%) consists of three 18:2 molecules.

Cottonseed oil also contains small quantities of cyclopropenoid fatty acids (CPFAs), presumably sterculic and malvalic, in amounts measured between 0.1% and 0.3% (Lawhon et al., 1977), 0.6% and 2.1% (Badami et al., 1978), or 0.6% and 1.1% (Badami et al., 1977). The removal of CPFAs is necessary, because the fatty acids have been shown to display several adverse biological effects (Carter and Frampton, 1964). In addition, as little as 25 mg/day of sterculic acid in the diet of laying hens was shown to cause pink coloration in the eggs (Masson et al., 1957). Fortunately, the deodorization step in the refining of cottonseed oil removes all but small amounts of the CPFAs. Eaves et al. (1968) reported a drop in CPFAs from 0.53% to 0.04% with conventional deodorization. Researchers continue to examine methods for the removal of CPFAs from cottonseed oil (Gilkison and Shone, 1993).

Traditionally, in the breeding and production of cottonseed, oil quality has been ignored. With increased competition from other oil crops, the cottonseed growers have recognized the need to produce better quality seed and oils. New cottonseed cultivars have been developed to improve several quality factors, including (1) quantities of oil and (2) changes in select fatty acids, in particular, a significant decrease in 16:0 and an increase in 18:1 (Cherry, 1983). One variety, Acala SJ-2, and a newer cultivar (Acala SJ-5) were shown to have increased oil contents, increased unsaturation, and reduced gossypol when compared with traditional cottonseed varieties. Some work on the effect of mutagens on fatty acids in cottonseed oil was reported by Russian scientists with decreases in 16:0 and 18:1 and increases in 18:2 (Daminov and Topvoldiev, 1974; Topvoldiev et al., 1975). The influence of herbicide applications on fatty acid composition in cottonseed oil has also been studied, with only minor changes in the fatty acids reported (Wilkinson and Hardcastle, 1972a,b). Novel gene constructs were applied to cottonseed to alter fatty acid composition of the oil (Green et al., 2001). The 18:0 was increased from ~2%–3% up to 40% by down regulating the *ghSAD-1* gene, and the 18:1 from ~15% up to 77% by silencing the *ghFAD2-1* gene (Liu et al., 2002). Furthermore, these researchers were able to stack the gene effects to achieve novel combinations of the major fatty acids in cottonseed oil, thus helping cottonseed oil enter the competitive market of nonhydrogenated, no-*trans* edible oils for use in margarines, deep-fat frying, and potentially high-value confections.

Interest in finding oils with altered fatty acid patterns has also resulted in searches of wild species within the *Gossypium* genus. Khattab et al. (1977) found that 16:0 ranged from 17.9% to 34.9% in *Gossypium sturtianum* and *G. hirsutum*, respectively, and that 18:1 ranged from 14.4% in *Gossypium somalense* to 32.5% in *Gossypium anomalum*. Earlier, Carter et al. (1966) observed a change in 16:0, from 22% for *Gossypium arboretum* L. to 35% for *Gossypium aridum* Skovsted; in 18:1, from 16% for *Gossypium aridum* to 36% for *Gossypium armourianum* Kearney; and in 18:2, from 35% for *G. armourianum* Kearney to 55% for *G. hirsutum* L. Perhaps the genes from the wild species would be valuable in the production of commercial genotypes with improved oil composition.

Starting in the early 1960s, there was considerable interest in the development of cottonseed varieties known as glandless, which contain no gossypol. It was thought that the gossypol-free seed might be used as a protein seed for human consumption. Although the protein and oil quality of some glandless varieties are comparable to or better than glanded varieties, the market for glandless seed did not catch on (Cherry, 1983). The oil produced from the glandless seed is light colored because of the absence of the gossypol pigment. Cherry (1983) showed that there was little difference in oil and fatty acid composition of seed from the glanded and glandless varieties; however, Lawhon et al. (1977) reported that glandless oil was slightly more unsaturated than glanded oil.

Cottonseed oil contains natural antioxidants in the form of tocopherols, with around 1000 mg/kg oil of total tocopherols in the crude oil (Müller-Mulot, 1976; List and Friedrich, 1989). Refined oils

generally retain about 60%–70% of the tocopherols found in the crude oil. Slover et al. (1969) recovered 320 mg/kg of alpha-tocopherol and 313 mg/kg of gamma-tocopherol from a commercially refined oil, for a total of 633 mg/kg tocopherol. Cottonseed contains high amounts of phenolic acids compared with other oilseeds, some of which would presumably be carried into the oil during extraction and could contribute to oxidative stability of the oil. The predominant phenolic acids of both glanded and glandless cottonseed include *trans*-ferulic, *trans-p*-coumeric, *p*-hydroxybenzoic, and *trans*-caffeic acids (Dabrowski and Sosulski, 1984).

Refined cottonseed oil is typically used as a salad and cooking oil and in the preparation of shortenings and margarines. The refined oil is not as stable to oxidation as is the crude oil, likely because of removal of the gossypol and part of the tocopherols. Berger et al. (1970) reported that cottonseed oil was not particularly stable when measured by a standard active oxygen test (AOM). Snyder et al. (1985) found cottonseed oil to be more resistant to peroxide development than corn, olive, peanut, safflower, sunflower, and soybean oils under storage conditions of 60°C for 16 days; however, at 8 days, cottonseed oil was only intermediate in its oxidative stability. The flavor of foods fried in pure cottonseed oil had the highest intensity of fried-food flavor (considered to be a positive attribute) when compared with foods fried in a variety of oil blends made from high-oleic sunflower and cottonseed oils (Warner et al., 1997). As might be predicted, however, the higher levels of 18:2 in the cottonseed oil resulted in reduced frying oil stability as measured by total polar compounds. In general, cottonseed is suitably stable for use in most foods, and provides desirable flavors in fried-food appearance, which is likely caused by the high proportion of triacylglycerol molecules containing two 18:2 and one saturated fatty acid, as noted earlier (Bland et al., 1991).

V. LINSEED OIL (FLAX)

Flax is grown primarily for the production of linseed oil, which, because of its high content of α-linolenic acid (18:3n-3), is an excellent drying oil that is used in paints, varnishes, and linoleum (Bhatty and Rowland, 1990). Worldwide production of linseed oil does not generally rank among the top ten major vegetable oils (USDA, 2006); however, its production as an edible oil product has increased in recent years, with the development of linseed varieties producing oils with modified fatty acid compositions. Linseed oil production in the United States was estimated to be 335 million pounds for 2005–2006 (Table 10.2) (USDA, 2006). There is only one original species of cultivated flaxseed, *Linum usitatissimum*, and it contains 18:3n-3 ranging from 40% to 63% or higher (Batta et al., 1985). A typical fatty acid distribution for linseed oil is shown in Table 10.1.

The fatty acid composition of linseed oil is highly affected by temperature and other climatic conditions (Yermanos et al., 1969; Agrawal, 1971). Rai et al. (1989) grew 35 different linseed genotypes under three different agroclimatic conditions and found highly significant differences among genotypes (and varieties) and between genotypes and environment. All the fatty acids were affected significantly except for 16:0. In general, flaxseed grown in northern, cooler climates in Canada produces linseed oil with more unsaturation than that grown in southern, warmer climates (also in Canada) (McGregor and Carson, 1961). Sosulski and Gore (1964) found 18:3 percentages of 48.1% and 51.6% for two flax types when grown at 65°F. At 75°F, the same two types produced 35.4% and 38.0% 18:3, respectively.

Recent reports on the nutritional value of n-3 fatty acids have prompted interest in the development of edible linseed oils with 18:3n-3 levels comparable to those found in soybean and canola oils (Bhatty and Rowland, 1990). With such high-18:3 content, linseed oil is not currently suited for use in foods because of its tremendous oxidative instability.

Mutation breeding of the cultivated flaxseed, *L. usitatissimum*, along with traditional methods of selective breeding, has resulted in new and improved linseed types, producing oil suitable for human consumption. Green and Marshall (1981) and Green (1986) reported some success in mutation breeding of flax, resulting in oil containing less than 2% 18:3. Australian researchers developed a low-18:3 linseed oil containing 2% 18:3 and 72% 18:2, which they call Linola™ (Haumann, 1990). Commercial production of Linola™ began in Australia during the 1993–1994 crop year,

and in Europe during 1995–1996. In Canada, solin is the generic name for flaxseed that yields oil containing less than 5% 18:3, and the Flax Council of Canada adopted the name solin oil as the common or usual name used for this oil. Under grade specifications established by the Canadian Grain Commission during 1995, solin must have a yellow seed coat. Linola™ 947, 989, and 1084 are exclusive lines developed by the United Grain Commission from the Australian variety (J. Daun, personal communication, 1998). The first Linola 947 crop was grown in Manitoba and Saskatchewan provinces in 1994. The Linola 989 variety, bred for early maturity and higher yield, was first grown in 1997. Researchers at the Crop Development Centre, University of Saskatchewan, developed solin varieties through mutagenesis of the Canadian flaxseed variety of McGregor (Rowland, 1991; G.G. Rowland, personal communication, 1998).

Malcolmson et al. (1998) evaluated the oxidative and photooxidative stability of solin oil under accelerated storage conditions. In the presence of light, solin oil was more stable to peroxide development and flavor volatiles than sunflower oil. In the absence of light, solin oil was more stable to peroxide development but was less stable to painty odor development than sunflower oil. Regardless, the high concentrations of 18:2 in Linola and solin oils make them particularly susceptible to oxidation when compared with most other vegetable oils (Łukaszewicz et al., 2004). The addition of natural antioxidants, β-carotene and quercetin, improved the oil stability (Łukaszewicz et al., 2004), as did a blend of alpha-tocopherol, ascorbyl palmitate, citric acid, ascorbic acid, and ethoxylated ethylene glycol (Rudnik et al., 2001).

VI. OAT OIL

Oat (*Avena sativa* L.) groats have the highest lipid concentration among the cereal grains, with lipid amounts ranging from 2% to 11% (Youngs, 1986). However, groats have not been considered a potential source of edible oil, because this amount is too low to make extraction profitable. The typical fatty acid composition of oat oil is listed in Table 10.1. By using a GLC equipped with a capillary column, Saastamoinen et al. (1989) detected myristic acid (14:0), palmitoleic acid (16:1), 20:0 and erucic acid (22:1) in most oat varieties and lines, and 16:0, 18:0, 18:1, 18:2, 18:3, and gadoleic (20:1) in all samples. Sahasrabudhe (1979) found 20:1–20:5 fatty acids in small amounts (0.5%–3.0% total) and traces of behenic, erucic, and lignoceric acids.

The 16:0, 18:1, and 18:2 composition makes up over 95% of the fatty acids; however, the exact percentage of each of these fatty acids varies depending on several factors. Table 10.3 lists the relative fatty acid composition of oil from different oat cultivars from five different studies, indicating considerable variation in the proportions of each fatty acid based on the cultivar. Data from several studies revealed that as the total groat lipids increase, 16:0 and 18:2 tend to decrease and 18:1 tends to increase (Youngs, 1986; Holland et al., 2001). Indeed, the greater amount of 18:1 and the lesser amounts of 16:0 and 18:2 noted in Table 10.3 for Holland et al. (2001) were after nine cycles of recurrent selection for greater groat-oil content. This shift is likely because the storage lipids (in the form of triacylglycerols), which are the ones to change as the total amount of lipid changes, contain relatively more 18:1 than do the structural lipids (glycolipids and phospholipids). Saastamoinen et al. (1989), however, found that low growth temperature increased overall lipid synthesis and synthesis of 18:1 and 18:2, with 16:0, 18:0, and 22:1 decreasing.

The relative fatty acid distribution changes during maturation of the oats. During oat development, the 18:3 percentage starts high and then drops, whereas 18:2 increases with maturation (Lindberg et al., 1964; Brown et al., 1970). As with many other plants, oats grown under cool temperatures generally have greater unsaturation than those grown in warm environments (Youngs, 1986; Saastamoinen et al., 1989).

Oats, like many other potential oil crops, have been studied for their ability to produce a better edible oil. In the case of oats, a better usable oil is based on increasing the percentage of oil from the oat and on controlling a potent lipase enzyme extracted with the oil, and that causes rapid hydrolysis and deterioration of the oil quality (Hutchinson and Martin, 1952). Frey and Hammond (1975)

TABLE 10.3
Range and Mean of Relative Fatty Acid Composition of Oat Cultivars from Five Studies

Fatty Acid	Youngs and Püskülcü (1976)[a] (%)	Frey and Hammond (1975)[b] (%)	de la Roche et al. (1977)[c] (mol. %)	Sahasrabudhe (1979)[d] (%)	Lasztity et al. (1980)[e] (%)	Holland et al. (2001)[f] (%)
Myristic	0.4–0.8 (0.6)	—	—	0.5–4.9 (2.1)	—	
Palmitic	16.2–21.8 (18.9)	14–23	17.2–23.6 (19.6)	15.6–25.8 (20.5)	12.9–25.8 (17.5)	13.8–16.0
Stearic	1.2–2.0 (1.6)	1–4	0.8–1.8 (1.4)	1.6–3.9 (2.6)	1.1–11.0 (2.5)	2.2–2.7
Oleic	28.4–40.3 (36.4)	29–53	26.5–47.5 (38.7)	25.8–41.3 (34.9)	25.4–36.9 (31.4)	44.1–50.2
Linoleic	36.6–45.8 (40.5)	24–48	33.2–46.2 (38.9)	31.3–41.0 (37.0)	38.1–46.7 (42.0)	32.4–36.7
Linolenic	1.5–2.5 (1.9)	1–5	0.9–2.4 (1.5)	1.7–3.7 (2.6)	1.5–19.4 (3.9)	0.8–1.0

[a]Data from groats of 15 oat cultivars, three replications of each, grown at three locations in the United States during two crop years.

[b]Data from groats of 64 cultivars and collections.

[c]Calculated from data from nine cultivars of oats grown in Canada.

[d]Calculated from data for 12 cultivars of oats (groats) grown in Canada. Not shown here is "other" fatty acids (range 0%–2.4%), which included C_{20} and C_{22} fatty acids.

[e]Data from oats of 12 cultivars grown in Hungary.

[f]Data from nine cycles of recurrent selection for greater groat-oil content in a genetically broad-based oat population.

Source: Youngs, V.L. (1986). Oat lipids and lipid-related enzymes, in *Oats—Chemistry and Technology* (F. Webster, ed.), American Association of Cereal Chemists, St. Paul, MN, pp. 205–226 and Holland, J.B., et al. (2001). *Euphytica 122*: 69–79.

estimated that for oats to be an economically feasible oilseed crop in Iowa, the oil percentage would have to be increased to around 16%. They reported that oil percentage was inherited polygenetically, and that there was a tendency for high oil percentage to be partially dominant. K.J. Frey and E.G. Hammond (personal communication, 1998) bred oat lines containing up to 16% oil and, for 300 oat lines bred for high oil, a mean oil content of 14.2% was reported. After many years of selection for oat quantity, and after nine cycles of recurrent selection in one population, the researchers achieved a consistent oil content of 15.8% (Holland et al., 2001). The possibility of using such an oil may depend on the ability to reduce the lipase activity in the oats. The lipase can be inactivated by heat or by 95% ethanol (Frey and Hammond, 1975), or it may be possible to breed low-lipase-containing oats. Kalbasi-Ashtari and Hammond (1977) reported that if Dal oats were extracted quickly, before the lipase could act, a relatively stable oil was produced. However, another problem encountered in oat oil production was the high (25%–30%) alkali-refining loss because of phosphatides and other gummy substances.

Kalbasi-Ashtari and Hammond (1977) compared petroleum ether-extracted oil from Dal oats that had been refined, bleached, and deodorized in the laboratory with refined soybean oil from a commercial manufacturer that had been deodorized in the laboratory. Citric acid was added to the oils. Storage at both 25°C and 55°C resulted in oat oil being significantly more stable than soybean oil, as measured by PV.

Oats are known to contain natural antioxidants in the form of ferulic and caffeic acids (Daniels and Martin, 1961; Daniels et al., 1963; Xing and White, 1997). Kalbasi-Ashtari and Hammond (1977) were unable to detect these compounds in their crude solvent-extracted oat oil; likely because the acids are not soluble in petroleum ether. They did detect alpha-tocopherol with 38 mg/kg oil present in the bleached oil. Other researchers have reported higher tocopherol levels in oat lipids, with Chow et al. (1969) reporting 175 mg/kg oil of total tocopherol in oat oil, including 122.5, 31.5, 12.3, and 8.7 mg/kg of alpha, beta, gamma, and delta homologues, respectively. They also reported

minor amounts of alpha-, beta-, gamma-, and delta-tocotrienols. Earlier, Green et al. (1955) measured a total of 610 mg/kg tocols in oat oil, including alpha-, gamma-, and delta-tocopherols and alpha- and beta-tocotrienols. White and Armstrong (1986), Duve and White (1991), and Tian and White (1994a) demonstrated the presence of a unique sterol (delta-5 avenasterol) in oat oil that protects against deterioration at frying temperatures. They removed the sterol from oats by methanol extraction and added it to soybean oil as a high-temperature polymerization inhibitor. Further work also demonstrated the usefulness of the methanolic extract of oats as a room-temperature antioxidant when added to soybean and cottonseed oils and their emulsions (Tian and White, 1994b) and in bread cubes stored after frying in oils containing the extracts (Tian and White, 1994a). The total sterol content in seven oat cultivars grown at three Swedish locations varied between 350 and 491 μg/g dry weight, with the most abundant being beta-sitosterol (237–321 μg/g) followed by campesterol (32–36 μg/g), delta-5-avenasterol (15–47 μg/g), and stigmasterol (11–21 μg/g) (Määtä et al., 1999). Many phenolic compounds were identified in the extracts, including ferulic, *p*-coumaric, caffeic, vanillic, *p*-hydroxybenzoic, 4-hydroxyphenylacetic, *o*-coumaric, sinapic, and salicylic acids, and vanillin and catechol (Xing and White, 1997). In particular, bran-rich fractions had greater phenolic acid concentrations and antioxidant activity than the starch-rich fractions (Gray et al., 2000). The polar lipid portion of oat oil has good emulsifying properties, which makes oat oil desirable in both food and cosmetic applications (Peterson, 2002).

VII. OLIVE OIL

Olive oil is briefly discussed here because of its significance as a major oil, but it is also discussed in the chapter on fruits and fruit products (see Chapter 11). Olive oil, which has been used since ancient times, is obtained from the fruit of an evergreen tree, *Olea europaea* (Rana and Ahmed, 1981). The olive tree grows best in the subtropical climates of the countries bordering the Mediterranean Sea and North Africa.

Olive oil is mechanically or physically pressed from the fruit pulp to obtain "virgin" olive oil, which is the highest grade (Firestone et al., 1996). Successive pressings yield lower grades of oil. Olive-pomace oil is obtained by solvent extraction of olive-pomace, yielding several categories of edible and inedible oils. Solvent extraction applied to the residue from the last pressing can be used to produce an inedible oil called "olive foots" or "sulfur olive oil" that can be used in the manufacture of soap and for industrial purposes (Sonntag, 1979). The world production of olive oil in 2005–2006 was projected to rank ninth among major vegetable oils, at 2.28 million metric tons, a ranking it has held for over a decade until world palm kernel oil production surpassed that of olive oil (Table 10.2) (USDA, 2006).

A typical fatty acid composition of olive oil is shown in Table 10.1, and it is characterized by its high (>70%) content of 18:1. In fact, olive oil is currently considered to be highly nutritionally desirable because of this amount of monounsaturated fatty acids (Grundy et al., 1988). Like many other vegetable oils, olive oil tends to become more unsaturated as the climate becomes colder and as the fruit matures, resulting in oils containing between 65% and 85% of 18:1, depending on the growing conditions (Sonntag, 1979). In partial agreement with this data, two Italian olive cultivars grown in Andalusia at two different altitudes, revealed greater 16:0 and 18:2 percentages, and a lesser 18:1 percentage when grown at the lower altitude (Aguilera et al., 2005). The International Olive Oil Council (IOOC) reported 18:1 ranges of 55%–83% (IOOC, 1993), but Libyan-grown olive oil contained only around 45% 18:1 and about 30% 18:2 and 18% 16:0 (Rana and Ahmed, 1981). Higher 16:0 and 18:2 contents were typical in the oils containing lower amounts of 18:1. Differences were noted in 18:1 content of olives grown in Tunisia (62.5%), Turkey (71.3%), and Europe (78%) (Firestone et al., 1996). Carpenter et al. (1976) analyzed 14 different consumer-available liquid vegetable oils, including one olive oil that contained 10.5% 16:0, 78.6% 18:1, and 6.2% 18:2. Eleven olive oils representing most of the native Tuscan olive varieties were surveyed for their fatty acid composition (Pinelli et al., 2003). The 18:1 ranged from 72.2% to 77.2% in 10 out of 11 varieties,

with one variety having 59%. The 16:0 ranged from 16.4% in the latter variety to 9.8%. In this case, the low-18:1 variety had a typical percentage of 18:2. The Cornicabra olive, as well as the Picual olive, both from Andalusia, have especially high concentrations of 18:1 and low concentrations of 18:2. The Cornicabra olive oil, evaluated from five crop seasons 1995/1996 to 1999/2000 with $n = 224$, ranged in fatty acid composition as follows: 7.0%–11.1% 16:0; 2.6%–4.4% 18:0; 76.5%–82.5% 18:1; and 3.1%–6.6% 18:2 with small amounts of other fatty acids (Aranda et al., 2004). The four most important olive varieties, Arbequina, Manzanilla, Nevadillo, and Ascolana, cultivated in the semiarid region of Traslasierra Valley, Córdoba, Argentina (Torres and Maestri, 2006) had somewhat lower 18:1 values than those from Andalusia and Tuscany. Fatty acid compositions ranged in 18:1 from 61.3% for Arbequina to 74.6% for Nevadillo. Correspondingly, the 16:0 was 17.8% and 18:2 was 15.8% in Arbequina and the 16:0 was 13.7% and 18:2 was 7.7% in Nevadillo.

Olive oil tends to be quite stable to oxidation because of its high content of 18:1, low (usually) content of 18:2, and lack of 18:3. It has only small amounts of tocopherols, with reported values in milligrams per kilograms of oil as follows: alpha, 145–154 and gamma, 21–25 (Slover et al., 1983); alpha, 93 and gamma, 7.3 (Müller-Mulot, 1976); and alpha, 70 and gamma, 20 (Carpenter, 1979). Carpenter et al. (1976) found total tocopherols to be 140 mg/kg oil in their consumer-available olive oil. Several phenolic compounds have been identified in virgin olive oil, including *p*-coumeric, syringic, vanillic, ferulic, caffeic, *p*-hydroxybenzoic, and protocatechuic acids and 4-hydroxyphenylethanol, 3,4-dihydroxyphenylethanol, and others (Nergiz and Unal, 1991; Montedoro et al., 1992; Tsimidou et al., 1992). One study showed that the antioxidant activity of the native olive oil phenols, caffeic acid, and 3,4-dihydroxyphenylethanol was much greater than that of alpha-tocopherol (Blekas et al., 1995). Elsewhere, a significant positive correlation was found between oxidative stability and total phenol content ($r = .52$) of the oil from the four most important olive varieties, Arbequina, Manzanilla, Nevadillo, and Ascolana, cultivated at Traslasierra Valley, Córdoba, Argentina (Torres and Maestri, 2006).

VIII. PALM, PALM KERNEL, AND COCONUT OILS

The oil palm, *Elaeis guineensis*, originated in West Africa and has spread to most parts of the tropical and subtropical zones of the world, with Southeast Asia, including Malaysia, being one of the main growing regions in the world (Jalani et al., 1997). The species, *Elaeis oleifera*, originated in Central and Latin America, with much less planted for commercial use. The oil palm produces a palm fruit that is quite unusual, because it yields two distinct oils, palm oil and palm kernel oil. Palm oil is obtained from the fruit itself, whereas the palm kernel oil is extracted from the seed inside the fruit. Oil from another palm fruit, the coconut (*Cocos nucifera*), is derived from the dried meat called copra. Palm oil is economically of much greater importance than palm kernel or coconut oils. For 2005–2006, palm oil was projected to rank first in world oil production among the major oils, at 34.80 million metric tons, whereas palm kernel and coconut oils ranked seventh and eighth, respectively (Table 10.2) (USDA, 2006). Palm oil overtook soybean oil in world production amount for the first time in 2004–2005. The majority of commercial palm and palm kernel and coconut oils come from trees grown in Malaysia, West and Central Africa, Indonesia, and Brazil and other Central and South American countries (Sonntag, 1979).

Palm kernel and coconut oils are very similar to each other in fatty acid composition. The other oil, palm oil (*E. guineensis*), has a much less saturated fatty acid profile. Typical fatty acid patterns for all three oils are shown in Table 10.1, although recent efforts to increase the unsaturated fatty acid composition of palm oil, and its nutritional quality, are providing oils with more 18:1 and 18:2. The *E. oleifera* palm tends to have more 18:1, with contents as high as 55%–56% (Rajanaidu et al., 1985), so it has been crossbred with *E. guineensis* used to diversify the genetic base. The fatty acid composition of the palm oils can vary with origin and variety. For example, the Nigerian population of *E. guineenis* had wide variance in fatty acids, such as 27%–55% 16:0, 28%–56% 18:1, and

6.5%–18% 18:2 (Rajanaidu et al., 2000). Palm fruits from the northeastern region of Brazil had 37% 16:0, 4.7% 18:0, 45% 18:1, and 10.7% 18:2 (Bora et al., 2003). Other reports revealed fatty acid variance also based on region, for the Congo (Kinkela and Vizard, 1993), Cameroon (Kapseu and Parmenther, 1997), and other Nigerian locations (Epka and Epke, 1996a,b; Akpanabiatu et al., 2001). The palm kernel oil from the Brazilian study (Bora et al., 2003) was more saturated than that listed in Table 10.1, with 53% 12:0, 19% 14:0, 10% 16:0, and 5.5% 18:1. Palm fruits have high amounts of enzymes that can hydrolyze the fatty acids, causing some palm (including palm, palm kernel, and coconut) oils to contain as much as 50% free fatty acids, thus proper processing techniques are necessary (Sonntag, 1979). Even good-quality palm oils have a higher free fatty acid content than do most oils. If the oil has been carefully processed, it is very stable to oxidative deterioration (Fritsch et al., 1971; Clegg, 1973).

Palm oil has about 500–800 mg/kg oil of total tocopherols, with the distribution being 288, 280, 80, and 80 mg/kg for alpha, gamma, delta, and other homologues, respectively (Clegg, 1973). Maclellan (1983) also reported 800 mg/kg of tocopherols in palm oil, with 360 mg/kg of alpha, 360 mg/kg of gamma, and 80 mg/kg of delta homologues. Other researchers measured lower total amounts of tocopherols, but also reported the presence of tocotrienols, with gamma-tocotrienol at 132 mg/kg (Van Niekerk and Burger, 1985). Chase et al. (1994) reported finding good amounts of gamma- and delta-tocotrienols (325 and 88.9 mg/kg, respectively) in refined, bleached, and deodorized palm oil, and Jalani et al. (1997) reported totals of 600–1000 mg/kg tocopherols and tocotrienols in crude *E. guineesis* palm oil, with gamma-tocotrienol making up 45% of the total. Coconut oil was reported to contain only very low levels of tocopherols, with 2.4 and 20.0 mg/kg oil, respectively, of delta- and alpha-homologues (Sonntag, 1979) and minor amounts of tocotrienols (Tan, 1989). Young (1983) stated that palm kernel and coconut oils contain total tocopherol contents of about 40–100 mg/kg oil. Even these low levels are important for protection against oxidation.

Palm oil is also a nutritionally important source of alpha- and beta-carotenes, which may improve its oxidative stability (Tan, 1989). Carotenoids in palm oil total about 400–1000 mg/kg and, in addition to the *trans*-alpha- and *trans*-beta-carotenes that comprise over 90% of the carotenoids, include *cis*-alpha- and *cis*-beta-carotenes; phytoene; phytofluene; gamma-, delta-, and zeta-carotenes; neurosporene; alpha- and beta-zeacarotenes; and lycopene (Yap et al., 1991; Jalani et al., 1997).

Although the source of most palm and palm kernel oils is the *E. guineensis* palm and of coconut oil, the *C. nucifera* palm, the entire family Palmae, is estimated to consist of about 217 genera and about 2500 species (Idiem' Opute, 1979). Researchers have analyzed the compositions of some of these unusual palms and have found considerable variation in their fatty acid patterns compared with the more common palm oil just described (Idiem' Opute, 1979; Cole et al., 1980). Among these are babassu (*Orbignya oleifera*) and murumuru (*Astrocaryum murumuru*) (Litchfield, 1970), tucum (*Astrocaryum vulgare* or *tucuma*), and cohune (*Attalea cohune*) (Sonntag, 1979). Their typical fatty acid compositions are listed in Table 10.1. These oils have fatty acid patterns similar to those of coconut and palm kernel oils.

IX. PEANUT OIL

Peanut (*Archis hypogaea* L.) seed is an important oil crop throughout the world and is grown in large quantities in Africa, India, and China. The oil is used in many edible products, including shortening, margarine, and mayonnaise, as a cooking and frying oil, and as a salad oil. In the United States, the main product for consumption is peanut butter. The amount of peanut oil produced worldwide increased from 2.47 million metric tons in 1961 to a projected 4.93 million metric tons in 2005–2006, but the relative rank in production dropped from second to sixth during that time (Table 10.2) (USDA, 2006). U.S. production for 2005–2006 was forecast to be 219 million pounds for a ranking of 9.

The typical fatty acid composition of peanut oil is presented in Table 10.1. Peanut oil differs from most other vegetable oils in that it can contain up to 6% of long-chain saturated fatty acids, including arachidic (20:0), behenic (22:0), and sometimes lignoceric (24:0) acids. If proper GLC

separation techniques are not used, 18:3, 20:0, and 20:1 fatty acids will elute at the same time, causing considerable confusion and improper reporting of the fatty acids present in peanut oil (Worthington, 1977). In fact, several papers have reported 18:3 contents in peanut oil of up to 1.4% (Koman and Kotuc, 1976). Worthington and Holley (1967) examined oils from seven genetically diverse peanut cultivars and reported less than 0.1% (0.02%–0.04%) of 18:3. Later, Worthington (1977) evaluated eight peanut cultivars grown in four locations and found 18:3 values ranging between 0.03% and 0.13%. To unambiguously identify and measure 18:3 in oils that also contain 20:0 and 20:1, GLC liquid phases must have polarity characteristics that permit elution of the C18 series of fatty acid methyl esters prior to elution of the C20 series.

The peanut cultivar, Florunner, which was released in 1969, has become the most popular runner-type peanut cultivar in the United States, and it accounted for over 50% of the total production area in 1998; however, newer cultivars with better oil stability and quality characteristics have been released (Branch et al., 1990). The fatty acid composition was determined among seven United States' runner-type peanut cultivars that had been released since 1982: Florunner, Sunrunner, GK-7, Southern Runner, Sunbelt Runner, Okrun, and Langley (Branch et al., 1990). Significant cultivar differences were found within these fatty acid profiles, with 3-year averages among cultivars ranging as follows: 16:0, 10.2%–10.9%; 18:0, 1.4%–1.9%; 18:1, 49.2%–56.3%; 18:2, 24.1%–30.6%; 20:0, 1.0%–1.4%; 20:1, 1.3%–1.4% (not significant); 22.0, 2.6%–3.1%; and 24:0, 1.5%–1.9%. Southern Runner had the best 18:1 to 18:2 ratio and iodine values, whereas Florunner, Sunrunner, and Langley were the highest in unsaturated and lowest in saturated and long-chain fatty acids. In addition to the genotypic differences, years were also found to have a significant effect on some of the fatty acids, including 16:0, 18:0, 18:2, and 22:0. Other researchers reported yearly effects on fatty acid composition of peanut oils (Young et al., 1974; Norden et al., 1987). A survey of 732 lines of peanuts grown during 1995 in Griffin, Georgia, revealed a great deal of native variation in fatty acid composition of the oils (Hammond et al., 1997). The 16:0 varied from 8.2% to 15.2%; 18:0, 1.1% to 7.2%; 18:1, 31.5% to 60.2%; 18:2, 19.9% to 45.4%; 20:0, 0.8% to 3.2%; 20:1, 0.6% to 2.6%; 22:0, 1.8% to 5.4%, and 24:0, 0.5% to 2.5%. The 20:1 was found to be *cis*-11-eicosenoate rather than the *cis*-9 isomer reported or assumed by other researchers. In addition, epoxy fatty acids were found in many of the lines, ranging as high as 2.5%. Several correlations among the fatty acid percentages were noted, including a positive correlation of 16:0 with 18:2 and a negative correlation with 18:1, 20:1, and 24:0.

Young et al. (1974) examined nine varieties or strains of Spanish-type peanuts for variations in fatty acid composition based on a number of different factors. In general, they found higher 16:0 and 18:1 contents and lower 18:2 contents in nonirrigated peanuts and those grown in Georgia as compared with those grown in Oklahoma. El-Hinnaway et al. (1978) grew one variety, Baladi-107, in three field experiments and found no influence of nitrogen and phosphorus fertilizers, together or individually, on the fatty acid composition of the peanuts. Maturity of the peanuts has also been shown to influence the total oil content as well as the fatty acid composition of peanuts (Young et al., 1972). The 18:1 increased with maturity, whereas 18:2 decreased. Iverson et al. (1963) were interested in the effects of roasting (a process used in the production of peanut butter) on the fatty acid composition of peanut oil. They determined that there was little effect on the fatty acids of commercial peanut oils during roasting.

In general, the stability of peanut oil is quite good. The oleic/linoleic acid ratio (O/L) has been used as an indicator of peanut oil stability and is often the value reported when estimating stability of peanut oils (Sonntag, 1979). Branch et al. (1990) predicted the best stability, among seven cultivars studied, from Southern Runner followed by Langley on the basis of their high O/L values. New peanut cultivars with at least 75% 18:1 have been developed and were shown to have much greater ($p < .01$) oxidative stability than peanuts with normal (56%) 18:1 compositions (O'Keefe et al., 1993). These experimental lines were used in breeding work to develop cultivars with high O/L ratios, including linoleic acid contents of 4% or less (Moore and Knauft, 1989; Pattee et al., 2002a; Branch, 2003, 2005). In follow-up work, two high-oleic (>80%) peanut varieties, F1250 and

BC93Q10, had much better flavor quality and stability than peanuts with 53% 18:1 during storage after roasting (Mugendi et al., 1998) or at –20°C (Pattee et al., 2002b).

Peanut oil antioxidants consist mainly of alpha- and gamma-tocopherols. Müller-Mulot (1976) reported tocopherol levels in peanut oil as follows: alpha, 169 mg/kg; beta, 5.4 mg/kg; gamma, 144 mg/kg; and delta, 13 mg/kg; whereas, Chase et al. (1994) found values of alpha, 77.4 mg/kg; beta, 16.2; gamma, 241 mg/kg; and delta, 40.5 mg/kg. These levels are relatively low when compared with the amounts found in other common vegetable oils such as corn, soybean, and sunflower. Van Neikerk and Burger (1985) also noted the presence of minor amounts of tocotrienols in peanut oil. High-oleic acid peanut cultivars, whose parent lines were Sunoleic and Tamrun 96, were analyzed for tocopherol, phytosterol, and phospholipid compositions (Jonnala et al., 2006). The breeding lines were rich in alpha-tocopherol and a line derived from Tamrun had the highest total phytosterol content.

Peanut oil was shown to be unexpectedly atherogenic in the diets of experimental animals (Tso et al., 1984). However, when the fatty acids were rearranged (randomized) on the glycerol backbone, the oil became less atherogenic. Therefore, it was suggested that the structure of the component triacylglycerols may be as important to atherogenicity as the fatty acids themselves. Native peanut oils contain more triacylglycerols with 18:2 in the 2-position and saturated fatty acids in the 1- and 3-positions than do randomized oils (Myher et al., 1977). The dietary significance of this finding in humans was questioned by Alderson et al. (1986), and, more recently it was suggested that the reduced atherogenic response of randomized peanut oil is likely a result of the chemical effects of randomization (Kritchevsky et al., 1997). During the randomization process, the oil is washed with strong alkali, a process that removes native lectins from the peanut oil. Lectins are proteins believed to enhance atherogenicity in humans. The topic of dietary influence of fats and oils on health and disease is discussed elsewhere in this book.

X. RICE BRAN OIL

Rice (*Oryza sativa*) bran, an industrial by-product composed primarily of the seed coat and associated layers and representing 5%–8% of the grain (da Silva et al., 2005), recently has been recognized as a source of edible oil. Indeed, rice bran oil is recognized as a premium health food in Japan (Arumughan et al., 2004). The rice grain contains 2%–3% fat, most of which is concentrated in the embryo or germ and in the outer seed layers. Milling of rice separates the germ and bran layers from the endosperm and concentrates the fat in the residue that is known as "bran," which contains 10%–26% oil (Prabhakar and Venkatesh, 1996; da Silva et al., 2005). Rice is grown in large quantities throughout the world, especially in Asia and India. In certain countries, among them Japan and Burma, rice bran oil already contributes significantly to the edible oil supply (Kahlon et al., 1992). The production of rice bran oil has been limited by several problems that influence the quality of the edible oil. The high-PUFA composition suggests that it could be used as a salad or cooking oil if properly handled; however, its stability problems need more attention before it could be widely accepted as an edible oil of consistent quality. If the lipase activity were controlled, rice bran oil has the potential to be a good-quality oil. The high-lipase activity in the bran quickly hydrolyzes the oil into fatty acids, causing severe flavor problems in the oil (Aoyagi et al., 1985; Orthoefer, 1996). Stabilization of the bran and oil has been studied by several groups (Prabhakar and Venkatesh, 1986; da Silva et al., 2005).

Limited research exists on the fatty acid composition of bran lipids; however, a few well-designed studies have been reported. The typical fatty acid composition of rice bran oil is listed in Table 10.1. Hemavathy and Prabhakar (1987) reported the total lipid composition of bran from three varieties of rice grown in India. The 16:0 ranged from 21.2% to 25.5%; 18:0, 09.3% to 3.0%; 18:1, 37.4% to 41.0%; and 18:2, 31.1% to 33.2%. In particular, the 16:0 content was somewhat different from the 16.4% listed in Table 10.1. Othoefer (1996) reported fatty acid values in rice bran oil that were similar to those reported by Hemavathy and Prabhakar (1987). Gaydou and Raonizafinimanana (1980) reported only small variability in fatty acid composition among six rice bran oils that are

widely grown in Madagaskar, including 16:0 (16%–20%), 18:1 (41%–44%), and 18:2 (31%–37%). Perhaps, as with other vegetable oils, there is some variability of fatty acid composition based on environmental conditions during growing or among different genotypes. The variability reported here is quite minor compared with that of oils such as sunflower oil. Efforts to increase the alpha-linolenic acid in rice by genetic transformation to enhance its nutritional value have been successful. A *chimeric* gene, constructed from a maize *Ubil-P-int* and a soybean *GmFAD3* cDNA, was introduced into rice plants by *Agrobacterium*-mediated transformation, resulting in up to a tenfold increase in the alpha-linolenic acid concentration in rice seed oil (Anai et al., 2003). Such a transgenic rice is an example of a novel change in the fatty acid composition of rice oil, to serve both commercial food and industrial interests.

Both microwave heating (Ramezanzadeh et al., 1999) and parboiling (da Silva et al., 2005) helped prevent hydrolytic rancidity in rice bran, treatments that could be used to stabilize the bran prior to oil extraction. Proctor and Bowen (1996) determined that rice bran oil extracted with isopropanol was significantly more stable to heat-induced oxidation than was hexane-extracted oil. They attributed the difference to increased levels of antioxidants in the oil extracted with isopropanol. Even hexane-extracted rice bran oil contains many natural antioxidants, including total tocopherols of about 400 mg/kg oil (322 alpha, 61 gamma, and a trace of delta) (Sonntag, 1979) and ferulic acid (Tanaka et al., 1971). One phenolic component, oryzanol, has gained attention because of its possible hypocholesterolemic activity (Sharma and Rukmini, 1986). Oryzanol is a compound composed of ferulic acid esters of sitosterol and cycloartenol (Orthoefer, 1996). Rice bran oil also contains a fair amount of waxes (Yoon and Rhee, 1982), but these could be removed by proper extraction procedures. The fatty acid steryl esters (FASE) and wax esters (WE) in rice bran oil can enhance its value in cosmetic, nutraceutical, and pharmaceutical formulations, accounting for about 4.0% of the weight of rice bran oil (Gunawan et al., 2006). Oleic and linoleic acids were the major fatty acids in the FASE fraction, and 4-desmethyl, 4-monomethyl, and 4,4-dimethyl sterols predominated. Phytosterol esters have been shown to lower plasma cholesterol concentration by inhibiting the absorption of cholesterol from the small intestine (Sierksma et al., 1999). The major constituents of WE were saturated esters of C_{22} and C_{24} fatty acids and C_{24}–C_{40} aliphatic alcohols (Gunawan et al., 2006).

XI. SAFFLOWER OIL

Safflower oil comes form the seed of the plant *Carthamus tinctorius* L. (Fedeli, 1983). It is a very old crop that was originally used in textile dyeing. With a reduction in hull content and an increase in the amount of seed oil, it has become commercially important as a vegetable oil (Kneeland, 1966). The amount of safflower oil produced worldwide does not rank among the top 10; however, U.S. 2005–2006 production of safflower oil was forecast to rank tenth among edible fat and oil sources, at 56 million pounds (Table 10.2) (USDA, 2006).

A typical fatty acid profile for safflower oil is shown in Table 10.1. With 77.7% 18:2, safflower oil has the highest 18:2 percentage of any known native oil, not considering modern genetic fatty acid modifications of certain oils. A recent study reported slightly greater amounts of 18:2 in a Korean safflower oil, with the fatty acid distribution as 16:0, 5.53%; 18:0, 1.62%; 18:1, 11.00%; 18:2, 81.5%; and 18:3, 0.40% (Lee et al., 2004). For this reason, most safflower oil is used by health-conscious individuals as a highly polyunsaturated oil even though it is expensive (Smith, 1985). High-oleic safflower oils have been developed as experimental lines, but commercial safflower oil is still primarily the "high-linoleic" type (Sonntag, 1979). The high-18:2 percentage makes safflower oil highly suitable as a drying oil for use in the paint and coating industry (Rheineck and Cummings, 1966).

The fatty acid composition of commercial safflower oil appears to be fairly consistent under most environmental conditions, with the 18:2 level ranging between 75% and 80% (Applewhite, 1966; Knowles, 1972). For example, seed from Arizona or Montana varied only 2%–3% in 18:2

content (Smith, 1985). Experiment lines have been developed that produce oils with different fatty acid compositions, including medium-linoleic lines with 56%–63% 18:2 (Knowles, 1972), high-oleic lines with 74%–79% 18:1 (Craig, 1953; Fuller et al., 1967; Knowles, 1972), and a high-stearic line with 5%–10% 18:0 (Ladd and Knowles, 1970). Bartholomew (1971) examined the effect of growing temperature on the fatty acid composition of safflower oils differing in levels of 18:2. The high-linoleic and high-oleic lines were relatively stable, but the medium-18:2 line showed a strong response, with low temperatures producing an oil with almost 75% 18:2 and high temperatures producing an oil more like the high-oleic oil. This response is similar to that of sunflower oil (Ermakov and Megorskaya, 1972). Low temperatures also reduced the levels of 18:0 in a high-stearic acid line.

Knowles (1972) also examined 12 wild species of safflower as a source of genes for modifying the fatty acid composition of safflower oil; however, they found limited variability in the fatty acids of these species, with most being remarkably similar to commercially grown high-linoleic types. Indeed Işiğigür et al. (1995) evaluated the fatty acid composition of 17 varieties of safflower seed of Turkish origin. One of these varieties was a high-oleic line containing 73.9% 18:1; however, the remaining 16 lines had relatively similar fatty acid profiles, with values ranging as follows: 16:0, 6.6%–9.6%; 18:0, 0.8%–3.6%; 18:1, 8.7%–13.7%; and 18:2, 73.2%–83.0%.

Müller-Mulot (1976) measured the tocopherols in safflower oil and found the following homologue distributions; alpha, 223 mg/kg; beta, 7 mg/kg; gamma, 33 mg/kg; and delta, 3.9 mg/kg for a total of 266.9 mg/kg. This level is somewhat lower than the amounts he found for other major vegetable oils such as cottonseed, corn, soybean, and sunflower oils. In safflower oil extracted by mechanical press in a laboratory setting, Lee et al. (2004) measured slightly greater total amounts of the tocopherol homologues, with distributions of alpha, 386 mg/kg; beta, 8.9 mg/kg; and gamma, 2.4 mg/kg. They also found 5.2 mg/kg gamma-tocotrienol and 8.4 mg/kg delta-tocotrienol. Lee et al. (2004) also reported four phospholipid classes, phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidic acid (PA), and phosphatidylcholine (PC), for a total of 19.4 mg/kg phosphorus, with PE providing 60% of the phospholipids, and PI providing 32.6%. Safflower oil, with its high-18:2 percentage and low levels of natural antioxidants, is not particularly stable to oxidation; however, the high-oleic types have improved stability. Fuller et al. (1967) examined the polymer formation at 185°C as a measure of stability, of a high-oleic safflower oil (UC-1), commercial safflower oil, soybean, and cotton-seed oils. The UC-1 oil was the most stable and the commercial safflower oil was the least stable of the oils tested. Purdy (1985) reported the oxidative stabilities of "normal" safflower and sunflower oils compared with high-oleic types of each oil. Normal safflower and northern-grown sunflower oils had similar active oxygen method (AOM) values, whereas the high-oleic types of each oil had improved AOM values of about 3.5 times. The oxidative stability was related directly to the 18:2 level. When Korus and Mousetis (1984) compared thermal stabilities of safflower and rapeseed oils, they also found a direct correlation between 18:2 percentage and polymerization. Snyder et al. (1985) compared PVs and total GLC volatiles of most major vegetable oils and found safflower oil to be the least stable by these measures.

It is difficult to predict the future of safflower oil production as an industry. Because the oil is not very stable and fairly high priced, it offers little advantage over other oils except for its possible health benefits as an oil high in PUFAs. The market for the more stable high-oleic safflower oil may increase, especially if the current nutritional interest in high monounsaturates continues.

XII. SESAME OIL

Sesame oil (*Sesamum indicum* L.) has been used as an edible oil since ancient history. Its seed has an oil content of around 45%, which can be removed fairly easily by pressing. Sesame oil is generally sold as a gourmet oil, with high natural oxidative stability and a unique flavor (Toro-Vazquez and Gallegos-Infante, 1996). Mexico is one of the main producers of the oil. World production of sesame oil does not usually rank among the top ten, as also forecast for 2005–2006 (USDA, 2006).

The typical fatty acid composition of sesame oil is listed in Table 10.1. The 18:1 and 18:2 percentages are generally almost equal, and 18:3 represents only a minor portion of the total fatty acids. Little variation in fatty acid composition occurred among sesame seed oils grown in different locations, although oils grown in India tended to have a slightly higher 16:0 composition (12%–17% vs. 10%) than those grown elsewhere (Kaufmann and Mankel, 1963; Sreenivasan, 1968; El Tinay et al., 1976). The fatty acid composition of oil from sesame seed grown in Taiwan was within 2%–3% of each fatty acid listed for same oil in Table 10.1 (Yen, 1990). The fatty acid composition of four collections of the cultivated *S. indicum* L. species grown in the Sudan also had very similar profiles to those just listed (Kamal-Eldin and Appelqvist, 1994). Three related wild species of sesame contained less total oil (approximately 30%) and somewhat greater variations in fatty acid composition than the cultivated species. For example, one species had approximately 35% 18:1 and 45% 18:2. East African sesame accessions evaluated over the 3 years of 2002–2004 showed significant variations in oil and fatty acid content among the years (Were et al., 2006). Oil content correlated negatively with 16:0 and 18:2, and positively with 18:0 and 18:1. The sesame crop from this geographic area is generally used in the confectionary industry, rather than as an oilseed, and has not been selected for oil content or quality.

The tocopherol level of sesame oil is relatively low, with the following reported distribution in milligrams per kilogram of pure refined sesame oil (unroasted): alpha, 13; beta, 5.6; gamma, 244; and delta, 32 (Müller-Mulot, 1976). Shahidi et al. (1997) reported finding only gamma-tocopherol in hexane-extracted sesame oil at a level of 330–387 mg/kg. Slover et al. (1983) found the following tocopherol levels in cold-pressed sesame oil: alpha, 82–88 mg/kg; gamma, 155–167 mg/kg; and delta, 0 mg/kg. They did not report levels of beta-tocopherol.

Although sesame oil contains low level of tocopherols, it has good amounts of other phenols that seem to be unique to sesame oil and that contribute to its superior oxidative stability. These compounds include sesamin, sesamolin, and sesamol (Budowski, 1964; Suja et al., 2004). The compound sesamol forms from sesamolin during processing and was originally thought to be responsible for the high stability of sesame oil (Budowski, 1964). Since then, however, products including a sesamol dimer (a positive intermediate of the oxidative degradation of sesamol) have been thought to be the antioxidative agents in sesame oil (Kikugawa et al., 1983). Fukuda et al. (1986) suggested that the conversion of sesamolin to sesaminol was responsible for the stability of sesame oil. The sesamin content in oils extracted from dehulled and coated seeds ranged from 5800 to 6490 mg/kg; whereas, the sesamolin content ranged from 1830 to 3490 mg/kg (Shahidi et al., 1997).

Sesame oils from both unroasted and roasted seeds are widely used (Fukuda et al., 1986). Both oils are stable to oxidation but the oil prepared from the roasted seed has a distinctive flavor and longer shelf life (Manley et al., 1974; Kikugawa et al., 1983). Yen (1990) determined that, among oil from unroasted seed and oils from seed roasted at different temperatures (180°C–260°C), the highest levels of sesamol and gamma-tocopherol were found in oil roasted at 200°C–220°C. He found 480 mg/kg gamma-tocopherol in oil from seed roasted at 200°C compared with 289 mg/kg in oil from unroasted seed. He attributed the remarkable stability of oil from roasted sesame seed to the high levels of these compounds. Abou-Gharbia et al. (1997) noted that sesame oil extracted from coated seeds was more stable to oxidation during storage than oil extracted from dehulled seeds after several different preextraction treatments. The difference was likely caused by the release of natural antioxidants from sesame seed hull into the oil.

XIII. SOYBEAN OIL

Soybean oil is obtained from the seeds of the legume *Soja max*. Total production of soybean oil has ranked number one in the United States for many years, with the 2005–2006 production forecast to be 20.04 billion pounds (Table 10.2) (USDA, 2006). The 2005–2006 world production of soybean oil was estimated to be 33.87 million metric tons, ranking second behind palm oil (Table 10.2) (USDA, 2006). In 2004–2005, palm oil overtook soybean oil for the first time in worldwide

production amount. Soybean oil, similar to most major oils, is refined, bleached, and deodorized before consumption.

The fatty acid composition of soybean oils varies depending on many environmental and genetic factors that were mentioned at the beginning of this chapter. The typical fatty acid composition of soybean oil is shown in Table 10.1. Although there is an environmental effect on fatty acid composition (e.g., soybeans grown in warmer climates produce more saturated oils and those grown in cooler climates produce more unsaturated oils), Hammond and Fehr (1984) demonstrated that the ranking of many soybean lines for 18:3 percentage remained the same when grown in Iowa (cooler climate) as compared with Puerto Rico (warmer climate). Thus "heritability" of the genetic influence on fatty acid production is high. A multilocational field trial with seven Indian soybean cultivars at four growing locations determined significant genotypic, locational, and geotypic × locational interactions for oil amount as well as for all the unsaturated fatty acids (Kumar et al., 2006). Average daily mean temperature during bean development was negatively associated with linolenic acid percentage, as mentioned previously. Nearly 100% of the 18:3 in soybean oil is reported to be in the form 18:3 (n-3) (Jaselskis et al., 1982; Manku, 1983). These n-3 fatty acids may have some nutritional advantages in reducing heart disease, a topic that is discussed elsewhere in this book.

A current objective of plant breeders is to improve the nutritional and/or functional properties of soybean oil by modifying the fatty acid composition (Durham, 2003). New genetically altered soybean lines have been developed, targeting different end uses. Reducing the PUFA composition and/or increasing oleic acid concentration improves oxidative stability of the oil without hydrogenation. In contrast, increasing the saturated fatty acid concentration can provide soybean oils with enough solids for use in margarine and shortening production, with no or minimal hydrogenation. The interest in lowering PUFA composition, and particularly the 18:3 content of soybean oil originally arose from the association of 18:3 with flavor instability. The relative oxidation rates of 18:1, 18:2, and 18:3 as fatty acid methyl esters, when present as mixtures, was reported to be in the ratio of 1:10.3:21.6, respectively (Fatemi and Hammond, 1980). Elevating 16:0 to 10.6% and/or lowering 18:3 to <2.6% increased the oxidative and flavor stability (Shen et al., 1997a). Earlier, White and Miller (1988) and Liu and White (1992a) reported soybean oil with elevated 18:0 percentage to have significantly greater oxidative stability than normal soybean oil, and soybean oils with low-18:3 percentage oxidized at significantly lower rates than did oils with normal 18:3 levels. Reducing the 18:3 and/or increasing the 18:0 percentage also resulted in enhanced frying stability of the oil (Miller and White, 1988; Liu and White, 1992b; Warner and Mounts, 1993; Mounts et al., 1994; Gerde et al., 2006). Lines have been developed containing oil with <3% 18:3 (Hammond and Fehr, 1983; Fehr et al., 1992), up to 28% 18:0 (Graef et al., 1985; Lundeen et al., 1987), with reduced palmitic, total saturated linolenic acids (Streit et al., 2001), and with high- (~80%) and mid- (~55%) oleic acid (Kinney, 1997; Liu, 1999; Wilson, 1999). Other soybean lines produce oils with even lower (<2%) 18:3 and/or higher 16:0 and/or 18:0 concentrations. A study comparing soybean oils with ~1% 18:3, ~3% 18:3, and typical fatty acid compositions showed a stability advantage to the oil with ~1% 18:3 (Gerde et al., 2006).

Oil from soybean cultivars with reduced 18:3 (3%) was first marketed in 1994 by Kraft Food Ingredients (Anon., 1994). Another experimental cultivar was developed to have low total saturated fatty acid composition to compete with new varieties of canola marketed as having less than 6% total saturated fatty acids (Fehr and Hammond, 1996a,b). Most recently, the push by industry to reduce or eliminate *trans* fats in the diet to comply with *trans*-fat labeling resulted in the release of newer low (<3%) and ultra-low (~1%) linolenic acid soybeans. The company, Asoyia, LLC, grows a soybean line developed by Iowa State University and markets the ultra-low linolenic acid oil by this name, with hexane processing and refining done by Cargill. Innovative Growers, LLC, uses expeller processing and physical refining to process ultra-low linolenic acid soybean oil. Similarly, Monsanto markets a low-linolenic acid bean, which they developed under the name, VISTIVE™, whereas a Bunge–Dupont alliance introduced a low-linolenic soybean oil from a soybean variety developed by Pioneer Hi-bred International, Inc., marketed under the NUTRIUM™ brand. Monsanto and Iowa

State University have goals to release both mid-oleic/low- or ultra-low linolenic beans and mid-oleic/low- or ultra-low linolenic acid/low (<7%) saturated fatty acid beans within the next few years.

The practice of partially hydrogenating oils to harden them for the production of margarines and shortenings is declining rapidly, because of nutritional concerns about *trans* fats. However, a small amount of fully hydrogenated, thus fully saturated and containing no *trans*-fatty acids, can be blended with oils to create the functions needed for use in manufacturing margarines and shortenings. Margarines and shortenings vary in fatty acid composition, depending on the manufacturer and the type of product produced. For example, the composite fatty acid values of 17 stick or brick margarines made from coconut oil, corn oil, cottonseed oil, palm oil, peanut oil, safflower oil, and/or soybean oil were reported as follows, listed in g/100 g margarine: 16:0, 9.2 ± 1.9; 18:0, 5.4 ± 0; 18:1, 37.5 ± 8.2; 18:2, 21.8 ± 7.5; and 18:3, 0.8 ± 1.0 (Weihrauch et al., 1977). Soft tub margarines (13) had fatty acid values as follows, listed in g/100 g margarine: 16:0, 9.1 ± 1.2; 18:0, 5.1 ± 1.1; 18:1, 31.2 ± 5.6; 18:2, 28.5 ± 6.2; and 18:3, 1.7 ± 1.1. The authors of the study summarized that margarines (and shortenings) formed relatively uniform groups of products regardless of the oil source. No distinction was made between *cis*- and *trans*-isomers in the study by Weihrauch et al. (1977). Enig et al. (1990), however, estimated that margarines produced at that time contained an average of 23% *trans*-fatty acids, whereas shortenings contained an average of 25.3%. Since 1990, however, many companies have traded *trans*-fatty acids for saturated fatty acids to create the desired functions. The new soybean oils high in 16:0 or 18:0 obviously are more solid, requiring less hydrogenation than normal oils. In addition, oils with at least 15% 16:0 product smooth margarines because of the interference of the 16-carbon fatty acid with the crystalline structure of a "solid" fat that is made up mainly of 18-carbon units.

Another factor besides the 18:3 content thought to affect the flavor stability of soybean oil is the presence of lipoxygenase enzymes that rapidly oxidize 18:2 and 18:3 to generate the "beany" undesirable flavor in soybean oils. Soybean lines lacking one or more of the lipoxygenase enzymes have been developed (Kitamura et al., 1983; Davies and Nielsen, 1986; Davies et al., 1987; Shen et al., 1996; King et al., 1998). The general findings, however, revealed no improvement in soybean oil quality with the removal of two or three of the enzymes from the beans, when optimal conditions were used (Shen et al., 1996, 1997b; King et al., 1998). It is possible that an improvement in oil quality of the oils from beans lacking the enzymes over that of oil from normal beans might be noted if soybean storage and/or oil processing conditions were unfavorable.

The general stability of soybean oil is aided by the presence of naturally occurring tocopherols and other minor constituents. Müller-Mulot (1976) reported tocopherol levels in refined soybean oil as follows: alpha, 116 mg/kg; beta, 34 mg/kg; gamma, 737 mg/kg; and delta, 275 mg/kg. Slover et al. (1983) found tocopherol levels similar to these amounts in two soybean oil samples that they measured. The following values in milligrams per kilogram were listed: alpha, 82–84; gamma, 662–758; and delta, 276–287. The beta homologue was not measured. Chase et al. (1994) compared tocopherol levels in crude and refined soybean oils, reporting only minor losses of the tocopherols during the refining, bleaching, and deodorizing process. The refined oil contained 1360 mg/kg, whereas the crude oil had a total of 1490 mg/kg tocopherols. Individual tocopherol homologues for refined oil followed by crude oil are listed: alpha, 69.2–72.2 mg/kg; beta, 32.9–33.9 mg/kg; gamma, 818–933 mg/kg; and delta, 436–453 mg/kg. Warner (2005) reported typical amounts of tocopherol homologues in soybean oil in milligrams per kilogram as follows: alpha, 120; gamma, 610; and delta, 260. These high levels of tocopherols, especially the gamma homologue, are thought to help protect soybean oil against oxidation and flavor instability (Warner and Mounts, 1990; Warner et al., 1990). A study, in which tocopherols native to soybean oil were replaced with tocopherols native to sunflower oil and vice versa, revealed greater oxidative and flavor stability of either oil aged in the dark when the tocopherol profile native to soybean oil was present, and greater stability of either oils aged in the light when the tocopherol profile native to sunflower oil was present (Warner, 2005). A comparison of soybean oil stability with that of other major vegetable oils is discussed under canola oil above. Expeller pressed and physically refined soybean oil tested favorably during frying

of French fries, even though it had less total tocopherols and phytosterols than hexane-extracted, refined, bleached, and deodorized soybean oil (Warner and Dunlap, 2006). The authors speculated that Maillard reaction products produced during the thermal processing step used for expeller oil contributed antioxidant products that enhanced lipid oxidation stability.

Vlahakis and Hazebroek (1998) reported significant correlations between total tocopherol level, PUFA composition, and decreasing temperature during seed development. Researchers previously have noted a positive link between tocopherol and PUFA composition, speculating that the plant produced more tocopherol as a protective measure against oxidation of the polyunsaturates. Vlahkis and Hazebroek (1998), however, explain that both these biochemically unlinked traits are controlled by temperature.

XIV. SUNFLOWER OIL

Sunflower oil is obtained from the seed of the plant *Helianthus annuus* L., which is native to North America (Campbell, 1983). The plant is grown in large quantities in Russia, Argentina, China, the European Economic Community (ECC), and in the United States (Anon., 1986). Worldwide, the production of sunflower oil is the fourth largest of edible oils, being surpassed by soybean, palm, and rapeseed (including canola) oils, with the 2005–2006 forecast at 10.46 million metric tons (Table 10.2) (USDA, 2006). U.S. production of sunflower oil for 2005–2006 was forecast to rank seventh, at 588 million pounds (Table 10.2) (USDA, 2006). Generally, sunflower oil is used for edible purposes as a cooking and salad oil and in the manufacture of shortenings and margarines (Sonntag, 1979). High-oil seed sunflowers (40% oil) are generally grown for oil production, whereas low-oil seeds (about 30% oil) are grown for confectionery, nut, and birdseed markets.

Sunflower oil is refined, bleached, and deodorized to produce a bland-flavored edible oil. The typical fatty acid composition of sunflower oil consumed in the United States is shown in Table 10.1. The fatty acid composition of sunflower oil is naturally variable, depending on climate, temperature, genetic factors, and position of seed location in the flower head (Howell and Collins, 1957; Campbell, 1983). In fact, few vegetable oils reflect the influence of these factors as significantly as does sunflower oil. The 18:2 and 18:1 averages of northern sunflower oil grown above 39° latitude in the United States compared with southern-grown sunflower oil varied, with 18:2 ranging from 44% to 68% and 18:1 from 19% to 47% (Campbell, 1983). The warmer the temperature during maturation of the seed, the lower the 18:2 and the higher the 18:1 levels became.

Nagao and Yamazaki (1983) found fatty acid compositions of four varieties of sunflowers grown under seven environmental conditions (planting location and date) in Japan to vary considerably in fatty acid composition. The 16:0 ranged from 4.2% to 6.2%, 18:0 from 2.4% to 6.0%, 18:1 from 13.6% to 49.9%, and 18:2 from 43.8% to 75.4%. There were significant differences in the percentage of 18:2 among the four varieties; however, the greatest differences were due to environmental conditions. The 18:2 percentage was negatively correlated with the temperature and the 18:1 percentage was positively correlated. The combined percentage of 18:1 and 18:2 was constant, at about 90%, and was not influenced by temperature. Therefore, it is likely that the temperature during maturation of the seed influenced the desaturation of 18:1–18:2. Other researchers have noted the close reverse dependence between 18:1 and 18:2 in sunflower oil (Ermakov and Megorskaya, 1972; Mancha et al., 1994). Similarly, two high-18:1 hybrids, Platon and Vyp70, developed by the Italian seed company, AGRA, experienced a decrease in 18:0 and 18:1 and an increase in 16:0 and 18:2 with irrigation (Flagella et al., 2002). Thus, stress conditions of drought actually increased the 18:1 concentration. Because of the variability in the 18:1 and 18:2 production, it is difficult to give an accurate fatty acid content of sunflower oil without actually measuring it. In general, however, most standard sunflower oil produced in the United States is grown in northern climates, so the typical fatty acid composition shown in Table 10.1 is fairly accurate for standard sunflower oil used in the United States.

Despite the great influence of temperature and other environmental conditions on fatty acid composition, sunflowers have been developed that consistently produce sunflower oil high in 18:1 even when grown in northern climates. Treatment of normal varieties of sunflower seed with chemical mutagens and development of their progenies have resulted in hybrids bearing oil with 18:1 contents greater than 80%, and 18:2 contents of less than 10% (Purdy, 1986). The fatty acid composition of the varieties seems to be unaffected by climatic conditions. Patents for these unique sunflower oils were issued to the Lubrizol Corporation (Fick, 1984, 1985). In 1984, high-oleic seed was grown commercially in the United States for the first time in North Dakota, California, and Texas, and very little difference in either 18:1 or 18:2 levels was noted among locations. High-18:1 sunflower oil is currently grown around the world in areas including North and South America, Europe, Asia, and Australia. Mid-18:1 NuSun® sunflower hybrids with 18:1 levels of 50%–70%, and high-18:1 hybrids, with 18:1 levels of >80% are available from Mycogen® (Dow AgroSciences, LLC). In Australia, Sunola is the registered trademark name given to high-18:1 sunflower oil sold by Meadow Lea Foods.

Since 1988, Mancha et al. (1994) have led an extensive mutagenic program to induce further variability in the fatty acid composition of sunflower seed oil. They have obtained seeds with high-16:0 (26%–34%) or high-18:0 (8%–9%) compositions. In Spain, by chemical mutagenesis, sunflower seeds with oil having very high-18:0 concentrations of ~35% have been developed (Fernández-Moya et al., 2000, 2002, 2005). In addition, a line with an 18:0 of 10.0% and an 18:1 of 38.3% was reported (Fernández-Moya et al., 2005). These lines have not yet been evaluated for agronomic performance, but a temperature impact was noted. The maximum 18:0 concentration was obtained when the plants were grown at 39°/24°C, and temperatures greater than 30°C/20°C were needed for good expression of the phenotype (Fernández-Moya et al., 2002).

The total tocopherol concentration in sunflower oil has been reported to be similar to that of soybean, corn, and cottonseed oils at about 700 mg/kg of oil weight (McLaughlin and Weihbrauch, 1979; Landers and Rathmann, 1981). For sunflower oil, the total included 500 mg/kg of the alpha homologue and 100 mg/kg of the gamma homologue, whereas soybean oil had 100 mg/kg of alpha and 600 mg/kg of gamma homologues. Warner et al. (1990) reported tocopherol levels in soybean oil of 120, 10, 610, and 260 mg/kg for alpha, beta, gamma, and delta homologues, respectively, whereas for sunflower oil, they reported levels of 610, 10, 30, and 10 mg/kg for alpha, beta, gamma, and delta homologues, respectively. The alpha form has the highest vitamin E activity; however, gamma-tocopherol has the highest antioxidant activity. In studies by Warner et al. (1990) and Warner and Mounts (1990), sunflower tocopherols were added to stripped soybean oil and vice versa. The stability pattern of sunflower oil, which is generally less stable than soybean oil, mimicked that of soybean oil. With sunflower tocopherols added, soybean oil had a stability pattern similar to that of sunflower oil. More specific follow-up work with the same experimental research design showed greater oxidative and flavor stability of both soybean and sunflower oils aged in the dark when the tocopherol profile native to soybean oil was present, and greater stability of either oils aged in the light when the tocopherol profile native to sunflower oil was present (Warner, 2005). Demurin et al. (1996) noted that oil from near-isogenic lines of wild sunflower species differed in their proportions of alpha- and gamma-tocopherols. They compared the oxidative stability of these oils, and confirmed that oils having the greatest amount of gamma-tocopherol were the most stable. These researchers suggested that this type of genetic variability in sunflowers be used to produce a more stable sunflower oil containing mainly gamma- rather than alpha-tocopherols. Other researchers, however, still suggest that alpha-tocopherols have the better activity.

The high-PUFA content of sunflower oil makes it susceptible to oxidative deterioration and, thus, reduced flavor stability. In general, sunflower oil tends to be less stable than many oils, including soybean oil (Snyder et al., 1985; deMan et al., 1987; Warner et al., 1989). Sunflower oil of normal 18:2 content was particularly susceptible to autoxidation in the presence of sunlight (Topallar et al., 1997). High-oleic sunflower oil, however, dramatically improved oxidative stability, as measured by the AOM when compared with normal sunflower oil (Purdy, 1985). The improved stability was

attributed entirely to the shift in fatty acids from 18:2 to 18:1. The alpha-tocopherol levels in the high-oleic sunflower oil were similar to those found in regular sunflower oil (Purdy, 1986). Other researchers demonstrated that polyunsaturated vegetable oils, including canola, corn, and soybean oils, blended with high-oleic sunflower oils had greatly improved oxidative stability (Frankel and Huang, 1994). Additionally, high-oleic sunflower oil had greater frying stability and oxidative stability of potato chips fried in the oil during subsequent storage than cottonseed oil or than cottonseed/sunflower oil blends (Warner et al., 1997). Foods fried in the high-oleic oil, however, lacked some of the good flavors normally associated with fried foods, presumably because of the formation of fewer volatiles arising from 18:2. Mid-oleic levels (65%) of sunflower oils have been developed to address this problem (Warner and Kleingartner, 1998). Dobarganes et al. (1993) also noted enhanced thermal stability and frying performance of high-oleic sunflower oil over normal sunflower oil. No difference in stability was noted between olive and high-oleic sunflower oil over normal sunflower oil. No difference in stability was noted between olive and high-oleic sunflower oils, each containing similar amounts of 18:1.

11 Fatty Acids in Fruits and Fruit Products

Basil S. Kamel and Yukio Kakuda

CONTENTS

I. INTRODUCTION

The search for new sources of fats and oils is an ongoing process. By far, plant seeds are the most promising sources of oils for nutritional, industrial, and pharmaceutical purposes. The application of an oil for a particular purpose, however, is determined by its fatty acid and triglyceride compositions. No oil from a single source has been found to be suitable for all purposes, because oils from different sources have different fatty acid compositions. It is for this reason that the search for new sources for novel oils is so important. So far, a large number of plants have been analyzed, and some of these have been cultivated as new crops (Hirsinger, 1989). Another approach to develop novel oils is to produce new cultivars from already established oil crops. The development of low-erucic acid cultivars of *Brassica* is one good example (Downey and Robbelen, 1989). Other novel crops that are finding greater utilization include hemp (Parker et al., 2003; Illingworth, 2004), crambe (Yaniv et al., 1991), sea buckthorn (Yang and Kallio, 2001), and cuphea (Isbell and Behle, 2003). In addition to the nutritional, industrial, and pharmaceutical uses of oil, the variation in fatty acid composition in plants has proven to be a useful tool in taxonomic and phylogenetic studies (Vickery, 1971).

The potential supply of lipid material from fruits and fruit by-products may be enormous and should be investigated. Palm oil, palm kernel oil, and coconut oil are good examples of commercially successful oils extracted from palm fruit. Future edible oil supplies may depend on the discovery and development of similar types of plants. A listing of the lipid content and fatty acid composition of oils extracted from well-established sources and from new plant sources would be an important first step in this search.

A relatively untapped source of lipid and protein raw material is the by-product of fruit-processing plants. Many millions of pounds of fruit seeds are discarded yearly and in some cases resulting in disposal problems. Proper utilization of these waste products could lead to important new sources of oil and meal.

Many developing countries that are unable to fulfill their edible oil requirements for lack of currency to purchase commercial oils may benefit from indigenous oil-yielding plant sources.

New sources of oil and fat could supplement conventional supplies or even replace imports. An adequate supply of fats and oils could help reduce hunger and improve the nutritional status of the population by furnishing essential fatty acids in the diet.

Fatty acid composition is an important consideration with many oils, especially in affluent countries, where the need for calories is not as important as health concerns. Information on the relationships between total fat consumption, saturated fats in the diet, blood cholesterol levels, and cardiovascular disease is contradictory and confusing. Nevertheless, the National Heart, Lung and Blood Institute has recommended a diet with no more than 30% of total calories coming from fats and with saturated fats providing no more than 10% of total calories. In an article published in the *New England Journal of Medicine* (August 17, 1989), it was shown that a mixed diet rich in monounsaturated fatty acids (12.9% saturates, 15.1% monounsaturates, and 7.9% polyunsaturates) was as effective in lowering serum low-density lipoprotein (LDL) cholesterol as a diet rich in polyunsaturated fatty acids (PUFAs) (12.6% saturates, 10.8% monounsaturates, and 12.7% polyunsaturates). Another class of PUFAs that has received a great deal of attention is the ω-3 fatty acids. These fatty acids are found in fish oils and in some vegetable oils. The two most common ω-3 fatty acids in fish oils are eicosapentaenoic acid (EPA, 20:5) and decosahexaenoic acid (DHA, 22:6). There is substantial evidence indicating that ω-3 unsaturated fatty acids may provide health benefits in preventing heart diseases, cancers, hypertension, and autoimmune disorders (Connor, 2000; Tapiero et al., 2002). Interest in the ω-3 fatty acids began with the observations that Greenland Eskimos who consume a high-fat, high-cholesterol diet have a very low incidence of cardiovascular disease. This was attributed to their consumption of fish oils high in the ω-3 fatty acids. Soybean and canola oils contain substantial levels of these types of fatty acids in the form of α-linolenic acid.

World production of fats and oil was about 137 million metric tons (MMTs) in 2004–2005 (Tables 11.1 and 11.2). At the same time, the consumption of oil is forecast to be 138 MMTs. This deficiency is of little concern to the developed countries that have resources to purchase these scarce oil supplies. The developing countries, on the other hand, with very little foreign exchange cannot compete and must depend on domestic production if available. For example, Pakistan produces 1.62 MMTs, and imports 1.83 MMTs of oil yearly, whereas Bangladesh imports 1.13 MMTs, and consumes 1.21 MMTs of oil and has only limited production capabilities. As the economy of these developing countries improves, greater and greater demands on the world's oil supplies will ensue as they utilize their new purchasing powers. China produced 18.4 MMTs of oil in 2004/2005 but consumed 25.3 MMTs and as a result had to import 7.02 MMT to meet its needs. The development of new sources of fats and oils is one way to help mitigate this growing problem.

The information presented in this chapter is by no means a comprehensive listing of all possible fruits and fruit by-products. In some tables, only a representative sample of the types and variety of plants is given. Also, because the fatty acid composition is so dependent on factors such as maturity, soil conditions, climate, and variety, the compositions stated in some cases are averages from a

number of studies or varieties, and in other cases a single representative composition is given. Where data are available, the toxicological properties of the oil are mentioned.

Each table presents the common name, scientific name, % lipid, fatty acid composition, % saturated, %unsaturated, and references. The fatty acid compositions are given for the fruit mesocarp, fruit kernel, tree nuts, palm fruits, vegetable butters, miscellaneous plants, spices, and condiments.

II. FATTY ACID COMPOSITION OF FRUIT MESOCARP

The mesocarp, or pulp, of fruits generally contains very low levels of lipid material (0.1%–1.0%) and as such does not constitute an important source of edible or industrial fats and oils. A few notable exceptions are avocado, palm, and olive. The avocado is a cultivated fruit in which the oil is a main component (on a dry weight basis). The tree grows in a number of countries, including India, Egypt, Mexico, and the United States. The high oil content (15%–30%) and fatty acid composition depend on many factors such as variety, geographical location, climate conditions, and stage of fruit development. Avocado oil is obtained by either solvent extraction or centrifugal separation. The oil is highly unsaturated, with 75%–80% oleic acid, 7%–10% linoleic acid, and only trace levels of stearic acid (Werman and Neeman, 1987). The values given in Table 11.3 for avocado mesocarp fatty acid composition are the averages from four cultivars grown in the Mediterranean region. *cis*-Vaccenic acid (1%–2%) has been identified and is reported as the sum of vaccenic and oleic acids, because it coelutes with oleic acid. The fatty acid composition has been shown to change with maturation. Thirty-six weeks after flowering, the oleic + vaccenic acid levels increased steadily, whereas all other major fatty acids decreased. The three minor fatty acids—palmitoleic, stearic, and linolenic acids—either decreased or remained constant (Ratovohery et al., 1988).

Olive oil has been used since ancient times. The tree grows in the subtropical climates of the lands surrounding the Mediterranean Sea and in North Africa. The olive fruit pulp may contain

as high as 75% oil on a dry weight basis. Olive oil is characterized by a high percentage of oleic acid—up to 93% in some cases (Rana and Ahmed, 1981). Olive oil is unusual among vegetable oils in that it has a low iodine number yet remains liquid at low temperatures (down to about 0°C). This oil is more stable to oxidation than most other liquid vegetable oils owing to its low-linoleic acid content and higher phenolic content. Three types of oil are produced from olive pulp: virgin olive oil, refined olive oil, and residue-refined olive oil. The first is used mainly for salad dressings, the second for cooking and salad oils, and the third for cooking (Fedeli, 1983).

The durian is a highly prized and delicious fruit that grows throughout Southeast Asia. Its delicate flavor has been attributed to low molecular weight thiols/thioethers and esters. The strong odor that emanates from the edible portion (aril) is not appreciated by all people. The aril surrounds the seeds and contains 4%–5% lipid (Berry, 1981). The oil from the aril is yellow and is free of cyclopropene fatty acids, which are commonly found in plants belonging to the order Malvales to which durian belongs. The oil is primarily composed of palmitic and oleic acids. Unsaturated fatty acids constitute 62%–70% of the total fatty acids. Linolenic acid is found in levels ranging from 2% to 7% (Berry, 1980). It is of interest to note that the palmitic/palmitoleic acid ratio shows a relationship to taste panel scores: The lower the ratio, the higher the organoleptic acceptance score (Berry, 1981). This relationship needs more investigation with respect to maturity; degree of ripeness; content of carbohydrates, proteins, and water; and total concentration of flavor constituents. The fruit of *Visnea mocanera*, the so-called mocan fruit, contains 1.5% fat. These fruits are small, red blackish berries that are the size of a cherry when fully ripe. They are consumed fresh and the seed and peel are spat out by the natives of the Canary Archipelago (Perez et al., 1994).

The sea buckthorn is a deciduous shrub that grows wild in Central Asia. It produces yellow to orange-red berries that have high nutritional and medicinal values. The fruit pulp oil (Table 11.3) contains a high level of palmitoleic acid (16:1n-7, 27%–39%), which is unusual in the plant kingdom. The pulp oil is also a good source of carotenoids, tocopherols, and phytosterols. The seed oil (Table 11.4) is rich in two essential fatty acids, linoleic acid (37%–43.6%) and linolenic acid (25.4%–36%). This new oil is gaining greater popularity as a food supplement and ingredient in Japan, Europe, and North America (Yang and Kallio, 2001).

Gac is a fruit indigenous throughout Asia and is used for food and medicine. The aril, the red fleshy pulp that surrounds the seeds, has a bland and nutty taste. The oil content of the aril is approximately 22% (dw) with 69% unsaturated fatty acids of which 35% are polyunsaturated. The oil contains significant amounts of vitamin E, lycopene (2227 μg/mL), and β-carotene (718 μg/mL), making this oil a valuable source of natural antioxidants (Ishida et al., 2004).

III. FATTY ACID COMPOSITION OF FRUIT KERNELS AND SEEDS

The processing of many fruits results in the accumulation of large quantities of seeds and kernels. Proper utilization of these by-products could reduce waste disposal problems and serve as a potential new source of fats and proteins for use in food and feed. The fatty acid compositions of a select group of fruit seeds and kernels are given in Table 11.4. The lipid contents are high, ranging in most cases between 20% and 60%. A few seeds such as litchi and longan (Matthaus et al., 2003), avocado, durian, jackfruit, and tamarind seeds have lipid levels below 10%. As a potential source of new oils, this group has as its major fatty acids palmitic, oleic, and linoleic acids. A comparison of four *Prunus* species (apricot, cherry, peach, and prune) revealed a very high oleic (>60%) and linoleic (30%) acid content. These two fatty acids give these fruit kernels over 90% unsaturation. It is interesting to note that apricot and peach kernel oils have fatty acid compositions very similar to that of almond oil (Javed et al., 1984).

The argan fruit has an outer fleshy coat that surrounds a hard shell that contains the seeds. The seeds of the organ nut, contain a rich and tasty hazelnut-like oil. The oil is high in mono- and diunsaturated fatty acids, phytosterols, and tocopherols and is widely traded on the dietetic, nutraceutic,

and cosmetology markets. The status of argan oil has changed from an exotic tourist curiosity into a prized oil over the past 15 years. It is now an important commodity of the Moroccan economy (Hilali et al., 2005).

Short-chain fatty acids (C_8–C_{12}) are found in the citrus seed oils of grapefruit, lime, mandarin, and orange. Mandarin seed oil contains the largest number of fatty acids (11 identified, including 15:0 and 15:1 and 6 unknown peaks), whereas grapefruit seed oil contains only six. The fatty acid pattern for orange oil is similar to that of cottonseed oil, whereas lime seed oil is similar in unsaturation to soybean oil. Lime seed oil also contains a high amount of linolenic acid (42%). Other oils in this group with high-linolenic acid are cranberry (22.3%), red currant seed (29%), gooseberry seed (19.5%), melon seed (15.9%), and fig seed (44.7%). It should also be noted that these oils have a more favorable n-6 to n-3 fatty acid ratio than many other oils with high-PUFA content.

Egusi belongs to the melon family (Cucurbitaceae) and is grown in Nigeria only for its seed, because the pulp is very bitter. Egusi kernels contain 52% oil composed mainly of linoleic (62.8%) and oleic (15.9%) acids. The meal from the seeds is made into patties and served as a meat substitute. Undefatted meal and whole seeds are also consumed (Akobundu et al., 1982). The increased use of this important raw material will depend on the knowledge of its chemical, functional, and nutritional properties. Other Cucurbitaceae seeds include watermelon (*Citrullus vulgaris*), sweet melon (*Cucumis melo*), and pumpkin (*Cucurbita mixta*). These seeds are consumed after frying in many parts of the world, and their high levels (42.0%–64.8%) of linoleic acid make them a very nutritious snack.

Linoleic acid and its homologs are the precursors of eicosanoids. These compounds regulate a number of physiological functions such as arterial pressure, contraction of smooth muscles, platelet aggregation, and contraction and dilation of vascular glands. It has been suggested that certain diseases are caused by deficiency not of linoleic acid (LA, *cis*-9, 12) but of its homologs such as γ-linolenic acid (GLA, all-*cis*-6,9,12-octadecatrienoic), dihomo-γ-linolenic (all-*cis*-8,11,14-eicosatrienoic), and archidonic (all-*cis*-5,8,11,14-eicosatetraenoic) acids. This deficiency may occur as a result of low 6-desaturase activity, which is responsible for the transformation of LA to GLA. It is possible to alleviate essential fatty acid deficient status by direct intake of GLA. The sources of natural GLA are few, and at present only borage (21%–25%), evening primrose (7%–10%), hemp (3%–6%), and hopseed oils (3%–4%) are well known. The fruit seeds belonging to the Ribes family have recently been shown to contain significant levels of GLA: black currant oil (15%–18%), red currant oil (4%–6%), and gooseberry oil (10%–12%). The Ribes family seeds appear to be one of the richest sources of GLA investigated until now. Black currant oil also contains 13.5% α-linolenic acid (α-LN, 18:3,9,12,15) and 3.5% of the unusual stearidonic acid (α-SA, 18:4,6,9,12,15). Both α-LN and α-SA belong to the ω-3 PUFA series, which are precursors of eicosapentaenoic and docosahexaenoic acids (Traitler et al., 1984, 1988).

A compilation of 23 wild berry species, and their nutritional composition, used for food by North American native people has been documented by Kuhnlein (1989). This is the first comprehensive report on the nutrient content in the edible portion of these berries that range in fat content from 0.4% to 5.6%.

Approximately 10 million tons of mango fruits are produced in India and 500,000 tons in Bangladesh. The seeds in most cases are a waste product and are thrown away after being separated from the pulp. The seed represents up to 15%–24% of the weight of the fruits and contains 25% water, 5.5% protein, and 7%–11% fat depending on the variety (Char et al., 1977; Ali et al., 1985). This represents a potential source of oils and fats for human and animal consumption. Mango fat has received attention in recent years as a cocoa butter substitute. The proportion of disaturated to monosaturated glycerides however is very low (0.4:1) compared to that of cocoa butter (3.7:1), making it unsuitable as a cocoa butter substitute. The fat has been fractionated from acetone at low temperatures to isolate suitable hard fractions that have physical properties closer to that of cocoa butter, and some of the acetone fractions can serve as a partial substitute for cocoa butter (Baliga and Shitole, 1981). The oil is rich in stearic (39%) and oleic (41%) acids and low in linoleic acid (7.6%).

Traces of 2% of 17:0 fatty acid are present. Some of the large variations in fatty acid composition observed between investigators could be due to variety, climatic conditions, soil type, and maturity differences in the plant (Lakshminarayana et al., 1983). The fat melts at 34.5°C and has a cream color (Rukmini and Vijayaraghavan, 1984). It is bland, has a good plastic range, and is free of toxic substances, which makes it a potential edible fat for pastries and other products for which a saturated fat is required. It has also been used in the preparation of quality soaps and as a deep-fat-frying oil for potato chips (Char et al., 1977).

Tamarindus indica is cultivated in many parts of the world: India, Florida, Egypt, Sudan, Formosa, Southeast Asian countries, and Madagascar. Large differences have been observed in the fatty acid composition of the oils from the various countries. The tamarind tree bears flat pods that on ripening yield an edible pulp and a dark brown hard seed. The kernel oil from India is unique in having a large proportion (22.3%) of the saturated fatty acid, lignoceric acid. Significant levels of arachidic and behenic acids were also detected. The only other oil that has been reported to contain substantial quantities of lignoceric acid comes from the seed of coral wood (*Adenanthera pavonia* L.). The Malagasy tamarind kernel oil is very different from the Indian oil. The major fatty acids are linoleic (36%–48%), oleic (15%–26%), and palmitic (15%–19%) acids. Stearic, arachidic, behenic, and lignoceric acids were detected in smaller amounts. Odd-numbered fatty acids such as pentadecanoic, heptadecanoic, heptadecenoic, and tricosanoic acids were also found in small amounts (Andriamanantena et al., 1983).

Guava fruit is one of the richest sources of vitamin C and is produced in large quantities in Brazil, United States, India, and Egypt. At the present time, large amounts of guava fruit seeds are discarded during processing, and this aggravates a serious disposal problem. The seeds represent 6%–12% of the whole fruit weight and constitute a potential source of edible oil. The oil contains 76.4% linoleic acid and resembles safflower oil in composition (Prasad and Azeemoddin, 1994). This extremely high linoleic acid content is in direct contrast to the lower values (29%) reported by Subrahmanyam and Achaya (1959).

IV. FRUIT NUTS

Tree nuts are one of the oldest sources of food for humans and animals. At present, the world production is in excess of 1 million tons. Nuts are concentrated stores of aroma, flavor, fat, and protein and supply approximately 5–6 calories per gram.

The fat content of most nuts is high, ranging from 70% to 78% in macadamia nuts, pecans, and hickory nuts to 1.7% in ginkgo nuts to 3.1% in chestnuts (Table 11.5). The majority contains more than 50% fat, and all are highly unsaturated. A few species (butternut, black walnut, English walnut, filbert, and pecan) contain less than 10% saturated fatty acids. Brazil nuts are characterized by a very high linolenic acid content of 47%. Black walnut, English walnut, and faveleira nuts all contain over 50% linoleic acid, and acorn, cashew, filbert, pecan, and pistachio nuts contain over 60% oleic acid.

A mixture of phenolic olefins (cardanol) has been isolated and identified in cashew seed and germ oils. The levels range from 20 to 40 mg/100 mL of oil. It appears that these compounds are derived from the cashew nut liquid during the processing of the nuts. Other potentially toxic compounds (cyclopropene fatty acids) have been identified in Chinese chestnuts. Their levels are 5.4% dehydrosterculic, 0.39% malvalic, and 19.1% sterculic acids. These acids produce adverse physiological effects on experimental animals and may be carcinogenic and atherosclerotic (Berry, 1982). Apparently, cooking the nuts does not decrease the levels of these fatty acids.

The tropical tree known as mafura that grows in Tanzania and other West African countries produces a seed that is high in oil and protein. Commercial utilization of mafura seed has been prevented by the presence of a strong, bitter, and nauseating taste and a brown coloration in the oil. These problems have been reduced by the use of oil-refining procedures to produce an oil of acceptable flavor and color. In contrast, the oil from the husk is pale yellow and has no bitterness or emetic properties. The husk contains 35%–45% oil (Fupi and Mork, 1982).

Macadamia nut oil contains predominantly oleic acid (57.4%) and palmitoleic acid (20.1%). Behenic, docosenoic, and lignoceric acids have also been reported (Beuchat and Worthington, 1978). This oil has a low-PUFA content and as such should have good oxidative stability. The high-linolenic acid content of Brazil nuts (46.6%), butternuts (16%), and English walnuts (13.1%) should make these kernels the least stable if the degree of unsaturation is a predictor of oxidative rancidity. It should be remembered that storage conditions, moisture levels, oil content, and stage of maturity also have a large influence on stability.

Almond oil is used in cosmetics, pharmaceuticals, and food products. In the food area, almonds are distributed to confectioners, salters, bakeries, ice cream manufacturers, nonsalted nut retail packagers, and exporters. The main fatty acids are oleic (44.5%) and linoleic (40.5%). Differences in fatty acid composition have been noted by various researchers. Fourie and Basson (1990) reported traces of myristoleic acid but no linolenic, arachidic, or eicosenoic acid. These discrepancies may be due to differences in the analytical techniques used for quantification, but more likely they are due to differences in the maturity of the kernels. It has been shown that oleic acid increases with kernel maturity, whereas linolenic and arachidic acids are greatly reduced. Overall the unsaturated fatty acids increase constantly, whereas the total saturated fatty acids decrease (Munshi and Sukhija, 1984; Soler et al., 1988).

The main fatty acids in pecan oil are oleic and linoleic acids, which account for 90% of the total. A total of 23 fatty acids have been positively identified in pecan oil; 13 of which account for less than 0.2%. Small quantities of linolenic, eicosenoic, and palmitoleic acids were positively identified (Fourie and Basson, 1990).

Walnuts are used in a wide variety of food products, including cookies, cakes, fudges, granola bars, candy, ice cream, cereal-based products, and especially light foods. Walnuts are a good source of vitamins, minerals, and proteins. They contain no cholesterol and are low in saturated fat, sodium, and sugar and high in dietary fiber. Oleic and linoleic acids represent 85% of the lipids in walnut kernels. The major difference between English walnuts and black walnuts is the higher content of linolenic acid and lower content of oleic acid in the English walnut samples. Twenty-one fatty acids ranging in chain length from C_{12} to C_{22} were identified in each of the five cultivars (Senter et al., 1982).

