24 Dietary Fatty Acids and Minerals

Elizabeth A. Droke and Henry C. Lukaski

CONTENTS

I. INTRODUCTION

The absorption of dietary minerals is determined by nutritional needs of the organism, by the amount present in the diet, and by factors influencing the bioavailability and utilization of the mineral. Whereas nutritional needs tend to modulate homeostatic mechanisms of absorption, the bioavailability of minerals is principally influenced by exogenous factors. Factors influencing mineral bioavailability can be grouped as to the site at which they occur and include luminal, mucosal, and postabsorptive events (Rosenberg and Solomons, 1984). Luminal events refer to the dissociation of the mineral from the chemical matrix with which it was associated in the food and possible interactions with factors that may enhance or reduce its solubility. Mucosal actions include uptake of minerals at the mucosal membrane, which may or may not include receptors. Postabsorptive transport of minerals away from the intestinal epithelium to body tissues and organs involves the participation of binding or transport proteins. Each of these factors or processes depends on nutrients and chemical compounds in the diet that directly or indirectly affect absorption and utilization of minerals. Other factors, such as enteral recycling and hormonal influences, may also play a role.

Many dietary components have been shown to influence mineral bioavailability in animals and humans (Solomons and Rosenberg, 1984). Understanding the influence of dietary components on

mineral absorption and utilization is critical to developing recommendations for the intake of minerals. Dietary components that have been evaluated for their impact on mineral bioavailability include protein, carbohydrate, fiber, organic acids, and other minerals. One dietary component, fat or fatty acids, has received minimal attention. One reason for the lack of evidence regarding the effect of fat on mineral bioavailability may be that there is little *in vitro* physicochemical evidence to suggest fatty acids will bind minerals, because stability constants are negligible or nonexistent (Sillen and Martell, 1964; Perrin, 1979; Martell and Smith, 1982). However, because dietary fat represents a significant fraction of daily energy intake in the United States, with estimates ranging from 30% to 40% of energy intake (Wright et al., 2004), and because *in vivo* physiological interactions between fatty acids and minerals have been reported (Simpson and Peters, 1987a,b; Simpson et al., 1988), there is increasing interest in examining the effects of dietary fatty acids on the bioavailability of minerals.

The purpose of this chapter is to summarize research findings on the effects of dietary fat on the bioavailability of some essential minerals, including calcium and magnesium and the trace minerals, copper, zinc, and iron. This chapter will also integrate the experimental findings on bioavailability with current understanding of the mechanisms of mineral absorption and end points of mineral utilization. In addition to the importance that interactions between dietary fat and minerals may have in the determination of dietary mineral intakes, knowledge of these interactions may be useful in the prevention and/or therapy of various conditions such as osteoporosis (Kruger and Horrobin, 1997).

II. EFFECTS OF DIETARY FATTY ACIDS ON MINERAL BIOAVAILABILITY AND UTILIZATION

A. Calcium

a. Animal Studies

i. Absorption

Apparent calcium absorption is defined as the difference between calcium intake and fecal calcium losses. The effect of fat on apparent calcium absorption in laboratory animals has been extensively studied; however, results have been equivocal. Essential fatty acids (EFAs) (as reviewed by Kruger and Horrobin, 1997) and arachidonic acid (Song et al., 1983) have been reported to increase calcium absorption. Tuna oil, high in docosahexaenoic acid (DHA; n-3), has also been shown to increase calcium absorption in young growing male rats in comparison with rats fed corn oil (linoleic acid; n-6) or evening primrose oil, which is also high in linoleic acid (25.4 ± 2.5 vs. 18.4 ± 1.8 and 18.1% ± 2.1%; respectively, for tuna oil, corn oil, and evening primrose oil) (Kruger and Schollum, 2005). Conjugated linoleic acid (CLA) fed to 4-week-old male rats for 8 weeks at 10 g CLA/kg diet, increased the net fractional (%; $p < .01$) and absolute (mg; $p < .05$) absorption of calcium when rats were fed a n-3 polyunsaturated fatty acid (PUFA)rich diet (menhaden oil–safflower oil) but not when fed an n-6 PUFA-rich diet (soybean oil) (Kelly et al., 2003). However, in adult, ovariectomized rats, intestinal calcium absorption was unaffected by CLA (Kelly and Cashman, 2004). In contrast, other studies have demonstrated decreased calcium absorption with diets containing 20%–25% dietary fat as corn oil (high in linoleic acid; n-6) (Kane et al., 1949), tripalmitin or tristearin (Nordin, 1968; Tadayyon and Lutwak, 1969), or cottonseed oil (Knudson and Floody, 1940), while others found no effect with 20% lard (Beadles et al., 1951) or 5% peanut oil (Calverly and Kennedy, 1949). These differences among studies may be the result of varying concentrations of n-3, n-6, and n-9 fatty acids. This possibility is further supported by the findings of Claassen et al. (1995) in which γ-linolenic acid (GLA, n-6) and eicosapentaenoic acid (EPA, n-3) were fed to male rats at a ratio of 3:1 (GLA:EPA), increased calcium absorption (mg/24 h) by 41.5% compared with the control group that was fed linoleic acid (n-6) and α-linolenic acid (ALA, n-3) at a ratio of 3:1.

The lack of a consistent effect of dietary fat on calcium absorption may be due to other factors besides the type and amount of dietary fat. One of these factors may be the age of the animals used. Calcium-binding ligands in the small intestine are different in young vs. older rats (Song et al., 1983). Kaup et al. (1990) observed that calcium absorption decreased as rats aged from 2 to 8 months and that increased butterfat ingestion (5% vs. 20%) had no effect on apparent calcium absorption in young rats but decreased it in mature rats. Experimental conditions in several studies were also optimized to evaluate the effect of dietary fat on calcium retention and utilization (e.g., low-dietary calcium, low-fat, or fat-free control diets) (Nordin, 1968; Tadayyon and Lutwak, 1969), further complicating the determination of the effect of dietary fat on calcium absorption.

ii. Medium-Chain Triglycerides and Absorption

Medium-chain triglycerides (MCT) fed at 11% of metabolizable energy intake (5.66% wet weight; 43% of total fat) to dogs did not significantly affect absorption of calcium or magnesium (Beynen et al., 2002). The authors suggested the level of calcium in the diets fed to the dogs may have been great enough to mask or prevent an observed effect of MCT on mineral absorption.

iii. Retention/Tissue Mineral Concentrations

The effects of dietary fat on calcium retention and tissue mineral concentrations appear to be related to the ratio of n-6:n-3, the amount of dietary fat, and the level of calcium intake. French and Elliot (1943) reported a decrease in calcium retention as fat increased from 5% to 45% oleo oil. A decrease in calcium retention has also been observed with 5% coconut oil or cottonseed oil (Calverly and Kennedy, 1949), or 20% cocoa butter (Beadles et al., 1951). Research with turkey poults demonstrated that type of dietary fat (5% of either tallow, corn oil, soybean oil, animal–vegetable blend fat or canola oil) had no effect on apparent retention of calcium (Leeson and Atteh, 1995). In contrast, when palmitic acid, oleic acid, or a 50:50 mixture of these fatty acids was fed to the turkey poults, a significant reduction in apparent calcium retention did occur (Leeson and Atteh, 1995). However, more recently, increased consumption of n-3 fatty acids increased calcium balance (mg/24 h) by 41.5% in rats (Claassen et al., 1995). In line with this, urinary excretion of calcium has been reported to be reduced by EFAs (Kruger and Horrobin, 1997) and negatively correlated with n-3 fatty acid levels in the diet (Claassen et al., 1995). In other research with mice, a 5% addition (w/w) of either corn oil (predominantly linoleic acid; n:6) or olive oil (predominantly oleic acid; n:9) resulted in increased liver and spleen calcium concentrations (Milin et al., 2001) compared with the control diets (normal fat content). Thymus calcium concentrations were also increased in mice fed the higher corn oil diet. However in a study with young growing rats, the type of dietary fat (safflower oil, flaxseed oil, olive oil, or beef tallow), varying in concentrations of n-3, n-6, and n-9 fatty acids, had no effect on plasma and liver calcium concentrations in the presence of adequate dietary calcium (Shotton and Droke, 2004). Another evidence suggests the type of dietary fat has an inhibitory effect on calcium metabolism when calcium intake is low (<0.4% of the diet by weight) (Nordin, 1968).

iv. Calcium Utilization

EFAs are critical for maintenance of skeletal health as demonstrated by the severe osteoporosis that develops in EFA-deficient animals (Kruger and Horrobin, 1997). EFAs enhance the synthesis of collagen in bone and increase deposition of calcium into bone (Kruger and Horrobin, 1997). Another evidence also indicates that the ratio of n-6:n-3 EFAs is important in the effect of dietary fat on calcium utilization in bone (Claassen et al., 1995), thus suggesting dietary fats with different ratios of n-6:n-3 will have varying effects on bone calcium metabolism.

Utilization of calcium in bone (i.e., prevention of rickets, increased bone calcification and ash) was increased with vitamin D deficient diets containing 10%–11% lard or olive oil (McDoughall, 1938;

Jones, 1940) or 5%–20% cottonseed oil (Knudson and Floody, 1940) in comparison with the low-fat or fat-free control diets. The femur calcium content of rats receiving 25% triolein or 5% fat as triolein, tripalmitin, or tristearin was also reported to be greater than that of the animals receiving the fat-free diet, and this was greater than those fed 25% tripalmitin or tristearin (Tadayyon and Lutwak, 1969). The femur calcium content also increased when the 25% tristearin diet was supplemented with 5% triolein. Research by Schlemmer et al. (1999) demonstrated that a diester-containing GLA and EPA increased femur calcium content to sham levels and potentiated the effect of an estrogen implant in ovariectomized rats. Other research also suggests n-3 fatty acids (i.e., EPA) increase bone calcium (Claassen et al., 1995).

In contrast, other evidence indicates fats have no or an inhibitory effect on calcium utilization. Evidence from turkey poults fed palmitic acid, oleic acid, or a 50:50 mixture of the fatty acids indicates that even though reduced mineral retention was observed with these fatty acids, this did not result in changes in concentrations of bone ash or bone calcium concentrations (Leeson and Atteh, 1995). Femoral bone mineral density (BMD) in adult ovariectomized rats was also unaffected by CLA (2.5, 5, or 10 g CLA/kg diet) (Kelly and Cashman, 2004). In other work, as fat intake increased in excess of 10% of daily energy intake, bone calcium content began to decrease in animals fed diets containing cottonseed oil (Knudson and Floody, 1940). In broiler chickens fed 8% palmitic or stearic acid, bone ash and bone calcium concentrations were significantly reduced whereas bone ash and bone calcium concentrations were unaffected by oleic acid (Atteh and Leeson, 1983).

In a more recent study to determine whether EPA could prevent the deterioration of bone mass that occurs with estrogen deficiency, Poulsen and Kruger (2004) found that in ovariectomized rats, 1.0 g EPA/kg of body weight decreased ($p < .01$) BMD. The authors proposed that an increase in lipid peroxidation may have decreased intestinal calcium absorption, thus stimulating parathyroid hormone-mediated bone resorption. This finding was supported by later research with young male growing rats in which tuna oil (4% + 1% corn oil; rich source of DHA) appeared to be more effective in improving bone mass than fish oil (4% + 1% corn oil; rich source of EPA) (Kruger and Schollum, 2005). Total calcium per bone was 172.6 ± 5.2 mg in the tuna oil-fed group vs. 152.4 ± 4.4 mg in the fish oil-fed group. This possible fatty acid-dependent effect on bone resorption is further supported by the finding that CLA (5 and 10 g/kg diet) reduced ($p < .001$) urinary markers of bone resorption in ovariectomized rats (Kelly and Cashman, 2004). However, this effect of CLA may be age- and gender-specific because in contrast to the results with the ovariectomized rats, young, growing male rats fed CLA (10 g/kg diet) did not alter concentrations of osteocalcin, a marker of bone formation, or insulin-like growth factor-I, a mediator of bone metabolism (Kelly et al., 2003). In this study with male rats, urinary markers of bone resorption were not significantly affected by CLA (10 g/kg diet), but the markers were greater in rats consuming an n-6 PUFA-rich diet (soybean oil) compared with an n-3 PUFA-rich diet (menhaden oil–safflower oil) suggesting n-6 fatty acids may increase bone resorption.

v. Calcium Soap Formation

The previous findings on calcium absorption, retention, and utilization were complemented by the recognition that dietary calcium per se may influence dietary fat absorption. The presence of ionized calcium in the intestine determines the extent of soap formation, although the amount ultimately excreted in the feces depends on the solubility of the soap formed, which is inversely related to chain length and degree of unsaturation. When a diet containing a relatively high-calcium intake (60–70 mg/day) was fed to rats, the formation of oleate, palmitate, and stearate soaps was found to be 90%, 38%, and 25%, respectively. Conversely, when a relatively low-calcium diet was used (13.5–41.4 mg/day), the absorption of palmitate and stearate was increased to 65% and 45%, respectively (Boyd et al., 1932). The fact that oleate soaps were used preferentially to the soaps of the saturated fatty acids indicates that the melting point is an important factor influencing the absorption of fats and their soaps. Gacs and Barltrop (1977) observed that the absorption of calcium was

inversely correlated with the chain length of the fatty acid, varying from 1% for calcium stearate to 60% for calcium hexanoate. Increasing the degree of unsaturation of the fatty acid was accompanied by increased calcium absorption. The degree of calcium-soap formation and the inhibition of calcium absorption were well correlated ($r = .82$, $p < .01$). No soap formation was noted when fats were given in the form of triglycerides. Other evidence from broiler chickens also supports the formation of calcium soaps and a reduction in calcium retention when palmitic and stearic acids (8%) are fed (Atteh and Leeson, 1983). The formation of calcium soaps has been suggested to be a normal part of lipid digestion (Patton and Carey, 1979). In summary, studies in animal models, although more inconsistent than suggestive, indicate two trends. First, calcium absorption and utilization are impaired when fat intakes exceed 10% of the energy intake. Second, saturated fatty acids reduce calcium utilization.

b. Human Studies

i. Absorption

Early studies in children consuming a mixed diet indicated a positive relationship between fat intake and apparent calcium absorption. Holt et al. (1920) reported calcium absorption of 40.4% when the intake exceeded 30 mg calcium/kg body weight, but when the intake was less, the absorption averaged only 20.3%. The greatest absorption of calcium occurred when the dietary fat intake exceeded 3 g/kg body weight and when there was an adequate intake of 300–500 mg calcium/kg body weight. The principal source of dietary fat was milk and butter. The excretion of calcium in stools was not related to the excretion of total fat but showed a minor relation to the excretion of fat as soap. Holt and Fales (1923) subsequently studied seven children aged 2–6 years who were fed diets containing fat at two levels (high fat: 30–65 g/day; and low fat: 5–8 g/day) with a constant calcium intake (1.7–1.9 g/day). Calcium absorption was markedly reduced when the low-fat diet was consumed. The composition of the high-fat diet was mostly saturated fat and the low-fat diet was principally unsaturated fat. Impaired calcium absorption was associated with the increased presence of calcium soaps in the stool. Other research also indicates that the apparent absorption of calcium may be improved by increasing the dietary fat content (Kies, 1985, 1988).

ii. Medium-Chain Triglycerides and Absorption

Similar to the findings of Beynen et al. (2002) with dogs, Haderslev et al. (2000) observed no changes in the absorption of calcium and magnesium with MCT (mixture of long- and medium-chain fatty acids totaling 50% fat in diet) in patients with intestinal resections. In contrast to these findings with adults, MCT-containing formulas (first, MCT, corn oil, and coconut oil, 40:40:20; second, MCT and corn oil, 80:20) fed to premature infants with birth weights less than 2000 g, significantly increased calcium absorption compared with the control formula containing corn oil, oleo, and coconut oil (39:41:20) (Tantibhedhyangkul and Hashim, 1978).

iii. Retention

Mallon et al. (1930) studied the calcium retention of two college-aged women consuming 450–500 mg calcium/day who were fed high- and low-fat diets based on milk products for 18 days. They found no significant change in the calcium balance or fecal calcium excretion during two consecutive 3-day balance periods, and they concluded that fat per se did not affect calcium retention. Aub et al. (1937) observed that the addition of 200 g fat to the diet of two healthy adults did not increase calcium excretion. Steggerda and Mitchell (1951) observed no effect on the calcium balance or fecal losses of calcium from milk fat (5–160 g/day) fed at 1%–32% of daily energy intake to 13 men. Fuqua and Patton (1953) studied nine college-aged women who consumed diets containing 600 mg calcium and

supplying 45, 91, and 135 g of fat (19%, 39%, and 58% energy as fat). Mean calcium balances were not significantly influenced by fat intake, but they were highly variable. In a study of 12 men, van Dokkum et al. (1983) reported no change in calcium retention with an increase in linoleic acid from 4% to 16% of energy intake when total fat intake was constant at 42% of energy. In very low birth weight infants, consumption of a long-chain PUFA supplemented formula (egg-lipid extracts and evening primrose oil; 5 g/100 kcal) had no effect on calcium balance (Martinez et al., 2002).

In contrast, Basu and Nath (1946) studied the mineral metabolism of four young men fed diets containing 187–512 mg calcium/day and in which fat was provided principally by mustard oil, coconut oil, groundnut oil, sesame oil, or butterfat. The control was a fat-free diet. The addition of each of the fats, except coconut oil, slightly decreased the excretion of fecal calcium. With coconut oil, there was an increase in the fecal calcium excretion.