Chestnuts are atypical of tree nuts in that they contain very little fat and are very high in starch. The lipid content for Chinese chestnut and European chestnut are 3.1% and 2.5%, respectively. The only other low-fat nut is the ginkgo nut (1.7% lipid).

The Cambodian nut, also known as "chambak or krabok," is collected in large quantities in the forest areas of Cambodia. The oil content of the nut is 70%. Most of the fatty acids are saturated and include 45.2% lauric acid and 42.1% myristic acid. These high-myristic acid levels are normally not found in common vegetable oils and to have both short-chain fatty acids in the same oil is completely unique. Because of its high fusion range (around 39°C), short-chain fatty acid, sterol and tocohpherol content, the Cambodian nut oil has very promising applications in the margarine, cosmetic, and pharmacology industries.

The pili nut (*Canarium ovatum*) that is native to the Philippines has a fruit kernel with 70% fat. The oil is light yellowish in color with 33.3% palmitic and 44.7% oleic acids. Fractional crystallization of the oil produces a high melting fraction with properties similar to cocoa butter and may find uses as a cocoa butter substitute in confectionery products (Kakuda et al., 2000).

Some minor nuts that are available but not in substantial amounts include chinquapins, or bushy chestnuts (*Castinea pumila*); heartnut, or Japanese walnut (*Juglans sieboldiana*); shellbark hickory (*Caryaovata laciniosa*), mocknut hickory (*C. tomentosa* and *C. alba*), and pignut hickory (*C. glabra*). Overall the fruit nuts are low in saturated fatty acids and high in unsaturates. They are a good source of the essential fatty acid linoleic acid and, in the case of Brazil nuts, butternuts, and English walnuts, are also a good source of the ω-3 fatty acid, α-linolenic acid.

V. PALM OILS

The palm family is estimated to consist of about 217 genera and over 2500 species. They are indigenous to the tropical and subtropical regions. They supply approximately 14% of the fats and oils in the world (Bandyopadhyay and Gholap, 1973). The majority of the palms contain neutral lipids, with lauric and myristic acids as the major components. This is reflected in the highly saturated fatty acid composition of these oils, that range from 80 to 95% (Table 11.6).

Coconut oil is obtained from copra that contains about 65%–68% oil and 4%–7% moisture. Approximately 3 MMTs of coconut oil are utilized annually for food and nonfood purposes. This oil contains a high amount of short- and medium-chain fatty acids and tends to be solid at room temperatures. It is characterized by having a sharp melting curve or short plastic range and a high resistance to rancidity (Swern, 1964).

Palm kernel oil is extracted from the kernel of the palm fruit. It is high in lauric and myristic acids and is very similar to coconut oil except for a slightly higher iodine value. Palm kernel oil can be separated into a stearin fraction for use as a cocoa butter substitute and a liquid fraction for use in baked goods and in soap manufacture (Swern, 1964). The oil extracted from the mesocarp of the same palm fruit has properties very different from those of the kernel oil. Palm oil is high in palmitic (40.1%) and oleic (42.7%) acids. The levels of lauric and myristic acids are less than 2%. Palm oil is produced in greater amounts than palm kernel oil and is used in making vegetable shortening, margarine, and soap. The main sources of palm oil are in Malaysia, West and Central Africa, and Indonesia. Other sources include Brazil and other South and Central American countries (Swern, 1964).

The *Arecastrum romanozoffianum* palm (queen's palm, plummy coconut, or pindo palm) is found both in the tropical and subtropical forests. The oval fruits grown in Nigeria consist of a slimy-sweet and fibrous pulp covering a hard shell. The kernel inside the shell yields 33% of a pale yellow fat with a nutty aroma. The cake from the defatted kernels is richer in carbohydrates and minerals and lower in fiber than *E. guineensis* kernel cake, making it a potentially better additive in livestock feed. Pindo palm oil has lauric acid (55%) as its major fatty acid and in general is similar to palm kernel oil, but it differs from coconut oil in having smaller amounts of C_{10} and C_8 and greater amounts of C_{12} and C_{14} fatty acids.

The fruit from the palm *Jubaea spectabilis* (subclass Cocoideae) weighs about 7.5 g and looks like a miniature coconut. This palm is native to certain parts of Chile. The oil from the kernel has a low melting point and remains fluid at low temperatures. This property is unique for an oil from the family Palmae and is due to a high content of short-chain fatty acids (C_8–C_{12}). Table 11.6 shows the much higher levels of these short-chain C_8 and C_{10} fatty acids (Cole et al., 1980).

The palm known as tucum or awarra (*Astrocaryum vulgare*) grows in Brazil, Peru, Venezuela, the Guianas, and Nigeria. The fruit yields a pulp oil used in soapmaking and a kernel fat that is consumed by the local population. The two oils are distinctly different; lauric acid is the predominant fatty acid in the kernel fat, whereas, as is generally seen in other pulp oils such as palm oil and olive oil, the pulp fat consists mainly of oleic and palmitic acids (Oboh and Oderinde, 1988, 1989).

Other palm kernel oils from Central and South American palms include the babassu, murumuru, ouricuri, and cohune. They are similar to the palm kernel oil from *E. guineensis* in fatty acid composition, with 42%–46% lauric acid and 9%–16% myristic acid. Murumuru oil is different, with 36% myristic acid and only 1.6% capric acid (Swern, 1964).

The Amazonian palms of the *Oenocarpus jessenia* complex produce an oil with a composition and taste very similar to those of olive oil. The most important species appears to be *Jessenia bataua*, which grows throughout the Amazon valley on either dry or swampy land. The oil is extracted from the mesocarp by pressing or boiling and is consumed as is or eaten with raw cane sugar or toasted cassava granules (Pryde et al., 1981). The major fatty acid is oleic acid (77.7%).

The kernel oil from the *Raphia* palm is characterized by high levels of polar lipids (phospholipids and glycolipids) and comparatively smaller amounts of triglycerides. The neutral lipids from

[a] Palm pulp contains 0.1% of 20:1.
[b] Two varieties: red and yellow fruit of *Dura* and *Tenera*.
[c] Other fatty acid consists of 0.2–4.6.
[d] C_{10} and below consist of 4.4%.
[e] Extremely wide variation exists among the estimated 260 species available.

these palm fruits contain negligible quantities of lauric and myristic acids but significant amounts of oleic (19%–36%), linoleic (15%–39%), and palmitic (23%–39%) acids. This is unusual and is contrary to the general belief that lauric and myristic acids are the principal fatty acids in all palms. Commercialization of these palm fruits is unlikely because of the low lipid content (<1.0%) of the kernel (Idiem-Opute, 1979).

An alternative source of medium-chain fatty acids is the oil from the *Cuphea* seed. This plant belongs to the Lythraceae family, which includes over 260 species. They are grown in Costa Rica, Mexico, Brazil, Peru, Panama, United States, and Nicaragua. Similar to the Palmae family, *Cuphea* seed oil contains high levels of lauric and capric acids, which may in the future augment or replace imports of coconut and palm kernel oils (Wolf et al., 1983; Graham and Kleiman, 1985; Thompson and Kleiman, 1988).

VI. BUTTERS FROM PLANT SOURCES

This group of fats is characterized by their unique melting and crystallization behavior. Their melting ranges are much narrower than those of common vegetable oils, and in the case of cocoa butter, can be as narrow as 35°C–36°C. This unique characteristic is due to the presence of a single dominant triglyceride, palmitooleostearin. There are six or possibly seven polymorphic states for cocoa butter that also contribute to its unique melting behavior. Because of cocoa butter's hardness and nongreasiness at room temperature and sharp melting point at body temperature, it finds many uses in the manufacture of chocolate confections and in coatings for chocolates and candies. Table 11.7 lists examples of butter substitutes.

Because of the high prices of cocoa butter and occasional shortages in supplies, a great deal of effort has been expended in finding replacers or extenders. Borneo tallow nuts are oil-bearing seeds that grow in Sarawak and Borneo (Kershaw, 1987). The fat from these kernels can be used as a cocoa butter substitute or extender. Borneo tallow resembles cocoa butter more than any other natural fat but differs in having a slightly higher and wider melting range, 34°C–39°C, and more stearic and less palmitic acid (Swern, 1964).

Theobroma bicolor is of the same family as cocoa butter, and accordingly its fat should have a similar chemical composition. The fatty acid and triglyceride compositions are very different from those of cocoa butter. The levels of stearic and oleic acids are higher, and that of palmitic acid is lower (Jee, 1984). The monounsaturated triglyceride levels are only 44% compared to 80% for cocoa butter. The high levels of diunsaturated triglycerides are responsible for the observed low melting point and softness of *T. bicolor* fat. Mixtures of more than very small amounts of this fat with cocoa butter will produce an unacceptably soft product.

Shea butter is even more unsaturated than *T. bicolor* and results in a soft and nonbrittle fat at room temperature. The fractionation of this fat has led to a stearin fraction that has been used as a cocoa butter substitute.

A few of the lesser known fats such as sal, kokum, and mowrah have been used as cocoa butter substitutes (Baliga and Shitole, 1981). Nutmeg butter and ucuhuba butter are characterized by high myristic acid levels of 77% and 68%, respectively. Nutmeg butter has been used in pharmaceutical preparations.

Chinese vegetable tallow is obtained from the outer covering of the seed from the Chinese tallow tree. The lipid from the kernel (stillingia oil) is used as a drying oil because of its high-linolenic acid content (20%–28%). The lipid from the shell contains significant amounts of palmitic acid (70%) and greatly reduced levels of linolenic acid (1.5%) (Echols, 1982). The current interest in this oil may arise from its possible use as a renewable energy source.

Cupuassu (*Theobroma grandiflorums*) is a tropical fruit found in the Brazilian forest. The production of cupuassu has increased from 10 MMT in 1998 to 21.4 MMT in 2000. The fruit has the form of a drupe with a strong and pleasant smell. The endocarp contains 25–50 superposed seeds in five rows. The seeds are fermented, roasted, milled, and pressed to obtain the fat in yields

[b] 0.3% 16:1.

of about 60%. Comparing the fatty acid composition with cocoa butter, the palmitic acid levels in capuassu fat is much lower (7.8%), stearic acid is nearly equal (32.9%), and oleic acid is higher (42.2%). The lower palmitic acid levels in cupuassu fat results in lower POP and POS type triacylglycerols and hence a lower solid fat content at all temperatures when compared to cocoa butter. The cupuassu fat could be modified by fractionation to make it resemble cocoa butter.

The prolific and diverse plant life in Brazil makes it an ideal location to search for new sources of food oils. The pequi tree grows naturally in the dry plains of Brazil and its fruit has been extensively used by the local population as an oil source. The oil is extracted by rendering the pulp, mesocarp, and kernel of the fruit and is used in cooking. The composition of the oil is predominately palmitic (44.2%) and oleic (48.7%) acids with lesser amounts of stearic (2.5%) and linoleic (4.4%) acids. Owing to its OOO, POO, and POP triacylglycerol composition, it can be used as a cocoa butter substitute.

Aceituno is an evergreen tree that is native to El Salvador in Central America. The plant produces brown-colored oval shaped seeds that contain kernels with 60% fat. The fat has a melting point of about 29°C with three major fatty acids: stearic (27%), oleic (56%), and palmitic (12.5%). This fat has the physical and chemical properties to make it a good candidate for use as a cocoa butter extender (Jeyarani and Reddy, 2001).

VII. LESSER KNOWN FRUITS AND FRUIT PRODUCTS

The fruits and fruit products listed in Table 11.8–11.11 are not currently of commercial importance. However, some of them are very important in certain countries and can make a significant impact on the economies of those countries. Where these plants are indigenous, they can sometimes serve as an alternative or supplementary source of edible oils. A number of them are excellent sources of fat and contain over 50% lipid material; examples are *Panda oleosa* (50.5%), *Carapa procera* (53.5%), *Allanblackia floribunda* (67.6%), and *Valenzuela trinervis* (67%). This collection of 50 plants is divided among Tables 11.8–11.11 according to the dominant fatty acid. In all cases, the genus and species are given, and where the common name is unknown the family name is substituted. Because of the wide diversity within this group, we are not certain whether the oils listed are derived from whole fruit or from fruit parts.

The sources of palmitic acid-rich oils are listed in Table 11.8. The levels of this saturated fatty acid range from 30% to 39%, which gives this group a saturated/unsaturated ratio close to 1:1. Oleic and linoleic acids are the other major fatty acids.

The sources of oleic acid-rich oils are listed in Table 11.9. The percentage of oleic acid ranges from 33% to 78%. The lipid content of these seeds is quite high (12%–67%), averaging around 39%. Guindilla seeds are grown in Chile and Argentina. The seed consists of 56% hull and seed coat and 44% cotyledon. The oil contains 12.9% gadoleic acid (20:1) and, as in most Sapindaceae, the oil also contains toxic cyanolipids (Aguilera et al., 1986). Roselle seed oil is very rich in oleic acid (73%). This oil also contains 2.9% sterculic acid, 1.3% malvalic acid, and cyclopropenoid at half the level found in okra seed and one-fifth the level found in cottonseed oil. The ratio of saturated to unsaturated fatty aids in this group is about 1:2.

The linoleic acid group is by far the largest (Table 11.10). The levels of this essential fatty acid range from 35% to 87%. These high-linoleic acid levels coupled with the oleic acid levels gives a saturated/unsaturated ratio of about 1:3. Buffalo gourd oil is unique in having 2.3% and 0.03% conjugated dienoic and trienoic acids, respectively. It is highly unsaturated, with linoleic acid levels ranging from 39% to 77%. In feeding trials, it was found to be free of toxic substances when fed to chicks (Khoury et al., 1982). Karaka is a nut-bearing tree that grows in New Zealand and is eaten by natives. Before being eaten, it must be extensively baked and washed to remove β-nitropropionic acid, a toxic substance formed by hydrolysis of karakin. Acacia seeds are produced on small trees that grow in Australia, Africa, India, and Americas. The oil from this seed contains an epoxy acid

[a] The seed of spurge (wolf's milk) contains 30.1 and 31.6 oil, respectively.
[b] Chia oil contains 1.4%, 0.4%, and 0.5% of c16:0, c22:1, and c22:0, respectively.
[c] Eleostearic acid, isomer of linoleic acid.
[d] 65.7% eleostearic acid.

(9,10-epoxy-*cis*-12-octadecanoic acid) in amounts that range from 3.1% to 6.2% (Chowdhury et al., 1983; Jamal et al., 1987). *Crotolaria retusa* belongs to the Leguminosae family and grows in India, Sri Lanka, and Malaysia. The oil from this seed contains 9.8% ricinoleic, 1.3% malvalic, and 3.5% sterculic acids and cyclopropenoid fatty acids (Daulatabad and Mirajkar, 1989). Many of the seeds from the Meliaceae and Sterculiaceae families contain cyclorproprene acids along with malvalic, sterculic, and dihydrosterulic acids.

The prickly pear plants are potential sources of food in many desert areas of the world. The fruit consists of 48% pericarp and a seed pulp that is consumed fresh in Turkey. An edible oil can be extracted from the seeds in yields of 5.8%–13.6%. The seed oil is highly unsaturated with high amounts of linoleic acid (53.8%–70.3%) (Coskuner and Tekin, 2003; Ennouri et al., 2005). The prickly pear peel on the other hand has 3.7% total lipids with 32.3% linoleic acid and equal amounts of palmitic (23.1%) and oleic (24.1%) acids. Although the α-linolenic was low, this oil has 8.6% γ-linolenic acid. It should be pointed out that the peel represents 48% of the prickly pear and would normally be a waste disposal problem. The extraction of oil from this by-product represents a potential new source of fats (Ramadan and Morsel, 2003b). Another plant that grows in the arid lands of Mexico is the columnar cacti. The fruits of this cactus are berries that contain hundreds of seeds embedded in a sweet pulp. The oil content of the seeds ranges from 28.4% to 30.7% with 51.2% linoleic acid and 36.2% oleic acid. The fruit is an important source of food for the people inhabiting the arid zones of Mexico (Ortega-Nieblas, 2001).

Two Acacia species (*Acacia colei* and *Acacia tumida*) have been investigated for their chemical and nutritional content as a first step prior to their incorporation in the diet of the population in the semi-arid sub-Saharan region of West Africa. The results showed 8.1%–10.9% fat from the seeds with a fatty acid composition of 50.1%–55.9% linoleic acid, 18%–22% oleic acid, and 9.4%–11.4% palmitic acid. The long-chain fatty acids (arachidonic, behenic, and lignoceric) were also detected. It was suggested that the polyunsaturated rich acacia seed oils be blended with oils rich in monounsaturated fatty acid to produce an oil with a ratio of saturated, monounsaturated, and PUFA of 1:1:1, which is considered to be ideal by FAO/WHO 1980 (Adewusi et al., 2003).

Table 11.11 lists the seeds that contain significant amounts (26%–76%) of linolenic acid in their oils. Generally, the presence of this fatty acid renders many of these oils inedible. The exceptions to this are spurge fruit, Indian wood apple, and chia seeds, which are eaten in a number of countries. Two common vegetable oils (soybean and canola) with approximately 10% linolenic acid are used extensively as edible oils. The majority of these high-linolenic acid oils, however, are used for the manufacture of paints, varnishes, linoleum, oilcloth, and printing inks. Tung oil is unique in containing 73% eleostearic acid, a fatty acid with *trans* and conjugated double bonds (18:3Δ9c,11t,13t) (Swern, 1964). Greater demand for linolenic-type oils may develop if the therapeutic benefits of consuming ω-3 fatty acids become established.

VIII. SPICES AND CONDIMENTS

Although spices and condiments are not true fruits, they are widely consumed and do represent a minor source of fatty acids in the diet. The lipid content and fatty acid composition of the seeds and bulbs of these plants therefore deserve investigation (Table 11.12). Coriander seeds contain petroselenic acid (octadeca-*cis*-6-enoic acid) in high amounts (75.1%). The seed matures in 50 days after flowering, during which time the lipids accumulate to 21%. The major change in the fatty acid composition is the steady increase in petroselenic acid and the concomitant decrease in the levels of the other fatty acids (Lakshminarayana et al., 1981).

The seeds of local Ethiopian mustard (*Brassica carinata* Braun) are high in erucic acid (40.6%) and glucosinolates. The *B. carinata* seed contains 29% oil and is in common use in Ethiopia but has not been developed as an oilseed crop elsewhere. Glucosinolate analyses indicate that sinigrin is the major glucosinolate (Mnzava and Olsson, 1990).

Another oilseed that contains high amounts of erucic acid and glucosinolates is taramira (*Eruca sativa*), a member of the Cruciferae family of plants. The erucic acid level is variable and ranges

from a low of 10% in Turkish seeds (Flanders and Abdulkarim, 1985) to over 42% in seeds grown in India (Kanya and Uvs, 1989). These variations in fatty acid composition depend on the maturity of the seed and frequency of irrigation. The average fatty acid composition of seeds from these two sources is given in Table 11.12. The penetrating pungency of taramira seed oil is due to the hydrolysis of glucoerucin (4-thiomethyl 3-butenyl glucosinolate), the major glucosinolate in taramira seeds (Kanya and Uvs, 1989).

Onions, garlic, and nutmeg are used as seasonings and condiments, in folk medicine, and in cosmetics in various Middle Eastern countries. In onions, the oleic and linoleic acids account for 70% and palmitic and stearic acids for 29% of the total identified fatty acids. In garlic oil, the unsaturated fatty acids (palmitoleic, oleic, linoleic, eicosenoic, and arachidonic) account for 70% of the total fatty acids, and palmitic, margaric, stearic, and arachidic acids account for the rest. Nutmeg oil, on the other hand, is much more saturated owing to the presence of 78% myristic acid (Al-Khatib et al., 1987).

Fenugreek is cultivated in India, North Africa, and Mediterranean countries. The leaves are eaten as a vegetable, and the seeds are used as a condiment. The seed contains 7.5% lipid and is highly unsaturated, with 52% oleic acid and 39.8% linoleic acid. The purified oil is golden yellow and has a bitter taste and disagreeable odor. The total lipids consist of 84.1% neutral lipids, 5.4% glycolipids, and 10.5% phospholipids (Hemavathy and Prabhakar, 1989).

Two herbs grown in Japan (*B. spicata* and *Boehmeria nivea*) belong to the family Urticaceae. The achenes from these plants were shown to contain 80%–83% linoleic acid (Kato and Tanaka, 1981).

Paprika is widely used as a flavoring in foods. When processing the flesh, the paprika seeds are separated from the pods and discarded. This waste product has good potential for conversion into nutrients such as oil and protein suitable for human consumption. Paprika seed oil is high in total unsaturates (82.4%) and low in saturates (17.5%). The major fatty acids are linoleic (67.7%), oleic (14.5%), and palmitic (13.8%) acids (El-Adawy and Taha, 2001a,b).

The seeds from *Nigella damascene* are used as a diuretic and for flavoring of foods. The total lipid content was 33.5% with linoleic acid (47.6%–50.8%) as the major fatty acid. Significant levels of eicosodienoic acid (4.76%) were detected along with 35%–51% free fatty acids and 21%–29% elemenes in the volatile oil fraction (Dauksas et al., 2002).

Turkey exported 7400 tons of oregano in the year 2000. Oregano is used as an industrial raw material for producing essential oils, as a tea and as a culinary herb. The seed oil from *Origanum onites* L. contains 14%–20% oil with 57% linolenic and 22% linoleic as the major fatty acids. The distinctive aroma of oregano is due to carvacrol, which is present in the essential oil fraction (Azcan et al., 2004).

IX. FUTURE TRENDS

Vegetable oils are used predominately as a source of food and nutrition but many nonfood applications such as in cosmetics, pharmaceuticals, biobased lubricants, biobased plastics, and biobased fuels as an alternative to petrochemical fuels have emerged. Fatty acids are important for human health and nutrition. These fat-soluble compounds form complexes with protein and are transported to various tissues in the body where they are incorporated into cell membranes, are metabolized into other compounds, or serve as a source of energy. Many of these fruit oils are also excellent sources of nutraceuticals and bioactive compounds. Both argan and sea buckthorn oils have high nutritional and medicinal values. Hemp seed (*Cannabis sativa*) can yield an industrial oil high in erucic acid, which is an intermediate in the production of some polyesters, plastics, and nylons.

Recent studies have shown that hydrogenated and saturated fatty acids can lead to health problems. These findings lead to a reduction in the consumption of animal fats and an increase in the utilization of highly unsaturated vegetable oils. Butter oil consumption underwent a steady decline over the years but the awareness of *trans* fatty acids in hydrogenated oils has put butter in a more favorable light. Over the past 10 years, a number of oils such as grapeseed oil, tomato seed oil, apricot seed oil,

and apple seed oil have gone from emerging oil status to full commercialization. It is expected that similar outcomes are in store for the novel oil from the argan nut, hemp, crambe, and sea buckthorn seeds.

It is clear that India, China, and other developing countries are consuming increasing amounts of oil and this growing demand will put new pressures on finding new sources of edible oils. Although the health conscious consumers in developed countries are turning to specific oils such as olive oil and at the same time reducing their total consumption of fats and oils, this trend may not compensate for the growing demands from the populations in the developing countries. An additional factor that is putting pressure on world seed oil production is the increasing cost of crude oil. With the continual rise in fuel prices, there is an urgent need to develop alternative and renewable fuels. The development of biodiesel from plant and animal fats is one such alternative. Although biodiesel will reduce the reliance on petroleum feedstock, it will siphon off large amounts of vegetable oil that could be used in the edible oil market. This scenario is important because the consumption of vegetable oils is projected to grow 2.9% annually over the next 10 years (Inform 1:286, 2006).

12 Fatty Acids in Food Cereal Grains and Grain Products

Robert Becker

CONTENTS

I. INTRODUCTION

The fatty acid composition of cereal grains is generally well established and is available to the reader in standard reference sources (Morrison, 1978; USDA, 2005). Typical total lipid contents of cereal grains are listed in Table 12.1; fatty acid compositions of lipids from each grain are given in appropriate sections. Future work can be expected to refine further these values and their ranges and document environmental and processing variations. This discussion focuses on current information to provide a context for a review of knowledge regarding the state of fatty acids in cereal foods as they are consumed, and developments in their effects on food processing, functionality, and nutritional properties.

II. OCCURRENCE

Cereal grain lipids are broadly classified as either polar or nonpolar compounds based on their solubility in different solvent systems. Fatty acids are major components of all lipid classes, but most occur as acyl esters of glycerol, which are nonpolar lipids. Fatty acids may also be bound to a wide variety of other cellular components, for example, long-chain alcohol esters, to form waxes and *N*-acyl compounds that are polar lipids. Unbound or free fatty acids are also usually present in

TABLE 12.1
Total Lipid Content of Cereal Grains

Cereal	Total Lipid Content (%), Moisture-Free Basis[a]	References
Barley, pearled	2.5–4.7 (3.6)	Bhatty and Rossnagel (1980)
Buckwheat	2.6–3.2 (2.9)	Mazza (1988)
Corn	5.2–6.0 (5.6)	Morrison (1978)
Millet, proso	3.9–4.9 (4.5)	Lorenz and Hwang (1986)
Oats	4.9–7.9 (6.4)	Morrison (1978)
Rice	0.9–3.1 (2.9)	Morrison (1978)
Sorghum	3.7–6.0 (4.6)	Morrison (1978)
Wheat, whole kernel	2.1–3.8 (2.9)	Morrison (1978)

[a]Averages in parentheses.

smaller and variable amounts. These result from metabolic accumulations and enzymatic or chemical hydrolysis of the parent compound.

The principal fatty acids in cereal lipids are almost invariably 16:0, 16:1, 18:0, 18:1, 18:2, and 18:3. Trace amounts of other fatty acids may also be present; highly unsaturated fatty acids are unusual, as are hydroxy acids.

Fatty acid lipids occur as components of intercellular membranes, spherosomes (small oil droplets), starch, and protein bodies in all parts of the cereal grain. The lipid contents of the embryonic, bran, and endosperm mill fractions are often reported, frequently without indication of the amount of the material in the parent grain. Thus, embryonic material may be rich in lipid but constitute a small amount of the grain and contain only small amounts of the total lipids. Conversely, endosperm material may contain low levels of lipid but, owing to its preponderance in the kernel, constitute a large percentage of the total lipids. Specific examples are given for individual grains.

III. DEGRADATIVE EFFECTS

In cereal grains, the first step in lipid degradation is usually the liberation of free fatty acids, which then may undergo a variety of oxidative degradation reactions. The fatty acids may be enzymatically liberated by lipases or by chemical saponification (Pomeranz, 1985).

Oxidation of the fatty acids occurs primarily at methylene groups activated by adjacent double bonds. Unless mediated by other oxidants or enzyme systems, oxidation proceeds through a free radical chain mechanism involving initiation, propagation, and termination steps. Consequently, the rate of oxidation increases somewhat geometrically with the increase in the amount of unsaturation in the fatty acids and the number of adjacent double bonds, as are found in polyunsaturated fatty acids. Oxygen reacts with unsaturated fatty acids at relative rates of oleic 1, linoleic 12, and linolenic 25. Trace amounts of heavy metals such as copper, iron, and manganese also promote oxidation, as do conformational effects.

Oils rich in linoleic acid, such as sunflower, safflower, cottonseed, and soy are less stable than peanut, palm, and coconut oils, which contain lesser amounts of unsaturated fatty acids. Marine oils with fatty acids containing more than three double bonds are most susceptible to oxidation. Measurement of lipid oxidation has been reviewed by Gray (1978).

Oxidation may be either chemical, as described above, or enzymatic. Enzyme-mediated oxidation in cereal grains is largely due to lipoxidase and other oxidative enzymes, which occur mainly in the seed germ (Reed and Thorn, 1971). Linoleic/linolenic acids have been shown to be oxidized through a cascade of enzyme reactions (see review by Gardner, 1988). Lipoxidase activity is

preponderant in the germ and has been shown to occur in doughs; oxidized fat affects dough mixing properties and bread structure, flavor, and color.

IV. FLAVOR

The flavor of oils is due to low concentrations of volatile degradation components. Slight oxidation is called *reversion* and may produce desirable flavors; as degradation progresses, the oil becomes less acceptable and is termed *rancid*. The volatile rancidity flavor components are lower molecular weight saturated and unsaturated aldehydes, ketones, and organic acids.

Hydrolytic release of free fatty acids may be extensive without the development of rancid odors and flavors, because C_{16} or longer fatty acids are nonvolatile and are not typically rancid tasting. The flavor of free fatty acids has been described as acidic or soapy.

In addition to contributing to flavor as described above, free fatty acids may initiate other reactions in foods. For example, free fatty acids may hydrolyze sucrose to form glucose and fructose, which in turn may form Maillard-type browning compounds with undesirable colors, off-flavors, and diminished nutritional and functional properties. Alternatively, fatty acid hydroperoxides may from polymers, react with protein or amino acids, or react with carbohydrates, all with undesirable effects.

V. FUNCTIONALITY

The functional effects of lipids in cereal products have been extensively studied, often from an economic perspective. Typical efforts are toward the utilization of liquid oil rather than solid shortening in baked products and the development of theories explaining the role of lipids in the appearance and texture of baked products. Detailed explanations of many such effects are still being pursued. Similar studies of fatty acids, although not as frequent, are also incomplete. Most studies have been focused on wheat lipids and wheat products (Pomeranz, 1985).

In general, addition of fat to doughs will cause a larger volume, the cell walls become more uniform and thinner with a resulting softness and better bite, and crumb characteristics and loaf-keeping quality improve. Reduction of the fat content produces a corresponding coarseness and crumb darkness. The ratio of solid to liquid fat (shortening and oil) is also important to many product characteristics. For example, larger amounts of solid fat will reduce cookie spread. In many baked products, excessive amounts of fat may decrease product quality. In puff pastries, the main function of fat is to separate the thin layers of dough to produce a uniform flaky texture and a high volume. This occurs when the fat does not penetrate into the dough, which keeps the dough layers separate during mixing. Fats have also been implicated in the hydration effects of cereal grain starch granules. Emulsifiers may be added to replace fats.

Mono- and diglycerides of fatty acids and/or their corresponding diacetyltartaric acid esters make useful bread soft, impart better loaf symmetry and favor uniform cell structure and tenderer crusts. These softeners are often incorporated into the shortening. In pound cakes, they increase volume while reducing amounts of eggs and butter and/or shortening needed. Other fatty acid-derived additives include sodium stearyl fumarate, calcium or sodium stearyl-2-lactylate, succinylated mono- and diglycerides, lactylic stearate, tallowyl-β-lactic acid, and propyleneglycol esters of fatty acids. Some of these compounds are proprietary, but all function in much the same manner.

VI. THERMAL DETERIORATION

Thermal and oxidative deterioration of the oil in cereal grains during cooking by boiling, baking, or frying is of significantly less importance than comparable effects in meats, with respect to health as well as the quality of the food prepared (Doolittle et al., 1989). Heating of fats and oils causes

degradation of triglycerides, which may involve hydrolysis into free fatty acids. The liberated free fatty acids may contribute to the taste of the food, or they may become chemical reactants affecting functionality and nutrition. Oleic and linoleic acids are known to inhibit the mutagenicity of heterocyclic amines (Hayatsu et al., 1981). Polyunsaturated fatty acids may also undergo free radical-mediated oxidation reactions with the formation of mutagenic products. In cereals and vegetables, which have low lipid levels, cooking conditions sufficiently severe to cause excessive lipid degradation usually result in unpalatable products, which serve to limit mutagenicity in these products. In meats, many of which have higher lipid levels, cooking to common levels of doneness is usually performed at higher temperatures, especially during boiling and frying. This can generate significant lipid thermal degradation with the accompanying mutagenic pyrolysis products as well as mutagenic heterocyclic amines from degraded proteins.

Since large amounts of vegetable oils are used for cooking, the excessive reuse of oils for deep-fat frying is of special interest. Cooking oils that have been thermally oxidized are thought to be mutagenic (MacGregor et al., 1985) and cause growth retardation, increased liver and kidney weights, and damage to the liver, thymus, and testes (Alexander, 1986). Related studies by Scheutwinkel-Reich et al. (1981) and van Gastel et al. (1984) were negative, but another work has indicated mutagenic activity associated with reused peanut oil (Fong et al., 1980). The mutagenicity of repeatedly reused cooking oils was studied by Hageman et al. (1988) using *Salmonella typhimurium* TA97, a strain not used by previous investigators. Frying oil was heated to 180°C for 10 h/day on four consecutive days. Foods were fried daily, cooking oil samples were collected and fractionated into polar and nonpolar portions, and the lipid peroxidation was measured as thiobarbituric acid reactants. Mutagenic activity was highest after 20 h frying. Rat liver activation enhanced mutagenesis by some fractions but inhibited others. In this initial study, a significant positive correlation was found between mutagenic activity and thiobarbituric acid reactants. In a subsequent study (Hageman et al., 1989), linoleic acid hydroperoxide levels, which are thiobarbituric acid reactants, were correlated with mutagenic activity in the presence of liver mix. Although these studies focus on the mutagenic involvement of lipid oxidation products, other pyrolysates should also be suspected. In any event, extremely thermally oxidized (excessively reused) cooking fats and oils should probably be avoided, and chronic or high consumption of fried foods should be of concern.

An association between lung cancer and heated cooking oils has been suggested by an epidemiological study of 672 Chinese women with lung cancer (Gao et al., 1987). The risk increased with the number of meals cooked by stir frying and deep-fat frying and with the degree of smokiness and frequency of eye irritation during cooking. These studies should be substantiated. Factors such as age, nutritional history, and smoking habits, as well as other pyrolysates and naturally occurring volatiles—for example, those from mushrooms and spices—should also be suspected.

VII. CEREAL GRAINS

A. Wheat

Because of its economic importance and the inherent complexity of many of its manufactured products, no commodity has been studied in as much detail as wheat. The location of wheat kernel lipids, their biochemical purpose, their extraction, functional effects in foods, and nutritional consequences have all been subjects of extensive investigations (Pomeranz, 1971, 1985).

The typical crude lipid and fatty acid composition of wheats and some of their mill fractions are shown in Table 12.2 and 12.3. Even though the endosperm contains only about 1% crude lipid, it contains roughly half of the total lipid content of the whole grain. The bran contains about one-third of the total oil and the germ the remainder. The germ also contains high concentrations of lipase-degrading enzymes.

Of the various changes that occur during grain deterioration, the hydrolytic break-down of fats and the formation of free fatty acids is the most rapid and signals the earliest stage of quality loss.

This "fat acidity" originates from enzymatic hydrolysis of the fats to release free fatty acids and to a lesser extent from oxidation of the unsaturated fatty acids to form acidic degradation products. This acidity (acid value) can be quantified by titration and has been defined as milligrams of potassium hydroxide required to neutralize the free fatty acids from 100 g of grain. Typically, fresh sound wheat has a fat acidity value of about 11, with a maximum of 20. Deterioration by improper storage, mold growth, high respiratory activity, or spontaneous heating may produce fat acidity values well over 100. Wheat stored under most practical storage conditions for several years will have fat acidity considerably higher than that of fresh sound wheat. Flour milled from deteriorated wheats will have reduced keeping and baking properties. Storage at low temperature and moisture content significantly reduces the changes in fat acidity values.

Flour containing severely deteriorated lipids can be easily detected by its typical rancid or "painty" off-odor. Less severe deterioration may not be as evident but will still be characterized by an increase in free fatty acids.

The practical consequences of deteriorated lipids (increased free fatty acids) are reduced loaf volume and diminished organoleptic parameters. Saturated fatty acids have little effect on doughs or gluten. However, unsaturated fatty acids produce "short," tough glutens and, when exposed to oxygen, significantly damaged baking performance.

B. Durum Wheat

Kobrehel and Sauvaire (1990) have shown that sulfur-rich glutenins from durum wheat have an intrinsic affinity for specific lipids. These protein lipids are tightly bound and have a fatty acid composition substantially different from that of total lipid extracts. As shown in Table 12.4, linoleic acid (18:2) is over 50% of the fatty acid content of the total lipids, whereas in the purified sulfur-rich glutenins, its relative concentration is only about 4%. Lipids from the isolated sulfur-rich glutenin proteins are also significantly richer in C_{14}, C_{16}, and 18:0 fatty aids than the total lipid extracts, with 18:0 being approximately 150% richer in the glutenins. It was suggested that only 16:0, 18:0, and 18:1 were specifically bound to the protein, with the other fatty acids, which occur in lesser amounts, being contaminants.

In addition to the fatty acids, significant quantities of fatty alcohols were observed in the sulfur-rich glutenins. Dodecanol ($C_{12}H_{26}O$) occurs in only trace amounts in the total lipid extract but is a major component in a glutenin extract from Mondur durum wheat. Lesser amounts of tetradecanol ($C_{14}H_{30}O$) and pentadecanol ($C_{15}H_{32}O$) were also observed; another wheat variety had less dodecanol.

The physiological role of these glutenins and their correlation with other low molecular weight proteins is yet to be determined. However, it was observed that the bound lipids appear to promote solubilization of the sulfur-rich glutenins in the presence of sodium salts of fatty acids. Since these sulfur-rich glutenin proteins probably are trypsin and α-amylase inhibitors, the lipid components may facilitate seed wound resistance.

Because of their high sulfide and disulfide content and the presence of bound fatty acids and fatty alcohols, these components also undoubtedly have an important role in technological applications. Other glutenins were shown to aggregate strongly upon heating and to contribute significantly to pasta firmness and elasticity and the surface condition of cooked pasta, primarily through hydrophobic and disulfide bonding (Feillet et al., 1989; Kobrehel and Alary, 1989).

C. Rice

Most of the oil in the rice kernel is located in the bran and embryo, which usually contain about 15%–22% oil and are obtained during the milling process used to produce white rice (Table 12.5). In the intact kernel, the oil is compartmentalized and not available to indigenous enzymes. Milling ruptures the cells, mixes the cellular contents, and initiates autolytic, hydrolytic, and oxidative degradation of the oil, often accompanied by chemical degradative effects.

This oil degradation can be followed by the liberation of free fatty acids. In the intact kernel and immediately after milling, rice oil contains only small amounts of free fatty acids. After milling, the oil in untreated rice bran degrades to produce free fatty acids at a rate of 5%–7% of the oil per day. However, if the enzymes are deactivated, the bran becomes stable and the oil is not degraded. Until recently, processing logistics precluded commercial extraction of the oil from the bran before degradation occurred, so the bran was a waste product or at best was used for animal feed. Bran stabilization has now been economically achieved by extrusion cooking, and rice bran oil has become an important commercial commodity. For discussions of rice bran extrusion and technological assessments, see review by Sayre et al. (1982, 1985) and Saunders (1986).

Rice oil obtained from stabilized bran from good-quality rice has a free fatty acid content of under 2%; proper purification, deodorization, and decolorization virtually eliminate all free fatty acids. Hydrolysis of the total lipids indicates that the oil has a fatty acid content (Table 12.6) similar to those of corn, cottonseed, sesame, and peanut oils, being rich in oleic (40%–60%), linoleic (29%–42%), and palmitic (12%–16%) acids. Rice oil has a very mild flavor, so it is a useful ingredient in lightly seasoned foods and as a flavor carrier.

When used as frying oil, rice bran oil has greater stability than other popular oils, probably because of its high level of unsaponifiables (4.2% vs. 1.3% for corn oil). The unsaponifiables in rice oil are high in the antioxidant ferulic acid esters, contain significant levels of sterols, and have amounts of tocopherols typical of other grains.

TABLE 12.5
Typical Distribution of Rice Lipids in Mill Fractions

A number of experiments have suggested that rice bran and rice bran oil have the effect of lowering serum cholesterol and low-density lipoproteins (LDLs) (Sharma and Rukmini, 1986; Raghuram et al., 1989; Kahlon et al., 1990). The specific dietary components in the oil responsible for these effects appear to be unsaturated fatty acids and unsaponifiables such as tocotrienols and β-sitosterol. In the bran, the effective components are thought to be hemicellulose, β-glucans, and protein.

Other work by Most et al. 2005 found that the unsaponifiables in rice bran oil, not fiber, lowers cholesterol in humans.

D. Maize

The occurrence, composition, chemistry, isolation, purification, properties, and uses of maize (corn) oil have been ably reviewed by Watson and Ramsted (1987). Because of the economics of production and processing, corn is the major cereal grain used for the commercial production of vegetable oil.

Corn oil is localized in the seed germ. The amount of germ in the kernel and oil in the germ are genetically controlled and vary widely. Both dry- and wet-milling processes are used to separate the germ from the remainder of the seed. Dry-milling yields germs containing about 18% (moisture-free basis, MFB) oil, which is rolled (flaked) and hexane extracted. Germ produced by wet milling contains about 56% (MFB) oil, which is heated and screw pressed to remove about 60% of the oil, with the remaining oil being solvent extracted.

Refining crude corn oil removes phosphatides, free fatty acids, pigments, waxes, and trace amounts of undesirable flavors and odors. Refined corn oil is pale yellow and bland and maintains clarity at refrigeration temperatures. Margarines are produced from corn oil by partial hydrogenation, giving products that usually contain more polyunsaturated fatty acids than margarines made from other fats or oils.

The composition of refined maize oil is shown in Table 12.7. Polyunsaturated fatty acids are higher in maize oil than oils from many competing sources, which lead to claims of increased health benefits.

The greater oxidative stability of corn oil is due to its higher levels of tocopherols and lesser amounts of linolenic acid.

E. Oats

Oat groats (caryopsis) have the highest lipid concentration of the common cereal grains (Morrison, 1978) (4.9%–7.9%) (see Table 12.1). These lipids are compositionally similar to other cereal grains, being highly unsaturated and containing considerable amounts of linoleic acid, an essential fatty acid for humans. Owing in part to this lipid content, oats are a good energy source (Webster, 1986).

There is a continuing interest (Youngs, 1986; Branson and Frey, 1989) in increasing the groat oil content to make the crop a source of edible oil (Frey and Hammond, 1975) and antioxidant compounds (Hammond, 1983), as well as a higher energy feed grain. The economics of producing oat oil indicate that a minimum 17% groat oil content is required (Frey and Hammond, 1975); based on production costs and multiple uses of the grain (protein and by-product utilization) and subject to variations in costs of competing sources. Breeding studies indicate that this is attainable (Branson and Frey, 1989) with favorable grain yields and retention of desirable agronomic characteristics. A potent lipase present in the seed may cause rapid hydrolysis and oil quality deterioration unless deactivated or diminished by breeding. Additionally, the higher oil content may make the grain more delicate, presenting shipping and processing problems.

F. Barley

Barley contains 2.5%–4.7% fat, with a fatty acid composition similar to that of other cereals. Crude fat was determined in 92 spring barley samples (81 of two-row and 11 of six-row type) and found to be 3.0% ± 0.2% in the two-row and 3.3% ± 0.3% in the six-row types (Aman et al., 1985). The typical composition of barley lipid is shown in Table 12.8.

The lipid content and composition of barley varies with the date of harvest or days after anthesis (DAA) (deMan and Cauberghe, 1988) as well as genotype and environmental and weather conditions before and after flowering (deMan, 1985). A relationship has also been found between barley fatty acid composition and kernel size as well as a similarity between the lipid composition of small mature grain and immature grain (deMan and Dondeyne, 1985; deMan and Bruyneel, 1987; deMan and Vervenne, 1988).

It was shown that the total fatty acid content (in mg/kernel) of spring barley increases to a maximum at 37 DAA, mainly due to an increase in the free lipid fraction, and diminishes rapidly in the next 5 days. Free and starch lipid contents decrease significantly during the final days of maturation.

Barley dried distillers grain (DDG) is a by-product of industrial "gasohol" production or brewing/distilling processes. Rich in protein, it has traditionally been used for animal feed or discarded. Attempts to incorporate it into food products have been hampered by its sharp, bitter soapy flavor with a distinct bitter or metallic aftertaste. Defatted and/or bleached DDG as an ingredient in oatmeal cookies was evaluated by a taste panel, and the changes in lipid composition correlated with panel acceptance (Dawson et al., 1984). Lipid changes occurring in the gasohol production process were followed, and DDG was tested as an ingredient in granola by Dawson et al. (1987). Unfortunately, the techniques employed in these studies did not satisfactorily address the myriad other compounds that may be present and are known to be related to bitterness (Belitz and Wieser, 1985).

Morrison et al. (1984) examined the lipid and amylose contents of 39 barley starch samples and reported a strong positive correlation between lysophospholipids and amylose overall. The amylose in all starches had similar lipid-binding capabilities, suggesting more uniform α-(1-4)glucan chain length and branching than are found in maize starches. Check feeding experiments indicate barley oil may have hypocholesterolaemic components (Linji et al., 1993).

G. Buckwheat

Buckwheat is cultivated in most temperature countries for food and for livestock and poultry feed. In North America, it is primarily used as an ingredient in pancake mixes, in Eastern Europe in porridges and soups, and in Japan as an ingredient with wheat in manufactured noodles.

Buckwheat seed and flour deteriorate rapidly with aging, changing from a light green seed and fresh, appetizing flour to a reddish brown seed and bland, somewhat rancid flour. The Japanese

market requires buckwheat flour to be milled within 1 week of use because of the flavor deterioration problem. These economic incentives have favored continued research of lipid and fatty acid composition of modern buckwheat varieties (Taira et al., 1986; Mazza, 1988).

The lipids in whole buckwheat and buckwheat tissues, buckwheat flour, and steamed and stored buckwheat have been reviewed by Pomeranz (1983). The lipid content and fatty acid composition of the three most important North American varieties were reported by Mazza (1988). Variations due to effects of seeding time were studied by Taira et al. (1986). The lipids and the fatty acid compositions of North American varieties are summarized in Table 12.9.

Buckwheat contains about the same amount of total lipids as wheat rye (see Table 12.1). In buckwheat, the neutral lipids constitute about 81%–85% of the total lipids compared to about 35% in wheat and rye. The major classes of fatty acids of all cultivars and all lipid classes were palmitic (16:0), oleic (18:1), and linoleic (18:2). Of the three cultivars examined, there were statistically significant differences only in the oleic and linoleic contents of total lipids, free lipids, and phospholipids. No evidence was found for changes in fatty acid composition during 25 months of room-temperature storage. Taira et al. (1986) found that oleic acid was the dominant fatty acid in early seeded cultures, which also had higher lipid contents, and linoleic acid was dominant in late-seeded cultures.

H. Millet

Because millet is one of the most drought-tolerant food crops, it is an important food in many parts of the world; estimated annual production is about 18 million metric tons (Hoseney et al., 1981). Although several small-seeded grains are called millets, the commonly grown varieties are pearl (*Pennisetum americanum*), proso (*Panicum miliaceum*), and foxtail (*Setaria italica*).

The chemical composition of millet has been well documented and compiled in reviews by Hulse et al. (1980) and Hoseney et al. (1981).

The odor instability of millet flour is a major factor in utilization of the grain (Varriano-Marston and Hoseney, 1983). The off-odor, which is detectable within days after milling, had been attributable to lipid deterioration (Lai and Varriano-Marston, 1980a). However, it was later shown by Kaced et al. (1984) that the odor was not the result of classical lipid oxidative deterioration. Reddy et al. (1986) concluded that the off-odor production is due to enzymatic action on the flavone portion of a *c*-glyco-flavone in the grain.

The free lipid (petroleum ether-extractable) composition of proso millet ranges from 3.03% to 7.40% and is rich in oleic (53.8%), linoleic (34.9%), and palmitic (10.8%) acids. Bound lipids ranged from 0.58% to 0.90% (Lai and Varriano-Marston, 1980b).

Hand-dissection of pearl millet and analysis of the anatomical parts indicated that 88% of the total lipid is in the germ, with the endosperm and bran each containing 6% (Abdelrahman et al., 1984). Osagie and Kates (1984) examined eight solvent systems for extracting lipids from *P. americanum* seeds and concluded that hot-saturated butanol was most efficient in extracting polar, neutral, and total lipids.

Lorenz and Hwang (1986) determined the lipid composition of flours and brans of nine proso millet varieties (Table 12.10). The lipids in glutinous and nonglutinous varieties of foxtail millet were analyzed by Taira (1984), who found that the glutinous varieties have more total lipid and a higher palmitic acid and lower stearic acid content but that there are overlapping ranges between the two varieties (see Table 12.11).

I. Sorghum

Sorghum is another drought-tolerant crop used for food in Asia and Africa. In Nigeria, it accounts for about 50% of the total cereal production; in South Africa, 90% of the crop is used for home-brewed beer production. Because of its coarseness and the bitterness caused by tannin in bird-resistant varieties, it is used as animal feed in most other countries. The production, evaluation, and nutritional value of traditional sorghum-based foods were reviewed by Rooney et al. (1986). Breeding programs have created varieties with lower tannin contents and improved protein quality.

Sorghum contains rather low levels of total lipids (3.9%), with most occurring in the germ fraction (Table 12.12). Oleic and linoleic acids are 84% of the total fatty acids (Table 12.13), making the lipids highly unsaturated. The improved varieties appear to have less oleic acid than traditional varieties, although the amount of total unsaturated fatty acids is the same.

TABLE 12.12
Typical Distribution of Sorghum Lipids in Mill Fractions

Sample	Mill Yield	Fat Content (%)	% Total Fat
Whole kernel	100	3.2–3.9	100
Endosperm	80–86	0.2–0.8	4–16
Bran	5–12	5–22	5–22
Germ	7–12	20–30	43–92

13 Fatty Acids in Fermented Food Products

Sue Joan Chang and Ching Kuang Chow

CONTENTS

I. INTRODUCTION

Fermentation is the chemical process that converts carbohydrates or sugars into alcohols or acids by microorganisms. The science of fermentation is known as zymology. As fruits and many foods ferment naturally, fermentation actually precedes human history. For centuries, humans have employed the fermentation process to produce and preserve many types of food products. Almost all cultures and ethnic groups have developed some typical forms of fermented foods.

Fermentation as part of food processing has been used for preservation, liberation of predigested nutrients, and production of alcoholic beverages (Solomons, 2002). By using special ingredients and carefully controlling temperature, pH, and other conditions of fermentation, the process allows the growth of "good" microorganisms in raw materials, while it prevents the growth of spoilage-causing microorganisms. Some common fermented food products and their respective ingredients, as well as microorganisms involved are shown in Table 13.1.

The common microorganisms involved in the fermentation process of food products are lactic acid bacteria, yeasts, and molds. In the making of yogurt and pickle vegetable, lactic acid bacteria (*Lactobacillus delbruckii* ssp. *Bulgaricus* and *Streptococcus salivarius* ssp. *Thermophius*) contribute to flavor, shelf life, structure, and consistency. During the production of wine and beer, yeasts (*Saccharomyces cerevisiae*) convert sugars into fruit juice and grains and produce ethanol, CO_2

TABLE 13.1
Some Fermented Products and Raw Materials

Product	Major Ingredients	Functional Microorganisms
Yogurt	Cow's milk	Lactic acid bacteria
Cultured milk	Cow's milk	Lactic acid bacteria
Sauerkrauts	Cabbage	Lactic acid bacteria
Picked olives	Olives	Lactic acid bacteria
Cheese	Cow's milk	Molds and/or lactic acid bacteria
Bread or sourdough bread	Wheat or rye flour	Yeasts and lactic acid bacteria
Yeast-leavened bread	Wheat flour	Yeasts
Lager beer	Barley, hops	Yeasts
White wine	Grapes	Yeasts
Sherry	Grapes	Yeasts
Soy sauce	Soybeans and wheat	Yeasts, molds, and lactic acid bacteria
Tempeh	Soybeans	Yeasts, molds, and lactic acid bacteria

and flavor, and molds (*Aspergillus sojae*) form proteolytic and saccharolytic enzymes, enabling solubilization and flavor production in soy sauce making. Also, bread is made by mixing dough with yeasts, which digest sugars (derived from starches in dough) and produce CO_2, causing the dough to rise.

The benefits of food fermentation include (1) enriching the diet through development of a diversity of flavors, aromas, and textures in food substrates; (2) preserving substantial amounts of food through lactic acid, alcoholic, acetic acid, and alkaline fermentations; (3) enriching food substrates with protein, essential amino acids, essential fatty acids, and vitamins biologically; (4) producing important nutrients or eliminate antinutrients, and making conditions unsuitable for undesirable microorganisms during food-fermentation processing; and (5) decreasing cooking times and fuel requirements (Steinkraus, 1995). Also, by converting lactose to lactic acid during the production of cheeses, yogurts, and acidified milk, the suffering of lactose intolerance by those who have insufficient expression of lactase on the intestinal mucosa can be alleviated (Solomons, 2002). The fatty acids in the fermented drinks, and food products of plant and milk origin, are the focus of this chapter.

II. FERMENTED FOOD PRODUCTS

Fermented foods of plant origin are derived from a variety of raw materials of different chemical composition and biophysical properties. Cereal grains and potatoes have high starch content, legumes and oil seeds have a high protein content, green vegetables have high moisture content, and fruits contain high concentration of reducing sugars. Milk is the main source of fermented foods of animal origin, although meat and fish have also been preserved to prolong the shelf life and to generate certain flavors, and a number of animal-based foods from different parts of the world are labeled as "fermented." However, the term "fermented" is scientifically incorrect because meats (beef, pork, goat, chicken, fish, seafood, etc.) are composed of mainly water, proteins, and fats, and contain very low lactic acid fermentable carbohydrates. Although acidification or fermentation by lactic acid bacteria in meats may be facilitated by adding sugar or starchy foods, the operative processes in the transformation undergone by these animal foods are essentially putrefaction and rancidification. Putrefaction is a general decomposition process of animal proteins, especially by anaerobic microorganisms (Ogielski et al., 1953), and the process usually results in the formation of amines such as putrescine and cadaverine, which have a putrid odor. Rancidification is the decomposition of fats and other lipids by oxidation. Rancid foods and oils develop highly reactive chemicals that produce

unpleasant and obnoxious odors and flavors, and destroy nutrients in food. The end products of animal-based foods resulting from these processes are quite different from those of fermentation, and are often dangerous for human consumption. Accordingly, the fatty acids in the fermented drinks and fermented food products of plant and milk origin are the focus of this chapter.

A. Fermented Drinks

A large number of fermented beverages, such as meads, wines, beers, ciders, vinegar, and tea, are available. As the majority of fatty acids present in the raw materials is consumed or converted to other compounds during fermentation, fermented drinks contain very little fats on a weighed or volume basis. Except for wines and beers, the information concerning fatty acids in fermented drink is rather limited.

a. Wines and Beers

A typical wine is composed of roughly 85% water, 12% ethyl alcohol, and 1% of tartaric, malic, and several other acids. Wine also contains various sugars and carbohydrates, less common alcohols, aromatic aldehydes, ketones, phenolics, enzymes, pigments, vitamins, and some minerals. There are over 300 separate ingredients identified in wine so far, and many other substances are yet to be identified. Most of these elements lend complexity to wine flavors with insignificant nutritional impact on the diet. There are, however, compounds in wine, such as catechins, flavinoids, resveratrol, and quercetin, which may have prophylactic effects against human diseases. A typical beer contains 3%–7% alcohol, over 90% of water, approximately 2% mono- and disaccharides, 1% polysaccharides, and small amounts of proteins, amino acids, minerals, and traces of vitamins. Wines and beers can be a significant source of calories from alcohol and carbohydrates. The caloric content of wines and beers varies between types, depending on color, alcoholic strength, and residual sugar. A 6-oz glass of dry wine (12.5% alcohol) contains about 150 kcal, which is close to a 6-oz glass of beer (110–120 kcal).

Wines and beers contain very little fats. The bulk, if not all, of fatty acids, especially unsaturated ones, originally present in fruit juice or grains are utilized for the growth and survival of yeasts during the fermentation process (Ancin et al., 1996, 1998; Guilloux-Benatier et al., 1998). During the first half of fermentation (50% of the sugar is used up) in Garnacha must, for example, practically all the fatty acids are consumed, with the exception of some medium-chain fatty acids. During the second half of fermentation, 80.1% of the fatty acids are consumed, with 28.8% of the remaining fatty acids being used up during aging. Similarly, during the first half of fermentation in Viura must, 46.9% of the total fatty acid concentration is used, with high consumption of unsaturated long-chain fatty acids (72.3%). During the second half of fermentation, 77.2% of the fatty acids are used, with high consumption of the long-chain saturated and unsaturated acids.

Fatty acids in the medium are taken up by cropped brewer's yeast and incorporated into cellular lipid fractions (Moonjai et al., 2003). The polar lipids of white and red table wines, dessert, and fortified wines account for 30%–40% of total lipids, and about 90% of the polar lipids consist of glycolipids and the minor portion is represented by phospholipids (Zherebin et al., 1981). During the aging of wine, medium-chain fatty acids are excreted by yeasts, and a small amount of unsaturated acids is consumed (Ancin et al., 1998). Biosynthesis of fatty acids by yeasts during alcohol fermentation is influenced by oxygen availabilities on grape must (Maurico et al., 1998). While long-chain fatty acids (C16:0 to C18:3) induce a positive effect on yeast growth and cell viability, medium-chain fatty acids (C10:0 and C12:0), especially in their esterified forms, may be toxic to *Oenococcus oeni* (Guilloux-Benatier et al., 1998).

The levels and types of fatty acids present in wines vary greatly depending on the raw materials and ingredients used, fermentation time and temperature, and type of yeasts used (Torija et al., 2003; Gomez et al., 2004). For example, palmitic acid, myristic acid, and lauric acid are the dominant fatty acids identified in commercial red wines, and the total fatty acids differ considerably (Yunoki et al., 2004). Depending on yeast population and fermentation kinetics and conditions, fatty acids

not found in grape must, such as tridecanoic acid and myristoleic acid, are detected in white wines (Varela et al., 1999). During the production of malt whisky, unsaturated fatty acids are converted to precursors of γ-lactones via hydroxy fatty acids produced by lactic acid bacteria during production (Wanikawa et al., 2000). 10-Hydroxystearic acid and 10-hydroxypalmitic acid are produced from oleic acid and palmitoleic acid, respectively, and then converted to γ-decalactone and γ-dodecalactone by yeast. Both γ-decalactone and γ-dodecalactone contribute to the sweet and fatty flavor, and quality of malt whisky.

Lipase, which is present in the grain of both rice and barley, catalyzes the hydrolysis of triacylglycerides at a lipid–water interface to yield free fatty acids. In brewing, free fatty acids are generally associated with negative effects, including the formation of stale or off-flavor aldehydes. Malt and rice lipases in the insoluble portion of the mash are quite thermostable, suggesting hydrolysis of triacylglycerides, and liberation of free fatty acids may continue through much of mashing (Schwarz et al., 2002). Also, the amount of lipid in barley decreases during malting and changes in the composition of lipid classes are minor, but the amount of free fatty acids increases, which is indicative that lipoxygenase is active during malting (Kaukovirta-Norja et al., 1993).

White must and wine fatty acids are present mainly in the free form or esterified as ethyl esters, and both contribute to flavor and foam properties of wine (Gallart et al., 1997). The free fatty acids, C8:0, C10:0, and C12:0, are negatively correlated with foamability, whereas the ethyl esters of hexanoic, octanoic, and decanoic acids are positively related, and the value of foamability is directly proportional to the ratio of esterified to unesterified fatty acids (Gallart et al., 2002). Fatty acids C6:0 to C10:0 have no impact on the foam stability, but C12:0, C14:0, C18:1, and C18:2 reduce the foam stability and the surface elasticity of beer. Also, C16:0 and C18:0 damage the foam very effectively, but do not influence the surface rheology (Wilde et al., 2003). The foam-damaging effect value of a free fatty acid is related to its extent of adsorption on a foam cell surface, and the addition of free fatty acid increases the foam-damaging effect of beers by decreasing the rate of foam thickness. Di- and trihydroxyoctadecenoic acids derived from linoleic acid are the decisive compounds determining the total foam-damaging effect value of the fatty acids in beers (Kobayashi et al., 2002). As di- and trihydroxyoctadecenoic acids decrease foam adhesion of beers, measurement of these hydroxyl fatty acids can be used to control various mashing conditions or the foam behavior of beer.

The release of lipids during the aging of sparkling wines in contact with yeast influences wine sensory attributes and, especially, foam characteristics. Pueyo et al. (2000) monitored the release of the different classes of lipids during the autolysis of three commercial yeast strains and found that a release of triacylglycerols, 1,3-diacylglycerols, 2-monoacylglycerols, free fatty acids, sterol esters, and sterols, but not phospholipids, during the first 2 days, a period that corresponded to the maximum loss of yeast viability. They also found that the mean lipid content in the autolysates was 8.6% for sterol esters, 3.8% for sterols, 2% for triacylglycerols, and <2% for 1,3-diacylglycerols and free fatty acids. The presence of C18:2 in brewing yeast can be used to distinguish these from closely related yeast species in the brewing industry (Morakile et al., 2002).

Similar to wines, very little of the lipid present in the raw materials survives the brewing process, and less than 0.04% of lipid remains in the finished beer (Anness and Reed, 1985). Spent grains, hot break, and cropped yeast are all effective means of removing lipids. Fatty acids of C14:0–C18:0 in beer are reduced during incubation at 60ºC, and the degradation of C18:1, C18:2 is accelerated by the addition of ferrous ion and is inhibited by ethylenediaminetetraacetic acid (EDTA), suggesting a role of free radical reaction in the degradation of these unsaturated acids (Kaneda et al., 1990).

Methylketones present in the headspace of Cognac are partly responsible for the desirable and complex characteristic called "rancio charentais" or "Cognac rancio," which is found in grape brandies aged in oak barrels for several decades. The ketones, 2-heptanone, 2-nonanone, 2-undecanone, and 2-tridecanone, are formed through β-oxidation and decarboxylation of long-chain fatty acids originating from yeast metabolism (Watts and Butzke, 2003). The concentrations of these ketones increase with Cognac age classification in the 42 brandies analyzed, and 2-heptanone is present at the highest concentration in most samples. The average concentrations and rates of formation

decrease with increasing chain length. The esters propyl octanoate and ethyl octanoate follow the same trend as the methylketones and appear to play an additional role in the formation of the rancio character.

b. Cider

Apple cider is another important fermented drink. Portions of sugars in apple juice are initially fermented to alcoholic apple cider, and the alcohol is then converted into acetic acid, with the help of yeasts and bacteria. Except for water, apple cider mainly consists of alcohol and sugars (Finnish Food Composition Database, 2006). However, a very small amount of fatty acids are present in apple cider in the free or esterified form, and contribute to both the flavor and foam properties of cider. The major fatty acids in cider are caproic, caprylic, capric, and palmitic acids (Blanco-Gomis et al., 2001). Linear discriminant analysis of fatty acids in cider from the region of Asturias (Spain) suggests that palmitoleic, pentadecanoic, linoleic, myristic, and linolenic acids are the most predictive variables to differentiate ciders made from apples grown in the Asturias region and ciders made from apples grown outside this region. Also, oleic, linoleic, caprylic, capric, stearic, and palmitic acids are related to the sweet cider apple category, while pentadecanoic acid is related to the sharp class (Blanco-Gomis et al., 2002). In aged cider, the concentrations of volatile components in distillates such as diethyl butanedioate, ethyl 3-methylbutanoate, ester of long-chain fatty acids, and 1-hexanol are increased, while the acetate esters and long-chain fatty acids are decreased (Mangas et al., 1996).

B. Fermented Plant Products

Fermented soy products are the most important fermented food products of plant origin. Soybeans contain high protein and fat and relatively low carbohydrates. The most abundant fatty acids in soybeans are linoleic acid (54%), oleic acid (23%), and palmitic acid (16%), although the lipid content and fatty acid composition in soybeans vary considerably depending on the season, maturity, and genetic factors (see Chapter 16 by Hammond, this book). The major fermented soy products include miso, soy sauce, soy yogurt, tempeh, and natto. Other ingredients, such as rice and barley, have been employed for miso making. Also, a large number of pickle vegetables are available commercially.

a. Miso

Miso is a rich, salty condiment that characterizes the essence of Japanese cooking, and is popularly used to prepare miso soup and to flavor a variety of foods in other meals. Miso is a rich source of proteins, fiber, minerals, vitamins, and isoflavones. There are many variations of miso, which are all basically made from koji. Koji are grains (mainly rice, but also barley) or soybeans that are mainly fermented with *Aspergillus oryzae* molds, which break down the proteins and carbohydrates, and aged in wooden kegs. The color of miso ranges from creamy white, red to cocoa-brown, and the texture and taste of these variations are just as diverse. Differences in ingredients and variations in length of aging produce different types of miso that vary greatly in flavor, texture, color, and aroma. The most common ones are red miso, white miso, barley miso, and soybean miso.

Red miso is made from white rice, barley, or soybeans, and the natural fermentation takes 1–3 years. Red miso contains the highest levels of protein of all types of miso, and is used for stir-fries, soups, and stews or to marinade meat, poultry, and vegetables. White miso is made by using more rice koji (about 60%) than soybeans in only a few weeks, and can be used as ingredient to make red miso. White miso has a relatively short shelf life, and contains the most carbohydrates and, therefore, tastes the sweetest and has smooth texture. Barley miso is made from barley grains, soybeans, and barley koji, and is naturally fermented for 1–3 years. Barley miso is dark in color and salty, but is rich in taste, and is used for seasoning rich soups, stews, beans, sauces, and spreads. Soybean miso is made from soybean, and the koji is produced from soybeans. Soybean miso has low carbohydrate

[a]Data are derived from the United States Department of Agriculture Nutrient Database for Standard Reference (1998).

content resulting in a very long fermentation period (>1 year). A special type of soybean miso called "Hatcho miso" is reddish-brown, and is often used to flavor hearty soups. Hatcho miso is normally aged for at least 16 months, and is considered the best miso. The koji for Hatcho miso contains a special mold, *Aspergillus hatcho*, instead of the usual *A. oryzae*.

During maturation of fermented rice-koji miso, triacylglycerol is gradually decomposed into free fatty acid, with distinct formation of fatty acid ethyl esters. Six months after the start of fermentation, the esters, constituted about 50% linoleic acid and 20% oleic acid, account for 35.0% of total lipid, and have no appreciable change in this proportion being observed during maturation (Yamabe et al., 2004). It is thus possible to monitor the maturation of the rice-koji miso by following up the increase with time in fatty acid ethyl ester.

As can be expected, the composition of miso varies greatly depending on the ingredients used and fermentation conditions employed. The nutritive values of a typical soy miso are shown in Table 13.2. Among the total fat (6.1% by weight) in miso, approximately 50% is attributed to linoleic acid (C18:2) and 20% to oleic acid (C18:1). The other significant fatty acids are palmitic acid (C16:0), stearic acid (C18:0), and linolenic acid (C18:3).

b. Soy Sauces

Soy sauce is a dark brown liquid made from fermented soybeans, and is the foundation of oriental cuisine. It is the essential ingredient and the most important condiment used to flavor food and also used to cook with. The soybean fermentation involves a special koji (*A. oryzae*), which converts soy proteins, starches, and fats into amino acids, simple sugars, and fatty acids. Most commercial soy sauces, however, are now made by a chemical process in which cereals and soybeans are mixed with acids. Soy sauce can be stored at room temperature for up to 1 year. However, soy sauce contains a lot of salt, and should be used sparingly to flavor dishes. The nutritive values of a typical soy sauce are shown in Table 13.3. As shown in the table, source sauce contains less than 0.1% of total fats, and 50% of the fatty acids are polyunsaturated.

c. Soy Yogurt

Yogurt production was invented probably by an accident by Balkan tribes thousands of years ago. Soy yogurt is made by fermenting soymilk (water extract of grinded soybean) with friendly

bacteria, mainly *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. During fermentation, the carbohydrates are converted by the bacteria to lactic acid, which causes the characteristic curd to form, and the bacterial enzymes partially digest the proteins making them easier for absorption. The lactic acid also restricts the growth of food poisoning bacteria. The process is similar to the production of yogurt from cow milk. In some countries, soy yogurt is labeled as "cultured soy milk" because the term "yogurt" is reserved for milk products. Some countries only allow using the name "yogurt" for products that have not been pasteurized to kill the bacteria after fermentation. The nutritive values of a typical soy yogurt are shown in Table 13.4. As expected the total fat content of soy yogurt is low (approximately 2.7%), and over 60% of fatty acids are polyunsaturated, and less than 20% are saturated.

d. Tempeh

Tempeh is a cultured soy food made by removing the hull of cooked soybeans, mixing with a culture, and aging for a day or two. The culture by yeasts, molds, and lactic acid bacteria helps hold the soybean in a cake form. Tempeh can also be made with added ingredients such as vegetables

or grains. Since tempeh is made from whole soybeans, it is a rich source of proteins and fiber, and a good source of many nutrients including B-vitamins and isoflavones. The natural tempeh fermentation process also makes the product more digestible. The nutritive values of a typical tempeh are shown in Table 13.5. The fatty acid composition is similar to that of soybean, with over 50% of fatty acids are polyunsaturated.

e. Natto

Natto is a traditional and popular fermented soy food in Japan, and has contributed to the nutrition, health, and well-being of the Japanese for many centuries. Traditional Japanese natto is essentially made by soaking and cooking whole soybeans until they are tender. The beans are then fermented for 14–18 h with *Bacillus* strain bacteria (Wei et al., 2001). The nutritive value of a typical natto is shown in Table 13.6. Natto contains about 11% of fat and over 50% of water. The lipid composition of natto is similar to that of raw soybean, except that much of the fatty acids are liberated from triacylglycerols. For example, free fatty acids account for 5%–18% of total lipids in Yukiwari-natto and 78% in Hama-natto (Kiuchi et al., 1976).

f. Pickle Vegetables

During the fermentations of vegetables, the conversion of carbohydrates to acids, alcohol, and carbon dioxide by the lactic acid bacteria constitutes the most important changes (Vorbeck et al., 1963). Changes in lipid composition also occur during fermentation. These changes are responsible for the unique texture, flavor, and color of fermented products. In addition, the lactic acid produced by the dominant bacteria inhibits the growth of all other microorganisms. Additionally, by consuming spoilage-sensitive parts of the food and releasing chemicals as by-products, the "good" microorganisms help preserving the vegetables, and generating the characteristic flavor and texture of the end products.

Same as other types of fermentation, marked changes occur in all lipid fractions during fermentation of dill pickle. The most striking difference is the decrease in the phospholipid fraction, and marked increases in free fatty acids and fatty acid esters. Pederson et al. (1964), for example, have identified 41 esters in dill pickle. Interestingly, marked increases of linoleic and linolenic acids occur in good pickle, while oleic acid is increased in bloated pickles. Also, tridecenoic acid that is present in cucumber is absent in pickles, and caproic, caprylic, and capric acids normally absent in

cucumbers are found in pickles. The hydrolytic alterations of lipids in pickled cucumber are analogous to that of sauerkraut fermentation by lactic acid bacteria (Vorbeck et al., 1963). The marked decrease in phospholipids during fermentation suggests their utilization by the bacteria (*Bacterium acetylcholine*) in cell protoplasma (Stephenson and Rowatt, 1947).

Similar to fresh vegetables, the fat content of fermented vegetable products is very small. For example, less than 0.2% of fat (about 50% saturated and 50% unsaturated) is found in pickle cucumber or dill. The nutritive value of a Finnish sour cabbage (sauerkraut) is shown in Table 13.7. Total fat in sauerkraut accounts for only 0.2% or less, while water accounts for the vast majority of the

weight or volume. The fatty acids in sauerkraut are free forms, and the major polyunsaturated fatty acids detected are linoleic and linolenic acids.

C. Fermented Milk Products

Among the fermented food products from animal origin, those made from milk are most important. Milk is the normal product of mammalian gland secretion. The average milk from cows consists of 88% water, 3.2% protein (mainly casein), 4.7% lactose (milk sugar), 0.74% minerals, and 3.4% fat. Milk fat consists of triacylglycerides (98%), diacylglycerides (0.25%–0.48%), monoacylglycerides (0.02%–0.04%), phospholipids (0.6%–1.0%), cholesterol (0.2%–0.4%), glycolipids (0.006%), and free fatty acids in milk (0.1%–0.4%).

The fatty acid composition of milk varies substantially among mammalian species, and diet plays a major role in modulating the fatty acid composition of milk in cattle (Jensen, 2002), goats (Chilliard et al., 2003), and sheep (Bocquier and Caja, 2001). The milk from ruminant animals, cow, sheep, and goat, contain much higher concentration of short-chain fatty acids (C4:0 and C6:0) than that from nonruminant animals. Milk fat from cow contains roughly 66% saturated fat, 4% polyunsaturated fat (mainly C18:2), and 30% monounsaturated fat (C18:1), and is greatly affected by seasonal variations. Goat's milk contains higher short- (17%) and medium-chain (32%) fatty acids, and lower monounsaturated (17%) fatty acids as compared to that of cow's milk. Also, the seasonal variation in fatty acid levels—goat's milk fat is lower than that of the cow's milk. The grazing conditions for dairy cattle significantly alter the proportion in milk and dairy products of conjugated linoleic acid isomers (Dhiman et al., 1999; Lock and Garnsworthy, 2003). Milk originating from cows, buffaloes, sheep, and goats has high moisture content and a neutral pH.

In general, the nutrient content of cultured or fermented dairy foods is similar to that of the milk from which these products are made. However, factors such as the type and strain of bacteria, milk (whole, low fat, nonfat) used, fermentation conditions, storage, and other treatments such as the addition of milk solids-not-fat, sweeteners, and fruits can influence the nutrient composition of cultured and culture-containing dairy foods. The probiotic bacteria used in commercial production of dairy products are mainly members of the genera *Lactobacillus* and *Bifidobacterium*. *Lactobacillus* species from which probiotic strains have been isolated include *L. acidophilus*, *Lactobacilllus johnsonii*, *Lactobacilllus casei*, *Lactobacilllus rhamnosus*, *Lactobacilllus gasseri*, and *Lactobacilllus reuteri*. *Bifidobacterium* strains include *Bifidobacterium bifidum*, *Bifidobacterium longum*, and *Bifidobacterium infantis* (Heller, 2001). A major aspect of the production of probiotic fermented dairy products is the interaction between probiotics and starter organisms. Acidification of milk by lactic acid bacterial fermentation, which reduces pH values to <4.5, inhibits the survival and growth of spoilage-causing or disease-associated bacteria. The principal fermented milk products are cheese and yogurt.

a. Cheese

Cheese, a concentrated dairy food made from milk, is the product obtained by draining the whey after coagulation of casein by acid produced by select microorganisms and/or by coagulating enzymes resulting in curd formation. Milk may also be acidified by adding food-grade acidulants in the manufacture of certain varieties of cheese, such as cottage cheese (Kealey and Kosikowski, 1986). Almost all cheese manufactured in the United States is made from cow's milk, although other sources of milk (sheep, goat) have been used in cheese making. Cheese may be unripened (fresh) or ripened (matured). In unripened cheeses such as creamed cottage and cream cheeses, the curd separated from the whey can be used immediately. In ripened cheeses such as Cheddar and Swiss cheese, the curd is further treated by selected strains of bacteria, molds, and yeasts, and ripening agents, resulting in a cheese of a specific flavor, texture, and appearance (Kosikowski and Mistry, 1997a,b; Mistry and Maubois, 2004). Fermentation of milk by lactic acid bacteria, and occasionally

by *propionibacteria*, yeasts, and molds, results in a variety of cheese. Cheeses may also be categorized according to manufacturing procedures such as the method by which the curd is formed (by acid and/or coagulating enzyme), the ripening agent (bacteria, mold, yeast, unripened), or according to rheology, or softness and hardness.

Cheese is an important source of high-quality proteins, vitamins, and minerals. The main protein in cheese is casein, although some lactalbumin and lactalglobulin may also be present, depending on the amount of whey entrapped in the cheese. Fermentation of milk by lactic acid bacteria, and occasionally by *propionibacteria*, yeasts, and molds, results in a variety of cheese. Lactic acid in turn acts with the added enzyme rennet to curdle the milk. Separation of the curd from the whey in cheese making causes a significant partition of nutrients and a considerable change in the nutrient content of cheese compared to that of the original milk. Milk's water-insoluble components, which are primarily retained in the curd, are concentrated in cheese. As about 5 quarts of milk are needed to make 1 pound of milk cheese and 9 pounds of whey, most ripened cheeses contain about ten times the amount of water-insoluble components as in milk. However, as most of milk's water-soluble constituents remain in the whey, these nutrients are lower in cheese than in milk.

The amount of various nutrients retained in the curd and whey largely depends on the type of cheese being manufactured, the type of milk (whole, reduced fat, nonfat) or whey used, the manner of coagulation (enzyme or acid coagulated), and ripening. The chemical composition of the end products is responsible for the characteristic odor and flavor of the finished cheese. As to be expected, the fat content of cheeses varies widely depending on the type of milk and milk products used to make cheese. Cheeses such as Cheddar, Brie, Blue, Limburger, Muenster, Gouda, and Swiss are generally made from whole milk and have about the same amount of fat and protein. A low-fat cheese has a higher protein-to-fat ratio. A small amount of polyunsaturated fatty acids (C18:2 and C18:3) is present in cheese.

The nutritive values of a 50% fat in dry matter Brie cheese are shown in Table 13.8. Brie is a soft cow's milk cheese named after Brie, the French province in which it originated. The majority of fatty acids in Brie cheese is saturated (C14:0, C16:0, and C18:0), and the major monounsaturated fatty acid is oleic acid (C18:1). The quantity of polyunsaturated fatty acids (C18:2 and C18:3) is relatively small.

Emmental is a yellow, medium-hard cheese, with characteristic large holes. Three types of bacteria, *Streptococcus thermophilis*, *Lactobacillus*, and *Propionibacter shermani*, are used in the production of Emmental. In the later stages of cheese production, *Propionibacter shermani* consumes the lactic acid excreted by the other bacteria and releases carbon dioxide, which slowly forms the bubbles that make holes. The nutritive value of Emmental (Swiss) cheese is shown in Table 13.9. Similar to that of Brie cheese, the majority of fatty acids present is saturated, and monounsaturated fatty acids account for about 25% of total fatty acids. Linoleic acid is the major polyunsaturated fatty acid, and almost 1% of the total fatty acids are of the *trans* form.

Seasonal variations in feeding condition are responsible for the variations in fatty acid composition of "Ossolano," a semihard cheese (Zeppaa et al., 2003). Long-chain mono- and polyunsaturated fatty acids are more abundant in the summer cheeses while short- and medium-chain saturated fatty acids are higher in winter products. The ratio of saturated to unsaturated fatty acids is thus lower in summer cheeses as compared with that of winter cheeses. Also, conjugated linoleic acids, n-3 and n-6 acids are higher in summer cheeses. The isomer of conjugated linoleic acid, C18:2 *cis*-9, *trans*-11 (rumenic acid), has potential anticarcinogenic and antiatherogenic property (see Chapter 34 by Huang et al., this book). Conjugated linoleic acid occurs in food as a result of microbial reactions, free radical-type oxidation, and heat treatment. Conjugated linoleic acid in the cheeses varied from 5.3 to 15.80 mg/g of cheese fat, and is dependent primarily on the origin of the milk (season, geography) and the production process (Lavillonniere et al., 1998). Addis et al. (2005) evaluated the effect on milk and cheese fatty acid compositions of feeding different fresh forages to dairy sheep and found that by using appropriate fresh forage-based regimens, the fatty acid profile of sheep dairy may be manipulated to maximize the content of conjugated linoleic acid and vaccenic acid.

[a]Data are derived from the Finnish Food Composition Database (2006).

The relative abundance of normal-chain free fatty acids in Cheddar-like hard goat cheeses, from greatest to least, is C10:0, C12:0, C8:0, C6:0, C4:0, C9:0, and C11:0 (Attaie and Richter, 1996). Similarly, the relative abundance of branched-chain fatty acids in Cheddar-like hard goat cheeses, from greatest to least, is 4-methyloctanoic, methyl-decanoic, 3-methylbutanoic, and 4-ethyloctanoic acids. These compounds have intense aromas, and even minute quantities can affect the flavor of dairy products. Also, ripening time significantly affects the concentrations of free fatty acids present. The concentrations of free fatty acids are increased during the initial 12 weeks of aging and remain relatively constant for the rest of the 24-week ripening period.

Cheese flavor is obtained through a series of chemical changes that occur in the curd during the early stages of ripening. Lipid hydrolysis leads to the formation of free fatty acids that serve as substrates for further reactions. Peptides and amino acids, which result from proteolysis, also lead to aroma compounds through enzymic and chemical reactions (Molimard and Spinnler, 1996). During cheese ripening, a small amount of the fat is hydrolyzed to volatile fatty acids, butyric, caproic, caprylic, and capric acids and higher carbon chain fatty acids, which contribute to the flavor of cheese. A marked increase in concentration of short-chain free fatty acids occurs during cheese ripening, ranging from 0.35 to 9.33 mg/100 g for butanoic acid, from 0.363 to 4.34 mg/100 g for hexanoic acid, from 0.343 to 2.0 mg/100 g for octanoic acid, and from 1.291 to 3.85 mg/100 g for decanoic acid (Pinho et al., 2002). In Manchego cheese, the free fatty acids that increase most throughout ripening are C4:0, C6:0, and C8:0, and the free fatty acids that are best correlated with ripening time are the short-chain fatty acids (Poveda et al., 1999).

Ripening time affects the content of free fatty acids of cheese. Total amounts of free fatty acids in Idiazabal cheese after 180 days of ripening, for example, are significantly higher in winter than in spring or summer. The major free fatty acids in winter are C10:0, C4:0, C18:1, and C16:0, and the amounts decrease as the cheese-making period progressed from winter to summer with C10:0 exhibiting the largest decrease and C18:1 the smallest decrease (Chávarri et al., 1999). The amounts of free fatty acids shorter than C12:0 are significantly higher in winter than either in spring or summer, and the percentage of volatile (C4–C8), medium (C10–C14), and long-chain free fatty acids (≥C16) changes during 180 days of ripening. Similarly, Macedo and Malcata (1996) monitored the changes in the concentrations of the free fatty acids in Serra cheese over a ripening period of 35 days throughout the cheese-making season, and found that the concentration of stearic acid increased significantly only during the first week of ripening, while palmitic and oleic acids increased significantly during all stages of ripening. They also found that the concentrations of butyric, caprylic, lauric, myristic, and linoleic acids were approximately constant during the first week and increased significantly thereafter, and the concentrations of butyric, caproic, and palmitic acids in cheeses manufactured in February were statistically lower than those in cheeses manufactured in May. The principal free fatty acids throughout ripening are butyric, capric, palmitic, stearic, and oleic acids.

Milk fat of sheep and goat contained significantly more 4-methyloctanoic and 4-ethyloctanoic acids than cow's milk fat. It is, therefore, not surprising that Pyrenees sheep's milk cheese contains significant amounts of methyl- and ethyl-substituted phenols, which contribute the characteristic sheep-like flavor notes to this cheese variety (Ha and Lindsay, 1991).

b. Cottage Cheese

Cottage cheese is a creamy, lumpy acid curd cheese, relying on the natural tendency of warm milk to curdle (no use of rennet). Once the floppy curd is formed, it is cut into pieces and heated gently in whey until it reaches the desired texture. After the whey is removed, the cheese is allowed to ripen for 1 or 2 days. Cottage cheese is an excellent source of calcium, phosphorus, protein, and vitamins. Cottage cheese contains live cultures of *Acidophilus* and *Bifidus*, which are probiotics. As cottage cheese has only trace amounts of lactose, it may not cause an intolerance problem.

Cottage cheese comes in several forms, including small-, medium-, and large-curds. Creamed cottage cheese is produced by adding 4%–8% cream dressing fermented by *B. infantis* to the dry curd,

and in low-fat cottage cheese, the cream is skimmed off. The minimum milk fat and maximum moisture content of most cheeses is governed by federal and state regulations. Low-fat and nonfat cottage cheese are now subject to the requirements of FDA's "general standard," which permits foods to be named by a defined nutrient content claim (e.g., low fat) and a standardized term (e.g., "cottage cheese"). Low-fat cottage cheese (0.5%, 1.0%, or 2% milk fat) must contain no more than 3 g total fat per serving (about 4 oz), and nonfat cottage cheese must contain less than 0.5 g total fat per serving. The nutritive value of Hytteost cottage cheese with 20% fat in dry matter is shown in Table 13.10. Over 60% of the total fatty acids are saturated, with C16:0 accounts for about half. Oleic acid is the major monounsaturated fatty acid, and the polyunsaturated fatty acids detected are C18:2 and C18:3. Also, significant amounts of *trans* fatty acids are present in cottage cheese. Essentially all fatty acids in cottage cheese are in free form (Finnish Food Composition Database, 2006).

c. Yogurt

Yogurt, an *acidophilus* cultured food (cow's milk), has been eaten for centuries all over the world. Because of the acidic nature, it helps absorption of iron and supports the growth of valuable intestinal bacteria. Recently, yogurt was allowed to claim to meet all or part of the meat/meat alternate requirements for child and adult nutrition programs because of the high-nutrient value of this dairy food. Yogurt and cultured milk products are important sources of high-quality protein, calcium, phosphorus, magnesium, riboflavin, and vitamins A and B_{12}. The nutritive values of low-fat yogurt

[b] Data are derived from the Danish Food Composition Databank (2006).

and natural yogurt are shown in Table 13.11. Similar to that of cheese and cottage cheese, and the majority of fatty acids in yogurt is saturated, and oleic acid accounts for about 25% of the total fat. Polyunsaturated (linoleic and linolenic acids) and *trans* fatty acids are also present in yogurt.

Milk, yogurt mix, and yogurt from cows fed with fish oil or fish oil and extruded soybeans diets have higher levels of conjugated linoleic acid, omega-3 fatty acids, and *trans*-vaccenic acid (Dave et al., 2002). Unsaturated fatty acids in the milk from cows fed with fish oil, fish oil and extruded soybeans, and extruded soybeans diets are also higher than that of the control diet. The processing of milk (85°C for 30 min) has no effects on fatty acids composition, and changes in fatty acids composition have no effects on the viable numbers of starter bacteria. As fermentation with yogurt and probiotic bacteria and storage does not alter the conjugated linoleic acid, *trans*-vaccenic acid, or omega-3 fatty acids, probiotic yogurt made from milk with increased conjugated linoleic acid and *trans*-vaccenic acid can be produced by changing the diets of cows. Most of the C18 fatty acids, including conjugated linoleic acid, are increased in the milk and cheese of cows fed extruded soybeans and cottonseeds, and processing into cheese does not alter the conjugated linoleic acid content (Dhiman et al., 1999). Similarly, supplementing soy oil or conjugated linoleic acid increases the conjugated linoleic acid contents of the milk and yogurt from Holstein cows (Boylston and Beitz, 2002). However, addition of conjugated linoleic acid to soy-oil-supplemented diets does not affect the conjugated linoleic acid and fatty acid composition of the yogurt.

III. SUMMARY AND CONCLUSION

Fermentation has long been employed to preserve foods, liberate nutrients, and make alcoholic beverages, and the common microorganisms involved in fermentation of food products are lactic acid bacteria, yeasts, and molds. Fermented foods of plant origin are derived from a variety of raw materials of different chemical composition and biophysical properties, and milk is the main source of fermented foods of animal origin. The nutritive value and fatty acids of fermented food products varies greatly depending on the raw materials and ingredients used and fermentation conditions employed.

Most of the fatty acids, especially long-chain and unsaturated ones, present in the fruit juices are utilized by yeasts and lactic acid bacteria during fermentation and aging of wine. The bulk of the fatty acids present in wines, beers, and cider are either in the free form or esterified as ethyl esters, and both contribute to flavor and foam properties. Major fermented food products of plant origin include miso, soy source, soy yogurt, tempeh and natto, and pickle vegetables, while cheese and yogurt are the major fermented products of animal origin. The fatty acid composition of fermented soy products is generally similar to their respective raw materials, except much of the fatty acids present are hydrolyzed to free fatty acids or form ethyl esters, which contribute to the characteristic flavor of the products. Fermentation of milk by lactic acid bacteria, and occasionally by *propionibacteria*, yeasts, and molds, results in a variety of cheese. The fat content of cheeses varies widely depending on the type of milk and milk products used to make cheese. During cheese ripening, a portion of the fat is hydrolyzed to volatile fatty acids and higher carbon chain fatty acids, which contribute to the flavor of cheese. Similarly, essentially all fatty acids in cheese are in free form, and the majority of the total fatty acids are saturated.

14 Fatty Acid Content of Convenience Foods

Maria G. Boosalis

CONTENTS

Even though it is not an exact definition, the term *convenience* foods refers to foods that have been either processed or created de novo to make them more appealing to the consumer (Briggs and Calloway, 1979). These types of foods include mixes, snack foods, desserts, preprepared or frozen items, including entrees, to name a few. The convenience foods selected to appear in this chapter are grouped together by the type of food items (e.g., snacks or pudding and custards) or similarities in the type of food products (e.g., French toast, pancakes, and waffles or doughnuts and muffins) and then listed alphabetically by their specific groupings as follows: baby foods; cakes and frostings; candies and syrups; cookies; doughnuts and muffins; French toast, pancakes, and waffles; frozen desserts, gelatin, and dessert topping; pastries and pies; pizza and entrees; puddings and custards; and snacks (chips, crackers, popcorn, pretzels, and trail mix).

Grouping similar types of convenience foods together in their respective tables does not necessarily mean that they have similar lipid content. The lipid composition data in convenience foods presented in this chapter were obtained and adapted from the U.S. Department of Agriculture (USDA), Agricultural Research Service, Nutrient Database for Standard Reference, Release 19 (USDA, 2006). This database is developed and maintained by the Nutrient Data Laboratory (NDL), one of the six units in the Beltsville Human Nutrition Research Center of the Agricultural Research Service. This laboratory and its predecessor organizations in the USDA have been compiling and developing food composition databases for over a century. The Standard Reference and the Primary Data Set food composition data serve as the numerical basis for most of the public and private work in the field of human nutrition. Most of these food composition data were previously published in the form of Agricultural Handbook 8 (AH-8), which is no longer available in printed form. Instead, the information contained in AH-8 is now provided via Internet access in the principle database the USDA Nutrient Database for Standard Reference (SR). This database includes 21 sections and 4 supplements of AH-8 that are updated on a timely basis. The most recent update of the SR is number 19, issued in August 2006, which is the database used for this chapter's fatty acid content.