Dietary fat is principally in the form of mixed-triglycerides, with different n-3, n-6, and n-9 fatty acids in the *sn*-1, *sn*-2, and *sn*-3 positions. This effect of dietary fat on calcium absorption and retention may be due in part to the types of fatty acids present within the triglycerides and their structural positions. Palmolein (PO) is used in infant formulas to match the palmitic acid content of human milk; however, evidence indicates that this can result in reduced calcium absorption in infants fed these formulas (Nelson et al., 1998), suggesting the structural position of the palmitic acid within a triglyceride may be important. In healthy term infants (5 weeks of age), fecal calcium excretion was significantly decreased when infants were fed a formula that more closely resembled human milk (24% palmitic acid with 66% esterified in the *sn*-2 position) than when they were fed formulas containing less esterified palmitic acid in the *sn*-2 position (24% palmitic acid, 39% esterified in *sn*-2; or, regular formula, 20% palmitic acid, 13% esterified in *sn*-2) (Carnielli et al., 1996). Calcium retention tended ($p = .10$) to be greater in those infants fed the formula with 66% palmitic acid esterified in the *sn*-2 position. Carnielli et al. (1996) also evaluated the correlation between the excretion of calcium and fatty acids. Positive correlations were found between palmitic acid ($r = .84$), oleic acid ($r = .60$), and linoleic acid ($r = .51$), and calcium excretion suggesting differing effects of saturated vs. unsaturated (e.g., n-6, n-9) fatty acids on calcium excretion.

iv. Calcium Utilization

It is unclear whether usual intakes of dietary fat independently affect calcium utilization in humans. Excessive intakes of fat in pathological conditions that result in steatorrhea can negatively influence human calcium utilization (Aub et al., 1937). The type of fat can also influence calcium utilization in bone. Healthy term infants were fed formulas varying in PO for the first 6 months of life and bone mineral content (BMC) and BMD were measured by dual x-ray absorptiometry at baseline, 3 and 6 months of age (Koo et al., 2003). The formula containing PO (45%/20%/20%/15% oil; PO/coconut/soy/high-oleic sunflower oils; ~22.1% palmitic acid) resulted in lower ($p < .001$) BMC and BMD when compared to a formula without PO (40%/30%/30% oil; high-oleic safflower/coconut/soy oils; 8.2% palmitic acid) fed to another group of infants. These findings suggest that not only the amount, but also the type of fat and positioning of fatty acids within triglycerides can influence calcium utilization.

Bone density improved in elderly women (mean age 79.5) fed GLA and EPA (Kruger et al., 1998). Recently, dietary intake of CLA (63.1 ± 46.8 mg, mean ± SD) was found to be a significant ($p = .040$; $r^2 = .286$) predictor of Ward's triangle BMD in healthy postmenopausal women (Brownbill et al., 2005). Years since menopause, lean tissue, energy intake, intakes of calcium, protein, fat and zinc, as well as current and past physical activity were all accounted for in their multiple regression model.

c. Mechanisms for Dietary Fat-Induced Alterations in Calcium Absorption and Utilization

Several mechanisms appear to be involved in the effects of dietary fat on calcium absorption and utilization. Song et al. (1983) demonstrated the existence of calcium-binding ligands in the small intestine of rats that appear to be age dependent. Jejunal transport processes may also be altered

by small changes in the percentages of EFAs and non-EFAs, without changes in total fat (Thomson et al., 1986). Haag et al. (2003) reported that, in *in vitro* models, the n-3 fatty acids, DHA and EPA, affected Ca^{+2}- and Na^{+},K^{+}-ATPases important in the intestinal absorption of calcium. In Caco-2 cells, 50 μM of the *trans*-10,*cis*-12 isomer of CLA increased paracellular epithelial transport whereas the *cis*-9,*trans*-11 isomer had no effect (Roche et al., 2001). Jewell and Cashman (2003) confirmed these findings and observed that only paracellular, not total transepithelial or transcellular transport, was affected by 80 μM of *trans*-10,*cis*-12 isomer of CLA. EFAs may also increase calcium absorption by enhancing the effects of vitamin D on calcium uptake and use (Kruger and Horrobin, 1997).

Dietary fat may also impact bone quality and quantity through effects on inflammatory cytokines (Kettler, 2001). Sources of n-3 fatty acids such as fish oil (i.e., EPA and DHA), flaxseeds, and flaxseed oil (i.e., ALA) can suppress production of the inflammatory cytokines, IL-1, IL-6, and TNF-α (Meydani et al., 1991; Blok et al., 1996; Caughey et al., 1996; Kettler, 2001). This reduction in cytokine production has been observed with a dietary intake of 1–5 g/day of EPA and/or DHA from fish or fish oil (Endres et al., 1989; Meydani et al., 1991, 1993) as well as from a dietary intake of 14 g/day of ALA from flaxseed oil or from fish oil added to a high-ALA diet (Caughey et al., 1996). The inflammatory cytokines increase the formation and activity of osteoclasts (Manolagas and Jilka, 1995) that are involved in bone resorption. Decreases in the production of inflammatory cytokines should decrease bone resorption and, thus, bone loss.

B. Magnesium

Scientific interest in the interaction between dietary fat and magnesium has been minimal in contrast to dietary fat and calcium. In fact, much of what has been reported about magnesium bioavailability relative to fat has been the beneficiary of research on calcium and fat interactions. In a review of the early literature, Seelig (1964) concluded that the available evidence was insufficient to define the effect of fat on magnesium metabolism. More recent experimental data may improve our understanding of this relationship.

a. Animal Studies

i. Absorption and Retention/Tissue Mineral Concentrations

Tadayyon and Lutwak (1969) studied the effects of dietary triglycerides on magnesium metabolism in weanling rats. Magnesium absorption was significantly correlated ($r = .43$; $p < .1$) with fat absorption. Animals receiving either a fat-free diet or 25% triolein excreted the least magnesium in feces. At 5% intake, triolein, tripalmitin, and tristearin had similar effects on magnesium absorption and resulted in higher absorption of magnesium than with 25% tripalmitin or tristearin. The magnesium content of the femur was highest in the groups fed 5% or 25% triolein and lowest in the group fed 25% tripalmitin. In contrast, Watkins et al. (1992) found no effect of varying dietary fat content (1%, 5%, or 10%) on magnesium absorption. In turkey poults, retention of magnesium was less with more saturated fats, and palmitic acid consumption significantly decreased bone magnesium content (Leeson and Atteh, 1995). Kaup et al. (1990) observed a variable effect of fat on magnesium absorption in young and mature rats. Magnesium absorption was consistently greater among young rats fed high-butterfat (20%) diets vs. low-butterfat (5%) diets. Magnesium absorption, however, tended to be reduced among mature rats fed more fat.

ii. Magnesium Soap Formation

The interactions between fatty acids and magnesium are generally accepted to occur within the intestinal lumen where soaps are formed (Boyd et al., 1932). This soap formation results in insoluble complexes that are not absorbed but are excreted in the feces (Gacs and Barltrop, 1977). The consistent observation that fecal magnesium losses are related to fecal fat excretion suggests that soap formation is the principal mechanism by which fats and minerals interact.

b. Human Studies

i. Absorption, Retention, and Utilization

In a study of young men (van Dokkum et al., 1983), magnesium retention was not affected by increasing dietary linoleate intake from 4% to 16% of energy intake (total fat intake was constant at 42% of energy intake). Similarly, reducing total fat intake from 42% to 22% with a constant linoleate intake of 18% did not affect magnesium retention. These findings are consistent with the conclusion of Seelig (1964) that there is little evidence to support a definite effect of dietary fat on magnesium absorption. However, as described in the above section on animal studies, other evidence suggests diets high (>20%) in saturated dietary fat tend to reduce magnesium absorption in mature animals. In premature infants, however, magnesium absorption was increased when the infants were fed an MCT-containing formula (MCT and corn oil, 80:20) in comparison with the control formula (corn oil, oleo, and coconut oil, 39:41:20) (Tantibhedhyangkul and Hashim, 1978).

C. Copper and Zinc

In contrast to macrominerals, such as calcium and magnesium, that are required in amounts of hundreds of milligrams per day, the daily human requirements for trace elements, such as cooper, zinc, and iron, are estimated to be in amounts ranging from about 3 to 15 mg (National Research Council, 2001). Factors affecting the bioavailability of these trace substances have been intensively studied (Halsted et al., 1974; Mason, 1979). However, the influence of absolute or relative amounts of fat has only recently come under investigation as a putative factor affecting copper and zinc utilization.

a. Animal Studies

i. Absorption

The effects of the type of dietary fat (coconut or safflower oil; 10% by weight) on copper and zinc absorption was studied in weanling, male Sprague-Dawley rats fed semipurified diets containing adequate amounts of copper and zinc (Lukaski et al., 1986). Absorption was estimated by determination of the remaining radioactivity by whole-body counting after labeling each animal with ^{67}Zn. The safflower oil-based diet was associated with a slightly depressed absorption of copper (35% vs. 39%) and zinc (79% vs. 84%).

In a rat model using *in vivo* jejunal perfusion, 1.0 mM of palmitate or stearate were observed to suppress copper absorption rates compared with controls (infusate without fatty acid or triglycerides; control: 104.4 ± 8.8 vs. palmitate: 12.5 ± 17.6 pmol/min × cm, $p < .01$; control vs. stearate: 37.2 ± 25.6 pmol/min × cm, $p < .05$) (Wapnir and Sia, 1996). Copper absorption was unaffected by medium-chain free fatty acids such as caprylate and caproate, or was it affected by an emulsion of medium- or long-chain triglycerides (1.0 or 2.5 mM). Earlier research indicated that 1 mM of palmitic acid significantly enhanced zinc absorption (Wapnir and Lee, 1990). The results of these studies suggest long-chain free fatty acids may impair copper absorption whereas zinc is increased by saturated fatty acids.