As shown in the Table 14.1 through 14.11, the lipid content of the particular food items is reported as total cholesterol, total fat, total saturated, monounsaturated, polyunsaturated, and *trans* fat, as well as the individual fatty acid content. Except for cholesterol (which is given in milligrams), all levels are given as grams of fatty acid per 100 grams (g) of food. With respect to the amount of fatty acid levels listed, their totals may not add up to the total lipid value, because the latter may also include some nonfatty acid materials such as glycerol, phosphate, sugar, or sterol. As an example, in the case of a vegetable oil that is 100% triglyceride, 95.6% is fatty acids and the remaining 4.4% is glycerol; therefore, its lipid conversion factor is 0.956. For other fats, the percentage of fatty acids present will be even lower. Zero values in the tables should be understood to mean that there

Abbreviation: CHOL, cholesterol; SFAs, saturated fatty acids; MUFAs, monounsaturated fatty acids; PUFAs, polyunsaturated fatty acids; TFAs, *trans* fatty acids.

is either no content of fatty acid or that trace amounts may still be present as reported in the USDA Nutrient Database for Standard Reference (USDASR); blanks indicate that no data were provided by the USDASR.

A word concerning the *trans* fatty acid content of the various convenience foods. As of January 1, 2006, food manufacturers have been required to include the content of *trans* fatty acids in their respective products' food labels if one serving of that product contains 0.5 g or more of *trans* fatty acids (or *trans* fat) per serving size (for a description of labeling law see http://www.cfsan.fda.gov/). To date, only a fraction of the 7293 foods currently included in the USDA, Agricultural Research Service, Nutrient Database for Standard Reference, Release 19 (USDA, 2006) have their *trans* fatty acid content included. For this reason, only a limited amount of convenience foods in this chapter have the total amount of *trans* fatty acid (as total *trans* fat) included in their respective tables.

This section for babyfood (Table 14.1) has been expanded considerably since the previous edition of this chapter (Boosalis, 1999). Included in this section are prepared babyfoods that contain lipids. Excluded are foods such as fruits, juices, and vegetables that would not naturally contain or have added lipids. Other than several of the meat products that are included, the total lipid content of most of the other foods is relatively low.

In contents of the "Bars" section of Table 14.2, as a group, have a low cholesterol content (per 100 g of foodstuff) but their percentage of total lipid ranges from 2.4% to 31%, primarily in the form of 18:1, 18:2, 12:0, and 16:0 fatty acids, whereas the "Cakes" themselves have a higher content of cholesterol, yet a lower percentage of total lipid (range 14.8%–18.6%) with 18:1 and 16:0 being the predominant fatty acids in that grouping.

In Table 14.3, the "Candies" section, the cholesterol content varies depending on whether caramel or chocolate is present in the product, and the total percentage of the product that is lipid also varies tremendously (1.6%–52.3%), with 18:1, 18:0, 16:0, and 12:0 being the predominant fatty acids. A small number of candy bars also have their content of *trans* fatty acids included.

In Table 14.4, the cholesterol content of "Cookies" is relatively low per 100 g with the exception of the ladyfingers. The percentage of lipid in the cookies also varies, from 1.5% to 34%, with 18:1, 18:0, 16:0, and 18:2 fatty acids being predominant. In fact, as one looks especially at this table, one can see that small changes (likely due to a change in the ingredients) can make a difference in the fatty acid content of the food. As examples, "chocolate chip, commercially prepared, regular,

lower fat" compared to "chocolate chip, commercially prepared, regular, higher fat" have a total lipid content that is about one-third less, owing primarily to a decrease in both the saturated and monounsaturated fatty acid content of the former vs. the latter product. When "chocolate sandwich, crème-filling, special dietary" is compared to the "regular" version of the same cookie, the total lipid and saturated fatty acid content of the products are about the same. The difference in those products seems to be in the type of fat used. The "special dietary" version seems to have more of its fatty acids in the form of polyunsaturated fatty acids compared to the "regular" version of the product, which is also reported to contain *trans* fatty acids.

In Table 14.5, the total cholesterol per 100 g of food ranges between 0 and 62 mg and the percentage of total lipids varies between 9.4% and 25.25%, with 18:1, 18:2, 16:0, and 18:0 fatty acids being predominant.

In Table 14.6, the cholesterol content per 100 g varies between 0 and 82 mg and the percentage of total lipid varies between 1.4% and 20.6%, with 18:1, 18:2, and 16:0 being the predominant fatty acids.

In Table 14.7, the cholesterol content per 100 g of foodstuff varies between 0 and 92 mg, whereas the percentage of the product that is total lipid varies between 0% and 43.5%, with 16:0, 18:1, 18:0, and 14:0 being the predominant fatty acids. Of note, the products that have the most total lipid per 100 g (31%–43.5%) are two types of Alaskan ice creams made from fish with either shortening or seal oil. As predicted, these products also have a relatively high content of both mono- and polyunsaturated fatty acids. One of the highest content of saturated fatty acids is found in semisolid frozen dessert topping per 100 g, but keep in mind that a 1-tsp serving weighs only 4 g.

In Table 14.8, the lipid content varies, primarily because of the total lipid content of puff pastry and pie crust.

In Table 14.9, "Pizza" is approximately 9%–15% total lipid, depending on whether cheese, cheese and meat, or pepperoni is added. For most products, depending on how you make them, the fatty acid content will also be affected.

As shown in Table 14.10 with respect to pudding mixes, the lipid content seems directly related to the type of milk used in their preparation. The data are reported using either whole milk or 2% milk. Although data are not provided on the USDASR for puddings prepared with skim milk, using the latter would further reduce the total lipid content and alter the fatty acid profile.

In Table 14.11, "Snacks," the total lipid content varies with the product, with the subcategory of "Chips" products containing the greatest percentage of total lipid. The fatty acid profile of these products also varies widely, depending on the particular product.

Since space does not permit the inclusion of a typical serving size in the tables, the author recommends that the readers either check the nutrition label on the product of concern to determine its serving size or consult the USDA website (http://www.mypyramid.gov/pyramid/index.html) to obtain specific information on the particular serving size for each food group of My Pyramid.

With respect to the clinical and public health implications of choosing convenience foods with respect to their fat intake, the author recommends that the readers become familiar with the various types of fat and fatty acids listed in these products and then compare the products with the type of fat or fats used in the ingredients as listed on their labels. In general, when making daily food choices, the author recommends that the readers follow the recommendations as outlined on the USDA website (http://www.mypyramid.gov/) (USDA, 2005) with the number of servings per group selected being appropriate for the individual's activity level, age, and gender. In addition, the acceptable macronutrient distribution range (AMDR) for total daily intake of fat is 20%–35% of total energy with the intake of saturated fatty acids is not more than 10% of the day's total kilocalorie intake (National Academy of Sciences, 2005). Owing to the observation of a positive linear trend between *trans* fatty acid intake and total and low-density lipoprotein (LDL) cholesterol, it is recommended "that *trans* fatty acid consumption be as low as possible while consuming a nutritionally adequate diet" (National Academy of Sciences, 2002). The information presented in this chapter should aid the readers in achieving these suggested goals.

15 *Trans*-Fatty Acids in Foods

Margaret C. Craig-Schmidt and Carmen A. Teodorescu

CONTENTS

I. INTRODUCTION

Hydrogenated fat has been an important component of the Western diet. The use of margarine and other products made from hydrogenated fat increased as consumers became concerned about their intake of saturated fat and cholesterol. Vegetable oils used in the manufacture of margarine contain polyunsaturated fatty acids that are modified in structure during processing. Similarly, dairy products and meats from ruminant animals contain fat that has been modified by biohydrogenation. The term *isomeric* in reference to dietary fat generally refers to those fatty acids that are formed as a result of partial hydrogenation of unsaturated fat. Whether the process occurs in a commercial plant or in the rumen of an animal, double bonds originally present are modified in both conformation and position.

The question of whether or not isomeric fatty acids should be termed *unnatural* has been debated (Applewhite, 1981; Sommerfeld, 1983; Wood, 1983). Isomeric fatty acids are formed by biohydrogenation in the rumen of animals and thus appear "naturally" in meat and dairy products. On the other hand, the commercial process of partial hydrogenation by which margarines and shortenings are manufactured results in the presence of isomeric fatty acids considered to be "unnatural," because they were not present in the original vegetable oils. The issue, however, is not one of semantics but one of whether current amounts of these isomeric fatty acids in the food supply are having an effect on the health of populations consuming hydrogenated fat. Concerns have been raised about the possible effects of these isomeric fatty acids in promoting the incidence of cardiovascular disease (Kummerow, 1975, 1979; Vergroesen and Gottenbos, 1975; Kritchevsky, 1983; Mensink and Katan, 1990; Siguel and Lerman, 1993; Willett et al., 1993; Judd et al., 1994; Aro, 1998; Mensink and Zock, 1998; Stender and Dyerberg, 2004; Mozaffarian et al., 2006) and cancer (Enig et al., 1978). Additionally, there has been concern about possible detrimental effects of *trans*-fatty acids in infant development (Koletzko, 1992, 1994; Berra, 1993; van Houwelingen and Hornstra, 1994; International Life Sciences Institute Expert Panel on *Trans*-Fatty Acids and Early Development, 1997; Craig-Schmidt, 2001). On the other hand, conjugated linoleic acid (CLA; predominantly 9-*cis*, 11-*trans*-octadecadienoic acid) found principally in ruminant products in small, but significant, quantities is believed to be antiathrogenic and anticarcinogenic. This active area of research has been reviewed by Pariza et al. (1991), Parodi (1994), Ip et al. (1994), Chardigny et al. (1996a), Ip (1997), and Banni and Martin (1998). The physiological effects of isomeric fatty acids as they are metabolized and incorporated into membranes have been reviewed by a number of authors (Aaes-Jørgensen, 1966; Kummerow, 1974, 1975, 1979, 1986; Kaunitz, 1976; Alfin-Slater and Aftergood, 1979; Emken, 1979, 1981, 1983, 1984; Applewhite, 1981; Brisson, 1981; Kinsella, 1981; Kinsella et al., 1981; Beare-Rogers, 1983a; Gottenbos, 1983; Holman et al., 1983; Hølmer, 1998; Sebedio and Chardigny, 1998) and are beyond the scope of this chapter.

The studies on the physiological effects of isomeric fatty acids, however, cannot be properly interpreted unless they are put in the context of consumption data. The purpose of this chapter is thus to summarize what is known to date about the amounts and types of isomeric fatty acids in various foods and to review current estimates of isomeric fatty acids in the food supply. Earlier reviews of this topic include the Canadian Report of the Ad Hoc Committee on the Composition of Special Margarines (Spence et al., 1980), an article by Sommerfeld (1983) that emphasizes work done in Germany and other European countries, and a report by the Life Sciences Research Office for the U.S. Food and Drug Administration (Senti, 1985). Hunter and Applewhite (1986), Enig et al. (1990a), Craig-Schmidt (1998), and Craig-Schmidt (2006) review estimates of isomeric fatty acids in the diet but do not summarize the food composition data of individual food items. Additional reviews include (1) a report by the International Life Science Institute Expert Panel on *Trans*-Fatty Acids and Coronary Heart Disease (1995); (2) the American Society for Clinical Nutrition/American Institute of Nutrition Task Force on *Trans*-Fatty Acids (1996); (3) the International Life Sciences Institute Expert Panel on *Trans*-Fatty Acids and Early Development (1997); (4) two reports by the British Nutrition Foundation (1987, 1995); (5) the Danish Nutrition Council Report by Stender et al. (1994, 1995); (6) the FAO/WHO Report of the Joint Expert Consultation on Fats and Human Nutrition (FAO, 1993) and reviews by Gurr (1983, 1986, 1996), Emken (1984), Sanders (1988), Schaafsma (1992), Enig (1993, 1995), Wahle and James (1993), Mensink and Katan (1993), Precht and Molkentin (1995), and Becker (1996).

II. FORMS AND SOURCES OF DIETARY ISOMERIC FATTY ACIDS

A. Forms of Dietary Isomeric Fatty Acids

The major fatty acid isomers formed in the process of hydrogenation are classified into two types: positional and geometric isomers (Dutton, 1979). The term isomeric fat refers to both these types as well as to minor amounts of other fatty acids found in hydrogenated fat.

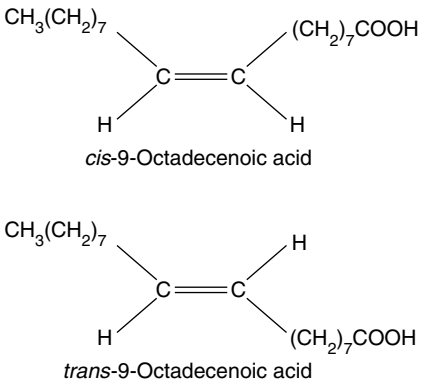

FIGURE 15.1 Geometrical isomerism in unsaturated fatty acids.

Positional isomers are formed in the hydrogenation process when double bonds shift from their original position in the unprocessed oil to other positions in the molecule. For example, fatty acids containing double bonds at the Δ9 and Δ12 positions are changed to isomeric forms containing double bonds ranging from positions Δ4 to Δ16 (Elson et al., 1981; Marchand, 1982), with the greatest concentration clustered in the vicinity of the original double bond (Scholfield et al., 1967; Carpenter and Slover, 1973; Parodi, 1976a; Emken, 1981; Sampugna et al., 1982).

Geometric isomers or *cis*/*trans*-isomers are formed when the "naturally" occurring *cis*-double bonds in vegetable oils are isomerized to the more thermodynamically stable *trans*-configuration; for example, *cis*-9-octadecenoic acid or oleic acid is transformed into *trans*-9-octadecenoic acid or elaidic acid (Figure 15.1). *Trans*-fatty acids have a higher melting point than the corresponding *cis*-fatty acids and thus contribute to the hardness of partially hydrogenated fat. Fatty acids containing a *cis*-double bond have a "bent" structure, whereas those containing a *trans*-double bond are more linear and thus resemble a saturated fatty acid rather than an unsaturated one. Because of their similarities in conformation, some investigators (Beare-Rogers et al., 1979; Enig et al., 1990b) believe that the sum of the *trans*- and saturated fatty acids is the physiologically meaningful value and have expressed their data as such. Enig et al. (1990b) term this sum "saturated-equivalents" and report that some snack and fast food items such as cheese corn chips and pizza crust contain as much as 60%–70% of the fatty acids as saturated-equivalents.

The composition of the hydrogenated fat depends in part on the composition of the original oil. If soybean oil and other vegetable oils are used as the source oil, then the hydrogenated product contains primarily isomers of octadecenoic acid (18:1), although much smaller amounts of isomeric fatty acids with shorter chain lengths are formed in some hydrogenated fats (Heckers and Melcher, 1978). If marine oil is used as the raw material, then the hydrogenated fat can contain isomers of fatty acids with chain lengths of 20–22 carbons (Hølmer and Aaes-Jørgensen, 1969; Beare-Rogers, 1983b).

In addition to the positional and geometrical isomers that are present in hydrogenated fat, small amounts of other isomeric fatty acids are found in these fats. Cyclic monomers, as well as intramolecular linear dimers, are known to be present (FAO, 1980). These minor components, however, have not been well studied.

B. Sources of Dietary Isomeric Fatty Acids

The primary source of isomeric fatty acids in the food supply is commercial hydrogenation of vegetable oils. Emken (1984) estimated that up to 90%–95% of isomeric fatty acids appearing in the U.S. diet at that time was contributed by commercially hydrogenated fat. These hardened fats and oils have been found in margarine, shortening, and frying fats and in various processed foods that contain

these fats. Commercial hydrogenation of vegetable oils results in a product that has a higher melting point appropriate for margarine and shortening products, is less susceptible to oxidative rancidity, and has improved flavor stability (Dutton, 1979). By controlling the conditions of the hydrogenation process, the manufacturers can provide the consumer with margarines and shortenings that have the desired consistency and spreadability. At the same time, however, the partial hydrogenation process results in the conversion of some naturally occurring fatty acids to isomeric forms in which both the conformation and position of the double bonds in the fatty acids have been altered.

A secondary source of isomeric fatty acids is biohydrogenation, which occurs in ruminant animals as a result of bacterial fermentation in the rumen (Reiser, 1951; Hartman et al., 1954, 1955). Isomeric fatty acids similar to those formed in commercial hydrogenation are formed by biohydrogenation (Hay and Morrison, 1970). The complex enzyme systems of rumen microflora transform the monounsaturated and polyunsaturated fatty acids in feedstuffs into more saturated products and into geometric and positional isomers not originally present in the feed. Thus, dairy products and other foods of animal origin contain small amounts of isomeric fatty acids (Hay and Morrison, 1970; Parodi and Dunstan, 1971; Smith et al., 1978; deMan and deMan, 1983; Wolff et al., 1998).

Finally, as summarized by Sommerfeld (1983), a number of plant species naturally contain small amounts of *trans*-unsaturated fatty acids in the seed fats and in the leaves. For example, vegetables such as leeks, peas, spinach, and lettuce contain *trans*-3-hexadecenoic acid (16:1Δ3t). Rapeseed oil is reported to contain brassidic acid (22:1Δ13t) and gondoic acid (20:1Δ11t) (Turchetto and Lorusso, 1977; Sommerfeld, 1983), but Fogerty et al. (1978) found neither of these fatty acids in rapeseed oil. The other vegetable oils commonly used in margarine and shortening do not naturally contain *trans*-isomers (Carpenter and Slover, 1973; Lanza et al., 1980; Sommerfeld, 1983).

III. POSITIONAL ISOMERS OF FATTY ACIDS IN FOOD

Hydrogenated vegetable oils, as well as fats from ruminant animals, may contain as many as 20 *trans*- and *cis*-positional isomers of octadecenoic acid. The distribution of positional isomers in margarine has been studied by several investigators, including Scholfield et al. (1967), Carpenter and Slover (1973), Carpenter et al. (1976), Parodi (1976a), Marchand (1982), Sampugna et al. (1982), Slover et al. (1985), and Caughman et al. (1987). Butter (Parodi, 1976b), milk fat (Hay and Morrison, 1970), and meat (Wood, 1983) have also been analyzed for positional isomers.

In Figure 15.2, the distribution of positional isomers of margarine is compared to that of butter, using data of Sampugna et al. (1982) for margarine and Parodi (1976b) for butter. The predominant *cis*-monoene in both butter and margarine is oleic acid (18:1Δ9c). In butter, this isomer comprises 95% of the total *cis*-octadecenoic acid fraction, and in margarine it typically comprises 60%. The fatty acid with a *cis*-double bond at position 11 (18:1Δ11c) is the second most prevalent *cis*-octadecenoic isomer in butter (Parodi, 1976b) and in meat (Wood, 1983), but in margarine the *cis*-positional isomers are more widely distributed among the Δ8–Δ12 positions (see Figure 15.2). Very small amounts of isomers with double bonds at the other positions are present.

In both butter and margarine, *trans*-octadecenoic acids with double bonds in positions Δ6–Δ16 are present (see Figure 15.2). In butter, the predominant *trans*-isomer is vaccenic acid, or *trans*-11-octadecenoic acid (18:1Δ11t), with 50%–70% of the *trans*-octadecenoic acid having a double bond in the Δ11 position. In a typical margarine, the majority of positional isomers of *trans*-octadecenoic acid have double bonds at Δ9–Δ12, although the exact distribution of positional isomers varies depending on the conditions of hydrogenation (Allen and Johnston, 1960). This variation can be seen in the five brands of margarine analyzed by Sampugna et al. (1982) (see Figure 15.3).

In addition to isomers of octadecenoic acid, *cis*-isomers of 14:1, 16:1, and 17:1 and *trans*-isomers of 16:1 are present in milk fat (Hay and Morrison, 1970; Wolff, 1994). The distribution of double bonds in *cis*- and *trans*-monoenoic fatty acids from bovine milk fat is illustrated in Table 15.1. Somewhat similar distributions of *trans*-positional isomers of octadecenoic acid in milk fats have been reported by other investigators (Parodi, 1976b; Wolff, 1994; Precht and Molkentin, 1995). In hydrogenated soybean oil, the *trans*-monoenes are almost exclusively isomers of octadecenoic acid.

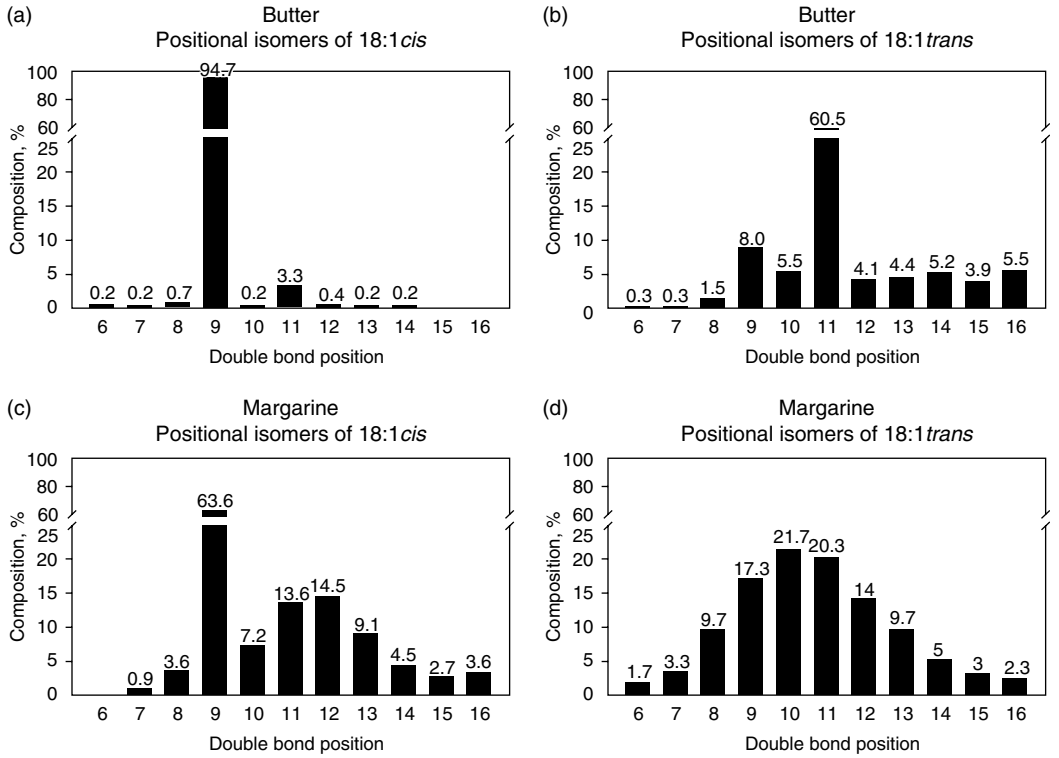

FIGURE 15.2 Distribution of positional isomers of the *cis*- and *trans*-octadecenoate fraction of butter and margarine. (Data for butter from Parodi, P.W. (1976b). *J. Dairy Sci. 59*: 1870–1873; data for margarine from Sampugna, J., et al. (1982). *J. Chromatogr. 249*: 245–255.)

Hydrogenation of vegetable oils to form shortening or margarine results in the conversion of linoleic acid (18:2Δ9c, 12c) to monoenes (Allen and Johnston, 1960). As a result, most of the positional isomers in partially hydrogenated fat are monoenoic fatty acids; however, small amounts of isomeric dienes are also formed. Dienes containing conjugated double bonds are present in hydrogenated fat, and concentrations of these conjugated dienes, ranging from 0.2% to 1.9% of fatty acids in margarine and shortening, have been reported by a number of investigators (Mabrouk and Brown, 1956; Sreenivasan and Brown, 1956; Scholfield et al., 1967; Hølmer and Aaes-Jørgensen, 1969; Carpenter and Slover, 1973; Parodi, 1976a; Smith et al., 1978). Animal fat of ruminant origin also contains about 1%–2% of the fatty acids as conjugated dienes (Parodi, 1977).

The methylene-interrupted diene system in linoleic acid is crucial to its role as an essential fatty acid. Since the double bounds in linoleic acid can be isomerized during hydrogenation in both conformation and position, enzymatic lipoxygenase activity specific for the *cis*,*cis*-methylene-interrupted structure is often used as a measure of "physiologically active polyunsaturated fat" (Smith et al., 1978). In comparing butter and margarine, Smith et al. (1978) reported that butter contained 3%–5% and margarine 15%–42% *cis*,*cis*-methylene-interrupted fatty acids.

IV. *TRANS*-ISOMERS OF FATTY ACIDS IN FOODS

In part because of methodological considerations, data exist primarily for the *trans*-fatty acid isomers rather than the positional isomers of specific food items. In this section, available information on the *trans*-fatty acid content of foods is summarized. The food items are grouped into four broad categories: (1) dairy products, meats, and animal fats; (2) margarines, shortenings, and vegetable oils; (3) fast foods and processed foods; and (4) human milk and infant foods.

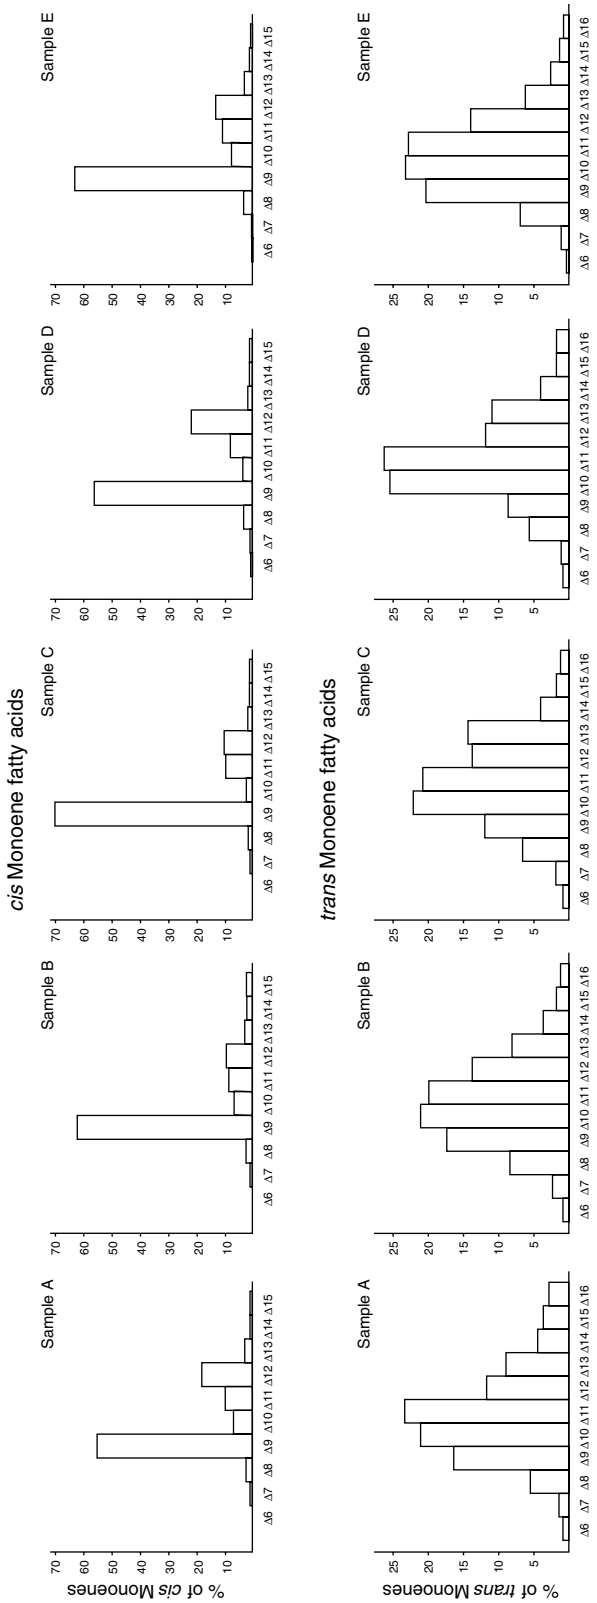

FIGURE 15.3 Distribution of positional isomers of *cis*- and *trans*-monoenes derived from selected margarines and shortenings. (From Sampugna, J., et al., (1982). *J. Chromatogr. 249*: 245–255; reprinted with permission from Elsevier Scientific Publishing Company, Amsterdam, The Netherlands.)

It is important to recognize from the outset the limitations of such data, particularly with regard to incorporation of these values into tables of food composition. First, values of *trans*-fatty acids determined prior to 1970 using older methodology, that is, before capillary gas chromatography, are considered to be less accurate (Brisson, 1981; Lanza and Slover, 1981). Recently, various methods for analyzing *trans*-fatty acids have been compared by Ratnayake (1998). Second, there is tremendous variability in values for any one type of food item. As a result, average values have limited use in food composition tables. Using minimum and maximum values for *trans*-fatty acids within a given food item (Innis et al., 1999) have shown that estimates of the *trans*-fatty acid content of the same diet can vary from a low of 1.4–25.4 g/day. Third, values for the *trans*-fatty acid content of food items presented as percentages of fatty acids without coupling these values to the fat content of food are also of somewhat limited use in food composition tables, because the gram quantity of *trans*-isomers in a serving of food cannot be determined. Fourth, products are constantly being reformulated, making it difficult to build up a reliable database. Industry responds to economic pressures and to public concerns over current health issues, and as a result changes the conditions of processing as well as the type and amount of fat used in various products. This has been particularly true recently as legislation that limits the content of industrially processed *trans*-fatty acids in the food has been passed in countries such as Denmark and as food-labeling regulations requiring *trans*-fat content have been implemented in countries such as the United States (Ratnayake and Zehaluk, 2005; Leth et al, 2006; Moss, 2006). Thus, the composition of the product may have changed by the time values are ready to be incorporated into food composition tables. With these limitations in mind, available data on the *trans*-fatty acid content of various food items are summarized here.

A. *Trans*-Isomers of Fatty Acids in Dairy Products, Meats, and Animal Fats

Foods such as butter, milk, beef, and lamb are derived from ruminant animals. *Trans*-fatty acids are formed as a result of biohydrogenation in the rumen of these animals, and thus dairy products

and meats contain small but significant quantities of isomeric fatty acids (Wolff et al., 1998). Vaccenic acid (18:1Δ11t) is the predominant *trans*-isomer in these foods, although smaller amounts of other *trans*-monoenes are found in the hexadecenoic (16:1) and octadecenoic (18:1) fractions of milk (Hay and Morrison, 1970) and meat (Wood, 1983). In fats of ruminant origin, the *trans*-fatty acids are located in the 1- and 3-positions of the triacylglycerol, with no measurable amounts at the 2-position (Woodrow and deMan, 1968).

The presence of CLA in meat and dairy products is of particular interest because of its reported anticarcinogenic effects as well as other possible beneficial biological effects. These biological effects of CLA and its occurrence in food have been reviewed recently by Banni and Martin (1998). Animal products are the principal dietary sources of CLA, although conjugated dienes are also found in low concentrations in plant oils and partially hydrogenated oils (Chin et al., 1992). The major conjugated diene in fats of ruminant origin is 9-*cis*,11-*trans*-octadecadienoic acid, with this isomer comprising 80%–90% of the total CLA in meat and dairy products (Chin et al., 1992; Parodi, 1994).

Dairy products are the richest dietary sources of CLA. The content of CLA in milk fat varies depending on pasture conditions and may contain up to 30 mg/g fat (Parodi, 1994). Chin et al. (1992) reported the CLA content of a variety of U.S. foods. For homogenized milk, condensed milk, and cultured buttermilk (three samples each), the total CLA content was 5.5 ± 0.30, 7.0 ± 0.29, and 5.4 ± 0.16 mg/g of fat, respectively. Similar values were reported by Lin et al. (1995), with values of CLA for fluid milk products ranging from 3.4 to 6.4 mg/g of fat. Yogurt contains CLA at approximately 4 mg/g of fat (Chin et al., 1992; Lin et al., 1995). Cheeses vary in CLA content, with Lin et al. (1995) reporting 3.59–7.96 and Chin et al. (1992) reporting 2.9–7.1 mg/g of fat. Banni et al. (1996) reported greater values for CLA in Italian dairy products with cow milk at 7.10, sheep milk at 11.72–29.68, yogurt at 7.98, and cheeses at 8.65–24.19 mg/g of fat.

Meats of ruminant origin contain more CLA than meats from nonruminant animals. Chin et al. (1992) reported values of 2.7, 2.9, 3.3, 3.8, 4.3, and 5.6 mg/g of fat for the CLA content of veal, beef round, beef franks, smoked beef sausage, fresh ground beef, and lamb, respectively, in contrast to values for pork (0.6 mg/g of fat) and chicken (0.9 mg/g of fat). Fresh ground turkey contained 0.25 mg/g of fat, whereas seafood contained 0.3–0.6 mg/g.

B. Milk Fat and Butter

Values for the *trans*-fatty acid content of milk fat and butter range from 1.75% (Ellis et al., 2006) to 8.6% (Woodrow and deMan, 1968) of total fatty acids (Table 15.2). In general, butter and milk fat appear to contain approximately 3%–6% *trans*-fatty acids (Table 15.2). The value of 0.65% triglyceride reported by Huang et al. (2006) appears to be much less than values reported by others.

Some of the variations seen in reported values can also be attributed to seasonable variation. Butter is reported to contain the lowest amounts of *trans*-fatty acids (4.3%–4.9%) in winter and the highest values (6.5%–7.6%) in spring and summer (Parodi and Dunstan, 1971; deMan and deMan, 1983). This seasonal variation is believed to be due to differences in the feedstuffs, with spring and summer pastures containing more polyunsaturated fatty acids than the winter feed supply. Henninger and Ulberth (1994) have reported a detailed analysis of the *trans*-fatty acid content of butter samples collected from Austrian dairies at monthly intervals. Consistent with earlier reports, greater values for *trans*-fatty acids were observed for samples collected during pasture feeding in the summer compared to samples collected during winter months. The values for 18:1t were greater if argentation thin-layer chromatography combined with gas chromatography was used rather than direct gas chromatography; however, the variation due to methodology was not as great as that due to seasonal variation. Similar variation in French butters collected at various times of the year has been reported by Wolff et al. (1995).

The *trans*-fatty acid values for cheeses and yogurt are shown in Table 15.2a. Most cheeses contain 3%–6% of total fatty acids as *trans*-fatty acids. As one would expect, the *trans*-content of cheeses, including those made from goat and ewe milk, reflect seasonal variation in the type of feed available (Wolff, 1995).

TABLE 15.2
***Trans*-Fatty Acid Content of Milk Fat and Butter**

Reference	Food Item	*Trans*-Fatty Acid[a] (%)

[a] *Trans*-fatty acids are expressed as percentage of total fatty acids.
[b] Range = 4.27%–7.64% with minimum values in the winter and maximum values in spring/summer.
[c] Fat content = 81%.
[d] 1.9% by GC/TLC method, 4.0% by AOCS method.
[e] 4.9% in winter; 6.5% in summer.
[f] 18:1t + 18:2t.
[g] 16:1t + 18:1t + 18:2t.
[h] Mean ± SD.
[i] Value includes 16:1t but not conjugated linoleic acid; range = 2.26–6.52 g/100 g milk fat, with high *trans*-fatty acid content reported for pasture feeding in the summer months.
[j] 2.70 g *trans* per 81.11 g fat.
[k] 18:1t only.
[l] Data expressed as percentage of fatty acid methyl esters.
[m] Without CLA t^{12}.
[n] *Trans*-fatty acids expressed as g/100 g food.
[o] Data expressed as percentage of corresponding triglyceride.

C. Meats

Data on the *trans*-fatty acid content of meats are summarized in Table 15.3. The most extensive early isomeric fatty acid analysis of meats was performed in the laboratory of Slover (Slover and Lanza, 1979; Lanza et al., 1980; Lanza and Slover, 1981; Slover, 1985; Slover et al., 1987a,b), although values for *trans*-fatty acids in meats have also been reported by Wood (1983). Since 1990, values for the *trans*-fatty acid content of meats and meat products have been reported in the United States (Litin and Sacks, 1993; USDA, 1995; Huang et al., 2006), Europe (Aro et al., 1998a), Spain (Boatella et al., 1993a; Fernandez San Juan, 1996), Canada (Ratnayake et al., 1993; Innis et al., 1999; Ratnayake and Zehaluk, 2005), France (Wolff, 1995), Costa Rica (Monge-Rojas et al., 2005), and New Zealand (Richardson, 1997), and are in general agreement with earlier values.

[a]Number of samples/brands analyzed appears in parentheses following food item.
[b]Percentage of total fatty acids.
[c]Values presented as g/100 g dry weight.
[d]Calculated from data for neutral lipids and phopholipids.
[e]Larger database than reported in Slover (1985).
[f]Represents total *trans*-18:1 content.
[g]Values presented as range; samples from 14 European countries. Data expressed as percentage of fatty acid methyl esters.
[h]16:1t + 18:1t + 18:2t.
[i]Data expressed as percentage of corresponding triglyceride.

Lipids in the separable lean of raw and cooked beef were analyzed by Slover et al. (1987a). The content of *trans*-monoene ranged from a minimum value of 1.3% in top round steak, choice grade to a maximum value of 4.4% in rib roast, large end, Good (now called Select) grade. Average content of *trans*-fatty acids in all 14 cuts of lean, raw beef was 3.2% of total fatty acids. In addition to *trans*-monoenes, small amounts of *trans*-dienes (18:2Δ9t, 12t and 18:2Δ9c, 12t) were also found, usually in amounts less than 0.2%. Moisture loss and other factors during cooking resulted in a slightly higher concentration of *trans*-fatty acids in the cooked samples than in the raw sample (Slover, 1985). The average value of 3.2% of fatty acids as *trans*-monoenes in lean beef is in relatively good agreement with the value of 2.9% calculated from the data of Wood (1983).

In addition to lean beef, processed meats were analyzed by Wood (1983). In part because of their high fat content, bologna, hot dogs, and Vienna sausage contained more *trans*-fatty acids per 100 g of food than the lean raw beef. On the other hand, beef liver appears to contain much smaller amounts of *trans*-isomers than raw or cooked beef samples (Lanza et al., 1980). Cuts of pork contain 0.2%–0.3% of the fatty acids as *trans*-monoene (Slover et al., 1987b), presumably derived from milk products in diets fed to pigs during the early weeks of life (Sommerfeld, 1983).

Slover and Lanza (1979) reported the *trans*-fatty acid content of baby foods, with strained beef liver containing 1.9% and strained lamb broth 7.6% of total fatty acids as *trans*-isomers.

[b] Percent of total fatty acids.
[c] Value for 18:1t content.

D. Animal Fats

Beef fat is reported to contain 1.8%–6.55% *trans*-fatty acids (Table 15.4). Lamb fat contains more *trans*-fatty acids than beef fat (Enig et al., 1983; Ball et al., 1993; Wolff, 1995; Bayard and Wolff, 1996), whereas lard, because it is derived from a nonruminant source, contains much less *trans*-fatty acid (Enig et al., 1983; Slover et al., 1987b; Boatella et al., 1993a; Mansour and Sinclair, 1993; USDA, 1995). Australian drippings are reported by Mansour and Sinclair (1993) to contain *trans*-fatty acids at 4.56% of total fatty acids. *Trans*-fatty acid values for turkey fat and chicken fat are reported to be 3.91 g/100 g of food and 0.75 g/100 g of food, respectively (USDA, 1995).

E. *Trans*-Isomers of Fatty Acids in Margarines, Shortening, and Vegetable Oils

Hydrogenated vegetable oils are the source of most of the *trans*-fatty acids in the North American diet. The 6–8 billion pounds of hydrogenated vegetable oil produced in the United States per year is used in the production of margarines, shortenings, and salad/cooking oils. The *trans*-fatty acid content of these products varies from small amounts in lightly hydrogenated salad oils—for example, 5% of total fatty acids as reported by Carpenter et al. (1976) (see Table 15.8)—to typical values of 40% or more in commercial frying fats (Smith et al., 1986) (see Table 15.7).

In margarines and other hydrogenated products, *trans*-fatty acids appear to be concentrated in the 2-position of the triglyceride. In some of the 10 margarine samples analyzed by Carpenter and Slover (1973), there was a greater percentage of *trans*-monoene at the 2-position than in the total

fatty acids in the triglyceride. This was probably due to the preferential placement of polyunsaturated fat (e.g., linoleic acid) at the 2-position in the original vegetable oil. In the process of partial hydrogenation, some of these polyunsaturated fatty acids at the 2-position would be converted to *trans*-monoenes. In contrast, as mentioned previously in this chapter, animal fats contain *trans*-fatty acids preferentially at the 1- and 3-positions of the triglyceride (Woodrow and deMan, 1968).

F. Margarines

The *trans*-fatty acid content of stick or hard margarines is greater than that of soft or tub margarines. Both Enig et al. (1983) and Slover et al. (1985) reported that stick margarines, on the average, contained 24% of the fatty acids as *trans*-isomers, with minimum values of 16%–17% and maximum values at 35%–36%. In contrast, tub or soft margarines collected at the same time as the stick margarines generally contained 14%–18% of fatty acids as *trans*-fatty acids with a range of 10%–30% (Table 15.5). Diet margarines analyzed in the 1980s in the United States were similar to soft margarines, containing about 15% *trans*-fatty acids (Enig et al., 1983). The value of 23% used by Enig et al. (1990a) in calculating per capita consumption of *trans*-fatty acids was based on tub margarines comprising 20% of the total margarine market. This value of 23% appears to be a reasonable estimate of the amount of *trans*-fatty acids in U.S. margarines at that time.

Margarines and table spreads, like other foods, have recently undergone reformulation to reduce the *trans*-fatty acid content. For example, this change for German margarines has been documented by Precht and Molkentin (2000) who reported a decrease in the *trans*-fatty acid content of margarine from 22% of total fatty acids in 1994 to 5% in 1999 (Table 15.5). Similarly, Henninger and Ulberth (1996) reported that stick and tub margarines collected in 1995 had decreased to about half of their 1991/1992 values (Table 15.5). Aro et al. (1998b) reported differences in the *trans*-fatty acid content of margarines dependent on the country in which they were collected. Soft table margarines collected in Iceland, Norway, and the United Kingdom had the greatest *trans*-fatty acid content with values ranging from 13.0% to 16.5% of total fatty acid methyl esters. Margarines collected in Italy, Germany, Finland, and Greece had a *trans*-fatty acid content of 5.1%, 4.8%, 3.2%, and 2.9% of total fatty acids, respectively; whereas margarines from other countries (Portugal, The Netherlands, Belgium, Denmark, France, Spain, and Sweden) contained less than 2% of the total fatty acids as *trans*-fatty acids.

Other countries, such as the United States and Canada, have lagged behind Europe in making significant decreases in the *trans*-fatty acid content of margarines (Table 15.5). With the recent advent of *trans*-fat labeling of foods (Moss, 2006), rapid change in the *trans*-fatty acid content of margarines is occurring in the United States. These changes, however, have not been documented in a systematic manner.

Most of the *trans*-fatty acids in margarine and other hydrogenated fats are monoenoic (18:1t) isomers; however, the *trans*-dienes (18:2t,c; 18:2c,t; and 18:2t,t) are found in much smaller amounts. Kinsella et al. (1981) reviewed the literature on possible physiological effects of high levels of *trans*,*trans*-octadecadienoate (18:2t,t) in the diet. Concern was expressed about this particular isomer because of its potential interference with the metabolism of the essential fatty acid linoleic acid (18:2Δ9c, 12c). Currently available data on the composition of margarine (Table 15.6) would indicate that hydrogenated fat contains small amounts of *trans*,*trans*-octadecadienoate and at the same time sufficient quantities of the all-*cis*-isomer (linoleate). Enig et al. (1983) reported maximum values of 5% for the sum of *trans*-dienes (18:2i)* in 40 margarine samples. Linoleic acid composed, on the average 26%–35%, of total fatty acids in these margarine samples (Table 15.6). Total *trans*-isomers of Δ9,12-octadecadienoate (18:2t,c, 18:2c,t, and 18:2t,t) in margarines analyzed by Slover et al. (1985) ranged from 0.17% to 11.6%, with an average of 1.9%. The *trans*,*trans*-Δ9,12-octadecadienoate (18:2t,t) made up only 0.19% of total fatty acids, with a maximal value of 1.5% in these margarine samples. Only four of the margarines tested by Slover et al. (1985) contained

*The term 18:2i or "isomeric" octadecadienoic acid is defined as the sum of 18:2c,t, 18:2t,c, and 18:2t,t.

[a] Number in parentheses following food item indicates number of samples/brands analyzed.
[b] PUFA = polyunsaturated fatty acids.
[c] Average includes one sample containing tropical oils; average if this sample is omitted = 30.8%.
[d] Based on margarine consumption of 20% tub and 80% stick.
[e] Data expressed as percentage of corresponding triglyceride.
[f] Margarines containing various combinations of vegetable oils, animal fat, and marine oil.
[g] Weighted mean.
[h] Represents only *trans*-18:1 content.
[i] Personal communication (1986) from Martin Leighfield, Nuffield Laboratories of Comparative Medicine, Institute of Zoology, Regent's Park, London.
[j] Number of European countries from which samples were analyzed appears in parentheses following food item. Values presented as range.
[k] Data expressed as percentage of methyl esters.

the *trans*,*trans*-isomer in amounts exceeding 1% of the fatty acids. Linoleate (18:2Δ9c, 12c) was found in much greater amounts, ranging from 6.1% to 46.4%. Whether the small amounts of *trans*, *trans*-diene found in margarine would interfere with essential fatty acid and prostaglandin metabolism, particularly if the overall diet provided adequate sources of linoleic acid, is not known.

Depending on the starting material, additional *trans*-isomers may be formed in margarine. For example, if marine oils are hydrogenated, *trans*-isomers of C_{20} and C_{22} fatty acids are present in the final product (Ovesen et al., 1996). Similarly, if the original oil contains significant quantities of 18:3n-3, *trans*-isomers of 18:3 are formed (Ratnayake et al., 1991; Ratnayake and Pelletier, 1992).

G. Shortenings

Values reported for shortenings made from hydrogenated vegetable oils range from 6% to 50% *trans*-fatty acids (Table 15.7). Scholfield et al. (1967) reported that the average *trans*-fatty acid content of four vegetable shortenings was 22.5%. This value agrees with the value of 26% *trans*-fatty acids used by Hunter and Applewhite (1986) to estimate *trans*-fatty acid intake from shortenings in 1960. According to values of the Institute of Shortening and Edible Oils (ISEO), the typical *trans*-fatty acid content of household vegetable shortenings decreased from 26% in 1960 to 17% in 1984 (Hunter and Applewhite, 1986). Enig et al. (1983) analyzed seven brands of shortening, including household brands as well as commercial frying fats (Table 15.7). The *trans*-isomer content (18:1t plus 18:2i) of these shortenings averaged 25.3% of total fatty acids, with values for the *trans*-isomers of octadecadienoic acid (18:2i) ranging from 1.9% to 4.4%. The average value reported by Smith et al. (1986) for *trans*-fatty acid content of commercial frying fats collected in California was 41.5% of total fatty acids. The content of *trans*-fatty acids in these shortenings was reported to decrease during

commercial deep-fat frying in fast food restaurants. The *trans*-C_{18} monoenes in these commercial fats decreased from over 40% in the fresh fat to as low as 13% in the used product (Table 15.7).

German and Austrian shortenings (Pfalzgraf et al., 1993; Molkentin and Precht, 1995, 1996; Henninger and Ulberth, 1996) appear to be somewhat less in *trans*-fatty acid content compared with those sold in North America. On the other hand, French shortenings were reported by Bayard and Wolff (1995) to contain relatively large amounts of *trans*-fatty acids (28%–64%, with an average of 50%). Ovesen and Leth (1955) reported that Danish shortenings made from hydrogenated fat contained 30%–37% of total fatty acids as *trans*-isomers; however, more recently Ovesen et al. (1996) reported 7% for Danish shortenings. New Zealand shortenings appear to be relatively low in *trans*-fatty acids, with an average value of approximately 6% (Richardson et al., 1997).

Like margarines, shortenings are also being reformulated to contain less *trans*-fat. Precht and Molkentin (2000) reported that the *trans*-content of German shortenings decreased from 12% of total fatty acids in 1994 to 6% in 1999. There is movement worldwide to make shortenings with little or no *trans*-fatty acids available to the baked goods industry.

H. Vegetable Oils

In general, nonhydrogenated vegetable oils contain minimal *trans*-fatty acids (Table 15.8). However, in the past soybean oil sold for use as salad and cooking oil was often lightly hydrogenated to reduce the content of α-linolenic acid (18:3) and thereby reduce the potential for oxidation and rancidity.

[e] Includes cottonseed oil (2), soybean oil (2), corn oil (3), peanut oil (1), olive oil (1), safflower oil (1), sunflower oil (1), vegetable oils (mixture or unspecified (3)). Trace amounts of *trans*-fatty acids were detected in two samples.

[f] Data on typical *trans*-fatty acid levels of products obtained from member companies of the Institute of Shortening and Edible oils (ISEO).

[g] Data of Litin, L., and Sacks, F. (1993). *N. Engl. J. Med. 329*: 1969–1970 are expressed as g/100 g of food.

[h] Number of European countries from which samples were analyzed appears in parentheses following food item. Data expressed as percentage of fatty acid methyl esters.

Reported values for the *trans*-fatty acid content of hydrogenated salad and cooking oils range from 5% to 15% (Table 15.8), with average values in the 1980s ranging from 8% (ISEO data; Hunter and Applewhite, 1986) to 12% (Enig et al., 1983). One exception to this is the *trans*-fatty acid content of Pakistani-hydrogenated vegetable oils (vegetable ghee/vanaspati) reported by Bhanger and Anwar (2004). These values for the *trans*-fatty acid content of ghee range from 14% to 34% of total fatty acids and are much greater than those reported for vegetable oils in other countries.

The content of *trans*-18:2 dienes (18:2i) in hydrogenated vegetable oils is high in comparison to the *trans*-18:1 content. For example, in one sample of partially hydrogenated soybean oil analyzed by Enig et al. (1983), 18:2i was 5.6% of the total fatty acids, with 18:1t comprising only 7.0%. Linoleate (18:2c,c) was reported to be 36.2% in this product. Thus, lightly hydrogenated products appear to have proportionately more *trans*-dienes and fewer *trans*-monoenes than more heavily hydrogenated products.

Many brands of salad and cooking oils contain oils that are not hydrogenated and thus contain no or only small amounts of *trans*-isomers (Table 15.8). Hunter (1990) has reported that since the mid-1980s, manufacturers have increased their production of household salad and cooking oils made from unhydrogenated oils. Processing of these oils can result in a minimal level of *trans*-fatty acids (Table 15.8). For example, Innis et al. (1999) reported that the content of nonhydrogenated vegetable oils ranged from 0.05 g/100 g food for extra virgin oil to 2.42 g/100 g of food for canola oil. Thus, these products contribute very little *trans*-fatty acids to the current food supply in the United States, Canada, or other countries.

I. Salad Dressings, Mayonnaise, Soups, and Sauces

Several samples of salad dressings, mayonnaise, and other sauces were analyzed for *trans*-fatty acids by a number of investigators (Table 15.9). This category of food contributes only small amounts of *trans*-fatty acids to the diet, and many of the products analyzed contain no *trans*-fatty acids (Table 15.9). For example, two out of the three salad dressings analyzed by Slover et al. (1980) contained small amounts of *trans*-fatty acids (0.24%), but none of the seven brands tested by Enig et al. (1983) contained *trans*-fatty acids. Of the five brands of mayonnaise analyzed by Slover et al. (1980) and Enig et al. (1983), only two contained *trans*-fatty acids. Elias et al. (2002) reported that most salad dressings contained less than 2 g/100 g of food as *trans*-fatty acids. Satchithanandam et al. (2004) found similar values for mayonnaise and salad dressings.

Prepared soups contain significant amounts of *trans*-fatty acids with values ranging from 10% for beef bouillon to 35% for onion cream soup (Pfalzgraf et al., 1993; USDA, 1995; Fernandez San Juan, 1996; Aro et al., 1998c; Innis et al., 1999). Thus, soups can contribute reasonably large amounts of *trans*-fatty acids to the diet if they are consumed routinely.

J. *Trans*-Isomers of Fatty Acids in Fast Foods and Processed Foods

Because commercial shortenings containing relatively large amounts of *trans*-fatty acids (Smith et al., 1986) are used as frying fats in fast food establishments and other restaurants, fast foods have the potential to contain relatively large amounts of *trans*-fatty acids. In addition, hydrogenated fats are used in many processed foods because of the increased shelf life, as well as the dependable consistency, the hydrogenation process affords the products. Therefore, many processed foods including cookies and other baked goods would be expected to contain significant amounts of *trans*-isomers. In fact, several investigators including Elias and Innis (2002) in Canada and Lemaitre et al. (1998) in the United States report that the greatest source of *trans*-fatty acids in the North American diet is baked goods.

Values for the *trans*-fatty acid content of processed foods and fast foods vary widely, depending on the type of fat used in processing. For this reason, some investigators prefer to present their data as ranges rather than as means. Values for the *trans*-fatty acid content of fast food items and processed foods are summarized in the remainder of this section.

K. Fast Foods

Fast food items can be a significant source of *trans*-fatty acids in the diet. In the lunch/dinner items analyzed (Table 15.10), the *trans*-fatty acid content varied from 0.04 g/100 g food for milk shakes to 1.38 g/100 g food for fried pies and turnovers to 3.0 g/100 g of food for French fries. Hamburgers, as well as items such as fried fish and fried chicken, are all sources of *trans*-fatty acids. Based on the data of Lanza and Slover (1981), a typical fast food meal could provide 3–4 g of *trans*-fatty acids (Table 15.11), and even more if the USDA (1995) data for French fries are used.

Recently, Stender et al. (2006) reported that a fast food meal of French fries and chicken nuggets contained over 10 g of industrially produced *trans*-fatty acids if purchased at McDonald's in New York City, USA, or almost 25 g if purchased at Kentucky Fried Chicken in Hungary. Breakfast items would also provide *trans*-fatty acids, with pastries providing relatively high amounts (Table 15.10).

The values for *trans*-fatty acids in fast foods, however, must be interpreted with caution, because many fast food restaurants have changed the type of fat used for frying since the analyses were done by Slover et al. (1980). On the other hand, if the data of Smith et al. (1986) on commercial frying fats and that of Pfaltzgraf et al. (1993), Fernandez San Juan (1996), USDA (1995) are typical of products used in the 1980s and 1990s, then fast food items in the United States and some countries in Europe contained significant amounts of *trans*-isomers at that time. In other countries, such as New Zealand (Lake et al., 1996), the *trans*-fatty acid content of commercial frying fats used in fast food restaurants appears to be less than in the Untied States; thus, the *trans*-content of a fast food meal in these countries would be expected to be less.

The report by Stender et al. (2006) on the *trans*-fatty acid content of chicken nuggets and French fries purchased at McDonald's or Kentucky Fried Chicken gives an interesting cross-country comparison. For a fast food meal at McDonald's, 5–10 g of industrially produced *trans*-fatty acids would be obtained if the meal was purchased in the United States, Peru, United Kingdom, South Africa, Poland, Finland, France, Italy, Norway, Spain, Sweden, Germany, or Hungary. The same meal of chicken nuggets and French fries would contain 1–5 g of *trans*-fat only if it were purchased in Austria, Portugal, the Netherlands, Russia, Czech Republic, or Spain. Only if the meal were purchased in Denmark would contain less than 1 g of *trans*-fatty acids. A meal of French fries and chicken from Kentucky Fried Chicken would contain 10–25 g of *trans*-fatty acids if purchased in Hungary, Poland, Peru, or Czech Republic; 5–10 g in the Bahamas, South Africa, or USA; 2–5 g in Germany (Hamburg), France, United Kingdom (London or Glasgow), Spain, or Portugal; and less than 2 g in United Kingdom (Aberdeen), Denmark, Russia, or Germany (Wiesbaden). Thus, the *trans*-fatty acid content of fast food can vary widely depending on the country and even the city.

L. Processed Foods

Several investigators have reported values for the *trans*-fatty acid content of snack items (Table 15.12). The *trans*-isomer content of these food items is highly variable, with some brands providing negligible amounts and others containing as much as 30%–50% of the fatty acids as *trans*-isomers. Enig et al. (1990b) contend that the *trans*-content of many of these snack items increased when food analyzed in 1978 were compared with comparable items analyzed a decade later. However, when labeling laws were implemented in 2006 in the United States, many snack items were reformulated and advertised as containing "0 *trans*."

The most comprehensive early analysis of processed food items is that published by Enig et al. (1983). In this study, the fat in 220 samples from 35 food types was analyzed for individual fatty acids including *trans*-octadecenoic acid (Table 15.13). None of the samples of peanut butter contained *trans*-fatty acids. Maximum values in the other categories ranged from 24% to 39% of the fatty acids as *trans*-isomers. Mean values for the *trans*-content of samples in which any amount of *trans*-fatty acids was detected ranged from 11% to 28%.

[a]Number in parentheses indicates number of samples analyzed. Food items are U.S. samples unless otherwise noted.
[b]Spanish samples.
[c]Total represents only *trans*-18:1 content.
[d]Canadian samples.
[e]U.S. samples.
[f]Data expressed as percentage of corresponding triglyceride.
[g]In Enig et al. (1983). *J. Am. Oil Chem. Soc. 60*: 1788–1795, french fries from seven national fast food chains were analyzed. The first three given are from the same chains as reported by Slover et al. (1980). *J. Food Sci. 45*: 1583–1591; values for the other four are from different chains.
[h]n.d. = not detected.
[i]French fries (labeled as potato chips in New Zealand) are from nationally (New Zealand) distributed retail takeaway chains.
[j]Number of European countries from which samples were analyzed appears in parentheses following food item. Data expressed as percentage of methyl esters.
[k]German samples.

TABLE 15.11
***Trans*-Fatty Acid Content of a Typical Fast Food Meal**

	Weight[a] (g)	*Trans*-Fatty Acids[b] (g/100 g)	Total *Trans*-Fatty Acids (g)
Cheeseburger	215	0.59	1.27
Fries	106	0.60	0.64
Milkshake	290	0.07	0.20
Turnover	125	1.38	1.73
			3.84

[a] Data from Table of Food Composition (Hamilton, E.M.N., et al. (1988). *Nutrition: Concepts and Controversies*, 4th ed., West, New York).
[b] Data from Lanza, E., and Slover, H.T. (1981). *Lipids 16*: 260–267. As summarized in Table 15.10.

M. *Trans*-Isomers of Fatty Acids in Human Milk and Infant Foods

Whereas isomeric fatty acids may have no effects on an adult, in theory infants may be particularly vulnerable to the effects of factors that interfere with essential fatty acid metabolism and normal membrane structure (ILSI, 1997; Craig-Schmidt, 2001). Thus, it is important to know the *trans*-fatty acid content of foods consumed during this period of rapid development.

Trans-fatty acids comprise 1%–7% of total fatty acids in human milk (Table 15.14). The amount of *trans*-octadecenoic acid (18:1t) appearing in the milk reflects the *trans*-content of the maternal diet consumed on the previous day (Aitchison et al., 1977; Craig-Schmidt et al., 1984). Friesen and Innis (2006) have found that the *trans*-fatty acid content of human milk has decreased from 7.1% in 1998 to 4.6% in 2005/2006.

Infant formulas contain variable amounts of *trans*-fatty acids, with values of 0.1%–4.5% of total fatty acids reported (Picciano and Perkins, 1977; Hanson and Kinsella, 1981; Permanyer et al., 1990; O'Keefe et al., 1994; Jorgensen et al., 1995; Ali et al., 1996; Chardigny et al., 1996; Fernandez San Juan, 1996; Ratnayake et al., 1997) (Table 15.14a). One brand of infant formula analyzed by Hanson and Kinsella (1981) contained 15.7% of the fatty acids as *trans*-isomers, but all the others contained less than 2%.

Three types of baby foods were analyzed for *trans*-fatty acids by Slover and Lanza (1979) and eight brands of dry infant cereals by Hanson and Kinsella (1981). All these products except the lamb broth (Slover and Lanza, 1979) contained less than 2% *trans*-fatty acids. More recent analysis (USDA, 1995) revealed that some U.S. infant foods contained greater than 5% *trans*-fatty acids.

Thus, foods normally consumed by infants contain relatively low levels of *trans*-fatty acids. In most cases, *trans*-isomeric fat in these products is no greater than that found in cow's milk (see Table 15.2).

V. ESTIMATES OF ISOMERIC FATTY ACIDS IN THE DIET

Several approaches can be taken in estimating isomeric fatty acids in the diet: (1) laboratory analysis of composite diets; (2) dietary analysis of diet records using food composition data such as those summarized above; (3) estimates based on *trans*-fatty acid content of biological tissues; and (4) estimates based on "disappearance" or market share data. All these approaches have been used although most estimates are based on disappearance data. These methods and their use worldwide have been reviewed recently by Craig-Schmidt (1998, 2006). The reader is referred to these references for an update on estimates of isomeric fatty acids in the diet throughout the world.

A. Analysis of Composite Diets

Estimates obtained by analysis of composite diets collected from a given population have the advantage of being based on data obtained by analytical methods in the laboratory. This method suffers from the fact that the diets or populations analyzed may not be representative of the population as a whole. A number of investigators (Aitchison et al., 1977; Åkesson et al., 1981;

[b] Percentage of total fatty acids.
[c] 18:1t only.
[d] Includes *trans*-isomers of 16:1, 18:1, 18:2, and 18:3.
[e] No 18:1t reported; values include *trans*-isomers of 18:2 and 18:3.
[f] Includes *trans*-isomers of 16:1, 18:1, and 18:2.
[g] Includes *trans*-isomers of 18:1, 18:2, and 18:3; does not include conjugated 18:2.

Craig-Schmidt et al., 1984; van den Reek et al., 1986b; Enig et al., 1990a) have used this approach, and the results are summarized in Table 15.15. Relatively, "raw" data are presented to allow the reader to see the variation both between the diets of individuals and within the day-to-day diets of a given individual.

Aitchison et al. (1977) reported that 3-day self-chosen diet collections from 11 adult subjects in the United States contained an average of 5.0% of the fatty acids as *trans*-isomers, with a range of 1.3%–8.3%. The *trans*-fatty acid content of the 33 diet collections ranged from 0.0 to 9.9 g/day,

[d]Primary data were not given.

with both minimum and maximum values exhibited by the same subject (see Table 15.15). Similar values for Swedish diets were reported by Åkesson et al. (1981). *Trans*-octadecenoic (18:1t) acid was 5.0%, 3.9%, and 1.8% of dietary fatty acids in the normal, lactovegetarian, and vegan diets of Swedish adults. Daily consumption ranged from 0.9 g/day for the vegans to 4.9 g/day for the male subjects. These values are in agreement with those of van den Reek et al. (1986b), who found that the amount of *trans*-octadecenoic acid (18:1t) in the diets of eight adolescent girls collected for a 7-day period ranged from 3.5% to 8.2% of total fatty acids, with an average of 5.3%. The total *trans*-fatty acid content of the diets on 56 individual days in this study ranged from 1.9% to 17.2% of total fatty acids, with an average of 6.5% (see Table 15.15). The average daily consumption of 3.1 g/day (range 0.45–7.97 g/day) is also in agreement with the two earlier studies.

In comparing these studies, it is important to note the large variation both within the diets of the same subject and between subjects. Taken collectively, *trans*-fatty acid intake in these studies ranged from 0.45 g/day in an adolescent girl consuming 500 kcal, with 33% of these calories from fat (van den Reek et al., 1986b), to 9.9 g/day in a lactating woman consuming 2185 kcal, with 42% of calories from fat (Aitchison et al., 1977). Possible extremes in *trans*-fatty acid consumption have been further defined by the analysis of experimental diets in which diets made with hydrogenated sources of fat were compared to diets made with nonhydrogenated sources of fat (see Table 15.15). In the study by Craig-Schmidt et al. (1984), one day's diet made with nonhydrogenated sources of fat provided 0.59 g of *trans*-fatty acids compared to 13.72 g in a diet made with only hydrogenated fat. As percentage of total fatty acids, 18:1t ranged from 0.73% in a "nonhydrogenated" diet to 17.1% in a "hydrogenated" diet (Craig-Schmidt et al., 1984). Because all the diets were designed for lactating women, total calories and other nutrients were kept relatively constant. It is thus easy to see from these studies that extremes can exist in *trans*-fatty acid content of both self-selected diets and experimental diets.

Enig et al. (1990a) reported that recent analyses of total diet composites show a range of 6%–12% of the total fatty acids as *trans*-fatty acids. This range is well within the extremes defined by the experimental diets of Craig-Schmidt et al. (1984).

B. Analysis of Dietary Records Using Food Composition Data

Diet records and dietary recall methods can also be used to estimate *trans*-fatty acid consumption. Using data obtained by a 1-day dietary recall followed by a 2-day dietary record and assuming that the average *trans*-fatty acid content of fats consumed in 1977 was 5.6%, Senti (1985) calculated per capita daily *trans*-fatty acid consumption to be 4.5–6.5 g/day.

From 7-day diet records and published *trans*-fatty acid values in foods, van den Reek et al. (1986a) estimated the dietary levels of *trans*-octadecenoic acid (18:1t) in the diets of eight healthy white adolescent girls to be 5.3% of total fatty acids. This value was the same as that determined by laboratory analysis of diets collected by the duplicate portion technique (van den Reek et al., 1986b).

This value is lower than values reported by Enig et al. (1990a) in which diet history and analytically determined food composition data were used to estimate per capita *trans*-fatty acid intake. Calculations based on data from individual diets developed by the USDA to comply with the Dietary Goals and known *trans*-fatty acid values for individual foods gave a range of 7.2%–20% of the total fat as *trans*-fatty acids. Values for fat intake for participants of the Lipid Research Clinic screening study were used in combination with an estimated dietary *trans*-fatty acid intake (Enig et al., 1990a). For adult males with fat intakes of 40–258 g/person per day, estimates of 2.4–20.6 g/person per day for total *trans*-fatty acid intake were obtained; for adult females consuming 31–179 g fat per day, *trans*-fatty acid intake was estimated to be 1.9–14.3 g/person per day. Ranges of energy intakes for these subjects were not reported by Enig et al. (1990a). *Trans*-fatty acid intake reported per 1000 kcal would be useful comparing results from various studies and in accounting for the extreme variations seen in these *trans*-isomer intake estimations.

C. Estimates Based on *Trans*-Fatty Acid Content of Biological Tissues

Another approach to the estimation of the consumption of dietary isomeric fatty acids is to extrapolate from the concentration found in biological tissues. Craig-Schmidt et al. (1984) estimated that the usual diets of the lactating women in their study contained 7.8% of the fatty acids as the *trans*-isomers of octadecenoic acid (18:1t; Table 15.16). This estimate was based on extrapolation of the relationship between 18:1t in the maternal diet vs. 18:1t in human milk samples. The average content of 18:1t in the milk of the subjects on day 1 of the experiment was believed to reflect the content of the self-chosen diets from the previous day.

A similar approach was taken by Enig et al. (1990a), who used the concentration of *trans*-fatty acids in human adipose tissue to estimate dietary *trans*-fatty acids. Analysis of human adipose tissue provides an indirect method of estimating dietary fatty acid isomer intake, because these isomers are not synthesized by humans. Adipose tissue fatty acids have a long half-life, and therefore the concentrations of *trans*-fatty acids in adipose tissue are believed to reflect the dietary *trans*-fatty acid content. Studies by Heckers et al. (1979) in Germany, Ohlrogge et al. (1981) and Ohlrogge (1983) in the United States, and Thomas et al. (1981) in the Untied Kingdom showed a range of 1.0%–11.6% total *trans*-fatty acids in adipose tissue. However, as Enig et al. (1990a) point out, a 1:1 relationship between dietary and adipose tissue does not necessarily hold true, because some of the *trans*-fatty acids are metabolized, and therefore the concentration of *trans*-fatty acids in adipose tissue would be expected to be lower than the concentration of *trans*-fatty acids in the diet.

TABLE 15.16
Estimates of Dietary *Trans*-Fatty Acids Based on Concentration of *Trans*-Fatty Acids in Human Biological Tissues

References	Tissue	Estimated Dietary *Trans*-Fatty Acid Content (% of Total Fatty Acids)
Craig-Schmidt et al. (1984)	Human milk	7.8
Enig et al. (1990a)	Adipose tissue[a]	2.4–11.1

[a]Data of Ohlrogge, J.B., et al. (1981). *J. Lipid Res. 22*: 955–960. See text for explanation.

Enig et al. (1990a) estimated dietary *trans*-fatty acids using the data of Ohlrogge et al. (1981) on human adipose tissue *trans*-fatty acid levels in combination with an equation expressing the relationship between dietary 18:1t and adipose tissue levels in rats and mice. The animal data were taken from several sources (Alfin-Slater and Aftergood, 1979; Bonaga et al., 1980; Moore et al., 1980; Royce et al., 1984; Selenskas et al., 1984; Ostlund-Lindqvist et al., 1985; Petterson and Opstvedt, 1988). Using a range of 2.0%–5.8% of total fatty acids as 18:1t in adipose tissue (Ohlrogge et al., 1981), Enig et al. (1990a) estimated that U.S. diets contain 2.4%–11.1% of total fatty acids as *trans*-18:1 isomers (see Table 15.16).

D. Estimates Based on "Disappearance" Data

Until recently, the most commonly used method of estimating *trans*-fatty acid consumption has been based on fat disappearance or market size/share data in combination with product composition data. The estimate of Kummerow (1975) that the total *trans*-fatty acid intake from visible fat is approximately 8% was based on 1971 USDA household consumption data and typical *trans*-fatty acid compositional data. In 1971, margarine represented 7%, shortening 13.2% and cooking and salad oils 12.4% of the visible fat intake. These data were combined with typical values for sources of hydrogenated fat, that is, stick margarine containing 25%–35%, tub margarines 15%–25%, shortening 20%–30%, and salad oils 0%–15% *trans*-fatty acids. The small contribution of isomeric fatty acids from meat and dairy products was not included in this estimate.

Several other researchers using similar approaches calculated comparable values for percent of fat as *trans*-fatty acid; for example, 8% (Enig et al., 1978) and 6.8% (Emken, 1981). Elson et al. (1981) stated that data provided by the ISEOs indicate that the dietary fat supply available for human consumption consists of 5%–15% *trans*-fatty acids. Senti (1985) estimated that total per capita consumption of dietary *trans*-fatty acids in the United States is 10.2 g/day (Table 15.17). When Senti (1985) adjusted this value to account for wastage of frying oils and separable fat of retail beef cuts, a value of 8.3 g/day *trans*-fatty acid consumption was obtained. This value is only slightly greater than the value of 7.6 g/day estimated by Hunter and Applewhite (1986). On the other hand, Enig et al. (1990a) contend that Hunter and Applewhite (1986) overestimated wastage in their calculations and estimate that the average person in the United Sates consumes 12.8 g/day of *trans*-fatty acids. The major difference between the estimate of Enig et al. (1990a) and earlier estimates is in the category of shortening, for which both the fat intake as shortening (26.5 g/day) and average percentage of *trans*-isomer concentration are high in comparison to the other estimates in Table 15.17. Estimates for *trans*-fatty acid intake for Canada and the United States are higher than the 4.5–6.5 g/day reported by Heckers et al. (1979) for Germany and 6.5 g/day by Enig et al. (1984) for Israel but lower than the value of 17 g/day reported by Brussaard (1986) for The Netherlands.

In general, estimates of average *trans*-fatty acid consumption using disappearance data are higher as one might expect than estimates obtained by laboratory analysis of composite diets (see Table 15.15). However, extremes in individual intakes, as the data in Table 15.15 show, may extend well beyond these estimates of average intake.

Some investigators (Brisson, 1981; Craig-Schmidt et al., 1984; Senti, 1985; Hunter and Applewhite, 1986; Enig et al., 1990a) have tried to account for the contribution of animal fats as well as that hydrogenated vegetable oils to total *trans*-fatty acid intake (see Table 15.17). Brisson (1981) estimated that about 94% (or 8.5 g of a total of 9.1 g) of *trans*-fatty acids per day is due to hydrogenated vegetable oils, with the remainder being due to fats of ruminant origin. The estimate of Senti (1985) for total *trans*-fatty acid intake (10.2 g/day) is only slightly greater than that of Brisson (1981), but the relative contribution of animal and dairy fats to the total is greater.

The average per capita daily consumption of *trans*-fatty acids of 7.6 g determined by Hunter and Applewhite (1986) is less than the estimates of Brisson (1981) or Senti (1985), which were based on food disappearance data without a wastage factor for discarded fat. The estimate of Hunter and Applewhite (1986) was based primarily on product composition and market share data provided by

TABLE 15.17
Estimated Per Capita Daily Consumption of *Trans*-Fatty Acids from Animal and Dairy Fats and from Vegetable Fats

Reference and Food Category	Fat Intake (g/day)	*Trans*-Fatty Acids

[b] Calculated for Canada.
[c] Value that takes into account a wastage factor for frying oils and separable fat of beef retail cuts.
[d] Values of Craig-Schmidt et al. (1984) were based on laboratory analysis of experimental diets designed to be adequate for lactating women; all other estimates were based on disappearance data.

the ISEOs, the National Association of Margarine Manufacturers, and A. C. Nielsen Company, and included a 50% wastage factor for deep-frying fat. Thus, estimates of *trans*-fatty acid intake using disappearance data range from 7.6 g/day estimated by Hunter and Applewhite (1986) to 12.8 g/day estimated by Enig et al. (1990a).

The experimental diets used in the study by Craig-Schmidt et al. (1984) also define the relative contribution of biohydrogenation to possible total dietary *trans*-fatty acid consumption. The diets for one experimental period (nonhydrogenated; NH) were made with sources of fat such as butter, corn oil, and lard that had not been subjected to commercial hydrogenation. The diets for the other period were identical to the first but contained hydrogenated (H) products such as margarine, hydrogenated soybean oil, and shortening. The *trans*-fatty acid content of the diets in the NH period average 0.86 g/day (0.64–1.17 g/day) and 1.0% of total fatty acids (0.73%–1.3%). These values would be an estimate of the *trans*-fatty acids appearing in the diet as a result of biohydrogenation in ruminants; that is, the contribution that meat and dairy products would make. The difference between the H and NH diets would then be an estimate of the amount of *trans*-fatty acids in the diet due to commercial hydrogenation. The amount of *trans*-fatty acids from margarines, shortenings, and hydrogenated soybean oil ranged from 6.6% to 16% of total fatty acids (average 10.8%) and from 5.74 to 12.72 g/day (average 8.86 g/day). Using these values, the average contribution of total dietary *trans*-fatty acids due to commercial hydrogenation would be 91%, with only amounts contributed by meat and animal products. This value is in agreement with Emken (1984), who assumed that 90%–95% of the isomeric fat in the adipose tissue is contributed by hydrogenated soybean oil and the rest by butter fat.

Using the consumption data as summarized in Table 15.17, values for the contribution of meat and dairy products to total *trans*-fatty acid intake ranged from 6% (Brisson, 1981) to 22% (Senti, 1985). Heckers et al. (1979) estimated that in West Germany approximately 35%–45% of the 4.5–6.4 g per capita per day *trans*-fatty acid consumption was due to ruminant products. This estimate is high, however, owing to the relatively low consumption of hydrogenated vegetable fat and not to an abnormally high consumption of dairy products.

E. Consumption of Positional Isomers

Almost all the estimates of isomeric fatty acid consumption are for the *trans*-isomers only. Emken (1984), however, used analyses of hydrogenated oil samples and figures for total fat consumption to

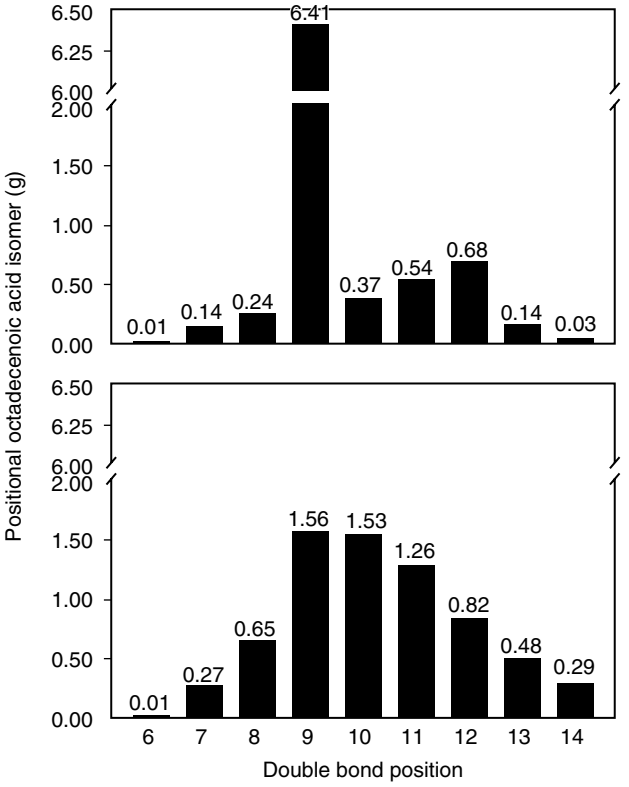

FIGURE 15.4 Daily intake of specific positional 18:1 isomers (top, 18:1c; bottom, 18:1t) as estimated by Emken, E.A. (1984). *Ann. Rev. Nutr. 4*: 339–376.

calculate a daily average intake of individual *cis*- and *trans*-positional monounsaturated isomers. The value for total isomer daily consumption minus oleic acid (18:1Δ9c) is estimated to be 9.0 g, with 2.2 g of this consisting of positional *cis*-isomers. Estimated values for the consumption of *cis*/*trans*-isomers containing double bonds ranging from position 6 to position 14 are shown in Figure 15.4.

VI. CONCLUDING PERSPECTIVE

This chapter has summarized available information on the isomeric fatty acid content (primarily 18:1t) of various food items and has reviewed estimates of per capita daily intake of these fatty acids from a methodological standpoint. To be useful, these data must be put into context.

First, the food composition data must be put into the context of the fat content of the food and overall fatty acid composition. Data on isomeric fatty acid composition should be reported along with the fat content of the food and expressed in grams per 100 g of food. It is crucial to consider the other fatty acids in the food as well. Adequate essential fatty acids (e.g., linoleic, 18:2Δ9c, 12c) must be provided in the diet to minimize possible deleterious effects of isomeric fatty acids. Ackman and Mag (1998) have reviewed the potential for having less *trans*-fat in commercial products.

Second, the desire to increase linoleic acid in the diet must also be balanced against the tendency of polyunsaturated fatty acids to become rancid. When this occurs, the consumer gets a product that is lower not only in organoleptic properties but also in "health-promoting" properties.

Third, the consumption data must be put into the context of the total diet of the consumer. The number of calories consumed, the total fat in the diet, and the percentage of calories provided by fat,

as well as the relative proportions of saturated, monounsaturated, and polyunsaturated fat, must be taken into consideration.

Fourth, the consumption data must be put into the context of studies on the physiological effects of isomeric fatty acids. The amount of dietary isomeric fat used in many human and animal experiments is greater than that normally consumed by the average person. As the possible deleterious effects of isomeric fatty acids are assessed, it is imperative to compare the amounts of these fatty acids in experimental diets with current consumption estimates. Only then can conclusions be drawn about the safety of hydrogenated fat in the diet.

Finally, realization of the detrimental health effects of *trans*-fatty acids has prompted a movement worldwide to eliminate industrially produced *trans*-fatty acids from the food supply. Denmark has been successful in doing this by regulating the amount of industrially produced *trans*-fat allowed in a food item (Astrup, 2006). In an alternate approach, enactment of legislation requiring *trans*-fat values on food labels has brought about rapid changes in the food supply of the United States as industry has responded to consumer pressure. Thus, the *trans*-fatty acid content of the diet may soon be dependent only on the amount of ruminant items it contains.

ACKNOWLEDGMENTS

We wish to thank Julie Taylor Baker, Hso-Chi Chaung, and Janet Johnson for their assistance in obtaining references and in compiling a database of the *trans*-fatty acid content of various food items.

16 Genetic Alteration of Food Fats and Oils

Earl G. Hammond

CONTENTS

I. REASONS FOR ALTERATION OF FAT AND OIL COMPOSITION

Interest in changing the composition of food fats and oils is driven by concerns about physical properties, oxidative stability, nutrition, government regulations, and economic advantage (Hammond and Glatz, 1989; Greiner, 1990; Gunstone, 2001). Unfortunately, some of these drivers are not compatible with each other, especially the optimization of nutrition with physical properties or stability. Often changes in fat and oil compositions seek to expand the market for a particular fat or oil commodity by making its properties more desirable than rivals' fats and oils, by reducing processing costs or increasing consumer appeal.

Long-chain saturated fatty acids are needed to produce plastic fats and oils for margarines and shortenings. For nearly a century, hydrogenation has been used to decrease unsaturation in oils and to achieve plasticity. But there has also been interest in producing vegetable oils that naturally contain more saturated stearic and palmitic acid groups to give plasticity while avoiding the cost of hydrogenation (Kok et al., 1999).

There has also been particular interest in increasing the palmitic acid content of vegetable oils that are destined for hydrogenation to plastic fats. Most of the fatty acids in vegetable oils contain 18 carbons (stearic, oleic, linoleic, and linolenic acids), and for plastic fats to have the optimum textural properties, it is desirable that the solid fat crystallizes in the β′-form rather than in the higher melting β-form. Oils with about 15% or more of palmitic acid groups favor crystallization in the β′-form (Erickson and Erickson, 1995; O'Brien, 1995). The unique triglyceride structure of cocoa

butter, in which the outer *sn*-1,3 positions of the glycerol contain saturated palmitic or stearic acid groups and the inner *sn*-2 position contains mostly oleic acid, makes cocoa butter melt sharply at human body temperature and also makes it very appealing for confectionery fats. Cocoa butter's high price has resulted in numerous attempts to find substitutes (Hammond, 2000).

Oils such as coconut and palm kernel oils that are rich in medium-chain length fatty acids have unique stability and melting properties and are sometimes in short supply and expensive. This has led to attempts to introduce saturated fatty acids of chain lengths 8–12 into other vegetable oils (Friedt and Lühs, 1998; Schultz and Ohlrogge, 2002; Scarth and Tang, 2006).

To obtain greater stability to oxidation while still retaining low melting points, there is interest in producing an oil that contains less polyunsaturated linoleic and linolenic acids and more oleic acid, which has more stability to oxidation (Fatemi and Hammond, 1980; Kinney, 1996; Schultz and Ohlrogge, 2002). Linolenic acid groups are particularly prone to producing undesirable flavors at low levels of oxidation, which has generated extensive efforts to reduce the amounts of linolenic acid in soybean and other oils (Hammond and Fehr, 1984; Hammond, 1985). High-oleic oils are particularly desirable for frying operations (Wilson et al., 2002), although if the content of linoleic acid is too low, the fried products may lack typical fried flavor (Warner and Knowlton, 1997).

Nutritional recommendations about the best oil composition have varied with time in many respects but have consistently encouraged the reduction of saturated fatty acids for preventing atherosclerosis. There is a growing consensus that not all saturated acyl groups are equally bad nutritionally (Ulbricht and Southgate, 1991). It may be that only the saturated fatty acids—lauric, myristic, and palmitic are atherogenic, but this is not yet recognized in food labels. Concern about these three atherogenic fatty acids has led to advertising about small differences in the amounts of palmitic acid in various vegetable oils and to attempts to reduce the amount of palmitic acid in soy and canola oils by breeding.

There is also increased appreciation of the nutritional value of linolenic and other fatty acids with their first bond on the third carbon counting from the methyl end of their chain, the so-called n-3 fatty acids (Simopoulos, 2000). These fatty acids have been reported to have various physiological effects, many of which arise from their being precursors of prostaglandin hormones. There is an increasing advocacy for increasing various n-3 fatty acids in food fats and oils. It is also recommended that a certain ratio of n-3 to n-6 fatty acids (such as linoleic acid) be consumed (Hibbeln et al., 2006). There are a limited number of plants that are rich in linolenic acid, and long-chain (20–22 carbon) n-3 fatty acids are mostly found in aquatic animals and fungi. There is also a growing interest in transferring the ability to produce long-chain n-3 fatty acids to oilseeds by genetic engineering. Because of the instability of polyunsaturated n-3 acyl groups to oxidation and the intensity of flavor that their oxidation entails, the incorporation of these materials into food can involve major problems with shelf life.

Recently, the U.S. Government has required food labels to state the amounts of *trans* fatty acids present in a food serving, and consumers have been warned about the importance of restricting intake of *trans* fatty acids (Food and Drug Administration, 2003). This requirement is causing a major change in the fats and oils industry because the food industry has relied on hydrogenation to convert liquid vegetable oils to plastic fats such as spreads and shortenings and to improve the oxidative stability of frying fats. But hydrogenation has also been the chief route by which *trans* fatty acids have found their way into consumers' diets (Craig-Schmidt and Holzer, 2000). A small but significant amount of *trans* fatty acids are also generated by rumen fermentation, and *trans* fatty acids generated in this way are present in ruminant meat and milk products.

The discovery that various conjugated diene and triene isomers of fatty acids have significant physiological effects in experimental animals has generated interest in introducing or increasing the concentration of conjugated fatty acids into various food products (Hunter, 2000). Conjugated dienes are not known in natural fats and oils but can be generated by alkali isomerization of linoleic acid and by hydrogenation. There are a number of sources of conjugated trienes in nature that could be transferred into oilseed by genetic engineering (Liu et al., 1997). Some of these trienes have been shown to have physiological effects similar to conjugated dienes.

II. THE MEANS OF CHANGING PLANT OIL COMPOSITION

Some changes in composition can be achieved rather simply by mixing fats and oils from different sources. This simple solution is sometimes limited by concern about whether a fat is of animal origin, whether an animal has been slaughtered in an acceptable manner or whether the fat or oil is from a species that is considered acceptable for food.

If one wishes to alter the composition of an oilseed crop for such things as oil content or fatty acid composition, traditional plant breeding technology has offered several approaches (Fehr, 1987; Orf, 1988). The technique selected will depend on the characteristics of the particular plant species and the availability of germplasm collections. Generally, the most efficient approach is to screen the germplasm collections of the species for strains that have the desired composition. Often one can find a range of two- or threefold in fatty acid compositions by this approach. Collections of various sizes are available for most commercially important species. In many instances, wild relatives of commercially important species are available that can be crossed with the domesticated species. It is worthwhile to make collections of such wild species and sample their variability as well.

If the desired composition cannot be recovered from germplasm collections or from wild relatives of the domesticated species, generally crossing and selection techniques are attempted. These techniques are good for extending the range of lipid components present in the oilseed, but it would be ineffective in introducing a component not normally present. If, for example, one wishes to decrease the oleic acid content of the seed oil, populations of plants that have the lowest available concentrations of oleic acid in their seed oil are selected and crosses are made. Then the progeny from such crosses are tested for the desired trait. Most of the progeny will have a composition that will fall between those of the two parents, but usually a few of the progeny will have compositions that fall outside the range of parental values. Plants having compositions that exceed the values of the parents in the desired direction are selected, and the cycle is repeated. Often a population can be moved in the desired direction in increments at each cycle of recurrent selection.

Mutation breeding can also be tried as a means of extending the range of compositions beyond that available in germplasm collections. For this approach, usually seeds are treated with mutagenic agents such as ionizing radiation, or soaked in solutions of mutagenic chemicals such as ethyl methanesulfonate, azide, *N*-nitroso-*N*-methylurea, or *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine. Frequently, a mutagen exposure that will reduce the germination of the seed by 50% is used. The resulting viable seeds are germinated and grown to maturity. It is desirable to advance the mutagen-treated population for a generation or two to allow for segregation of the mutated traits before the progeny are tested for the desired trait. This approach has been successful in producing large changes in the fatty acid composition of a number of oilseeds and in discovering the genes that are involved.

Molecular genetic techniques can be used to alter the amounts of the acyl groups normally present in a species or to introduce exotic acyl groups. There has been considerable research activity in these applications in recent years, and there are a number of good reviews of these techniques and their reach, both from the view of molecular geneticists (Liu, 2001; Schultz and Ohlrogge, 2002) and plant breeders (Friedt and Lühs, 1998; Wilson et al., 2002; Scarth and Tang, 2006). Studies of oilseed plant genomes have made it possible to relate certain DNA fragments or genes to various traits (Pantalone et al., 2004). These tests identify particular gene modifications present in a variety and can accelerate breeding experiments. In general, it is possible to use these techniques to extend or contract the amounts of the acyl groups typically present in fats and oils. It has also been possible to introduce significant amounts of shorter-chain acyl groups not normally present in an oilseed.

The introduction of exotic fatty acids into oilseed by genetic engineering is also possible (Hildebrand et al., 2002; Kinney, 2002). There is interest in introducing fatty acids that contain a branch, hydroxy or epoxy group or a positional double-bond isomer into edible oilseeds such as soybean or canola. In instances where the exotic fatty acid is found in a wild plant, it is generally believed that it will be easy to introduce the trait into a domestic oilseed than to domesticate wild

plants that contain the exotic fatty acid (Schultz and Ohlrogge, 2002). Oils with such fatty acids have potential or current industrial uses and may be sold at prices considerably above those of edible vegetable oils because their production entails greater costs. The successful introduction of such exotic fatty acids into soybeans or canola could reduce the cost of such industrial oils and increase their utilization. Some of these altered fats and oils could achieve acceptance as foods, and some could pose a danger if mixed in the food supply. So far it has been difficult to get extensive expression of many of these exotic fatty acids in oilseeds; for example, genes for unusual double-bond isomers can be expressed in a plant but only at the level of a few percent. It may be necessary to incorporate changes in the genes that transfer the exotic fatty acyl groups into triacylglycerols to overcome this problem (Hildebrand et al., 2002; Schultz and Ohlrogge, 2002; Weselake, 2002).

III. BARRIERS TO CHANGING PLANT OIL COMPOSITION

Once the desired seed composition is attained, it is frequently present in a strain that does not have desirable agronomic properties such as high yield, disease resistance, or suitable maturity date. Usually the desired composition can be transferred to material with good agronomic properties by a process known as backcrossing. To do this, the line with the desired composition is crossed with a line with good agronomic properties, and the progeny are tested. The process can be repeated to generate lines with the desired composition and agronomic properties.

The effectiveness of these techniques for change can vary with the species of oilseed and its genetics. Obviously, plants such as oil palm or olive that require several years to mature and come into full oil production are more difficult to work with than annual oilseed crops such as soybean or canola.

Breeding for changes in seed composition often entails some loss in yield. Certain traits have also shown a tendency to reduce oil percentages or germination. These can often be overcome, but the more traits the breeder wishes to optimize in a particular line, the more difficult it becomes to keep them all at the optimum.