In contrast, n-3 fatty acids and palmitate have been reported to enhance absorption of zinc (Lee and Wapnir, 1993). In rats with or without experimental osmotic diarrhea, 1 mM stearate enhanced zinc absorption, whereas 1 mM palmitate was effective only in normal rats (Lee and Wapnir, 1993). The authors suggested that saturation and a longer-chain length were positive factors in the enhancement of mineral absorption.

ii. Retention/Tissue Mineral Concentrations

The effects of dietary linoleic acid on the tissue status of zinc and copper were examined in adult male Fisher 344 rats (Koo and Ramlet, 1984). One group received a diet containing 4% hydrogenated

coconut oil (about 0.8% linoleate) and the other received a diet containing 3.4% nonhydrogenated coconut oil plus 0.6% linoleic acid. The linoleate contents of the diets were 0.8% and 2.55%, respectively. After 6 weeks, the high-linoleate diet resulted in a significant depression in serum zinc (23.7 vs. 21.4 μmol/L) and a slight decrease in serum copper concentration (20.5 vs. 19.7 μmol/L). Liver and tibia wet weights were similar between the groups. The higher linoleate diet was associated with a significantly depressed zinc content of the tibia (145 vs. 156 μg/g wet weight) and copper content of the tibia (0.20 vs. 0.33 μg/g wet weight). Zinc and copper content of the liver were not significantly affected by linoleate intake.

The effects of the type of dietary fat (coconut or safflower oil; 10% by weight) on copper and zinc retention were studied in weanling, male Sprague-Dawley rats fed semipurified diets containing adequate amounts of copper and zinc (Lukaski et al., 1986). Retention was estimated by determination of the remaining radioactivity by whole-body counting after labeling each animal with ^{65}Zn. The safflower oil-based diet was associated with a slightly depressed half-life of copper (10 vs. 11 days) and zinc (82 vs. 85 days). Safflower oil marginally depressed hepatic copper content (10.9 vs. 11.2 μg/g dry weight), but significantly decreased liver zinc (287 vs. 381 μg/g dry weight). Lynch and Strain (1989) also reported an effect of type of dietary fat on hepatic copper. They studied weanling, male Wistar rats fed diets containing 20% by weight of either coconut or safflower oil with two different copper contents (0.4 and 11 ppm) for 56 days. In the rats fed with adequate copper diets, the liver copper content was significantly less (7.5 vs. 18.2 μg/g wet weight) when safflower oil was the fat source. Similarly, safflower oil significantly decreased hepatic copper in the rats fed with copper-deficient diet (7.5 vs. 8.1 μg/g wet weight). In addition to the evidence for an effect with the type of dietary fat, Wapnir and Devas (1995) observed that a high-fat diet (45% as corn oil and hydrogenated vegetable oil) decreased plasma copper in rats fed either a normal- or low-copper diet. Tallman and Taylor (2003) also demonstrated that mice fed a high-fat diet (39% kcal from lard and 16% kcal from soybean oil) had significantly increased fat pad weights and lower adipose zinc concentrations than those mice fed a low fat diet (16% kcal from soybean oil). The adipose tissue zinc concentration of the high-fat fed mice was 192 ± 14 nmol/g vs. 241 ± 18 nmol/g in the low-fat-fed mice. The findings of these animal studies indicate that the consumption of a diet consisting of predominantly PUFAs can depress zinc and copper status and that the dietary fat content may also influence tissue distribution of trace minerals.

b. Human Studies

i. Absorption and Retention

The influence of the type and amount of dietary fat on human trace element metabolism has not been intensively investigated. Three highly trained endurance cyclists lived in a metabolic unit and consumed diets made of conventional Western foods for 3 months (Lukaski et al., 2001). The diets, which were high (45%–55%) in carbohydrate and saturated or polyunsaturated fat, were presented in random order for about 28 days each; the effects of the type and amount of dietary fat were evaluated by the chemical balance technique. Zinc and copper balance data were expressed as the values of two consecutive 6-day balance periods at the end of each dietary period. Zinc retention was significantly affected by the type of dietary fat (Table 24.1). Although a small difference in average zinc intake occurred, probably the result of changes in food used to accommodate the required changes in carbohydrate and fat composition of the diets, the zinc balance was significantly decreased by polyunsaturated fat as compared to saturated fat or carbohydrate. Relative zinc losses in the feces increased when polyunsaturated fat was consumed. The difference of approximately 5 mg in zinc retention exceeds the difference of 1.5 mg in zinc intake. There was no significant effect of dietary fat on the copper excretion and balance. Interestingly, the copper balance was positive although not different from 0, only when saturated fat was consumed.

Because of the differences in the calculated linoleate intake between the polyunsaturated and saturated fat diets, it was possible to evaluate zinc and copper balances relative to intake of this fatty

TABLE 24.1

acid. Table 24.2 shows the effects of high- and low-linoleate intakes on zinc and copper balances. Low daily intakes of linoleate (about 13 g or less) were associated with a significantly greater zinc balance than higher intakes (140 g or more). Zinc retention was inversely and significantly related ($r = –.49$; $p < .5$) to linoleate intake. The copper balance was not affected by linoleate intake.

Boeckner and Kies (1986) observed that zinc retention in adolescents tended to be less with high- vs. low-fat diets; however, the amount of dietary zinc likely affected this association.

c. Mechanisms for Dietary Fat-Induced Alterations in Copper and Zinc Absorption and Utilization

Experimental data from rats indicate that although absorption and retention of copper and zinc determined by using radioisotopes are not significantly influenced by the type of fat, tissue pools of

these trace elements are decreased by polyunsaturated fat (Koo and Ramlet, 1984; Lukaski et al., 1986; Lynch and Strain, 1989). These findings suggest that dietary fat influences copper and zinc redistribution in the body. The mechanism underlying these changes in tissue redistribution may be alterations in transport proteins, such as zinc transporters. Recent evidence indicates that rats raised and/or maintained on a diet deficient in n-3 PUFA (7% safflower oil, 6.7% palmitic acid, 2.6% stearic acid, 16.7% oleic acid, 71.9% linoleic acid, and 0.2% ALA of dietary fat with no long-chain n-3 PUFA) had significantly decreased plasma zinc concentrations as well as increased expression of *ZnT3* in the brain compared with rats on a control diet with n-3 PUFA (5.84% safflower oil and 1.16% flaxseed oil; 6.5% palmitic acid, 2.3% stearic acid, 15.0% oleic acid, 63.0% linoleic acid, and 11.4% ALA of dietary fat with no long-chain n-3 PUFA) (Jayasooriya et al., 2005). Similar to the findings in rats, data from men indicate that retention of zinc is significantly reduced when a diet high in polyunsaturated fat is consumed (Lukaski et al., 1992). This impairment is related to the increased fecal excretion of zinc. These findings in animals and humans suggest that fats may act at either the intestinal lumen or the cell membrane to exert the observed effects.

Although intensively studied, little is known about the factors that regulate copper and zinc absorption (Cousin, 1985). Copper and zinc are taken up by brush-border membrane transport systems at the mucosal cell. These systems are not well understood, but they are thought to involve a carrier-mediated transport protein. Whether dietary fat directly affects the structure and function of these transport systems is not known. However, it is generally accepted that changes in dietary fat intake can significantly influence membrane fluidity, and thereby significantly affect cellular functions, including carrier-mediated transport and membrane-bound enzyme activities (Spector and Yorek, 1985).

D. Iron

The importance of iron in maintaining health and optimizing biological function has been long recognized by nutritionists (Dallman, 1986). However, there has been intensive research to extend our understanding of the dietary factors affecting the availability of iron for absorption and utilization (Bowering et al., 1976). The effects of micronutrient factors, such as other minerals, ascorbic acid, and phytic acid, have been studied in detail (Hallberg, 1981), but the influences of macronutrients, such as protein, carbohydrate, and fat, are less well understood.

a. Animal Studies

i. Absorption

Amine and Hegsted (1975) reported an effect of dietary fat on iron absorption. In one experiment, iron absorption was determined by using ^{59}Fe in adult, iron-deficient, female rats fed diets containing varying amounts of coconut or corn oil. Diets high in fat (30% vs. 5% or 15%) apparently promoted iron retention. Iron absorption was greater in diets in which fat was supplied as coconut oil than those in which fat was provided as corn oil. The difference between the oils was greatest when fat in the diet was low (5% coconut oil: 38% ± 3% ^{59}Fe retained vs. 5% corn oil: 25% ± 2% ^{59}Fe retained, $p < .05$).

The effect of changing the amount and type of dietary fat on iron absorption in weanling male, iron-deficient rats fed varying amounts of heme and nonheme iron was studied by Bowering et al. (1977). Changes in the fat content included an increase from 5% to 20% of the diet and exchange of lard for corn oil. Increasing the fat content and changing to a more saturated fat source were associated with small but significant increases in iron absorption. The enhancing effect on iron absorption observed with changing the type of dietary fat was observed only when ferrous sulfate, and not heme iron, was fed at a suboptimal (15 ppm) amount in comparison to adequate (25 ppm) or luxuriant (350 ppm) amounts.