A significant number of genetic specialty crops could be produced, and the number that is possible is increasing, but until recently this has not resulted in many oils with genetically modified compositions being on the market. The reasons have been economic. Oilseeds have been handled very efficiently as a single commodity, and there has been resistance to the introduction of a number of kinds of an oilseed. The advantages of new traits introduced into an oil crop must at least pay for the cost involved. If a special variety has a lower yield than is typical for the crop and growing area, farmers will not grow it without a premium to make up for this loss. Often a special variety must be grown on contract, and this often entails a small premium to the grower. Crop handlers will lose flexibility in keeping a special variety segregated and will encounter additional costs. The incoming seed must be tested to make sure it meets specification when it is received by the crop handlers. The oil extractors will often need to modify their processing plants to handle multiple varieties that must be kept segregated. If the oil content is lower than that typical for the crop, oil extraction will run less efficiently.

Often the value of modified crop is uncertain. Its ability to extend shelf life or reduce processing costs is ambiguous, and the impact of flavor changes in a product line is nebulous. Will the improved product increase the number of customers and only leave current customers better pleased? New traits are embraced more readily if they promise an expanded market. Many people fear or are prejudiced against crops modified by direct genetic manipulation or interspecies gene transfer and these attitudes vary geographically.

Oilseed crops with the desired composition may already exist. For example, low-linolenic soybean oil is very much like traditional corn oil, and low-saturate soybean oil is very much like traditional canola. The price difference between oil from the potentially modified crop and the existing oils usually sets the price that a modified oilseed crop can bring. Often this difference is not great

enough to pay the costs of growing a special variety, and this appears to be the primary reason why oilseed crops with altered fatty acids have not been produced on very large scales so far.

As these words are being written we seem to be standing on the threshold of a new era that will see the rapid expansion of oilseed crops with altered fatty acid composition. The new rules about *trans* fatty acids promise to strongly affect what is acceptable to consumers and food manufacturers. It will be difficult to meet all the demands for low-*trans* fats and other traits that are important to consumers with the current technology, especially for frying fats and oils. Seed suppliers are busy trying to furnish seeds with compositions that will meet these needs and find farmers to grow these crops. Contracts with oilseed processors have been made to process the harvest. Some food companies have pledged to use only *trans*-free fats and oils in their products. The next few years should witness interesting changes.

A. Animal Fats

In animals there has been considerable reduction in muscular fat by genetic selection as well as feeding practices in recent years in response to consumer demand (Rhee, 2000). These trends are continuing and being supplemented by molecular genetic tools.

Genetic selection of cows yielding a heart-healthy milk fat composition appears to be feasible and could result in an important decrease in saturated fatty acids such as lauric, myristic, and palmitic that are considered atherogenic (Karijord et al., 1982; Bobe et al., 2003; Chen et al., 2004). Such milk could be segregated and collected from about 5% of the cows in typical herds. Dairy products made from such milk have normal properties and, in the case of butter, improved spreadability. Such products could sell at a premium that will pay for the cost of segregation and collection. The chief technical barrier to such marketing is the availability of an inexpensive, rapid method of testing for cows producing such milk.

IV. CONSTRAINTS ON THE COMPOSITION OF PLANT FATS AND OILS

Fats and oils that are obtained in commercial quantities from plants are generally obtained from the seed or fruit coat. In seeds, the fats and oils usually are present as triacylglycerols and serve as an energy source to fuel the metabolism of the seed during germination until the new plant establishes its photosynthetic ability. In many species, starch is stored as an energy source in the seed as an alternative or in addition to storing fat. The proportion of this oil reserve in seeds varies considerably, from about 5% in cereals to as high as 68% in coconut (Sonntag, 1979). The lipid in fruit coats presumably serves to interest animals in helping with seed dispersal. In animals subcutaneous fat is believed to serve as insulation as well as an energy reserve.

The fatty acid composition of seed oils varies greatly. Generalizing on the analytical data from numerous seed oils, Hilditch (1954) concluded that oleic and linoleic acids together generally accounted for over 80% of the total fatty acids and that most species contained about 7%–8% palmitic acid. In some species, especially those from the tropics, palmitic and stearic acids were more prominent. Other variations on this basic pattern occurred primarily in two ways: (1) A whole family of plants would produce seed oils that contained another fatty acid in addition to the basic oleic–linoleic–palmitic acid mixture. (2) An unusual fatty acid would occur in a single species of seed oil and almost replace the basic mixture usually found.

A possible reason for conservatism in the fatty acid pattern of seed oils may be the necessity to maintain the triglycerides in a liquid state under the conditions in which the plants and animals normally flourish. The importance of liquidity was emphasized by Kartha (1954), but his hypothesis was based on very limited evidence. Many seed oils have low melting points when isolated and obviously are liquid at the temperature at which the plant flourishes. In other instances, isolated seed oils melt in the general vicinity of the growth temperatures, and it is not certain whether the oil is liquid

at all temperatures at which the seed might be growing. It is not easy to observe directly the physical state of the minute droplets of oil dispersed in the seed. The picture is also clouded by crystalline fats that are able to take several different polymorphic forms with different melting points and stabilities (Bailey, 1950). The polymorph with the highest melting point may melt 10°C–20°C above the lower melting polymorphs. The polymorph that separates on cooling depends on the rate of cooling, the presence of seed crystals, and the fatty acid composition. In the microscopic oil droplets of seed, the crystal nuclei that do form cannot grow very far; so much of the oil may not be in equilibrium with its crystalline phases. In addition, phospholipids that may be present in seed oil droplets can act as crystal inhibitors and limit the growth of crystals that do form by adsorbing to their surfaces (O'Brien, 1995). Thus, the oil in a seed might crystallize considerably below the highest melting point observed in isolated bulk oil.

The hypothetical need for liquidity in seed oils is attributed to the inability of various enzymes to exercise their catalytic role on solid fats (Kartha, 1954). The evidence for this was based on observations of the action of lipase on various saturated triglycerides. The work of Willstätter and Waldschmidt-Leitz (1923), who used adsorption on tristearin to purify pancreatic lipase, was cited. Other observers (Collins, 1933; Tofte, 1934; Balls et al., 1937; Schonheyder and Volqvartz, 1944; Wills, 1965) showed that as the chain length of saturated triglycerides increased, the rate of hydrolysis by lipases decreased. For solid triglycerides the rate drops precipitously, but the hypothesis that the rate is zero was not clearly demonstrated by the data.

It is questionable whether the action of enzymes on substrates such as crystalline tristearin is a good model for the fat that might form in a cooled seed droplet. Natural fats and oils usually do not have sharp melting points. As the isolated oil is cooled, the solubility of one of its components is exceeded, and this component crystallizes into a network that holds the remaining liquid oil in its interstices, producing a semisolid, plastic fat. The solid fat in such a mixture has much more surface than chunks of crystalline tristearin, and this may be important in the rate of lipase reactions (Sarda and Desnuelle, 1958).

Table 16.1 shows the melting points of some fatty acids and their simple triglycerides. Triglycerides containing only the long-chain saturated fatty acids obviously have too high a melting point to be liquid at temperatures at which plants normally flourish. Even a small amount of such saturated triglycerides cannot be tolerated if it is necessary to maintain complete liquidity.

TABLE 16.1
Melting Points (°C) of the Highest Melting Polymorph of Some Fatty Acids and the Three Polymorphic Forms of Their Monoacid Triglycerides

Fatty Acid	Fatty Acid Compositions	Fatty Acid m.p.	Triglyceride m.p.		
			β	β′	α
Palmitic	16:0	62.9	65.5	56.0	45
Stearic	18:0	69.6	73.1	65.0	54.5

Source: Bailey, A. E. (195). *Melting and Solidification of Fats*, Interscience, New York.

The solubility of triglycerides in each other is approximated by ideal solution theory (Bailey, 1950; Boatman et al., 1961) so that

$$\ln N = -H(T_m - T)/RTT_m,$$

where N is the mole fraction of high-melting triglycerides in a mixture, T_m is its melting point, T is the temperature of observation in degrees Kelvin, H is the molar heat of fusion of the high-melting triglyceride, and R is the gas constant. From this equation one can determine the amount of high-melting triglyceride soluble in a typical liquid oil at various temperatures as shown in Table 16.2.

Plants do seem to maintain very low levels of long-chain trisaturated triglycerides in their seed oil, and they accomplish this limitation by two strategies: (1) they produce relatively small amounts of long-chain saturated fatty acids or (2) they rigorously exclude long-chain saturated acyl groups from the *sn*-2 position of triglyceride (Mattson and Volpenhein, 1961; Litchfield, 1972). Table 16.2 shows the gains in solubility achieved by the introduction of an oleoyl group into saturated triglycerides. Tropical butters, such as cocoa butter, rely almost entirely on the second strategy, because they consist almost entirely of *sn*-1,3-disaturated 2-oleoyl triglycerides. Isolated cocoa butter melts rather sharply at about 38°C (Bailey, 1950). Seed oils from the temperate zones generally contain saturated acyl groups much below the 63+ mol.% levels of cocoa butter.

Duncan (1984) has summarized the evidence showing that for maximum lowering of the melting point by an unsaturated acyl group, it is important for the double bond to be in the *cis* configuration and near the middle of the chain. Oleic acid meets these criteria. Since most plants flourish at temperatures greater than 5°C, presumably a plant could achieve liquidity of its oil by producing an oil that contained mostly oleic acid (Table 16.1). Additional double bonds in an 18-carbon chain reduce the melting point further, but the effect of additional double bonds is much less than that of the first. Possibly, the presence of linoleic and linolenic groups in plant triglycerides results from the role these fatty acids play in biological membranes more than from their contribution to the liquidity of the storage triglycerides. It is important that the membranes have suitable flexibility (Duncan, 1984; Thompson and Martin, 1984), and unsaturation is important in the attainment of this flexibility. Polyunsaturated acyl groups are often concentrated in biological membranes. Galactosyl diglycerides are often rich in linolenic acid and are important constituents of chloroplasts

TABLE 16.2
Temperatures (°C) Necessary to Dissolve Various Mole Fractions of the β-Form of Various Triglycerides in Liquid Triglycerides according to Ideal Solution Theory

Mole Fraction	Tristearin	Tripalmitin	2-Oleoyldistearin[a]	2-Oleoyldipalmitin[a]
1.00	72.4	65.4	41.6	35.2
0.50	69.0	61.8	38.5	32.0
0.25	65.8	58.2	35.4	28.8
0.12	62.3	54.5	32.3	25.5
0.06	59.2	51.1	29.4	22.4
0.03	56.1	47.7	26.6	19.4
0.01	51.3	42.6	22.1	14.8

[a]The oleoyl group was estimated to reduce the heat of fusion by 4.84 kcal/mol for 2-oleoyldistearin and 2.94 kcal/mol for 2-oleoyldipalmitin (Duncan, 1984).

(Mudd and Garcia, 1975). Wang et al. (1997) have shown that genetic alteration of the fatty acid composition of soybean oil has a great effect on the fatty acid composition and class proportions of its phospholipid. It is possible that structural features of triglycerides that seem to contribute to their liquidity are simply a consequence of the triglycerides arising from the phospholipids by the Kennedy pathway (Appleqvist, 1975; Slack and Browse, 1984) and have no great significance for the melting characteristics of seed triglycerides. The limitation on total saturated fatty acids and the exclusion of saturated fatty acids from the *sn*-2 position may be strategies only to ensure the flexibility of biological membranes. Even so, the result is that storage triglycerides have similar restraints on their structure.

As Hilditch (1954) noted, individual species or families of plants sometimes depart from the basic pattern present in most species by including additional acyl groups in their seed triglycerides. It is usually not clear what advantage the species or family gains by the unusual pattern, but often the occurrence of the unusual acyl group is limited to the oilseed depots (Appleqvist, 1975; Cahoon and Ohlrogge, 1994; Liu et al., 1997). The seeds of the palm family are rich in short- and medium-chain saturated fatty acids (hexanoic to myristic) and have limited amounts of unsaturation (Rossell et al., 1985). The short-chain fatty acids greatly depress the melting point of the palm kernel oils. This results in oils much more stable to oxidation than the vegetable oils that follow Hilditch's basic pattern, but it is not clear why oxidative stability should be of greater importance in palms than in other plant families. Indeed, some plant families produce oil with considerable amounts of linolenic acid, and many plant oils seem to contain more linolenic acid than is necessary to maintain liquidity (Hammond, 2000). The presence of these methylene-interrupted polyenes greatly decreases the stability of the oil to oxidation (Fatemi and Hammond, 1980).

Defense against attack by predators has often been cited as a reason for the accumulation of various materials in oilseeds. There is some evidence that the short-chain fatty acids found in palm kernels have maximum bactericidal activity (Karabinos and Ferlin, 1954). It may be that the instantaneous production of peroxides and aldehydes by the action of lipoxygenases on polyunsaturated fatty acids when seeds are damaged is a defense mechanism (Galliard, 1975; Shibata and Ohta, 2002). Unusual fatty acids such as ricinoleic in castor beans may serve to make the fat reserves of the plant seed unavailable to many predators because they lack the means of metabolizing the unusual structure. Röbbelen (1975) suggested that such unusual acyl groups are relics of plant evolution.

Auld et al. (1989) examined a number of *Brassica* species and collections and found erucic acid nearly always present. They speculated that the conservation of erucic acid in this family occurred because the longer chain erucic acid allowed plants to generate more energy per triglyceride molecule by β-oxidation. This was thought to be significant in a small-seeded family such as *Brassica*. Erucic acid was limited to 66% by its exclusion from the *sn*-2 position of the triglycerides. Auld et al. (1989) suggested that this was because glyceryl trierucate would have an unacceptably high melting point (Table 16.1).

Although these are reasonable hypotheses, there is little evidence that the removal of lipoxygenases or most large changes in fatty acid composition have exposed plants to noticeable increases in predator attack or diminished vigor or germination under modern field conditions.

One reason why plants are rather conservative in varying their triglyceride composition may be that the enzymes involved in fat metabolism are limited by their specificity. For example, the enzymes involved in producing triacylglycerols from fatty acids may have specificities for certain chain lengths and double-bond position and configuration (Slack and Browse, 1984). Thus, for a new acyl group that does not have the correct characteristics to be incorporated into the seed triglycerides of a plant, not only must there be a mutation for the production of the new acyl group, but there also must be coordinated changes in various enzymes involved in its transfer and metabolism. The probability of such multiple coordinated mutations is very low, and the prevalence of radical changes from the basic pattern of seed triglycerides is relatively rare. This hypothesis has been cited to explain why the introduction of exotic fatty acids into domesticated oilseed plants usually results in their express at very low levels (Hildebrand et al., 2002; Schultz and Ohlrogge, 2002; Weselake, 2002).

V. OIL CONTENT AND FATTY ACID COMPOSITION IN VARIOUS PLANT SPECIES

Table 16.3 gives the range of oil content reported for a number of oil-bearing tissues. The percentage of oil is under genetic control, and there has been success in recent years in increasing the oil content of corn (Weber, 1983) and oats (Frey et al., 1975; Branson and Frey, 1989a,b; Holland et al., 2001). In both these cereals, oil contents as high as about 15% are now possible. In corn, the oil is concentrated in the germ, which may be as high as 45% oil. After dry or wet milling the germ is separated and extracted. In oats the oil is dispersed throughout the endosperm.

In many oilseeds, the meal remaining after extraction of the oil is a rich source of protein that can be used for animal feed. This is particularly true of soybeans, the protein of which is as valuable as the oil, and it has been suggested that breeding for soybean protein at the expense of oil may now be profitable (Greiner, 1990). In soybean, the oil and protein contents tend to be inversely correlated, but some progress has been made in increasing both (Wilcox, 2001). Factors partitioning the products of photosynthesis into carbohydrate, oil, and protein are poorly understood (Hildebrand et al., 2002; Weselake, 2002), although genomic approaches are beginning to identify many gene loci that affect oil concentration in soybean (Pantalone et al., 2004).

Table 16.4 shows the range of fatty acid compositions reported for natural populations of several commercially important oilseeds. Obviously, considerable variation occurs naturally for all

TABLE 16.3
Range of Oil Content for Various Oil-Bearing Plant Tissues

Oil-Bearing Tissue	Tissue Type	Oil Content
Cocoa bean	Oilseed	50–55
Coconut	Oilseed	65–74
Corn	Starchy seed	3–16
Cottonseed	Oilseed	15–24
Hempseed	Oilseed	30–35
Linseed	Oilseed	35–45
Oat	Starchy seed	2–16

the major fatty acids in the various species. The table also illustrates the limitations on variation discussed previously. For example, none of the species listed shows any great tendency to produce saturated fatty acids with chain lengths less than 16 carbons except the palm family, and none shows much tendency to produce saturated chain lengths of more than 18 carbons. Of the oils listed in Table 16.4, only rapeseed contains erucic acid. Linolenic acid is present in very small amounts except in soybeans and rapeseed. Palmitic acid content is less than 15% except in the cereal species and oil palms, and in the cereals it never exceeds 30%. The content of stearic acid is less than 15% in these plant species.

Some of these variations are attributable to climatic as well as genetic differences. Fatty acid variations with growth environments has been documented for oats (Hammond, 1983), palm, palm kernel and coconut (Rossell et al., 1985; Tan et al., 1985), and soybean (Hammond and Fehr, 1984; Rennie and Tanner, 1989). In general, low temperatures encourage greater amounts of unsaturated groups and high temperatures favor saturated groups. These are the responses that would maintain the liquidity of membranes and storage fats.

The fatty acid composition of seed also changes considerably during maturation. These data have been summarized by Appleqvist (1975), Hammond and Glatz (1989), and Weselake (2002). They report that in many species of seeds the linolenic and saturated fatty acid content decreased during maturation. In the soybean mutant A6, Graef et al. (1985b) showed that the stearic acid level increased during maturation instead of decreasing while the oleoyl content failed to increase as it normally would. In a high-palmitic soybean mutant, Schnebly et al. (1996) reported that the palmitic acid content started out slightly higher than normal and failed to decrease. In a low-palmitic mutant, the palmitic acid content started out low and decreased even further. In rapeseed, the erucic acid content increases during maturation.

The data in Table 16.4 have been gleaned from the literature, and some of the extreme values may not be reliable. For example, the linolenoyl group content of soybean oil was reported by O'Connor and Herb (1970) to range naturally as low as 2%, but it certainly has not been possible to find values this low in plants grown under normal conditions when modem analytical techniques have been used (Mounts et al., 1988). Probably 4.2% is a more realistic value for the minimum percentage of linolenoyl groups in natural populations of soybeans.

A. Rapeseed and Canola

The modification of fatty acid composition has its oldest and most successful example in canola. This began with the successful identification of rapeseed cultivars that were free of erucic acid groups (Stefansson et al., 1961). Nutritional concerns about the consumption of oils containing erucic acid (Formo, 1979) led to extensive adoption of low-erucic oils, which are now known as canola. Rapeseed belongs to the genera *Brassica* and the family Cruciferae. This family has the advantage that *Arabidopsis thaliana* is also a member and has had its genome sequenced and studied extensively. Plants in this family are easy to transform with exotic genes, and molecular geneticists often prefer to try their ideas first on *Arabidopsis*. The fatty acid composition of *Brassica carinata* can also be determined rapidly by near-infrared reflectance (Velasco et al., 1997).

Efforts to improve canola oil next centered on reducing its linolenic acid content in an effort to increase the oxidative stability of the oil. Mutation breeding with ethyl methanesulfonate (Rakow and McGregor, 1973; Röbbelen and Nitsch, 1975; Röbbelen, 1984) followed by further selection (McVetty and Scarth, 2002) resulted in cultivars with linolenic acid contents of 1.6%–2.8% (Daun, 1998). Such low-linolenic strains have improved oxidative stability in room odor tests (Prevot et al., 1990).

Typical canola contains about 60% oleic acid, and recurrent selection techniques have pushed this up to 85%–90% (Vilkki and Tanhuanpää, 1995). Mutagen treatment of seeds or microspores yielded strains with 80%–86% oleic acid. A molecular engineering approach has yielded similar values of oleic acid (Scarth and Tang, 2006). High-oleic canola with reduced linolenic acid

are being produced commercially as Clear Valley 75® by Cargil, Monola® by Nutrihealth Pty Ltd in Australia, and Natreon® by Dow AgroSciences. Monola® contains 2.5% linolenic and about 70% oleic. Natreon® contains less than 3.5% linolenic and 70% oleic. Clear Valley® is advertised as low-linolenic high-oleic oil. Similar lines are being produced in Europe (Laga et al., 2004).

One of the heavily advertised advantages of canola oil has been its low content of saturated (palmitic and stearic) acids, about 6%–7%. There is interest in lowering the saturated fatty acid content even further. *Brassica* engineered with genes from *Cuphea pullcherrima* and safflower gave 3.4% saturated fatty acids (Scarth and Tang, 2006). There is also interest in increasing the levels of palmitic and stearic acids. The introduction of Cuphea (Jones et al., 1995), elm, or nutmeg (Voelker et al., 1997) genes has raised palmitic acid to 34%. Several strategies have been tried for raising the stearic acid content (Scarth and Tang, 2006), and the highest value reported was 55%–68% for *Brassica napus* transformed with a mutated mangosteen gene (Facciotti et al., 1999).

The Calgene group has developed a high-lauric acid canola by transforming canola with an acyl carrier protein thioesterase from the California bay laurel, which produces short-chain fatty acids (Del Vecchio, 1996; Voelker et al., 1996). Lines with 56 mol.% lauric acid content were produced. When a gene coding for a coconut enzyme that will place short-chain acids on the *sn*-2 position of glycerol was included lines with as much as 67 mol.% lauric acid were obtained.

There is interest in introducing genes for making γ-linolenic acid (all *cis*-6,9,12-octadecatirenoic acid) in oilseeds for human consumption because it lies on the route to arachidonic acid (all *cis*-5,8,11,14-eicosatetraenoic acid), and some believe that this will improve human health. Genetic engineering has allowed γ-linolenic acid to be expressed at levels of 25%–40% in rape (Knutzon et al., 1999; Liu et al., 2001; Hong et al., 2002; Qiu et al., 2003; Huang et al., 2004).

Although erucoyl-free strains are desired for human consumption, erucic acid has a number of industrial uses, and rapeseed with high-erucic acid content has been selected (Calhoun et al., 1975; Röbbelen and Nitsch, 1975). It has been possible to produce strains with 64%–66% erucic acid groups, but the high-erucic cultivars used in Canada are in the 40%–50% range (Daun, 1998). As erucoyl groups normally occur only on the *sn*-1 and -3 positions of *Brassica* species (Ohlson et al., 1975; Zadernowski and Sosulski, 1979), it was believed that the erucoyl content in this plant family could not exceed about 66%. Zou et al. (1997) were able to incorporate erucoyl groups on the *sn*-2 position of the triglycerides of *Brassica napus* by transforming it with a yeast gene that normally places acyl groups on sphingolipids. Molecular engineering approaches have also been tried to increase the chain elongation capacity of rape and to improve the transfer of erucoyl groups to the *sn*-2 position (Friedt and Lühs, 1998). These changes have made it possible to produce glyceryl trierucate in the engineered plants, but have not made it possible to produce much more total erucic acid in the oil. Possibly the expression of erucic acid in the seeds is limited by the melting point of glyceryl trierucate as Auld et al. (1989) suggested.

Genes expressing monounsaturated fatty acids with double bonds in unusual positions as well as epoxy and hydroxy fatty acids have been reported in *Arabidopsis* seed oil at levels between 5% and 15% (Scarth and Tang, 2006).

B. Soybeans

White et al. (1961) attempted to reduce the linolenic acid content of soybean oil by recurrent selection. Their efforts have been continued by others (Hammond et al., 1972; Hammond and Fehr, 1975, 1984; Wilson, 1984; Hammond, 1985). Mutation-breeding techniques have resulted in the production of varieties that will consistently contain about 3.5% linolenoyl groups. Strains with less than 1% linolenic acid have been obtained by crossing certain lines with reduced linolenic content (Fehr and Hammond, 1996a,b). Genetic analyses of low-linolenic crosses indicated that the low-linolenic trait in soybeans is a quantitative character influenced by minor genes and environmental effects (Fehr et al., 1992). Byrum et al. (1997) showed that the low-linolenic acid trait in the variety A5 was caused by a full or partial deletion of the microsomal desaturase gene. Wilson et al. (2002)

have reviewed the recent progress in understanding the genetic relations among the genes controlling linolenic acid content. Because of the recent requirement for putting information about *trans* fatty acids on food labels, there is considerable activity to meet this goal by producing low-linolenic soybean oil that will not require hydrogenation for certain oil applications. Three groups are offering low-linolenic oil: Iowa State with Asoyia containing less than 1%, Monsanto with Vistive and Pioneer Hy-Bred International with Nutrium both containing less than 3% linolenic acid. Asoyia® is free of genetic engineering, but Vistive® and Nutrium® are both Roundup®-tolerant. Pioneer and Monsanto also report that they are working on other modified soybeans that will contain, among other things, elevated oleic acid content.

Besides soybeans with reduced linolenic acid content, mutation breeding with ethyl methanesulfonate, sodium azide, and *N*-nitrosourea has led to changes in the content of other fatty acids. The ranges of palmitic and stearic acids have been expanded so that both have ranges of about 3.5% and 30%, compared with 11% and 3.5%, respectively, in typical strains (Graef et al., 1985a,b; Lundeen et al., 1987; Fehr and Hammond, 1996c–e, 1997a,b). The high-stearic trait appears to be controlled by one genetic locus. High-stearic lines were associated with lower yields, although it appears possible to increase stearoyl content to some extent with no loss in yield (Hartmann et al., 1997). High-stearic lines are also subject to inconsistent germination. The palmitic content of soybeans is controlled by at least four independent loci (Schnebly et al., 1994), and both the reduced- and elevated-palmitoyl traits are associated with lower oil content in the seed (Horejsi et al., 1994; Ndzana et al., 1994; Hartmann et al., 1996). A soybean strain containing 28% stearoyl and 17% palmitoyl chains have been produced, for a total of 45% saturated acyl groups. Such high levels of saturation are very unusual for a temperate zone vegetable oil. Kok et al. (1999) have shown that this oil can make an acceptable margarine by transesterification, which avoids the production of *trans* fatty acids. The genetic control of saturated fatty acids in soybeans has been reviewed by Wilson et al. (2002). Liu et al. (2003) claims that a stable high-stearic acid trait can be introduced into oilseed by suitable genetic engineering.

A group at DuPont has produced a strain with a stable high-oleic percentage of about 85% by multiple expressions of the gene responsible for Δ-12 unsaturation. This "sense suppression" effect turns off both the endogenous and added gene (Kinney, 1996, 1997). Yields were as good as those of the soybean line that was transformed and the oleate content was environmentally stable. There is considerable interest in increasing the oleic content of low-linolenic soybean oil to produce a very stable frying oil, but there seems to be a reluctance to use genetic engineering to achieve this end, probably because of anticipated consumer resistance. The North Caroline breeding program has produced soybeans with low-linolenic and oleic ranging from 29% to 60% (Wilson et al., 2002). However, similar to many oleic mutants in soybeans, the oleic acid content varied considerably with growth environment. Liu et al. (2003) claim that a stable high-oleic acid trait may be introduced into oilseeds by suitable genetic engineering.

Comparisons of typical soybean oil with those containing reduced levels of linolenic and elevated levels of stearic acids have shown that these changes in composition increase oxidative stability (Mounts et al., 1988; White and Miller, 1988; Miller and White, 1988a,b). The high-oleic, low-polyenoic line produced by the DuPont group was tenfold more stable than typical soybean oil (Kinney, 1996).

The gene for making the conjugated triene calendic acid (*trans*-8-, *trans*-10-, *cis*-12-octadecatrienoic acid) has been transferred from *Calenduala officinalis* L. to soybeans, and expressions of 20%–25% calendic acid have been achieved (Cahoon et al., 2001). Oils with this fatty acid may make good surface coating and may also have interesting physiological effects.

C. Linseed

Australian workers have been successful in reducing the level of linolenic chains in linseed oil from typical values of 45%–65% to 1%–2% by mutation breeding and crossing of low-linolenic lines (Green and Marshall, 1984; Green, 1986; Tonnet and Green, 1987). These lines, which are

being grown in Canada, have a linoleic content of about 73% and are finding use as substitutes for sunflower seed oil (Daun, 1998).

D. Safflower and Sunflower

Knowles (1972, 1975) developed cultivars of safflower that yield oils containing up to 85% oleic acid or up to 85% linoleic aicd. Fick (1983) developed sunflower varieties yielding oil with more than 80% oleic acid. These sunflower lines were based on a Russian variety, Pervenet, that had been obtained by mutation breeding with dimethyl sulfate (Purdy, 1986). These varieties have enjoyed considerable commercial production and have commanded premium prices. The high-oleic oils are valued for their stability to oxidation, and the high-linoleic safflower oil has been used to maximize the polyunsaturated acyl content of margarine. The National Sunflower Association has encouraged the development of a sunflower containing 50%–75% oleic acid and 30%–32% linoleic acid as a frying oil. Sunflower is naturally low in linolenic acid. This is being marketed under the name NuSun® (Gupta, 1998, 2001). These changes were brought about by conventional breeding (Vick and Miller, 2002). Cargill has applied for a patent for producing high-oleic sunflower oil by molecular engineering (DeBonte et al., 1998).

E. Peanut

Norden et al. (1987) reported a high-oleic acid variety with a content of about 80% oleic and a much reduced linoleic content in the Florida peanut collection. The high-oleic trait has been shown to be controlled by two recessive genes, one of which occurs commonly in peanut germplasm cultivars (Moore and Knauft, 1989; Knauft et al., 1993; Isleib et al., 1996). High-oleic peanuts had better oxidative stability than common cultivars (Braddock et al., 1995).

F. Corn Oil

Corn oil containing 82% and 89% oleic acid and 10% and 4% linoleic acid, respectively, has been produced by DuPont. They were reported to have enhanced flavor stability compared with typical corn oil by Warner and Knowlton (1997). Dow AgroSciences has applied for a patent on introducing various acyl carrier protein thioesterases in corn that resulted in a decrease in palmitic acid content (Rubin-Wilson et al., 1998).

G. Palm Oil

Targets being pursued for palm oil are converting more of its palmitic acid to oleic acid and increasing its stearic acid and lycopene contents (Parveez et al., 2003; Shah et al., 2003).

VI. GLYCERIDE STRUCTURE VARIATION

The triglyceride composition of vegetable oils can vary considerably as the fatty acid composition changes. Complete triglyceride analyses are available only for the simplest vegetable oils, but stereospecific analyses of vegetable oils indicate that the fatty acid composition of the *sn*-1, -2, and -3 positions of the glycerol differ (Brockerhoff, 1971; Litchfield, 1972). Generally, the *sn*-2 position contains more oleic and linoleic groups and the *sn*-1 and -3 positions contain more long-chain saturated and erucic acid groups. Often the compositions of the *sn*-1 and -3 positions are quite similar. Generally, the amounts of the triglycerides are predicted reasonably well by assuming that the acyl groups on the three positions of the glycerol are carefully controlled, but the biosynthesis at one *sn*-position is oblivious about what is going on at a neighboring *sn*-position. This triglyceride composition can be calculated by the so-called 1-random-2-random-3-random hypothesis (Litchfield, 1972; Fatemi and Hammond, 1977a,b). Deviations from the 1-random-2-random-3-random values can be attributed to changes in the fatty acid proportions available for esterification during oil deposition in the seed.

Christie and Moore (1970) looked for patterns in triglyceride composition by plotting the amounts of particular acyl groups on the *sn*-1, -2, or -3 position vs. the amounts in the whole triglyceride. They found that for such plots, observed values fall on straight lines over the range of fatty acid compositions that were available. Lines of different slopes were obtained for each fatty acid and for each position of the glycerol. These kinds of "stereospecific plots" for soybean oil are shown in Figure 16.1. Fatemi and Hammond (1977a) suggested that if genetic variation in the triglyceride structure of plant oils exists, it could be recognized by finding individual plants that deviate from such typical patterns. Pan and Hammond (1983) performed a stereospecific analysis on the triglycerides from a number

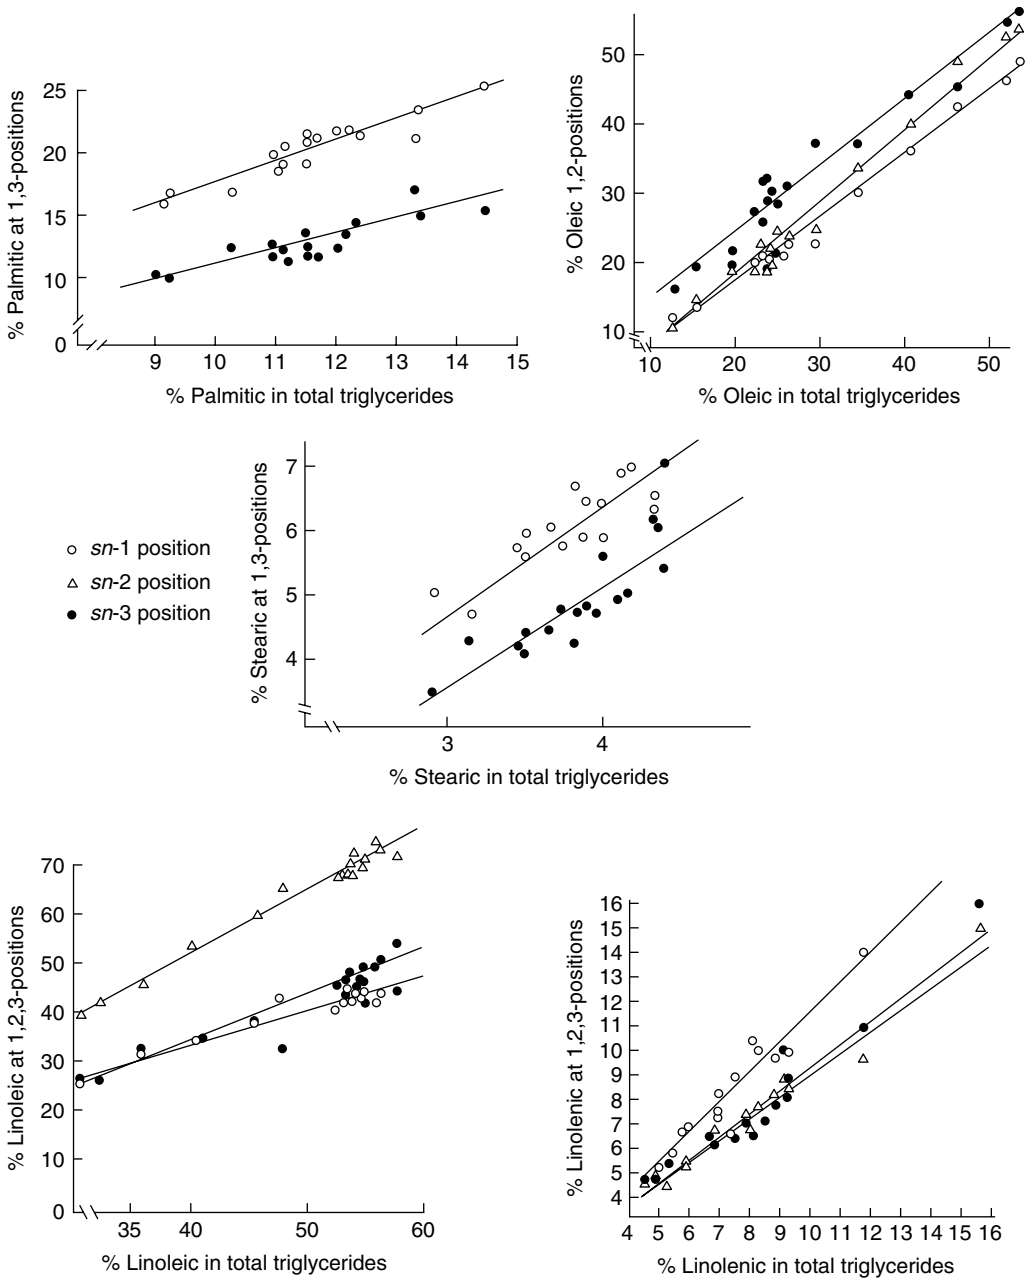

FIGURE 16.1 The amounts of various acyl groups found on the *sn*-1, -2, and -3 positions of glycerol vs. amounts of acyl groups found in the whole triglyceride of soybean lines.

of individual plants of soybean—*Glycine max*, its wild relative *Glycine soja*, as well as oats, *Avena sativa* and its wild relative *Avene sterilis*. Figure 16.1 illustrates the typical deviation from linear plots of individual soybean plants. Ohlson et al. (1975) generated similar data for species of Cruciferae. It has not been verified that the deviation of individual plants from linear plots is reproducible from generation to generation or if such deviations are under genetic control. Lee et al. (1993) fed the oleaginous yeast *Apiotrichum curvatum* (now renamed *Cryptococcus curvatus*) various fatty acid mixtures and found that the stereospecific distribution of fatty acids in the triacylglycerols that were formed could be fit by simple models. One model assumed that the only constraint was the specificity of the enzymes placing fatty acids on the three glycerol positions. Harp and Hammond (1998) obtained stereospecific plots for soybeans in which the stearoyl and palmitoyl content varied over a much wider range than those reported in previous surveys. They found that the plots for linoleic and linolenic acids showed much more scatter and that the direction of the scatter was a function of the amounts of saturated acyl groups. They suggested that this additional scatter did not result from these plants being glyceride-structure mutants but rather that the amounts of saturated acyl groups on the *sn*-1 and -3 positions affected the transfer of the linoleic and linolenic acids from the *sn*-2 position. They could not fit the models of Lee et al. (1993) to these soybeans, suggesting that additional constraints exist in the stereospecific distribution of soybean triglycerides.

17 Fat-Based Fat Substitutes

Casimir C. Akoh

CONTENTS

I. INTRODUCTION

Fat substitutes are a class of fat replacers. Fat substitutes are often referred to as lipid- or fat-based fat replacers. The other fat replacers are protein- or carbohydrate-based fat mimetics. Fat substitutes are macromolecules that physically, chemically, and functionally resemble triacylglycerols found in fats and oils. In food formulations and nutrition, fat substitutes can be used to substitute for conventional fats and oils with the advantage of being lower in calories, zero calorie, partially absorbed, or for better functionality and nutritional attribute than the fat or oil being replaced. Although fat consumption is declining, probably due to the increased availability of low- and reduced-fat products, fat consumption is greater than the recommended levels, and an increase in the prevalence of the population classified as overweight (Frazao, 1996). It was estimated that 2076 new low- and reduced-fat products were introduced in 1996 (Calorie Control Commentary, 1997). A good fat substitute or replacer must have the taste, mouthfeel, and stability to frying and baking, be able to reduce calories, or provide health benefits to the consumer. Protein- and carbohydrate-based fat replacers can sometimes withstand baking or retort operation, but they are not suitable for deep-fat frying. A variety of fat substitutes can duplicate many of the functional and physical attributes of fats and oils.

Adapted in part from the IFT Scientific Status Summary on *Fat Replacers*, published by Institute of Food Technologists' Expert Panel on Food Safety and Nutrition, Chicago, March 1998.

II. ZERO- AND REDUCED-CALORIE FAT-BASED FAT SUBSTITUTES

A. Olestra/Olean

Sucrose fatty acid polyester (SPE), commonly known as olestra or Olean®, is made up of six to eight fatty acids chemically esterified to the sucrose molecule (Figure 17.1). Olestra was discovered by Procter & Gamble (P&G) (Cincinnati, OH), who obtained the original patent. The synthesis of olestra has evolved from a solvent to a solvent-free process. So far, olestra is synthesized only with chemical catalysis. Olestra was approved by the U.S. Food and Drug Administration (FDA) in January 1996 for replacing up to 100% of the conventional fat in savory snacks (i.e., snacks that are salty or piquant but not sweet, such as potato chips, cheese puffs, and crackers) and not for frying of savory snacks (FDA, 1996). It was estimated that olestra will generate $400 million in annual revenue from its use in savory snacks. In approving olestra, the FDA concluded that olestra is not toxic, carcinogenic, genotoxic, or teratogenic; all safety issues were addressed; and there is reasonable certainty that no harm will result from the use of olestra in savory snacks (FDA, 1996). The Center for Science in the Public Interest (CSPI, Washington, DC), an advocacy and educational organization opposed the FDA approval of olestra on the basis of several allegations, including gastrointestinal (GI) disturbances, and petitioned the FDA to repeal the approval. Olestra passes through the GI tract without being digested or absorbed and, therefore, has the potential to cause GI effects, such as abdominal cramping and stool softening. Olestra can reduce the absorption of fat-soluble vitamins (A, D, E, and K) and nutrients such as carotenoids, which partition into olestra when ingested at the same time. Initially, the FDA required that foods containing olestra be labeled to inform consumers about potential GI effects and the addition of fat-soluble vitamins to compensate for the effects of olestra on their absorption (Table 17.1). Subsequently, the FDA Food Advisory Committee (FAC) reviewed the olestra postmarketing surveillance data that included additional clinical studies under

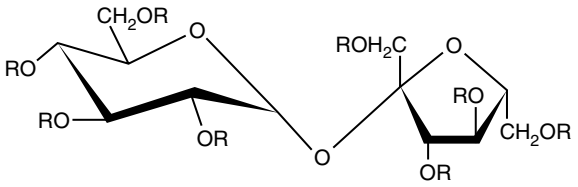

FIGURE 17.1 Structure of SPE (olestra or Olean®). Where R = acyl group of fatty acids.

TABLE 17.1
Compensation Levels of Fat-Soluble Vitamins in Olestra-Containing Snacks

Vitamin	Suggested Supplementation Level
A	51 retinol equivalents/g olestra as retinyl palmitate or retinyl acetate = (170 IU/g olestra or 0.34 × RDA/10 g olestra)
D	12 IU vitamin D/g olestra = (0.3 × RDA/10 g olestra)
E	1.9 mg alpha-tocopherol equivalents/g olestra = (0.94 × RDA/10 g olestra)
K	8 μg vitamin K_1/g olestra = (1.0 × RDA/10 g olestra)

Abbreviations: IU = international unit; RDA = recommended daily allowance.

Note: The suggested levels are to compensate for amounts that are not absorbed the diet because of olestra action.

Source: Adapted from FDA (1996). *Fed. Reg. 61*: 3118–3173.

normal snacking conditions between June 15 and 17, 1998, and reaffirmed their original decision that olestra is safe for salty snacks. The FAC review focused on GI effects, nutritional safety, and the interim label.

A series of studies (Suttie and Ross, 1997) was published in a supplement to the *Journal of Nutrition* to assess the nutritional effects of olestra in pigs and human subjects. In a randomized, double-blind, parallel group (olestra vs. full-fat control), placebo-controlled, single-center study, 1123 human subjects, aged 13–88 years, were given *ad libitum* potato chips made with olestra to assess whether olestra results in different levels of GI symptoms than the consumption of regular full-fat potato chips as placebo (Cheskin et al., 1998). The study concluded that *ad libitum* consumption of olestra potato chips during one sitting was not associated with an increased incidence or severity of GI symptoms, nor does the amount consumed predict who will report GI effects after short-term consumption of either olestra or regular potato chips (Cheskin et al., 1998). The first olestra product was sold by PepsiCo's Frito-Lay units as Wow! Chips in February, 1998. The P&G's Pringles started selling in March 1998. Chips and snacks made with olestra contain about half the calories of regular chips. As of June 1998, more than half a billion servings of olestra snacks were sold with Frito-Lay selling 80-million bags of chips.

Olestra is a completely nonabsorbable zero-calorie fat-based fat substitute that can successfully mimic both the culinary and gastronomic characteristics of fats and oils (Goldman, 1997). Olestra appears to impair the absorption of fat-soluble but not water-soluble nutrients. Highly lipophilic drugs are most likely to interact with olestra (Goldman, 1997).

The physical properties of olestra are controlled by the fatty acids attached to the sucrose molecules. The melting points of triacylglycerols are dependent on the chain length and degree of unsaturation of their fatty acid constituents. Likewise, the melting point of olestra also reflects their fatty acid constituents and degree of esterification. For example, sucrose octaoleate is a liquid and sucrose octastearate and octapalmitate are solids at room temperature (Jandacek and Webb, 1978). It is well known that lipids with high melting points are organoleptically undesirable and leave an unacceptable waxy taste in the mouth. Fat substitutes with a melting point body temperature are preferred for food formulations except in salad dressings where liquid oils are more desirable. Since most foods are formulated with partially hydrogenated vegetable shortening, olestra can be produced with shortening consistency by blending appropriate amounts of liquid oils and fats prior to synthesis (Akoh and Swanson, 1990). Olestra is completely miscible with triacylglycerols. Heating or frying with olestra does not produce any new class of products that are not normally found in heated triacylglycerols. The apparent viscosity of olestra is however higher than that of triacylglycerols with a similar fatty acid composition (Jandacek and Webb, 1978; Akoh and Swanson, 1990). The oxidative stability of liquid olestra is lower than comparable vegetable oils, but the addition of antioxidant results in more stable olestra (Akoh, 1994; Shieh et al., 1996). The density, specific gravity, and refractive indices of olestra approximate those of commercial vegetable oils (Akoh and Swanson, 1990; Akoh, 1994; Shieh et al., 1996). It was suggested that the physical properties of SPEs can be adjusted by varying the degree of unsaturation and chain length of the fatty acid used in the synthesis to produce sucrose polyesters with functional properties appropriate for food use (Akoh and Swanson, 1990).

Olestra can cut calories. Examples of how olestra cuts calories are given in Table 17.2. Possible food applications and functions of some fat-based fat substitutes are shown in Table 17.3. A dialog conference on The Role of Fat-Modified Food in Dietary Change was recently held at Tufts University (1998). Essentially, the conference participants discussed (a) dietary fat consumption and health, (b) physiology of fat replacement and fat reduction, (c) behavioral and social influences on food choice, (d) educating consumers regarding choices for fat reduction, and (e) recommendation on what needs to be done in the future. They concluded that efforts to reduce fat and calories from the diet must be pursued both in the context of the total diet and overall healthful lifestyle that includes adequate regular physical activities. A recent review on fat replacers can be found elsewhere (Akoh, 1998).

TABLE 17.2
How Olestra Cuts Fat and Calories in a 1-Oz Serving of Triacylglycerol and Olestra-Made Snack Foods

Food	Fat Content (g)	Calories (kcal)	Fat Reduction (%)	Calorie Reduction (%)
Potato chips				
With triacylglycerol	10	150		
With olestra	0	60	100	60
Tortilla chips				
With triacylglycerol	7	140		
With olestra	1	90	85	36

TABLE 17.3
Possible Food Applications and Functions of Some Fat-Based Fat Substitutes

Food Application	Fat Substitute Type	Functions
Baked goods	Sucrose esters, mono- and diacylglycerols	Emulsification, cohesiveness, tenderizer, flavor carrier, shortening replacer, antistaling agent, prevent retrogradation of starch, dough conditioner
Frying and cooking	Olestra,[a] SLs	Texturizer, provide flavor, crispiness, heat conduction, calorie reduction[b]
Salad dressing	Olestra, SLs	Emulsification, mouthfeel, hold flavorants, calorie reduction
Frozen desserts	Olestra, SLs	Emulsification, texturizer, calorie reduction
Margarine, shortening, spread, butter	Olestra and olestra-type molecules, SLs	Spreadability, emulsification, provide flavor, plasticity, calorie reduction
Confectionery	SLs, olestra	Emulsification, texturizer
Processed meat products	Sugar esters, SLs	Emulsification, texturizer, provide mouthfeel
Dairy products	Olestra, SLs	Provide flavor, body, mouthfeel, texturizer, stabilizer, increase overrun calorie reduction
Soups, sauces, gravies	SLs, olestra	Provide mouthfeel, lubricity, calorie reduction
Snack products	SLs, olestra	Emulsification, provide flavor, calorie reduction

[a] Means olestra and olestra-type molecules such as sorbitol, raffinose, stachyose, and alkyl glycoside polyesters can be used to achieve the same functionality.
[b] Calorie reduction can be achieved with the products given in "a" above and with some types of SLs such as Benefat and caprenin.

B. Polyol or Carbohydrate Fatty Acid Polyesters

Other polyol or fatty acid polyesters with a potential for use in place of SPEs as zero- or reduced-calorie fats and oils are the monosaccharides (mannitol, sorbitol), disaccharides (lactitol, trehalose), trisaccharide (raffinose), and tetrasaccharide (stachyose) fatty acid polyesters. If the degree of the polyol hydroxyl group substitution with fatty acids is greater than 4, the susceptibility of the polyol fatty acid polyester to lipolysis decreases. Their synthesis, purification, analysis, and physical properties are essentially the same as that of SPEs (Goldman, 1997). None of the molecules listed above is approved for use in foods by the FDA. However, further studies and product developments will be required before petition can be filed. Now that olestra is approved, it is expected that the approval process for new polyol fatty acid polyesters will take less time and these are expected to compete with olestra for the fat-based fat-substitute market.

C. Alkyl Glycosides Fatty Acid Polyesters

Alkyl glycosides suitable for the synthesis of fatty acid polyesters include methyl or ethyl glucose and galactose or octyl-β-glucose. Among these, methyl glucoside fatty acid polyester has received the greatest attention as a possible reduced-calorie replacement of conventional fats and oils in foods. The preparation of alkyl glycoside fatty acid polyesters and their physical properties have been described elsewhere (Meyer et al., 1990; Akoh, 1994). In general, up to four to five of the available hydroxyl groups of the glycosides are esterified with fatty acids. Alkyl glycoside fatty acid polyesters can be used as frying oils and in preparing Italian or white salad dressings. Curtice Burns, Inc. (Rochester, New York) owns the patent on the application of alkyl glycoside fatty acid polyesters (Meyer et al., 1989). No approval petition has been filed with the FDA.

D. Sorbestrin

Sorbestrin was developed by Pfizer, Inc. (now owned by Cultor Food Science, Inc., New York). Sorbestrin is a mixture of tri-, tetra-, and pentaesters of sorbitol and sorbitol anhydrides with fatty acids. Sorbestrin contributes 1.5 kcal/g to diet. It has a bland oil-like taste with a cloud point between 13°C and 15°C. Sorbestrin is mainly in liquid form and can serve as a reduced-calorie fat-based fat substitute. Sorbestrin is thermally stable and can withstand deep-fat-frying temperatures. It is intended for use in frying, baking, and salad dressings. Sorbestrin is not yet commercially available and will require FDA Food Additive approval prior to use. Akoh and Swanson (1989) synthesized sorbitol hexaoleate as a low-calorie fat substitute. Recently, Chung et al. (1996) optimized the synthesis of sorbitol fatty acid polyesters. Procter & Gamble also worked on sorbitol polyesters but did not follow up with further developments as with olestra. Table 17.4 lists the calories available from selected fat-based fat substitutes.

E. Dialkyl Dihexadecylmolonate

Dialkyl Dihexadecylmolonate (DDM) is a noncaloric synthetic fat substitute developed by Frito-Lay, Inc. (Dalls, TX). DDM is synthesized from malonic acid, hexadecane, and fatty acids (Haumann, 1986). It can be used for high-temperature frying operations like potato chips or can be blended with vegetable oils for the same purpose. No toxicity effect has been reported, but anal oil leakage is possible when consumed in large amounts (Calorie Control Commentary, 1996). No formal petition has been filed with the FDA. Usually, approval of a Food Additive Petition (FAP) will require many years. For example, it took Procter & Gamble almost 10 years from the date of the FAP to obtain FDA approval for olestra. This process can be costly and may prevent commercialization of many potential fat substitutes.

TABLE 17.4
Caloric Availability of Selected Fat-Based Fat Substitutes

Product	kcal/g
Olestra	0
Caprenin	5
Benefat	5
MCTs	8.3
Sorbestrin	1.5

F. Esterified Propoxylated Glycerol

Esterified propoxylated glycerol (EPG) differs from triacylglycerols, because it contains an oxypropylene group between the glycerol and fatty acids. Glycerol is first propoxylated with propylene oxide to form a polyether polyol that can be subsequently esterified with fatty acids. EPG can be used to replace conventional triacylglycerols in most foods, because EPG resembles fats and oils; examples include frozen desserts, salad dressings, baked goods, and spread. EPG is heat stable and can be used for cooking and frying operations. It has similar physical properties to triacylglycerols, but EPG is not hydrolyzed (Gershoff, 1995) by lipases owing to steric hindrance and therefore is not absorbed by the body. EPG becomes resistant to lipases when the propoxylation number exceeds 4. EPG contributes zero to few calories to the diet. It was developed by the ARCO Chemical Company (Wilmington, DE) and CPC International/Best Foods (Englewood Cliffs, NJ). EPG is not commercially available and no FAP has been filed with the FDA to date.

G. Polycarboxylic Acid Compounds

Trialkoxytricarballylate (TATCA), trialkoxycitrate (TAC), and trialkoxyglyceryl ether (TGE) are polycarboxylic acid esters and ethers proposed by Hamm (1984) as possible low-calorie replacements for edible oils. Owing to the nature of their structures (some with ester group reversed), they are not susceptible to complete hydrolysis by lipases. Their synthesis and properties have been reported (Hamm, 1984). Consumption of polycarboxylic acid esters and ethers can lead to anal leakage, weakness, depression, and death in animals. No FAP has been filed for TATCA, TAC, or TGE, and it appears no active research is ongoing with these molecules.

III. EMULSIFIERS

A. Sucrose Fatty Acid Esters

Sugar fatty acid esters have a lower degree of substitution or esterification of the sucrose hydroxyl groups with fatty acids (Ds, 1–3) compared to olestra (Ds, 6–8). Sucrose fatty acid esters (SFEs) are easily hydrolyzed by the digestive lipases and contribute reduced calories to the diet. They are made by transesterification reactions essentially like the SPEs (Osipow et al., 1956) except that the ratio of the reactants and reaction time are used to control the degree of esterification. The product contains five to seven hydroxyl groups of sucrose unesterified with fatty acids. Free hydroxyl groups together with the esterified fatty acids impart both hydrophilic and lipophilic character to SFEs and thus are excellent emulsifier surfactants. SFEs were approved for use in the United States as emulsifiers in baked goods and baking mixes in dairy product analogs, and as components of protective coatings for fresh apples (Drake et al., 1987), bananas, pears, pineapples, avocados, plantains, limes, melons, papaya, peaches, and plums to retard ripening and spoilage. In addition, SFEs are useful as antimicrobials (Marshall and Bullerman, 1994) and can be used for food, cosmetic, and pharmaceutical applications. As emulsifiers, SFEs function by lowering interfacial and surface tension of emulsions (Gupta et al., 1983).

B. Other Emulsifiers

Polyglycerol esters and other emulsifiers such as mono- and diacylglycerols, sodium stearoyl-2-lactylate (SSL), and lecithin can be used as fat substitutions where their main function is emulsification. They possess both hydrophilic and lipophilic properties that enable them to stabilize the interface between fat and water droplets through hydrogen bonding. Emulsifiers play an important role in fat reduction and in reduced-calorie food formulations involving fat mimetics (protein- and carbohydrate-based fat replacers). Emulsifiers work best with other ingredients as part of a fat-reduction system (Calorie Control Commentary, 1996). The addition of mono- and diacylglycerols

to cake shortenings is known to allow a reduction in fat content. Emulsifiers can also increase the perception of lubricity by emulsifying the fat in the mouth (Calorie Control Commentary, 1996). Emulsifiers can be combined, by experimentation, to achieve superior performance in a food system (full- or low-fat product).

The synthesis of polyglycerol esters has been described (Babayan, 1985, 1986). They have a wide hydrophilic–lipophilic balance (HLB) as found in the sugar fatty acid esters. The more unesterified hydroxyl groups available, the more hydrophilic the polyglycerol ester becomes. Polyglycerol esters, lecithin, SSLs, SFEs, and mono- and diacylglycerols can be used in margarines, baked goods, frozen desserts, dairy products, spreads and shortenings, and confectioneries. Many emulsifiers serve as tenderizers in baked products. Polyglycerol esters serve as aeration agents in food containing fat replacers. The functions of emulsifiers in low-fat products include serving as shortening and starch-complexing agents, syneresis control, air entrapment, foam stabilizer, flavor carrier, and as rheology control agents.

IV. STRUCTURED LIPIDS

Structured lipids (SLs) are triacylglycerols containing short-chain fatty acids (SCFAs) and/or medium-chain fatty acids (MCFAs) and long-chain fatty acids (LCFAs) preferably on the same glycerol molecule (Akoh, 1995). SLs can be prepared as specialty lipids for nutritional, pharmaceutical, or medical applications (Jensen and Jensen, 1992) or as reduced-calorie lipids (Akoh, 1995). SLs containing MCFAs and LCFAs were developed to meet the energy requirements of specific individuals (Heird et al., 1986). Pure medium-chain triacylglycerol (MCT) emulsions do not provide essential fatty acids to the diet but provide readily absorbed nonglucose energy. A physical mixture of MCT and long-chain triacylglycerols (LCTs) can meet both the nutritional and energy requirements of hospitalized patients. However, SLs with modified absorption rate is a preferred alternative to physical mixtures (Bell et al., 1991; Kennedy, 1991). SLs can improve fat utilization in patients with cystic fibrosis, pancreatic insufficiency, and a fat-absorption disorder.

SLs are prepared by chemical and/or enzymatic transesterification reactions (Heird et al., 1986; Kennedy, 1991). When two triacylglycerols are the substrates, SLs are synthesized by ester interchange reactions (Akoh, 1995). Application of lipases in the synthesis of SLs offers advantages over conventional chemical catalysts such as synthesis of positional-specific SL molecules and stereoisomers under mild reaction conditions. The type of fatty acid at the 2-position of the glycerol moiety is critical to fat metabolism. Generally, the absorption of fatty acids (including poorly absorbed fatty acids such as palmitic and stearic acids) or linoleic at the 2-position of glycerol backbone are enhanced. Akoh (1995) reviewed the strategies for enzymatic synthesis of SLs and discussed their potential health benefits. The use of enzymes to synthesize reduced-calorie SLs with the potential to lower cholesterol, modulate the immune response, and reduce the caloric content of foods are being explored (Akoh, 1995). The general structure of SLs or structured triacylglycerols is shown in Figure 17.2.

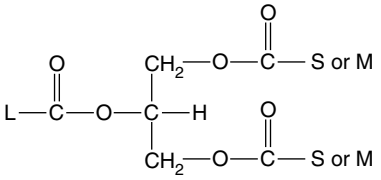

FIGURE 17.2 SLs or structured triacylglycerols. S, M, and L are for SCFA, MCFA, and LCFA, respectively. The position of S, M, or L is interchangeable.

A. Caprenin

Caprenin is a reduced-calorie SL providing 5 kcal/g compared to 9 kcal/g for conventional fats and oils. Caprenin consists of saturated caprylic (C8:0), capric (C10:0), and behenic acids (C22:0) esterified to a glycerol molecule. Behenic acid is poorly absorbed and contributes less calories than other fully absorbable unsaturated LCFAs found in fats and oils. Caprenin was originally produced by Procter & Gamble from coconut and palm kernel oils, and it was intended for use in soft candies and as a confectionery fat to replace cocoa butter. Procter & Gamble filed an FDA Generally Recognized As Safe (GRAS) affirmation petition to use caprenin as a confectionery fat in soft candy and confectionery coatings (Calorie Control Commentary, 1996). Caprenin was used by M&M Mars (Hackettstown, NJ or Elizabethtown, PA) and Hershey Foods Corp., Hershey, PA) in reduced-calorie chocolate bars such as Milky Way II, but was not commercially successful, because it proved difficult to temper. These products are no longer in the market, and caprenin is not currently available commercially. Procter & Gamble does not seem to be aggressively pursuing further research on caprenin at this time.

B. Benefat

Benefat, originally known as salatrim (*s*hort *a*nd *l*ong *a*cyl *tri*acylglycerol *m*olecules), is also a reduced-calorie SL with a caloric content of 5 kcal/g. It is composed of a mixture of SCFAs (C2:0, C3:0, or C4:0 fatty acids) and at least one LCFA (predominantly C18:0, stearic acid) randomly attached to the glycerol molecule. In making salatrim, SCFAs are randomly transesterified with vegetable oils such as highly hydrogenated canola or soybean oil using a chemical catalyst. Salatrim, a family of structured triacylglycerols, was developed by Nabisco Foods Group, Parsippany, NJ (Smith et al., 1994), and licensed to Cultor Food Science (New York, NY) under the brand name, Benefat. It has the taste, texture, and functional properties of conventional fats and oils. Stearic acid is partially absorbed resulting in salatrim only 55% or 5/9 of the value of conventional fats and oils (Smith et al., 1994), to the overall molecule. Benefat I was developed primarily for cocoa butter replacement. Benefat cannot be used for deep-fat frying, because the SCFA components will volatilize. Benefat can be produced to have select functional and physical properties, for example, a range of melting points, hardness, and appearance by adjusting the amounts of SCFAs and LCFAs used in their chemical synthesis. Products on the market that contain Benefat are the reduced-fat chocolate-flavored baking chips introduced in 1995 by the Hershey Foods Corporation and Snack Well's fudge-dipped granola bars. Benefits can also be used as a cocoa butter substitute. The Nabisco Foods Group intends to introduce Benefat-containing granola bars under SnackWell's brand. Benefat is intended for use in chocolate-flavored coatings, deposited chips, caramels, fillings for confectionery and baked goods, margarines and spreads, savory dressings, dips, and sauces and in dairy products (Kosmark, 1996). FDA accepted for filing in 1994 a GRAS affirmation petition submitted by the Nabisco Foods Group (Calorie Control Commentary, 1996).

C. Neobee and Captex Series

The Neobee series of SLs are manufactured chemically by interesterification and marketed by the Stepan Company (Maywood, NJ). These SLs are tailor-made for customers and for specific applications such as in medicine. For example, Neobee-1814 is made by random interesterification of MCTs and butter oil (50:50, w/w). Other products from the Stepan Company are SL-110 (interesterified MCT and soybean oil), SL-120 (MCT and menhaden oil), SL-130 (MCT and sunflower oil), SL-140 (MCT, menhaden, soybean oils, and tributyrin), SL-210 (coconut and soybean oil), SL-220 (coconut, menhaden, and canola oils), SL-230 (coconut, menhaden, and soybean oils and tributyrin), SL-310 (MCT and menhaden oil), and SL-410 (MCT, butter, and sunflower oil). Abitec Corporation (Columbus, OH) makes and markets the synthetic Captex series of SLs. Examples include Captex-350 (transesterified coconut oil with caprylic and capric acids) and 810D (contains

caprylic to linoleic acids). The main MCFAs in the Neobee and Captex products are caprylic, capric, and lauric acids, whereas the LCFAs include oleic, linoleic, eicosapentaenoic, and docosahexaenoic acids. Uses include nutritional supplements and clinical and consumer products. Their use in food applications has not received adequate attention. However, Akoh et al. (1998) recently showed that the consumption of a Captex 810D diet resulted in increased heat production and altered energy metabolism in obese Zucker rats. This study compared the effects of Captex 810D and Simplesse, a protein-based fat replacer, on energy metabolism, body weight, and serum lipids in lean and obese Zucker rats.

V. MEDIUM-CHAIN TRIACYLGLYCEROLS

MCTs contain saturated fatty acids of chain length C6:0–C12:0, predominantly C8:0–C10:0 fatty acids with traces of C6:0 and C12:0. A typical fatty acid composition for an MCT is C6:0 1–2%, C8:0 65–75%, C10:0 25–35%, and C12:0 2% (35). MCTs are different from the conventional fats and oils. Babassu, coconut, cohune, palm kernel, and tocum oils are the main sources of the fatty acids required for MCT synthesis after fractionation of the oils (Babayan, 1987; Megremis, 1991; Bach et al., 1996). MCTs are prepared by hydrolysis of the oils followed by fractionation of the resulting fatty acids to concentrate MCFA and reesterification with glycerol to form triacylglycerols (Babayan, 1987). Clinically, MCTs have been used since the 1950s in enteral and parenteral diets for the treatment of lipid absorption, digestion, or transport disorders. They provide 8.3 kcal/g and are commercially available on the basis of GRAS self-determination. They are more soluble in water than LCTs, and they can be used as a solvent for flavors and drugs and to carry vitamins. Because MCTs are not incorporated into chylomicrons, they are less likely than LCTs to be stored in adipose tissue. They are readily metabolized for energy. MCTs bind to serum albumin and are transported to the liver via the portal system rather than the lymphatic system. Infants and hospital patients, body builders, and fitness-conscious individuals may obtain a dense source of readily metabolizable energy from MCT consumption. MCTs can be incorporated into reduced-calorie foods because of their reduced-calorie content. They can be used in baked goods, beverages, frostings, dairy products, frozen desserts, snack foods, soft candies, and confectioneries. MCTs can be used in enteral and parenteral diets for people who cannot digest, absorb, or transport LCTs. Those that contain saturated fatty acids are oxidatively stable and have been used in food for over 30 years. Recent research on the metabolism of MCTs is available (Bach et al., 1996). MCTs are available from the Abitec Corporation (Columbus, OH) and the Stepan Company (Maywood, NJ).

VI. CONCLUSION

The desire by the American public to maintain good health while enjoying tasty foods has resulted in the development of a number of fat-based fat substitutes. The availability of a wide variety of fat replacers or fat substitutes is a step in the right direction toward providing consumers with many choices as they look for ways of reducing total fat calories. However, some fat is needed, because fat supplies essential fatty acids required for growth, proper development, and physiological functions. Fat substitutes are no "magic bullet" and there is no simple solution to fat replacement, but proper nutrition (choice of food groups), a healthy lifestyle, regular exercise, and a choice of appropriate fat-substitute-containing diets may lead to better nutrition and good health. Partial replacement and reduction in the amount of total fat consumed in the diet may be prudent. Research on structured fats with desired specific functionality, physical properties, and healthy appeal are being performed at various food industries and in academia. The future of fat replacement may well depend on the structure–function relationship of the molecules. In other words, fat replacers that possess healthy appeal, good taste, and desirable functionality will be acceptable to majority of consumers and could mean a sizeable share of the fat-replacer market.

18 Commercial Applications of Fats in Foods

Ronald Jandacek

CONTENTS

I. INTRODUCTION

Since the previous edition of this book, the high level of interest in dietary fat has continued to grow. There have been advancements in the understanding of the reasons why fat in foods appeals to many people. Effective pharmaceutical treatments of elevated blood lipids that are risk factors for the development of atherosclerosis have appeared and have made it relatively easy to reduce these risk factors when dietary approaches have failed. The understanding of the metabolism of ω-3 fatty acids has contributed to recommendations for their inclusion in the diet for optimum nutrition. Labels requiring the level of *trans* acids are now required to appear on packaged foods.

The discussion of commercial applications of fatty acid-based food components that is presented in this chapter will discuss both broad applications and niche markets. This chapter will address the production and composition of dietary fats and oils, the physical properties of solid fats, margarines and spreads, triacylglycerol substitutes, triacylglycerols with specific structures, and fatty acid derivatives with beneficial physical or metabolic functions.

II. TRIACYLGLYCEROLS—PRODUCTION AND COMPOSITION

In terms of economic impact and total dietary consumption, triacylglycerols (triglycerides) in vegetable oils and animal fats are commercially the most important forms of fatty acids in foods. Although diet composition discussions often cite the "fatty acid composition" of the diet, essentially all of ingested fat is composed of esterified fatty acids in the form of triacylglycerols. The production and sale of edible oils and fats on an international scale is enormous, with projected 2005/2006 world production forecast of 145 million metric tons (Anonymous, 2005a). Approximately 85% of all edible oil produced is used in foods. On the basis of world population (6.5 billion people), edible fat production could potentially supply 470 kcal/person daily.

In 2004–2005, the principal sources of food oils were soybeans and palm, with 27.7 and 26 million metric tons produced, respectively (Gunstone, 2005). Canola oil was the third largest product, with 12.9 million metric tons produced in 2004–2005.

The method of production of edible vegetable oils varies with the source. Soybeans and canola seed are generally extracted with hexane. Purification steps include removal of residual lecithin (degumming) and removal of color pigments with bleaching earth. Steam deodorization removes materials that can give undesirable flavors to the oils. Olive oil is obtained by pressing. Palm oil is obtained from the fruit primarily by pressing a steamed digest mash of the palm fruit.

The fatty acid composition of the world's principal edible oils has become a major and evolving focus in the areas of health and nutrition. The positive correlation between elevated blood levels of low-density lipoprotein (LDL) cholesterol and the risk of atherosclerosis has become generally accepted. In addition, it has been generally accepted that blood cholesterol levels are affected by the type of dietary fatty acids, with saturated fatty acids increasing LDL cholesterol and polyunsaturated and monounsaturated fatty acids decreasing LDL cholesterol (Kris-Etherton and Yu, 1997). A significant exception to this generalization is that the long-chain saturated stearic (octadecanoic) acid, does not contribute to the elevation of LDL cholesterol. The fatty acid composition of widely consumed fats and oils is presented in Table 18.1 (Technical Committee, 2006).

As noted below and elsewhere in this book, high dietary levels of the geometric isomers of the unsaturated fatty acids in the *trans* form have been demonstrated to cause unfavorable increases in LDL cholesterol and decreases in high-density lipoprotein cholesterol (HDL). Since HDL levels are negatively correlated with the risk of the development of atherosclerosis, reduction in dietary *trans* fatty acids has become a focus in nutritional recommendations. Effective January 1, 2006, food label requirements in the United States require the inclusion of the level of *trans* acids or a statement that notes that the food is not a significant source of *trans* acids.

Dietary *trans* fatty acids primarily enter our diet in fats containing unsaturated fatty acids that have been partially hydrogenated. Although this process is generally viewed as a product of an industrial metal-catalyzed reaction of unsaturated fatty acids at elevated temperatures and pressures, it has in fact been with us since ruminant animals began grazing. Butter and dairy products contain small amounts of *trans* acids resulting from the biohydrogenation of fatty acids catalyzed by bacterial enzymes in the rumen of the cow.

The major portion of *trans* fatty acids in the diet has, however, been the result of partial hydrogenation of vegetable oils. Hydrogenation has been carried out to achieve two purposes. First, the production of higher melting fatty acids by saturating the double bonds of lower melting fatty acids yields higher melting triacylglycerols with physical properties that may be desirable for baking (semisolid shortening) or in spreads (stick margarine). Second, the saturation of double bonds in oxidatively unstable unsaturated fatty acids, particularly the triunsaturated α-linolenic acid, reduces the rate of development of rancid off flavors.

In response to the negative attributes of *trans* acids, food producers have sought alternative means to optimize physical and oxidative properties. Hunter (2005) recently reviewed the approaches that have been taken to produce alternatives to *trans* fatty acids in foods.

TABLE 18.1
Fatty Acid Composition of Commercial Edible Oils

Oil or Fat	Carbons: Double Bonds	Butyric	Caproic	Caprylic	Capric	Lauric	Myristic	Pentadecanoic	Palmitic	Margaric	Stearic	Arachidic	Behenic	Lignoceric	Myristoleic	Palmitoleic	Oleic	Margaroleic	Gadoleic	Linoleic	α-Linolenic
		4:0	6:0	8:0	10:0	12:0	14:0	15:0	16:0	17:0	18:0	20:0	22:0	24:0	14:1	16:1	18:1	17:1	20:1	18:2	18:3

Approaches to reducing *trans* acids include modification of the hydrogenation process. Selection of catalyst and process conditions can affect the production of *trans* acids, although minimizing the production of saturated fatty acid production is a constraint that is important (Beers and Mangnus, 2004). Another approach is to use fats and oils that are naturally high in solids, such as cottonseed oil, although saturated fatty acid content must also be considered (O'Brien and Wakelyn, 2005). The development of oilseeds that are low in α-linolenic acid has been and is being actively pursued. By reducing the level of this oxidatively unstable fatty acid, a stable oil can result without the need to reduce α-linolenic concentration by hydrogenation (Ross et al., 2000). This development has been achieved by conventional seed development methods to give a commercial oil with 3% α-linolenic acid (Monsanto, Vistive™), compared with a typical level of 8% in soybean oil. Planting of this cultivar is expanding to meet the demands for a fat low in α-linolenic acid. Finally, semisolid fat-oil compositions appropriate for shortenings can be produced by interesterification of fats to favorably alter the solid content and crystalline phase behavior (Cowan and Husum, 2004). This interesterification is being performed by standard chemical methods, and increasingly, by enzymatically catalyzed processes.

Although taste, texture, cost, and consistency appear to be the principal driving forces for desirability of foods, the understanding of the relationship between diet and health continues to generate recommendations for individuals to optimize their diets for better health. These recommendations have had a commercial impact, as seen in the move to reduce dietary *trans* fats.

Extensive studies have examined the relationship of dietary triacylglycerol fats to obesity, heart disease, health development, and cancer. There have been controversies about these roles, but there are dietary recommendations for the amount and type of dietary fat that are prudent in health. In the publication, "Dietary Guidelines for Americans, 2005," published jointly by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture, there are several recommendations related to dietary fat (Anonymous, 2005d). These guidelines recommend a total fat intake of 30%–35% of calories while reducing *trans* fatty acids and minimizing dietary cholesterol. They also recommend saturated fatty acid intake below 10% of calories, and mono- and polyunsaturated fatty acid from 20% to 35% of calories (including sources of ω-3 fatty acids).

Although these recommendations are somewhat general, they do provide guidance to the consumer. Moreover, the food industry has shown sensitivity to nutritional needs by directing efforts toward the development of products that are consistent with these guidelines. Marketing and advertisement of these products may emphasize conformance with dietary guidelines to enhance sales, but these efforts can also serve as a source of nutritional education for consumers.

In the United States, the fatty acid composition of cooking oils and oil-based products such as margarine and spreads is readily available to the consumer on the required labels. As noted above, the label now includes the level of *trans* acids as well as total fat and total saturated fatty acids. If there is less than 0.5 g of *trans* or saturated acids in a serving, there is no requirement for the amount to be included on the label. The amount of polyunsaturated and monounsaturated fatty acids in the food is indicated by subtracting label values for saturated and *trans* fat from total fat.

It is also now generally recognized that ω-3 long-chain polyunsaturated fatty acids are desirable in a healthy diet. This requirement is most important in newborns since the ω-3 acid, docosahexaenoic acid (DHA), a principal component of the brain and retina, is needed for normal neurological development. Sources of ω-3 fatty acids include fish oil (DHA and eicosapentaenoic acid, EPA); soybean, canola, and flax oils (α-linolenic acid); and single cell systems grown to maximize DHA production. The oxidative instability of oils with high concentrations of these fatty acids is a challenge that has limited their use in foods. Low levels of oils high in DHA are included in infant formulas and in gelatin-encapsulated supplements.

Oils from vegetable sources account for most of the "visible" forms of dietary fat and oils. Dietary fat from animal sources accounts for a significant portion of the diet. With the exception of butter, most animal fat is "hidden" as part of the meat, fowl, fish, and dairy products.

III. FUNCTIONALITY PROVIDED BY SOLID FATS

For several decades, most discussion of dietary triacylglycerols has emphasized the value of the lower melting, unsaturated fatty acids. The nutritional essentiality and LDL-lowering property of linoleic acid, and the healthfulness of oleic acid in Mediterranean-like diets have been foci from a nutritional viewpoint. In addition, the health benefits of the long-chain polyunsaturated ω-3 fatty acids have become a major topic for research and recommendations.

Higher melting saturated and *trans* fatty acids, however, continue to play a major role providing foods with texture and stability appropriate for specific food uses. The functional benefits of high-melting fats are due to their phase behavior. Many studies of this phase behavior have contributed to improving the use of high-melting fats in foods, and some of this understanding of the properties of lard and shortening is given below to provide historic perspective.

Lard, fat rendered from swine, was for many decades the standard ingredient in many baking and frying applications because of its ready availability. Although its oxidative stability is relatively low, its performance in baked goods was the time-tested standard. Its commercial importance has greatly decreased because of the nutritional concerns about animal fats described above. Nutritional recommendations for reductions in saturated fat intake emphasize the replacement of animal-based fats with fats from vegetable sources. As a result, the vegetable oil shortenings essentially displaced lard from a position of commercial importance. From 1970 to 1995 lard consumption in the United States decreased from 4.6 to 1.7 lb per capita per year (Putnam and Allshouse, 1997). Interestingly from 1996 to 2003, the per capita consumption increased to 2.4 lb per capita (Anonymous, 2005b).

A discussion of the composition and properties of lard is important, because cooking experience with lard once set the standards against which shortening performance was compared. The fatty acid composition and the structure of the principal triglyceride in lard are related to the properties of foods prepared with lard.

A feature of lard that distinguishes it from the vegetable oils and hydrogenated vegetable oils is the high level of triacylglycerols of the class with unsaturated fatty acids esterified to the 1- and 3-positions of glycerol and saturated fatty acids (principally palmitic acid) esterified to the 2-position. This dominant structure in lard triglycerides contrasts with those in vegetable oils, in which virtually all of the saturated fatty acids are on the 1- and 3-positions. It is of interest that this high level of palmitic acid in the 2-position of the triglyceride, although rare in natural fats, is also seen in human milk triglycerides (as discussed later in this chapter).

The melting range of lard is 91°F–115°F (33°C–46°C). Lard contains crystalline triacylglycerols at room and lower temperatures. The principal stable crystalline phase (or polymorph) of lard is the β-form, the most ordered and stable polymorph of triglyceride solid phases. β-Triglycerides are the highest melting of the phases. β-Phase triglycerides in lard and in shortening tend to grow readily to form large crystals within the liquid oil phase.

Although most solid triglycerides are stable in the highly ordered β-phase, some are stable in a lower melting β′-solid phase generally tend to form very small crystals. As discussed below, this limitation on crystalline size is important in the formulation of shelf-stable, homogeneous shortenings. In addition, the β′-phase fat crystals are preferred as the solid fat components in icings.

The stability of lard in the β-phase is the result of the high level of 2-palmitoyl triacylglycerols described above. It was found that the rearrangement of the fatty acids of lard to form a high level of triacylglycerol with essentially random positional distribution of fatty acids results in an improvement in melting behavior. Although rearrangement (interesterification) improves the performance of lard in some baking applications, this process is seldom used today, presumably because vegetable oil shortenings dominate this market segment.

Substitution of shortenings for lard came from the trend toward replacement of animal fats with vegetable fats over several decades. While the use of lard in foods in the United States declined from 1970 to 1995, shortening use increased from 17.3 to 22.5 lb/person per year during the same period (Putnam and Allshouse, 1997). This replacement presumably reflected the emphasis on nutrition

that directed consumers to select fats and vegetable oils without cholesterol and with minimal levels of saturated fatty acids. The recent increase in consumption of lard noted above may reflect concern about *trans* fatty acids in shortening.

The term *shortening* originates from the addition of fat to pastry dough to make it tender and flaky, or to "shorten" it. The principal objective for shortening formulation has therefore been to provide performance in baked goods. Shortenings used as ingredients in icing as well as baked products are called *all-purpose* shortenings. Shortenings used commercially and in households are also often used as frying fat. In addition to baking performance, the formulation of shortening has also been directed toward shelf stability and nutritional effects. The relationship of composition to these product requirements is discussed below.

Shortenings are mixtures of triacylglycerol components and phases that combine to provide the levels of solid and liquid fat that are appropriate for baking. Shortenings are predominantly liquid oil that is stabilized by a relatively low level of a crystalline fat matrix. The amount of solids in the shortening depends on temperature, and it decreases to zero at the complete melting point of all the components.

The solids content of the shortening has traditionally been measured by dilatometry. Dilatometry measures the volume of a mass of fat as a function of temperature. With the use of a predetermined calibration curve for the different changes in volume (density) for solid and liquid fats, the percentage of solid fat in a solid–liquid mixture can be determined. Dilatometry is a time-consuming procedure, and an alternative method has replaced it in many laboratories. This methodology is pulsed nuclear magnetic resonance, which makes use of the difference in relaxation times for hydrocarbon chains that are rapidly moving in the liquid phase or are relatively static in the solid (Madison and Hill, 1978).

The solids content of the shortening over a range of temperatures is an important determinant of the performance of a shortening in baking or in the preparation of icings and fillings. The shortening performance depends on the range in which it remains plastic, that is, between essentially completely liquid and a low-temperature hard form. At room temperature, the level of solids (solid fat index, SFI) typically ranges from 15% to 30%.

In consideration of the nutritional effects of shortenings, it is important to note that the principal component of vegetable shortenings is liquid oil. A relatively low level of triacylglycerol crystals dispersed in a liquid oil can result in a plastic mixture that appears solid. A common misconception is that this solid appearance reflects a composition of the shortening that is virtually entirely saturated fatty acids. In fact, commercial shortenings can be formulated with approximately equivalent levels of saturated and polyunsaturated fatty acids. The fatty acid composition of shortenings can vary considerably. For example, the composition of a current household shortening without *trans* fatty acids is 23% saturated fatty acids, 37% monounsaturated fatty acids, and 34% polyunsaturated fatty acids, and that of an industrial partially hydrogenated shortening is 19% saturated fatty acids, 31% *cis* monounsaturated fatty acids, 40% *trans* monounsaturated fatty acids, and 5% polyunsaturated fatty acids of which approximately half are *cis*, *cis* (Anonymous, 2005c). Not only is the level of crystalline solids in a shortening a requirement for its performance, but also the phase of its fat crystals may be more important. Solid components that crystallize in the β′-phase can be used in all-purpose shortenings that are used in baking and frying. The β′-crystal-based shortenings perform best in icings and in cakes.

β′-Crystals control the liquid triacylglycerol of a shortening for very long periods. This stability contrasts with that due to β-crystals, which grow, aggregate, and result in an inhomogeneous shortening that separates into liquid and solid regions, giving a "soupy" appearance. This distinguishing property of the β′-crystalline polymorph apparently results from the small needle-like crystals that form in this phase. These small crystals maximize the surface area for the adsorption of the liquid phase and minimize the separation of the oil and solid phases. β-Crystals, on the other hand, tend to grow in a crystal "ripening" process as small crystals dissolve and reprecipitate as contributors to the growth of larger crystals. β-Crystalline shortenings therefore may not be desirable as all-purpose shortenings that will be stored on shelves or used in preparations of icings or other creaming applications.

Most solid triacylglycerol fats will eventually crystallize in the β-polymorphic phase. The β-phase is highly ordered and is the highest melting triglyceride phase for most fats. An exception is the triacylglycerol 1,3-dipalmitoyl-2-stearoyl glycerol (PSP). The β′-phase of this triglyceride is its stable, equilibrium phase. Early shortening formulations included a high-melting fraction of cottonseed oil, which provided a significant level of PSP. Later shortenings used completely hydrogenated palm oil to provide the required amount of PSP to direct the solids of the shortening to the desired β′-crystals. The emphasis on the reduction of *trans* fatty acids has once again suggested the suitability of cottonseed oil in shortening and oils (O'Brien and Wakelyn, 2005). Shortenings currently available to consumers also include a fraction of triacylglycerol with an intermediate melting range that contributes to the β′-crystallization. The high-melting β′-phase constituent of a shortening typically has accounted for approximately 7% of the total composition.

Pourable fluid shortenings are also used by the food industry. These shortenings are suspensions of high-melting β-fat crystals in a continuous liquid oil phase. The crystals are formed by a variety of processing techniques to produce crystals of the right size to remain suspended and provide performance. The amount of undissolved, suspended solid fat in a pourable shortening may range from 2% to 10% of the total mixture.

An advantage to the pourable shortening is the convenience of measurement and transfer of the shortening in food preparation. Another approach to these properties is the use of powdered shortenings. Powdered shortenings are composed of the appropriate fat and an encapsulating material that is soluble in water. Encapsulating materials have included milk proteins and other added emulsifiers.

Emulsifiers can be added to shortenings by plasticizing them with the semisolid fat matrix. Monoacylglycerols (monoglycerides) or mixtures of monoacylglycerols and diacylglycerols (diglycerides) have been the most frequently used emulsifiers. The addition of emulsifiers contributes to the performance of the shortening in cake and icing products by stabilizing the mixture of the hydrophilic and lipophilic phases.

Some shortenings are used exclusively for frying. Based on the definition of a shortening, a "frying shortening" is an apparent contradiction in terms. Nevertheless, frying shortenings include a range of formulations from the solid–liquid mixtures described above to completely liquid oils. The totally liquid shortenings may not differ from cooking oils except in terminology.

IV. MARGARINES AND SPREADS

The standard of identity of margarine as defined by the Food and Drug Administration (FDA) requires a minimum of 80% fat. This requirement is part of the goal of providing the same nutrient levels contained in butter, for which margarine is considered to be a substitute. For this same reason, margarine must include at least 15,000 I.U. of vitamin A per pound. The remaining 20% of margarine consists of the aqueous phase and components that are compatible with the aqueous phase. Milk-derived proteins, emulsifiers, preservatives, and coloring agents are included.

The emphasis on the nutritional properties of fat-based foods has also encouraged the use of bread spreads that are substitutes for margarine, which is required to contain 80% fat. Spreads are typically formulated with 55%–60% fat by substituting water and emulsifiers for triacylglycerols. The appearance and packaging of these spreads are similar to those of margarine. The high level of water in spreads does, however, alter their performance in cooking and melted applications. They generally cannot be substituted in baking and perform poorly in frying.

Further efforts to develop low-fat spreads continue with various means of stabilizing the water phase of the spread and providing the lubricity of the higher fat spreads and margarines. Gelatin and other proteins have been used in combination with fat, water, and emulsifiers. Spreads with as little as 20% fat have been introduced to the market.

In terms of consumer usage, margarine (and spread) usage remained relatively constant from 1970 to 1995, ranging from 10.3 to 11.9 lb/person per year (Putnam and Allshouse, 1997). Prior to that period,

margarine had replaced a significant portion of butter usage, which declined from 5.4 to 4.5 lb/person per year from 1970 to 1995 (Putnam and Allshouse, 1997). In 1995, margarine per capita consumption was estimated to be 9.2 lb/person per year (Putnam and Allshouse, 1997). Although cost certainly has an influence, the emphasis on the elimination of animal fats, saturated fats, and cholesterol from the diet undoubtedly contributed to the use of margarine in place of butter. Since 1995, there has been a marked decrease in per capita consumption of margarine and spreads, falling one-third to 6.2 lb/person per year (Anonymous, 2005b). It would seem reasonable to attribute this decline to consumer concerns about solid and *trans* fats, and margarine and spreads are readily recognized visible fats.

Margarines are emulsions with an oil continuous phase. The high ratio of oil to water, the emulsification system, and the processing produce a dispersion of water droplets in the oil, a water-in-oil emulsion. Because of the high level of fat and the presence of relatively high-melting fats, margarine is used frequently as a shortening in baking. Frying with margarine is limited to low temperatures because of the rapid darkening of the protein constituents.

The fatty acid composition of the triacylglycerols in margarine and spreads varies greatly from product to product. Oils that have been hydrogenated to varying degrees have been used in virtually every product. The saturated and *trans* unsaturated fatty acids produced by hydrogenation provide texture and melting behavior appropriate for the product. The melting range, solids content, and emulsion properties can be controlled by the hydrogenation process.

As with other fat-based products, nutritional concerns have directed the formulation of margarines and spreads and the selection of triacylglycerols that are their principal components. Efforts have been made to reduce total saturated fatty acid levels and increase unsaturated fatty acids. Margarines and spreads with greatly reduced or essentially zero levels of *trans* fatty acids have also been developed and are marketed (Berger and Idris, 2005; List et al., 1995). One spread, "Smart Balance," is reported to have 0.71 g *trans* acids per 100 g, compared with 19 g in some other spreads (Anonymous, 2005c).

The structure and physical form of the margarine product are determined by the physical properties of the triacylglycerol component. Margarine produced as traditional "sticks" requires a relatively high-melting triacylglycerol to allow the molded product to retain its shape. As a result, most stick margarines have somewhat higher levels of high-melting fatty acids (including saturated and *trans* unsaturated acids) than margarines sold in tubs (Slover et al., 1985). These margarines do not require this rigidity and can be produced with lower levels of the high-melting fatty acids. Liquid margarines with fatty acid compositions in the range of the lowest saturate and highest unsaturate are also on the market (Reeves and Weirauch, 1979; Anonymous, 2005c).

V. TRIACYLGLYCEROL SUBSTITUTES

Dietary fats and oils provide functional properties to foods, and they also provide the hedonic properties of desirable texture and lubricity. The high-caloric density of fats (at 9 kcal/g, more than twice that of carbohydrates and proteins) is a benefit in situations where food is scarce. However, high-caloric density is associated with health risks when caloric intake is in excess of energy expenditure. It seems reasonable that there is a link between the hedonic properties and the caloric density of triacylglycerols. In the early development of *Homo sapiens*, individuals who consumed fat when available presumably had a survival advantage through the storage energy in adipose tissue for availability of energy during lean times.

With modern agriculture, however, food has become readily available for much of the population in many societies. However, this development over the several decades has not had an effect on the feeding-satiety signal system that developed over millennia to deal with periods of food scarcity. As a result, much of the population has responded with a positive energy balance and the gain of excess body weight and fat. This excess energy storage that can provide a benefit in times of famine has instead resulted in detrimental effects on health. There have been numerous reports that relate excess body fat to the risk of heart disease, diabetes, and joint problems.

Given the high-caloric density of fat, it has become a frequent target for nutritional recommendations designed to optimize health. However, recommendations to reduce dietary fat intake run headlong into its hedonic property, which is an often insurmountable driving force for excessive fat consumption even in the light of nutritional advice.

Several approaches have arisen to address this conflict between the desirable hedonic properties and undesirable caloric density of dietary triacylglycerols. Discussed below are three of these approaches: olestra, diacylglycerol oils, and "structured" lipids.

A. Olestra

Olestra is the generic name given to the class of compounds made by the interesterification of sucrose with fatty acid methyl esters to yield sucrose with 6–8 long-chain fatty acids bonded by ester links (Figure 18.1). The synthesis is a base catalyzed reaction that requires initial steps to provide miscibility of the hydrophilic and lipophilic reactants. The reaction is driven with an excess of the fatty acid methyl esters.

Olestra has two important characteristics that have driven its entry into the edible fat market. First, its physical and organoleptic properties are essentially identical to those of triacylglycerol fats with the same fatty acid composition. For example, olestra made from soybean oil fatty acid methyl esters has a melting point and an oil–water interfacial tension that is similar to soybean oil. The viscosity of this olestra is slightly higher than that of soybean oil, presumably because of the size of the molecule.