Factorial studies were undertaken to examine the effects of dietary iron intake (10 vs. 35 ppm), fat intake (5% vs. 35%), and type of fat (safflower oil vs. coconut oil) on heme and nonheme iron

absorption (Johnson et al., 1987). Rats were made moderately anemic by feeding an iron-deficient diet and were then fed one of the eight experimental diets. Iron absorption was determined by feeding a ^{59}Fe test meal and by determining the remaining radioactivity in each animal by using whole-body counting for the following 5 weeks. Unlike in humans, nonheme iron was better absorbed than heme iron regardless of other dietary factors. Both heme and nonheme iron absorption was greater when high (30%) rather than low (5%) dietary fat was fed.

Other evidence also indicates a higher amount of dietary fat (15% or 30% of dietary energy vs. 7% or 14% of dietary energy) can enhance iron absorption in rats fed low dietary iron (10 μg Fe/g diet) (Droke and Lukaski, 1996). The type of fat (unsaturated vs. saturated) had an effect on iron absorption; absorption was significantly enhanced when rats were fed 7% or 15% stearic acid (fatty acid form), cocoa butter, or beef tallow than when rats were fed safflower oil. No differences in absorption was observed between stearic acid, cocoa butter, or beef tallow. Iron absorption was also significantly greater in rats fed 7% or 15% cocoa butter or 15% beef tallow than in rats fed 7% safflower oil, suggesting a more saturated fat source, regardless of the fat content of the diet, may increase iron absorption in iron-deficient animals (Droke and Lukaski, 1996).

ii. Retention/Tissue Mineral Concentrations

The importance of the interaction between dietary fat and iron was highlighted by Kaufman et al. (1958). In adult male rats, the liver iron concentration decreased significantly from 88.6 to 15.7 mg/100 g when dietary fat (lard) was reduced form 30% to 10% and protein (casein) was maintained at 10%. When the diet was supplemented with additional iron (2% as ferric citrate), the liver iron also increased when fat was high (88.6–113.5 mg/100g) or low (15.7–22.5 mg/100 g). Thus, both fat and iron increased the hepatic iron content in iron-adequate rats. Liver iron in weanling male rats was increased to the greatest extent when the rats were fed an iron-adequate diet (35 μg/g) containing 15% fat (Droke and Lukaski, 1996). The lowest amount of liver iron was observed in rats fed iron-deficient diets (10 μg/g) containing 7% or 15% fat. An iron-adequate diet containing 7% fat resulted in liver iron concentrations that were intermediate between both the deficient diets and an adequate diet containing 15% fat. However, in later research, liver iron concentrations were unaffected by safflower oil, flaxseed oil, olive oil, or beef tallow (Shotton and Droke, 2004).

iii. Iron Utilization

The development of iron deficiency has been promoted by feeding diets low in iron and/or high in polyunsaturated fat (Amine et al., 1976; Rao et al., 1983; Droke and Lukaski, 1996). In contrast, feeding fat-free or saturated fat diets has been used to inhibit the development of iron deficiency in animals and fowl (Rao et al., 1980, 1983).

Factorial studies were undertaken to examine the effects of dietary iron intake (10 or 35 ppm), fat intake (5% or 35%), type of fat (safflower or coconut oil), and iron source (heme or nonheme) on indices of iron status (Johnson et al., 1987). Rats were made moderately anemic by feeding an iron-deficient diet and were then fed 1 of the 16 experimental diets. Rats fed both heme or nonheme iron had significantly greater hemoglobin, change in hemoglobin, and liver iron content when fed coconut oil compared to safflower oil. Rats fed nonheme iron had greater liver iron, but not hemoglobin or change in hemoglobin, when fed high- rather than low-dietary fat. Rats fed heme iron had greater hemoglobin, change in hemoglobin, and liver iron when fed high- rather than low-fat diet.

Later research (Droke and Luksaki, 1996) using the same model as Johnson et al. (1987) demonstrated that the effects of dietary fat on iron utilization (i.e., regeneration of hemoglobin) were observed only in rats fed low-dietary iron (10 μg/g). In addition, iron utilization was the greatest when rats were fed 15% stearic acid than when they were fed diets containing 7% or 15% safflower oil, cocoa butter, or beef tallow. Similar to these findings, suckling and weanling rats fed more saturated fat (coconut oil, human milk fat) had a greater percentage of ^{59}Fe in the blood (suckling rats), a greater hemoglobin regeneration (weanling), and significantly higher retention of ^{59}Fe (weanling)

(Pabon and Lonnerdal, 2001). Subsequent research (Shotton and Droke, 2004) evaluated the effects of fat source (safflower oil, flaxseed oil, olive oil, or beef tallow; 30% of dietary energy) in combination with different concentrations of dietary iron (10, 35, or 100 μg/g) on iron utilization. As in the previous research, the male weanling rats were initially fed a low-iron safflower diet to promote iron depletion. The results indicated that iron status and iron utilization (hemoglobin regeneration) were not significantly affected by an interaction between dietary fat source and iron concentration. However, rats fed low iron tended to have an increase in iron utilization when they were fed either olive oil or beef tallow. These conflicting results between studies may be due to differences in experimental design such as duration of feeding and dietary fat content.

These findings strengthen the growing evidence that the amount of dietary fat and its degree of saturation can affect the utilization of dietary iron. In general, the findings indicate that increasing amounts of saturated fat enhance and increasing amounts of unsaturated fat inhibit dietary iron absorption and utilization in rodent models.

b. Human Studies

i. Absorption and Retention

In a study of competitive male cyclists (Lukaski et al., 2001), the effects of the type and amount of fat on iron retention were also examined. Iron retention was significantly affected by the type of fat consumed (see Table 24.1), and it was either significantly decreased by polyunsaturated fat or enhanced by saturated fat. On the basis of the apparent increase in fecal iron excretion, unsaturated fat apparently impairs iron absorption. High intakes of linoleate were associated with a reduced iron retention (see Table 24.2). The iron balance was inversely and significantly related ($r = .64$; $p < .004$) to linoleate intake.

Similar findings were reported by van Dokkum et al. (1983), who examined the effects of changing the total fat intake and the amount of dietary linoleic acid on iron balance and blood biochemical indices of iron status in 12 men fed experimental diets for 28-day periods. Increasing the total fat intake from 22% to 42% of energy did not affect the iron balance. However, increasing the linoleic acid intake from 4 to 16%, while the total fat intake remained at 42%, resulted in a significant decrease in iron retention from 3.3 to 2.3 mg/day. At the same time, hemoglobin concentrations declined slightly from 9.6 to 9.1 mmol/L and the hematocrit decreased from 48% to 46%.

c. "Meat Factor"

Meat is another factor known to influence iron absorption. It is well recognized that heme iron, found primarily in meat or muscle, is better absorbed by humans than nonheme iron (Hallberg, 1981). Furthermore, meat or meat products facilitate nonheme iron absorption. Efforts to identify the factor or factors in meat that promote nonheme iron absorption have been extensive (Cook and Monsen, 1976; Hazell et al., 1978; Bjorn-Rasmussen and Hallberg, 1979; Hallberg and Rossander, 1982; Layrisse et al., 1984). Some investigators concluded that the active factor in meat that promotes nonheme iron absorption is an amino acid, such as glutathione or histidine, or small peptides, such as glutathione, but the effects of these and other components of meat on iron absorption have not always been consistent. Zhang et al. (1990) proposed that the "meat factor" must be a chemical compound, which binds iron through an action or mechanism that is different than chelation with an amino acid or peptide.

A candidate for the role of the meat factor is a fat or fatty acid. Mahoney et al. (1980) reported a relationship between a fat effect and the meat effect on iron absorption. They demonstrated that animals fed beef fat, compared to turkey fat, corn oil, or pork fat, were most efficient at converting iron from turkey meat into hemoglobin. One of the principal differences between beef fat and the other fats used in their study is that beef fat contains about 19% stearic acid (18:0), which is 10 times more than the stearic acid content of corn oil, 3.0 times more than that of turkey fat, and 1.5 times

more than in lard (Mahoney et al., 1980). The findings suggest dietary stearic acid may be important in facilitating iron absorption.

Johnson et al. (1992) investigated the effects of stearic acid on iron utilization in rats. Anemic, male rats were fed diets containing stearic acid plus safflower oil (22% stearate + 2% safflower oil and 20% stearate + 4% safflower oil) or safflower oil (24%) and low (10 ppm) or high (39 ppm) iron as ferrous sulfate. The repletion of hemoglobin, hematocrit, liver iron, and absorption of ^{59}Fe were assessed. Compared to safflower oil, stearic acid had a significant positive effect on the repletion of hemoglobin, hematocrit, and liver iron. The effect was greatest when dietary iron was low.

In another experiment (Lukaski et al., 1992), rats were fed low-dietary iron (10–11 ppm) and 24% safflower oil, 20% stearic acid + 4% safflower oil, 3.2% stearic acid + 20.8% safflower oil, or 20% beef tallow + 4% safflower oil. The 20% beef tallow provided 3.2% stearic acid. Rats fed beef tallow had significantly greater hemoglobin (6.9 vs. 5.6 g/L) and hematocrit (2.15% vs. 18.1%) repletion than did rats fed safflower oil, although the degree of repletion was less than that observed in rats fed 20% stearic acid (8.2 g/L and 25.98%). There was no difference in iron repletion of rats fed 3.2% stearic acid and rats fed beef tallow. Thus, stearic acid apparently increases iron utilization in rats fed nonheme iron.

Another experiment was designed to distinguish between the effects of meat protein and meat fat on iron utilization (Lukaski et al., 1992). Anemic rats were fed diets low or adequate in iron with either casein or beef (prime rib or fat-extracted beef) as the protein source and safflower oil, tallow, or stearic acid as the fat source. Dietary iron was low or adequate. Animals fed diets with tallow or stearic acid had the highest circulating hemoglobin regardless of the amount of iron in the diet. In addition, rats fed prime rib had reticulocyte counts three to five times greater than rats fed casein or lean beef with safflower oil. These findings indicate that beef fat enhances the utilization of ion for hemoglobin and red blood cell production.

The effects of combinations of various protein (lean beef, skim milk, and egg white) and fat (beef fat, milk fat, and partially hydrogenated vegetable fat) sources on iron absorption in iron-adequate weanling rats have been examined (Kapsokefalou and Miller, 1993). Whole-body retention of ^{59}Fe was similar for lean beef plus tallow as compared to lean beef plus vegetable shortening (78% vs. 70%) but was significantly less with egg plus shortening (78% vs. 57%). Overall, there was no effect of fat type within a specific protein group, but beef was a significantly better protein source for promoting iron absorption. The authors concluded that the fat source (e.g., tallow) played an important role in facilitating the ability of lean beef to promote nonheme iron absorption.

A novel method has been used to examine the effects of dietary fat on *in vivo* mucosal iron kinetics. This experimental approach uses two radioisotopes of iron to estimate *in vivo* iron absorption and plasma iron kinetics into tissues (Nathanson et al., 1984). In mature dogs made iron deficient by consumption of an iron-deficient diet and serial phlebotomy, stearic acid (20%) significantly increased iron absorption (50% vs. 21%), hemoglobin (25 vs. 6 g/L), and erythrocyte volume (83 vs. 32 mL) regeneration (Lukaski et al., 1993). This beneficial effect of stearic acid was the result of a significantly increased rate of transfer of iron from the mucosal cell to the plasma. Beef tallow, a typical source of dietary stearic acid, was shown to promote iron absorption and utilization as compared to safflower oil (McLaren et al., 1993).

These experiments were repeated with reduced amounts of fat (10%). It was found that stearic acid and beef tallow similarly enhanced iron absorption and utilization in anemic dogs (McLaren et al., 1997). Therefore, these findings support the hypothesis that dietary stearic acid may be one of the chemical factors in meat that promotes nonheme iron absorption and utilization.

d. Mechanisms for Dietary Fat-Induced Alterations in Iron Absorption and Utilization

Despite increasing evidence that dietary fat can influence iron absorption and retention (van Dokkum et al., 1983; Johnson et al., 1987, 1992; Lukaski et al., 1993, 2001; McLaren et al., 1993), there is a

paucity of information about the mechanism of this action. The mechanism(s) of these effects may be related directly to changes occurring within the lumen of the intestine or indirectly due to alterations in the integrity of enterocyte membranes and/or paracellular transport. In the early 1990s, it was proposed that bioavailable lipophilic complexes between ferrous iron and free fatty acids could be formed and taken up by mucosal cells (Kapsokefalou and Miller, 1993). This is supported by observations that saturated fat, particularly stearic acid, appears to promote iron uptake. Research involving chemical analyses of combustion products of tobacco smoke demonstrated that stearic acid has the capacity to affect the reduction of ferric to ferrous iron, to bind the resulting ferrous iron, and to transport the iron within the pulmonary macrophage (Qian and Eaton, 1989). Such enhancement of iron uptake by stearic acid may be related to the formation of stable monolayer stearate iron films (Wheeler et al., 1971). Monolayer films of anions may function as ionophores in the translocation of cations across biological membranes (Patel and Cornwell, 1977).

Fatty acids have been determined to participate in the uptake of iron at the mucosal membrane. Isolated brush-border membrane vesicles have been reported to have a high concentration of nonesterified fatty acids (Simpson and Peters, 1987a,b). It was demonstrated by using an *in vitro* brush-border membrane preparation that the major iron-binding components were associated with free fatty acids and that oleic and stearic acids show iron-binding capacities (Simpson and Peters, 1987a,b; Simpson et al., 1988). Abnormal fatty acid changes in cellular membranes were later shown to occur with iron deficiency (Tichelaar et al., 1997) and the authors suggested additional n-3 and n-6 fatty acids may be necessary to correct the changes occurring with iron deficiency. Later research by Pabon and Lonnerdal (2001) suggested the increase in absorption observed with saturated fats may have been due to changes in the fatty acid composition of the intestinal mucosa as significant positive correlations were found between dietary oleic and linoleic acids and intestinal mucosa concentrations of these fatty acids (oleic: $r = .95$, $p < .05$; linoleic: $r = .97$, $p < .05$).

Recently, research with Caco-2 cells provided support for the findings of Pabon and Lonnerdal (2001) by demonstrating a significant increase in ^{59}Fe uptake with 1 mM of oleate, palmitate, or stearate (Droke et al., 2003). Transport of ^{59}Fe by the Caco-2 cells was also significantly enhanced by 1 mM of palmitate or stearate. Palmitate increased transport to a greater extent than stearate, which could have been due to fatty acid metabolism within the cells and the elongation of palmitic acid to stearic acid. Overall, the results suggested that the fatty acids affected iron uptake to a greater extent than iron transport. These effects may have been the result of changes in monolayer integrity and paracellular transport that were observed with the cells, suggesting possible alterations in tight junctions.

III. CONCLUSION

Experimental evidence in animals and humans indicates that dietary fat may be important in mineral metabolism. The consensus is that dietary fat does significantly influence calcium and magnesium metabolism in healthy people with usual fat intakes, and there is accumulating evidence that fat may impact trace mineral metabolism.

Polyunsaturated fat may adversely affect the absorption and utilization of copper and zinc in animals. It apparently reduces the absorption of zinc in humans. Although the fecal excretion of zinc is increased with polyunsaturated fat, the mechanism of action is not known, it may involve alterations in the intestinal milieu that inhibit zinc-membrane receptor dynamics, or changes in cellular membrane receptor function by altering membrane fluidity.

The most striking effect of dietary fat on trace mineral metabolism is the finding of the enhancement of iron uptake and utilization by saturated fat, specifically stearic acid. The effects are prominent when dietary iron is limiting, and they thus indicate a novel role in promoting and adequate iron status in humans. The practical importance of using stearic acid to facilitate iron absorption in humans is that it has a minimal impact on serum cholesterol concentrations (Keys et al., 1965; Bonanome and Grundy, 1988) and it does not adversely effect platelet function and clotting (Schoene et al., 1993).

IV. DIRECTIONS FOR FUTURE RESEARCH

Additional research is needed to determine the mechanisms through which dietary fat and fatty acids affect mineral metabolism. It remains to be determined which intakes of a fat and which fatty acids significantly change mineral absorption and utilization, and if this results in a significant accumulation of the minerals. The use of new experimental approaches, including cell culture techniques and cell biology tools, is recommended to further delineate physical and chemical interactions between fatty acids and minerals at the cellular level. The use of microarray DNA technology to study gene expression in enterocytes may also provide valuable clues regarding the mechanism(s) for the effects of dietary fat on mineral absorption and utilization. This information will be useful in understanding the factors that affect the bioavailability of minerals in the diet to optimize human health and function.

25 Interaction of Dietary Fatty Acids, Carbohydrates, and Lipids on Carbohydrate Metabolism

Béla Szepesi

CONTENTS

I. INTRODUCTION

The effects of dietary carbohydrates differ qualitatively and quantitatively from the effects of other nutrients. These differences between carbohydrates and other nutrients should be well understood before the various roles of carbohydrates and their effects of human health are considered. The first of these differences relates to the requirement for carbohydrate in the food. Whereas vitamins, minerals, proteins, individual amino acids, or polyunsaturated fatty acids (PUFAs) can be shown to be required for minimum human health, there is no absolute requirement for the intake of dietary carbohydrate. Apparently, human beings are able to maintain at least a minimal health status with a relatively wide range of consumption of carbohydrates with respects to both amount and type.

The second of these differences relates to the magnitude of the responses involved. Deficiencies in vitamin, mineral, protein, or PUFA consumption lead to often clear-cut and large physiological changes demonstrable over a relatively short period of time, and overconsumption of some of these substances again can lead to relatively large changes, which also are demonstrable. Overconsumption of saturated fatty acids and cholesterol, for example, has been recognized as a risk factor in arterial and heart diseases. The effects of such overconsumption are readily apparent on blood lipids and can be demonstrated in animal models and human beings in a matter of weeks. Changes induced by carbohydrates are smaller and are more difficult to demonstrate. The smaller magnitude in response to dietary carbohydrates imposes problems in demonstrating such changes in a statistically significant manner (Szepesi and Michaelis, 1986). Scientists and nonscientists who are used to the magnitude of changes that are seen with nutrient deficiency or excess in the case of vitamins, minerals, protein,

and lipids find it difficult to accept the biological significance of changes seen with the consumption of carbohydrates. Statistical constraints imposed on research with carbohydrates would require experimenters to use a large number of experimental subjects. This is often difficult, especially in human studies. Therefore, experimenters have opted to enlarge the response to carbohydrates by (1) selecting more responsive individuals and/or (2) increasing the amount of carbohydrate fed. By such techniques, the magnitude of the response can be enlarged and the time required to observe the response shortened. However, although such techniques are readily accepted with studies of other nutrients (including the feeding of large amounts of cholesterol to vegetarian rabbits to show arterial damage), the feeding of large amounts of simple sugars to either animals or humans has been criticized on numerous occasions (Bossetti et al., 1984).