The second and equally important characteristic of olestra is its inertness in the presence of pancreatic lipase. Unlike triacylglycerols, which are readily hydrolyzed by the action of pancreatic lipase at the oil–water interface in the intestine, olestra remains intact during gastrointestinal transit. It is of interest that studies performed during the early development of olestra clearly demonstrated that lipase-catalyzed hydrolysis of fats is obligatory for the absorption of dietary fat, thereby putting to rest a controversy about whether or not triacylglycerol oil droplets might be absorbed without digestion (Mattson and Nolen, 1972a; Mattson and Volpenhein, 1972b). This understanding about the requirement of hydrolysis explains why this second characteristic of resistance to hydrolysis is important. It was also established that ingested olestra, because it is not hydrolyzed, is excreted intact and therefore does not provide energy that can be used by the body. The studies that led to this understanding have been reviewed previously (Jandacek, 1991).

Although olestra is not hydrolyzed by pancreatic enzymes, it is metabolized by microorganisms in activated sludge (Lee and Ventullo, 1996). It is therefore degraded in municipal sewage treatment facilities.

The combination of organoleptic desirability with the absence of absorption resulted in this "zero calorie" fat with texture, mouth feel, and cooking properties of normal triacylglycerol fats. Olestra became the subject of a food additive petition to the U.S. FDA, and it was approved for use in the commercial preparation of savory snacks in January 1996.

The physical and hedonic properties of olestra are essentially identical to those of triacylglycerol fats with the same fatty acid composition. Its behavior as a frying fat is also similar to that of triacylglycerol fats. Olestra therefore meets both the biological and the physical requirements of a fat

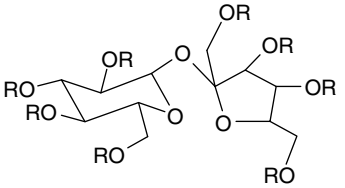

FIGURE 18.1 Olestra is the mixture of long-chain fatty acid esters of sucrose, with 6–8 ester bonds.

substitute. It does not provide calories that the body can use, and it provides the lubricity and texture of triacylglycerol fats.

The selection of the fatty acids that are used in the preparation of olestra was the result of a balance of two considerations. First, olestra that is used in food preparation must provide a desirable nonwaxy mouth feel. Second, olestra that enters the large intestine must not readily separate from fecal matter during gastrointestinal transit. These two requirements led to a blend of olestra made from soybean oil fatty acids along with olestra made with the high-melting fatty acid, behenic (docosanoic) acid. This blend evolved to provide satisfactory hedonic properties and to minimize the separation of oil in the large intestine that can cause undesirable gastrointestinal effects (Jandacek et al., 1999).

The approval of olestra required that a label informing the consumer about the potential for gastrointestinal effects be printed on packages of snack foods made with olestra. As of August, 2003, the FDA decided that this label requirement was unnecessary based on the commercial consumer experience with the products containing olestra.

Because olestra provides the small intestine with a lipid "sink" that can dissolve lipophilic substances, it interferes with the absorption of lipophilic compounds. Cholesterol, chlorinated hydrocarbon pollutants, and fat-soluble vitamins are affected in this manner, and their absorption from the intestine is reduced. The approval of olestra therefore required that the fat-soluble vitamins, A, D, E, and K, are supplemented with the olestra to compensate for the reduction in their absorption.

B. Diacylglycerols

Another fatty acid-based substitute for dietary triacylglycerol fat has been successfully marketed in Japan for several years and is currently being introduced as an edible oil product in the United States. The development of this substitute, 1,3-diacylglycerol (DAG), was based on the understanding of the digestion/absorption of typical triacylglycerol fats. As noted above, triacylglycerol digestion and absorption requires the lipase-catalyzed hydrolysis of emulsified fat droplets in the intestine to give fatty acids and 2-monoacylglycerols. The reesterification of these fatty acids and 2-monoacylglycerol then takes place in the enterocyte, the newly synthesized triacylglycerol is packaged into lipid-rich chylomicron particles that are transported in lymph.

Important to the rationale for the benefit of DAG is the transport of fat in chylomicrons to peripheral tissues after their entry into the blood circulation from the lymphatic circulation. A significant portion of recently absorbed dietary fat is thereby delivered to peripheral tissues prior to entry into the liver.

The digestion, absorption, and distribution of DAG can differ from that of triacylglycerols. Dietary DAG can be hydrolyzed by pancreatic lipase in the manner in which triacylglycerols are hydrolyzed, with splitting of ester links of the primary alcohol groups of glycerol. With DAG, the resulting products are fatty acids and glycerol (Figure 18.2). The rationale for the benefit of DAG is that the resynthesis of fatty acids and glycerol into triacylglycerol is inefficient in the enterocyte due to the absence of 2-monoacylglycerol. This inefficiency may then result in a portion of the fatty acids being absorbed via the portal vein rather than in chylomicrons, in the manner in which medium-chain fatty acids are absorbed.

This redirection of fatty acid absorption to the portal vein is reported to have benefits based on the liver's ability to metabolize the fatty acid prior to its storage in adipose tissue (Nagao et al., 2000). This hepatic metabolism is reported to reduce the deposition of fat in the visceral adipose tissue, with a resulting reduction in the risk to health associated with excess visceral fat accumulation.

Investigators comparing the effects of dietary triacylglycerol and DAG on visceral fat loss in humans in caloric deficit reported greater loss of visceral fat in the DAG group after weeks. A 12-month clinical trial comparing triacylglycerol and DAG in a reduced energy diet resulted in a 3.6% weight loss in the DAG group compared with 2.5% in the triacylglycerol control group (Maki et al., 2002). Fat mass decreases were 8.3% and 5.6% for the DAG and triacylglycerol groups, respectively. Clinical trials and metabolic studies of DAG were recently reviewed (Rudkowska et al., 2005).

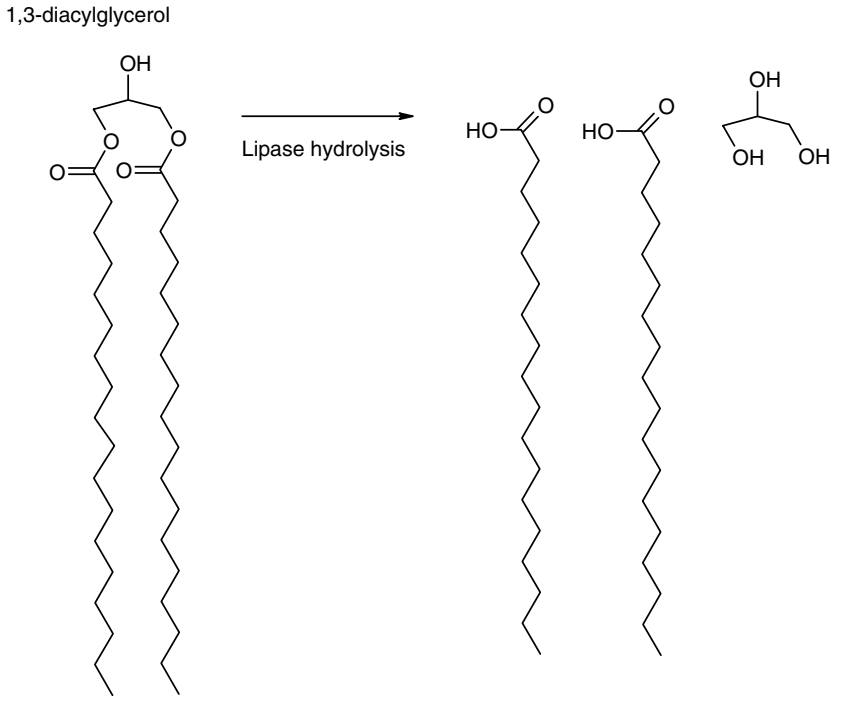

FIGURE 18.2 The lipase catalyzed hydrolysis of 1,3-diacylglycerols results in free fatty acids and glycerol.

The DAG is synthesized by enzymatic direction of fatty acids to the 1- and 3-positions of glycerol. The resulting oil contains <20% triacylglycerol and 80% diacylglycerol. The ratio of 1,3-diacylglycerol to 1,2-diacylglycerol is 7:3 (Watanabe et al., 2004). Because diacylglycerols melt at higher temperatures than triacylglycerols with the same fatty acid composition, the marketed DAG contains very low levels of saturated fatty acids to minimize crystallization of the oil. The flashpoint of DAG is 30°C–40°C lower than that of analogous triacylglycerols (Nakajima et al., 2004).

DAG has been commercially successful in Japan, with sales of 28 billion yen announced by Kao for 2003. These sales reflect the markedly higher price of DAG relative to typical triacylglycerol cooking/salad oil. As noted above, the marketing of DAG is in an early stage in the United States.

C. Triacylglycerols with Specific Structures

a. Medium-Chain Triacylglycerols and Structured Lipids

As discussed above, essentially all dietary fat is in the form of long-chain triacylglycerols. The metabolism of these triacylglycerols follows a sequence of hydrolytic, absorption, and resynthesis steps. Gastric lipase acts in the stomach to remove a fatty acid from some triacylglycerol molecules to form the 1,2-diacylglycerol. A mixture of triacylglycerol and diacylglycerol then enters the duodenum where it is emulsified by bile acids and phospholipid to form small droplets with a large oil–water interfacial surface. Pancreatic lipase/colipase acts at the interface to hydrolyze fatty acids in the 1- and 3-positions of the triacylglycerol to yield free fatty acids and 2-monoacylglycerols. These relatively polar products are transported to the enterocyte membrane via mixed micelles containing bile salts. In the enterocyte, the fatty acid and 2-monoacylglycerol are synthesized into triacylglycerol and packaged with apolipoproteins into chylomicrons for transport into the lymph.

This process is dependent on the chain length of the fatty acids. When the chain length is less than 12 carbon atoms, the lipase-catalyzed hydrolysis is more rapid than that seen for fatty acids

with longer chain length. In addition, it is clear that hexanoic, octanoic, and decanoic acids are primarily transported via the portal vein rather than in chylomicrons in lymph. Dodecanoic acid (lauric acid) can be transported both in lymph and in the portal vein blood.

Absorption in chylomicrons results in fatty acids being delivered to peripheral tissues after hydrolysis of triacylglycerol by lipoprotein lipase. Fatty acids absorbed via the portal vein encounter the liver and its metabolic processes during the first pass, before delivery to peripheral tissues. These fatty acids can therefore be oxidized before delivery to peripheral tissues.

The digestion process of triacylglycerols containing primarily hexanoic, octanoic, and decanoic acids has provided a means to provide dietary lipid to patients with insufficient pancreatic lipase secretion resulting from cystic fibrosis and other disorders. Triacylglycerols have been synthesized from hexanoic, octanoic, and decanoic acids and have been termed medium-chain triacylglycerols (MCT). These fatty acids are available from coconut oil, in which they account for approximately 12% of the total fatty acids. They are available as by-products when the coconut oil is used as a source for dodecanoic acid for industrial uses in surfactant synthesis and other products.

MCT oil was originally produced as a dietary fat for patients who were unable to digest and absorb long-chain triacylglycerol fat. It is still used for this purpose, however, it is well recognized that MCT oil does not provide essential fatty acids that are necessary for health (linoleic acid, α-linolenic acid). MCT oil has more recently been marketed as a health-oriented oil because of its metabolic pathway. Its postprandial metabolism in the liver has been reported to increase dietary thermogenesis relative to long-chain triacylglycerols. This effect suggests that MCT will result in less deposition of dietary fat into peripheral tissues, including adipose tissue, and thereby may provide a benefit to those seeking to reduce body fat. It may also be noted that the caloric content of MCT is approximately 10% less than that of the 9 kcal/g typical of long-chain fats.

The use of MCT in cooking is possible, however, it is recognized that the low molecular weight of the triacylglycerol and its fatty acids results in a flash point that is lower than that of long-chain fats. Frying with MCT oil therefore is a safety concern.

The absence of essential fatty acids in MCT has been addressed by the production of triacylglycerols made from blends of medium-chain fatty acids and long-chain fatty acids. These triacylglycerols may be made by transesterification reactions to yield a random positional distribution of fatty acids on the glycerol, so that medium-chain fatty acids are esterified both in the 2- and in the 1(3)-positions. They may also be made by enzymatic processes or by positionally selective synthesis to give triacylglycerols with medium-chain fatty acids predominantly in the 1(3)-positions. Both the random and the positionally selective mixed chain length triacylglycerols have been termed "structured lipids" (Figure 18.3). The properties of MCT and structured lipids were reviewed by Babayan, who was responsible for much of their development (Babayan, 1987).

Structured lipids can provide some benefits. For example, it has been shown that triacylglycerols with octanoic acid in the 1- and 3-positions are hydrolyzed as rapidly as trioctanoin. This observation indicates that it is possible to provide long-chain essential fatty acids in the 2-position of the triacylglycerol and still allow digestive hydrolysis to occur even in cases of low levels of pancreatic lipase.

It has also been reported that structured lipids may have advantages in fat-containing formulas that provide energy in intravenous feeding (Bellatone et al., 1999; Rubin et al., 2000). This effect may result from optimizing the rate of hydrolysis of intravenously administered fat, so that peripheral tissues may readily utilize the fat component of the diet.

Subsets of the class of structured lipids were developed to offer reduced calorie fats as substitutes for long-chain triacylglycerol fats. Two fats, salatrim and caprenin, resulted from an approach to reduce the utilizable caloric density of fats by synthesis of a triacylglycerol with a composition that included a poorly absorbed long-chain fatty acid along with short- or medium-chain fatty acids. The fatty acids of salatrim included stearic acid and short-chain fatty acids that included acetic,

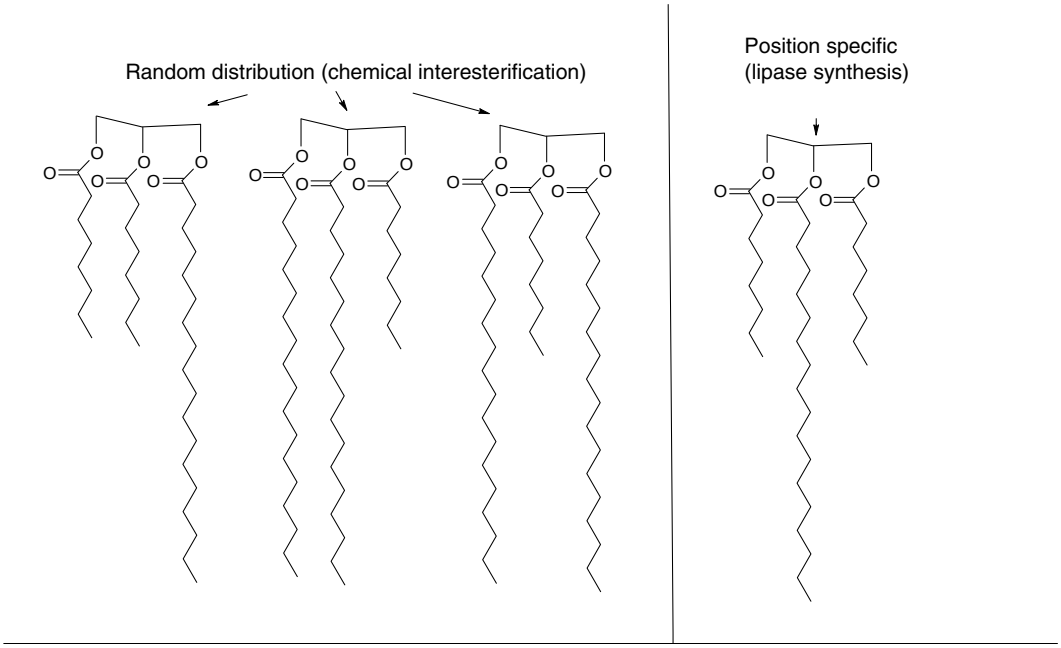

FIGURE 18.3 Structured lipids are triacylglycerols that include both medium- and long-chain fatty acids. They may be of random (chemical interesterification) or specific (lipase directed) structures.

propionic, and butyric acids. The fatty acid composition of caprenin comprised behenic acid (docosanoic acid) with medium-chain fatty acids including hexanoic, octanoic, and decanoic acids. Selected ratios of the long-chain to short/medium-chain acids resulted in fats with appropriate food qualities. The lipase-catalyzed hydrolysis of these fats in the intestine produced readily absorbed short- and medium-chain fatty acids (and/or monoacylglycerols) that are readily absorbed from the intestine. This hydrolysis also yielded the long-chain, saturated fatty acids, stearic acid (from salatrim), and behenic acid (from caprenin). These fatty acids are poorly absorbed from the intestine, so that salatrim and caprenin provide less than 9 kcal/g of energy. At the time of this writing, caprenin is not marketed, and salatrim is sold as Benefat®.

b. Human Milk Fat Mimic

Human milk fat is relatively unique in nature. It provides a relatively large amount of palmitic acid in the 2-position of the triacylglycerol. This positional specificity contributes to two nutritional benefits, improved fat absorption and improved calcium absorption (Kennedy et al., 1999). These benefits result because of the preferential production of 2-monopalmitin relative to palmitic acid during the digestion of the triacylglycerol. Since free palmitic acid can precipitate as the calcium soap in the intestine, the absorption of both the fatty acid and calcium are reduced. The 2-monopalmitin, however, does not precipitate as the calcium soap, and both the calcium and the fatty acid of the monoacylglycerol are available for absorption. Fat that is produced by enzymatic interestification for use in infant formulas has been included in European infant formulas, and its Generally Recognized as Safe (GRAS) approval in the United States was granted in 2004. It contains approximately 20% palmitic acid, of which approximately half is in the 2-position. The specificity of fatty acid position in this fat seems to make it more appropriately termed as a structured lipid than the random structures of mixed medium- and long-chain fatty acid triacylglycerols.

VI. FUNCTIONAL FATTY ACID DERIVATIVES

In terms of mass consumption of foods containing fatty acids, triacylglycerols as vegetable oils and animal fat account for essentially all of human consumption. The substitutes for triacylglycerols replace a small fraction of dietary vegetable oils and animal fats.

There are, however, food additives that are derivatives of fatty acids that provide important functions as minor components of foods. The functions of these derivatives may be categorized as physical and biological (health oriented) as presented in the discussion below.

A. Fatty Acid Derivatives Providing Textural Benefits

The lipophilic carbon chain and the functional carboxyl head group of fatty acids have allowed them to be combined with hydrophilic moieties via ester links to give compounds with surface active properties. The combination of hydrophilic compounds that are normally found in foods in combination with edible fatty acids has resulted in a variety of compounds that are safe food emulsifiers.

Although emulsifiers are added to most foods in trace quantities, their use is widespread. The market projected for fatty acid-based emulsifiers was 280 million pounds in the United States in 1995 (Dziezak,1988) and worldwide was estimated to be 660–880 million pound tons per year according to the report of a presentation at the 2005 International Palm Oil Congress.

Virtually all emulsifiers that are added to foods or are intrinsic to foods include one or more fatty acids as part of the emulsifier molecule. Emulsifiers are surface-active molecules with affinity for both a polar (aqueous) and a nonpolar (oil) phase. The hydrocarbon chain of the fatty acid provides the lipophilic portion of food emulsifiers, whereas the hydrophilic portion may be one of a wide range of polar groups including anionic (e.g., carboxylate), nonionic (e.g., ethoxylate groups), or zwitterionic (as in lecithin). An example of an emulsifier frequently used in foods is a monoglyceride. The two hydroxyl groups of glycerol are compatible with an aqueous phase, whereas the hydrocarbon chain of the fatty acid will dissolve in an oil phase.

The principal function of emulsifiers in foods is to stabilize oil–aqueous mixtures. In addition, emulsifiers stabilize aerated systems and foams, form a complex with starch in foods, and modify the crystal and polymorphic formation of high-melting fats.

The hydrophilic/lipophilic balance (HLB) value of an emulsifier is a measure of its relative affinity for the hydrophilic and lipophilic phases. The HLB ranges from 1 to 20, with a value of 20 indicating the maximum in affinity for hydrophilic materials. Commercial preparations of monoglycerides are usually mixtures of monoglycerides and diglycerides, with the HLB increasing as the concentration of monoglycerides increases. The HLB values for mono- and diglyceride emulsifiers are generally in the range 2.8–3.5. The HLB can be useful in screening emulsifiers for particular functions, although difficulties are encountered in its application (Graciaa et al., 1989).

As a surface-active agent, an emulsifier will adsorb and concentrate at oil–water, water–air, or oil–air interfaces and will reduce the interfacial tensions at these interfaces. Perhaps the most important role of food emulsifiers is the stabilization of emulsion particles. Thus, milk, ice cream, butter, margarine, cake batter, and many other foods are stable emulsions that resist phase separation because of the presence of emulsifiers.

In addition to the most recognized function of emulsion stabilization, food emulsifiers provide other benefits in food formulation. They can interact with hydrophilic food components such as the amylose in starch to prevent staling through retrogradation, the alignment of amylopectin molecules. Emulsifiers bind to wheat gluten in dough to produce a more elastic substance than that made without emulsifiers. The fatty acid component of emulsifiers can be incorporated into the array of fatty acids in triglyceride crystals and alter the polymorphic behavior of the pure triglyceride. As part of their emulsification functions, food emulsifiers also stabilize foams in aerated emulsions.

A compilation of fatty-acid-based emulsifiers is given in Table 18.2. Representative molecular structures and the principal uses of commercially important emulsifiers are also presented in that table.

TABLE 18.2
The Structure of the Hydrophilic Groups of Food Emulsifiers (Esterified with One or More Fatty Acids)

	Hydrophilic Group	Emulsifier	Use
Lactic acid		Stearoyl lactate	Dough conditioning
Propylene glycol		Propylene glycol monoesters; PGMs	Cake mixes
Lecithin	 R=  Lecithin  Phosphatidyl ethanloamine  Phosphatidyl inositol	"Lecithin," a mixture of phosphatides, principally lecithin, but containing phosphatidyl ethanolamine, and phosphaditYl inositol	Chocolate confectionery coatings
Sorbitan		Sorbitan esters	Confectionery coatings, fat-crystallization modifier
Ethoxylated sorbitan	 	Ethoxylated sorbitan esters; polysorbates	Dough conditioning, cakes, and icings
Sucrose		Sucrose mono-, di-, and triesters; sucroesters	Dough conditioning; emulsification

Continued

TABLE 18.2 (Continued)

	Hydrophilic Group	Emulsifier	Use
Polyglycerol		Polyglycerol esters	Whipping agents, icings, emulsification
Glycerol		Mono- and diglycerides; GMO	Shortening, icing, bread dough, margarine
Ethoxylated glycerol		Ethoxylated monoglycerides	Dough crumb softening
Acetylated glycerol		Acetylated monoglycerides	Food coatings
Lactylated glycerol		Lactylated monoglycerides	Shortening, cake mixes

Although emulsifiers account for only a small percentage of the total use of fatty acid derivatives in foods, their importance is more than that reflected by this small amount. A large number of processed foods include fatty-acid-based emulsifiers as components that are necessary to the texture and stability of the food. In addition, the emulsifiers that occur naturally in foods, such as the phospholipids in milk products and in eggs, give these foods many of the desirable characteristics that are associated with them.

B. Fatty Acid Derivatives Providing Metabolic Benefits

a. Plant Sterols

The current understanding of the relationship of elevated blood cholesterol levels to the risk of the development of atherosclerosis has resulted in increased emphasis on the development of food products that reduce blood cholesterol concentration. The commercialization of plant sterols in foods is an example of this focus.

It has been known for many years that ingested plant sterols can reduce blood cholesterol concentration. Cytellin®, a suspension of plant sterols, was marketed as a cholesterol-reducing pharmaceutical in the 1950s–1980s. This early use of plant sterols was in a prescription drug, in contrast with currently marketed foods discussed here.

Plant sterols are very similar in chemical structure to cholesterol. They are found in vegetable oils, but not in animal fats. Presumably because of their structural similarity to cholesterol, they compete with cholesterol for micellar solubilization in mixed bile salt micelles in the lumen of the small intestine. If ingested in sufficient quantity, this competition reduces the absorption of cholesterol from the intestine. This reduction in the absorption of dietary and biliary cholesterol can result in reduced levels of circulating LDL cholesterol.

Another very important characteristic of plant sterols is the well-known fact that they are sparingly absorbed from the intestine. In spite of their similarity to cholesterol, their absorption of 0%–5% is markedly less than that of cholesterol, which is generally absorbed in the range of 40%–60% of that ingested. An explanation for this phenomenon has recently emerged with the identification of intestinal transport proteins, ABCG5 and ABCG8, which normally exclude plant sterols from systemic absorption (Hubacek et al., 2001).

A practical problem that has limited the commercialization of plant sterols in drugs and foods is their relative insolubility in edible oils. Cytellin® was a suspension (not a solution) of crystalline plant sterols that was unappealing to many patients. Although plant sterols are consumed in vegetable oils as natural constituents of the oils, their solubility is limited to 1%–2% of the oil. In addition, the presence of water in an oil solution of plant sterols results in precipitation of the crystalline sterols as hydrates that are less soluble than the anhydrous sterols (Jandacek et al., 1977).

A solution to this solubility problem was disclosed by Erickson (1973). He found that plant sterols esterified with oleic acid were markedly more soluble than the free sterols, and that the presence of water did not cause precipitation of the sterol esters. The absence of the free hydroxyl reduces the interaction of at the oil–water interface (Figure 18.4).

Mattson found that plant sterol esters reduced dietary cholesterol absorption in the manner of the free sterols (Mattson et al., 1982). The observation that dietary plant sterols are efficacious in preventing cholesterol absorption is consistent with their hydrolysis to free sterol and fatty acid

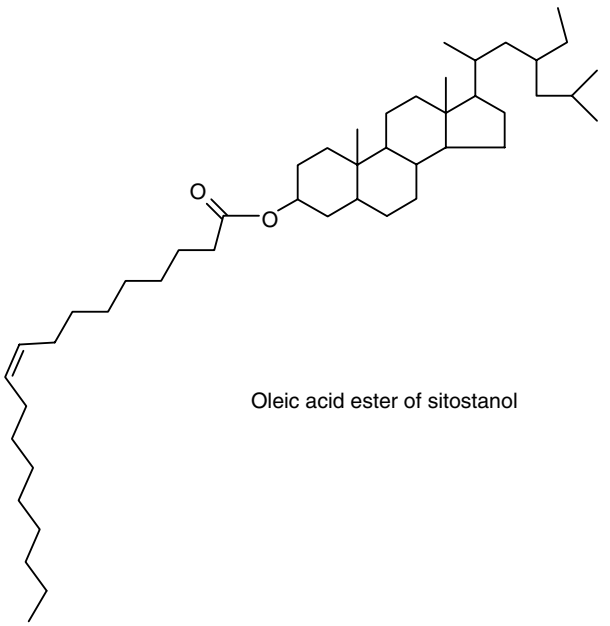

FIGURE 18.4 Sitostanyl oleate, a plant sterol ester, used in margarine and other foods.

in the intestinal lumen, presumably by cholesterol ester hydrolase. The free sterol product is then available for competition with cholesterol in micelles that are necessary for transport and absorption of cholesterol. Consumption of 3.6 g/day of plant sterol esters reduced LDL cholesterol by 9.7% without changing HDL cholesterol relative to a control diet (Judd et al., 2002).

The modification of plant sterols by low-melting fatty acids allows them to be dissolved in edible oils. Vegetable oils with dissolved plant sterol esters are now used in the production of spreads with normal taste and texture. These spreads provide a palatable means for the ingestion of plant sterols by consumers with little or no change in their normal dietary lifestyle.

b. Conjugated Linoleic Acid

Although conjugated linoleic acid (CLA) is a minor component of fatty acids sold and consumed in foods, it has been the subject of numerous studies because of its potentially impactful metabolic properties. CLA is a mixture of octadecadienoic fatty acids, with double bonds at carbons 9 and 11 or at carbons 10 and 12. CLA includes the *cis*,*cis*; *cis*,*trans*; *trans*,*cis*; and *trans*,*trans* isomers of these fatty acids. Biological studies have focused not only on the mixtures of CLA isomers but also on specific isomers. CLA is currently marketed as a free fatty acid provided in gelatin capsules.

Early studies of CLA indicated a protective effect against tumorigenesis in experimental animals (Ha et al., 1987). This observation stimulated numerous investigations into the properties of CLA, and it was found that mice eating CLA gained markedly less weight and fat than control animals that did not eat CLA (Park et al., 1997). On the basis of subsequent studies, it appears that the effect of CLA on weight and fat may be species dependent (Park et al., 2005). Other studies continue to address the differences in the metabolic effects of the CLA isomers (Macarulla et al., 2005; Valeille et al., 2005).

Trials of CLA that address its effects on body weight have generated mixed results (Gaullier et al., 2005; Larsen et al., 2006). Tricon et al. (2005) have reviewed studies of CLA and its specific isomers in humans.

c. Fatty Acids from Single Cell Organisms

Recognition that long-chain polyunsaturated fatty acids provide metabolic benefits has given rise to the production of specific fatty acids by single cell organisms. The principal focus of this production has been on arachidonic acid (ARA, 20:4, ω-6), and DHA (22:6, ω-3). These fatty acids are known to be necessary for the healthy development of infants, and infant formulas now include them. Single cell organisms, such as the dinoflagellates, can produce lipids highly enriched in these fatty acids in a controlled setting that minimizes impurities (Kyle, 1997; Kyle, et al., 1995). These sources also provide long-chain polyunsaturated fatty acids for dietary supplements for purposes other than supplementation of infant formula.

VII. OVERVIEW

This review of the commercial applications of fatty acids in foods illustrates the many roles of fatty acid-based compounds in our diets. Fats provide calories, taste, texture, and both good and bad metabolic effects. Their production is absolutely essential to providing energy and health to a world population that continues to grow. New understanding continues to generate changes in production, processing, and seed compositions. It is clear that these processes will continue to evolve with the sciences of agriculture, health, and nutrition.

19 Effects of Processing and Storage on Fatty Acids in Edible Oils

Vickie Tatum and Ching Kuang Chow

CONTENTS

I. INTRODUCTION

The goal of commercial oil or fat processing is to obtain the maximum possible yield of oil or fat from the oil-bearing material while maintaining high quality and nutritive value eliminating undesirable impurities, and retaining desirable components (e.g., tocopherols) that may be present (Carr, 1989). The finished product normally consists of 98%–99% triacylglycerols and is odorless, bland, and oxidatively stable (Carr, 1989; Jung et al., 1989).

Crude oils contain naturally occurring compounds such as gums, phospholipids, pigments, color bodies, tocopherols, and free fatty acids (Brekke, 1980a; Pryde, 1980). Crude oils also contain compounds and contaminants formed or introduced during processing such as soaps, hydroperoxides and their breakdown products, hydrogenation catalysts, bleaching clays, moisture, and trace metals (List and Erickson, 1980). Many of these compounds are responsible for the development of undesirable odors, flavors, and colors in the oil; therefore, most steps of processing are carried out to remove these unwanted contaminants.

Some steps of processing are carried out to modify the physical characteristics of the oil or fat for specific applications. Hydrogenation, for example, raises the melting point of fats and oils and affects their plasticity, spreadability, and hardness (Grothues, 1985). This allows oils that are normally liquid to be utilized in solid products such as margarine (Latondress, 1985). However, processing may also induce or promote undesirable changes in the oil. Fats and oils contain essential nutrients such as tocopherols and linoleic acid. Some processing steps reduce the nutritive value of the oil or fat by removing or chemically altering these components. For example, although the naturally occurring *cis*-form of linoleic acid is an essential fatty acid, its *trans*-isomers, which may be formed during processing, have no essential quality and may in fact be harmful (Grothues, 1985; Chow, 1989). In addition, tocopherols are lost at several stages of processing most notably deodorization (Jung et al., 1989).

The most frequently occurring cause of oil quality deterioration during processing and storage is autoxidation (Patterson, 1989). The breakdown products of the autoxidation of unsaturated fatty acids are the major source of off-flavors and odors in the oil (Patterson, 1989). The second most frequent cause of deterioration of fats and oils is hydrolysis, which occurs when a triglyceride reacts with water and the fatty acids are split off from the glyceride backbone (Patterson, 1989). Hydrolysis reduces the final yield of finished product as well as increasing the susceptibility to oxidation.

II. EFFECTS OF PROCESSING ON FATTY ACIDS

Refined oils are usually bland in flavor, more stable to oxidation, and can be stored for extended time period. Fatty acids are affected during refining process in a variety of ways, both direct and indirect. Refining, for example, directly affects the fatty acid content of fats and oils by removing phospholipids, diglycerides and monoglycerides, and free fatty acids that may be present. Hydrogenation, a method of reducing the degree of fatty acid unsaturation, is the primary processing step in which the fatty acid composition of oil and fat is intentionally directly altered. Fatty acid composition may also be affected by processing in an indirect manner. Numerous impurities present in crude oil can act to initiate and/or enhance autoxidation and photooxidation of unsaturated fatty acids or cause hydrolysis of triglycerides. An important goal of oil processing is to remove these impurities, thus preventing undesirable changes in fatty acid content or character.

Table 19.1 lists the major steps involved in the processing of edible oil and the undesirable changes that may be caused by each step. The various stages of processing are briefly described in the following section, with particular emphasis on the ways in which they affect fatty acids.

TABLE 19.1
Steps in Processing of Edible Oils and Fats

Processing Step	Purpose	Side Effects
Seed selection; cleaning	Select nature undamaged seeds; remove dirt, rocks, wood, and scrap iron	—[a]
Drying	Remove moisture	Autoxidation
Dehulling	Remove outer seed coats to facilitate processing	Hydrolysis, autoxidation
Cooking	Inactivate lipoxidase and hydrolytic enzymes, kill molds and bacteria	Autoxidation
Extraction	Separation oil from the oil-bearing material	—[a]
Miscella stripping	Separate oil from solvent and fines	Autoxidation
Degumming	Remove phosphatides and iron	Hydrolysis, isomerization
Caustic refining	Remove free fatty acids, phosphatides, and unsaponifiable material	Autoxidation
Bleaching	Remove pigments, metals, soaps, and oxidation products	Hydrolysis, isomerization, autoxidation
Physical refining	Remove free fatty acids, aldehydes, ketones, and other volatile oxidation products	Hydrolysis, loss of tocopherols
Hydrogenation	Modify physical characteristics and improve oxidative stability	Isomerization, loss of essential fatty acids
Deodorization	Remove free fatty acids, aldehydes, ketones, and other volatile oxidation products	Hydrolysis, loss of tocopherols

[a] Little or no effect.

A. Oilseed Processing

a. Seed Selection and Cleaning

Seeds that are sprouted, immature, or damaged physically or by heat are usually not satisfactory for oil production because oxidative and hydrolytic processes have probably already begun to damage the oil (Becker, 1978; Adhikari et al., 1992). After seeds have been selected for processing, they must be cleaned of dust, chaff, rocks, scrap iron, wood, and so on (Becker, 1978; Carr, 1989).

b. Drying and Storage of Raw Materials

Because moisture promotes deterioration of oils, it is important to reduce oilseed moisture content before storage and keep dry during storage (Becker, 1978; Carr, 1989). Otherwise, both oxidative and hydrolytic damage to the old may occur. Pretreatment of oil seeds affects oxidative stability. For example, crude oil obtained from roasted plus microwaved, or roasted plus steamed sesame seeds has higher oxidative stability than from steamed or roasted seeds (Abou-Gharbia et al., 2000). Moreover, different processing treatments show considerable effects on lipid fractions, and the influence on all components after roasting plus steaming is more pronounced than microwave treatment.

c. Dehulling and Grinding, Rolling, or Flaking

The outer seed coats of some seeds may have to be removed, because they interfere with the next processing step, which is to grind, roll, or flake the seeds or beans in order to rupture oil cells and increase surface area (Carr, 1989). Once this has been done, the oil should be extracted as soon as possible, because the increase in surface area also increases susceptibility to oxidation and hydrolysis of the oil (Becker, 1978).

d. Cooking

Lipoxygenases and lipases are released when the cells are ruptured during grinding, rolling, or flaking. Heating inactivates these enzymes and prevents any enzyme-catalyzed oxidation or hydrolysis (Engeseth et al., 1987; Carr, 1989). Engeseth et al. (1987) found that steaming under pressure was most effective for inactivating lipoxygenases in soybeans. Heating also acts to destroy molds and bacteria (Carr, 1989) that attack fatty acids and yield a wide variety of oxidized products (Patterson, 1989). However, the heating must be carefully controlled because excessive heat can promote autoxidation.

e. Extraction

Expellers or screw presses are used for mechanical extraction of oil from oil-bearing materials. Production of some oils, such as virgin olive oil, consists solely of mechanical extraction followed by centrifuge separation (Di Giovacchino et al., 1994). Oil products in this way are often of high quality, because very little heating is required (Carr, 1989). For some seeds, mechanical extraction is followed by extraction with solvents, most commonly hexane. The use of other solvents, such as methanol or isopropanol, has been explored, but has not been widely adopted (Hoffmann, 1989; Proctor and Bowen, 1996; Thobani and Diosady, 1997).

When carbon dioxide (CO_2) is heated under pressure, it reaches a physical state known as the supercritical fluid state, in which it has properties of both a liquid and a gas. Supercritical CO_2 can be used to dissolve, suspend, and remove undesirable impurities from edible oils and fats. Supercritical CO_2 offers several advantages over traditional solvent (most commonly hexane) and steam processing techniques, including the fact that removal of the extraction "solvent" is easy and that the extraction capacity of supercritical CO_2 can be "fine tuned" by adjusting the pressure and/or temperature of the system or by adding modifying solvents, such as pentane or ethanol, to the supercritical fluid. In addition, CO_2 is nonflammable, nontoxic, low cost, and easily available. Additionally, its critical temperature and pressure are low (31°C, 7.38 MPa), and its solvent capacity for numerous compounds is appreciable at pressures of 10–40 MPa (Fattori et al., 1988).

The usefulness of supercritical CO_2 for the extraction or refining of cereal, seed, or vegetable oils and animal fats has been examined (Ziegler and Liaw, 1993; Merkle and Larick, 1995; Young and Chao, 1995; Garcia et al., 1996; Ooi et al., 1996; Zhiping et al., 1996; Dunford and Temelli, 1997). Maheshwari et al. (1992) measured the solubility of various fatty acids in supercritical CO_2 over a range of temperatures and pressures, and concluded that free fatty acids could effectively be separated from vegetable oil by supercritical CO_2. Similarly, Ziegler and Liaw (1993) reported that supercritical CO_2 extraction removed both odorous volatiles and residual free fatty acids from peanut oil. The total amount of oil recovered from canola seeds by CO_2 extraction was found to be strongly dependent on the pretreatment, and the amount of oil extractable from flaked and cooked seeds was comparable to that recoverable by conventional hexane extraction (Fattori et al., 1988).

The ability to modify the extraction characteristics of supercritical CO_2 through changes in system temperature and pressure has also been explored. Merkle and Larick (1995), for example, extracted beef fat under various processing conditions in an effort to alter the fatty acid composition of various lipid fractions. They reported that beef lipid fractions high in monounsaturated and polyunsaturated fatty acids could be produced and suggested commercial utilization of beef fat in foods might be improved through production of such specific fractions. Similarly, Eller and King (2001) investigated the supercritical CO_2 extraction of fat from ground beef and the effects of several factors on the gravimetric determination of fat. Oven-drying ground beef samples prior to extraction inhibited the subsequent extraction of fat, whereas oven-drying the extract after collection decreased the subsequent gas chromatographic fatty acid methyl ester fat determination. None of the drying agents tested was able to completely prevent the coextraction of water, and silica gel and molecular sieves inhibited the complete extraction of fat. The findings suggest that supercritical CO_2 can be used to accurately determine fat gravimetrically for ground beef.

Palm oil processed by supercritical CO_2 extraction alone retains a similar triglyceride composition with reduced levels of free fatty acids, monoglycerides and diglycerides (Ooi et al., 1996). Addition of ethanol to the CO_2 produces oils with 0.04% free fatty acids, trace amounts of monoglycerides, and much reduced diglycerides. A higher processing temperature results in a very different product, one with lower C_{48} and C_{50} triglycerides, much reduced diglycerides, and higher carotene content. Similarly, Dauksas et al. (2002) have shown that ethanol (1%) increased the yield of liquid CO_2 extraction of *Nigella damascena* seeds by 50%, and increased the yield two times at 150 bars. Linoleic acid was the major fatty acid (43.71%–50.83%), followed by oleic (14.87%–23.65%), stearic (15.07%–23.24%), and palmitic (10.13%–12.07%) acids. Elemenes (21.38%–29.16%) were the most abundant volatile constituents, free fatty acids constituted from 35.04% to 51.18%, the majority being linoleic (32.83–40.58) and oleic acids (4.96–13.32).

As supercritical CO_2 extraction procedure has the capacity to modify extraction selectivity by relatively minor changes system conditions, the extraction procedure offers the edible oil and fat processor unique opportunities to control the final composition of their products. However, this same quality poses additional challenges to those processors, and operating conditions must be optimized according to the main objective of the refining process as well as according to the nature of the starting product (Maheshwari et al., 1992). Dunford and King (2000) evaluated supercritical CO_2 fractionation technique as an alternative process for reducing the free fatty acid content and minimizing the phytosterol loss of rice bran oil during the process, and examined the effects of pressure (20.5–32.0 MPa) and temperature (45°C–80°C) for isothermal operation of the column on the composition of the resultant fractions. They found that low-pressure and high-temperature conditions were favorable for minimizing triglycerides and phytosterol losses during the free fatty acid removal from crude rice bran oil. Rice bran oil fractions with <1% free fatty acid, about 95% triglycerides, and 0.35% free sterol with 1.8% oryzanol content could be obtained utilizing the described supercritical CO_2 fractionation technique.

High-intensity ultrasound may facilitate oil extraction by reducing the time required. Li et al. (2004) evaluated the application of 20 kHz high-intensity ultrasound during extraction of oil from two varieties of soybeans using hexane, isopropanol, and a 3:2 hexane–isopropanol mixture. In a simplified extraction procedure, ground soybeans were added to solvents and ultrasonicated between 0 and 3 h at ultrasonic intensity levels ranging from 16.4 to 47.6 W/cm^2. Using hexane as a solvent, yield generally increased as both application time and intensity of ultrasound increased. Solvent type influenced the efficiency of the extraction, that is, the highest yield was obtained using ultrasound in combination with the mixed solvent. Gas chromatography analysis of ultrasonicated soybean oil did not show significant changes in fatty acid composition.

f. Miscella Stripping

Miscella is the material obtained by solvent extraction. It is a mixture of crude oil, solvent, sediments, and moisture (List and Erickson, 1980). The crude oil must then be separated from the other components of the miscella. Sediments are readily separated from the miscella by filtration. Hexane and moisture are removed by evaporation followed by flashing and low-pressure steam stripping to give 98% crude oil containing less than 0.15 wt.% moisture and volatile content (Becker, 1978; Mustakas, 1980). During miscella stripping it is important to use the lowest temperature possible, because high temperatures can promote oxidation, remove antioxidants, and cause color fixation (List and Erickson, 1980).

g. Degumming

Solvent-extracted oils contain up to 3% gums, which are mostly phosphatides. Phosphatides act as emulsifiers in the oil during refining and can reduce yields of purified oil (Carr, 1989). The presence of phosphatides has also been associated with the development of an off-flavor after deodorization (Ohlson and Svensson, 1976).

TABLE 19.2
Effects of Processing Steps on Some Minor Components of Soybean Oil[a]

Oil Sample	Phosphorus (ppm)	FFA (%)	Chlorophyll (ppm)	PV (mEq/kg)	Tocopherol (ppm)
Crude	510.0	0.74	0.30	2.4	1.67
Degummed	120.0	0.36	na	10.5	1.58
Refined	5.0	0.02	0.23	8.8	1.55
Bleached	1.4	0.03	0.08	16.5	1.47
Deodorized	1.0	0.02	nd	nd	1.14

[a] FFA, free fatty acids; PV, peroxide value; na, not available; nd, not detected.

The principal reason for degumming crude oil is to remove phosphatides (Table 19.2). During degumming, the oil is mixed with water or steam to hydrate the gums, which then precipitate out and are separated from the oil by centrifugation. Because the oil is heated during this process, it is recommended that air be excluded to prevent oxidation (Carr, 1989). In addition, the amount of water used should be the minimum required for effective degumming, because excess water will promote hydrolysis (Carr, 1978).

Evidence available suggests that the removal of iron is closely related to phosphatide removal (Jung et al., 1989), and, in fact, the iron may be present in the form of an iron–phosphatide complex (Dijkstra and Van Opstal, 1989). As even a trace amount of iron is capable of catalyzing fatty acid oxidation, its removal from the oil is important. It has been suggested that the development of off-flavors attributed to phosphatides is actually due to the presence of iron (Dijkstr and Van Opstal, 1989).

In most cases, crude oil is pretreated with phosphoric acid before being degummed (Carr, 1978, 1989; List et al., 1978a; Dijkstra and Van Opstal, 1989). This pretreatment is helpful in reducing the iron content; it apparently acts by converting the iron into a form that is more easily removed during processing (Carr, 1978; List et al., 1978a; Brekke et al., 1980; Dijkstra and Van Opstal, 1989).

The reported effectiveness of phosphatide removal from soybean oil is quite variable, ranging from 75% to 98% (Carr, 1978; List et al., 1978a, 1978b; Brekke, 1980b; Jung et al., 1989). Removal of iron from soybean oil varies with the producer as well as with the method chosen for degumming. Water degumming alone led to the removal of 14%–65% of the iron during processing (List et al., 1978a, 1978b), whereas use of phosphoric acid pretreatment increased the removal to 93% from finished oil (List et al., 1978b).

h. Caustic Refining

Crude or degummed oil is treated with caustic soda to saponify impurities. The mixture is heated to break the emulsion, and then the soapstock is removed through centrifugation (Carr, 1976, 1978, 1989; Cowan, 1976). This refined oil is washed with warm water to remove the last traces of soap, separated again by centrifugation, and then dried under vacuum (Carr, 1989). The primary actions of the caustic are to react with free fatty acids to form soapstock, hydrolyze phosphatides, and remove unsaponifiable matter (Carr, 1976, 1978).

Jung et al. (1989) found that degumming and caustic refining were the most important steps of processing for removing free fatty acids from soybean oil. In their study, the free fatty acid content of 0.74% in crude oil was reduced to 0.36% by degumming and to 0.02% by caustic refining (Table 19.2).

Because refining is carried out at high temperatures, the susceptibility to oxidation is increased. For this reason, hermetic centrifuges are used to exclude air during refining, and refined oil is cooled before being placed into storage tanks (Carr, 1989).

i. Bleaching

Degummed or refined oil is heated and mixed with natural or acid-activated bleaching clay to remove various impurities such as chlorophyll, carotenoids, phospholipids, metals, soaps, and oxidation products (Cowan, 1976; Richardson, 1978; Boki et al., 1989; Taylor et al., 1989). Bleaching is generally carried out under vacuum to minimize possible oxidation (Carr, 1989). The effects of bleaching on several components of soybean oil are illustrated in Table 19.2.

Generally, the goal of bleaching is to reduce the color pigments in order to produce an oil of acceptable color. However, there is another reason to remove some of these pigments. Kirisakis and Dugan (1985) showed that chlorophyll in olive oil acts as a photosensitizer, leading to rapid oxidation of the oil.

Acid-activated clay is usually used because its bleaching power is greater than that of natural clay (Richardson, 1978; Morgan et al., 1985; Boki et al., 1989; Taylor et al., 1989). The mechanism of action is believed to depend on chemical adsorption along with chemical reaction between the acid of the clays and the compounds being affected (Sarler and Guler, 1988; Boki et al., 1989). However, although the acidity of the clay contributes to its activity, it may also lead to two detrimental side reactions: free fatty acid formation and isomerization of the triglyceride alkyl chain (Morgan et al., 1985). These side reactions can be avoided by carefully controlling the temperature of the oil during bleaching (Richardson, 1978; Morgan et al., 1985). The processor must find a compromise temperature high enough to effectively bleach the oil but at the same time minimize the increase in free fatty acids (Richardson, 1978).

The effect of bleaching on peroxide value is variable and depends on the type and amount of clay used (Richardson, 1978). Jung et al. (1989) reported an increase in peroxide value after bleaching with acid-activated clay (see Table 19.2), but others (Brekke, 1980c; Boki et al., 1989) have reported decrease in peroxide value.

j. Physical Refining

Some oils, particularly those with high-free fatty acid and low-phospholipid content, may be refined via physical refining rather than caustic refining (Carr, 1978). In this case, crude oil is degummed and bleached, deaerated, then steam refined for about 1 h at 260°C under a vacuum of 1 mm Hg or less (Carr, 1978, 1989; List et al., 1978c). Exclusion of oxygen is extremely important, because of the high temperatures involved, so both the oil and the steam should be fully deaerated and the vessel used must be completely airtight (Mounts and Khym, 1980). The steam acts to volatilize most of the free fatty acids (Carr, 1978, 1989). This process also removes aldehydes, ketones, and other volatile compounds, which are formed through oxidation, and destroys peroxides and carotenoid pigments (Carr, 1989). Vacuum steam distillation reduces the peroxide value of soybean oil to below measurable levels (Jung et al., 1989; see Table 19.2). However, this process also removes some of the beneficial tocopherols (Cowan, 1976; Jung et al., 1989), so antioxidants may have to be added to the oil after physical refining is completed (Gavin, 1978). In order for physical refining to produce quality oil, the oil must be thoroughly acid-degummed and bleached to remove phosphatides and prooxidant metals such as iron and copper (Carr, 1978; List et al., 1978a, 1978b). Nitrogen has been proposed as an alternative to steam for physical refining. Laboratory studies suggest that nitrogen removes free fatty acids with greater efficiency than steam, while reducing losses of hydrocarbons, sterols, and triglycerides (Ruiz-Mendez et al., 1996).

k. Hydrogenation

The fluidity and susceptibility to autoxidation of oils and fats is dependent on the degree of unsaturation of the fatty acids found in the triglycerides. During hydrogenation, unsaturation is reduced by direct addition of hydrogen to the double bonds of the fatty acid chains of the triglycerides.

TABLE 19.3
Effect of Hydrogenation Catalyst on Fatty Acid Composition of Soybean Oils (wt.%)

Fatty Acid	Unhydrogenated	Nickel-Catalyzed Hydrogenation	Copper Chromate-Catalyzed Hydrogenation
Palmitic	10.2	10.5	10.4
Stearic	3.4	4.2	3.7
Oleic	22.3	47.6	41.3
Linoleic	55.5	34.4	44.2
Linoleic	8.6	3.3	0.4

Source: Adapted from Mounts, T.L., et al. (1978a). *J. Am. Oil Chem. Soc. 55*: 345–349.

The goals of hydrogenation are to increase the melting point, solidity, and oxidative stability of the oil (Allen, 1978; Grothues, 1985; Carr, 1989).

During hydrogenation, the oil is mixed with gaseous hydrogen and a metal catalyst (most commonly nickel) at carefully controlled temperatures, pressures, and agitation rates (Allen, 1978; Grothues, 1985). Generally, mono-, di-, and triunsaturated fatty acids are hydrogenated in stepwise fashion to form the respective saturated, monounsaturated, and diunsaturated fatty acids (Mounts, 1980). As can be expected, hydrogenation has the most profound effect on the fatty acid composition of oil. The effect on the fatty acid content is illustrated in Table 19.3 using soybean oil as an example. In addition, some double bonds may be shifted, and some may be changed from the *cis*- to the *trans*-form (Allen, 1978, 1986; Mounts, 1980). All of these reactions occur during hydrogenation; however, the relative rates can be affected by controlling the reaction conditions and type and concentration of catalyst (Mounts, 1980).

The ideal catalyst selected for hydrogenation is very active and selective, and it hydrogenates rapidly and reduces linoleic acid to oleic acid with little concurrent reduction of oleic to stearic (Grothues, 1985; Allen, 1986). The use of a very selective catalyst produces oils that are oxidatively stable but not overly hard (Allen, 1978, 1986). Nickel catalysts are most commonly used for hydrogenation, and are extremely versatile. By varying the reaction conditions, the selectivity can be controlled and the hydrogenation reaction can be stopped at any chosen end point (Coenen, 1976). However, the use of nickel has several limitations, including the lack of selectivity for linolenic acid over linoleic acid (Coenen, 1976; Allen, 1978). Therefore, in order to eliminate all the linolenic acid when nickel is used, a considerable amount of linoleic acid must be reduced (Coenen, 1976). A second limitation of nickel is that selectivity and isomerization are coupled; high selectivity is always accompanied by high formation of *trans*-isomer (Coenen, 1976).

Copper catalysts are superior to nickel in some respects; they have a much higher preference for linolenic acid (Coenen, 1976; Mounts et al., 1978b) and can produce an oil with a lower melting point than nickel-catalyzed oils that have the same peroxide value (Coenen, 1976). However, copper catalysts are much less active than nickel and can initiate autoxidation. Therefore, the oil requires special treatment to eliminate all traces of copper after hydrogenation is complete because of copper's prooxidant capabilities (Mounts et al., 1978b).

In addition to catalysts type, other processing conditions can affect the selectivity of the hydrogenation reaction as well as the degree of *trans*-fatty acid formulation and reaction rate. Increases in temperature and catalyst concentration, for example, led to corresponding increases in selectivity, *trans* acid formulation, and reaction rate. Increases in pressure and agitation also increase the reaction rate but decrease selectivity and *trans* acid formation (Allen, 1978).

L. Deodorization

The last step in the processing of edible oils, deodorization, is used to remove undesirable substances that occur naturally or are generated during processing (Gavin, 1978; Brekke, 1980d). The process is essentially the same as that used for physical refining (see above). Table 19.2 shows the effects of deodorization on some components of soybean oil.

B. Animal Fat Processing

Meat fats are generally uniform raw materials. This, along with their high degree of saturation, makes the processing of meat fats much easier than that of vegetable oils (Latondress, 1985). The actual processing steps are similar to those used for vegetable oils, but the extent of processing required is usually less.

a. Rendering

Two types of rendering are used: edible and inedible. Only edible rendering produces oils suitable for human consumption. In a typical edible rendering system, fat trimmings are ground and placed in a tank, where they are melted and then pumped into a disintegerator (Prokop, 1985). The disintegrator acts to rupture the fat cells completely and facilitates the separation of protein solids from melted fat. A polished edible fat is separated from solids and moisture via a two-state centrifugation system. Maximum fat quality is achieved by keeping heat exposure to a minimum: generally no more than 30 min at 200°F or less (Prokop, 1985).

b. Caustic Refining

Generally, meat fats are not caustic refined. The only demand for caustic-refined meat fat is for use in French frying potatoes. This product is produced by caustic refining, double water washing, and vacuum drying. It is not bleached or deodorized, contains about 0.5% free fatty acids, and has a fresh tallow flavor (Latondress, 1985).

c. Bleaching

Prior to physical refining, proteinaceous material must be removed from the fat. This can be accomplished by mixing diatomaceous earth or bleaching clay with the fat and then filtering. Bleaching to remove pigments and other impurities is standard procedure for vegetable oils but is rarely done for meat fats (Latondress, 1985).

d. Physical Refining

Once the proteinaceous matter has been removed by mixing with bleaching clay, the primary impurities remaining in the fat are free fatty acids (Latondress, 1985). These can be effectively removed by physical refining, and this is the usual refining method used by processors of meat fats.

e. Hydrogenation

Vegetable oils are hydrogenated to remove their oxidative stability and change their physical characteristics. Meat fats are hydrogenated primarily to change their physical characteristics; since they are already very high in saturated and monounsaturated fatty acids, they do not have the same oxidative stability problems as vegetable oils. In the hydrogenation of meat fats, it is very important to use conditions that lead to the highest selectivity possible. If selectivity is less than perfect, the monounsaturated acids will be converted to saturated acids in large quantities (Latondress, 1985).

Rumenic acid (*cis*-9, *trans*-11 C18:2) accounts for over 80% of total conjugated linoleic acid (CLA) in processed cheeses, and the second main CLA isomers are *trans*-11, *cis*-13 and *trans*-11,

trans-13. Luna et al. (2005) assessed the level and type of CLA isomers in two commercial processed cheeses (portions and slices) and monitor their evolution during the different manufacturing stages. They found that the processing parameters had negligible effects on the CLA content of processed cheese and did not modify the isomer profile in these dairy products, thereby confirming the stability of rumenic acid during manufacturing.

f. Oil Modifications

Fats and oil modification is one of the prime areas in food processing industry and tailored vegetable oils with nutritionally important structured triacylglycerols and altered physicochemical properties have a big potential in the future market. Gupta et al. (2003) have suggested that lipases, especially microbial lipases that are regiospecific and fatty acid specific, can be used for retailoring of vegetable oils and can be carried out at moderate reaction conditions. For example, bulk available cheap oils can be upgraded to synthesize nutritionally important structured triacylglycerols such as cocoa butter substitutes, low-calorie triacylglycerols, polyunsaturated fatty acid-enriched, and oleic acid-enriched oils. It is also possible to change the physical properties of natural oils to convert them into margarines and hard butter with higher melting points or into special low-calorie spreads with short- or medium-chain fatty acids. Once the technologies are established, the demand of lipases in oil industry may increase tremendously in the near future for specific modifications of fats and oils to meet the changing consumers' dietary requirements.

C. Fish Oil Processing

Marine oils were approved for use in the United States as food ingredients only recently (Bimbo, 1987; Dziezak, 1989). Federal approval for the use of partially hydrogenated menhaden oil in food products was granted in 1987. However, the consumption of fish oils as dietary supplements in increasing because of the reported health benefits (Bimbo, 1987; Luley et al., 1988; Kinsella et al., 1990). The processing of marine oils is very similar to the processing of oils originating from oilseeds.

Fish are generally processed using the wet reduction method where they are steam cooked and then pressed to remove the oil and water (Bimbo, 1987). The oil–water mixture is centrifuged to separate the oil from the water, and the oil is refined to remove undesirable substances such as moisture, free fatty acids, trace metals, oxidation products, sulfur, halogen and nitrogen compounds, pigments, sterols, and organic contaminants from the environment (Addison et al., 1978; Bimbo, 1987). Marine oils used for human food products are usually partially hydrogenated, although some oils high in n-3 fatty acids are bottled or put capsules without modification for use as food supplements (Bimbo, 1987).

III. EFFECTS OF STORAGE ON FATTY ACIDS

Degradation of quality during storage is usually a result of moisture, temperature, metal soaps, oxygen, long storage times, and equipment condition or design (Carr, 1978). Moisture can cause hydrolysis of the fat and can also lead to degumming of crude oils within the storage tank (Burkhalter, 1976; Carr, 1978).

The temperature of stored oil should be kept as low as possible, because high temperatures not only increase the oxidation rate but also increase the solubility of water in oil, resulting in an increased rate of hydrolysis (Burkhalter, 1976; Carr, 1978; Woerfel, 1985). If tanks have heating coils, they should also be equipped with a mechanism for agitation, because local overheating near the coil may induce oxidation reactions (Erickson, 1978; Berger, 1985).

The rate and degree of oxidation is also enhanced by contact with air. For this reason storage tanks should be filled from the bottom, and any head space should be filled with inert gas

(Burkhalter, 1976; Carr, 1978). It is important to use proper agitation speeds and refrain from clearing lines by blowing air through them (Erickson, 1978).

Metallic contamination, especially by copper, iron, and brass, is very effective at inducing autoxidation (Burkhalter, 1978; List and Erickson, 1980; Woerfel, 1985; Eboh et al., 2006), so contact with these metals should be avoided. Berger (1985) reported examples of oil deterioration caused by rusty storage tanks, heating coils made from an aluminum-brass alloy, and the use of brass thermometers and sampling instruments. If stored long enough, any fat or oil is subject to deterioration even under ideal conditions (Erickson, 1978). A small quantity of old oil residue in the storage container can speed up the deterioration of fresh oil (Erickson, 1978; Berger, 1985; Woerfel, 1985).

Treatment of almond oil with accelerated electrons (electron beam processing) at the dose of 3 kGy during a storage period of 5 months has no effects on linolenic acid content, whereas, at 7 and 10 kGy, the content in 18:3 disappears from the first moment (Sanchez-Bel et al., 2005). The quality indices of the oil decreased at all doses and remained stable during the time of storage. The peroxide value did not show changes at the doses of 3 and 7 kGy, in nonirradiated samples, but significantly increased when the maximum dose of 10 kGy was applied. These changes were reflected in the sensory analysis, in which the tasters did not find sensory differences between the controls and those irradiated at doses of 3 or 7 kGy, whereas almonds irradiated at 10 kGy exhibited a rancid flavor and a significant decrease in general quality.

The high-stability oils produced from high-oleic oils require less processing and bring additional nutritional benefits such as lower *trans* and saturated fat contents. Accurate and reproducible oxidative stability measurement of these oils is necessary to assess the performance. The accelerated oxidative stability measurement method often used in the fats and oils industry, the oxidative stability index is unreliable for higher stability oils due to poor reproducibility. Kodali (2005) developed a rapid and reproducible pressure differential scanning calorimetry (PDSC) method, to measure the oxidative induction time of oils under high temperature and pressure in the presence of pure oxygen. The oxidative induction times of a number of hydrogenated oils with different unsaturation and oxidative stability are measured. Unlike oxidative stability index data, the PDSC oxidative induction time measurement is highly reproducible and precise and requires only a small sample and a couple of hours. In addition, oil stability can be predicted by high-resolution ^{13}C nuclear magnetic resonance spectroscopy when applied to chromatographically enriched oil fraction (Hidalgo et al., 2002).

IV. UNDESIRABLE CHANGES IN FATTY ACIDS THAT OCCUR DURING PROCESSING AND STORAGE

The main undesirable changes of fats/oils during processes and storage are oxidation and hydrolysis. In oil oxidation, the carbon atoms next to the double bonds in the oils are oxidized, which results in a break of the hydrocarbon chain and the formation of volatile compounds, including aldehydes, ketones, alcohols, short-chain fatty acids, and other compounds that may introduce an off-odor to the oil. In oil hydrolysis, the fatty acids are hydrolyzed off the triacylglycerides at high temperatures in the presence of water, yielding free fatty acids, monoglycerides, diglycerides, and glycerol. These breakdown products will speed up the degradation of the remaining triacylglycerides as they allow greater emulsification of water from the food into the oil.

A. Oxidation

a. Autoxidation

Polyunsaturated fatty acids are more susceptible to autoxidation than monounsaturated or saturated fatty acids, and it is the breakdown products of their oxidation that are the major source of off-flavors in oil (Patterson, 1989). The sequence of events that has been suggested to lead to the development of flavor and odor in oil begins with the oxidation of a fatty acid to a hydroperoxide. Oxygen is

required for this oxidation, and the process is catalyzed by the presence of metals, heat, and light. Hydroperoxides themselves are tasteless and odorless. However, continued oxidation causes these hydroperoxides to be broken down into various short-chain organic compounds such as aldehydes, ketones, alcohols, and acids, which are actually responsible for the strong odors and flavors characteristic of rancidity (Sherwin, 1978; Patterson, 1989).

There are numerous factors, including the presence of free fatty acids, lipoxygenases, metals, light, heat, and oxygen, that are capable of initiating and/or accelerating autoxidation during processing, refining, and storage. Free fatty acids, even at levels as low as 0.5% in the oil, act as prooxidants (Mistry and Min, 1987; Patterson, 1989). Higher levels of volatile compounds and peroxides are found in oils containing free fatty acids than in oils containing no free fatty acids after storage at 55°C for as little as 1 day (Mistry and Min, 1987). Interestingly, saturated fatty acid stearic acid is equally as effective at initiation of oxidation as polyunsaturated fatty acids linoleic and linolenic acids (Mistry and Min, 1987). The findings suggest that the carboxylic group of the free fatty acid is responsible for the prooxidant activity, and that it is essential to the production of good quality oil to remove the free fatty acids through refining.

Lipoxygenases are naturally present in all plant and animal tissues, and act to catalyze the oxidation of polyunsaturated fatty acids (Sherwin, 1978; Engeseth et al., 1987; Patterson, 1989). Metals in trace amounts are very effective prooxidants and are active in the breakdown of hydroperoxides (Sherwin, 1978; Patterson, 1989). Heat greatly increases the rate of oxidation, particularly in the more unsaturated oils, with a doubling in oxidation rate for every 15°C increase in temperature above 60°C (Sherwin, 1978). Light, especially ultraviolet and near-ultraviolet, can provide the energy necessary for both initiation and propagation of oxidation (Sherwin, 1978; Patterson, 1989). Finally, as oxidation cannot proceed without oxygen, any process that increases oil–air contact aeration increases the likelihood of oxidation (Sherwin, 1978; Patterson, 1989).

b. Photooxidation

As mentioned above, ultraviolet light is capable of both initiating and propagating autoxidation. However, light in the visible range is capable of initiating another, mechanically distinct type of oxidation known as photooxidation (Frankel, 1980). Unlike the process of autoxidation, which relies on a free radical mechanism for propagation, photooxidation results from the direct attack of singlet oxygen molecules on fats and oils (Patterson, 1989). Singlet oxygen is produced following the reaction of visible light with a sensitizer such as chlorophyll, riboflavin, hemoglobin, or certain dyes (Frankel, 1980; Patterson, 1989). The excited sensitizer reacts with molecular oxygen to form the excited singlet state oxygen molecule. Highly reactive singlet oxygen then reacts directly with the olefinic groups of lipids to produce lipid hydroperoxides. The breakdown of these lipid hydroperoxides generates, among other things, free radicals, which can in turn initiate autoxidation.

Photooxidation is a much more rapid process than autoxidation, and only trace amounts of sensitizers are sufficient to initiate autoxidation (Frankel, 1980). Most chain-breaking antioxidants that are typically used to prevent autoxidation in oils are ineffective against photooxidation (Patterson, 1989). Singlet oxygen quenchers such as tocopherols and carotenes do, however, inhibit it (Patterson, 1989). Fortunately, the majority of sensitizers such as chlorophyll and dyes are removed during processing. However, most of the singlet oxygen quenchers or free radical scavengers naturally present in the oil are also removed.

Exposure of oil to UV radiation induces changes on the chemical and sensory characteristics of oils. For example, Luna et al. (2006) have shown that even small doses of UV radiation-induced oxidation of the virgin olive oil samples. Total phenols and fatty acid contents decreased during the process as well as the intensity of the bitter and fruity sensory attributes, while the intensity of the rancid sensory attribute notably increased. In addition, acetaldehyde, 2-butenal, 2-pentenal, octane, octanal, hexanal, nonanal, and 2-decenal were increased during the irradiation process, and nonanal, hexanal, and pentanal showed high correlation with the rancid sensory attribute (90%, 86%, and 86%, respectively).

B. Hydrolysis

The next most frequent cause of deterioration of oils and fats during processing and storage is hydrolysis, which occurs when a triglyceride reacts with water and the fatty acids are split off from the glyceride backbone (Patterson, 1989). This has two major implications for the processor. First, the final yield of purified triglycerides is reduced. Second, the free fatty acids that are produced are much more susceptible to autoxidation than those bound to a glyceride backbone (Patterson, 1989). Hydrolysis is catalyzed by the lipolytic enzymes present in plant and animal tissues and can be enhanced by both moisture and heat (Sherwin, 1978).

C. Isomerization

Hydrogenation leads to the creation of both positional and geometrical isomers. The double bonds of unsaturated fatty acids may be shifted to other locations within the fatty acid, and *cis*-double bonds may be isomerized to the *trans*-form (Allen, 1978, 1986). In addition, processes using acids, degumming, for example, may induce *cis–trans* isomerization (Hudson, 1987). *Cis–trans* isomerization affects oil quality in two ways. Increased amounts of *trans*-isomers result in a harder oil than oil with the same degree of hydrogenation but high in *cis*-isomers (Mounts, 1980). In addition, *trans*-fatty acids lack the essential quality of the comparable *cis*-fatty acids (Grothues, 1985). The conventional heating methods of milk did not cause any significant increase in the *trans*-isomer content, with the exception of milk heated at 63°C for 30 min and milk microwaved for 5 min, which were significantly increased by 19% and 31%, respectively. The chemical changes of lipids were generally accelerated with the severity of the heat treatment and duration of storage. The CLA content of cheese heated in a microwave oven for 5 min decreased by 21%, and microwave heating for 10 min caused a decrease of 53% compared with that of freshly boiled cheese (Herzallah et al., 2005).

V. ANTIOXIDANTS AND METAL CHELATORS IN FAT AND OIL PROCESSING

Oxidation during processing and storage is the major cause of quality loss in oils and fats. Autoxidation can be minimized by controlling exposure to conditions that enhance oxidation, such as heat, metal contaminants, and air, and by adding antioxidants and chelating agents to the products. Photooxidation can be minimized by reducing exposure to light and adding appropriate antioxidants.

The oxidative stability of fats and oils is related to their triacylglycerol composition and antioxidants present (Hrncirik and Fritsche, 2005; Mateos et al., 2005) and iron content (Coscione and Artz, 2005). Vegetable oils contain natural antioxidants such as tocopherols (Latondress, 1985; Patterson, 1989), so even without added antioxidants, they exhibit some resistance to oxidation (Kincs, 1985). Del-Carlo et al. (2004) studied the contribution of the phenolic fraction to the antioxidant activity and oxidative stability of extra-virgin olive oil and found no individual compounds was identified as the main cause of the overall antioxidant activity, and the total polyphenol determination was better correlated to antioxidant activity and oxidative stability than each tested polyphenols or polyphenol groups such as o-diphenols.

The effectiveness of commonly used antioxidants butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and *tert*-butylhydroquinone (TBHQ) in vegetable oils has been studied (Erkilla et al., 1978; Kincs, 1985; Hawrysh et al., 1988). Table 19.4 shows the effectiveness of BHA/BHT and TBHQ at preventing a rise in peroxide value during storage of canols oils.

Unlike vegetable oils, for which hydrogenation is the primary method of increasing oxidative stability, animal fats achieve a large degree of their stability from the addition of antioxidants (Latondress, 1985). BHT, BHA, and TBHQ are all very effective in preventing oxidation of meat

TABLE 19.4
Peroxide and Thiobarbituric Acid Values for Antioxidant-Treated Canola Oil during Accelerated Storage at 65°C

	Treatment			
Storage Time (days)	Untreated Control	BHA/BHT (100 ppm ea) + Citric Acid	TBHQ (200 ppm)	TBHQ (200 ppm) + Citric Acid
Peroxide value (mEq/kg)				
0	0.67	0.46	0.61	0.51
4	9.84	5.29	1.21	1.32
8	23.64	20.52	1.99	2.13
16	61.71	40.00	3.34	3.40
TBA value (532 nm)				
0	0.67	0.68	0.68	0.68
4	6.41	3.63	0.91	0.96
8	9.36	8.46	2.57	1.93
16	11.64	10.79	1.70	1.56

fats (Kincs, 1985; Eboh et al., 2006). Heavy metal contaminants adversely affect the composition, storage stability, and fatty acid profiles (Eboh et al., 2006). The use of metal chelators such as citric acid or ethylenediminetetraacetic acid (EDTA) also helps prevent oxidative damage to fats and oils (Sherwin, 1978; Patterson, 1989) by removing trace metals that could act to initiate oxidation.

If antioxidants or chelators are to be used, certain precautions must be taken to achieve the best results (Sherwin, 1978; Patterson, 1989). First, the antioxidant selected must be compatible with the oil or fat and effective in the situation in which it is used. Next, the appropriate concentration must be used; low concentrations may be ineffective, and high concentrations may enhance oxidation. Third, the antioxidant must be thoroughly dispersed throughout the oil to prevent areas of high and low concentration. Finally, the antioxidant must be added at the appropriate stage of processing. If it is not added soon enough, oxidation will begin and once begun cannot be reversed. On the other hand, if added too soon, the antioxidant may be removed during processing, leaving the processor with the false belief that the oil or fat contains sufficient antioxidants (Sherwin, 1978; Patterson, 1989).

VI. SUMMARY AND CONCLUSION

The goal of commercial oil processing is to obtain the maximum yield while at the same time achieving desirable physical characteristics, retaining nutritive value, and improving oxidative stability. Hydrogenation, which reduces the degree of unsaturation, has the most profound effect on the fatty acid composition of oils. Other processing steps, which are mainly designed to remove various undesirable elements, have only minor or indirect effects on the fatty acid composition. The elimination of impurities, such as free fatty acids, phosphatides, pigments, trace metals, and oxidation products, during processing not only improves product quality but also increases oxidative stability.

Various processing steps are generally beneficial to the production of good-quality edible oils. However, processing may also bring about changes in fatty acids that are detrimental to product quality, leading to losses of both esthetic and nutritive value. For example, hydrogenation can cause the formation of isomeric fatty acids and the loss of essential fatty acids. Additionally, during processing and storage, the oil may be exposed to certain conditions that can lead to autoxidation of fatty acids and results in the formation of hydroperoxides, aldehydes, and other undesirable oxidation products.

Factors such as moisture, heat, air, metals, and light can enhance hydrolysis and promote autoxidation of fatty acids. Antioxidants are normally added to edible oils to improve oxidative stability and prolong the shelf life of the products. If potentially damaging conditions are avoided or controlled, each step of processing will contribute to the production of an oil or fat that is bland, free of impurities, and oxidatively stable.

20 Effect of Heating and Frying on Oil and Food Fatty Acids

Francisco J. Sánchez-Muniz, Sara Bastida, Gloria Márquez-Ruiz, and Carmen Dobarganes

CONTENTS

I. INTRODUCTION

Edible fats and oils usually contain more than 95% triglycerides. The main characteristics of the acyl groups forming triglycerides are chain length (number of C-atoms) and the number and position of unsaturations in the molecules. Before absorption, triglycerides must be hydrolyzed into free fatty acids and monoglycerides. These triglyceride-derived compounds are placed into intestinal micelles and absorbed. Later triglycerides are reesterified within the enterocyte and incorporated to chylomicrons (Sánchez-Muniz and Sánchez-Montero, 1999). Chylomicrons and other lipoproteins participate in the very complex lipoprotein metabolism carrying cholesterol, fatty acids, and other fat-soluble compounds to/between the different body tissues (Elmadfa and Wagner, 1999). The amount and quality of dietary fats and oils may influence the cell, tissue, and body physiology (Elmadfa and Wagner, 1999; Mahungu et al., 1999). Diet supplies some fatty acids that are essential or play very important metabolic regulations. A basic function of the *mother* dietary fatty acids,

oleic (C18:1, n-9), linoleic (18:2, n-6), and linolenic (c18:3, n-3), apart from being metabolic energy substrates, is to be unsaturated and elongated to long-chain fatty acids of 20 and 22 C-atoms. These long-chain fatty acids, once incorporated to membrane phospholipids or cellular membrane regions enriched in esfingomielins (Jump, 2004), can modulate the cell gene expression and generation of several bioactive molecules, through different and complex metabolic ways. Moreover, the balanced quantitative and qualitative intake of fatty acids can reduce the cholesterolemia, the lipid and lipoprotein oxidizability, and the thrombogenesis, and also modify the lipogenesis–lipolysis equilibrium, and so forth (Mensink and Katan, 1992; Massaro et al., 2002, 2006; Mata et al., 2002). Thus, adequate intake of dietary fat is essential for health. At present, it has been accepted by most of the Nutrition Organizations that total fat must contribute up to 30% and saturated fatty acids only less than 10% of the total energy intake (Kris-Etherton, 1999; Ros, 2001).

Mediterranean diet has been considered one of the most healthy standard diets worldwide (Keys et al., 1986; De Lorgeril et al., 1999). Basically, it contains a large proportion of vegetables, cereals, fruits, and olive oil (Trichopoulos et al., 2003). One of the most interesting characteristics of this diet is the frequent inclusion of fried foods (Varela and Ruiz-Roso, 1998; Sánchez-Muniz and Bastida, 2006). According to Henry (1998), fried foods eaten moderately provide important nutrients to our diet although they are often considered to be "bad" foods. Unfortunately, some indiscriminate general recommendations to decrease the consumption of fried foods could negatively affect the dietary habits of certain populations traditionally used to produce and consume fried foods (Bastida and Sánchez-Muniz, 2001a).

Some potential toxic compounds have been suggested to be specifically produced during frying. Thus, the formation of carcinogenic substances in frying oil and in fried foods has been investigated. However, it has to be pointed out that the main compounds associated with mutagenic effects are not specifically related to fatty acids. Otherwise, such compounds are polycyclic heterocyclic compounds formed from proteins or amino acids (Pokorný, 1999), nitrosamine compounds whose precursors are *N*-nitroso derivatives (Buckley et al., 1989); and acrylamide, found to be present in high concentrations in heat-treated food products rich in carbohydrates (Tareke et al., 2002; Boon et al., 2005). Therefore, in this chapter, the postulated formation mechanisms of these potential toxic substances and the methods used for their isolation and quantification will not be described.

Frying is a very old method of cooking food and represents a particular way of cooking food using oil or fat as a fluid heat vector. Frying modifies the physicochemical and organoleptic properties of foods (Varela, 1988), producing, for example, the crispy texture and the rich flavor and aroma that make food a pleasure to eat (Sánchez-Muniz and Bastida, 2006). Normally, less than 10 min are needed to fry any foodstuff (Cuesta and Sánchez-Muniz, 2001; Bastida et al., 2003; Sánchez-Muniz and Bastida, 2006), much less than that required by other culinary techniques.

There are two main frying techniques: *shallow* and *deep-fat frying*. Shallow frying is performed in relatively flat pots or pans containing little oil in which the product is not completely immersed. The food in direct contact with the hot oil is fried and the rest is cooked. In deep-fat frying the entire food is immersed in oil and the frying process takes place throughout the product. This kind of frying is performed in domestic and industrial fryers and in deep pans containing large amounts of oil (Monferrer and Villalta, 1993). According to Bognár (1998), oil uptake in meat and fish fried using the deep-fat frying method is lower than that in shallow frying.

Frying can be carried out either with *frequent*, *slow*, or *null replenishment* of fresh oil. As will be discussed in this chapter, frequent addition of fresh oil minimizes oil alteration (Cuesta and Sánchez-Muniz, 1998; Romero et al., 1998, 2000a,b). Frying can also be performed in a *continuous* or *discontinuous* manner, depending on whether the oil is left to cool (sometimes to room temperature) between frying operations. Jorge et al. (1996a) reported that laboratory continuous potato frying displayed lower degree of oil alteration than that after discontinuous frying.

In this chapter, the general modifications occurring during heating/frying will be summarized. The following sections will be dedicated to fatty acid changes in oils/fats used for cooking and oil transfer between food being fried and fryer oils/fats.

II. GENERAL CHANGES IN OILS AND FATS DUE TO HEATING AND FRYING

As the fat or oil is heated, the quality decreases as evidenced by a decrease in heat capacity, surface and interfacial tension, and increases in specific gravity, viscosity, acid values, anisidine values, and polymer content. Surface tension and interfacial tension are reduced by low- and high-polarity oxidative polymers causing excessive oil uptake by the food (Blumenthal and Stier, 1991).

It is well known that unsaturated fatty acids are prone to *autoxidation*, which is a free radical chain process, consisting mainly of three steps (i.e., initiation, propagation, and termination) (Porter et al., 1995; Lambert, 1999; Frankel, 2005) (Figure 20.1):

1. The formation of a lipid radical ($R^{\bullet}$) from an unsaturated fatty acid (RH) is the key event in the *initiation* step. This can occur by thermal or photochemical homolytic cleavage of the RH double bond or by hydrogen atom abstraction from RH by a free radical initiator.
2. *Propagation* normally begins with the addition of molecular oxygen to $R^{\bullet}$ but the rate-limiting reaction consists of abstraction of a hydrogen atom from RH by peroxyl radical ($ROO^{\bullet}$) to form hydroperoxides (ROOH) and another radical $R^{\bullet}$. Propagation observed in oxidation (Figure 20.1) may be more complicated than the simple transfer and addition (Porter et al., 1995). The primary products formed from the peroxidation of lipids generally include oxygen coupling to radical, hydrogen atom, or group transfer from substrate to the chain carrying the peroxyl radical, fragmentation of the chain containing the peroxyl radical to supply oxygen and a lipid radical, rearrangement of the chain containing the peroxyl radical, and cyclization of the peroxyl radicals, essentially by intramolecular radical addition (Frankel, 1991).
3. The *termination* reactions yield nonvolatile compounds of monomeric or polymeric structure, mostly containing oxygenated groups such as hydroxy, hydroperoxy, keto, epoxy

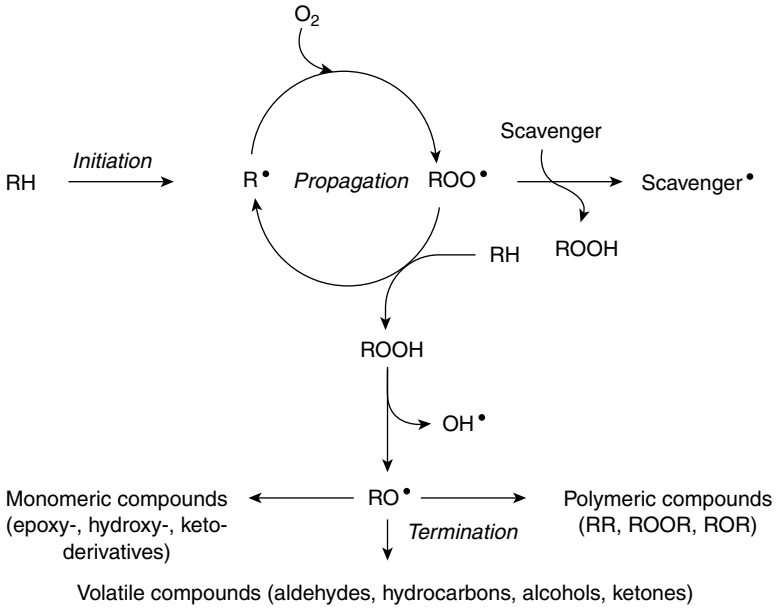

FIGURE 20.1 Major steps in oxidation. RH, a lipid containing an unsaturated fatty acid; $R^{\bullet}$, alkyl radical; $OH^{\bullet}$, hydroxyl radical; $RO^{\bullet}$, alkoxyl radical; $ROO^{\bullet}$, alkylperoxyl radical; and scavenger$^{\bullet}$, radical scavenger.

(Márquez-Ruiz and Dobarganes, 1996a), as well as volatile products (Brewer et al., 1999) including hydrocarbons, aldehydes, and ketones (Frankel, 1991). Alternatively, the propagation reaction also ends when peroxyl radicals combine with a radical scavenger such as vitamin E (Porter et al., 1995) (Figure 20.1).

The heating of oil (in the absence of food) increases the speed of autoxidation (Nawar, 1984). Thus, when the temperature of the reaction medium is relatively low (below 100°C), the formation rate of hydroperoxides is higher than that of their decomposition. Therefore, the compounds formed are mainly monomers of triglycerides with one or more acyl chains at any possible stage of oxidation. All these compounds are classified as oxidized triglyceride monomers.

At higher temperatures, all autoxidation reactions speed up, and the amount of altered compounds formed, mostly secondary oxidation products, depends on the heating time. At temperatures close to 200°C, decomposition and other reactions of hydroperoxides are faster than their formation. In this case, the major compounds generated are dimers and polymers of triglycerides (Nawar, 1984). Thermal alteration is also responsible for the formation of cyclic compounds such as triglyceride monomers showing intermolecular cyclization or triglyceride monomers showing intramolecular cyclization.

Frying clearly differs from heating because the presence of food in the fryer oil makes the situation rather more complex (Figure 20.2). During frying, the food is submerged in fat, which is heated in the presence of air. Therefore, the fat is exposed to the action of moisture from the foodstuff, oxygen from the atmosphere, and high temperature at which the operation takes place. In frying, autoxidation is also accelerated due to the relatively high temperature of the process; oxidation and thermal alterations take place in the unsaturated fatty acids, leading mainly to modified triglycerides with at least one of the three fatty acyl chains altered. Moisture from foods may

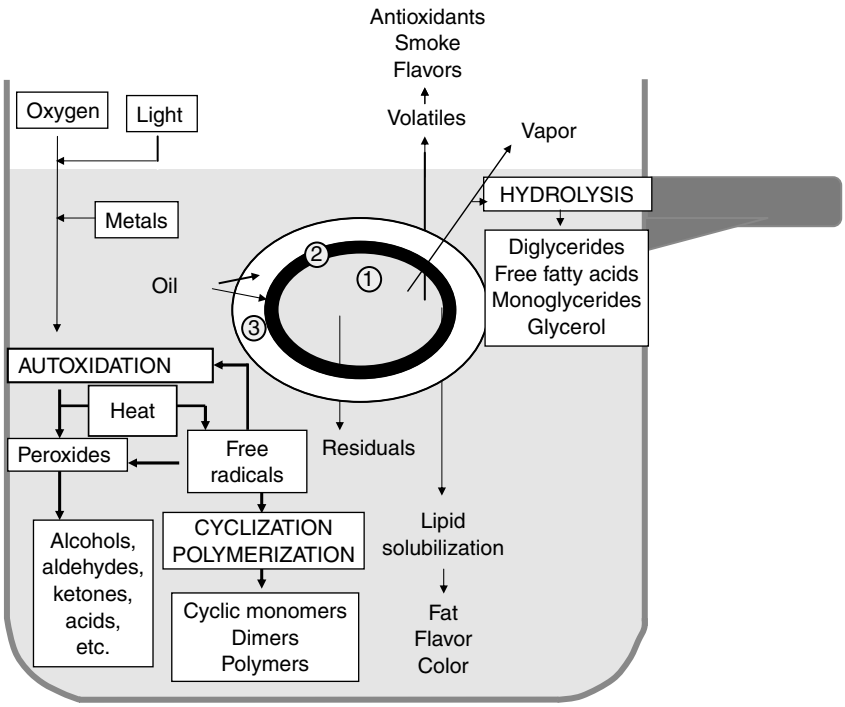

FIGURE 20.2 Major frying changes in frying. (1) Interior of food. Cooking is performed around 100°C due to vapor production. (2) The fat content increases and the water content decreases. (3) Total dehydration occurs. Browning and caramelizing take place.

induce hydrolytic alteration, thus yielding monoglycerides, diglycerides, and free fatty acids that are commonly classified as hydrolytic products (Table 20.1 and Figure 20.2). All these thermally oxidized and hydrolytic compounds are present in different quantities depending on a considerably high number of frying variables (Figure 20.3).

Finally, apart from migration of lipids from the food into the frying oil, it is important to take into account that the presence of some compounds from the foods can substantially affect the thermal oxidation reactions. Thus, (1) amphiphylic compounds such as phospholipids and emulsifiers can contribute to early foaming; (2) lipid-soluble vitamins and trace metals leaching into the frying oil may inhibit or accelerate oil oxidation depending on their antioxidant or prooxidant effects; (3) cholesterol and its oxidation-derived compounds from fatty animal foods can be transferred to vegetable frying oils and then incorporated into nonfatty foods during subsequent frying operations; (4) pigments and Maillard browning products can modify the susceptibility against oxidation of

In *Olive oil and Health*, Quiles, J.L., Ramírez-Tortosa, M.C., and Yaqoob, P., eds., CABI. Org., Oxfordshire, U.K., 2006, p. 74. With the publisher permission.)

frying oils and contribute to darkening; (5) phenolic compounds present in the foods or in added spices can increase the frying oil stability; and (6) volatile compounds coming from strongly flavored foods like fish or onions can contribute to specific off-flavors (Figure 20.2)

Although it is not easy to find studies addressed to know the specific effect of minor compounds from foods, some interesting information can be found in general reviews (Pokorný, 1980, 1998, 1999; Stevenson et al., 1984; Fillon and Henry, 1998).

Moreover, during frying the substrate surface is almost totally dehydrated and crust formation occurs (Figure 20.2). According to Varela (1988) the crust acts as a barrier avoiding excessive food fat uptake and dehydration. Furthermore, monounsaturated or nonaltered oils produce a thinner and defined crust than polyunsaturated and thermal oxidized oils. Therefore, the crust contributes to produce leaner, safer, and healthier foods.

III. CHEMICAL CHANGES IN FATTY ACIDS DUE TO HEATING AND FRYING

This section will be dedicated first to the changes at the level of total alteration and second to the major nonvolatile altered fatty acids produced in used frying oils and fats (i.e., modified monomers, dimers, and higher oligomers).

A. Total Changes in the Oils and Fats: Polar Compounds

The overall quality of an oil or fat comprises those attributes that affect the nutritional, acceptability and commercial quality. Consumption of relatively high amounts of altered oil can be harmful to health (Cuesta et al., 1988; López-Varela et al., 1995; Márquez-Ruiz and Dobarganes, 2006; Lambert, 1999; Garrido-Polonio et al., 2004). Thus, adequate fat/oil alteration assessment is of great technological and nutritional importance.

The compounds produced due to changes during heating or frying are known as polar compounds, polar materials, or polar artifacts. In this chapter the term polar compounds will be generally used. Such alteration compounds show higher polarity than the original triglycerides and thus can be measured by techniques based on polarity discrimination.

Adsorption chromatography has been widely used for determining total polar compounds. The standard method uses a classical silica column. Nonpolar and polar fractions are eluted with 150 mL of a mixture hexane/diethyl ether (87:13) and 150 mL diethyl ether, respectively. After solvent evaporation, the polar compounds are determined gravimetrically (Waltking and Wessels, 1981; IUPAC, 1992a) (Figure 20.4a). Nonpolar and polar fractions can be further analyzed by high-performance size-exclusion chromatography (HPSEC), using 100 and 500 Å columns with polysterene divinylbenzene highly cross-linked macroporous packing connected in series; tetrahydrofuran as mobile phase (flow rate: 1 mL/min); and a refractive index detector (Dobarganes et al., 1988). The methodology has been recently standardized by the IUPAC Commission on Oils, Fats and Derivatives with slight modifications, for the analysis of used frying oils, and also for virgin and refined oils (Dobarganes et al., 2000a) (Figure 20.4b).