The third difference relates to the interactive nature of the carbohydrate effects. Cohen and coworkers (Cohen et al., 1970; Yanko et al., 1972; Rosenmann et al., 1974) championed the hypothesis that the induction of type II diabetes in rats requires both a dietary vector (simple sugar) and heredity. Berdanier (1974) elucidated the concept of "carbohydrate sensitivity" (a subpopulation that has a greater response to carbohydrate) with the BHE rats. This concept was later generalized by Reiser and coworkers (Reiser et al., 1981, 1989; Hallfrisch et al., 1983) to humans. In these and numerous other studies, it was recognized that dietary carbohydrate strongly interacts with genetic predisposition. Dietary carbohydrates strongly interact with lipids as well. In the recommendations of the Senate Select Committee on Nutrition (U.S. Senate, 1973), recommendations were made to reduce the intake of dietary saturated fat, cholesterol, and simple sugars. The interactive nature of dietary lipid and carbohydrate was emphasized by an U.S. Food and Drug Administration (FDA) review that concluded that dietary sucrose is not an independent risk factor (Sugar Task Force, 1986). This chapter focuses primarily on the interaction of dietary carbohydrate and lipid.

II. GENERAL PHYSIOLOGICAL INTERACTIONS

A. Dietary Carbohydrate, Blood Lipids, and Lipoproteins

There is a well-known species difference in the utilization of glucose as a precursor of fatty acid synthesis. This difference should be kept in mind when evaluating the effect of dietary carbohydrates on blood lipids. In the pig, conversion of glucose to lipid takes place primarily in the adipose tissue; therefore, dietary carbohydrate should have very little effect on blood lipids. In humans, glucose is converted to fatty acids and cholesterol primarily in the liver and transported to the adipose tissue via the blood; thus dietary carbohydrate is expected to influence blood lipids. The rat uses glucose for lipid synthesis in both organs (Gandemer et al., 1983). The pig, then, is not appropriate as a model to study carbohydrate effects on blood lipids. Although one would not expect the rat to be used as a model of carbohydrate effects on blood lipids because of the relatively high-density lipoprotein (HDL), a number of studies indicate that even the rat responds to carbohydrate feeding. Feeding of sucrose (as compared to glucose) has been shown to increase triacylglycerol synthesis (Boogaerts et al., 1984), the plasma concentration of triacylglycerol, free cholesterol, cholesterol ester, and apolipoproteins (Boogaerts et al., 1984; Hostmark et al., 1984) as well as apolipoprotein synthesis (Boogaerts et al., 1984). Plasma triglyceride, very low density lipoprotein (VLDL) triglycerides, and total blood cholesterol were shown to be increased in Sprague-Dawley and lean Zucker rats, but not in obese Zucker rats (Sheehan et al., 1984). Other formulations of dietary sucrose produced elevated plasma triglyceride in the obese Zucker rat, and this was accompanied by an elevation of postheparin lipolytic activity (Basilico et al., 1984). Holtzman rats were shown to have increased liver lipids when fed a sucrose-glycerol diet (fat free) (Narayan, 1986). Dietary fructose by itself also elevates plasma triglyceride and increases insulin resistance (Thorburn et al., 1989). The two effects may be strongly connected (Haito et al., 1984). Postabsorptive serum cholesterol and phospholipid increase with age in the rat; food restriction reduces this trend (Liepa et al., 1980). The rat can therefore be used as an appropriate subject for study, but one must be careful in generalizing the phenomena observed in the rat to human beings.

A strong interaction between dietary carbohydrate and dietary cholesterol has been reported in cynomolgus monkeys (*Macaca fascicularis*) (Srinivasan et al., 1983, 1984). In the first study, sucrose produced an increase in total plasma cholesterol in the absence of added dietary cholesterol; this difference disappeared when cholesterol was added to the diet (Srinivasan et al., 1983). In the second study, in the absence of added dietary cholesterol, there was no carbohydrate effect on plasma cholesterol, and blood cholesterol in starch-fed rats was actually lower than in sucrose-fed rats when cholesterol was added to the diet (Srinivasan et al., 1984). Reports of contradictory trends are not uncommon in this field and are especially acute when considering human studies. The effect of dietary carbohydrates on blood lipids has been reviewed in detail (Sugar Task Force, 1986). Only a few relevant papers will be reviewed here to illustrate the controversy.

Dietary sucrose (Yudkin et al., 1980; Reiser et al., 1981; Hallfrisch et al., 1983; Yudkin et al., 1986) and fructose (Hallfrisch et al., 1983; Reiser et al., 1989) have been shown to increase blood lipids in hyperinsulinemic or even normal men. Some of the changes noted in other studies (Porikos and Van Italie, 1983) can be attributed to the ease of obtaining excessive calories when consuming sucrose, but a sucrose effect per se was also shown (Porikos and Van Itallie, 1983). Blood lipids were shown to increase when a high-carbohydrate, low-fat diet was fed to hyperglyceridemic men (Liu et al., 1983). Even in long-distance runners, a 30% increase in triglycerides was shown when such athletes were fed a high-carbohydrate diet (Thompson et al., 1984). The sucrose effect is reduced with the inclusion of dietary fiber (Albrink and Ullrich, 1986), exercise (Ullrich and Albrink, 1986), and nibbling (Gwinup et al., 1963). There are even more studies that show that inclusion of sucrose or fructose alters blood lipids (Sugar Task Force, 1986). Yet this conclusion is not accepted by a sizable portion of the scientific community. Dissent from the "sugar hypothesis" began early. A typical example (Bossetti et al., 1984) is a study of eight healthy volunteers receiving one third of their carbohydrate as either sucrose or fructose. No beneficial effects of fructose were found as compared to sucrose (Bossetti et al., 1984). Such a possible beneficial effect was suggested earlier (Brunzwell, 1978; Olefsky and Crapo, 1980), but the authors used regular food (and regular meals with sweetened drinks) with no starch control. Apart from arguments about the possible equivalence of sucrose and fructose, the effect of sucrose in humans is also challenged on various grounds. Size of meals, amount of carbohydrate fed, selection of subjects, and other food components besides carbohydrate are all factors cited to confound the data. Even the Framingham Study (Gordon et al., 1977) is cited by both sides to prove/disprove the possible role of sugar in heart disease. The final word on the subject seemed to have been the FDA report that concluded that sucrose consumption is not an "independent" risk factor (Sugar Task Force, 1986). Since that time, the subject has receded into obscurity.

Dietary carbohydrates can have diverse effects on lipid metabolism. Carbohydrate intake influence ketogenesis in the obese during weight loss (Pasquali et al., 1987) by a noninsulin-mediated process; carbohydrate can also alter blood lipid levels by lowering lipoprotein lipase (Haito et al., 1984; Lithell et al., 1985). A fructo-oligosaccharide was shown to reduce fasting blood glucose, total serum cholesterol, and low-density lipoprotein (LDL) cholesterol in diabetic subjects (Yamashita et al., 1984) at an intake level of 8 g/day per subject. It is very likely that polyfructose exerts its effect via the production of volatile fatty acids in the lower intestine, as do some other complex carbohydrates, rather than by providing fructose.

B. Thermogenesis and Energy Utilization

If there is a more controversial area of nutrition than the role of carbohydrates in heart disease, it is the role of thermogenesis in obesity. The problems are perhaps similar—relatively small effects, cumulative effects that take a long time to develop, confounding variables that are difficult to control, a relatively large number of scientists who cannot confirm the results. It is a common claim that obese patients find it difficult to maintain a desired body weight because of a low-energy requirement. Although many scientists dismiss such claims on various grounds, there is strong evidence to indicate that a twofold difference in food intake may exist in children (Widdowson, 1947)

and adults (Edholm et al., 1970), who nonetheless manage a similar amount of physical activity. The resting metabolic rate of obese and obese/reduced human subjects was found to be one third to one half that of normal-weight patients (who report that they can eat anything and still maintain normal weight) when heat production is stimulated by the infusion of norepinephrine (noradrenaline) (Jung et al., 1979). Brown adipose tissue (BAT) had been suggested as a major site of thermogenesis by the work of Foster and Frydman (1978, 1979). The "proton conductance" or "leakage pathway" (Heaton et al., 1978; Nicholls, 1979) is generally believed to be the mechanism by which BAT generates heat. Heat production by this mechanism involves the coupling of H^+ transport from ATP production in the mitochondria (Heaton et al., 1978). The uncoupling is prevented by purine dinucleotides (such as GDP) binding to the mitochondria via a 32-kDa protein (Heaton et al., 1978). Other processes, such as Na^+ transport and futile cycles (e.g., fatty acid turnover), may also be a source of heat production. This has been confirmed in "cafeteria-fed" animals, obese mice, and animals with ventromedial lesions (Trayhurn et al., 1982). However, although some experimenters failed to show a role for the sympathetic nervous system in BAT thermogenesis (Seaton et al., 1984), other experiments do imply a role for the nervous system in the regulation of BAT (Granneman and Campbell, 1984).