HPSEC is usually applied for the determination of polymerized triglycerides taking advantage of their molecular weight, much higher than that of the main oil components (IUPAC, 1992b) (Figure 20.4c). Further, the advantages offered by combination of adsorption chromatography–HPSEC (Figure 20.4b) are enormous. First, a substantial increase in the possibilities for quantification of all the groups of alteration compounds is achieved because of the effect of concentration. Second, oxidized monomers, a measurement of oxidative degradation can be determined independently, since the coeluting major peak of nonoxidized triglycerides is separated in the nonpolar fraction. Third, concomitant evaluation of diglycerides as a marker of hydrolytic degradation is possible. Finally, a substantial increase in sensitivity is achieved in quantification of polymerization compounds due to the effect of concentration, overcoming the limitation of the IUPAC Standard Method

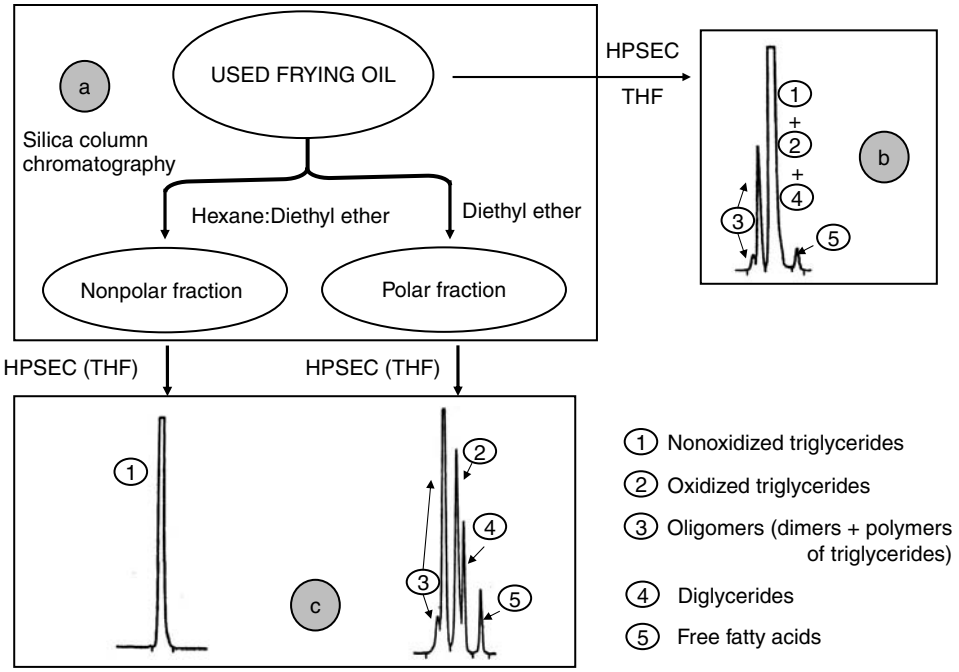

FIGURE 20.4 Analytical procedure for determination of altered oxidized and polymerized compounds. (a) Separation of nonpolar and polar fractions from used frying oils by silica gel chromatography (SGC); (b) direct HPSEC of used frying oils: unaltered and oxidized triglycerides and diglycerides elute together; (c) combination of SGC and HPSEC permits identification of compounds in the nonpolar and polar fractions, and the overlapping of nonaltered triglycerides with oxidized triglycerides and diglycerides. (Modified from Dobarganes, M.C. et al. In *Frying of Food. Oxidation, Nutrient and Non-Nutrient Antioxidants, Biologically Active Compounds and High Temperatures*, Boskou, D. and Elmadfa, I., eds, Technomic Publishing Co. Inc., Lancaster, PA, 1999, p. 143; Sánchez-Muniz, F.J. et al., *J. Nutr.*, 133, 2302, 2003; Sánchez-Muniz, F.J., and Bastida, S. Effect of frying and thermal oxidation on olive oil and food quality. In *Olive oil and Health*, Quiles, J.L., Ramírez-Tortosa, M.C., and Yaqoob, P., eds., CABI. Org., Oxfordshire, U.K., 2006, p. 74. With the publisher permission.)

2.508 to a minimum of 3% content for analyses of total samples by HPSEC. The groups of compounds quantified can be differentiated between thermally oxidized compounds (oxidized monomers, dimers, and oligomers), associated with negative physiological effects, and hydrolytic products (diglycerides and fatty acids), naturally released from lipolysis in the gut before absorption.

An alternative technique intended to reduce the quantity of the sample and solvents, shorten and analysis time is based on the use of silica cartridges for the separation and monostearin as the internal standard. This modified procedure is useful for samples with a wide range of alteration products and especially for those of low levels of degradation. In the latter case, quantification with an internal standard shows significantly lower errors compared to gravimetric determination, based on relative standard deviations (Márquez-Ruiz et al., 1996).

Polar compound determination constitutes the main basis of the used frying oils and fats regulations. The debate on deep-fat frying is primarily focused on the point at which any oil used for frying should be discarded. Many European countries have established legislation that it is compulsory to discard a frying oil when its altered part (polar material) surpasses 25% of total oil mass (Firestone, 1996; Dobarganes and Márquez-Ruiz, 1998; Sánchez-Muniz and Bastida, 2003).

Figure 20.5 shows comparative behaviors of different oils during discontinuous frying of fresh potatoes. Monounsaturated oils were more stable than sunflower oil. This implies that they can be

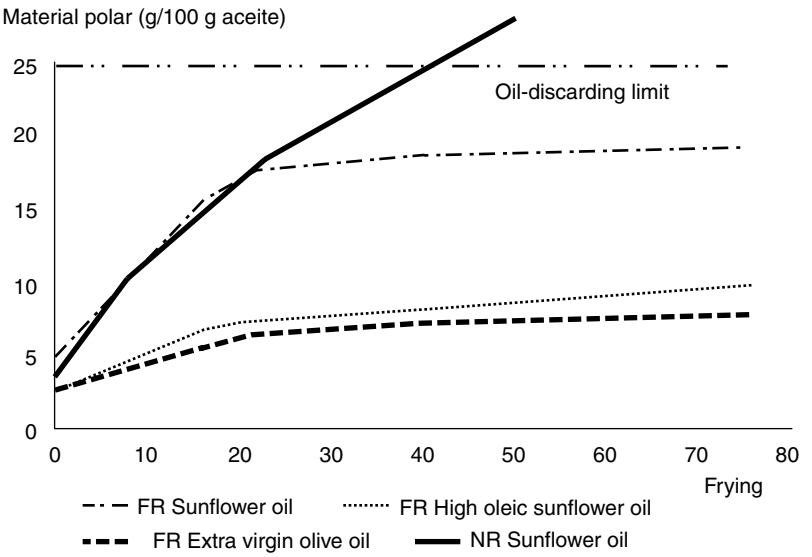

FIGURE 20.5 Polar material content (g/100 g oil) change in extra virgin olive oil, high-oleic acid sunflower oil and sunflower oil used in 75 fryings of fresh potatoes performed with frequent addition of fresh oil, and in 75 fryings of fresh potatoes in sunflower oil performed with null turnover. (Adapted from Arroyo, R. et al., *Fat Sci. Technol.*, 95, 292, 1995; Cuesta, C. et al., *J. Am. Oil Chem. Soc.*, 70, 1069, 1993; Romero, A. et al., *J. Agric. Food Chem.*, 47, 1168, 1999. With the publisher permission.)

used for frying for a higher number of occasions before reaching the 25% polar content cut-off point and, thus, have a longer frying life than other extensively used oils. The comparison between the oil alteration tendencies also suggests that frying life highly depends on the frequency of oil addition. Nonetheless, in a parallel study performed by frying fresh potatoes under null fresh oil addition, it was found that palm olein displayed very high stability (Arroyo et al., 1995). These results are relevant but it has also to be pointed out that frying/cooking with palm olein increases the palmitic acid content of the food giving rise to a dietary energy contribution of saturated fatty acid >10% (Cuesta et al., 1998), which is regrettable taking into account the relationship of these fatty acids and some degenerative diseases, such as cardiovascular diseases (Keys et al., 1986; Mensink and Katan, 1992; Cuesta et al., 1998).

In the past years, a plethora of studies on frying fats and oils based on application of this methodology has been published, and the results obtained have contributed to improve knowledge on important issues related to frying, such as performance of different oils (Dobarganes et al., 1993; Arroyo et al., 1995; Sébédio et al., 1996; Masson et al., 1997, 1999, 2002; Márquez-Ruiz et al., 1999; Abidi and Warner, 2001; Bastida and Sánchez-Muniz, 2001a,b; Abidi and Rennick, 2003; Houhoula et al., 2003; Marmesat et al., 2005), composition of oils absorbed by the fried food and lipid interchange between frying oil and food (Pérez-Camino et al., 1991; Pozo-Díaz et al., 1995; Jorge et al., 1996b; Sébédio et al., 1996), the action of the main variables involved in the continuous and discontinuous frying processes (Jorge et al., 1996a,b), and the effect of oil replenishment during frying on oil quality (Cuesta et al., 1993; Romero et al., 1995, 1998, 1999; Cuesta and Sánchez-Muniz, 1998).

Beside applications on used frying oils, the methodology has also been applied to thermally oxidized fats and oils (Abidi et al., 1999; Barrera-Arellano et al., 1999; González-Muñoz et al., 1999, 2003; Verleyen et al., 2001, 2002; Barrera-Arellano et al., 2002; Kamal-Eldin et al., 2003), and food lipids and oils subjected to microwave heating (Beatriz et al., 1994; García-Ayuso et al., 2000; Caponio et al., 2002; Luque-García et al., 2002).

B. Total Changes in Fatty Acids

The analysis of polar compounds starting directly from the used frying oil is very useful because of their significance in terms of the total new compounds formed. However, from a chemical and even nutritional point of view, the analysis of modified fatty acids provides more interesting information. On one hand, evaluation of polar compounds does not permit to differentiate triglycerides with either one or more polar fatty acyl groups. In this regard, quantification of polar fatty acid methyl esters (FAME) is of great use as it overcomes this limitation and provides additional information. On the other hand, in the past years, nutritional aspects have merged on the potential biological effects of oxidized lipids and there is increasing evidence that they may be detrimental to health, particularly in connection with the development of atherosclerosis, liver damage, and promotion of intestinal tumors (Márquez-Ruiz and Dobarganes, 2006; Dobarganes and Márquez-Ruiz, 2003).

This subsection covers a double aspect concerning formation of new fatty acids during heating and frying: (i) the evaluation of the total modified fatty acids and (ii) the loss of the nonpolar fatty acids present in the oils and fats before heating.

a. Polar Fatty Acids

As already noted, determination of polar fatty acyl groups included in triglyceride molecules is essential to evaluate specifically the oxidative changes undergone in fats and oils after heating or frying since oxidation takes place in the unsaturated fatty acyl groups. In addition, it is of great value in relation to the nutritional consequences of frying oil consumption as it is focused on the fatty acyl groups, which are the products of fat digestion ultimately absorbed. However, even though evaluation of polar compounds in used frying oil is an excellent measurement of oil degradation, it does not permit to differentiate altered triglycerides with either one or more oxidized fatty acyl groups.

Methodologies used to quantify polar fatty acyl groups included in triglyceride molecules are based on the most simple fatty acid derivatives of triglycerides, the FAME. The first approach used enabled direct evaluation of the polar FAME by gravimetric determination following separation in silica column (Dobarganes et al., 1984a; Perrin et al., 1985; Sánchez-Muniz et al., 1990, 1993, 2000a; Cuesta et al., 1991). Briefly, FAME are obtained by transesterification of 1 g of sample with sodium methoxide and hydrochloric acid–methanol. FAME are quantitatively recovered and separated by silica column chromatography in two fractions. When using 150 mL hexane/diethyl ether (95:5), the first fraction includes exclusively the most abundant nonpolar FAME. Then, elution with 150 mL diethyl ether yields a minor fraction of polar FAME. It is interesting to note that two groups of modified FAME elute in the fraction of nonpolar FAME: *trans* FAME and cyclic FAME. These groups have similar polarity than those corresponding to nonmodified FAME and, consequently, they cannot be separated by silica column. However, their quantitative importance as compared to the total new FAME formed as well as to the group of nonmodified FAME is minimal.

Evaluation of polar FAME by silica column in used frying oil samples collected by Food Inspection Services, with polar compound levels close to the limit for frying oil rejection (25%), showed clearly that additional information on the alteration level can be gained (Márquez-Ruiz et al., 1995). Overall, samples at the limit of rejection had alteration levels as high as 10% expressed specifically on polar FAME, which means that significant amounts of altered fatty acids may occur in the diet. In addition, samples with the same percentage of total polar compounds (27.6%) showed different levels of polar FAME (8.7%–11.3%), in part due to the fact that diglycerides form a considerable part of total polar compounds in certain oils and, after transesterification, their resulting FAME will be included in the nonpolar fraction.

A different approach used consists of direct analysis of FAME derivatives by size-exclusion chromatography (Perkins et al., 1973; Perrin et al., 1984; Christopoulou and Perkins, 1989c). In this case, the analysis is very simple as it only requires to inject total FAME, but resolution and detection of polar FAME are very poor due to the presence of nonmodified FAME as major components.

The most complete evaluation of polar FAME can be achieved by combining adsorption chromatography (silica column) to obtain the polar FAME fraction and further analysis by HPSEC to separate groups of compounds possessing different molecular weights (i.e., oxidized monomeric, dimeric, and polymeric FAME) (Márquez-Ruiz et al., 1990). In the case of the samples collected by Food Inspection Services mentioned above, with polar compound levels close to the limit for frying oil rejection, particularly relevant was the high occurrence of oxidized FAME monomers, approximately 30 mg/g, apart from the presence of substantial amounts of oxidized FAME dimers and polymers. Quantification of dimers and polymers directly in the oils and after transesterification of the samples revealed some insight into the complexity of the triglyceride polymer structure. The values found for the fatty acid polymers-to-triglyceride polymers ratio were very low in contrast to those for fatty acid dimers/triglyceride dimers, which ranged from 0.6 to 0.8. These data are evidence to the considerable contribution of dimeric linkages to the structures of trimeric and higher oligomeric triglycerides in this group of samples.

Applications of this latter methodology to animal studies have permitted to evaluate hydrolysis and digestibility of oxidized, dimeric, and polymeric fatty acids (Márquez-Ruiz et al., 1992, 1993; Márquez-Ruiz and Dobarganes, 1995). Following analysis of dietary oils and fecal lipids, high-digestibility coefficients were found for oxidized fatty acid monomers, thus indicating their utmost importance from the nutritional standpoint, supported also by their quantitative relevance in the diet. Polymeric fatty acids showed generally poor digestibility, in great part attributable to low activity of pancreatic lipase on triglyceride polymers.

b. Fatty Acid Composition

Besides the determination of the total content in polar FAME, the complementary analysis of the fatty acids that have not been affected by high temperature and air is also of great interest (Dobarganes and Pérez-Camino, 1985).

Analyses of fatty acid composition after different treatments at high temperature are common in studies on performance of fats and oils. However, the most usual form of expressing the results is the normalized composition (the percentage of each acid on the total of those analyzed). The first part of Table 20.2 shows the changes in major fatty acids for different refined vegetable oils before and after heating at 180°C for 20 h. From the normalized composition, the apparent increase in saturated fatty acids and the decrease in polyunsaturated fatty acids can be observed, while it is not clear why the change undergone by oleic acid that seems to decrease in palm and olive oils and to increase in sunflower and soybean oils.

This form of expression is very useful in the analysis of fats and oils when triglycerides constitute more than 95% of the total sample because it is a good quantitative measurement. However, after formation of new compounds through different reactions quantification of fatty acids becomes necessary to avoid erroneous interpretations.

Determination of total polar fatty acids by column chromatography, as commented above, or quantification of fatty acids with an internal standard (Cuesta et al., 2001; Romero et al., 2000b) is very useful to understand the real changes undergone by the different fatty acids. The second part of Table 20.2 shows the composition of the same oils expressed as wt.% on oil and calculated from the total content of remaining FAME in the samples obtained by silica column (nonpolar methyl esters) and from the normalized composition. The results indicate that the degradation took place in all the unsaturated fatty acids being greater as the fatty acid unsaturation increases. In addition, the loss of oleic acid, the only monounsaturated acid in the samples in significant amounts, was notably influenced by the content of polyunsaturated fatty acids, being higher when the content of polyunsaturated fatty acids was lower. Finally, palmitic and stearic acids remained at their initial levels. The exact loss of each fatty acid can be easily deduced by subtraction from the initial contents (Dobarganes and Pérez-Camino, 1988a,b).

Source: Adapted from Dobarganes, M.C., and Pérez-Camino, M.C., *Grasas y Aceites*, 36, 186, 1985; Dobarganes, M.C., and Pérez-Camino, M.C., *J. Am. Oil Chem. Soc.*, 65, 101, 1988. With the publisher permission.

In addition, determination of polar fatty acids by silica column chromatography in combination with fatty acid analysis has the advantage of making possible the analysis of FAME starting out from the nonpolar fraction, thus avoiding impurification of the column by oxidized and polymeric fatty acids present in the total sample, which would not elute in the gas chromatography analysis.

C. Modified Fatty Acids

The next step in the analysis of the modified compounds formed during frying is the detailed evaluation of the main constituents within the groups of monomers, dimers, and oligomers. In this respect, there is a growing interest in the oxidized monomers because of their possible nutritional implications due to their high absorbability and their presence in used frying fats at nonnegligible levels (Márquez-Ruiz et al., 1995).

In this subsection, the two main groups of modified fatty acids are considered separately:

1. Compounds with molecular weight similar or identical to those of nonmodified fatty acids (i.e., isomeric fatty acids, cyclic fatty acids, and oxidized fatty acids).
2. Polymerization compounds formed through interaction of two or more fatty acids and, thus, with molecular weights much higher than those of nonmodified fatty acids (i.e., nonpolar dimers, polar dimers, and higher oligomers).

a. Modified Fatty Acid Monomers

It is interesting to note that among the groups of modified fatty acids, isomeric fatty acids and cyclic monomers have the same polarity and molecular weight than those of nonmodified FAME and, consequently, when obtaining two fractions of different polarity by silica column they would be included in the nonpolar FAME. However, their quantitative importance as compared to the total new FAME formed as well as to the group of nonmodified FAME is minimal and therefore, quantitative results of nonpolar and polar FAME are representative of nonmodified and modified FAME.

The three groups of modified fatty acid monomers are analyzed by gas chromatography. Improved stationary phases and column design have contributed significantly in recent years to the identification and quantification of specific structures.

i. Positional and Geometric Isomers

Trans polyunsaturated fatty acids and cyclic fatty acid monomers (CFAM) are present in human diets as a consequence of heat treatment of fat and oil (Grandgirard et al., 1984; Sébédio and Grandgirard, 1989), and after catalytic partial hydrogenation. Present nutrition guidelines recommend decreasing the intake of *trans* fatty acids due to the negative effect of such fatty acids on lipoprotein metabolism (Zock and Katan, 1992). These compounds are also formed during refining. In fact, *trans* isomerization of linoleic and linolenic acids can occur during deodorization (Ackman et al., 1974; Devinat et al., 1980). For linoleic acid, isomerization mainly occurs in the Δ9 and Δ15 positions, while minor amounts of isomers with the *trans* double bond in the Δ12 are found (Grandgirard et al., 1984).

According to Sébédio and Chardigny (1996), nonnegligible quantities of linolenic geometric isomers were found in commercial oils while linoleic acid was slightly isomerized. The critical temperature at which some *trans–trans* linolenic isomers are formed is 200°C. Conjugated linoleic acids (*cis*/*trans* and *trans*/*trans* isomers of $C_{18:2}$) were also detected.

Frying different frozen foods with extra virgin olive oil, sunflower oil, and high-oleic acid sunflower oil resulted in relatively negligible amount of *trans* fatty acids (Romero et al., 2000a). The *trans*/*trans* fatty acids were higher in sunflower oil than in the monoenoic oils. Higher amount of these *trans* fatty acids were also found when a null turnover of fresh oil was performed. In that paper, it was probed that frying at 180°C was a poor source of *trans* fatty acids, and a relevant proportion of these fatty acids should come from the prefried frozen foods (Romero et al., 2000a).

In addition, when nonhydrogenated vegetable oils are used in frying of very low-fat content foods, the levels of *trans* oleic and linoleic isomers formed during frying were very low, in the order of mg/kg (Beatriz et al., 1994; Gamel et al., 1999).

ii. Cyclic Monomers

Cyclization is one of the changes occurring through frying. This alteration has been referenced to be more frequent in abused heated oils, and related to temperature, type of oil, and length of heat treatment (Sébédio et al., 1987). CFAM are basically formed in oils from linoleic and linolenic acids after heat treatment of fats and oils. The cyclization between C15 and C10 gives rise to a typical cyclohexane ring, while cyclization between C15 and C11 will produce a cyclopentane ring. Monounsaturated fatty acids are known to cyclize to monocyclic fatty acids (Figure 20.6).

The usual procedure for isolation of the cyclic fatty acids involves conversion to methyl esters followed by chromatography on silicic acid. The nonpolar fraction from such a separation is then fractionated with urea to give the cyclic FAME of up to 99% purity (Hamilton and Perkins, 1997). Since the number of positional isomers can be enormous, it is often necessary to hydrogenate the nonpolar fatty acids. This provides a simpler mixture of compounds for subsequent gas chromatography–mass spectrometry.

Adverse physiological conditions have been described in experimental animals after feeding them with increased amount of CFAM (Cuesta et al., 1988). These adverse effects were more deleterious in animals fed low levels of protein. Nonetheless, the CFAM structure seems relevant because very low toxicity of six-carbon-membered ring cyclic monomers have been suggested due to their rapid urine excretion (Iwaoka and Perking, 1978).

Many studies on the structure and formation of cyclic fatty acids were carried out heating oils under laboratory conditions (Sébédio et al., 1987) but the data from real frying conditions are less available. Available data ranged from 100 to 6600 mg/kg in most altered samples. The CFAM in different oils used to fry fresh potatoes and frozen prefried foods is summarized in Table 20.3. Frying fresh potatoes produces less CFAM content. Moreover, frequent oil addition decreases the CFAM formation with respect to null oil addition in the three oils (Romero et al., 2003, 2006a,b).

The type of CFAM formed depends on the kind of fatty acid involved. Linoleic acid in sunflower oil produces cyclic monoenes (Christie et al., 1993) while linolenic acid in linseed oil produces

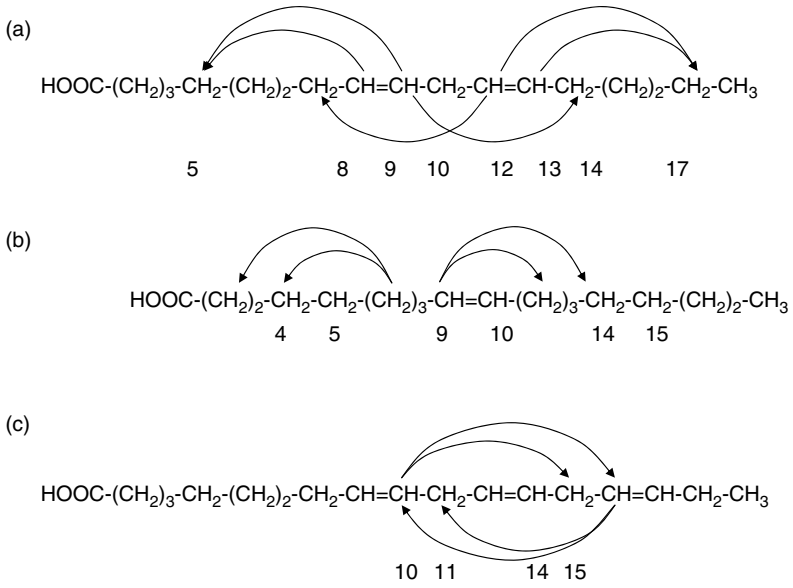

FIGURE 20.6 Possible mechanisms for cyclization: (a) oleic acid, (b) linoleic acid, and (c) linolenic acid. (Modified from Le Quéré, J.L., and Sébédio, J.L., Cyclic monomers of fatty acids. In *Deep Frying. Chemistry, Nutrition, and Practical Applications*, Perkins, E.G. and Erickson, M.D., eds., AOCS Press, Champaign, IL, 1996, p. 49. With the publisher permission.)

cyclic dienes (Mossoba et al., 1994; Dobson et al., 1995) on heating. Most CFAM formed from linoleic acid in heated sunflower oil contain a disubstituted cyclopentenyl ring. The spectra of CFAM esters, before and after hydrogenation, indicated the presence of six major structures. However, for cyclic dienes isolated from heated linseed oil cyclization was always directed internally toward other double bonds and never involved the double bond at position C12. Four major structures were identified (Le Quéré and Sébédio, 1996).

Extra virgin olive oil, high-oleic acid sunflower oil, and sunflower oil used in repeated frying show a trend to increase both cyclopentyl and cyclohexyl ring compounds (Romero et al., 2003). Bicyclic fatty acids were found in significantly higher amounts in SO than in other oils, after 20 fryings of frozen foods, with a null turnover of fresh oil (Table 20.3).

iii. Oxidized Monomers

Oxidized monomeric FAME are characterized by the presence of an extra oxygen in the molecule. They are final stable products formed from hydroperoxides and the expected major compounds are FAME containing different oxygenated groups, mainly epoxy, keto, and hydroxy (Capella, 1989).

Quantification of these compounds in heated and used frying fats has only been reported in recent years (Velasco et al., 2002, 2004a, 2005). Essential requirements of the derivatization technique selected were good repeatability and recovery of the compounds of interest, avoiding artifact formation (Berdeaux et al., 1999a). After selecting the appropriate methodology for FAME derivatization, quantification of monoepoxy compounds in thermal oxidized FAME and triglyceride model systems can be performed (Berdeaux et al., 1999b).

Two distinct mechanisms have been proposed for epoxide formation either at the site of the double bond or nearby the double bond. In the latter case, the original double bond remains (Neff and Byrdwell, 1998). However, only the compounds formed when the oxygen added across an existing double bond (Figure 20.7) were detected by combination of gas chromatography and mass spectrometry in methyl linoleate and oleate heated at 180°C. Thus, two saturated epoxides,

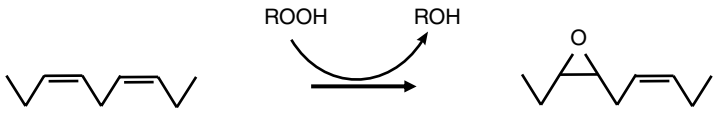

FIGURE 20.7 Suggested mechanism for epoxide formation via external hydroperoxide.

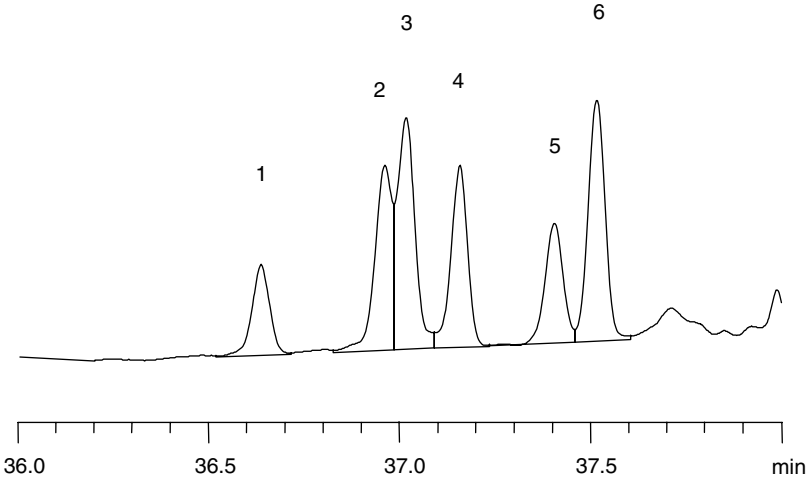

FIGURE 20.8 Partial gas chromatograms showing separation of monoepoxy FAME in used sunflower frying oil. Conditions: HP Innowax capillary column (60 m × 0.25 mm i.d.). Temperature program: 90°C (2 min), 4°C/min, 240°C (25 min). (1) *trans*-9,10-Epoxystearate; (2) *trans*-12,13-epoxyoleate; (3) *cis*-9,10-epoxystearate; (4) *trans*-9,10-epoxyoleate; (5) *cis*-12,13-epoxyoleate; (6) *cis*-9,10-epoxyoleate.

trans-9,10- and *cis*-9,10-epoxystearate, were formed from methyl oleate and four monounsaturated epoxides, *trans*-12,13-, *trans*-9,10-, *cis*-12,13-, and *cis*-9,10-epoxyoleate, from methyl linoleate (Berdeaux et al., 1999b). In the case of heated oils and fats, degradation depends on a large number of triglyceride species. As a consequence, the separation and accurate quantification of the epoxy FAME required more complex analyses and elimination of interference by minor or major components naturally present in fats and oils. After separation of nonpolar FAME by solid-phase extraction, separation, and quantification of six individual epoxy FAME present in used frying oils and fats was possible (Figure 20.8).

Quantification of epoxides in thermal oxidized olive and sunflower oils, and in used frying oils, demonstrated that, for similar levels of polar compounds, monounsaturated oils showed higher levels of monoepoxides than polyunsaturated oils. This was attributable to two concurrent facts for monounsaturated oils: first, their lower tendency to polymerize, and, second, their greater stability. Hence, accumulation of the major monoepoxides formed in monounsaturated oils (i.e., monoepoxystearates), in contrast to susceptibility to further reactions of the most abundant monoepoxides found in polyunsaturated oils (i.e., monoepoxyoleates). It was also found that monoepoxides were major oxidized compounds, accounting for about 25% of the total oxidized monomers in used frying oils at the limit of rejection (Velasco et al., 2004a).

As compared to epoxy FAME, quantification of specific structures of hydroxy FAME and keto FAME is more difficult due to the higher unsaturation of the compounds formed and the existence of conjugated double bonds in polyunsaturated molecules. Thus, from methyl linoleate, two and three conjugated double bonds are expected in hydroxy FAME and keto FAME, respectively. Figure 20.9a shows the significant part of chromatograms of polar FAME from thermal oxidized

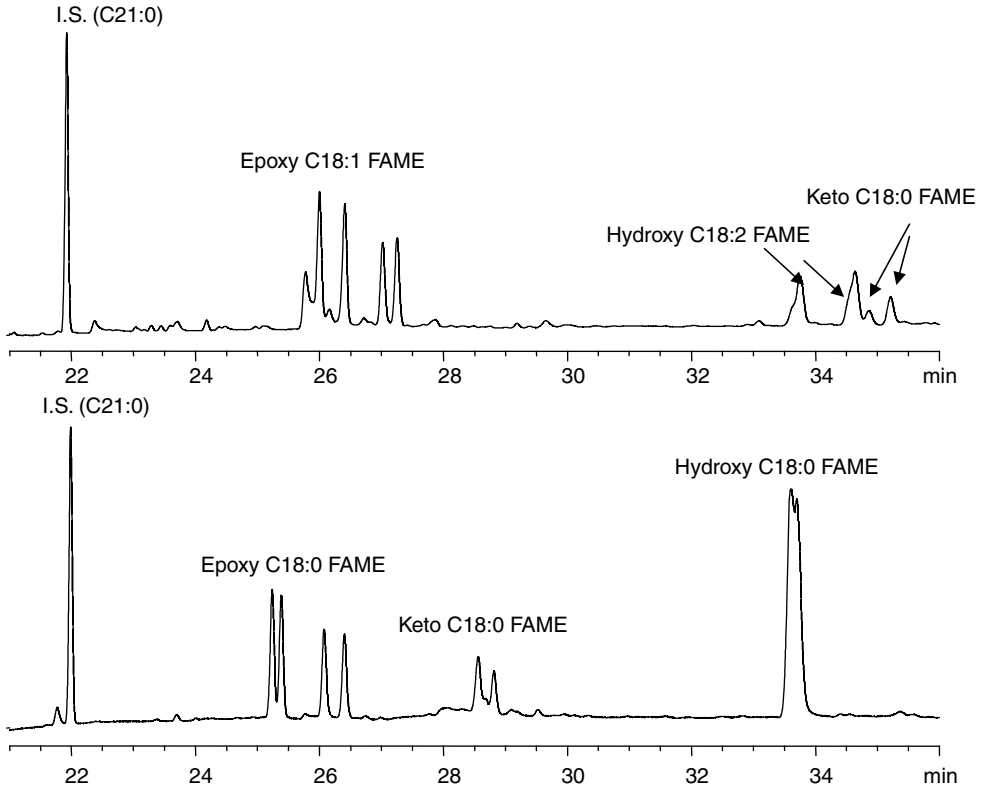

FIGURE 20.9 Partial gas chromatograms showing separation of major compounds in methyl linoleate heated at 180°C for 15 h. (a) Before hydrogenation and (b) after hydrogenation. Conditions: HP Innowax capillary column (30 m × 0.25 mm i.d.). Temperature program: 90°C (2 min), 4°C/min, 240°C (25 min).

methyl linoleate at 180°C, before and after hydrogenation. The differences between the three groups of compounds can be easily observed. The four monounsaturated epoxides are well separated while the major diunsaturated hydroxy and keto FAME elute at similar retention time. Despite the lower polarity of keto FAME as compared to hydroxy FAME, the existence of three conjugated double bonds in ketodienes increases significantly the retention time in gas chromatography. The quantification of hydroxy FAME and keto FAME can be performed after elimination of nonpolar FAME by solid-phase extraction in silica cartridges and further hydrogenation of polar FAME. In these conditions, the separation of three well-defined groups of epoxy FAME, keto FAME, and hydroxy FAME are obtained as shown in Figure 20.9b. From the analysis of used frying fats it is deduced that these three groups of compounds accounted for more than 80% of total oxidized monomers (Dobarganes, Velasco, and Marmesat, unpublished data).

Separation and identification of the main structures in FAME from used frying fats indicate that the fraction of oxidized monomers also contains significant amounts of compounds with lower molecular weight than that of the original fatty acids. Among these compounds are the short-chain n-oxo FAME, originally triglyceride-bound aldehydes, resulting from homolytic β-scission of the alkoxyl radical from allylic hydroperoxide (Kamal-Eldin and Appelqvist, 1996; Kamal-Eldin et al., 1997). The quantification of the nonvolatile aldehyde derivatives in used frying fats and fried products is of great importance from a nutritional point of view since they remain attached to the triglycerides and thus retained in the fried food ingested by the consumer. In this respect, there are some reports on 9-oxononanoic acid, the major esterified aldehyde in oxidized lipids, which indicate that such structures could induce lipid peroxidation and affect hepatic metabolism (Minamoto et al., 1988; Kanazawa and Ashida, 1991).

Methyl octanoate (C8:0), methyl 9-oxo-nonanoate (9-oxo-9:0), and dimethyl nonanodiate (C9:0 diester) were the major compounds formed in thermoxidized methyl linoleate (Berdeaux et al., 2002); besides lower amounts of methyl heptanoate (C7:0), methyl 8-oxo-octanoate (8-oxo-8:0), and dimethyl octanodiate (C8:0 diester) probably coming from 13-hydroperoxide breakdown of linoleic acid and further oxidative reactions (Berdeaux et al., 1999a) and from 8-hydroperoxide of oleic acid (Márquez-Ruiz and Dobarganes, 1996).

The quantification of C8:0 in heated and used frying fats was the first example of an accurate determination of short-chain compounds formed during thermal oxidation (Peers and Swoboda, 1982). Later, C7:0 formed from 8-hydroperoxide of oleic acid in monounsaturated frying oils was also quantified. Interestingly, the ratio between both methyl esters was very useful to deduce the extent of degradation of the main fatty acids—oleic and linoleic acids—present in edible fats and oils. In addition, it was found that the level of C8:0 + C7:0 in used frying fats—at the rejection limit of 25% polar content—ranged from 1.8 to 2.4 mg/g (Márquez-Ruiz and Dobarganes, 1996) whereas the level of total oxidized FAME found in the samples was between 28.3 and 37.7 mg/g (Márquez-Ruiz et al., 1995).

With respect to analysis of aldehydic acids and diacids, quantification of FAME derivatives has been reported (Velasco et al., 2004b, 2005). These authors showed the detailed quantification of the six major compounds (C7:0, C8:0, 8-oxo-8:0, 9-oxo-9:0, C8:0 diester, and C9:0 diester) in thermal-oxidized olive and sunflower oils as well as in used frying fats of different sources supplied by Food Inspection Services. Among them, the most abundant compounds in thermal-oxidized olive and sunflower oils were C8:0 and 9-oxo-9:0, which were derived from the 9-hydroperoxide of unsaturated fatty acids. A more significant participation of oleic acid, as the level of alteration increased, led to higher formation of the compounds derived from the 8-hydroperoxide. Used frying oils with total polar contents ranging from 18.8 to 55.5 g/100 g oil showed levels of total short-chain compounds between 2.13 and 7.56 mg/g oil. In samples with polar content around 25 g/100 g oil, the content of total short-chain compounds was close to 3 mg/g oil. These results demonstrate that these compounds were not major components of oxidized monomers in frying fats and oils as compared with epoxy, keto, and hydroxy FAME (Velasco et al., 2004b).

D. Fatty Acid Polymers

Formation of dimers and polymers during frying is also associated with the autoxidation process. They represent excellent chemical markers of oil degradation at high temperature. After obtaining the FAME derivatives, three major groups of compounds stand out: nonpolar dimers, polar dimers, and higher oligomers. The scarce information available on specific compounds and on the mechanisms of polymerization reactions has been obtained working with FAME heated under well-defined conditions, either in the absence or in the presence of air. Detailed results can be found in excellent general reviews (Figge, 1971a,b).

a. Nonpolar Dimers

Mechanisms and reactions participating in the formation of nonpolar dimers, that is, compounds formed through C–C linkages without any extra oxygen in the molecule, were studied by using FAME subjected to experimental conditions different from those normally used in frying, that is, temperatures between 200°C and 300°C and absence of air to inhibit oxidative reactions. Mass spectra of isolated dimers before and after hydrogenation gave clear evidence of the number of double bonds and rings present in the original structures by determining the parent mass peaks. Additional evidence of isomeric forms was obtained from the pattern of fragments observed (Sen Gupta, 1969; Wheeler et al., 1970; Dobarganes and Pérez-Camino, 1987; Dobarganes, 1998).

The two main routes described for nonpolar dimer formation are radical reactions involving the allyl radical and Diels Alder reactions when a conjugated double bond is present in the molecule.

Noncyclic, bicyclic, and tricyclic dimers as well as Diels Alder dimers in hydrogenated soybean oil used for frying have already been reported (Christopoulou and Perkins, 1989c). The presence of Diels Alder dimers in the low-polarity fraction isolated from heated soybean oil FAME had previously been reported by Ottaviani et al. (1979). However, at frying temperatures (below 200°C) dehydrodimers (two fatty acids linked by formation of a new bond adjacent to the double bonds) are by far the major compounds (Dobarganes et al., 1984b; Dobarganes and Pérez-Camino, 1987).

b. Polar Dimers

The structure of polar dimers is still largely unknown due to the following facts. First, different oxygenated functions are likely to be present in oxidized monomers before dimer formation, or generated by the oxidation of nonpolar dimers. Second, more than one functional group can be present in the same dimeric molecule. Finally, the oxygen may or may not be involved in the dimeric linkage. Therefore, the large number of possible combinations results in a complex mixture that is difficult to separate. Under these circumstances, studies have paid more attention to defining the composition of alteration products than to elucidating the mechanisms involved in dimer formation.

The basic knowledge on polar dimers has been obtained by heating FAME, triglycerides or fats and oils in the presence of air, or by thermal decomposition of FAME hydroperoxides. Perkins and Kummerow (1959) reported the presence of three different polar dimers corresponding to dihydroxy, trihydroxy, and tetrahydroxy dimers with C–C linkages when they subjected corn oil to thermal oxidation (200°C, 48 h) with forced aeration.

Systematic studies have been performed to increase knowledge of dimeric structures (Christopoulou and Perkins, 1989a–c). Thus, dimers from methyl stearate-containing hydroxy and keto groups were synthesized to represent structures that may be formed during the thermal oxidation of fats (Christopoulou and Perkins, 1989a). Dimers were isolated from used frying fats by size-exclusion chromatography and further separated by gas chromatography and high-performance liquid chromatography (HPLC). Identification by gas chromatography/mass spectrometry provided evidence of the presence of monohydroxy, dihydroxy, and keto groups in the C–C linked dimers of methyl linoleate, together with the previously mentioned structures of nonpolar dimers (Christopoulou and Perkins, 1989c).

c. Higher Oligomers

Definite structures for compounds with molecular weight higher than dimers have not been reported, neither in methyl esters from frying fats nor in FAME model systems. This is not strange, considering that much more research remains to be carried out on structure elucidation and quantification of simpler molecules, that is, oxidized monomers and dimers, which are intermediates in trimer and higher oligomer formation. Moreover, the potential number of different structures in trimer formation increases exponentially with respect to those compounds of lower molecular weight, as many different dimeric structures may interact with many different monomeric structures. Furthermore, the limitation of the techniques for isolation, separation, and identification increases. Nevertheless, some information has been reported on the chemical composition of the residual oligomeric fraction obtained after distillation of dimer methyl esters, solvent fractionation of polymeric material, or a combination of chromatographic techniques. In general, the results reported indicate that the polymers formed were essentially FAME dimers and trimers joined through C–C and C–O–C linkages (Williamson, 1953; Chang et al., 1978; Ottaviani et al., 1979). However, when drastic conditions were applied, even FAME pentamers were found in significant amounts (Perkins and Kummerow, 1959).

At present, the total content of triglyceride dimers and higher oligomers is quantified by HPSEC starting from the oil (IUPAC, 1992b) (Figure 20.4b). Results obtained from numerous samples have clearly shown that polymeric triglycerides constitute the major fraction among the different groups

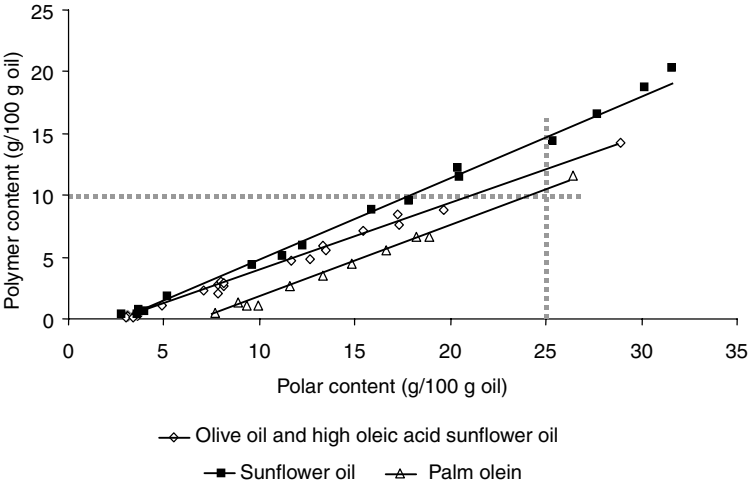

FIGURE 20.10 Relationships between polar compound and polymer contents in vegetable oils of different degree of unsaturation. (Modified from Sánchez-Muniz, F.J., and Bastida, S., *Forum Nutr.*, 56, 345, 2003. With the publisher permission.)

of alteration compounds formed during frying, normally accounting for more than 50%, and their levels have been found to correlate well with those of polar compounds (Perrin et al., 1985; Masson et al., 1997). Sánchez-Muniz and Bastida (2003) found that the 25% polar material content in palm olein correspond to a polymer level of about 10%, while the same polar material level in sunflower oil approximately correspond to a 15% polymer content. In monounsaturated oils, 25% polar content correspond to about 12% polymer content (Figure 20.10).

Some European countries have selected the level of polymers (10% or 16%) as a cut-off point, after which oil must be discarded (Firestone, 1996). Given the simplicity of the HPSEC technique, determination of polymers has been recently proposed as a general good method to control the quality of used frying fats. A maximum content of 12% has been suggested for discarding used frying fats (DGF, 2000).

Identical methodology is applied for quantification of dimers and oligomers starting from FAME derivatives, and finally combination of adsorption chromatography and HPSEC allows independent quantification of three groups of FAME (i.e., nonpolar dimers, polar dimers, and higher oligomers) (Márquez-Ruiz et al., 1990, 1995). However, owing to the complexity of the polymerization compounds, quantification of specific structures of dimers and oligomers has not been possible until now. It is expected that improvements in liquid chromatography systems contribute to the increase in the knowledge on this group in the near future.

As an example, Table 20.4 summarizes the most complete information that can be obtained for modified fatty acids in used frying oils and fats (Márquez-Ruiz et al., 1995; Velasco et al., 2004a,b, 2005). The results correspond to the analysis of samples supplied by Food Inspection Services with levels of polar compounds around the limit of used frying oil rejection (25% polar compounds). As can be observed, the level of modified fatty acids is around 10%. From this total content, around 65% correspond to FAME dimers and higher oligomers and 35% to FAME monomers. Among the latter group, epoxy, keto, and hydroxy FAME are major compounds while the short-chain acids are in much lower amounts.

IV. FAT AND OIL TRANSFER DURING FRYING

Food quality is greatly affected by the quality of used frying fats and oils although the influence of the food being fried on the quality of the frying oil may be of similar importance. Frying implies a

mass transfer involving a partial exchange between the oil in the pan/fryer and the water/fat in the interior of the food (Ramanna and Sen, 1983; Varela, 1988) (Figure 20.2).

In this section, general modifications on both food fatty acid content and profile and the fatty acid transfer between the food fat and the cooking oil/fat will be described.

A. Food Fatty Acid Changes

The selection of oil seems to be a very important fact because the profile of the fried food may, thus, reflect a more suitable final saturated/monounsaturated/polyunsaturated fatty acid ratio (Sánchez-Muniz et al., 1992a; Sánchez-Muniz and Bastida, 1997; García-Arias et al., 2003).

García-Arias et al. (2003) studied the changes produced by deep-fat frying in the fatty acid composition of chicken meat and chicken-based products, and found that frying with olive oil and sunflower oil increased the percentage of oleic acid and linoleic acid, respectively, in chicken meat. These increases were higher in chicken burgers than in chicken sausages. According to that study, the final fat and fatty acid content of fried chicken and fried chicken-based products depends on (1) the fat content of the raw product, (2) the presence of an edible coating that limits the penetration of fat during frying, and (3) the composition of the oil used.

Sardines fried in olive oil became greatly oleic acid-enriched, while their n-6/n-3 ratio varied moderately from that of their raw counterparts. Sardines fried in sunflower oil, on the other hand, displayed a significant increase in the linoleic acid content and with the n-6/n-3 ratio varying greatly (Sánchez-Muniz et al., 1992a).

Results of these two last studies are of nutritional importance because, according to Varela and Ruiz-Roso (1998), a large percentage (more than 50%–60%) of the fat consumed in the Mediterranean countries comes from culinary oils/fats. Cooking performed with monounsaturated oils enriches the diet in oleic acid, whereas frying with corn, sunflower, safflower, or soybean oils produces linoleic acid-enriched diets. In the same way, culinary use of saturated oils such as palm olein, employed extensively in the sweet roll or prefried food industry (Pantzaris, 1999) implies a palmitic acid enrichment of the diet (Cuesta et al., 1998).

These findings are very important because lipoprotein metabolism, and therefore the cholesterol and low-density lipoprotein (LDL) level, can be modulated by the type of fatty acids available in the liver, which in turn depends on the predominant dietary fatty acids consumed (Dietschy, 1998). According to Dietschy (1998), unsaturated fatty acids (oleic acid more than linoleic acid) increase gene expression of LDL receptors, maintaining the amount and activity of these receptors high and, thus, decreasing the concentration of serum LDL, while palmitic acid in the liver maintains gene expression of LDL receptors low and serum LDL concentration high.

As frying thoroughly changes the fatty acid composition of food, Sánchez-Muniz et al. (1992b, 1996) studied whether the hypolipidemic properties of fatty fish remain intact after frying. Data of both studies indicate that consumption of fried sardines by hypercholesterolemic rats induced both hypotriglyceridemic and hypocholesterolemic effects. Moreover, hypercholesterolemic rats fed fried sardines displayed much lower levels of some cell-damage markers than their respective basal counterparts; probably related to a more balanced n-6/n-3 ratio in cells of rats given the fried sardine diet. It has also been found that growing Wistar rats recover more quickly from hypercholesterolemia when they were fed whole olive oil-fried sardines as the only dietary source of protein and fat, instead of casein plus fat extracted from olive oil-fried sardines or casein plus olive oil (Sánchez-Muniz et al., 2003).

Cooking–freezing–reheating (CFR) has become an alternative system of handling foods in catering, where the prepared food is either frozen or chilled before the reheating procedure is carried out shortly prior to eating (Skjöldebrand, 1984). Thus, in addition to the frying itself, other culinary maneuvers can modify the food fatty acid composition. García-Arias et al. (2003) studied the effect of CFR on fat content and fatty acid composition of sardine fillets using three different ways of cooking (frying, oven-baking, and grilling) and two reheating systems (conventional and

microwave ovens). Both cooking and freezing–reheating significantly affected the fat content. Frying significantly affects the fatty acid composition of sardine, increasing oleic acid and linoleic acid contents. Freezing–reheating significantly affected the fatty acid composition of sardine, increasing oleic and linoleic acids and decreasing eicosapentaenoic and docosahexaenoic acids. Oven-baking and grilling minimally affected the fatty acid content. Freezing–reheating significantly affected the fatty acid composition with the content of oleic acid increasing and those of the n-3 fatty acids decreasing more in microwave oven-reheating than in conventional oven-reheating. Thus, according to the positive effect attributed to n-3 fatty acids, cooked samples with no further treatment would be preferred to their respective CFR counterparts. However, oven-reheating should be used instead of microwave oven-reheating when the CFR system is performed.

B. Fat Interchange during Deep Frying of Fatty Foods

From a quantitative point of view, composition of used frying oils and fats is mainly affected by mixture with fats or lipids from foods that migrate to the frying medium. Two different types of fatty foods can be considered separately; on one hand, fresh fatty foods, that is, fish or meat, normally coated by batter or bread before frying, and hence characterized by a low content of lipids on their surface and, on the other hand, the increasing group of frozen prefried foods (potatoes, fish, vegetables, etc.) where the fat or oil used for prefrying is mainly located on the surface. Lipid exchanges as well as final lipid composition and quality might be very different in both groups.

a. Fresh Fatty Foods

As previously commented, during frying the crust formation occurs. Great differences can be found in lipid composition depending on the method of frying, type of food, and surface composition (i.e., batter, bread, or uncoated food) (Figure 20.3). It has been found that battered fish absorbed less fat than breaded fish. The reason seems to be the rapid formation of a crust that prevents the transfer of oil and water into the battered food while the amount of coating in breaded fish is much lower and less protective (Makinson et al., 1987).

As a consequence of a variable fat absorption, it is difficult to foresee the fatty acid composition of the final product. The higher the amount of oil absorbed, the better the final lipid composition reflects that of the frying fat and the higher the energy density of the food.

During frying, changes in fatty acid composition of used frying oils occur (Dobarganes et al., 2000b) (Figure 20.2). Thus, food can be enriched in some altered and nonaltered fatty acids during frying; therefore, the altered compounds present in it. This fact can change both food digestibility and nutrient utilization (Cuesta et al., 1988; Márquez-Ruiz et al., 1993; Márquez-Ruiz and Dobarganes, 2006; González-Muñoz et al., 1998, 1999, 2003). Moreover, the altered compounds undergo intestinal absorption and thus may present potential toxicity. For general information on this subject see reviews (Márquez-Ruiz and Dobarganes, 2006; Sánchez-Muniz and Sánchez-Montero, 1999).

Some authors (Garrido-Polonio et al., 1994; Pokorný, 1998, 1999) have suggested that slightly higher concentrations of these altered compounds are present in food than in the oil media. Pokorný (1999) indicated that oxidized and other polar lipids enter the fried material relatively more easily than the original frying oil.

The possible diffusion of food lipids into the frying oil during the process is also important from the nutritional point of view. Lipid interchange is obvious in foods such as meat or chicken whose lipid content after frying might even be lower than before frying (Henry, 1998) but exchanges occur as a general fact during frying of fatty foods, as demonstrated by the presence of minor compounds (i.e., cholesterol, phospholipids, vitamins, etc.) of food lipids in the frying oil. Thus, it has been clearly shown that fatty fish release fat during frying (Sánchez-Muniz et al., 1992a). As fish oil contains long-chain polyunsaturated fatty acids, the frying oil can be relatively rapidly deteriorated when frying. Nonetheless, frying with lard or sunflower oil increased the oxidized FAME more

in the fryer oil than when frying with olive oil (Sánchez-Muniz et al., 1990, 1992a). Hamburgers contain high percentage of fat as well, which may be delivered to the frying oil. During frying of animal foods, cholesterol can diffuse to the frying oil/fat and contaminates it with decomposition or oxidation products as well.

Surprisingly, there is no information on lipid transfer during frying of fish in detailed studies (May et al., 1978; Gall et al., 1983; Sánchez-Muniz et al., 1992a) even though lipid exchanges can be easily calculated from the fat content and fatty acid compositions of the foods before and after frying (Pérez-Camino et al., 1991). Reinterpretation of the results obtained from the quoted papers would indicate that a significant percentage of the initial food lipids had passed into the frying medium, mainly from fish with high lipid content. A similar conclusion is deduced from the analysis of fatty acid composition of used frying oils after a high number of frying operations (Sébédio et al., 1993). Consequently, from a nutritional point of view, great care should be taken regarding the composition of the dietary fat ingested as both absorption of the frying oil and migration of lipid into the fryer would contribute to modify the fatty acid composition of the finished fried product, which may be far different from that of the initial food.

Transfer of polar substances and their degradation products from the substrate to the frying oil may either protect the oil against oxidation or increase its alteration level (Sánchez-Muniz and Bastida, 2006). Transport of substances through the surface of fried substrate is inhibited by batter; however, particles separated from the batter in oil soon get deep colored by pyrolitic reactions, and contribute to frying oil degradation.

b. Frozen Prefried Foods

Lipid exchanges in frozen prefried foods are of special interest as the lipid constituents have two specific characteristics:

1. Prefried products contain significant amounts of absorbed used frying fat or oil of unknown composition and quality, depending on the variables of the prefrying process.
2. As a consequence of the previous frying process, the oil is preferably located in the external layers of the food and thereby is in close contact with the frying oil during the second frying operation.

Fat absorption, lipid exchange, and possibilities of preferential adsorption of polar compounds on food surface during frying of frozen prefried foods have been studied in detail (Thomson and Aust, 1983; Sébédio et al., 1990; Pérez-Camino et al., 1991; Pozo-Díaz et al., 1995; Romero et al., 2000a; Cuesta et al., 2001).

Thus, similar fatty acid profiles were found for the oil and the food fried in it, indicating that lipid exchange was very high. When the fatty acid profile of the frozen prefried food and that of the oil used for frying were very different, both the initial lipids remaining in the fried product and those being transferred to the frying oil could be calculated with high accuracy. Irrespective of the oil used and of the prefried food subjected to frying, more than 90% of the fried food lipids came from the frying oil while more than 85% of the prefried food lipids were released into the frying oil (Pérez-Camino et al., 1991). It has also been reported in prefried frozen potatoes that after being fried with high-oleic acid sunflower oil showed that 89%–93% of their fat belonged to the frying oil, while frozen potatoes transferred between 76% and 84% of their initial fat to the bath oil. These figures were 90%–93% and 55%–70%, respectively, when frying with sunflower oil (Romero et al., 2000b; Cuesta et al., 2001).

With respect to the preferential adsorption of polar compounds, no differences was found between the fat food and the oil; although slightly higher values have been reported for the food fat. Thus, Romero et al. (2006b) show that polar material compounds in high-oleic sunflower oil and in the fat extracted from frozen potatoes fried in this oil changed very similarly in repeated fryings

whereas in the case of conventional sunflower oil, the fat extracted from frozen potatoes fried in sunflower oil remains about 1.2–2.5 mg/100 mg higher than in the oil counterpart. Nonetheless, polymers changed very similarly in oils and in the fat extracted from fried potatoes. These results show the benefits of frying potatoes in the monounsaturated oil with respect to the polyunsaturated one because less alteration compounds are formed in the oil and absorbed by the food during frying.

No preferential adsorption of *trans* fatty acids can be deduced from the study of Romero et al. (2000a), although the content of these fatty acids tend to be higher in the fat extracted from frozen potatoes fried in different oils. A percentage of these fatty acids already present in the raw frozen prefried food are retained by the food during the frying. Thus, differences between fried food and oil/fat are not related to *trans* fatty acid formation during frying and/or preferential adsorption. Nonetheless, *trans* fatty acids appear in lower amounts than 5 mg/g in frozen potatoes fried in different oils but data suggest that frequent addition of fresh oil vs. the null addition minimizes the fatty acid alteration contributing to obtain fried foods with less amount of *trans* fatty acids. The consumption of a large ration of those fried potatoes would imply the irrelevant amount of less than 0.13 g of *trans* fatty acids.

Altered fatty acids increased linearly through 20 fryings within frequent and null oil additions in the frying oil and in the fat extracted from fried frozen foods. As expected, changes tend to be higher in the extracted fat of food fried by the null oil addition modality as a consequence of the absence oil renovation and fat exchange between the frying oil and the food. In addition, changes tend to be more evident in the food-extracted fat (Romero et al., 2000b; Cuesta et al., 2001).

Table 20.5 shows changes in significant fatty acids after frying prefried potatoes, prefried hake, and sardines in olive oil to remark the differences between fresh fatty foods and prefried foods. As can be observed, the amounts of selected fatty acids in the fried potatoes and hake were very similar to those present in olive oil while in the case of sardines almost 50% of their characteristic fatty acids ($C_{14:0}$ and $C_{22:6}$) remained in the fried product (Pérez-Camino et al., 1991; Dobarganes et al., 2000b).

C. Food Matrix–Cooking Oil/Fat Interaction

Much attention has been paid to changes occurring in the frying oil but much less to changes occurring in the fried substrate due to interactions between frying oil and food matrix. Thus, apart from oil thermal oxidation and fat exchange, the free peroxy radicals and hydroperoxides, as well as

TABLE 20.5
Quantification of Significant Fatty Acids (g/100 g Lipids) before and after Frying Different Fatty Foods in Olive Oil

Sample	C14:0	C18:1	C18:2	C22:6
Before frying				
Olive oil	—	76.3	8.3	—
Prefried potatoes	—	40.9	2.9	—
Prefried hake	—	28.9	52.8	—
Sardines	6.6	13.2	1.2	11.5
After frying				
Potatoes	—	73.4	7.9	—
Hake	—	72.3	11.2	—
Sardines	3.1	47.9	2.8	6.0

other secondary oxidation products may react with the substrate, particularly with thiol, sulfide, disulfide, and primary amine groups of proteins. They are deactivated, and partially remain attached to the protein moiety (Pokorný, 1998, 1999). The protein matrix has great effect on fat transfer. Hamburgers have relatively unstable fat fraction and course protein matrix, thus an easy fat uptake can be expected. In sausage, on the contrary, the fat fraction is relatively stable and meat protein matrix is dense; thus, much lower fat exchange and fat–matrix interaction may occur (Tornberg et al., 1989).

In addition, starch present in vegetable react with oxidized frying oil as well as polypeptides or protein, forming interaction products where triglycerides are bound to starch macromolecules in several ways (i.e., by ether bonds) (Fedelli et al., 1983). According to Pokorný (1998), the frying oil was oxidized more rapidly when frying starch-rich substrates than when frying protein-rich ones. This inhibition could be due to reactions of lipid peroxides with amino acid residues.

V. FINAL REMARKS

Evaluation of all changes occurring in fats and oil fatty acids during frying is a difficult task due to the complexity of the reactions involved and the great variety of compounds formed depending on the frying conditions. Still, efforts made during the past two decades to develop chromatographic techniques have enabled us to gain useful information on the nature and levels of modified fatty acids. Overall, used frying oils and fats close to the limit of rejection, with levels of polar compounds around 25%, contain normally levels of around 10% modified fatty acids. Even though the major part of them is composed of fatty acid dimers and higher oligomers, a relevant proportion are oxidized fatty acid monomers. Among the latter group, epoxy, keto, and hydroxy function compounds are predominant while short-chain acids are present in much lower amounts. In this context, much work remains to be carried out to clarify the specific structures of the new modified fatty acids resulting from frying and to evaluate their nutritional implications at the levels normally found in used frying fats and oils and fried products.

As to the frying methods, while information is abundant on deep-fat frying performed in fryers, less data are available on pan frying, which is the frying method most commonly used in household. Moreover, determination of differences between shallow and deep frying has to be studied in more detail. The accessibility of oxygen is much greater in the former inducing probably earlier hydroperoxide formation.

On the other hand, changes produced in the fryer oil have been more extensively studied than those occurring in food nutrients and minor compounds, or interactions between the frying oil and the food fat and matrix. Since it has been reported that the alteration level could be similar in the fat food than in the corresponding frying oil, special care should be taken when performing frying or cooking with low-stability oils. It is clear that frequent addition of fresh oil is recommended because it decreases the oil alteration, and hence helps to obtain safer foods. Finally, frying with monounsaturated oils rather than with polyunsaturated ones is also recommended to get an adequate balance between nutritional properties (e.g., fatty acid composition) and thermal oxidation stability.

21 Consumption of Fatty Acids

Sue Joan Chang and Ching Kuang Chow

CONTENTS

I. INTRODUCTION

With improving economy and abundant food supply, excess food intake has been strongly linked to the increasing epidemic proportion of overweight or obesity in the United States in recent decades. Obesity is an important risk factor contributing toward the development of leading causes of death, such as cardiovascular disease, cancer, and diabetes, in the United States (Engelhart et al., 2002; Ernst et al., 1997; Hu et al., 2000; U.S. Department of Health and Human Services, 2001). The medical expenses and lost productivity resulting from these diet-related diseases are already very high, and are continuously increasing at a rapid rate (Heffler et al., 2002; Westerhout, 2006).

Dietary fat serves a number of important functions and is essential for normal growth and maintenance. However, the energy density of fat (9 kcal/g) is much higher than that of protein and carbohydrate (4 kcal/g). Therefore, dietary fat is often blamed as the major source of excess energy, although it is difficult to differentiate the effects of dietary fat and other energy nutrients independent of total energy intake (Arab, 2003). Evaluating trends in energy nutrient intake is important in understanding the role of individual energy nutrient in the development of obesity and obesity-related illness over time. In addition to quantity, the type of dietary fat consumed is also an important factor contributing to the development of cardiovascular disease, cancer, diabetes, and other degenerative

diseases (Das, 2000; Grundy, 1997; Larsson et al., 2004; Slattery et al., 1997; von Schacky et al., 1999). This chapter focuses on the consumption of total fat and major fatty acids in the U.S. populations. For information concerning dietary *trans* fat, fish oil, and other specific types of fats/oils, please refer to the respective chapters in this volume.

II. NATIONWIDE DIETARY INTAKE SURVEYS

For over a century, the U.S. Department of Agriculture (USDA) has maintained a nutrition monitoring system for the U.S. population. A dietary surveillance program conducted by the Food Surveys Research Group, Agricultural Research Service (ARS), USDA, known as the *Continuing Survey of Food Intakes by Individuals* (CSFII), measures foods actually eaten by individuals over a specific period of time (e.g., two nonconsecutive 24-h dietary recalls in the CSFII 1994–1996) (U.S. Department of Agriculture, 1998; U.S. Department of Health and Human Services, 2006a,b). The survey also collects demographic information, such as household size, income, race, age, and sex, and information on where a food was purchased, how it was prepared, and where it was eaten. Therefore, CSFII data are useful in policy formation, regulation, program planning and evaluation, education, and research. The CSFII data provide up-to-date information on food intakes by Americans. In addition, CSFII monitors diet quality and changes over time in the food choices Americans make and the adequacy of their diet. This can be done, for example, by comparing intake data obtained from the CSFII 1994–1995, the Nationwide Food Consumption Survey (NFCS) 1977–1978, and the CSFII 1989–1991. NFCS is another food consumption survey program of USDA. The CSFII 1994–1996 targeted population in all 50 States vs. the 48 conterminous States in the NFCS 1977–1978 and CSFII 1989–1991.

Snice 1960, the National Center for Health Statistics, Division of Health Examination Statistics, Center for Disease Control and Prevention, and U.S. Department of Health and Human Services (USHHS) have conducted a unique series of health and nutrition surveys, known as *National Health and Nutrition Examination Surveys* (NHANES), to obtain health examination data periodically, and in recent years on a continuous basis. The major objectives of the NHANES include (1) estimation of the number and percentage of the population with selected diseases and risk factors; (2) monitoring of trends in the prevalence, awareness, treatment, and control of selected diseases; (3) monitoring of trends in risk behaviors and environmental exposures; (4) analysis of risk factors for selected diseases; (5) study of the relationship between diet, nutrition, and health; (6) exploration of emerging public health issues and new techniques; (7) establishment of a national probability sample of genetic material for future research; and (8) establishment and maintenance of a national probability sample of baseline information on health and nutritional status (U.S. Department of Health and Human Services, 2006a). NHANES provides an ideal setting for collecting high-quality representative data on the health and nutrition data of the U.S. civilian, noninstitutionalized population, and is the most comprehensive and best to represent the changing trend of nutrient intake in the United States.

The first NHANES includes data collected during 1971–1974, the second NHANES during 1976–1980, the third NHANES during 1988–1994, and the fourth one during 1999–2000. New nationwide dietary intake data for the years 2001–2002 have become available for public use. The first NHANES studied persons residing in the contiguous 48 states, and the subsequent NHANES deal with population in all 50 states. All of the surveys consist of a household interview followed by an examination at an examination center, and include a dietary recall interview conducted at the examination center to obtain information on all foods and beverages consumed during the preceding 24 h. The upper age limit is 74 years at the time of the household interview for the first two NHANES (1971–1974 and 1976–1980), and no upper age limit is established for the subsequent NHANES.

In order to examine the changes in dietary intake over time, the analysis of data obtained from the NHANES is restricted to subpopulations consistently sampled in the years available and for which the basic variables of interest are collected. Thus, the analysis included only adults aged

20–74 years to compare estimates across all surveys (Wright et al., 2004). Because of differences in the relative age distribution, estimates for persons aged 20–74 years are adjusted by direct standardization to the 2000 U.S. Census population by using the age groups of 20–39, 40–59, and 60–74 years. The recommended age categories used are based on the survey sample domains (U.S. Department of Health and Human Services, 2005). Persons who reported fasting during the preceding 24 h are excluded from these analyses. Sample weights and design variables are analyzed statistically to generate national estimates (U.S. Department of Health and Human Services, 2006b).

The two nationwide dietary intake surveys, USDA's CSFII and USHHS's NHANES, which collect national dietary intake data, were integrated in 2002 (Dwyer et al., 2001, 2003). Under the integrated framework, USHHS is responsible for the sample design and data collection, and USDA is responsible for the survey's dietary data collection methodology, maintenance of the databases used to code and process the data, and data review and processing. The new integrated survey, also known as *What We Eat in America*, is to collect dietary intake data on a continuous yearly basis. The collection process for foods in the integrated survey consists of an in-person 24-h recall using a computerized five-step method and a second nonconsecutive 24-h recall via telephone. A food frequency questionnaire, which was pilot-tested, is to provide information on the propensity to consume certain foods. Dietary supplement intakes over the past 30 days are assessed for all persons during the household interview (Dwyer et al., 2003). Strengths of the integrated survey include information on food and supplement intakes in a representative sample of the civilian noninstitutionalized population of the United States that can be linked to anthropometric, biochemical, clinical, and disease history information in NHANES (U.S. Department of Health and Human Services, 2006a,b). As discussed in *What We Eat in America*, food intake data are linked to health status data from other NHANES components, the relationship between dietary intake and health state can be explored.

The self-reported data obtained from CSFII and NHANES are subject to recall bias, and changes in the 24-h dietary recall interview method between two different periods may account for some of the differences in average energy intake occurred. In addition, beginning in 1988, dietary recall data are collected for weekend days as well as weekdays because food consumption differs on weekend days. The revised interview format and added questions may allow for collection of more complete dietary intake data than earlier surveys. Since 1980, the U.S. Government has published dietary recommendations, known as *Dietary Guidelines for Americans*, issued jointly by the USDA and USHHS (U.S. Department of Health and Human Services, 2005). On the basis of the information obtained from these dietary intake surveys, the Dietary Guidelines for Americans recommends a reduced consumption of total fat and saturated fat as a way to reduce the risk of chronic diseases.

III. INTAKE OF TOTAL FAT AND FATTY ACIDS IN THE UNITED STATES

The mean total energy intake from individual energy nutrients, carbohydrates, protein, and fats by weight, and percentage of energy contributed by individual energy nutrients, total fats, as well as by saturated, monounsaturated, and polyunsaturated fatty acids among U.S. population, obtained by the NHANES during the period of 1971–2002, and CSFII during 1994–1996, are summarized below.

A. Mean Total Energy Intake

The mean total energy intake in kilocalories (kcal) of the first four NHANES is shown in Figure 21.1. As expected, the mean total energy intake was higher in men than in women during 1971–2000. The average energy intake increased significantly from the period of 1971–1980 to 1988–2000 for both men and women. The average energy intake increased from 2450 kcal to 2618 kcal ($p < .01$) for men, and from 1542 kcal to 1877 kcal ($p < .01$) for women (Wright et al., 2004). The increase in caloric intake is consistent with previously reported trends in dietary intake in the United States

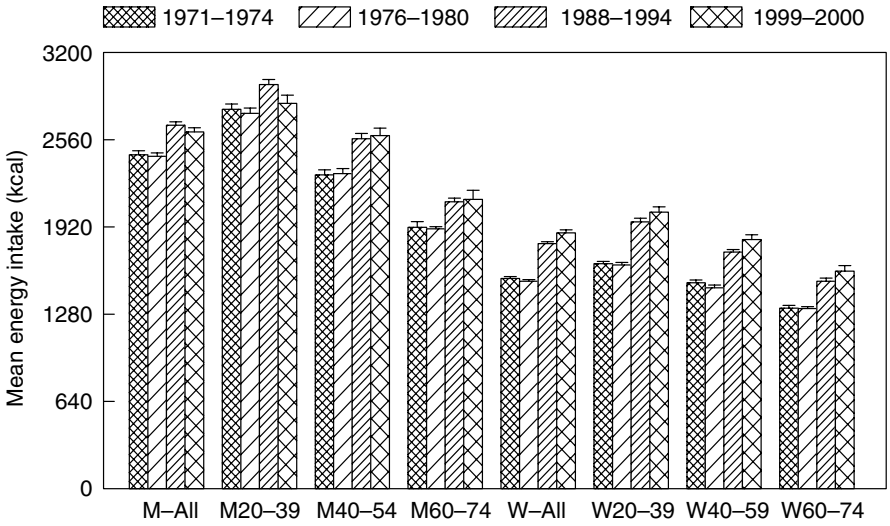

FIGURE 21.1 Estimated mean energy intake among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1976–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). M represents men; W, women; all, all subjects; 20–39, subject age 20–39; 40–59, age 40–59; and 60–74, age 60–74.

(Federation of American Societies for Experimental Biology, 1995). The estimated total energy intake includes kilocalories from alcoholic beverages, which ranged from 2.5% to 4.5% for men and from 0.5% to 2.0% for women (Wright et al., 2004).

B. Mean Energy Intake from Carbohydrates, Proteins, and Fats

The mean energy intake contributed by individual energy nutrients, carbohydrate, protein, and fats, in kcal is shown in Figure 21.2. The energy intake from carbohydrate increased from the period of 1971–1980 to 1988–2000 for both men and women, while energy intake from protein changed little during the same period. The mean energy intake from total fat and saturated fat decreased slightly for men, while those of women increased during the period. Similarly, USDA food consumption survey data from the CSFII 1989–1991 and CSFII 1994–1996 indicate that the increased energy intake was caused primarily by higher carbohydrate intake, with a 62.4-g increase among women ($p < .01$) and a 67.7-g increase among men ($p < .01$) (Chanmugam et al., 2003). The survey data for the period between 1977 and 1996 suggest that factors contributing to the increase in energy intake in the United States include increased consumption of food away from home or increased energy consumption from salty snacks, soft drinks, and pizza (Nielsen et al., 2002), and increased portion sizes (Nielsen and Popkin, 2003).

Similar trend was found for USDA's data on the disappearance of the fats and oils as well as domestic per capita consumption for fats and oils from 1970 to 1995 (Putnam and Allshouse, 1997). Although disappearance data tend to overestimate consumption, by keeping track of disappearance trends over time, relative changes in fats and oils consumed can be determined. In 1995, total fat and oil consumption was composed of approximately 85% vegetable oils and 15% animal fats. Per capita animal fat and oil consumption decreased 28% from 14.1 to 10.2 pounds between 1970 and 1995. During the same period, vegetable oil consumption increased 40% from 38.5 to 53.9 pounds. Thus, despite declines in animal fat consumption, total fat and oil consumption actually rose 22%

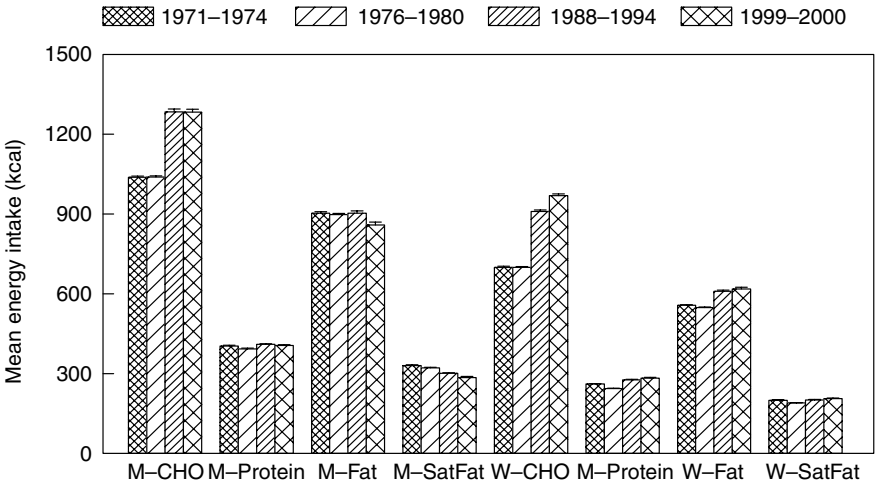

FIGURE 21.2 Estimated mean energy intake from carbohydrate, protein, total fat, and saturated fat among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1876–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). M represents men; W, women; CHO, carbohydrate; and SatFat, saturated fat.

from 52.6 to 64.1 pounds during this period. In addition, since 1970, butter per capita consumption decreased 17% to 4.5 pounds in 1995, and margarine consumption declined 15% from 10.8 to 9.2 pounds. Recent reports of the adversary biological effect of *trans*-fat, however, are likely to shift margarine consumption to butter (Allison et al., 1999).

C. Percentage of Energy Intake from Carbohydrates, Proteins, and Fats

The percentage of energy intake contributed by carbohydrates, proteins, and fats is summarized in Figure 21.3. The percentage of kcal from carbohydrate, between 1971–1974 and 1999–2000, increased from 42.4% to 49.0% ($p < .01$) for men, and from 45.4% to 51.6% ($p < .01$) for women. The percentage of kcal from protein decreased from 16.5% to 15.5% ($p < .01$) for men and from 16.9% to 15.1% ($p < .01$) for women between 1971–1974 and 1999–2000. The percentage of kcal from total fat decreased from 36.9% to 32.8% ($p < .01$) for men and from 36.1% to 32.8% ($p < .01$) for women. The decrease in the percentage of kcal from fat during 1971–1991 is attributable to an increase in total kcal consumed as absolute fat intake in grams was actually increased (Ernst et al., 1997). Total fat intake in grams increased among women by 6.5 g ($p < .01$) and decreased among men by 5.3 g ($p < .01$) during this period. Data from NHANES for 1971–2000 indicate a similar trend (Wright et al., 2004).

D. Percentage of Energy Intake from Total Fats

The percentage of energy intake contributed by total fats is shown in Figure 21.4. The percentage of energy from total fat changed from 36.9% (1971–1974) to 36.8% (1976–1980), 33.9% (1988–1994) and 32.9% (1999–2000) for men, and from 36.1% to 36.0%, 33.4% and 32.8% for women. For both men and women, the rate of decline accelerated between 1985 and 1990. Average daily fat consumption for women is 73.3 g in spring of 1977, and declined significantly by 3.7 g in 1985. Average fat consumption for women decreased significantly by an additional 7.5 g to 62.2 g per day

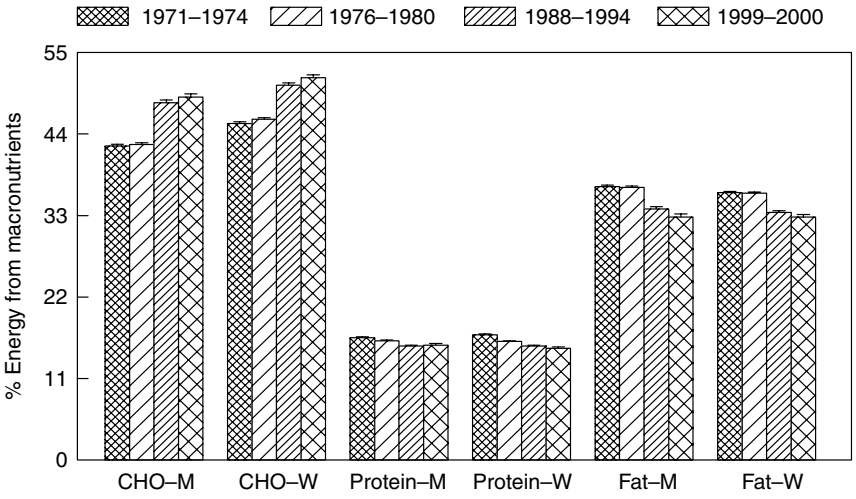

FIGURE 21.3 Estimated percentage energy intake from carbohydrate, protein, and fat among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1876–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). CHO represents carbohydrate; M, men; and W, women.

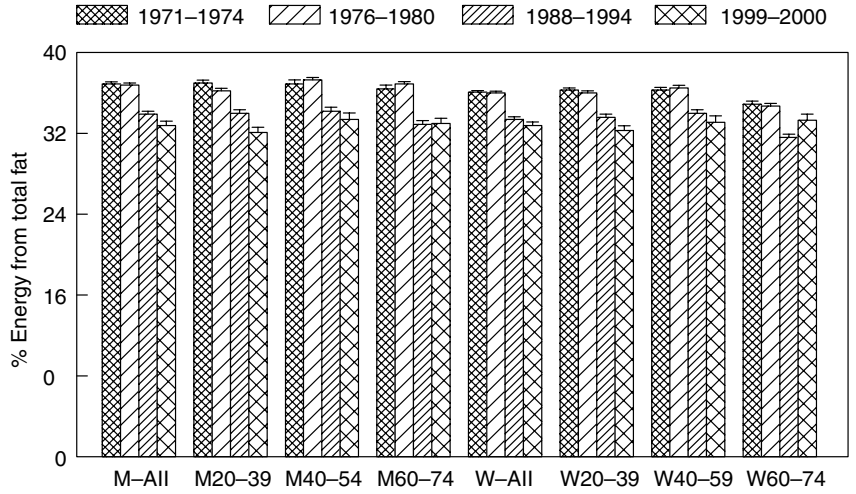

FIGURE 21.4 Estimated percent energy intake from total fat among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1876–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). M represents men; W, women; all, all subjects; 20–39, subject age 20–39; 40–59, age 40–59; and 60–74, age 60–74.

during 1989–1990. For men, fat consumption in summer 1977 was 112.8 g per day, and declined significantly by 5.3 g by 1985, and decreased to 92.6 g by 1989–1990 (Lichtenstein et al., 1998). In each of the age and gender groups reporting consumption of 30% or less of energy from fat, and less than 10% of energy from saturated fatty acids. Fat-modified foods play a more important role in their diets than for people who are consuming higher levels of fat and saturated fat. As a result

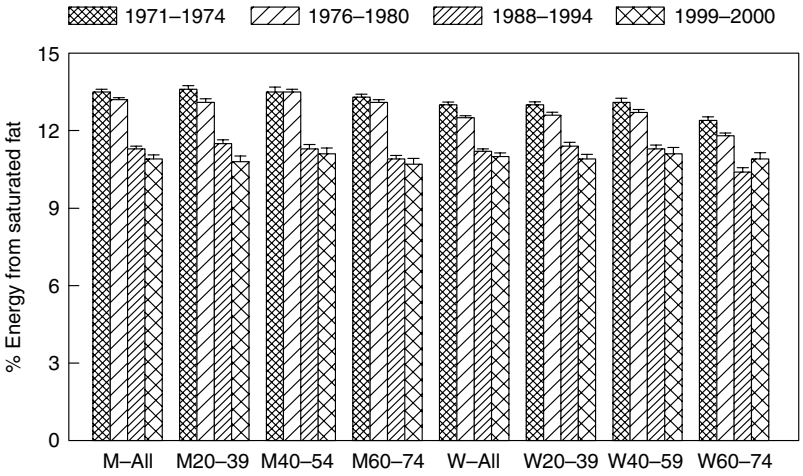

FIGURE 21.5 Estimated percent energy intake from saturated fat among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1876–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). M represents men; W, women; all, all subjects; 20–39, subject age 20–39; 40–59, age 40–59; and 60–74, age 60–74.

of increased consumer awareness of the link between dietary fat and risk of heart disease, annual per capita consumption of added fats and oils declined 7% between 1993 and 1997 (Putnam and Allshouse, 1997).

E. Percentage of Energy Intake from Saturated Fats

The percentage of energy intake derived from saturated fats is summarized in Figure 21.5. As the figure shows, estimated percentage of energy intake from saturated fats decreased from 13.5% in 1971–1974 to 10.9% in 1999–2000, and the decreases are similarly found in every age group for men. The trend is also true for women with the exception of the age group 60–74. Changes in saturated fat consumption are largely parallel changes in fat consumption. As with total fat, the absolute reductions in saturated fat consumption are larger during the 1976–1980 and 1988–1994 periods. For women, the average daily saturated fat consumption was 26.2 g in spring 1977 and 25.2 g in 1985. Consumption was decreased by an additional 3.5 g per day in 1985 to 21.7 g per day in 1989–1990. For men, the average daily saturated fat consumption declined by 1.0 g from 1977 to 1985 and an additional 7.2 g in 1989–1990 to 32.4 g (Lichtenstein et al., 1998).

F. Percentage of Energy Intake from Unsaturated Fats

The percentage of energy intake from unsaturated fats is summarized in Figure 21.6. As the figure shows, the trend of estimated percentage energy intake from unsaturated fat during 1971–2000 is similar to that of total fat or saturated fat, but with a relatively slower rate of decline. As more and more consumers are now more aware of the health consequences of the fats, they tend to include less saturated fat in their diets. Polyunsaturated and monounsaturated oils, rich in safflower, canola, and olive oil, have been suggested to be healthy choices for consumers who wish to reduce the risk of heart disease. Food disappearance data between 1985 and 1994 indicate that the ratio of n-6 to n-3 fatty acids has decreased from 12.4:1 to 10.6:1. This reduction reflects a change in the profile of vegetable oils consumed and, in particular, a big increase in canola oil use. However, the ratio of n-6/n-3 fatty acids remains much higher than the recommended value of 2.3:1 (Kris-Etherton et al., 2000).

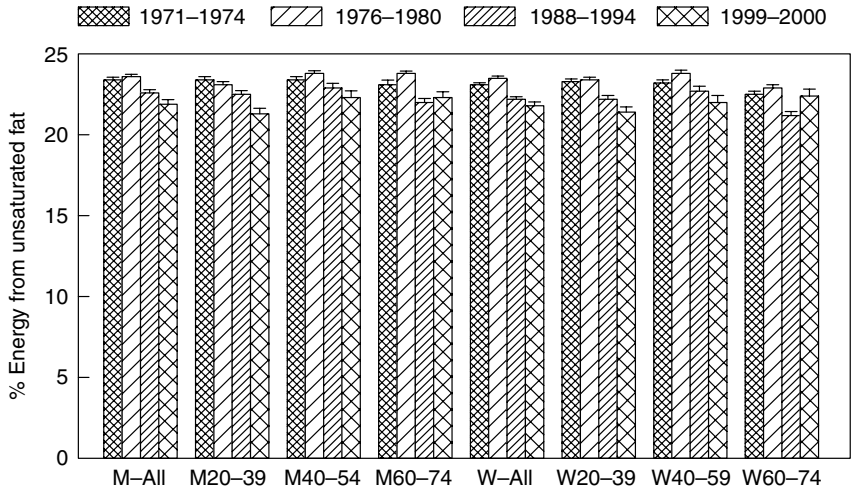

FIGURE 21.6 Estimated percent energy intake from unsaturated fat among U.S. adults aged 20–74. Data (mean ± standard error) are derived from NHANES (Wright et al., 2004). Sample sizes ranged from 4902 men and 7984 women in NHANES I (1971–1974), 5568 men and 6227 women in NHANES II (1876–1980), 6630 men and 7537 women in NHANES III (1988–1994), and 1730 men and 2003 women in NHANES IV (1999–2000). M, represents men; W, women; all, all subjects; 20–39, age 20–39; 40–59, age 40–59; and 60–74, age 60–74.

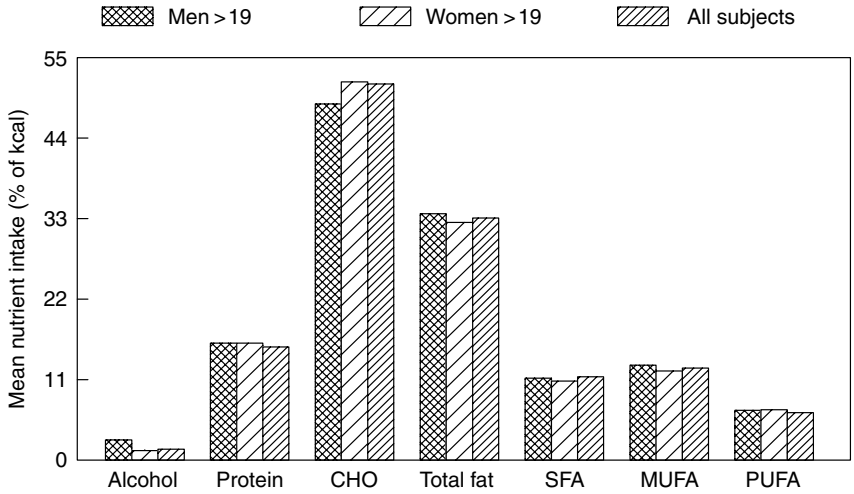

FIGURE 21.7 Mean percentage of calories from alcohol, protein, carbohydrate, and total fat, and from saturated, monounsaturated, and polyunsaturated fatty acids. The data are derived from USDA's 1994 CSFII (U.S. Department of Agriculture, 1998, 2004). Subjects were male aged 20 and over (Men > 19), female aged 20 and over (Women > 19), or all subjects (including those aged 19 and under). The mean food energy intakes were 2460, 1613, and 1985 kcal, respectively, for Men > 19, Women > 19, and All subjects. CHO represents carbohydrate; SFA, saturated fatty acids; MUFA, mono-unsaturated fatty acids; and PUFA, polyunsaturated fatty acids.

G. Percentage of Energy Intake from Total, Saturated, Monounsaturated, and Polyunsaturated Fats, and Alcohol

The percentage of energy derived from total, saturated, monounsaturated, and polyunsaturated fats, as well as from alcohol, carbohydrate, and protein is shown in Figure 21.7. The one day data is

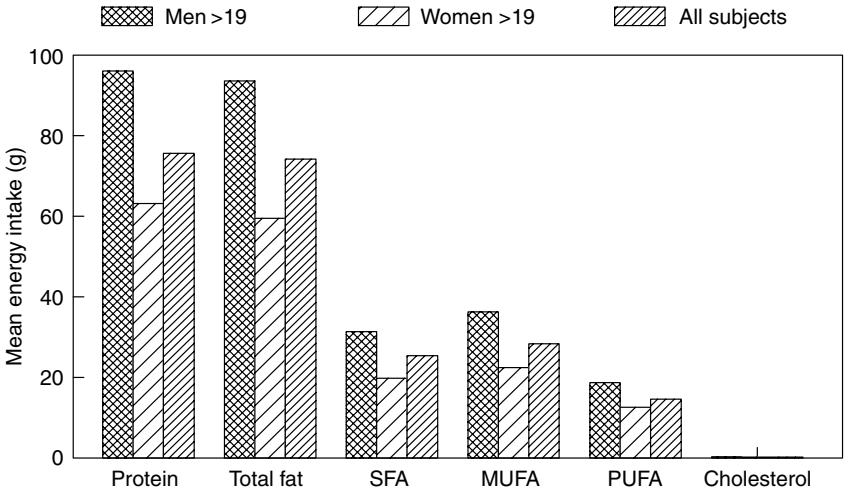

FIGURE 21.8 Mean energy nutrient intake from protein, total fat, and from saturated, monounsaturated, and polyunsaturated fatty acids, and cholesterol. The data are derived from USDA's 1994 CSFII (U.S. Department of Agriculture, 1998, 2004). Subjects were male aged 20 and over (Men > 19), female aged 20 and over (Women > 19), or all subjects (including those aged 19 and under). The mean food energy intakes were 2460, 1613, and 1985 kcal, respectively, for Men > 19, Women > 19, and All subjects. SFA represents saturated fatty acids; MUFA, mono-unsaturated fatty acids; and PUFA, polyunsaturated fatty acids.

derived from USDA's 1994 CSFII. For men and women aged 20 and over, or all subjects (including those under 19), the mean percentage of kcal contributed by proteins, carbohydrates, total fats, and saturated, monounsaturated, and polyunsaturated acids are rather similar. The mean percentage of kcal contributed by carbohydrate is higher for women (51.7%) than men (48.7%) aged 20 and over. In addition, the percentage of kcal from alcohol is higher for men (2.8%) than in women (1.5%) aged 20 and over.

H. Energy Intake from Protein, Total Fat, and Saturated, Monounsaturated, and Polyunsaturated Fats, and Cholesterol

The averaged daily energy intake by weight (g/day) contributed by total, saturated, monounsaturated, and polyunsaturated fats, as well as by cholesterol and protein is shown in Figure 21.8. The one day data are derived from USDA's 1994 CSFII. For men aged 20 and over, the amounts contributed by proteins, cholesterol, total fats, and saturated, monounsaturated, and polyunsaturated acids are all higher than that of women aged 20 and over. Although all subject groups consumed more protein than total fat, the total energy intake contributed by total fat is about twice as much as that of protein. The relative amount of fatty acids in the dietary fat is monounsaturated > saturated > polyunsaturated. In terms of total energy intake, the contribution by cholesterol is insignificant.

I. Percentage of Energy Intake from Snack Foods

The mean percentage of nutrient intake as kcal contributed by foods eaten as snacks (including beverage breaks) is shown in Figure 21.9. The one day data are derived from USDA's 1994 CSFII. Of the mean food energy intakes, the percentage of calories contributed by food eating as snacks averaged 16.1%, 15.2%, and 17.1%, respectively, for men aged 19 and older, for women aged 19 and older, and for all subjects. Individuals eating snacks are 73.3% for men aged 20 and over, 73.5% for women aged 20 and over, and 75.3% for all subjects. The figure also shows that the percentage of calories contributed by snacks is higher in each nutrient intake category for subjects under 19 than

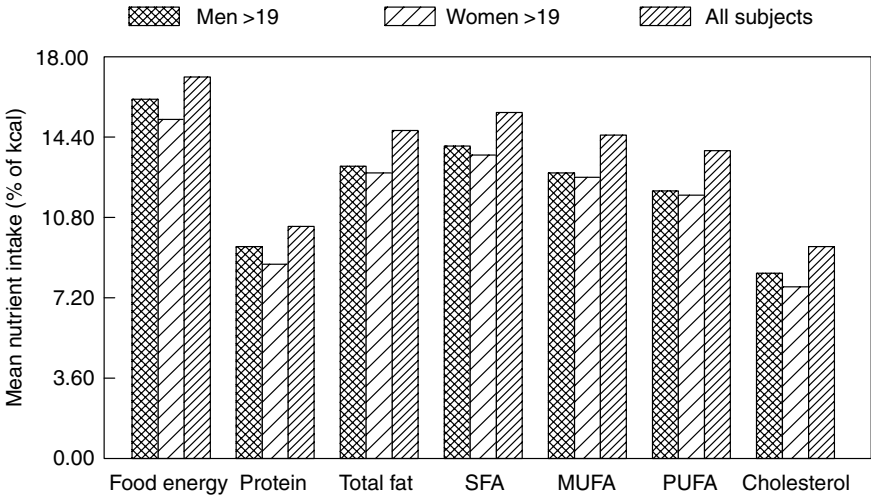

FIGURE 21.9 Mean percentage of nutrient intake as calories contributed by foods eaten as snacks. The data are derived from USDA's 1994 CSFII (U.S. Department of Agriculture, 1998, 2004). Subjects were male aged 20 and over (Men > 19), female aged 20 and over (Women > 19), or all subjects (including those aged 19 and under). The mean food energy intakes were 2460, 1613, and 1985 kcal, and percentage of individuals eating snacks were 73.3, 73.5, and 75.3%, respectively, for Men > 19, Women > 19, and All subjects. SFA represents saturated fatty acids; MUFA, monounsaturated fatty acids; and PUFA, polyunsaturated fatty acids.

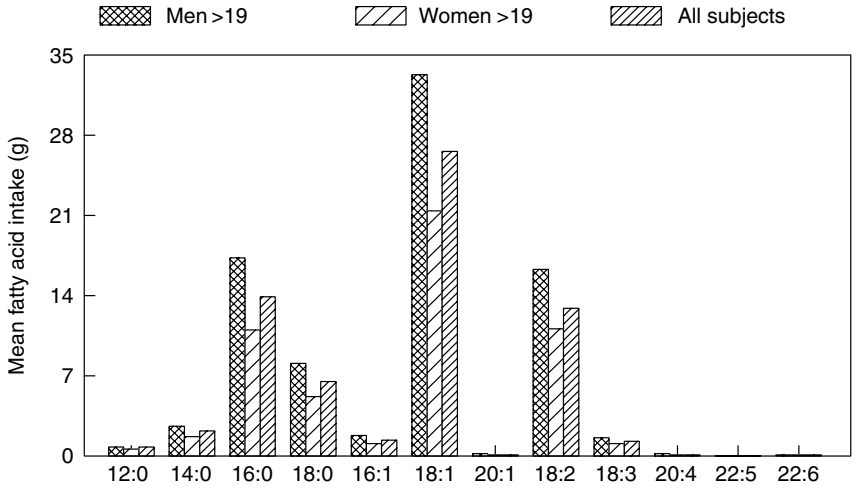

FIGURE 21.10 Mean fatty acid intake. The data are derived from USDA's 1994–1996 CSFII (U.S. Department of Agriculture, 1998, 2004). Subjects were male aged 20 and over (Men > 19), female aged 20 and over (Women > 19), or all subjects (including those aged 19 and under). The mean food energy intakes were 2460, 1613, and 1985 kcal, respectively, for Men > 19, Women > 19, and All subjects.

those aged 20 and over. In addition, for subjects aged 20 and over, men consume relatively more snacks than women.

J. Mean Intake of Major Fatty Acids

The mean one day intake of major fatty acids by grams derived from USDA's 1994–1996 CSFII is shown in Figure 21.10. Among the 16,103 participants, who were asked to recall food intake

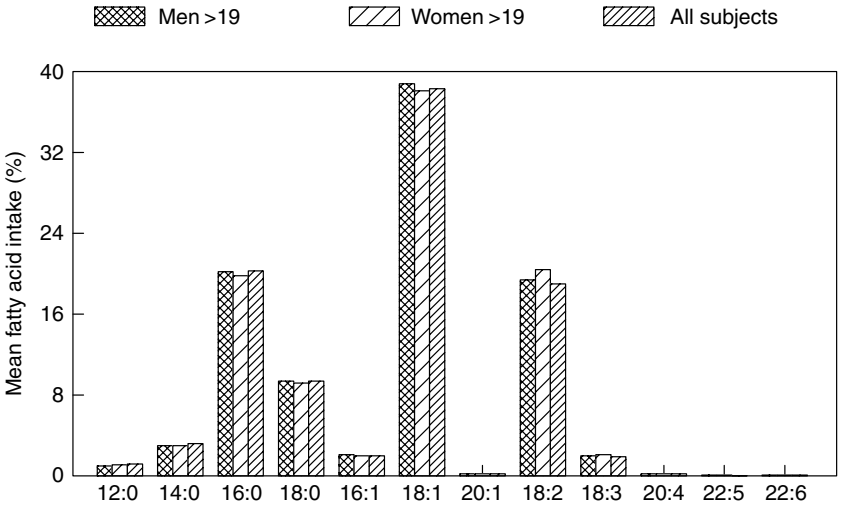

FIGURE 21.11 Mean percentage of fatty acid intake. The data are derived from USDA's 1994–1996 CSFII (U.S. Department of Agriculture, 1998, 2004). Subjects were male aged 20 and over (Men > 19), female aged 20 and over (Women > 19), or all subjects (including those aged 19 and under). The mean food energy intakes were 2460, 1613, and 1985 kcal, respectively, for Men > 19, Women > 19, and All subjects.

information for two separate days, of the CSFII 1994–1996, 5,765 of them were aged 20 and over. As the figure shows, men consumed relatively more fatty acids than that of women in every major fatty acid, and 18:1 is the most abundant fatty acid in the American diet. The next important ones, in decreasing order, are 16:0, 18:2, 18:0, 14:0, 16:1, 18:3, 12:0, and 20:4.

K. Mean Percentage of Fatty Acid Intake

The contribution of important fatty acids as percentage of total fatty acid in the American diet is shown in Figure 21.11. The one day data are derived from USDA's 1994–1996 CSFII. Similar to by weight, the percentage calories contributed by 18:1 is the highest, followed by 16:0, 18:2, 16:0, 14:0, 16:1, 18:3, 12:0, and 20:4. In addition, there is little difference among men and women aged 20 and over, and all subject.

L. Mean Polyunsaturated Fatty Acid Intake

The mean intake of the major polyunsaturated fatty acids, 18:2 and 18:3, by subjects of various age groups is shown in Figure 21.12. The data are derived from *What We Eat in America*, and NHANES 2001–2002. As expected, men consumed more 18:2 and 18:3 than women across all age groups, and all subject groups consumed much more 18:2 than 18:3 during this period.

M. Mean Fatty Acid Intake from Major Food Sources by Male Subjects

The important fatty acids derived from major food sources for male subjects aged 20 and over are shown in Figure 21.13. The one day data are derived from USDA's 1994–1996 CSFII. Meat and fish provide more 16:0, 18:0, and 18:1 than other food sources, and is a rich source for 18:2 for men aged 20 and over. Grain products are the richest source for 18:2 and a good source for 16:0, 18:0, and 18:1. Milk and milk products are good source for 16:0, 18:0, and 18:1, and legumes provide most 18:3.

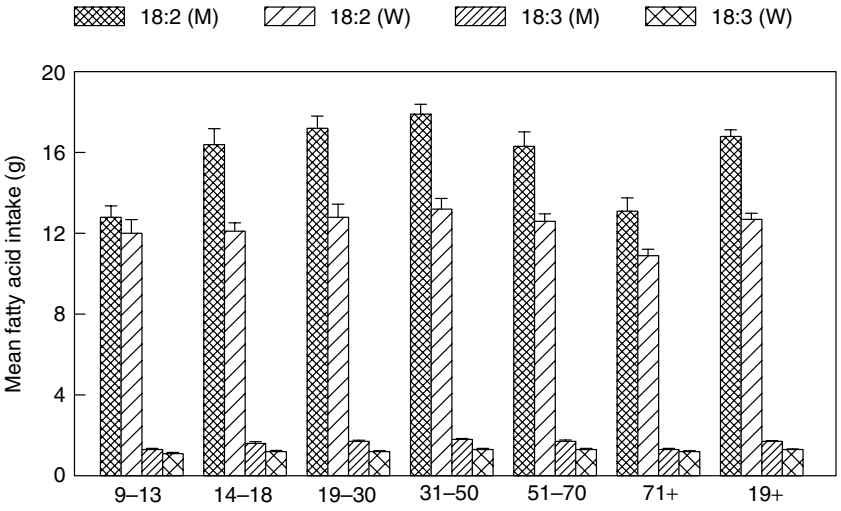

FIGURE 21.12 Mean polyunsaturated fatty acid intake from foods. The data are derived from *What We Eat in America*, NHANES 2001–2002 (U.S. Department of Health and Human Services, 2006a). Subject groups were male aged 9–13 (N = 574), 14–18 (N = 727), 19–30 (N = 552), 31–50 (N = 785), 51–70 (N = 651), 71+ (N = 392), and 19+ (N = 2380), and female 9–13 (N = 597), 14–18 (N = 677), 19–30 (N = 465), 31–50 (N = 754), 51–70 (N = 643), 71+ (N = 405), and 19+ (N = 2267).

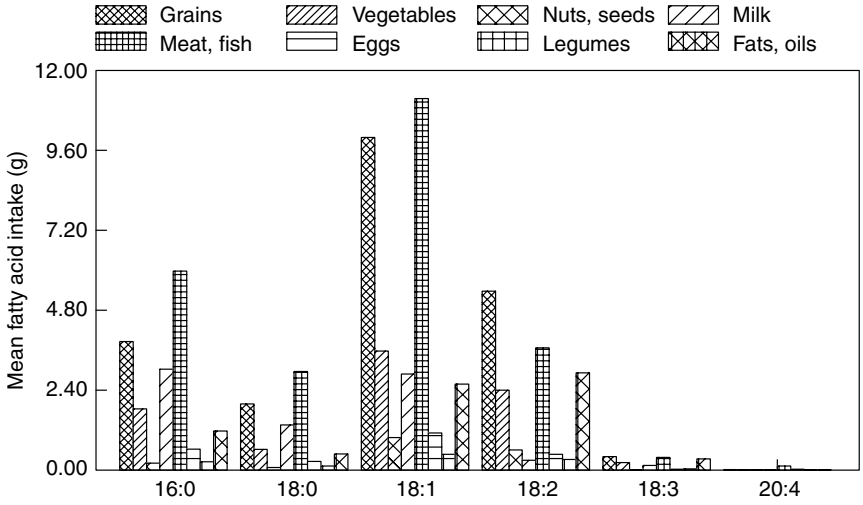

FIGURE 21.13 Mean fatty acid intake from major food sources by males 20 and over (N = 5056). The data are derived from USDA's 1994–1996 CSFII (U.S. Department of Agriculture, 1998, 2004). The category milk includes milk products, and meat includes poultry.

N. Mean Fatty Acid Intake from Major Food Sources by Female Subjects

The important fatty acids derived from major food sources for female subjects aged 20 and over are shown in Figure 21.14. The one day data are derived from USDA's 1994–1996 CSFII. Somewhat different from the male counterpart, grain products provide more 18:1 and 18:2 than other food sources, and are good source for 16:0 and 18:0 for females. In addition, meat and fish are the richest

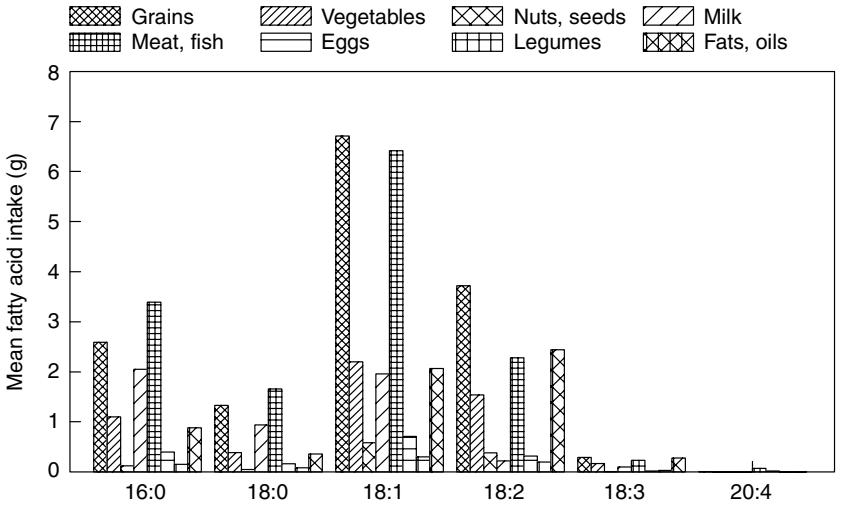

FIGURE 21.14 Mean fatty acid intake from major food sources by females 20 and older (N = 4816). The data are derived from USDA's 1994–1996 CSFII (U.S. Department of Agriculture, 1998, 2004). The category milk includes milk products, and meat includes poultry.

source for 16:0 and 18:0, and good source for 18:1, and fats/oils are rich source for 18:1, 18:2, and 18:3 for women.

A typical American diet consists of high calories contributed by fats, oils, and sweets. In 1995, Americans reported an average of 25% of daily calories from fats added in food or meal preparation and at the table. As total calories from fat averaged 33% of daily calories, most fats consumed are added at the discretion of food processors, consumers, or preparers rather than naturally occurring. Salad and cooking oils are the leading source of added fats, followed by shortening, margarine, and dairy fats. These added fats are consumed in addition to the fats occurring naturally in meats, fish, nuts, eggs, and dairy products. Therefore, in order to achieve the goal of a healthy diet based on the USDA Food Guide Pyramid, consumers need to reduce the amount of added fats by one-third (Putnam and Allshouse, 1997), in addition to reducing total and saturated fats (Ernst et al., 1999).

Although the reported total fat and saturated fatty acid intakes as a percentage of total energy have been declining over the past decades in the United States, most individuals do not consume a diet that meet the levels of fat and saturated fatty acids recommended by the Dietary Guidelines for Americans (Lichtenstein et al., 1998). On a relative basis, saturated fat intake has decreased less than that of total fat intake. In addition, individuals of all ages who consume a diet with 30% or less of energy from fat consistently have lower-energy intakes. The data suggest that fat-modified foods make a more significant contribution to diets of consumers with low-fat intakes, and that the focus on overall diet quality is often lost in the national obsession with lowering fat intake.

From 1971 to 2000, the mean percentage of energy from total and saturated fat has decreased, but remained above recommendations, with overall means of 33.5% of energy from fat and 12.2% of energy from saturated fat. During 1988–1994, only about one in four youths met the recommendations for intakes of fat and saturated fat and three in four met the recommendation for cholesterol intake (Troiano et al., 2000). Beverages contribute 20%–24% of energy across all ages and soft drinks provide 8% of energy in adolescents. The lack of evidence of a general increase in energy intake among youths despite an increase in the prevalence of overweight suggests that physical inactivity is a major public health challenge in this age group. Efforts to increase physical activity and decrease nonnutritive sources of energy are essential to counter the rise in overweight prevalence.

High-fat diets have been associated with increasing obesity, and high intake of total fat and saturated fat is linked to the increased risk of cardiovascular disease and other degenerative diseases.

However, the prevalence of obesity has increased incidence of 14.5%–30.9% in the United States during 1971–2000, while dietary fat intake (both in absolute terms and as a percentage of total dietary energy) has decreased during this period (Flegal et al., 2002). The findings suggest a role of sedentary behaviors in the causation of overweight or obesity (U.S. Department of Health and Human Services, 2001). For example, children who ate fast food, compared with those who did not, consumed more total energy (187 kcal), more energy per gram of food (0.29 kcal/g), more total fat (9 g), more total carbohydrate (24 g), more added sugars (26 g), more sugar-sweetened beverages (228 g), less fiber (–1.1 g), less milk (–65 g), and fewer fruits and nonstarchy vegetables (–45 g) (Bowman et al., 2004). Thus, a concomitant decrease in total dietary energy and modifications of other lifestyle factors, including physical activity, need to be emphasized.

IV. SUMMARY AND CONCLUSION

Data obtained from NHANES show that the mean energy intake from carbohydrate, either by weight or percentage of kcal, has increased, while little changes from protein during 1971–2000 in the U.S. adult population. On the other hand, the mean percentage of total energy intake from total fat, saturated fat, and unsaturated fat has decreased during this period. The total energy intake during 1988–2000 is higher than that of 1971–1980 for both men and women, and the increase is primarily attributable to increased carbohydrate intake. Of the mean food energy intakes, the percentage of calories contributed by food eating as snacks averaged 17.1% for all subjects. Data obtained from CSFII and NHANES 2000–2002 show that men consumed relatively more fatty acids than that of women. The percentage calories contributed by 18:1 is the highest, followed by 16:0, 18:2, 16:0, 14:0, 16:1, 18:3, 12:0, and 20:4. In addition, 18:1 is the most abundant fatty acid in the American diet, and is followed by 16:0, 18:2, 18:0, 14:0, 16:1, 18:3, 12:0, and 20:4. Data obtained from CSFII also show that meat and fish provide more 16:0, 18:0, and 18:1 than other food sources, and are rich sources for 18:2 for men aged 20 and over. On the other hand, grain products provide more 18:1 and 18:2 than other food sources, and are good source for 16:0 and 18:0, and meat and fish are the richest source for 16:0 and 18:0 for females aged 20 and over. Given the increasing rates of obesity in the United States at an earlier age, a reduction in total energy intake is an essential part of an overall strategy to balance energy consumption with energy needs. Focus to achieve total energy balance is fundamental to preventing and reducing obesity in the United States.

22 Absorption and Transport of Dietary Lipid

Vernon A. Welch and Jürgen T. Borlak

CONTENTS

I. INTRODUCTION

In recent years, there has been considerable interest in determining both the amount and type of fat in the diet that commensurate with good health. This has led both to official reports such as the Committee on Medical Aspects (COMA) of food policy reports (Department of Health and Social Security, 1984; Department of Health, 1991) and to books offering nutritional advice to the general public (e.g., Anderson, 1986; Le Fanu, 1987). This chapter considers the absorption, transport, and desaturation of dietary lipid and some of the possible effects on human health.

II. THE NATURE AND FUNCTION OF DIETARY LIPID

Lipids are important constituents of food that not only provide a concentrated source of energy but also affect the texture and flavor of food and therefore its palatability. The principal lipids found in the diet and in the body include the free fatty acids (FFAs); the esters of glycerol and fatty acids (triacylglycerol, diacylglycerol, and monoacylglycerol); the esters of glycerol that, in addition to fatty acids, also contain a phosphate group (glycerophospholipids); the esters that contain a long-chain hydroxylic base esterified to a long-chain fatty acid and a phosphate group (sphingolipids); the lipids that contain a sugar group (glycolipids); and cholesterol and its esters.

In the body, lipids have several functions—triacylglycerols (TAGs) are stored in adipose tissue, provide insulation, and can be mobilized to meet energy requirements; phospholipids (PLs), glycolipids, and cholesterol play a structural role in cell membranes; and triacylglycerol, diacylglycerol, and monoacylglycerol (MAG), sterols and steryl esters, FFAs, wax esters, and hydrocarbons have a protective function in skin. Lipids also have important metabolic roles to play. They can be oxidized to provide energy (TAGs), and they can serve as precursors for biologically active substances such as prostaglandins (unsaturated PLs) and steroid hormones and bile acids (cholesterol).

Certain lipids such as the fat-soluble vitamins, A, D, E, and K, and the essential fatty acids (EFAs) are not synthesized in the body and have to be supplied in the diet. The fat-soluble vitamins are necessary for vision (vitamin A), regulation of calcium metabolism (vitamin D), prevention of autoxidation of unsaturated lipids (vitamin E), and normal clotting of blood (vitamin K). The role of EFAs will be discussed in more detail later. A comprehensive review of the role of lipids in food is given by Gurr (1984).

III. DIGESTION AND ABSORPTION OF LIPID

Digestion and absorption of lipid has been reviewed by Johnston (1970, 1978), Tso (1985), Zilversmit (1978), Green and Glickman (1981), Norum et al. (1983), Gurr (1984), and Brindley (1985).

A. Digestion in the Intestine

The principal constituent of dietary lipid is TAG, in which mainly long-chain fatty acids and also some medium- and short-chain fatty acids are esterified to glycerol. The other constituents of dietary lipid include PLs, and cholesterol and its esters.

In the stomach, lipid is liberated from lipoproteins by proteolysis, but comparatively little lipolysis takes place in the stomach of the adults. In infants, pancreatic lipase activity is not fully operative, and the activity of a lingual lipase assumes greater importance. This lipase is active at acid pH and preferentially releases the short- and medium-chain fatty acids in milk fat TAG, to leave diacylglycerol (DAG) (Edwards-Webb and Thompson, 1977).

Lipid, emulsified by mechanical action in the stomach, enters the duodenum; the entry of food stimulates secretion of the hormone cholecystokinin–pancreozymin into the proximal small intestine, resulting in the contraction of the gallbladder and the release of bile and pancreatic juice.

The bile acids attach themselves to the emulsion particles, imparting a negative charge and attracting colipase, a protein present in pancreatic juice, that binds to the TAG. In the absence of colipase, pancreatic lipase is inhibited by bile salts, at a concentration exceeding the initial micellar concentration, but colipase overcomes the inhibition by binding pancreatic lipase. The presence of bile salts facilitates lipolysis by increasing the pH optimum of pancreatic lipase from pH 6 to pH 7; the approximate pH of the contents of the upper small intestine (Johnston, 1970).

Pancreatic lipase acts as the oil–water interface of emulsion particles and releases fatty acids from the 1- and 3-positions of the triacyl-*sn*-glycerol, leaving the 2-monoacyl-*sn*-glycerol, which can partially isomerize to 1-monoacyl-*sn*-glycerol. Pancreatic juice also contains a carboxylic esterase that can cause the complete lipolysis of 10%–15% of the TAG and may also hydrolyze the cholesteryl esters (Brindley, 1985). Phospholipases A1 and A2 are also present; they remove fatty acids from the 1- and 2-positions, respectively, of dietary *sn*-PL or *sn*-PL present in the bile; digestion can be complete or can stop at the formation of lysophospholipid. Cholesteryl esters are hydrolyzed by pancreatic cholesterol esterase, whose action is enhanced by bile salts (Dietschy, 1978).

As lipolysis proceeds, the oil phase becomes smaller and the lipolytic products (FFA, MAG, and lysophosphatidylcholine [LPC]), together with the bile salts, form negatively charged polymolecular aggregates, called *micelles*, which are about 1/100 as large in diameter as the emulsion particles (Johnston, 1970). Calcium, present in relatively high concentration in both bile and pancreatic juice, aids the adsorption of lipolytic products from the oil–water interface (Tso, 1985). The presence of a third phase, a lipid crystal phase saturated with bile salts, which may be important in the absorption of MAG and fatty acid in bile salt-deficient patients, has also been reported (Tso, 1985).

B. Absorption of the Products of Digestion

The lipolytic products are taken up by passive diffusion from the micelle by the microvilli of the enterocytes. The bile acid micelles greatly facilitate the uptake of lipid by taking it through the unstirred water layer that is adjacent to the cell membrane and that presents the major barrier to passage of lipid from the lumen to the cell. It is not clear whether micelles can be taken up by the cell, but it seems likely that the aggregated lipid molecules in the micelle are in equilibrium with the monomer forms, which are concentrated at the cell surface and passively absorbed into the cell (Dietschy, 1978; Thomson, 1978).

Bile salts are essential for the uptake of cholesterol (Thomson, 1978), and polar lipids are also necessary for its solubilization. The absorption of polar lipids in the proximal intestine can result in precipitation of cholesterol, and this may provide a partial explanation for why only about half of the cholesterol is absorbed (Norum et al., 1983). The bile salts pass on the distal intestine. There, they are absorbed and returned to the liver, via the portal vein, and incorporated into bile once more, thus completing the enterohepatic cycle (Beynen et al., 1986; Liepa and Sullivan-Gorman, 1986).

C. Metabolism of Absorbed Lipid in the Enterocyte

Fatty acid absorbed into the cell is transported to the endoplasmic reticulum in association with a fatty acid-binding protein. The fatty acids are activated to their coenzyme A (CoA) derivatives by acyl CoA synthetase and reesterified to TAG by either the MAG or the α-glycerophosphate pathway. The enzymes of the MAG pathway, associated mainly with the smooth endoplasmic reticulum (SER),

acyl CoA synthetase, monoacylglycerol transacylase, and diacylglycerol transacylase, are present in one complex called triacylglycerol synthetase, whose preferred substrate is 2-MAG (Tso, 1985).

The other pathway of TAG synthesis, which takes place mainly in the rough endoplasmic reticulum (RER), involves activation of the fatty acids to their acyl CoA derivatives by acyl CoA synthetase, formation of L-α-glycerophosphate from glycerol by glycerol kinase, conversion of L-α-glycerophosphate to phosphatidic acid by glycerophosphate acyl transferase, conversion of phosphatidic acid to DAG by phosphatidate phosphohydrolase, and finally acylation of DAG by diacylglycerol transacylase. Although both pathways synthesize DAG, the DAGs do not equilibrate. Only the DAG synthesized via the α-glycerophosphate pathway can serve as a precursor for *sn*-phosphatidylcholine, which has a different fatty acid distribution in positions 1 and 2 from that of dietary triacyl-*sn*-glycerol. The distribution of fatty acids on the TAG synthesized via the MAG pathway is similar to that of dietary TAG (Johnston, 1970).

About 75%–85% of TAG is synthesized via the MAG pathway, and MAG inhibits the α-glycerophosphate pathway. The α-glycerophosphate pathway assumes more importance when only long-chain fatty acids are absorbed, as in the case of ruminants. Absorbed LPC can be reesterified to phosphatidylcholine by the action of lysolecithin acyltransferase, which is found in both SER and RER (Tso, 1985).

A high proportion of the absorbed cholesterol is esterified. One mechanism for this is by reversal of the action of pancreatic cholesterol esterase, which is absorbed into the cell. Hydrolysis of cholesteryl ester catalyzed by cholesterol esterase is favored by the pH in the intestinal lumen (pH 6.6–8.1), whereas reesterification is favored by the pH in the cell (pH 5.0–6.2) (Thomson, 1978).

D. Assembly of Triacylglycerol-Rich Lipoproteins

In order for lipid to be transported out of the cell and into the lymph, it is bound to protein to form a lipoprotein that is soluble in an aqueous medium. This particle is called a *chylomicron* and consists of a nonpolar core containing TAG and a variable amount of cholesteryl ester that is covered by a surface coat of protein (apolipoprotein), unesterified cholesterol, and PL. The particles vary in size from 75 to 600 nm, depending on the rate of lipid absorption and the nature of the lipid, being larger during the absorption of high-fat loads and when unsaturated fat is being absorbed (Zilversmit, 1978; Norum et al., 1983; Sparks and Sparks, 1985; Tso, 1985).

The enterocyte also produces smaller lipoprotein particles similar in size to the plasma very low density lipoprotein (VLDL), which are termed intestinal VLDL or small chylomicrons, depending on whether they are considered distinct from chylomicrons or not. Some studies suggest that the chylomicrons and the intestinal VLDL are assembled separately, but others indicate one population of TAG-rich lipoproteins that varies in size according to the amount of core lipid and surface material. Intestinal VLDL is the principal form secreted during fasting, but secretion continues when fat is fed (Tso, 1985).

The fatty acid composition of chylomicron TAG depends on the diet, but that of PL and cholesteryl ester does not. The composition of lymph chylomicrons is TAG, 86%–92%; cholesteryl ester, 0.8%–1.4%; unesterified cholesterol, 0.8%–1.6%; PL (PC), 6%–8%; and protein, 1.0%–1.5% (Green and Glickman, 1981). Intracellular chylomicrons or prechylomicrons contain more FFA, cholesterol, and protein and less PL than the lymph chylomicrons, possibly as a result of contamination with intracellular components or because of changes that take place after excretion from the cell (Green and Glickman, 1981). The specialized proteins found in the lipoproteins, termed *apolipoproteins* (apo), are described in more detail below.

It has been demonstrated in the rat that the intestine and the liver are sole sources of the plasma apolipoproteins, and that the intestine is responsible for 19% of the total synthesis (Wu and Windmueller, 1979). The apolipoprotein composition of rat and human lymph chylomicrons is similar and varies according to source and size: apo A-I, 15%–35%; apo C, 45%–50%; apo A-IV, 10%; apo E, 5%; and apo B, 10%. Apo A-II and apo A-V have also been observed (Sparks and Sparks, 1985). The contribution of the intestine to the synthesis of rat apolipoproteins is apo A-IV, 59%; apo A-I, 56%; apo B,

16%; apo C-II, 10%; apo C-II-0, 7%; apo C-III-2 (–1), <10%; apo C-III-3, <1%; and apo E, <1% (Wu and Windmueller, 1979).

During fat feeding, the intestine actively synthesizes apo A-I, apo A-IV, and apo B, and, in the case of humans, also apo A-II. The apo C and apo E are acquired by the chylomicrons after secretion from the cell (see later) (Sparks and Sparks, 1985). Apolipoprotein A-I is synthesized as a preproapolipoprotein with a 24-amino acid extension that is secreted as a proapolipoprotein with a hexapeptide prosegment that is converted extracellularly to apo A-I (Edelstein et al., 1983).

The form of apo B present in chylomicron is apo B_{48}, so-called because its apparent molecular weight is 48% of apo B_{100}, which is found in VLDL of hepatic origin. In the rat, there appears to be two apo B_{48} subunits per chylomicron (Sparks and Sparks, 1985). Apolipoprotein B plays an essential role in the formation and transport of chylomicrons. Small amounts of apo B are synthesized continually during fasting, but synthesis increases during fat feeding. Apo A-I also increases during fat feeding but does not appear to be so important in the secretion of chylomicrons (Tso, 1985).

The lipid of the prechylomicron particle is synthesized mainly in the SER, the protein in the RER, and sugar in the Golgi apparatus, but not exclusively so, and carbohydrate can also be added to the protein in the endoplasmic reticulum. The SER and Golgi apparatus are closely linked to the endomembrane system. Protein synthesized in the RER is incorporated into the TAG-rich particle at the junction of the RER and the SER (Zilversmit, 1978), and the particle is transported to the Golgi apparatus where both protein and lipid can be glycosylated. Prechylomicron particles migrate to the plasma membrane in vesicles that fuse with the plasma membrane and are released into the intercellular space by exocytosis (Sparks and Sparks, 1985; Tso, 1985).

After secretion, changes in the composition of the chylomicron take place in the lymph and, more important, in the plasma. In the rat, very little apo C or apo E is synthesized in the intestine (Krause et al., 1981), although apo C-II may be an exception (Fidge and Nestel, 1986), and the chylomicron acquires these apolipoproteins after secretion, primarily by transfer from high-density lipoprotein (HDL) (Gotto et al., 1986). When hydrolyzed, the chylomicrons lose PL, apo A-I, and apo A-II from the surface to HDL (Tall, 1986a).

E. Absorption of Short-Chain Fatty Acids

The shorter-chain length fatty acids are usually esterified to position 3 of triacyl-*sn*-glycerols and are therefore not found in the 2-monoacyl-*sn*-glycerols. They are easily released from TAG in the stomach and small intestine and can partition into the aqueous phase and be transported, bound to albumin, in the portal vein to the liver (Brindley, 1985). A more prominent role for the portal vein in transporting intestinal lipoproteins has been suggested (Bauchart et al., 1988) and adds weight to much earlier evidence (Barna, 1963).

IV. TRANSPORT OF LIPID ON LIPOPROTEINS

A. Structure of Lipoproteins

Lipoprotein structure and lipid binding have been discussed by Morrisett et al. (1975), Smith et al. (1978), Bradley and Gotto (1978), Nicoll et al. (1980), Tall and Small (1980), Sparks and Sparks (1985), and Gotto et al. (1986). The composition of human plasma lipoproteins is given in Table 22.1.

Because of their hydrophobic nature, lipids are transported in plasma in the form of macromolecular lipid–protein complexes termed *lipoproteins*. These consist essentially of a hydrophobic, neutral lipid core surrounded by a surface film of protein and polar lipid. The lipoproteins may be divided into several classes on the basis of differences in their chemical composition and physical properties. In addition to the chylomicrons synthesized in the intestine, which have already been described, there are the plasma lipoproteins. These can be separated by a variety of techniques, which include selective precipitation with sulfated polysaccharides, electrophoresis, isoelectric focusing, gel filtration, immunoaffinity chromatography, and ultracentrifugation. Many of these are

TABLE 22.1
Human Plasma Lipoprotein Composition

	Protein and Lipid Constituents[a] (g/L)						Apolipoprotein Present[b]					
	Protein	TL	TAG	PL	UC	CE	A-I	A-II	B	C	D	E
VLDL	0.1	0.9	0.6	0.10	0.06	0.05	(+)	(+)	+	+	(+)	+
LDL	0.95	3.1	0.2	0.95	0.35	1.65			+	(+)		
HDL	1.85	1.7	0.15	0.8	0.15	0.55	+	+		(+)	(+)	(+)

Abbreviations: TL, total lipid; TAG, triacylglycerol; PL, phospholipid; UC, unesterified cholesterol; CE, cholesteryl ester; VLDL, very low density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; +, major constituent; (+), minor constituent.

described in the journal *Methods in Enzymology*, Volumes 128 (Segrest and Albers, 1986) and 129 (Albers and Segrest, 1986).

The traditional way to separate lipoproteins has been to exploit the differences in their hydrated densities and separate them by differential floating in the ultracentrifuge. This has given rise to the classification based on hydrated density: VLDL $d < 1.006$ g/mL; intermediate-density lipoprotein (IDL) $1.006 < d < 1.019 < d < 1.063$ g/mL; and HDL $1.063 < d < 1.21$ g/mL. There are also subclasses of HDL, which will be discussed later. The density intervals quoted are those that have been used to isolate human plasma lipoproteins and may have to be adjusted to separate the lipoproteins of other animal species.

The protein moieties of the lipoproteins are termed *apolipoproteins* or *apoproteins* (apo) and owe their lipid-binding characteristics to the presence of amphipathic helical regions, one face of which consists of hydrophobic amino acids, whereas the other has predominantly hydrophilic polar amino acids. It is thought that lipid binding takes place as a result of hydrophobic interaction between the nonpolar face of the amphipathic helix and the fatty acids of the PLs. The polar face of the helix serves to orient the apolipoprotein at the surface of the particle in contact with the aqueous medium. In addition to PL, the surface coat also contains unesterified cholesterol. The hydrophobic core into which fatty acyl group extends from the surface lipid consists of the nonpolar lipids, TAG, and cholesteryl ester.

The principal apolipoprotein of LDL, apo B, in addition to having regions of amphipathic helix, also has a β-pleated sheet structure. Addition of lipid increases the β-structure of apo B but increases the α-helix of HDL apolipoprotein (Sparks and Sparks, 1985). The apolipoproteins have particular roles to play in the secretion, transport, and metabolism of lipoproteins. These are detailed in Table 22.2 and will be discussed in the appropriate part of the section on lipoprotein metabolism that follows.

It is now recognized that there are discrete lipoprotein families that are characterized by a unique qualitative apolipoprotein composition but that can have varying lipid/protein ratios and hydrated densities and can hence occur in more than one of the traditional lipoprotein classes. These families of lipoproteins are based on apo A or apo B either alone or together with some of the other apolipoproteins. Thus, it has been established that there are three families of lipoproteins based on apo A—LP-A-I, LP-A-I: A-II, and LP-AII—together with subspecies of these that can have apo C, apo E, and so on. There are five major families based on apo B: LP-B, LP-B:C, LP-B:E, LP-B:C:E, and LP-A-II: B:C:D:E (LP-A-II:B complex). The LP-B particle is enriched in cholesteryl ester, whereas LP-B:C, LP-B:C:E, and LP-A-II:B complex are rich in TAG. As the density of apo B-containing lipoproteins increases, the content of apo B also increases, but that of apo C and apo E decreases (Alaupovic, 1988).

The presence of a particular lipoprotein family in a lipoprotein class can confer particular properties. For example, LD-A-I promotes cholesterol efflux from cells, whereas LP-A-I:A-II does not (Barbaras et al., 1987).

TABLE 22.2
Metabolic Role of Apolipoproteins

Role	Apolipoprotein
Lipoprotein secretion	B_{48}, B_{100}
Enzyme activation	
LPL	C-II
LCAT	A-I, C-I, A-IV
HL	A-II
Receptor recognition	
LDL receptor (B/E)	B_{100}, E
Chylomicron remnant receptor (E)	E
HDL receptor	A-I
Inhibition of receptor recognition	C-I, C-II, C-III (A-II)
Lipid transfer	D
Reverse cholesterol transport	A-I, A-IV, E

Abbreviations: LPL, lipoprotein lipase; LCAT, lecithin-cholesterol acyl transferase; HL, hepatic lipase; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

Visek, Eds., American Oil Chemists' Society, Champaign, IL, p. 530; Introduction to the plasma lipoproteins. Barbaras, R., et al. (1987). *Biochem. Biophys. Res. Commun. 142*: 63; Stein, Y., and Stein, O. (1988). Reverse cholesterol transport, Abstracts of International Conference, Lipoproteines at Phospholipases Present et Futur, Paris, France; *Bull. Soc. Chim. Biol. 53*: 13.

Dyslipoproteinenmias can be characterized by altered proportions of the lipoprotein families, and these proportions can be selectively changed by drug action (Alaupovic, 1988; Alaupovic et al., 1988).

B. Synthesis of Lipoproteins

The synthesis of the chylomicron and of the intestinal VLDL has already been discussed. The liver is the other major site of lipoprotein synthesis and is the principal source of apo C and apo E (Gotto et al., 1986).

C. Synthesis of VLDL

The large, TAG-rich VLDL is synthesized in the liver. As with the chylomicron, apo B is essential for VLDL formation, but in humans this takes the form of the higher molecular weight apo B_{100}, although in rats, hepatic VLDL contains both apo B_{100} and apo B_{48} (Sparks and Sparks, 1985). Nascent VLDL normally contains only a small amount of cholesteryl ester, but this can be increased when acyl CoA-cholesteryl acyl transferase (ACAT) is stimulated, for example, by cholesterol feeding (Norum et al., 1983; Gotto et al., 1986). Although IDL and LDL are principally derived from VLDL in the plasma, they may also be secreted directly by the liver (Beynen et al., 1987; Shepherd and Packard, 1987b) (also see Section IV.G).

D. Synthesis of HDL

Plasma HDL is a spherical particle that consists of a hydrophobic core of TAG and cholesteryl ester stabilized by a coating of PL and apolipoprotein. The HDL particles in plasma have undergone considerable changes since their formation as precursor or nascent HDL, which are either secreted by the liver and intestine or are products of lipolysis of TAG-rich lipoproteins (Tall and Small, 1980).

Both small, spherical HDL particles containing newly synthesized core and surface components and discoidal forms of HDL have been observed in rat intestinal lymph. There is evidence that the spherical particles have been actively secreted into lymph, but the discoidal particles have not been recovered from intracellular preparations and may not be secreted via the Golgi apparatus (Glickman and Magun, 1986).

The lymph HDLs are relatively enriched in PL and apo A-I and poor in cholesteryl ester and apo E. The discoidal form of nascent HDL has also been observed in liver perfusates and has apo E and apo A-I as its principal apolipoproteins, plus, unlike the intestinal nascent HDL, some apo C. The ratio of apo E to apo A-I is greater than that of plasma or intestinal HDL (Nicoll et al., 1980).

The evidence for the secretion of nascent HDL by human liver or intestine is indirect, and an alternative possibility is that it is formed from surface materials (PL, unesterified cholesterol, and apo C) resulting from the lipolysis of the TAG-rich lipoprotein. An alternative possibility that could account for the presence of discoidal particles in liver perfusates or intestinal lymph is that free apolipoprotein secreted by cells could become associated with PLs derived from cells or lipoproteins during or after secretion. Possibly polar materials could be supplied from both of these sources (Eisenberg, 1984).

Whether or not the nascent HDL particle is formed from surface components during the lipolysis of TAG-rich lipoproteins, there is unequivocal evidence that the conversion of nascent HDL to mature plasma HDL and further HDL metabolism do involve such transfers, and that cells and cell membranes can also contribute PL to this process (Eisenberg, 1986). The conversion of the nascent discoidal form of HDL to the mature spherical form is the result of esterification of cholesterol and the entry of the nonpolar cholesteryl ester into the core of the particle, thereby swelling it and producing the spherical pseudomicellar form (Nicoll et al., 1980; Eisenberg, 1986).

The esterification of cholesterol at the expense of phosphatidylcholine is catalyzed by lecithin-cholesterol acyl transferase (LCAT) that has been activated by apo A-I already present on the nascent particle or transferred to it from the TAG-rich lipoproteins or the free apoprotein pool. The other product of the reaction, LPC, is mainly transferred to albumin and can be subsequently reacylated (Gotto et al., 1986).

E. Lipoprotein Metabolism

A general scheme for lipoprotein metabolism is shown in Figure 22.1 (see also Schaefer et al., 1978; Polonovski and Beucler, 1983; Thompson, 1984; Gotto et al., 1986; Rifai, 1986; Welch, 1986). Some enzymes of importance in lipid and lipoprotein metabolism are listed in Table 22.3.

F. Chylomicron Metabolism

The chylomicrons that are secreted by the intestinal cell and whose surface components have been modified by exchange in plasma, as described previously, then undergo lipolysis by lipoprotein lipase (LPL), which is activated by the newly acquired apo C-II (Kinnunen et al., 1983; McClean et al., 1986). LPL is attached to the endothelial surface of capillaries by heparan sulfate (McClean et al., 1986), and its activity is regulated by those hormones that promote its activity in adipose tissue, such as insulin, and those that depress it, such as catecholamines. Thus, the activity of LPL can be regulated reciprocally between muscle and adipose tissue so as to favor either energy production or storage of TAGs (Brindley, 1985).

As a result of LPL action, most of the TAG and some of the phosphatidylcholine are hydrolyzed rapidly; the liberated fatty acids are taken up by the tissues and either reesterified and stored as TAG (adipose tissue) or oxidized as in muscle in the fasting state. The remaining PL, together with apo A and most of the apo C, is transferred to HDL (Gotto et al., 1986), leaving a smaller remnant particle enriched in cholesteryl ester. The loss of apo C-II renders the remnant less suitable as a substrate for LPL, and so it is released back into the circulation, from where it is removed by the liver, after binding to the chylomicron remnant receptor that recognizes apo E. The presence of apo C on the chylomicron inhibits recognition by the apo E receptor, and its loss facilitates recognition of the remnant.

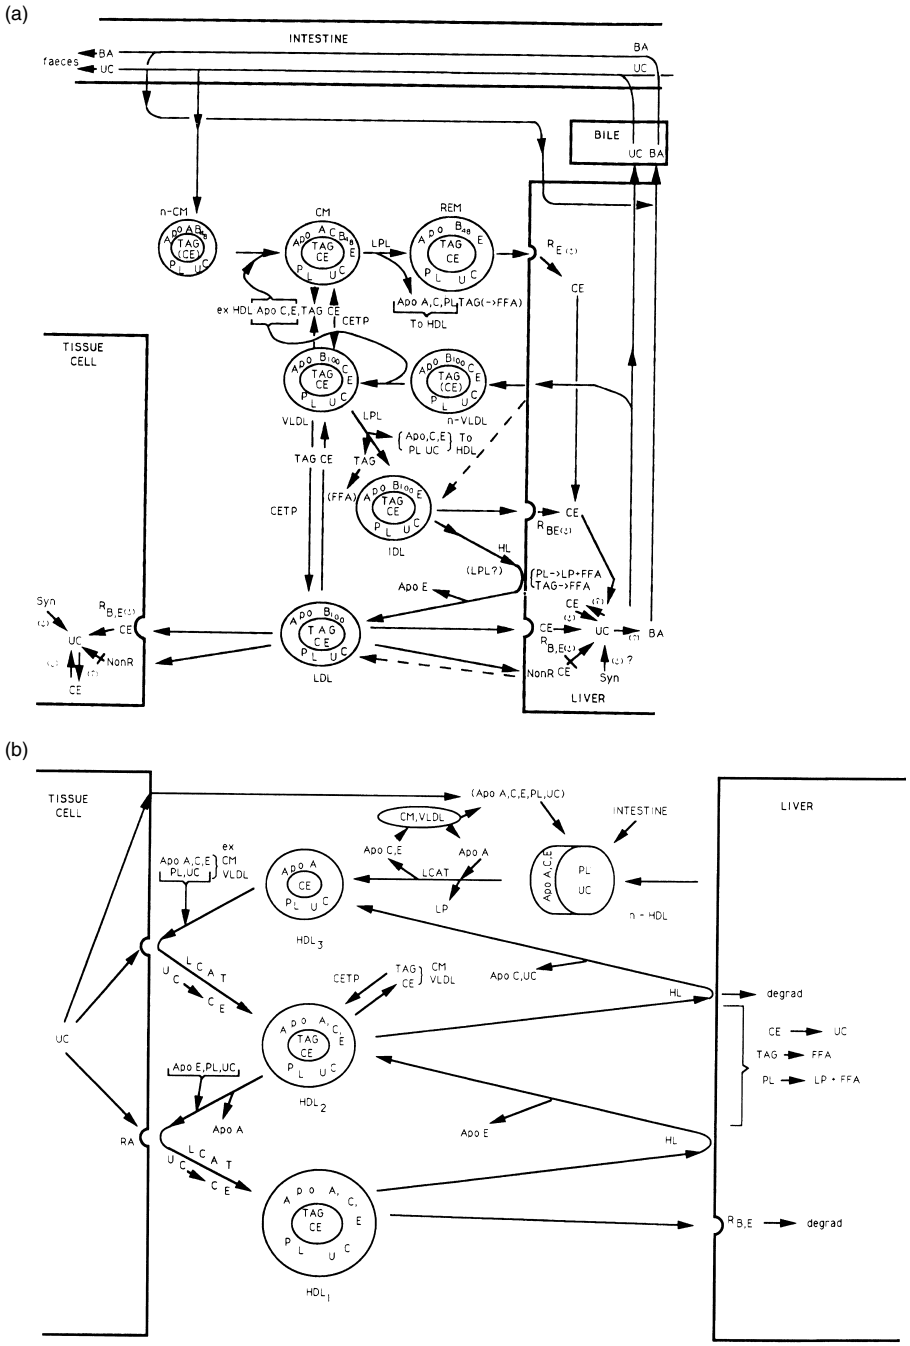

FIGURE 22.1 (a) Triacylglycerol-rich lipoprotein metabolism and (b) high-density lipoprotein metabolism. Outer circles represent surface materials of lipoproteins; inner circles represent core lipids. (↑) Upregulation; (↓) downregulation; and (↕) absence of regulation. Parentheses indicate a component of variable concentration. Solid arrow lines, principal pathways; broken arrow lines, minor pathways. *Abbreviations:* Syn, synthesis; Degrad, degradation; LPL, lipoprotein lipase; HL, hepatic lipase; LCAT, lecithin-cholesterol acyl transferase; CETP, cholesteryl ester transfer protein; apo A, B, C, E, apolipoproteins A, B, C, E; R_E, receptor recognizing apo B and apo E (LDL receptor); R_A, receptor recognizing apo A; non-R, uptake by nonreceptor pathway; CM, chylomicron; VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; REM, remnant; n-, nascent; TAG, triacylglycerol; PL, phospholipid; LP, lysophospholipid; FFA, free fatty acid; UC, unesterified cholesterol; CE, cholesteryl ester; BA, bile acid.

TABLE 22.3
Some Enzymes of Importance in Lipid Transport and Metabolism

Enzyme	Function
Pancreatic lipase	Hydrolysis of fatty acids at position 1 and 3 of emulsified triacyl-*sn*-glycerols in the intestine
Lipoprotein lipase	Hydrolysis of triacylglycerol-rich particles; some phospholipase activity; activated by apo C-II
Hepatic lipase	Hydrolysis of tri-, di-, and monoacylglycerols, acyl-CoA thiol esters, and phospholipids; conversion of HDL_2 to HDL_3; activated by apo A-II
Lecithin-cholesterol acyl transferase (LCAT)	Catalysis of reaction of lecithin with cholesterol to give lysolecithin and cholesteryl ester; activated by apo A-I and apo C-I
Pancreatic cholesterol esterase	Esterification of cholesterol in the intestinal lumen; hydrolysis of cholesteryl ester in the intestinal cell
Acyl CoA-cholesterol acyl transferase (ACAT)	Esterification of cholesterol within cells
HMG CoA reductase	Rate-limiting enzyme of cholesterol biosynthesis

G. VLDL Metabolism

Normal VLDL, similar to the chylomicron, is not taken up by cell receptors directly because of its relatively high apo C content, although small VLDLs can bind to the LDL B_{100}/E receptor (see below), presumably because of greater exposure of apo B (Owen and McIntyre, 1982; Gotto et al., 1986). The VLDLs bind to the endothelial LPL where their TAG is largely hydrolyzed, the rate of lipolysis being a function of size, possibly because more of the LPL cofactor, apo C-II, is associated with the larger particles (Gotto et al., 1986). As with the chylomicrons, surface components including unesterified cholesterol, phopholipid, apo C, and some apo E are transferred to HDL. The resultant VLDL remnant or IDL particle is relatively enriched in unesterified cholesterol, cholesteryl ester, apo B, and apo E. The VLDL remnant, similar to the chylomicron remnant, is a poor substrate for LPL and can either be taken up by the liver directly or be further metabolized to LDL.

Although large IDLs with a high apo E/apo B ratio may be taken up by the hepatic chylomicron remnant apo E receptor, the presence of apo B_{100} normally appears to mask the binding of apo E to the apo E receptor, thereby directing the IDL to the LDL B_{100}/E receptor, where it binds by virtue of the high affinity between apo E and the receptor (Brown and Goldstein, 1983, 1984). Whether IDL is taken up directly by the liver or further metabolized to LDL is dependent on the activity of the hepatic LDL B_{100}/E receptor and the size of the VLDL precursor. The IDL from the largest VLDL is more likely to be removed directly by the liver, possibly because of the greater number of apo E molecules (Gotto et al., 1986; Havel, 1987; Shepherd and Packard, 1987a,b), and since the VLDL of most mammals is larger than that of humans, this could account for the difference in the proportion of VLDL converted to LDL in different species and the generally low level of LDL in species other than humans.

Thus, in the rat, a major part of the VLDL (80%–90%) is converted to IDL and catabolized by the liver, and only 5%–15% is converted to LDL, whereas, in the humans, a greater proportion (although less than originally thought [Havel, 1984a, 1987]) is converted to LDL (Eisenberg, 1983). Another factor is that rat VLDL also contains apo B_{48}, whose presence favors hepatic uptake (Sparks and Sparks, 1985). The large size of the chylomicron and its species of apo B (apo B_{48}) may determine that the chylomicron remnant is taken up by the liver directly with no apparent conversion to a form of LDL (Havel, 1984b; Sparks and Sparks, 1985), although the latter possibility is not completely ruled out (Eisenberg, 1983). The large size of remnant particles also appears to preclude their uptake by extrahepatic tissues (Norum et al., 1983).

The formation of LDL from IDL is more likely to be effected by hepatic lipase than by LPL (Deckelbaum et al., 1982; Havel, 1984a; Eisenberg, 1986). This conversion is accompanied by further loss of TAG, PL, and apo E to give a particle that is enriched in cholesteryl ester and in which the apolipoprotein is almost entirely apo B, which alone of the VLDL apolipoproteins is conserved during the conversion of VLDL to IDL and of IDL to LDL (Eisenberg, 1986). It is unlikely that the conversion of IDL to LDL by hepatic lipase is mediated by the LDL receptor, or that hepatic lipase plays a role in the uptake of VLDL remnants (Havel, 1984a). Subspecies of LDL that differ in size and density have been described (Krauss, 1987; Musliner and Krauss, 1988). Direct hepatic secretion of particles resembling LDL but with an apolipoprotein composition similar to that of nascent VLDL has also been observed (Havel, 1984a). LDLs are removed from circulation by interaction of apo B with the LDL B_{100}/E receptor in hepatic and extrahepatic tissues. Since the affinity of this receptor for apo B is less than that for apo E, the half-life of LDL in circulation is greater than that of IDL, whose binding is mediated by apo E as described previously (Brown and Goldstein, 1984).

H. Receptor-Mediated Uptake of Lipoproteins

a. Chylomicron Remnant Receptors (E)

Most dietary cholesterol is taken up by the liver in the form of chylomicron remnants that bind to the apo E receptor in the liver. The influx of cholesterol depresses the synthesis of cholesterol from acetyl CoA and the activity of the LDL (apo B/E) receptor; however, the number of apo E receptors is not downregulated (Ho et al., 1976; Brown and Goldstein, 1983; Beynen et al., 1986; Gotto et al., 1986). Chylomicron remnants contain apo B_{48}, and high-affinity binding of these remnants, containing apo B_{48} and very little apo E, to hepatic cells has been demonstrated (Sparks and Sparks, 1985). A small proportion of chylomicron remnants containing apo E and apo B_{48} may bind to LDL receptors (Brown and Goldstein, 1983; Smith and Gotto, 1985).

b. LDL Receptors, B_{100}/E

The work of Goldstein and Brown and their coworkers has demonstrated that the uptake of circulating LDL by both hepatic and extrahepatic cells is mediated by a receptor that is specific for apo B_{100} and apo E (Goldstein and Brown, 1976, 1977, 1984; Brown and Goldstein, 1979, 1984; Brown et al., 1981; Schneider, 1989). The dual ligand specificity of the B_{100}/E receptor was established by binding studies with HDL_c, a form of HDL that accumulated in cholesterol-fed dogs and whose sole apolipoprotein is apo E, and LDL whose sole apolipoprotein is apo B.

The affinity of the receptor for apo E was found to be much greater than that for apo B, and this was attributed to the association of apo E with four receptor sites, whereas apo B interacts with only one (Pitas et al., 1979). The ligand–receptor interaction involves the acidic amino acids glutamate and separate the receptors E and B_{100}/E with the basic amino acids lysine and arginine of the ligands (apo E and apo B) (Mahley, 1986). The receptor is a protein of apparent molecular weight 160,000 (Goldstein and Brown, 1984; Schneider, 1989) and is principally located in coated pits on the cell surface. The coated pits, which have a life span of less than 5 min, invaginate to form a coated vesicle. The fusion of several of these vesicles produces an endosome, from which the receptor dissociates and returns to the cell surface. The LDL is digested by lysosomes to amino acids and unesterified cholesterol.

The increase in cellular unesterified cholesterol has the effect of depressing the activity of hydroxymethylglutaryl (HMG) CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis, stimulating acyl CoA-cholesterol acyl transferase (ACAT), which converts cholesterol to cholesteryl ester for storage, and suppressing the synthesis of further LDL receptors, thereby reducing further uptake of LDL by the cell. The overall effect is to regulate the level of unesterified cholesterol within the cell.

The nature of the molecules that downregulate cholesterol biosynthesis has not been completely resolved. The fact that release of unesterified cholesterol from the cell to a suitable acceptor (see below) stimulates HMG CoA reductase points to unesterified cholesterol as a regulator per se. However, studies *in vitro* have shown that highly purified cholesterol does not inhibit cholesterol synthesis, whereas oxygenated derivatives such as 25-hydroxycholesterol are potent inhibitors. This has led to the suggestion that it is small amounts of these oxygenated sterols that are responsible for the inhibition. It may be that cholesterol exerts a mass action effect in the regulatory pool and that the effect of the oxygenated sterols is mediated by an oxysterol-binding protein (Smith and Gotto, 1985).

Species and individuals differ in the degree of control of cholesterol metabolism. Although cholesterol synthesis is suppressed in the cholesterol-fed rat, the expression of the receptor is not diminished, and consequently the rat does not become hypercholesterolemic (Goldstein and Brown, 1984). Feedback inhibition of cholesterol synthesis may not operate in human liver (Schneider, 1989), possibly because of a low rate of hepatic synthesis (Grundy, 1983; Dietschy, 1984). The degree of hypercholesterolemia that develops as a result of cholesterol feeding can vary widely among individuals, and the defect in hyperresponders could be inadequate suppression of cholesterol biosynthesis or greater efficiency of cholesterol absorption. In hyporesponders, as in rats, it may be that the number of receptors is not downregulated to the same degree as in hyperresponders (Beynen et al., 1987).

I. Receptor-Independent Uptake of LDL

Even in subjects or animals that lack LDL receptors, there can still be considerable uptake of LDL. The extent of this receptor-independent pathway can be determined by measuring the turnover of LDL in which the lysine or arginine has been suitably blocked, thereby preventing receptor recognition (Shepherd and Packard, 1986). In the liver, endocrine glands, lung, and kidney, over 90% of LDL uptake is receptor mediated, but in the small intestine, and particularly in the spleen, the receptor-independent pathway is more important (Dietschy, 1984).

The receptor-independent pathway has a high capacity for lipoprotein uptake but a low affinity, and is nonspecific insofar as HDL can compete with LDL for binding to the low-affinity binding sites (Durrington, 1982). The LDL that binds to this site may be taken up by both fluid endocytosis and adsorptive endocytosis.

The LDL cholesterol taken up *in vitro* does not downregulate HMG CoA reductase or stimulate ACAT, suggesting that the cholesterol is not in the same pool as that taken up by the receptor-mediated pathway. However, in receptor-deficient states *in vivo*, there does appear to be some regulation, although this may occur at a higher than normal intracellular cholesterol concentration (Shepherd and Packard, 1986).

a. β-VLDL Receptor

Cholesterol feeding results in the appearance of cholesteryl ester rich, apo E-containing VLDLs termed β-VLDLs because of their β mobility on electrophoresis. These are taken up by specific high-affinity receptors on macrophages, and the expression of these receptors can be depressed and the formation of cholesteryl ester stimulated most by β-VLDL. This receptor also takes up chylomicrons and the large VLDL that occurs in hypertriacylglycerolemia, but not normal (VLDL, LDL, or HDL) (Gotto et al., 1986). The β-VLDLs are also taken up by the apo B/E receptor on fibroblasts, smooth muscle cells, and hepatic cells (Daugherty and Schonfeld, 1985; Smith and Gotto, 1985).

b. "Scavenger" or Acetyl LDL Receptor

This has been demonstrated in macrophages, smooth muscle cells, and endothelial cells and is responsible for the uptake of lipoproteins whose negative charge has been increased, as in acetylated lipoprotein. The receptor will also take up lipoprotein that could be modified *in vivo*, by combination

with malondialdehyde or by contact with endothelial cells (Smith and Gotto, 1985). This receptor is not downregulated by the uptake of cholesterol and has been implicated in the pathogenesis of atherosclerosis (Steinberg, 1983).

J. HDL Metabolism

The metabolism of HDL is shown in Figure 22.1b. The conversion of discoidal nascent HDL to the spherical plasma HDL was discussed earlier. The first major mature HDL to be formed in this way is termed HDL_3. It has a molecular weight of 175,000 and a hydrated density in the range 1.125–1.210 g/mL and contains 3 mol/mol HDL of apo A-I and 1 mol/mol HDL of apo A-II. HDL_3 is interconvertible with the large HDL_2, which has a molecular weight of 360,000 and a hydrated density in the range 1.063–1.125 g/mL and has 4 mol/mol HDL of apo A-I, 1 mol/mol HDL of apo A-II, and 1 mol/mol HDL of apo C (Eisenberg, 1983; Gotto et al., 1986). In turn, HDL_2 can be converted into HDL_1, which is larger than HDL_2 but is isolated in the same density range. It contains apo A-I, apo A-II, and variable amounts of apo E up to 60% of total protein. A considerable proportion of rat HDL occurs in this form (Nicoll et al., 1980; Eisenberg, 1984).

When the composition of HDL is considered from the point of view of lipoprotein families, it appears that LP-A-I and LP-A-I:A-II occur in both HDL_2 and HDL_3, but LP-A-I predominates in HDL_2 and LP-A-I:A-II in HDL_3 (Cheung and Albers, 1984). As a consequence of lipolysis of VLDL, HDL_3 can acquire unesterified cholesterol, PL, and apo C and be converted to HDL_2 (Patsch, 1982). Additional apo A-I is also required, and this could come from a free apo A-I pool or from chylomicron surface materials (Eisenberg, 1984; Tall, 1986a). The activity of extrahepatic LPL is strongly correlated with the level of human HDL_2 (Eisenberg, 1984). The HDL_2 level (Cavallero et al., 1988), LCAT activity (Tall, 1986a), and cholesteryl ester transfer rate (Fielding, 1987) (see below) are all increased during lipemia.

The addition of PL and unesterified cholesterol to HDL_3 lowers its density, but unless the cholesterol is esterified by LCAT and transferred to the hydrophobic core, the lipid can be removed again, making the process reversible (Eisenberg, 1984). Polar lipids resulting from the lipolysis of TAG-rich lipoproteins can also be accepted by HDL_2, and the LCAT reaction can produce an even larger particle, HDL_1, particularly in species such as the rat where there is no cholesteryl ester transfer protein (CETP) (see below), which can transfer the cholesteryl ester formed in the LCAT reaction to other lipoproteins. In this conversion, apo E arising from the lipolysis of TAG-rich lipoproteins replaces apo A-I, possibly as a result of the lower affinity of apo A-I for large particles (Eisenberg, 1984, 1986).

By loss of lipid and apolipoprotein, HDL_2 can be reconverted to HDL_3. It is envisaged that the first step is exchange of HDL_2 cholesteryl ester for TAG from chylomicrons and VLDL, which is facilitated by CETP. The TAG-rich HDL_2 is then hydrolyzed, principally by hepatic lipase, although LPL may play a part (Miller et al., 1978; Eisenberg, 1984; Tall, 1986a). Lipolysis removes TAG from the core and PL from the surface, followed by the release of other surface components, unesterified cholesterol, and apolipoproteins; apo C would be transferred to nascent TAG-rich lipoproteins. The regenerated HDL_3 could return to the plasma or be further metabolized (Nikkila et al., 1982).

It has been suggested that HDL_1 could be reconverted to HDL_2 by hepatic lipase action after binding to hepatic cells by virtue of its apo E content, and that the lipid-depleted particle, after dissociation of apo E, could be released back into circulation by retroendocytosis (Kinnunen et al., 1983).

K. Reverse Cholesterol Transport

Since peripheral cells do not catabolize cholesterol, the only way that the cell can lose cholesterol in order to maintain homeostasis is by efflux. Whether there is a net efflux or net influx of cholesterol or an exchange with a suitable acceptor depends on the cholesterol balance between the cell and the medium and the physical properties of the acceptor, particularly the unesterified cholesterol/PL ratio

(Rothblat et al., 1986; Phillips et al., 1987; Steinberg, 1987). In cells in which cholesterol is activity utilized, as in the steroidogenic cells and the liver, unesterified cholesterol can be extracted from lipoproteins (Eisenberg, 1984). The removal of cholesterol from cells is termed reverse cholesterol transport (RCT) and can be effected by PL liposomes and nascent HDL particles, which will accept cholesterol from cells, a process that is enhanced by the presence of apolipoproteins A-I, E, and A-II (Tall and Small, 1980; Daugherty and Schonfeld, 1985; Stein and Stein, 1988).

Similarly, HDL_3 promotes cholesterol efflux from cells (Ho et al., 1980; Oram et al., 1981; Nikkila et al., 1982; Eisenberg, 1984; Phillips et al., 1987; Barbaras et al., 1988). The efflux of cholesterol depends on the presence of LP-I particles that are postulated to bind to specific sites on the cell; apo A-II binds to the same site as apo A-I but does not promote cholesterol efflux and therefore behaves as an antagonist (Barbaras et al., 1988). Downregulation of the HDL receptors suppresses cholesterol efflux (Bierman and Oram, 1987). Both low-affinity nonsaturable (nonspecific) and high-affinity saturable binding sites have been identified on fibroblasts. The binding of HDL is not followed by internalization and degradation and can be upregulated by preloading the cells with cholesterol or downregulated by promoting efflux of cholesterol (Eisenberg, 1984).

If HDL_3 does compare closely to LP-A-I:A-II (Cheung and Albers, 1984), which does not promote cholesterol efflux (Barbaras et al., 1987), then it is curious that it appears to be the principal HDL class responsible for cholesterol efflux. However, it must also be borne in mind that the HDL classes do not have a monopoly of any of the lipoprotein families (Cheung and Albers, 1984). The cholesterol that is removed from the cell by the HDL acceptor is esterified by LCAT and transferred to the hydrophobic lipid core, leaving the surface free to pick up more cholesterol (Paul et al., 1980).

In those species that possess an active CETP, the cholesteryl ester can be exchanged for TAG with the TAG-rich lipoproteins and be ultimately returned to the liver in the form of remnant particle or LDL. In species, such as the rat, that do not possess an active CETP, the cholesteryl ester could be incorporated into HDL_1—an apo E-containing form of HDL—that can be recognized by the LDL B_{100}/E receptor (Nicoll et al., 1980; Scanu, 1983; Havel, 1984b). During lipemia, the activities of LCAT and CETP both rise (Tall, 1986a; Fielding, 1987), and there is an increase in the removal of cholesterol from cells. It has been suggested that postprandial lipemia is a physiological mechanism for the enhanced removal of excess cholesterol from the peripheral cells (Fielding, 1987).

The cholesterol in non-apo E-containing HDL could be removed either by uptake of the whole particle or by preferential removal of cholesteryl ester followed by retroendocytosis and recycling of the particle in the circulation (Phillips et al., 1987). Both of these pathways appear to operate, and the relative proportion of cholesterol metabolized by each route varies with the tissue and cholesterol status. Preloading of fibroblasts with cholesterol effectively inhibits preferential uptake of cholesteryl ester (Rinninger and Pittman, 1988). Whole particle degradation seems highest in liver and intestinal cells and lowest in fibroblasts and endocrine cells (Eisenberg, 1984).

High-affinity binding sites that differ from those of LDL have been demonstrated in the liver, adrenals, ovaries, and kidneys (Eisenberg, 1984) and arterial smooth muscle cells (Bierman and Oram, 1987). It is possible that RCT by means of HDL, LCAT, and CETP may not be wholly responsible for the regulation of tissue cholesterol and that other cholesterol acceptors that do not depend on LCAT on LCAT may be involved (Tall, 1986b). Most of the evidence for RCT has been obtained *in vitro*, but there is also *in vivo* evidence to support the hypothesis (Miller et al., 1985).

L. Lipid Transfer Protein

Many of the interactions between lipoproteins depend on the presence of lipid transfer proteins (LTPs) that are associated with the denser HDL in plasma. Although CETP facilitates exchange and net transfer of cholesteryl ester, TAG, and PL, there is a PL transfer protein (PTP) that does not transfer cholesteryl ester. The PTP promotes the exchange and transfer of PL between VLDL and HDL. The CETP promotes the exchange or transfer of cholesteryl ester and TAG between HDL and

the TAG-rich lipoproteins (Tall, 1986b) and between VLDL and LDL. The latter exchange results in the VLDL having more cholesteryl ester per particle than LDL and a smaller TAG-rich LDL. The excess cholesteryl ester in VLDL could be removed by either LPL or hepatic lipase during conversion to IDL and LDL (Grundy, 1983).

The binding of CETP to both VLDL and HDL and the CEPT-mediated transfer of cholesteryl ester are both stimulated by lipolysis. The increase in CETP activity could result from the increase in TAG-rich lipoproteins, which enhances the exchange of TAG for cholesteryl ester from the HDL (Tall, 1986b). Although PTP activity is high in several species, some mammals, such as dog, pig, rat, and cow, have very low CETP activity, which may be due to the presence of an inhibitor (Calvert and Abbey, 1985; Tollefson and Albers, 1986). In these animals, the LCAT-derived cholesteryl ester remains in the HDL fraction, sometimes in the form of HDL_1.

Since LCAT activity is inhibited by the accumulation of cholesteryl ester, the action of CETP in promoting the transfer of cholesteryl ester could regulate the activity of LCAT and the efflux of cholesterol from cells (Tall, 1986b; Barter et al., 1987). As the species that lack CETP have high levels of HDL and are markedly more resistant to diet-induced atherosclerosis, it has been suggested that high activity of CEPT leads to low-HDL levels and to increases in cholesterol in remnants and LDL, which are believed to be atherogenic (Calvert and Abbey, 1985; Tall, 1986b). However, it has been argued that LDL of normal composition, as distinct from that present in subjects at risk from coronary artery disease, is not atherogenic, and that transfer of cholesteryl ester from cells to VLDL and LDL, whose uptake is well regulated, could be beneficial (Fielding, 1987).

M. Utilization of Cholesterol

The cholesterol taken up by cells or synthesized within the cell can be incorporated into membranes or used for steroidogenesis. Both LDL and HDL contribute cholesterol to the adrenals, with HDL being the major source in the rat. Only HDL is bound with high affinity to membranes in rat testes and is the principal source of cholesterol; in other species, LDL is also utilized (Norum et al., 1983). Loss of cholesterol from the body is affected by sloughing of skin or by excretion in the bile as unesterified cholesterol or after conversion to bile acids. The steroid hormones are also excreted in bile or urine (Dietschy, 1984). The cholesterol taken up by the liver could suppress cholesterol biosynthesis, stimulate esterification, and increase synthesis of bile acids. Cholesterol could also be recirculated in lipoproteins (Grundy, 1983).

N. Desaturation Reactions

Except for a limited number of bacteria (Eubacteriales), the pathway of monounsaturated fatty acid synthesis involves an oxidative mechanism in which a double bond is introduced directly into saturated long-chain fatty acids with oxygen and NADPH as cofactors. The mechanism is not fully understood, although the microsomal electron transport chain apparently undergoes a complex cascade of redox reactions in which NADH-cytochrome b_5 reductase (EC 1.6.2.2) becomes reduced by NADH and in turn reduces an oxidized desaturase that catalyzes the desaturation of the fatty acid-CoA ester. Desaturation involves the removal of two hydrogen atoms that are transferred to molecular oxygen, leading to the formation of a double bond in the fatty acid CoA substrate and water.

The stoichiometry of electron flow was investigated by Rogers and Strittmatter (1974), who showed conclusively the reduction of cytochrome b_5 by NADH. The overall equation can be summarized as follows:

$$\text{NADH} + \text{H}^+ + \text{O}_2 + \text{R–CH2–CH2–R} \rightarrow \text{NAD}^+ + 2\text{H}_2\text{O}\ \text{R–CH=CH=R} \qquad (22.1)$$

The 1:1 molar relationship between NADH utilization and oleyl CoA formation has been confirmed by Strittmatter et al. (1972), who showed that the two electrons required for the introduction

of the double bonds are provided by reduced cytochrome b_5. The reduction of cytochrome b_5 by NADH follows the scheme (from Holloway, 1983)

$$E_{FAD} + NADH \rightleftharpoons E^{NAD}_{FADH_2} \rightarrow E^{NAD}_{FADH_2}$$

$$E^{NAD^-}_{FADH_2} + \text{cyt } b_5 \text{ oxidized} \rightarrow E^{NAD}_{FADH_2} + \text{cyt } b_5 \text{ reduced}$$

$$E^{NAD^-}_{FADH} + \text{cyt } b_5 \text{ oxidized} \rightarrow E^{NAD^-}_{FAD^+} + \text{cyt } b_5 \text{ reduced}$$

$$E^{NAD^-}_{FAD} \quad E_{FAD^+} + NAD^+$$

Holloway (1983) postulated a mechanism by which desaturation and concomitant removal of hydrogen occurs, which is analogous to cytochrome P-450-dependent drug oxidation, as follows:

1. Reduction of the prosthetic group of cytochrome P-450 via the first electron transfer.
2. Binding of molecular oxygen.
3. Oxidation of the prosthetic group and superoxide formation.
4. Second electron transfer.
5. Substrate binding that probably produces an epoxy fatty acid (epoxy acid radical).
6. Cleavage of the oxygen–oxygen bond and transfer of extracted hydrogen atoms to form water and a desaturated product.

Evidence for superoxide involvement in desaturation (Sreekrishna and Joshi, 1980) is shown by superoxide scavengers and copper chelates inhibiting desaturase activity. Enoch and Strittmatter (1979) purified an NADPH-dependent stearoyl CoA desaturase from membranes and reconstituted its activity in lipid vesicles using purified NADPH-cytochrome P-450 reductase. They suggested that NADPH is the physiological reductant rather than NADH.

In animals, the double bond (usually the *cis* configuration) can be introduced at the Δ4, Δ5, Δ6, Δ8, and Δ9 positions but not at the Δ12 or Δ15 positions; these EFAs are of plant origin. Further desaturation and insertion of a methylene group (e.g., elongation) leads to the formation of polyunsaturated fatty acids (PUFAs). Unsaturated fatty acids are important, for example, in regulating the physical properties of membranes and lipoproteins or as precursors for physiologically active metabolites. For example, arachidonic acid is a principal precursor for prostaglandins, prostacyclins, leukotrienes, and thromboxanes, which have important roles in smooth muscle stimulation, control of platelet aggregation, and the release of histamine in anaphylactic shock and other allergic reactions. The mechanism involved in the control of desaturation is poorly understood, although the following observations have been made.

O. Dietary Control

Prasad and Joshi (1979) demonstrated that dietary induction of Δ9 desaturase in chicken liver was due to an increase in the amount of terminal desaturase. Holloway and Holloway (1975) showed that the fourfold decrease in Δ9 desaturase activity of mice fed an essentially fat-free diet compared with mice fed a safflower-supplemented diet could not be related to differences in the lipid composition, NADH-cytochrome b_5 reductase, or cytochrome content of membranes. They concluded that the difference was due to a change in the amount of hepatic Δ9 desaturase. Excess dietary carbohydrate increases Δ9 desaturation, probably to maintain the physical properties of the fatty acyl chains of membrane PLs and hence maintain the optimal "fluidity" of membranes. Brenner (1981) reviewed the regulation of Δ5 and Δ6 desaturases; the latter appears to be less responsive to induction by high-carbohydrate diets, but diets deficient in EFAs cause a fourfold increase in Δ6 desaturation activity and a specific decrease in Δ5 desaturase activity with concomitant accumulation of 20:3n-9, which is characteristic of EFA deficiency.

P. Hormonal Control

The relationship between insulin and Δ9 desaturation activity has been studied in rats (Prasad and Joshi, 1979), embryonic chicken liver explants (Joshi and Aranda, 1979), and cultured 3T3-L1 murine cells (Kasturi and Joshi, 1982). In all cases, changes in desaturase activity were due to changes in the amount of the terminal Δ9 desaturase. In diabetic rats, insulin restored Δ9 desaturase to values in fructose-fed normal rats. With the chicken liver explants, insulin increased the very low amount of Δ9 desaturase, and this stimulation was potentiated by triiodothyroxine and hydrocortisone (Joshi and Aranda, 1979). The authors suggested that induction by insulin may regulate Δ9 desaturase mRNA, as measured by the inhibition of chromatin-bound poly(A) polymerase. 3T3-L1 murine cells also showed a 100-fold induction of Δ9 desaturase in response to insulin.

Lippiello et al. (1979) demonstrated a close relationship between membrane composition, fluidity, and desaturase activity in the tissue of roosters. Desaturase activity was high when membrane fluidity and the proportion of double bonds was low, and the change in activity was shown to be caused by an increase in the amount of enzymatic protein rather than by allosteric effects. Joshi and Aranda (1979) estimated the half-life of Δ9 desaturase to be 4 h. Strittmatter et al. (1972) purified stearoyl CoA desaturase and obtained a single polypeptide with M_r of 53,000 with 458 amino acid residues, of which 62% were nonpolar. Enoch and Strittmatter (1978) suggested that arginyl residues may be part of the binding site for the CoA moiety of the substrate. Prasad and Joshi (1979) isolated and purified Δ9 desaturase from chicken liver, as judged by immunochemical analysis. It is considerably smaller (M_r 33,500) than the rat hepatic enzyme (M_r 53,000). Sreekrishna and Joshi (1980) clearly demonstrated that Δ9 desaturase activity in chicken liver microsomes and in a reconstituted system was inhibited by divalent copper and chelated copper. They concluded that this inhibition is due to the destruction of superoxide (see above), which further substantiated the proposed involvement of cytochrome P-450 in desaturase activity.

Brenner (1981) reviewed the control of Δ5 and Δ6 desaturases. As with Δ9 desaturases, insulin increased their activity, whereas all other hormones tested decreases Δ5 and Δ6 desaturation. For example, Joshi and Aranda (1979) demonstrated loss of Δ6 desaturase activity in chicken liver explants within 3 h of injection of epinephrine (adrenaline). The work of Jones and Gaylor (1979) demonstrated that cytoplasmic protein stimulates microsomal Δ9 desaturase activity despite its inability to bind to acyl CoA esters. Δ9 Desaturases appear less responsive to cytoplasmic stimulation than Δ5 and Δ6 desaturases, which largely depend on the presence of these proteins. Extensive washing of microsomes led to the loss of Δ6 and Δ5 desaturase activities, which were restored by the addition of cytoplasm or a protein fraction isolated from it (Larsson and Brimer, 1979).

V. EFFECT OF DIETARY LIPID ON LIPOPROTEIN CHOLESTEROL

A. Dietary Cholesterol

A comprehensive, retrospective view of the effects of dietary cholesterol is given by McGill (1979a,b). More recent reviews include those of Coates (1983), Goldberg and Schonfeld (1985), Welch (1986), Beynen et al. (1987), McNamara (1987), and Gurr et al. (1989). When interpreting the results of feeding trials, it is important to bear in mind the possibility of a transient response to the diet that could be misleading if the experiment is of short duration. Adaptation and restoration of plasma lipid levels can sometimes occur if the experiment is of sufficient duration (Oliver, 1984; Price et al., 1985; Edgington et al., 1987).

B. Human Studies

According to McNamara (1987), a 70-kg man on a typical North American diet synthesizes 840 mg of cholesterol and absorbs 250 mg/day of a dietary intake of 450 mg/day of cholesterol.

The mechanism for plasma cholesterol homeostasis, in the face of increased cholesterol intake, include decreased absorption, decreased endogenous synthesis, increased biliary excretion, and, to a lesser extent, increased fecal bile acid excretion (McNamara, 1987; Quintao and Sperotto, 1987).

If the intake of cholesterol is relatively moderate (250–750 mg/day), some studies have shown that the compensating mechanisms largely prevent a rise in plasma cholesterol concentration (McNamara, 1987; Gurr et al., 1989). However, other studies have demonstrated an increase in plasma cholesterol concentration with an intake of cholesterol in the range of 0–600 mg/day, with little additional effect above 600 mg/day (McGill, 1979a,b). The response can be greater if the control diet is low in cholesterol and if the initial plasma cholesterol concentration is high. There is some evidence that hypercholesterolemic subjects have a greater response than normolipidemic subjects, but this has not been the experience of all investigators (Gurr et al., 1989).

The variation in the experimental findings could also be explained by the occurrence of hyper- and hyporesponders to dietary cholesterol. The differences between them are possibly due to inadequate suppression of cholesterol biosynthesis, greater efflux of cholesterol in lipoproteins, or more efficient absorption of cholesterol in hyperresponders (Beynen et al., 1987). In some studies, the effect of dietary cholesterol on plasma cholesterol concentration has been potentiated by the cholesterol being given with saturated fat rather than with PUFAs (Goldstein and Brown, 1976; McGill, 1979a,b).

C. Animal Studies

Most animal species are more sensitive than humans to dietary cholesterol and develop high-plasma cholesterol concentrations and aortic lesions that resemble human atheroma (McGill, 1979a,b). It has been claimed, however, that cholesterol-feeding experiments simply lead to lipid storage disease (Stehbens, 1989). Cholesterol supplementation of the diet results in an increase in IDL and LDL, a decrease in HDL_2, the appearance of a cholesteryl ester-rich, apo E-containing form of HDL, termed HDL_c, which is possibly HDL_1 present at a high concentration, and a cholesteryl ester-rich form of VLDL, termed β-VLDL, which contains both apo B and apo E and migrates with β mobility on paper electrophoresis (Mahley, 1978).

The β-VLDL from cholesterol-fed dogs can be fractioned into two classes, one of which resembles chylomicron remnants, and the other, VLDL of hepatic origin. Cholesterol-fed animals develop atherosclerotic lesions in which β-VLDL can be detected (Daugherty and Schonfeld, 1985). The HDL_c appears to represent a form of HDL that is loaded with cholesteryl ester and may play a role in transporting cholesterol from overloaded peripheral cells (Daugherty and Schonfeld, 1985). Lipoproteins similar to β-VLDL and HDL_c have also been identified in humans as a result of diet-induced hypercholesterolemia (Mahley, 1978; Daugherty and Schonfeld, 1985).

D. Dietary Fatty Acid Composition

It is generally believed that, in humans, the fatty acid composition and content of the diet are more important than the cholesterol content in affecting plasma cholesterol concentrations (Beynen et al., 1987). The saturated fatty acids (SFAs) 12:0, 14:0, and 16:0 are those that are principally associated with elevated plasma cholesterol concentration, especially LDL-c. Dietary PUFAs lower the plasma cholesterol concentration, the effect on lipoproteins being dependent on the type of PUFA. The n-6 fatty acids in vegetable oils primarily lower LDL-c, whereas n-3 fatty acids in marine oils primarily lower VLDL-TAG and VLDL-c. When the *P*/*S* ratio of the diet is high, HDL-c can also be lowered (Gurr et al., 1989).

The cholesterol-lowering effects of PUFAs are dependent on the basal conditions, that is, the initial plasma cholesterol concentration and the amount of cholesterol in the diet. It has been demonstrated that when there is no cholesterol in the diet, the increase in the *P*/*S* ratio is ineffective in reducing plasma cholesterol concentration (Connor et al., 1964; Mulvihill and Walker, 1984; Vergroesen, 1986). When the plasma cholesterol concentration is low initially, as in rats or rabbits, any increase in dietary lipid can cause it to increase, whatever the composition of the lipid, although

SFAs are more effective than PUFAs (Gurr et al., 1989). Individual response to dietary saturated lipid varies as with dietary cholesterol, and it appears that human hyperresponsiveness to dietary cholesterol is associated with hyperresponsiveness to SFA (Beynen et al., 1987).

E. Triacylglycerol Structure

The distribution of fatty acids on dietary TAG also has an effect on plasma cholesterol concentration. Thus, randomization of the fatty acids of both peanut oil and butter results in their having a cholesterol-lowering effect as compared to the unmodified materials (Beynen and Kritchevsky, 1986).

F. Level of Dietary Lipid

Nutritional advice intended to produce a lowering of plasma cholesterol has emphasized the need to reduce fat intake, based on the epidemiological evidence, but from nutritional experiments it appears that a high-fat diet with a high *P/S* ratio is as effective in lowering plasma cholesterol as a low-fat, high-carbohydrate diet, and the latter tends to raise VLDL-TAG (Gotenbos, 1985; Berry et al., 1986; Beynen and Kritchevsky, 1986; Gurr et al., 1989). Shepherd and Packard (1984) pointed out that the increase in VLDL production that results from a high-carbohydrate diet would increase VLDL-c and deplete hepatic cholesterol. This would stimulate hepatic cholesterol production and promote hepatic LDL receptors, resulting in a reduction in LDL.

VI. POSSIBLE MECHANISMS OF THE HYPOCHOLESTEROLEMIC EFFECTS OF DIETARY POLYUNSATURATED FATTY ACID

The subject has been reviewed by Paul et al. (1980), Goodnight et al. (1982), Grundy (1983), Welch (1986), McNamara (1987), Beynen et al. (1987), and Gurr et al. (1989).

A. Effects on Cholesterol Metabolism

a. Reduced Absorption of Cholesterol

Evidence in the literature is conflicting (Paul et al., 1980), but it appears that there is little effect of dietary PUFA on dietary cholesterol absorption (McNamara, 1987). Beynen et al. (1987), however, suggested that differences in cholesterol absorption may contribute to the difference in response to dietary cholesterol.

b. Redistribution of Cholesterol to Tissues

There is little evidence for this in humans (Paul et al., 1980; Beynen et al., 1987; Gurr et al., 1989), but there is some evidence in rats (Paul et al., 1980). Edwards-Webb et al. (1986) found that inclusion of PUFA in the diet of guinea pigs led to increases in both PUFA and cholesterol in erythrocyte membranes.

c. Increased Excretion of Cholesterol and Bile Acids

The evidence in animals is conflicting (Paul et al., 1980). In rabbits whose diet was supplemented with either butter- or PUFA-rich margarine plus an equivalent amount of cholesterol, it was found that the proportion of the plasma pool of cholesterol that was excreted daily was significantly greater on the margarine diet (Jadidi, 1989).

Studies in humans suggest that there is a greater fecal excretion of steroids, particularly endogenous cholesterol, as a result of PUFA in the diet (Paul et al., 1980; Liepa and Sullivan-Gorman, 1986). However, it has been suggested that the increased excretion may be a transient response only (McNamara, 1987). An increased intake of PUFA increases both the rate of bile flow and the

degree of unsaturation of biliary PL, which leads to greater solubility of cholesterol in the bile. Thus, increased amounts of cholesterol could be excreted into the intestine via the bile.

Pigs fed on soybean oil had increased concentrations of bile acid compared to pigs fed on tallow, and they also exhibited an increase in coprostanol in the gut, a metabolite of cholesterol that is less readily reabsorbed than cholesterol (J. D. Edwards-Webb and M. I. Gurr, personal communication).

d. Reduced Synthesis of Cholesterol

Most investigators agree that dietary PUFA does not inhibit cholesterol synthesis. However, Strain and Sherry (1985) concluded from balance studies that PUFA did have such an effect.

e. Enhanced Activity of LCAT

The enzyme LCAT catalyzes the reaction between lecithin (phosphatidylcholine) and cholesterol to give lyso lecithin (LPC) and cholesteryl ester. The most favored substrate for the LCAT reaction in humans is linoleate bound to the 2-position of *sn*-phosphatidylcholine (Dobiasova, 1983). An increase in PUFA in the diet increases the linoleate content of HDL PLs (Morrisett et al., 1977; Paul et al., 1980). In an earlier section, it was described how HDL acquires PL from TAG-rich lipoproteins when they are hydrolyzed. The phosphatidylcholine of the chylomicron coat is primarily of biliary origin and is principally 1-palmitoyl-2-linoleoyl-*sn*-phosphatidylcholine (Tso, 1985). It has been observed that patients suffering from acute myocardial infraction have particularly low levels of plasma LPC, which could have been due, at least in part, to a fall in LPC formation *in vivo*. A low level of LPC could exacerbate cardiovascular disease (CVD), because LPC inhibits platelet aggregation (Gillett and Besterman, 1975). There is also a low level of linoleate in the plasma cholesteryl ester of patients suffering from CVD (Grojec et al., 1983).

Wells and coworkers (1986) found that the LCAT molar esterification rate (MER) and LPC concentration were not significantly less than normal in cases of myocardial infraction, but that in patients without myocardial infractions, the severity of coronary atherosclerosis was related to increases in LCAT MER and LPC concentrations and a decrease in unesterified cholesterol. Since LPC was found to mediate the diffusion of LDL through the endothelium of the artery, the authors concluded that increased concentrations of LPC would promote the development of atherosclerosis. However, an increase in LPC would also have the beneficial effects of increasing LDL uptake by the liver (Dobiasova, 1983) and inhibiting platelet aggregation as noted above.

Changes in the fractional esterification rate (FER) are probably of greater significance than changes in MER. Dobiasova (1983) calculated the relative FERs from a number of studies involving comparisons of LCAT activity healthy controls and CVD patients. She concluded that in the disease state, the relationship between LCAT activity and the size of the plasma pool of cholesterol was impaired because either the LCAT activity did not increase proportionally with the plasma cholesterol concentration or the LCAT activity was inhibited at normal cholesterol concentrations. In patients with familial LCAT deficiency, there is a reduced rate of removal of atherogenic remnants of TAG-rich lipoproteins, because they are deficient in apo E, which they normally acquire as a consequence of the LCAT reaction (see Figure 22.1) (Norum et al., 1982).

Hawthorne et al. (1981) suggested that feeding soy lecithin would increase the proportion of linoleic acid in plasma PL and by doing so would lead to an increased production of cholesteryl linoleate via the LCAT reaction and thus facilitate removal of cholesterol from the body. They suggested that the LCAT reaction was more active after lecithin feeding and that sterol excretion increased. An advantage of feeding PUFA in the form of lecithin was that LDL levels were reduced and HDL levels raised. Similar conclusions were reached by Blaton and Hollez (1986). Sinclair (1980, 1984) also drew attention to the greater ease of transport and removal of cholesteryl linoleate from the body compared to cholesteryl oleate, which would be formed in the absence of EFA. Moilanen et al. (1986) reported that the percentage of plasma cholesteryl linoleate was negatively correlated with plasma total cholesterol and LDL concentrations in humans.

It has been suggested that the increased fluidity of the PL resulting from feeding PUFA could increase the rate of LCAT reaction (Morrisett et al., 1977). There are few experimental studies on the effect of dietary lipid on LCAT activity. Gjone et al. (1972) reported a reduction in esterification rate when PUFA replaced saturated fat in the diet. Miller et al. (1975) also reported a lower esterification rate when subjects were fed on PUFA-rich diets. A recalculation of the data of Miller et al. (1975) by Dobiasova (1983) showed that the change from a saturated fat-rich diet to a PUFA-rich one resulted in a decrease in the MER but no change in the FER, so the reduction in the free cholesterol pool was paralleled by a reduction in MER. Janetschek et al. (1983) reported a significant decrease in FER in normal females when a diet high in PUFA and low in cholesterol (*P/S* 1.0) was substituted by a control diet low in PUFA and high in cholesterol (*P/S* 0.3). There was also a nonsignificant decrease in MER.

In an experiment in our laboratory, in which the diet of pigs was supplemented with either butter or PUFA-rich margarine plus an equivalent amount of cholesterol (Jadidi, 1989), there was an increase in plasma cholesterol concentration on the butter diet that was accounted for by an increase in cholesteryl esters, and no significant change in the plasma cholesterol of the margarine-fed pigs, although there was a significant decrease in unesterified cholesterol and a significant increase in cholesteryl ester. The butter diet resulted in a nonsignificant increase in both MER and FER via the LCAT reaction, whereas the margarine diet produced a very significant increase ($p < .001$) in both MER and FER.

It seems likely, therefore, that a diet rich in PUFA leads to an increase in linoleate, the preferred substitute of LCAT, in phospholipids, and increased formation of LPC and cholesteryl linoleate via the LCAT reaction. The increase in linoleate in HDL-PL and HDL-cholesteryl ester could increase the fluidity of the particle and allow easier transfer of cholesteryl ester to the hydrophobic core, thereby leaving the surface free to pick up more cholesterol via the reverse cholesterol pathway (Paul et al., 1980; Blaton and Hollez, 1986).

B. Effects of Lipoprotein Metabolism

a. Reduction in Rate of Synthesis of VLDL and LDL

Substitution of a diet rich in PUFA for a diet rich in saturated fat decreased the synthetic rates of both VLDL apo B and LDL apo B (Cortese et al., 1983). However, other workers reported that a PUFA-rich diet had no significant effect on the synthetic rate of LDL, although they did not rule out a contribution to cholesterol lowering by this means (Shepherd et al., 1980). McNamara (1987) concluded from a study of the literature that large increases in the *P/S* ratio reduced the production of VLDL and LDL apo B to a greater extent than they increased the fractional catabolic rate (FCR) (see below), but the paucity of data prevented a conclusion as to the effect of more modest increases in *P/S* ratio. The lowering of plasma LDL by feeding n-3 fatty acids has been attributed to a reduced synthesis of apo B (Illingworth et al., 1984).

b. Increase in FCR and Changes in Fluidity of Lipoproteins and/or Their Receptors

In the experiment described above, Cortese et al. (1983) found no change in the FCR of LDL on substituting a PUFA-rich diet for a saturated fat-rich one but Shepherd et al. (1980) and others (Goodnight et al., 1982) have observed increases in the FCR. Dietary saturated fat has been found to downregulate LDL receptors (Schonfeld, 1988).

Increases in lipoprotein fluidity as a result of PUFA-rich diets have been reported (Morrisett et al., 1977), and it has been suggested that dietary unsaturated fat may promote increased fluidity of the lipoprotein, which could increase receptor affinity and promote endocytosis (Havel, 1983). Increased fluidity of membranes could also facilitate the incorporation of LDL receptors. It has also

been suggested that because PUFA occupies a greater area than SFA, incorporation of PUFA into LDL could change its configuration and decrease the cholesterol/protein ratio, thereby reducing its capacity to transport cholesterol (Spritz and Mishkel, 1969; Shepherd et al., 1980). LPL will hydrolyze TAGs containing PUFA faster than those containing SFA (Morrisett et al., 1977), and this could lead to enhanced clearance of lipoproteins and increased production of HDL.

c. Change in Size of Lipoprotein Particles

It is generally believed that relative atherogenicity is inversely related to particle size, because small particles such as LDL could permeate the arterial intima more easily than the larger VLDL or IDL (Morris et al., 1984) and because there is a negative correlation between the level of small LDL particles and that of HDL (Shen et al., 1981). It would appear to be paradoxical, therefore, that hyperlipidemia characterized by high levels of VLDL and LDL leads to an enhanced incidence of atherosclerosis. However, it has been demonstrated that a greater range of particle size in the VLDL and IDL occurs in such hyperlipidemias, with the mean particle sizes being lower than normal. The decrease in particle size is accompanied by an increase in TAG content and a decrease in cholesterol content (believed to be mainly cholesteryl ester) and is therefore indicative of a change in core lipid composition. It was concluded that the enhanced atherogenicity was due to the decreased size and altered composition of the particles (Morris et al., 1984).

Similarly, Sniderman and coworkers (Sniderman et al., 1980; Sniderman and Kwiterovich, 1984) attributed enhanced atherogenicity to a class of LDLs found in a subgroup of coronary patients who had a normal LDL cholesterol level but an elevated level of LDL apo B. They suggested that the increased number of LDL particles of smaller size could have resulted from either impaired catabolism or overproduction of VLDL, and that the risk of CVD is more closely related to the number of LDL particles than to the level of LDL-c. Subsequently, it has been demonstrated that in such cases of hyperapobetalipoproteinemia, there is increased production of VLDL and LDL. The situation is exacerbated by a high level of dietary fat, which resulted in higher levels of chylomicrons and VLDLs as a result of delayed clearance (Kwiterovich, 1988). The small LDL is removed from the plasma more slowly than large LDLs (Thompson et al., 1987; Kwiterovich, 1988; Musliner and Krauss, 1988). However, Rudel and coworkers (Rudel et al., 1983, 1986; Johnson et al., 1985; Clarkson et al., 1986) maintain that the size of LDL is positively correlated with coronary atherosclerosis. They found that the American green monkey is a good model for atherogenesis in humans and that the effect of changing from a diet rich in saturated fat to one rich in PUFA was to reduce the plasma cholesterol concentration and both LDL-c and HDL-c. There was a reduction both in the size of LDL and in aortic atherosclerosis. However, similar changes in the diet of cynomologus monkeys produced no change in plasma or LDL cholesterol concentrations, and although there was a decrease in HDL-c, there was an increase in LDL size. The authors suggested that dietary PUFA may be atherogenic in this species of monkey. Jadidi (1989), working with rabbits, also found that dietary PUFA in the form of margarine, as compared to butter, increased the size of LDL.

Large VLDL is removed from the plasma more rapidly than small VLDL and does not give rise to LDL (Shepherd and Packard, 1987a,b). Similarly, large chylomicrons and their remnants are more rapidly cleared from the plasma than smaller ones (Quarfordt and Goodman, 1966; Eisenberg, 1983). Dietary PUFA gives rise to larger chylomicrons than does saturated fat (Caselli et al., 1979; Mattson, 1983), and if it is possible that small chylomicrons (intestinal VLDL) could give rise to a form of LDL (Eisenberg, 1983), then this could be a contributory factor in the hypercholesterolemic effect of saturated fat.

There are differing accounts on the effect of dietary fat on the size of VLDL. Hojackni et al. (1977) found that a dietary supplement of corn oil, as compared to coconut oil, produced large VLDL in cebus monkeys, but Jadidi (1989) found that dietary polyunsaturated margarine, as compared to butter, produced smaller VLDL.

d. Modification of Apolipoproteins

The activation of LCAT by apo A-I and the section of apo A-I in the form of a preapoprotein, which undergoes cleavage to give the active mature form, have been discussed in previous sections. Mengheri et al. (1985) found that when rats were given a high-fat, high-cholesterol diet-containing casein, their LDL-c increased, and this was accompanied by the appearance, in the apolipoprotein electrophoretic pattern of all the lipoproteins, of an anomalous apo A-I band with greater than normal mobility. When fava bean or its ethanol extract was added to the diet, plasma cholesterol concentration was reduced and the apo A-I disappeared from the LDLs, but both the abnormal and the normal form were present in HDL.

The authors suggested that the structure of the cholesterol- and TAG-rich particles leaving the intestine was such that the normal cleavage of preapo A-I to apo A-I was inhibited and that cleavage took place at a different site, to give a smaller form of apo A-I with greater electrophoretic mobility. This form of apo A-I could have a reduced ability to activate LCAT. The addition of fava bean or its ethanol extract could have supplied a polyunsaturated lecithin that could promote the LCAT reaction and facilitate the correct processing of preapo A-I to the mature form of apo A-I.

23 The Effects of Dietary Fatty Acids on Lipid Metabolism

Madhuri Vemuri and Darshan S. Kelley

CONTENTS

I. INTRODUCTION

Both the amount and type of dietary fatty acids affect the development and progression of several human chronic diseases including cardiovascular diseases (CVD) and cancer. One of the mechanisms by which dietary fatty acids impact human health is by altering lipid metabolism.

In this chapter we review the effects of dietary saturated, monounsaturated and polyunsaturated fatty acids (PUFAs) of chain length C-12 and longer, on the metabolism of fatty acids, cholesterol, and eicosanoids. We will also summarize the sources of fatty acids, their digestion, absorption, and transport, and describe in some detail *de novo* fatty acid synthesis and catabolism. This chapter has been prepared to replace the chapter published by Dr Gary J. Nelson in the second edition of this book (Nelson, 2000).

Results from studies published prior to 2000 will be summarized here and those published since then will be discussed in detail. For details regarding the earlier literature, the readers are referred to the second edition of this book and some other reviews (Sprecher et al., 1995; Sprecher, 1996; Mohammed et al., 1997); for more recent advances in this field the reader is referred to following reviews (Mu and Porsgaard, 2005; Arterburn et al., 2006; Breslow, 2006; Carpentier et al., 2006; Gebauer et al., 2006; Goyens et al., 2006; Hibbeln et al., 2006).

One should recognize that dietary fatty acids, including the essential fatty acids (EFA) are a macronutrient in the human diet. In the Western diet, consumed primarily in Europe and North America, fatty acids can be the major source of calories. (Carbohydrates are usually the largest source of calories in many Asian and third-world countries.) In reality, the influence of dietary fatty acids on

lipid metabolism cannot be separated from the effects of carbohydrate and protein in the diet, but this subject is not within the scope of this chapter.

II. CHARACTERISTICS OF DIETARY FATTY ACIDS

A. Sources and Quantities

Approximately 99% of the fatty acids consumed are as acyl esters, usually triacylglycerols, occasionally mono- or diglycerides (in the Western diet these compounds are often added to processed foods), and, to a lesser extent, phospholipids and other complex lipids found in plant and animal tissues (Norris, 1983). Chemically, triglycerides (TGs) are the triacylglycerols or a glycerol molecule esterified with three fatty acids. Animal fats are a rich source of saturated medium-chain fatty acids and oleic acid (18:1n-9). Plant seed oils are good sources of linoleic acid (18:2n-6, LA) and contain only trace amounts of n-6 fatty acids with chain lengths longer than 18 carbons. Arachidonic acid (20:4n-6, AA) is found in all animal tissues and animal-based food products (Jonnalagadda et al., 1995). Brain and several other organ meats contain hydroxy fatty acids in small amounts (Rouser et al., 1968; Hakamori, 1983), and long-chain saturated fatty acids (SFA) up to 26 carbons in length can be found in small amounts in most animal tissues.

Conjugated linoleic acid (18:2n-6, CLA) and gamma linoleic acid (8:3n-6, GLA), are other important n-6 fatty acids that are found in relatively small amounts in the diets but have significant physiological effects. CLA is a collective term for isomers of LA that have conjugated double bonds. Depending on the position and geometry of the double bonds, more than a dozen isomers of CLA have been reported; two of those isomers, *cis* 9, *trans* 11-CLA (*c*9, *t*11-CLA) and *trans* 10, *cis* 12-CLA (*t*10, *c*12-CLA), have been studied regarding their health effects. The major dietary sources of *c*9, *t*11-CLA are dairy products and ruminant meat, while that of *t*10, *c*12-CLA are partially hydrogenated vegetable oils from margarines and shortenings. Primrose, borage, and black currant seed oils contain considerable amounts of GLA. Dietary fatty acids of the n-3 series include α-linolenic acid (18:3n-3, ALA), eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA). Flax and perilla seed oils are very rich sources of ALA, while deep ocean fish and the fish oils are good sources of EPA and DHA. Another good source of DHA-TG is the oil from genetically engineered algae in which DHA represents approximately 50% of the total fatty acids. In addition, certain animal tissue like brains have significant amount of DHA. Humans cannot insert the first double bond at C3 or C6, but can elongate and desaturate LA and ALA. Therefore, fatty acids with 18, 20, or 22 carbons, with 2–6 double bonds in *cis* configuration, and the first double bond between C3 and C4, or C6 and C7, are considered EFA.

Modern diets based on industrial agriculture are considered to be deficient in n-3 fatty acids (Lands, 1986a; Simopoulos et al., 1994; Broadhurst et al., 1998; Cordain et al., 2005). This is the result of both increased consumption of n-6 fatty acids and decreased consumption of n-3 fatty acids. Other populations, particularly Eskimos, who maintain a traditional life-style, are a prime example, as are the Japanese and other societies who consume a large amount of fish and obtain significant amounts of n-3 fatty acids in their diets and conditions are better health status seen in these populations (Bang et al., 1980; Dyerberg and Jorgensen, 1982). Endogenous synthesis of fatty acids, such as palmitic, stearic, and oleic acids, is triggered by consumption of excessive calories from carbohydrate or protein.

Americans consumed approximately 36%–37% of their calories as fat in 1985 (Ernst, 1991); this was comprised of 13.2% saturated, 13.8% monounsaturated, and 7.0% polyunsaturated fatty acids. According to the data from NHANES 1999–2000 survey (CDC, 2001), the percentage of energy from fat decreased to 32.8% in both men and women. The reduction in fat intake was largely from the reduction in saturated fat intake, which reduced to approximately 11% in both sexes. SFAs consumed are primarily 14:0, 16:0, and some 18:0. The monounsaturated fatty acids are almost exclusively 18:1n-9 unless one is eating much fish or rapeseed oil, containing 20- and 22-carbon

monounsaturated fatty acids. The PUFAs are almost exclusively 18:2n-6 or 18:3n-3, unless fish consumption plays a large role in one's diet, in which case long-chain, polyunsaturated n-3 fatty acids (n-3 PUFAs) such as EPA and DHA can contribute to the composition of dietary PUFAs. However, 18:2n-6 and 18:2n-3 probably account for more than 95% of the PUFAs consumed in the typical Western diet.

Recent data from NHANES III indicate that an average daily intake of n-3 PUFA is about 1.6 g (0.7 en%), out of which EPA and DHA constitute only 0.1–0.2 g/day (Hibbeln et al., 2006). Thus, the current intake of long chain n-3 PUFA is much higher than 50 mg reported in some of the earlier reports (Ernst, 1991; Jonnalagadda et al., 1995). Recommendations for daily intake of n-3 PUFA vary between several scientific and health organizations. American Heart Association recommends eating one serving of oily fish at least twice a week and includes oils rich in ALA if one does not have documented CVD (Kris-Etherton et al., 2002). For patients with documented CVD, the recommendations are 1 g/day of EPA + DHA and for those with hypertriglyceridemia, 2–4 g/day of EPA + DHA is recommended. ISSFAL (2004) recommended for healthy adults 2 en% from LA, 0.7 en% from ALA, and a minimum intake of 500 mg/day of EPA + DHA. Similar but different recommendations have also been made by WHO 2003, NCEP 2002, and USDA dietary guidelines 2005.

III. DIGESTION OF FATTY ACIDS

Although this topic has been discussed extensively, it is necessary to review briefly some salient points as they cannot be easily separated from the topic of this chapter.

Fat digestion and absorption is a multistage metabolic process, the complexity of which is compounded by the insolubility of most lipids in aqueous media (Small, 1983). When fat is consumed, either in natural foods or in a purified form (in experimental dietary protocols), a series of physiological events begin that last for 16–24 h if no other food is consumed after the initial meal (Bisagaier and Glickman, 1983). Initially, the fatty food, if consumed orally and masticated (rather than as capsules or by stomach tube), is mixed with lingual lipase, followed by hydrolysis of the TGs by gastric lipase in the stomach (Muller et al., 1975; Moreau et al., 1988). Both lingual and gastric lipases preferentially hydrolyze short-chain fatty acids at the sn-3 position to produce diacylglycerols (Phan and Tso, 2001; Mu and Porsgaard, 2005). Considerable species differences exist regarding the occurrence and abundance of lingual lipase and gastric lipase. Rats and mice have lingual lipase and essentially no gastric lipase, whereas humans and baboons have high levels of gastric and pancreatic lipase and very little lingual lipase. Gastric lipase has a significant metabolic role in the digestion of fat by human neonates who have a relatively low activity of pancreatic lipase and in patients with pancreatic insufficiencies.

Very short-chain (up to eight carbons) fatty acids are absorbed directly from the stomach into the venous circulation. In addition, small but variable amounts of long-chain free fatty acids (FFAs) can be absorbed directly by the portal circulation (McDonald et al., 1980; Surawicz et al., 1981; Carey et al., 1983; Vallot et al., 1985; Jandacek et al., 1987). In healthy rodents, 30%–70% of the intraduodenally infused long-chain fatty acids bypasses the lymph and directly enters the portal vein (McDonald et al., 1980). Such information in healthy human subjects is not available, however, the portal vein absorption of dietary long-chain unsaturated fatty acids in patients with advanced cirrhosis has been reported (Cabre et al., 2005).

Most of the C_{14}–C_{18} fatty acids, as free or esterified fatty acids, are passed into the intestinal lumen, where pancreatic lipase, colipase, and bile are added to the digestive ferment followed by further lipolysis. The composition of fat entering the upper duodenum is made up of 70% of TGs with the reminder consisting of a mixture of partially digested hydrolysis products formed primarily by gastric lipase. Under normal digestion and absorption, majority of the fatty acid hydrolysis is caused by pancreatic lipase which acts mainly on the sn-1 and sn-3 position of the natural TGs, leaving the 2-monoglyceride intact (Borgstrom, 1974; Tso, 1985; Mu and Porsgaard, 2005). A rearrangement of sn-2 monoglyceride into sn-1(3) monoglyceride may result in complete degradation into

glycerol and FFAs by pancreatic lipase. Even though the pancreatic lipase is active toward fatty acids located in the sn-1(3) positions, the activity toward n-3 fatty acids, particularly EPA and DHA, is lower compared with activity toward other fatty acids at the same position (Mu and Porsgaard, 2005).

Phospholipids are hydrolyzed by pancreatic enzymes to FFAs and their derived lyso compounds (Tidwell et al., 1963; Borgstrom, 1974). Pancreatic phospholipase A_2 acts on the sn-2 position of phospholipids to produce 1-lyso compounds. Pancreatic lipase (1,3-acylglycerol ester hydrolase) also acts on the 1-position of phospholipids (Borgstrom, 1974; Tso, 1985); however, most phospholipids are absorbed by the enterocyte as the 1-lyso compound after being hydrolyzed by phospholipase A_2 (Nilsson, 1969; Borgstrom, 1974). Cholesterol esters, if present, are hydrolyzed completely (Nilsson, 1969) to free cholesterol and FFA by cholesterol esterases.

Once the ingested fats have been hydrolyzed to FFA, monoglycerides, lysophospholipids, and free cholesterol, the hydrolysis products are absorbed by the enterocytes of the intestinal wall. The process of absorption from the intestinal lumen into the enterocyte is by passive diffusion (Carey et al., 1983). Studies by Stremmel have also indicated the possibility of presence of a fatty acid binding protein associated with brush border membrane, and that it might play a role in fatty acid uptake by enterocytes (Stremmel, 1988). However, this carrier-mediated process might play a role only in low fatty acid concentrations. FFA, lysophospholipids, and 2-monoglycerides can be absorbed almost completely in the absence of bile salts (Borgstrom, 1977a), although the presence of bile is obligatory for the absorption of free cholesterol (Borgstrom, 1977b).

IV. FATTY ACID TRANSPORT

In the enterocyte, the lipolysis products are re-esterified in the endoplasmic reticulum to TG, phospholipids, and other complex lipids (Brown and Johnston, 1964). Cholesterol can be synthesized de novo if there are inadequate dietary quantities, but even if no cholesterol is supplied by the diet, the bile supplies appreciable quantities to the enterocyte during fat absorption (Borgstrom, 1977a, b). However, the enterocyte treats dietary cholesterol and endogenous cholesterol differently. For instance, cholesterol derived from the intestinal lumen does not mix evenly with the free cholesterol pool and is preferentially reesterified in the enterocyte for export into TG-rich lipoproteins (Stange and Dietschy, 1985; Pool et al., 1991). The newly synthesized TGs, phospholipids, and cholesterol esters are combined with de novo-synthesized apolipoproteins, mainly apo B-48, with some apo A-I, A-II, A-IV, and E to form chylomicrons (Simmond, 1972). The chylomicrons are then secreted into the lymphatic system and carried by the thoracic lymphatic duct to the superior vena cava, where they enter the blood circulation (Simmond, 1972).

Lipoprotein lipase released by the capillary endothelial cells hydrolyzes the TGs in chylomicrons, releasing FFA and 2-monoglycerides. Lipoprotein lipase is activated in the presence of apo C-II as cofactor (Fielding and Fielding, 1977) and inhibited by apo C-III (Jong et al., 1999). It has positional specificity for the primary ester bonds of acylglycerols (Nilsson-Ehle et al., 1973) and hydrolyzes the TGs to 1,2- and 2,3-diacylglycerols and FFA. It also hydrolyzes 1,2- and 2,3-diacylglycerols to 2-monoacylglycerols and 1- and 3-monoglycerides to free glycerol and fatty acids (Morley et al., 1975). Lipoprotein lipase has no effect on 2-monoglycerides (Scow et al., 1977); 2-monoglycerides are hydrolyzed by lipases in the liver (Havel, 1985).

FFA and monoglycerides released by the lipoprotein lipase are taken up by the peripheral tissue (Fielding and Fielding, 1977). Some of the FFAs released bind to albumin and are cleared by the liver (Bergman et al., 1971). The chylomicron remnants have some apo B-48, apo E, phospholipids, cholesterol, cholesterol ester, and some TGs (Havel, 1982). These remnants are then cleared from circulation by the liver low-density lipoprotein (LDL) receptor and LDL receptor-related protein (LRP) (Redgrave, 2004). Though both contribute to chylomicron remnant clearance, LDL receptor normally predominates.

Apo E is the major apoprotein constituent of the TG-rich lipoproteins. It is a determinant for the receptor-mediated catabolism of very low-density lipoproteins (VLDLs), chylomicrons, and their

remnants. Thus, high Apo E levels are generally expected to increase lipid clearance (Chalas et al., 2002). Apolipoprotein B-48 does not bind to the LDL receptor (Hui et al., 1981) and thus does not aid in the clearance of chylomicron remnants.

Another lipoprotein that plays a crucial role in endogenous lipid transport is high-density lipoprotein (HDL). HDLs are involved in the transport of cholesterol from peripheral tissues to liver, a process referred to as reverse cholesterol transport. HDL particles consist of apo E, apo A-I, apo A-II, and apo C with phospholipids and unesterified cholesterol. It was believed that the apoprotein–phospholipid–cholesterol coat of the chylomicron remnants buds off to form precursor HDL particles (Nicoll et al., 1990). However, more recent findings indicate that nascent HDL particles originate in liver and intestine as lipid free or lipid poor apolipoproteins (Basso et al., 2003; Brunham et al., 2006). The newly secreted HDL particles acquire additional cholesterol and phospholipids via ATP-binding cassette transporter A1 (ABCA1) from the liver to form discoidal HDL particles. ABCA1 is an important cellular protein that facilitates efflux of cellular cholesterol to lipid poor apo A-1 as the preferred acceptor. Targeted disruption of hepatic ABCA1 in mice dramatically reduced circulating HDL (Timmins et al., 2005). These discoidal HDL particles acquire additional cholesterol and phospholipids from cells in extrahepatic tissues via ABCA1-mediated efflux, progressively generating particles that are more cholesterol enriched. The enzyme lecithin cholesterol acyltransferase (LCAT), carried on HDL particles, then esterifies the free cholesterol molecules to form cholesteryl ester, which migrate to the core of the HDL particle to form mature spherical HDL particles (Lewis and Rader, 2005; Krimbou et al., 2006). HDLs are further remodeled by cholesteryl ester transfer protein (CETP), which mediates the transfer of cholesteryl esters from HDL to VLDL and chylomicrons.

The liver catabolizes chylomicron remnants, resynthesizes TGs from fatty acids, and repackages them into VLDLs, consisting predominantly of TGs, small amounts of cholesterol and phospholipids, and release them into circulation (Havel, 1985). Small intestine also synthesizes and secretes VLDL-like particles formed from endogenously synthesized lipids in the fasting and postprandial state (Gangl and Ockner, 1975; Tso and Simmonds, 1984). VLDLs are also substrates for endothelial lipoprotein lipase. They lose TGs by hydrolysis and are transformed to intermediate-density lipoproteins (IDLs) and finally to LDL. LDL is taken up by the LDL receptor (Goldstein et al., 1983) of peripheral tissue and liver by receptor-mediated endocytosis. LDL primarily transports cholesterol esters to the peripheral tissues, where they are hydrolyzed to free cholesterol and then reacylated (Sodhi et al., 1978).

V. FATTY ACID METABOLISM

A. Fatty Acid Synthesis

The liver is the primary site for lipid metabolism (Volpe and Vagelos, 1973; Bloch and Vance, 1977; McGarry and Foster, 1980) and is the organ most susceptible to diet-induced changes in lipid metabolism. Adipose tissue is also a major organ system in which fatty acid synthesis occurs when excess calories are consumed; however, in humans it is less active than in many animal species (Hollands and Cawthrone, 1981; Large et al., 2004; Stich and Berlan, 2004).

In the initial step of fatty acid synthesis, acetate as acetyl CoA is condensed with bicarbonate to form malonyl CoA by acetyl-CoA carboxylase. Acetyl CoA is then combined with a series of malonyl CoA molecules by fatty acid syntheses to form fatty acids of different carbon lengths. For example, four malonyl CoA residues are combined by fatty acid synthase to form lauric (12:0) acid. Two more malonyl CoA residues are added to this to produce palmitic acid (Wakil et al., 1958; Lynen, 1967a; Vagelos and Larrabee, 1967; Arslanian et al., 1976; Stoops et al., 1976). If only one malonyl CoA is added to lauric acid, myristic acid (14:0) would be formed. The synthetic reactions up to this point all take place within the fatty acid syntheses complex (Wakil et al., 1958; Lynen, 1967a; Vagelos and Larrabee, 1967; Tanabe et al., 1975; Arslanian et al., 1976; Stoops et al., 1976).

$$CH_3–CO–S–CoA + 7HOOC–CH–CO–S–CoA + 14NADPH + 14H^+ \longrightarrow CH_3–(CH_2)_{14}–COOH + 8CoA–SH + 7CO_2 + 6H_2O + 14NADP^+$$

FIGURE 23.1 The general chemical equation for the de novo synthesis of palmitic acid from acetyl-CoA in most tissues.

Biotin is a required cofactor for the conversion of acetyl CoA to malonyl CoA by acetyl CoA carboxylase (Lynen, 1967a). Acetyl CoA carboxylase is a ubiquitous enzyme found in most mammalian tissues (Waite and Wakil, 1962; Kleinschmidt et al., 1969) and in other species as well (Bimbaum, 1969). It is the rate-limiting enzyme for fatty acid synthesis in most mammalian tissues (Vagelos and Larrabee, 1967), although in some circumstances fatty acid synthase may be rate-limiting (Chang et al., 1967; Majerus et al., 1968; Numa et al., 1970). Regulation of acetyl CoA carboxylase is usually achieved through the supply of acetyl CoA or citrate produced by the Krebs cycle (Lane et al., 1974, 1979). Palmitoyl CoA (and other medium-chain acyl CoA) is a strong inhibitor of acetyl CoA carboxylase *in vitro* (Taketa and Pogell, 1966; Tsutsumi and Takenaka, 1969; Goodridge, 1973; Nikawa et al., 1979). Regulation by dietary fatty acid may proceed through the formation of medium-chain acyl CoA derivatives (Leveille, 1967a,b; Goodridge, 1969; Numa and Nakanishi, 1970; Kitajima et al., 1975; Jeffcoat and James, 1977; Kamirgo et al., 1979).

The summary of reactions involved in the condensation of malonyl CoA to palmitic acid is shown in Figure 23.1. This reaction is catalyzed by fatty acid synthase and requires one molecule of acetyl CoA, seven malonyl CoA, seven NADPH molecules, and 14 H^+. Fatty acid synthase is a multienzyme complex (Veech and Guynn, 1974; Stoops et al., 1979; Wakil et al., 1983) and the central component of the fatty acid synthase complex is the acyl carrier protein (ACP). Despite having no catalytic properties of its own, ACP is essential to the binding of acyl CoA molecules as they are condensed into longer chain fatty acids within fatty acid synthase complex (Prescott and Vagelos, 1972). Free palmitic acid is the primary product of fatty acid synthase reactions in animal tissues (Volpe and Vagelos, 1973; Brindley, 1978). Some myristic and lauric acids are also formed, and a trace of stearic acid may also be produced (Wakil et al., 1983).

Once free palmitic acid is released from the synthase complex, it can be esterified into complex lipids, elongated to stearic acid, or desaturated to palmitoleic acid (Beare-Rogers, 1977; Brenner, 1989). Different enzymatic pathways are involved in these reactions. The regulation and control of these secondary pathways are poorly understood (Beare-Rogers, 1977). However, little or *no de* novo fatty acid synthesis takes place in humans when adequate or excess calories are consumed in a high-fat diet. Conversely, when carbohydrate is fed in excess of caloric requirements, the conversion of carbohydrate to fatty acids is rapid (Groener and van Golde, 1977) and occurs mostly in the liver. The products are mainly palmitic, stearic, and oleic acids, which are esterified to glycerol to form triacylglycerols (Masoro et al., 1950; Lamb and Fallon, 1974; Brenner, 1989). In liver, these triacylglycerols are incorporated into VLDLs and transported out into circulation, but in adipose tissue they are stored in lipid droplets.

Adipocytes do not absorb VLDLs or intact TGs directly (Kane et al., 1983). The TGs must first be hydrolyzed by lipoprotein lipase localized in the capillary endothelial cells (Kane et al., 1983). The FFA released by this reaction diffuse through the capillary wall and are then taken up by the adipocytes and reesterified to form TGs (Bergman et al., 1971). The fatty acid composition of the adipose tissue reflects that of the diet (Lands et al., 1990), but if a low-fat, high-carbohydrate diet is eaten consistently, the adipose tissue would consist mainly of TGs containing palmitic, stearic, oleic, and LAs. Individuals eating diets containing large amounts of LA will deposit this compound readily in the adipose tissue (Thomas et al., 1987). Rats fed diets high in polyunsaturated 20- and 22-carbon n-3 fatty acids store the excess in the adipose tissue (Nelson et al., 1987).

In individuals eating high-fat diets with excess caloric intake, much of the exogenous fatty acids get stored directly in the adipose tissue without going to the liver through chylomicrons formed in

the enterocytes. Chylomicrons formed in the gut are also hydrolyzed by lipoprotein lipase in the capillary endothelial cells (Scow et al., 1977). Uptake of the liberated FFA can then proceed similarly to that described for FFA liberated from VLDL made in the liver.

Fatty acid synthesis in mammalian systems produces only SFAs and monounsaturated fatty acids of the n-9 series, usually oleic acid (Volpe and Vagelos, 1973; Wakil et al., 1983). Animals lack the ability to desaturate fatty acids in the n-6 or n-3 position of the fatty acid chain. Only plants possess the enzyme systems necessary to affect those reactions (Pollard et al., 1979; Stumpf and Pollard, 1983). Many land plants also lack the n-3 desaturase. Aquatic plants and planktons in colder water produce abundant amounts of the n-3 fatty acids (Lee and Loeblich, 1971). Delta 9-10 dehydrogenases that convert stearic acid to oleic acid are ubiquitous in both the plant and animal kingdoms. Indeed, delta 9-10 dehydrogenase in mammalian tissue is the most active lipid enzyme (Elovson, 1965). It has been postulated that the reason stearic acid is not hypercholesterolemic may be because of its rapid conversion to oleic acid, a presumably non-hypercholesterolemic fatty acid (Bonanome and Grundy, 1988).

In animal tissues the desaturation of de novo synthesized fatty acids stops with the production of the monounsaturated fatty acid with double bond in the 9-10 position of the fatty acid chain. (If palmitate is the substrate for the dehydrogenase, the double bond would appear between n-7 and n-8 position of the chain as the 9,10-dehydrogenase desaturates nine carbons from the carboxyl end of the molecules.) Thus, palmitoleic, oleic, and *cis*-vaccenic acids are the main products of this reaction. Chain elongation by another enzymatic system, the fatty acid elongase, produces eicosaenoic, erucic, and nervonic acids by the elongation of oleic acid by this system (Seubert and Podack, 1973; Bernert and Sprecher, 1977; Ludvig and Sprecher, 1979; Sprecher, 1981).

In the absence of dietary EFA, the same enzymes that desaturate linoleic and α-linolenic acids will desaturate eicosaenoic acid to produce the eicosatrienoic acid, or "Mead acid," characteristic of EFA deficiency (Fulco and Mead, 1959; Mead, 1968). This long-chain PUFA of the n-9 series has double bonds at the n-9, n-12, and n-15 positions of the carbon chain. It is not an EFA and cannot replace AA or alleviate the symptoms of EFA deficiency. However, it would be incorporated into the same tissues and complex lipids as AA. The Mead acid is not a substrate for the cyclooxygenase (COX) reaction, and no eicosanoids are produced from it.

Much of the recent work in the biosynthesis of fatty acids has been concentrated on the conversion of dietary EFA, usually linoleic or α-linolenic acid, to their longer chain, more unsaturated products, such as AA, EPA, docosapentaenoic acid (DPA), or DHA (Emken et al., 1992; Pawlosky and Salem, 1992; Sprecher, 1992; Sprecher et al., 1995; Sprecher, 1996; Goyens et al., 2006). The Δ5 and Δ6 desaturases prefer substrate fatty acids with double bonds in the n-6 and, secondarily, the n-3 position of the carbon chain. The fatty acid 22:5n3 does not accumulate appreciably when adequate n-3 fatty acids are in the diet; 22:6n3 is the dominant product (Sprecher, 1992; Sprecher et al., 1995; Sprecher, 1996).

Dietary EFA are, of course, the precursors of the biologically active eicosanoids (Dustig et al., 1981; Granstrom et al., 1982; Oats et al., 1988). This is an area that in the past 20 years has come to dominate much of the research on PUFA metabolism. Most people except strict vegetarians consume some AAs, but most of the body stores come from the conversion of dietary LA to AA by its desaturation and elongation as shown in Figure 23.2. This is a pathway found in all omnivores (Lands, 1986a).

As Sprecher and colleagues (Sprecher and Lee, 1975; Bernert and Sprecher, 1977; Sprecher, 1991) have shown, dietary PUFAs are not elongated and then desaturated, but are desaturated and then elongated. Figure 23.3 displays the main sequence of reactions that yield PUFAs from their dietary precursors. The Δ5 and Δ6 desaturases, which convert linoleic to AA and α-linolenic acids to EPA, have been extensively studied (Sprecher and Lee, 1975; Brenner, 1977; Sprecher and James, 1979).

In the past several years, Sprecher and colleagues (Sprecher, 1992; Moore et al., 1995; Sprecher et al., 1995; Luthria et al., 1996; Rotstein et al., 1996; Sprecher, 1996) have shown conclusively that the purported Δ4 desaturase that had been assumed to convert 20:3n3 to 20:5n3 and 22:6n3

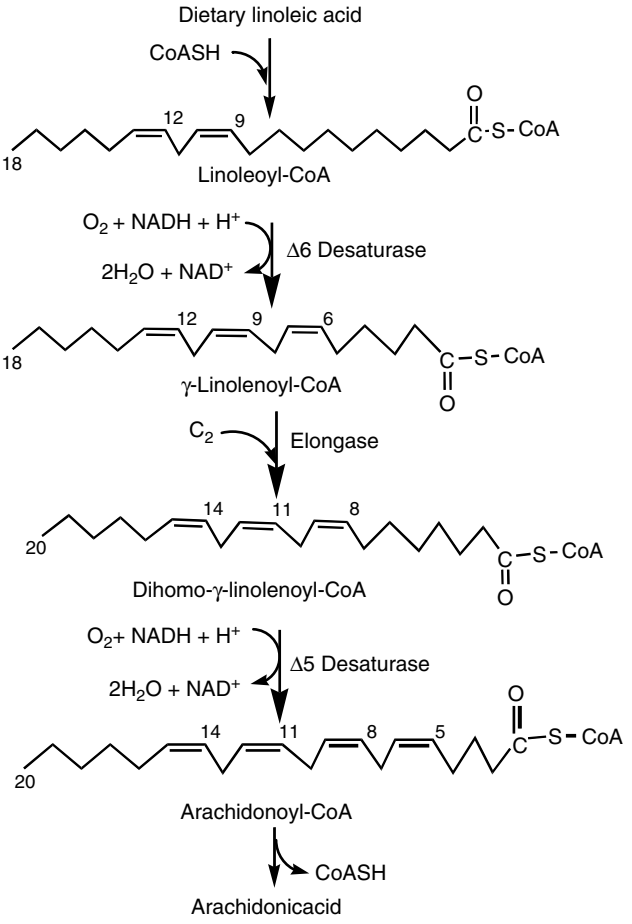

FIGURE 23.2 Metabolic pathway for the conversion of dietary linoleic acid to arachidonic acid *in vivo* by the Δ5 and Δ6 desaturases, and long-chain fatty acid elongases.

does not exist in microsomes. Thus, the metabolic pathway for the biosynthesis of EPA and DHA cannot simply be one of desaturation followed by elongation. In a series of elegant experiments, Sprecher and colleagues (Moore et al., 1995; Luthria et al., 1996; Rotstein et al., 1996) have shown that 20:3n3 is elongated and desaturated to 24:6n3 and that this fatty acid is then retroconverted to 22:6n3 and 20:5n3 by β-oxidation in the peroxisomes. This peroxisomal pathway is also active in converting 22:5n-6 to 20:4n-6. These pathways need only the Δ5 and Δ6 desaturases of the microsomal desaturase system but require a chain-shortening step involving the β-oxidation mechanism in the peroxisomes (Moore et al., 1995). Thus, the metabolism of PUFAs is much more complex than previously thought. Figure 23.4 (modified from the work of Sprecher) is a schematic presentation of the biosynthesis of long-chain PUFAs as the process is now understood.

B. Catabolism

The enzymatic pathways for the catabolism of fatty acids are essentially the same for dietary and endogenously synthesized fatty acids. Still, there may be significant functional differences between the utilization of dietary fatty acids and those synthesized endogenously. Dietary α-linolenic acid is a good example of a fatty acid not readily incorporated into tissue lipids. It is the most rapidly oxidized fatty acid of all unsaturated fatty acids (Nettleton, 1991). Of course, some is converted to

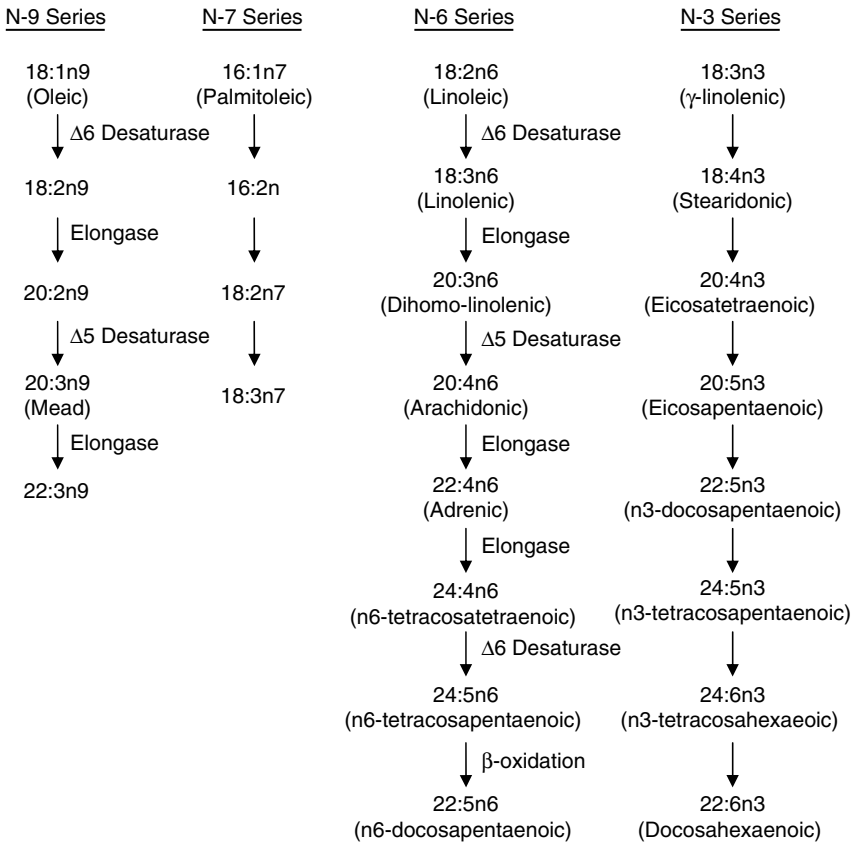

FIGURE 23.3 The metabolic pathways for the conversion of dietary unsaturated fatty acids to their long-chain, polyunsaturated metabolites.

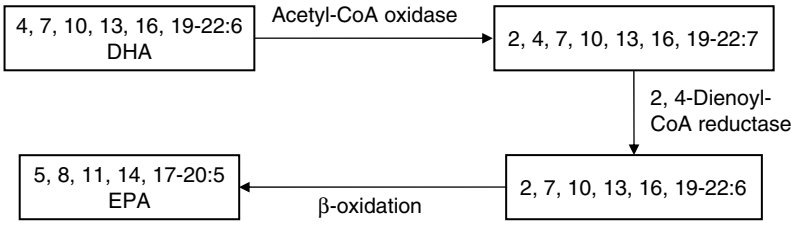

FIGURE 23.4 The probable metabolic pathway for the retroconversion of docosahexaenoic acid to eicosapentaenoic acid *in vivo*. Based on the information from this chapter in the previous edition by Nelson and from papers by Sprecher et al. (2000) and Reddy et al. (2001).

EPA and DHA, but only a small proportion of the α-linolenic acid enters this pathway (de Gomez-Dumm and Brenner, 1975; Aeberhard et al., 1978; Nelson and Chamberlain, 1995; Arterburn et al., 2006). If all other fatty acids are removed from the diet and α-linolenic acid is fed as the only source of dietary fat, then a higher percentage would be incorporated into tissue lipids (Mohrhauer and Holman, 1963). Thus, it is a competitive discrimination that prevents α-linolenic acid from being stored in tissues, not an intrinsic property of this compound.

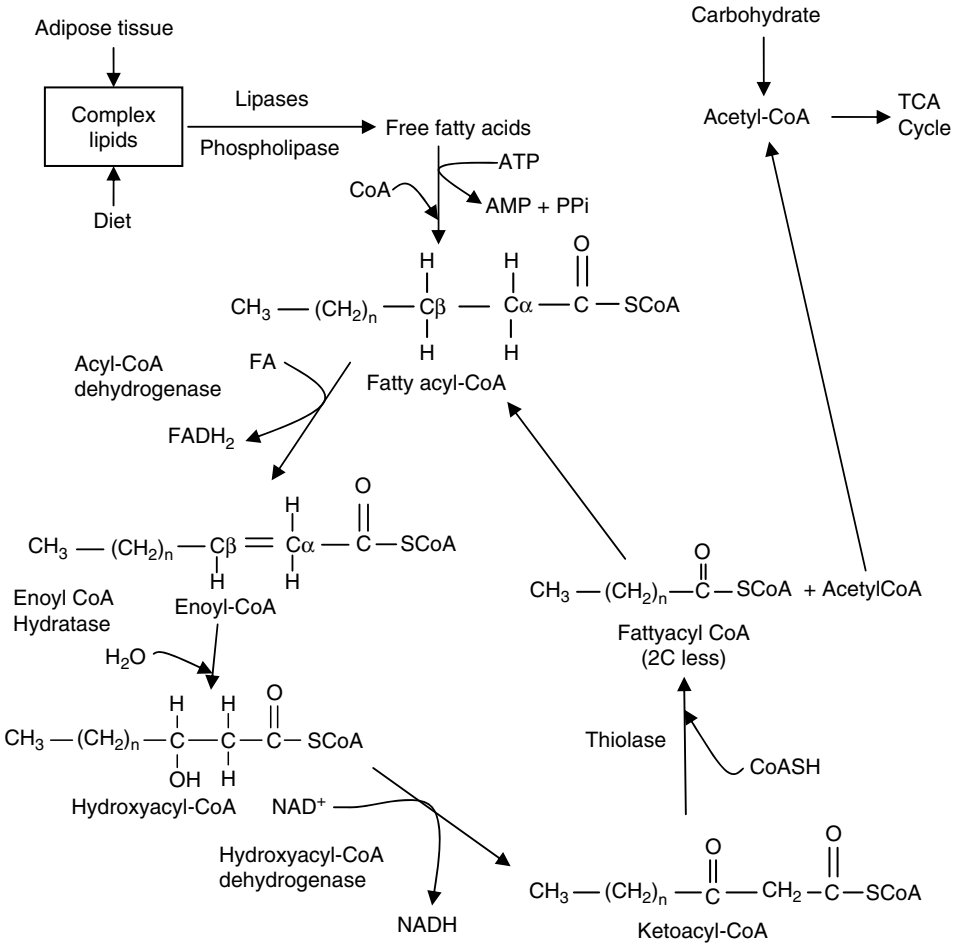

FIGURE 23.5 The classic β-oxidation cycle for the metabolic degradation of fatty acids in mitochondria. This cycle degrades fatty acids of 18 or less carbon atoms. See text for further information on degradation of 20 carbon and longer fatty acids.

Fatty acids are oxidized by β-oxidation to CO_2 and water by enzyme systems in both mitochondria and peroxisomes (Bronfman et al., 1979; Pande and Parvin, 1979; Pande, 1983). The β-oxidation system depends on carnitine as a cofactor (Bieber et al., 1982; Zammit, 1984). Mitochondria, which produce metabolic energy via ATP and the Krebs cycle, use the classical β-oxidation (see Figure 23.5), whereas peroxisomes use a modified β-oxidation system with a fatty acyl CoA oxidase in the first step of the reaction. This step produces hydrogen peroxide and is the rate-limiting step of the oxidation (Foerster et al., 1981). Both pathways use fatty acyl CoA as substrates, but the peroxisomes have a very different preference for fatty acid chains (Osumi et al., 1980; Lazarow, 1981). Fatty acids shorter than 16 carbons are oxidized at the same rate by both systems (Christiansen et al., 1977). Peroxisomes oxidize fatty acids with chain lengths longer than 18 carbons that mitochondria will not normally degrade. Peroxisomes will oxidize the monounsaturated fatty acids such as 20:1n-9, 22:1n-11, 22:ln-9, 24:1n-9, and 22:ln-9*t* that are not substrates for the mitochondrial β-oxidation system (Christiansen et al., 1977). It has been speculated that the peroxisomal oxidation pathway is primarily a chain-shortening mechanism for these long-chain fatty acids so that they can enter the mitochondrial β-oxidation system (Osmunden, 1987). In this manner, peroxisomes can be involved in the regulation of the fatty acid composition of the tissues.

Published results of He et al. (1995) demonstrated that peroxisomes contain all the necessary enzymes to affect the β-oxidation of unsaturated fatty acids through a novel reductase-dependent pathway. These authors reported that peroxisomes from rat liver contain a $\Delta^{3,5}$, $\Delta^{2,4}$-dienoyl-CoA isomerase that is immunologically similar to that found in mitochondria. However, the peroxisome enzyme may be a dimer as its molecular weight is 64 kDa and the enzyme found in liver mitochondria has a molecular weight of 32 kDa. Luthria et al. (1997) have shown that peroxisomal β-oxidation can produce metabolites of arachidonate that can then be reconverted to LA in the microsomes. Thus, there is a potential for recycling of PUFAs within various organelle. Depending on the type and amount of dietary fatty acid, the organism can burn them for energy, convert them to important metabolites such as eicosanoids, isoprostanes, and hydroxyeicosatetraenoic acid (HETEs), or store them in adipose tissue. It has been generally assumed that the regulation of PUFA metabolism is largely dependent on dietary intake coupled with energy expenditure. The work of Sprecher and colleagues (Sprecher, 1996; Luthria et al., 1997; Mohammed et al., 1997) and others (Emken et al., 1992; Pawlosky and Salem, 1992; Pawlosky et al., 2001; Brenna, 2002; Burdge et al., 2002; Wilkinson et al., 2005) have elucidated the fatty acid metabolic pathways and the mechanisms involved.

In addition to the mitochondrial and peroxisomal β-oxidation of the fatty acids, peroxisomal alpha and microsomal omega oxidations need to be mentioned. Fatty acids, such as phytanic acid, with a methyl group at the β-position cannot undergo direct β-oxidation. Phytanic acid first undergoes alpha oxidation whereby the terminal carboxyl group is removed as CO_2. The other product of this alpha oxidation is pristanic acid, a 2-methyl branched-chain fatty acid, which can undergo normal β-oxidation similar to any 2-methyl fatty acid (Reddy and Hashimoto, 2001; Wanders et al., 2001; Wanders, 2004). Microsomal cytochrome P450 and flavin monooxygenase 3 (FMO3) are involved in the ω hydroxylation of the fatty acids and the production of dicarboxylic fatty acids (Sanders et al., 2005; Weng et al., 2005). Once formed, dicarboxylic fatty acids can be shortened from either end of the molecule by β-oxidation. This pathway plays a significant role in overall fatty acid oxidation during starvation and diabetes.

As mentioned above, DHA can be retroconverted to EPA (Kunua, 1968; Stoffel et al., 1970; Sprecher and James, 1979; Schulz and Kunau, 1987). EPA is normally present only in trace amounts in the tissue lipids of animals eating a diet derived largely from terrestrial plants and animals. Interestingly, EPA is not a major fatty acid in the tissue of aquatic mammals (Nelson, 1971). Conversely, DHA is the major n-3 fatty acid in most tissues in mammals; a few tissues contain 22:5n-3 in specific organs (Rouser et al., 1968; Pooviah et al., 1976). As EPA appears to have several unique pharmacological and biochemical actions when consumed in large amounts (Leaf and Weber, 1988; Kremer, 1991; Reddy, 1991; Robinson et al., 1991; Nettleton, 1995), it is possible that DHA, through retroconversion, supplies EPA on demand if there is an inadequate dietary supply of α-linolenic acid.

Consequently, the variable activity of each fatty acid's metabolic pathway acts to produce the fatty acid composition of the tissues. The fatty acid composition of any particular tissue is determined by a complex interplay among synthesis, degradation, and diet. Yet there are limits within which some variation is possible and beyond which it is impossible to alter the composition without interfering with the metabolic function of the tissue. Mammalian species have evolved over a long period, presumably eating a constant diet. Tissues and organs evolved to have specific functional roles. Presumably, the fatty acid composition of any particular tissue has been optimized by evolutionary forces for efficient functioning. One would naturally expect that deviations from normal fatty acid composition in an organ would impair its function. Thus, although it is not often mentioned, the fatty acid composition of a tissue is important to its function and not simply the reflection of yesterday's diet. Even human adipose tissue is not simply a repository of dietary fatty acids but an active endocrine tissue releasing several adipokines that effect metabolism. The fatty acid composition of adipose tissue is determined only partially by diet, a significant portion of its composition is affected by metabolic determinants under genetic control.

Similar to TGs in adipose tissue, FFAs are also released from phospholipids in cellular membranes of other tissues by the action of phospholipase A_2 (Lands and Crawford, 1976). The FFAs

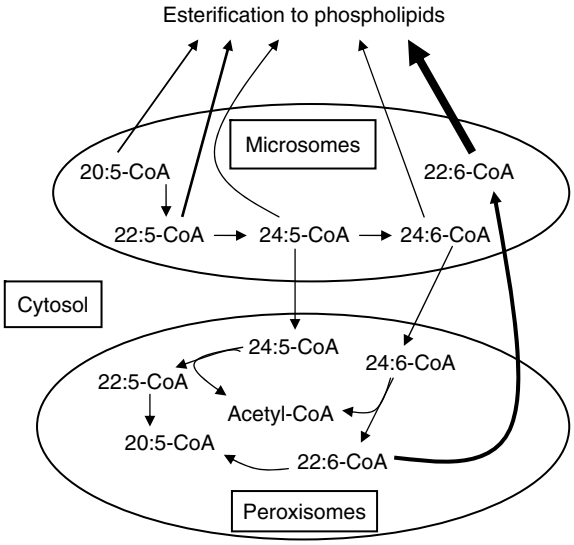

FIGURE 23.6 Metabolism of n-3 long chain PUFAs in peroxisomes and microsomes. Long-chain PUFAs may be oxidized in the peroxisomes or esterified into phospholipids in microsomes. Conversely, fatty acids liberated from phospholipids by phospholipases can migrate to the peroxisomes to undergo chain-shortening by oxidation. Adapted from Luthria et al. (1996). *J. Biol. Chem. 271*: 16020–16025 and Reddy et al. (2001).

are metabolized or reesterified as mentioned earlier. Luthria et al. (1996) have speculated that one mechanism for regulating the fatty acid composition of phospholipids in tissues is the selective esterification of fatty acid metabolites as they move back and forth between peroxisomes and microsomes. Figure 23.6 shows this process schematically.

In both the mitochondria and the peroxisomes, the initial substrate for fatty acid oxidation is an acyl CoA derivative of the fatty acid. Conversely, the COX and lipoxygenase (LOX) systems that produce eicosanoids will accept only the FFA as substrate (Struijk et al., 1966). As FFA does not normally exist in tissues, this is one method by which the production of eicosanoids is regulated. Trauma and disease produce FFA in tissues by liberating acid hydrolases (lipases and phospholipases) from lysosomes in damaged cells (Pitt, 1975). It is also now well recognized that AA can be oxidized to isoprostanes by pathways that do not require either COX I or II (Awad et al., 1996; Morrow and Roberts, 1996). Whether isoprostanes exert their physiological actions through prostanoid receptors is not yet known, but there is some evidence to suggest that they may have their own receptors (Elmhurst et al., 1997; Fukunaga et al., 1997). Obviously, much remains to be learned about the physiological regulation of dietary PUFA metabolism.

VI. PHYSIOLOGICAL EFFECTS OF DIETARY FATTY ACIDS

The effect of dietary fatty acids on lipid metabolism and physiology can be separated into three major categories: (1) the influence of dietary fat on de novo fatty acid synthesis and fatty acid oxidation; (2) the influence of dietary fatty acids on circulating lipoproteins, blood lipids, and cholesterol; and (3) the influence of dietary fatty acids on eicosanoid production and maintenance of physiological homeostasis. Each topic is discussed separately below.

A. De Novo Synthesis

The first category is well understood, and many of the biochemical mechanisms have been described (Volpe and Vagelos, 1973; McGarry and Foster, 1980; Wakil et al., 1983). The regulatory processes

are generally known and predictable. Dietary fatty acids suppress de novo fatty acid synthesis, and so does starvation. Although the two conditions are quite different physiologically, the regulatory processes are very similar. Both acetyl CoA carboxylase and fatty acid synthase are inhibited by excess acyl CoA, particularly palmitoyl CoA (Volpe and Vagelos, 1973; McGarry and Foster, 1980; Wakil et al., 1983; Large et al., 2004). As described earlier, after the hydrolysis of TGs in lipoproteins, the remnants are transported to the liver where they are converted to acyl CoA derivatives for further metabolism (Jelsema and Morre, 1978; Gurr and James, 1980). The excess acyl CoA produced in the liver suppresses de novo fatty acid synthesis by inhibiting both acetyl CoA carboxylase and fatty acid synthase. For some time it was thought that only PUFAs suppressed fatty acid synthesis *in vivo*, but Kelley et al. (1986) showed that SFAs also suppressed fatty acid synthesis in cultured rat hepatocytes. Hence, it is likely that all dietary fatty acids, except short-chain fatty acids absorbed through the portal vein, suppress de novo fatty acid synthesis. Furthermore, the effects of various dietary fatty acids on fat metabolism can be isomer specific as in the case of CLA. In this case, dietary *t*10, *c*12-CLA increased the relative proportion of 18:1n-9 and decreased that of 18:2n-6 in mouse liver lipids, while the *c*9, *t*11-CLA had the opposite effects (Kelley et al., 2004).

Starvation mobilizes fatty acids from adipose and peripheral tissues and transports them to the liver as FFA bound to albumin. These FFAs are converted to their acyl CoA derivatives in liver, and suppress de novo fatty acid synthesis, identical to dietary-derived acyl CoA derivatives. The release of the FFA from adipose tissue is a complex phenomenon caused by the drop in blood glucose after the liver glycogen stores are depleted by fasting. The drop in blood glucose levels causes a decrease in insulin levels and an increase in glucagon levels (Cahill, 1971). This reduction in insulin level stimulates adipocytes to hydrolyze their triacylglycerol stores to FFA while simultaneously turning off de novo fatty acid synthesis (Cahill, 1971; Beynen et al., 1979; Geelen et al., 1980).

B. Circulating Lipoproteins, Lipids, and Cholesterol

Dietary fatty acids have a profound effect on the lipids and lipoprotein levels in the circulation. Since circulating cholesterol levels and lipoproteins are intimately related to the pathology of CVD (Lindgren et al., 1951; Fredrickson et al., 1967; Goldstein et al., 1973, 1983; Brown and Goldstein, 1976; AHA, 2005; Breslow, 2006), there is great interest in this topic both in the scientific community and on the part of the general public, albeit on different levels of sophistication.

As the gut and the liver are the major sites of lipoprotein synthesis and catabolism, it is certainly not surprising that the transport system for delivery and removal of fatty acids to and from peripheral tissues responds to dietary fatty acids. It has been known for many years that diets high in fat and cholesterol tend to raise blood cholesterol (Anitschkow and Chalatov, 1913; Keys, 1975; Mattson and Grundy, 1985; Keys et al., 1986; Lands, 1986a). It was soon observed that isocaloric substitution of n-6 PUFA for SFAs caused a reduction in the plasma cholesterol level (actually a reduction in LDL and VLDL levels) even when cholesterol was present in the diet (Insull et al., 1959; Glueck and Connor, 1978; Horrobin and Manku, 1983; Mattson and Grundy, 1985). However, modulation of cholesterol synthesis is not the major mechanism by which PUFAs lower plasma LDL cholesterol (Mattson and Grundy, 1985). In addition, the observed increase in plasma cholesterol concentrations due to SFAs do not appear to be related to increased de novo synthesis; this has been confirmed by sterol balance studies as well as by studies using the more sensitive method of deuterium incorporation into newly synthesized cholesterol (Jones et al., 1998). Deuterium incorporation studies also revealed that cholesterol synthesis increases with PUFA intake. Thus, the lowering of plasma LDL with PUFA intake may be due to other mechanisms such as redistribution of cholesterol between plasma and tissue pools and upregulation of LDL receptors (Fernandez and West, 2005). Mustad et al. (1996) demonstrated in murine model that diet enriched with SFA markedly decreased LDL receptor protein levels in liver and a PUFA-enriched diet increased LDL receptor levels. Keys et al. (1965) and Hegsted et al. (1965) had shown that stearic acid was an exception to the rule that SFAs raise blood cholesterol levels, although the two equations that these investigators proposed did not specifically eliminate stearic acid. More recent studies indicate that compared with other SFAs,

stearic acid lowers LDL cholesterol. Although the effects of stearic acid on HDL cholesterol have been variable, but most of these studies suggest that stearic acid reduces the ratio of total to HDL cholesterol slightly when compared to palmitic or myrisitic acid. Without doubt the effects of stearic acid were more favorable than *trans* monounsaturated fatty acids (Mensink, 2005). Monounsaturated fats were considered neutral, that is, it did not raise or lower the plasma cholesterol level. However, more recent studies show that replacing SFAs with either monounsaturated fatty acids (MUFAs) or PUFAs lower total and LDL cholesterol (de Roos et al., 2001; Hodson et al., 2001; Gulesserian and Widhalm, 2002; Kratz et al., 2002; Montoya et al., 2002; Nicklas et al., 2002); but the effect on HDL is inconsistent. Some studies found no differences in the HDL concentrations between MUFA and PUFA diets (Montoya et al., 2002; Nicklas et al., 2002), whereas others found a higher level of HDL with MUFA diets (Hodson et al., 2001; Kratz et al., 2002). MUFAs really mean oleic acid unless some exotic oil, similar to high-eruric acid rapeseed oil, is being fed as a source of fat in the diet (Ackman, 1983). MUFAs have beneficial effects as an isocaloric substitution for lauric, myristic, or palmitic acids because the substitution has the same effect as removing the saturated fat from the diet. Either way, substituting MUFAs or simply removing the saturated fat from the diet would get the same cholesterol lowering (Grundy, 1991). Substituting PUFAs (again PUFA in the human diet usually means LA) will lower the plasma cholesterol level beyond the value observed when saturated fat is simply removed from the diet (Shore et al., 1983). Mattson and Grundy (1985) have shown that oleic acid lowered plasma cholesterol as much as LA, although Hegsted (1991) has questioned this claim.

A number of epidemiological studies indicate a positive association between the intake of *trans* fatty acids and the incidence of CVD (Ascherio et al., 1994; Bolton-Smith et al., 1996; Oomen et al., 2001; de Roos et al., 2003; Lichtenstein et al., 2003). CLA, a *trans* fatty acid, has gained significant attention in the past few years both in the research communities as well as in the general population because of its claimed health benefits of reducing obesity, particularly central obesity, improving lean body mass, and its potential anticancer effects. CLA isomers are formed by the shifting of the double bonds in LA and the two most abundant isomers are the *c*9, *t*10-CLA and *t*10, *c*12-CLA, formed primarily as a result of biohydrogenation in ruminant stomachs and industrial food processing, respectively. There have been a number of intervention studies using a mixture of CLA isomers. Because of the variable compositions of the CLA isomers used and the distinctly different effects of the individual isomers, results from these studies have been variable and were reviewed recently (Terpstra, 2004; Tricon et al., 2005). Results from human studies conducted with single isomers showed that the *c*9, *t*11-CLA did not have any adverse or beneficial effects on blood lipids, while the *t*10, *c*12-CLA increased TGs and the ratios of total cholesterol:HDL-cholesterol and LDL-cholesterol:HDL-cholesterol (Riserus et al., 2002, 2004; Burdge et al., 2004; Tricon et al., 2004). Overall, these studies have failed to see any beneficial effects from the use of these *trans* fatty acids and in contrast indicate detrimental health effects (insulin resistance, increased lipid peroxidation, and inflammation) particularly with *t*10, *c*12-CLA.

The role of dietary n-3 long-chain fatty acids in raising or lowering blood cholesterol levels is complex. Previous reports (Ahrens et al., 1959; Bang and Dyerberg, 1972; Harris and Connor, 1980) suggested that these compounds were similar to their n-6 counterparts in lowering plasma cholesterol. Other studies did not confirm that observation, particularly the effect of substituting polyunsaturated fatty acids for SFAs was considered (Phillipson et al., 1985; Simons et al., 1985; Bruckner et al., 1987). Long-chain, n-3 PUFAs may raise LDL levels in normolipemic individuals. This may be because, the main effect of these compounds is not on the plasma cholesterol levels but a reduction in TG and VLDL levels; this phenomenon was first reported by Harris and coworkers (Connor et al., 1981; Harris et al., 1984, 1988). Subsequent studies have shown that long-chain n-3 PUFAs reduce fasting as well as postprandial TGs in both normal and hypertriglyce(ri)mic human subjects (Harris, 1996). Increased postprandial TGs have been positively correlated to increased blood coagulation, reduced LDL particle size, and impaired endothelial functions, all of which are risk factors for CVD (Endres et al., 1989; Roche and Gibney, 1995; Jagla and Schrezenmeir, 2001; Silveira, 2001). Thus, TG lowering effect of n-3 PUFA can reduce the risk for CVD.

The reduction in VLDL levels, particularly in hyperlipemic individuals, explains why investigators first thought that long-chain n-3 PUFAs lowered plasma cholesterol levels. VLDL carries mainly TGs but does have about one-fifth as much cholesterol as LDL. Lu et al. (1999) reported that the marine omega-3 fatty acid supplementation in humans enhances the propensity of VLDL to be converted to LDL. This explains the rise in LDLs reported by some of the studies with fish oil supplementation. If an individual's VLDL is elevated, both the cholesterol and TG may be elevated as well. Normalizing one's VLDL could lower one's cholesterol level and raise one's LDL levels because of the conversion of VLDL to LDL, but the final result still may be a reduction in one's total plasma cholesterol level.

The role of elevated plasma LDL in the development of atherosclerosis has been studied extensively (Chapman et al., 1998; Staprans et al., 2005) and the effect of different types of dietary fats in modulating blood LDL levels has been the focus for several years now. Until recently, only LDL particles were thought to be the primary culprits in the development of atherosclerosis, however, it has now become clear that chylomicron remnants, especially oxidized chylomicron remnants are also highly atherogenic (Tomkin and Owens, 2001; Yu and Cooper, 2001; Wilhelm, 2003) and can penetrate artery walls like the LDLs and are retained in the subendothelial space (Proctor et al., 2002). Fatty acid composition of the chylomicron remnants influences their propensity to oxidative modification. Remnants enriched with n-6 PUFAs as compared to n-3 PUFA appeared more susceptible to copper-induced oxidation (Napolitano et al., 2004). Thus, reduction in oxidizability of chylomicron remnants by dietary n-3 PUFAs could be another mechanism by which the fish oils exert their cardioprotective effects. Consumption of ≈1g of fish oil for 12 weeks by normolipidemic and hyperlipidemic subjects has been shown to reduce plasma concentration of remnant-like particle-cholesterol (RLP-C) (Hamazaki et al., 2003). RLP-C are a subfraction of lipoproteins that are highly heterogeneous in size but normally of the size of large LDL particles in healthy individuals and are enriched in Apo E, Apo CIII, and ApoB-100; high RLP-C has been positively correlated with increased risk of atherosclerosis (Twickler et al., 2004). Thus, dietary fat can affect both the quantity and quality of circulating lipoproteins.

Recent comparative studies with EPA and DHA, the two main long-chain PUFAs found in fish oils, indicate that both these fatty acids reduce the TGs but DHA is more effective than EPA (Grimsgaard et al., 1997; Buckley et al., 2004). Effects of DHA on total, HDL and LDL cholesterol have been variable; increased LDL and HDL cholesterol was reported in some (Grimsgaard et al., 1997; Theobald et al., 2004; Geppert et al., 2006) but not in other studies (Mori et al., 2000; Buckley et al., 2004). A closer look at the distribution pattern of cholesterol indicates that DHA alters its distribution between different LDL and HDL subfractions. DHA but not EPA increased the HDL_2 cholesterol and also increased the LDL particle size in mildly hyperlipidemic men (Mori et al., 2000). Furthermore, it is only DHA that increased blood flow and reduced heart rate (Mori et al., 2000; Stark and Holub, 2004). Thus, the effects of EPA and DHA are similar in some aspects of lipid metabolism and yet distinct in others.

This subject is also confounded by the influence of caloric level and percent fat in the diet. Reducing total fat calories in the diet will usually lower the plasma cholesterol regardless of the type of fatty acids reduced. Replacing saturated fat with monounsaturated fat or polyunsaturated fat, either n-6 or n-3, will also lower plasma cholesterol levels, with the magnitude of the lowering being n-6 > monounsaturated > n-3. Similarly, removing all saturated fat from the diet will usually produce maximal lowering (Harris et al., 1983; Harris, 1989). Individuals eating a low-fat diet over a long period of time will invariably have lower plasma cholesterol levels than individuals eating a high-fat diet regardless of the type of fatty acid in the diet (Liebman and Bazzarre, 1983). More recent studies have cast doubt on this idea. Reports by Hayes and colleagues (Hayes et al., 1991; Hayes and Khosla, 1992; Khosla and Hayes, 1992) and Nelson et al. (1995) suggest that it is the ratio of the various fatty acids in the diet as well as the dietary amounts of each class of fatty acids that determine an individual's blood cholesterol level. Nelson et al. (1995) showed that normolipidemic individuals on either a low-fat (22% of calories from fat) or a high-fat diet (38% of calories from fat) showed no change in their blood cholesterol content as long as the ratios of the various fatty acids, saturated, monounsaturated, and polyunsaturated, were held constant.

Although AA is not a major component of the human diet, it is a normal constituent of the nonvegan human diet (Phinney et al., 1990). Lacto-ovo vegetarians would consume AA from egg yolks. Based on NHANES 1999–2000 data, the average intake of AA in the United States diets is 180 mg/day for men and 110 mg/day for women (Gebauer et al., 2006). O'Dea K and Sinclair (1985) reported that the Australian diet contained between 80 and 100 mg/day of AA. This fatty acid has a reputation of being a harmful substance if it is consumed in significant amounts. AA injected as the free acid intravenously in rabbits causes rapid disseminated intravascular coagulation and the death of the animals (Gerritsen and Cheli, 1983; Lefer et al., 1983). In animal studies, large amounts of AA in the ester form do not seem to cause significant harm to the animals in the short term (Weiner and Sprecher, 1984; O'Dea and Sinclair, 1985; Sinclair and O'Dea, 1987; Steel et al., 1990, 1993; Whelan et al., 1993; Mann et al., 1994). Seyberth et al. (1975) reported a human feeding study in which 6 g/day of AA were given to normal male subjects in the form of ethyl ester. Although the study was planned to continue for a month, it was terminated after 3 weeks due to markedly increased *ex vivo* ADP-induced aggregation (10%–60%) of platelets from the volunteers. Nelson et al. (1996a,b,c) reported results from a study in which 1.5 g of AA as TG was fed to normal male volunteers. At this level of intake dietary AA did not alter plasma lipoprotein levels, and there was no adverse effects noted during the 50 days of this study. Thus, it would appear that dietary AA, if fed as a TG, is not harmful to humans (or rats, see Koskelo et al., 1997) and it does not alter blood lipids at least in the presence of adequate amounts of LA.

The mechanism by which dietary fatty acids raise or lower blood cholesterol levels is fairly well understood now (Grundy, 1991). It would appear that regulation is partly achieved through the stimulation or suppression of LDL receptors (Spady and Dietschy, 1985; Fox et al., 1987; Nicolosi et al., 1990; Grundy, 1991). In an *in vitro* study with fibroblasts and HepG2 cells, it was demonstrated that 25-OH cholesterol reduced the protein and mRNA levels of low-density lipoprotein receptor (LDLr) and AA, EPA and DHA treatment increased LDLr by one to three fold (Yu-Poth et al., 2005). In an *in vivo* study in golden syrian hamsters, it was shown that compared to a diet enriched in butter, a diet high in canola oil or soybean oil had a four fold or eight fold higher LDLr expression, respectively. Different fatty acids differentially regulate expression of different genes involved in cholesterol and fatty acid synthesis and metabolism. Details of this will be discussed in the chapter by Sampath and Ntambi (Chapter 29).

It was suggested by Bonanome and Grundy (1988) that stearic acid is not hypercholesterolemic because it is converted rapidly to oleic acid by the active 9–10 dehydrogenase present in the liver. Although this is a plausible explanation, when deuterium-labeled stearic acid was fed to human volunteers, Emken (1981) found no significant conversion of dietary stearic acid to oleic acid. Therefore, it is questionable if conversion of stearic to oleic acid can explain the nonhypercholesterolemic character of stearic acid.

The mechanism by which long-chain, n-3 PUFAs reduce VLDL is now partially understood (Nestel et al., 1984; Wong et al., 1985; Wong and Nestel, 1987; Yamazaki et al., 1987; Wong and Marsh, 1988; Nestel, 1990; Yeo and Holub, 1990; Harris and Bulchandani, 2006). It appears that these compounds suppress both TG synthesis in the liver and gut and the assembly of nascent VLDL (Nestel et al., 1984; Yeo and Holub, 1990). Wong and Nestel (1987) and others (Nelson et al., 1988; Rustan et al., 1989) have investigated this phenomenon in considerable detail. It has been shown that PUFA-rich diets suppress the transcription of lipogenic genes by suppressing the transcription and reducing maturation of the protein, sterol response element binding protein (SREBP) (Fernandez and West, 2005). The role of SREBPs in lipogenesis and cholesterol metabolism is well established (Xu et al., 1999). It has been shown that n-3 PUFAs are more potent than n-6 PUFAs in suppressing SREBP-1 expression. Vasandani et al (2002) using LDL-receptor-deficient mice model showed that dietary n-3 PUFAs markedly decreased TG and cholesterol ester levels in the liver and reduced Apo B containing lipoproteins in plasma. On the basis of the current evidence, the mechanisms by which n-3 PUFA affect blood lipids has been summarized by Fernandez and West (2005) as follows: (1) suppress SREBP 1 expression and processing, thus leading to decreased lipogenesis and VLDL

secretion; (2) decreasing the LPL inhibitory ApoCIII levels and increasing LPL expression and facilitating enhanced hepatic clearance of lipoproteins; and (3) possibly increasing reverse cholesterol transport.

Results from earlier studies regarding the effects of *trans* fatty acids on blood lipids have been variable. Vergroesen (1972) and Vergroesen and Gottenbos (1975) found some elevation of plasma cholesterol after feeding 35% partially hydrogenated dietary fat containing *trans* fatty acids. Conversely, Matson et al. (1975) did not observe an elevation of plasma cholesterol in subjects fed diets containing 34% partially hydrogenated fat. Gottenbos (1983) reviewed this topic and concluded that *trans* fatty acids can raise plasma cholesterol levels and may be mildly atherogenic but have no effect on EFA metabolism. Additionally, dietary LA eliminated the hypercholesterolemic influence of dietary *trans* fatty acids consumed concurrently. Kritchevsky (1983) also concluded that *trans* fatty acids act metabolically much like SFAs and have no other significant adverse metabolic consequences. Emken (1991) demonstrated that *trans* fatty acids are metabolized much like their *cis* analogues and had no immediate adverse effects on lipid metabolism.

Results from recent studies indicate that *trans* fatty acids increase LDL and decrease HDL cholesterol (de Roos et al., 2003; Lichtenstein et al., 2003). Mensink and Katan (1990), in a carefully controlled human feeding study, compared the effects of diets containing either saturated (19%), monounsaturated (23%), or *trans* (11%) fatty acids on blood lipids. Polyunsaturated fat and the other dietary constituents were held constant. They found that *trans* fatty acids raised plasma cholesterol levels but less than the equivalent amount of saturated fat. They confirmed the work of Vergroesen (1972); however, they also reported that *trans* fatty acids lowered plasma HDL cholesterol levels, which SFAs do not, and raised plasma LDL levels in a quantity equivalent to SFAs, thus increasing the ratio of total cholesterol to HDL cholesterol. This increase in the ratio of total cholesterol to HDL cholesterol is a strong predictor of CVD (Stampfer et al., 1991). *Trans* fatty acids also increased blood levels of TGs as compared with the intake of other fats (Mensink et al., 2003), increased levels of Lp (a) (Ascherio et al., 1999), reduced particle size of LDL cholesterol (Mauger et al., 2003) and impaired endothelial function (de Roos et al., 2001), each of which may further increase the risk of CVD. These fatty acids have been shown to also promote inflammation by increasing plasma concentrations of tumor necrosis factor-α (TNF-α), interlukin-6 (IL-6), and C-reactive protein (Mozaffarian, 2006). These findings suggest an adverse effect of these *trans* fatty acids on one's cardiovascular risk profile (Grundy, 1990) beyond that suggested by the change in total plasma cholesterol levels.

In a recent analysis of the CVD incidence in a large-scale epidemiological study of professional nurses (Nurses Health Study) (Hu et al., 1997), it was estimated that a 2% reduction in energy intake from *trans* fatty acid would decrease the risk of developing CVD by 53%. In this study, the intake of *trans* fatty acids was estimated from the self-reported intake of margarine; margarine is one of the primary source of *trans* fatty acids in the U.S. diet. In a more recent meta-analysis (Mozaffarian et al., 2006) of four prospective cohort studies (Ascherio et al., 1996; Pietinen et al., 1997; Oomen et al., 2001; Oh et al., 2005) involving nearly 140,000 subjects, it was reported that a 2% increase in energy intake from *trans* fatty acids was associated with a 23% increase in the incidence of CVD. Thus, the consumption of even relatively small amounts of *trans* fatty acids may have major adverse health consequences, especially on cardiac health. The reader is pointed to recent reviews for more details on this subject (Blackburn and Khaodhiar, 2003; Mensink, 2005; Mozaffarian, 2006; Mozaffarian et al., 2006). Because of the proven adverse effects from consumption of *trans* fatty acids, Department of Agriculture food guide pyramid recommends limited intake of *trans* fatty acids; Dietary Guidelines Advisory Committee recommends consumption of *trans* fatty acids be kept below 1% of total energy intake (DHHS, 2005; Dietary Guidelines Advisory Committee, 2005). Recognizing the adverse health effects of *trans* fatty acids, Food and Drug Administration (FDA) ruled that, effective from January 1, 2006, the nutritional labels for all conventional foods and supplements must indicate the content of *trans* fatty acids (FDA, 2005). It is anticipated that adherence to these regulation regarding the consumption of *trans* fatty acids will reduce the risk for CVD.

C. Conversion to Eicosanoids

Eicosanoids are a key link between PUFAs and inflammation; they are generated from 20-carbon PUFAs (AA, EPA, DHGLA) released from membrane phospholipids by phospholipases, primarily phospholipase A2. Depending on the enzyme implicated (COX or LOX), eicosanoids produced include prostaglandins (PGs), thromboxanes (TXAs), leukotrienes (LTs), and HETEs. Different series of metabolites are formed depending on the nature of the 20-carbon precursor. When DHGLA (20:3n-6) is the substrate of COX, PGs of series 1 are formed while AA (20:4n-6) as substrate forms PGs and TXA of series 2 and EPA (20:5n-3) forms PGs and TXA of series 3 (Roland et al., 2004). See Figure 23.7 for a brief overview of the different types of eicosanoids produced by the three 20-carbon PUFAs. The different series of eicosanoids have distinct physiological effects. PGE_1 formed from DHGLA is antiinflammatory, while PGE_2 formed from AA is proinflammatory causing fever, increased vascular permeability and vasodilatation. LTB_4, also formed from AA, is a potent chemotactic agent for leukocytes, enhances generation of reactive oxygen species, and increases production of inflammatory cytokines such as TNF-α, interleukin-1 (IL-1), and IL-6. PGE_3 formed from EPA is mildly antiinflammatory and immune enhancing.

Lands (1986a) speculated that excess dietary n-6 fatty acids are the major cause of many chronic diseases in the Western world. Production of AA-derived eicosanoids increase during inflammatory conditions and elevated levels of these eicosanoids are observed in blood and tissues from patients with acute and chronic inflammatory conditions (Calder, 2006). There has been a great increase in n-6 PUFAs in the diets of the Western world in the past 100 years corresponding to the rise in the debilitating chronic diseases, such as heart disease, cancer, and autoimmune diseases. Lands' (1986a) view is that current levels of linoleate in the Western diet are much higher than those that would be obtained on a diet not strongly influenced by agricultural oilseed production. His conjectures seem to be true; it has been shown that the membrane phospholipids of inflammatory cells taken from people eating a Western-type diet typically contain approximately 20% of fatty acids as AA while that of other 20-carbon PUFAs such as DHGLA is only about 2% and that of EPA is <1% (Calder, 2006). Our current Western diet evolved quite recently with the development of efficient

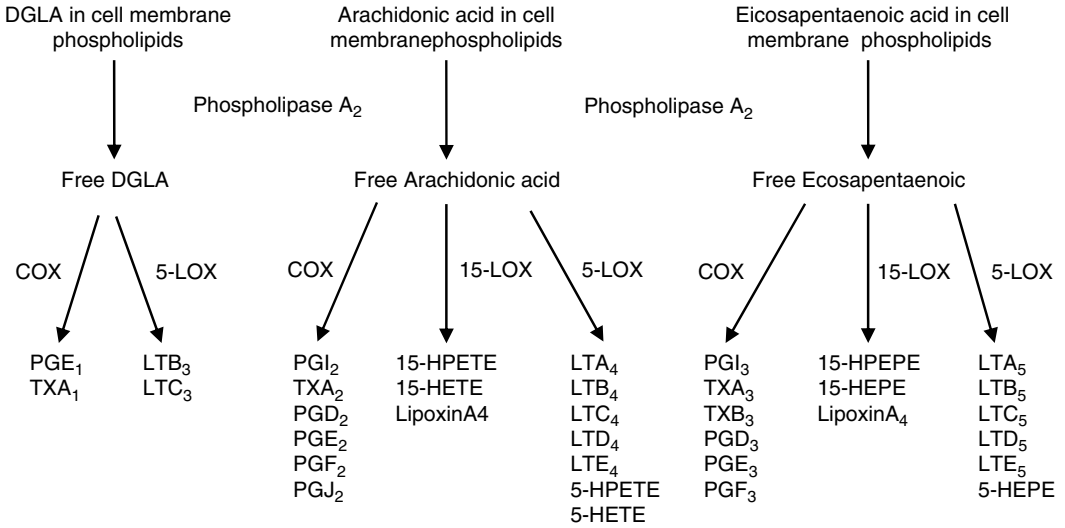

FIGURE 23.7 Synthesis of eicosanoids from the three different 20 carbon fatty acids, arachidonic acid, Dihomo-gamma-linolenic acid and eicosapentaenoic acid; COX, cyclooxygenase; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; LOX, lipoxygenase; LT, leukotriene; PG, prostaglandin; TX, thromboxane. Adapted from Calder (2006).

seed processing methods in the late nineteenth and early twentieth centuries. Prior to that time the Western diet generally had lower fat content, lower linoleate content, and perhaps a higher n-3 PUFA level. Lands hypothesized that the increase in linoleate levels will lead to a concomitant increase in AA levels and this presumably would make more AA available for eicosanoid production.

Zollner et al. (1979), Nugteren et al. (1980), Adam et al. (1980, 1982), and Adam and Wolfram (1984), all suggested that diet could alter eicosanoid production rates. Adam et al. (1982) used two different levels of linoleate (0% and 20%) in the diet of human volunteers to show a difference in the excretion of tetranorprostanedioic acid, a product derived from E and F series of PGs (PGE and PGF). Ferretti and coworkers (1989) evaluated the effects of moderate dietary changes on eicosanoid production. They found that less eicosanoid (PGE-M) was excreted in the urine by subjects who consumed a diet low (6 en%) in n-6 PUFAs as compared to subjects eating a diet high (9 en%) in LA. In another study, increasing the LA content of diet from 3 en% to 8.3 en% increased urinary PGE_2 by 40% (Blair et al., 1993). Kelley et al. (Kelley et al., 1998) reported that supplementing the diets of healthy men with 1.5 g of AA per day for 7 weeks resulted in increased production of AA-derived PGE_2 and LTB_4 by endotoxin-stimulated mononuclear cells. Thus, moderate increase in the consumption of both LA and AA increases the production of PGE_2 and LTB_4.

Consumption of a diet rich in n-3 PUFAs such as EPA and DHA, typically found in fish and fish oil liquids, has been shown to reduce production of inflammatory eicosanoids and reduce the risk of inflammatory diseases. Increased consumption of n-3 PUFAs by humans results in increased proportions of these fatty acids in the phospholipids of inflammatory cell (Gibney and Hunter, 1993; Healy et al., 2000; Thies et al., 2001; Calder et al., 2002). This incorporation of n-3 PUFAs in human inflammatory cells occurs in a dose response fashion and is partly at the expense of AA (Calder et al., 2002), thereby reducing the amount of substrate available for eicosanoid synthesis from AA. This is evident from the fish oil supplementation studies in humans, which report decreased production of AA-derived eicosanoids such as PGE_2, TXB_2, LTB_4, 5-HETE, and LTE_4 by inflammatory cells and an increase in EPA-derived eicosanoids such as LTB_5, LTE_5, and 5-hydroxyeicosapentaenoic acid (Calder, 2006). Ferretti et al. (1991) reported that total eicosanoid production as measured by PGE-M in the urine was reduced in a group of subjects consuming salmon diet compared to the group consuming a diet without salmon. In this study, the level of linoleate in the diet and percent calories from fat were held constant in both the groups. Ferretti et al. (1998) reported that normal subjects consuming 6 g/day of DHA in the absence of EPA showed a reduction in the excretion of $TXAB_2$, but no reduction in the excretion of prostacyclin metabolites. In the same study, *ex vivo* secretion of PGE_2 and LTB_4 by mononuclear cells stimulated with LPS was reduced (Kelley et al., 1999), however, bleeding times, *in vitro* coagulation, and platelet aggregation were unaffected (Nelson et al., 1997a). These authors (Nelson et al., 1997b) did report that there was a marked increase in both the EPA and DHA content of both the plasma and platelets in their volunteers with a reduction in the amount of n-6 fatty acids in these tissues.

The switch from AA-derived eicosanoids to EPA-derived eicosanoids as seen after a high n-3 PUFA diet is important because eicosanoids formed from AA as substrate have highbiological activity and are mostly proinflammatory and those formed from DHGLA and n-3 PUFAs such as EPA and DHA have less biological activity and are antiinflammatory. For example, EPA-derived LTB5 is 10- to 100-folds less potent as a neutrophill chemotactic agent then the AA-derived LTB_4 (Goldman et al., 1983), while PGE_3 (from EPA) is less potent inducer than PGE_2 (from AA) of COX-2 gene expression in fibroblasts (Bagga et al., 2003). N-3 PUFAs alter eicosanoid synthesis not only at the substrate level but also at the level of gene expression. N-3PUFAs have been shown to reduce expression of COX-2, 5-LOX, and 5-LOX activating protein in chondrocytes (Curtis et al., 2000, 2002). EPA and DHA have been shown to inhibit toll-like receptor 2 mediated up-regulation of COX-2 in monocytes (Lee et al., 2003).

Recent research suggests that EPA and DHA, in addition to modulating eicosanoid production by acting as a substrates to COX and LOX enzymes, also produce a novel group of mediators termed E-series resolvins formed from EPA and D-series resolvins formed from DHA by COX-2

(Serhan, 2005b). Both E- and D-series resolvins seem to have antiinflammatory effects. In addition to resolvins, other DHA derived mediators called docosatrienes and neuroprotectins, also produced by COX-2, have been identified and appear to be antiinflammatory (Serhan, 2005a).

Though most of the AA-derived eicosanoids are proinflammatory, recent studies have suggested that some of the AA-derived eicosanoids may have both pro- and antiinflammatory effects and others, such as PGI_2, are mostly antiinflammatory. For example, PGE_2, which is pro-inflammatory, also inhibits 5-LOX and so decreases the production of inflammatory 4-series LTs and induces 15-LOX, which promotes formation of lipoxins that have been found to be anti-inflammatory (Calder, 2006). In a crossover study, Ferretti et al. (1997) reported that feeding 1.5 g/day of AA to a group of normal male volunteers was associated with increased production of thromboxane A_2 and PGI_2 (prostacyclin) compared to when the subjects were consuming 100 mg/day of AA. Excess thromboxane production is considered undesirable because it enhances platelet aggregation, however, the concomitant rise in PGI_2, a thromboxane inhibitor, may counterbalance the effect of thromboxane. In fact, this study did report that *ex vivo* platelet aggregation in response to collagen and ADP was not altered after increased AA consumption. Thus, production of eicosanoids with opposing effects may be one of the mechanisms by which body modulates proinflammatory effects of AA-derived eicosanoids. Thus, both the absolute amounts and the ratio of n-6 and n-3 PUFAs in diet may influence the production of inflammatory eicosanoids.

VII. SUMMARY AND CONCLUSIONS

Dietary fats have profound effects on lipid metabolism. The inhibition of endogenous fatty acid synthesis by exogenous dietary fat is now well understood. However, there is some controversy about whether dietary saturated fat is effective in suppressing de novo fatty acid synthesis, but the suppression of liver fatty acid synthesis by dietary PUFAs, particularly LA is well established.

Depending on their degree of unsaturation and chain length, dietary fatty acids can affect blood lipids and lipoprotein levels. Both SFAs (12:0–16:0) and dietary cholesterol increase blood cholesterol, and PUFAs reduce it. *Trans* fatty acids, even though are polyunsaturated, increase LDL and decrease HDL cholesterol, possibly because of the presence of *trans* bonds affecting metabolism. MUFAs, mainly oleic acid (18:1n-9) reduce total and increase HDL cholesterol. Most studies with long-chain n-3 PUFA did not find a change in total cholesterol, but both the LDL and HDL cholesterols were increased and TGs were reduced in those studies. Studies with purified DHA and EPA supplementation found both fatty acids were effective in reducing plasma TGs, although some found DHA to be more effective than EPA. These studies also indicated that it is only DHA that reduced the number of small dense LDL particles and increased the concentration of HDL-2, increased blood flow, and reduced heart rate.

Increased consumption of n-6 PUFAs has been found to enhance the production of inflammatory eicosanoids such as PGE_2 and LTB_4, while EPA and DHA reduced the tissue concentration of AA and production of inflammatory eicosanoids. N-3 PUFAs have also been found to reduce the expression of genes for inflammatory cytokines (IL-1β, IL-6, and TNF-α) and have antithrombotic and antiarrhythmic effects. Despite the high degree of unsaturation and susceptibility to oxidation, EPA and DHA have been reported by some investigators to reduce oxidative stress. Evidence from a number of epidemiological, prospective, and intervention studies clearly show that increased intake of long-chain n-3 PUFAs reduces the risk for CVD. Because of limited elongation of ALA to EPA and DHA, its health effects are not as dramatic as those of the long-chain n-3 PUFA. Despite the knowledge of the many health benefits of n-3 PUFAs, their consumption remains at a minimal level in the United States. On the other hand, consumption of proinflammatory n-6 PUFAs has markedly increased. The reduced intake of n-3 PUFAs and increased intake of n-6 PUFA over the past several decades may be the major reason for the increase in inflammatory diseases. Thus, an increase in the consumption of n-3 PUFAs and a decrease in the consumption of n-6 PUFAs are needed to balance the ratio between the consumption of these two groups of fatty acids. Reduction in the consumption of

trans fatty acids and SFAs will also reduce the risk for CVD. Further studies are needed to determine the dose dependent effects of n-3 PUFAs, interaction between n-3 and n-6 PUFAs, and the underlying mechanisms.

ACKNOWLEDGMENTS

We are most thankful to Dr Gary J. Nelson for providing us the opportunity to write this chapter and for allowing us to use some of the information from his previously published chapter in this book.