It has been known for many years that the ingestion of food is followed by the production of an increased amount of heat, the so-called thermic effect of food. As a percentage of energy given, carbohydrate has been reported to produce an average of 18% dissipation of the energy intake (13.8%–26.1%) in overfed men (Bisdee and James, 1984) compared to a 10% dissipation from men overfed fat (Dallosso and James, 1984). Jequier (1986) reported a glucose-induced thermogenesis in young adult equivalent to 12%–15% of the total carbohydrate load. This total thermic effect was divided into two parts: "obligatory thermogenesis" (due to the cost of carbohydrate storage) and "faculative thermogenesis" (due to other processes such as active transport and futile cycles) (Jequier, 1986). In another study, the thermic effect of a 500-g carbohydrate load was found (as percentage of the load) to be 5.2% from a high-fat diet, 6.5% from a mixed diet, and 8.6% from a high-carbohydrate diet (Acheson et al., 1984). Dietary fat, therefore, seems to reduce the utilization of carbohydrate (Acheson et al., 1984) and its thermic effect. The thermic effect of either a mixed meal or a high-fat meal is lower in obese humans (Swaminathan et al., 1985). Other experiments suggest that glucose is used as a primary fuel for exercise in the obese and that restriction of dietary carbohydrate in these subjects will reduce endurance (Bogardus et al., 1981). The foregoing reports would predict that a high fat/carbohydrate ratio would promote increased energy retention even in healthy individuals. However, a study with healthy Trappist nuns showed no significant difference in energy consumption or retention when the carbohydrate/fat ratio was varied (Van Stratum et al., 1978).

Overfeeding is a technique used to assess population variability and the ability of specific foods (or food in general) to promote weight gain. In an experiment that overfed young men diets high in fat, greater than expected variability was found in weight and fat gain (Norgan and Durnin, 1980). In another study, where carbohydrate was overfed (Welle et al., 1984), thyroid hormone status was altered (T_3 was increased and T_4 was reduced). Such changes indicate an adaptive mechanism to waste energy in normal subjects who are overfed, especially when such subjects are overfed diets rich in carbohydrate.

Another way to study this phenomenon is by feeding a "cafeteria diet" (Sundin and Nechad, 1983; Tulp and Shields, 1984; Bailey et al., 1985; Naim et al., 1985). Such diets have the composition of diets found in a cafeteria (hence the name) and are usually very palatable and tasty. LA/N-cp fats were shown to have an impaired adaptation to cold (Tulp and Shields, 1984). Lean LA rats had an improved thermic response to cold, and no improvement to cold adaptation was noted in the obese rats (Tulp and Shields, 1984). Cafeteria diets increased food intake even in normal rats (Naim et al., 1985). Dietary fat alone is enough to increase food intake (Naim et al., 1985). In addition, glucose was shown to induce a trophic response in the size and functionality of BAT but not lipids (Sundin and Nechad, 1983). The glucose effect can be suppressed by L-adrenergic blockade (chemical sympathectomy) (Sundin and Nechad, 1983). Finally, dietary glucose (but not fructose)

(Glick et al., 1984) can produce this trophic response in rats. Some of the effects may be confounded by other variables such as the protein/carbohydrate ratio (Kanarek et al., 1987) or the heating of food (Westringel and Potter, 1984).

In summary, dietary glucose produces a thermic response and a trophic response in BAT, the latter being dependent on the sympathetic nerves. Dietary fat produces less thermic response and may even reduce or eliminate the thermic response to glucose. Dietary fructose does not produce the trophic BAT response. The thermic response is reduced by obesity. Thus, the feeding of a cafeteria diet (high in fat and fructose, well-flavored, and palatable) can be lead to weight gain. These conclusions are based on solid data and make sense in terms of what is known about physiological adaptations. Negative evidence from some laboratories (i.e., those who cannot replicate the results) is unimpressive.

C. Other Interactions

Another type of interaction occurs between dietary fat and an organism with impaired glucose utilization, such as a diabetic rat. The response to long-chain triglycerides (LCTs) vs. medium-chain triglycerides (MCTs) is altered in diabetic rats (Edens and Friedman, 1984). Although LCTs are preferred by both the normal and diabetic rat, fat preference disappears when MCTs are fed (Edens and Friedman, 1984). Dietary cholesterol induces insulin resistance in mildly diabetic male rats (Wey et al., 1985) but not in females. Substitution of ω-3 fatty acids from fish oil for ω-6 fatty acids was shown to prevent the development of insulin resistance in noninsulin-dependent diabetic rats (Storlien et al., 1987). A three-way interaction between dietary fat, dietary carbohydrate and dietary cholesterol has also been reported (Meijer and Beynen, 1988). It has been recognized that the intake of fats, cholesterol, carbohydrate in general, sucrose (fructose), and dietary fiber, the health status and age of the individual, and exercise are all important factors that interact in various ways to alter carbohydrate and lipid metabolism (Jenkins, 1984). The FDA report (Sugar Task Force, 1986) on sucrose was, therefore, wrong to deemphasize the importance of sucrose in cardiovascular disease, because in a multifactorial disease, all risk factors are interactive. Whether risk factors are independent of interactive is or lesser importance.

In some species, such as predators, carbohydrate intake is low, and this has given rise to work with reduced carbohydrate diets. As reported in a previous section, interactive effects are sometimes different than expected: A high-protein diet reduces lipogenesis in the rat even if fat intake is low (Schmid et al., 1984), whereas butyric acid can alter the glycosylation of the α-subunit of the glycoprotein hormones secreted by glucose-starved Chang human liver cells (Morrow et al., 1983). High-protein diets, on the other hand, can reduce the lipotropic effect of sucrose (taken in as extra calories in the water).

The effect of dietary lipid on carbohydrate metabolism is strongly interactive with the periodicity of eating (Leveille, 1970; Szepesi and Freeland, 1971; Romsos and Leveille, 1972). Intermittent feeding induces a cycle of rapid glycogen synthesis and depletion (Leveille, 1970; Szepesi and Freedland, 1971) and a large variation in lipogenesis (Romsos and Leveille, 1972). The source of metabolic fuel (and hence the RQ) can change drastically (Leveille, 1970) during a 24-h period when eating is permitted only during a 1- or 2-h period. Under such circumstances, the effect of dietary lipid is expected to vary from hour to hour.

Finally, carbohydrate vs. fat effects may cause alterations that are not immediately evident unless these effects are the specific object of the study. For example, the effect of dietary fat in increasing insulin resistance was commented upon in a previous section. Such an effect may be due in part to (or is exaggerated by) the tendency of dietary lipid to enlarge fat pad size by enlarging the average size of fat cells (Madeiros et al., 1984). In such context, the dietary effect of increasing insulin resistance is not a direct effect on the membrane but an indirect effect due to cell enlargement and reduced insulin sensitivity.

III. CONTROL OF HEPATIC ENZYME ACTIVITY AND LIPOGENESIS BY DIETARY FAT

Although the interaction of dietary fat and carbohydrate is very controversial (especially the effect on blood lipids), surprising consensus exists on the subject of fat and carbohydrate interaction with regard to the control of lipogenesis and lipogenic enzymes. Early work showed that the reduction equivalents needed for reduction in fat biosynthesis are supplied by the pentose phosphate shunt and malic enzyme (ME) (Kather and Brand, 1975). This section, therefore, concentrates primarily on the control of glucose-6-phosphate dehydrogenase (G6PDH) and ME.

A. Source of NADPH and Its Influence on Metabolism

Glucose-6-phosphate dehydrogenase (G6PDH) (EC 1.1.1.49) and ME (EC 1.1.1.40) are the major sources (along with 6-phosphogluconate dehydrogenase [6PGDH, EC 1.1.1.44]) of the reducing power needed for hepatic fatty acid synthesis (Kather and Brand, 1975). A fourth NADP-linked dehydrogenase of the liver, isocitrate dehydrogenase, has only a minor role in the production of NADPH.

The G6PDH reaction involves the orderly addition of NADP and glucose-6-phosphate (in that order) and the sequential release of the endproducts (NADPH last) (Thompson et al., 1976). NADPH does not bind to the enzyme (Holten et al., 1976); this property was used to prepare NADP-free G6PDH (Holten et al., 1976). The enzyme cannot bind glucose-6-phosphate without NADP (Holten et al., 1976). The NADPH/NADP ratio regulates G6PDH and 6PGDH activity (Eggleston and Krebs, 1974), so the combination of enzyme induction and change in the NADPH/NADP ratio can alter enzyme activity by a factor of 30 (Holten et al., 1976). The NADPH/NADP ratio (decrease) and an increase in GSSG concentration could both activate the pentose phosphate cycle (Henderson, 1966). Paraquat can also activate the cycle (Fabregat et al., 1985). Current consensus is that any pathway or physiological effect that maintains a high NADPH/NADP ratio has an inhibitory effect on the pentose phosphate cycle and, conversely, that any pathway or reaction that reduces the ratio accelerates the pentose phosphate cycle.

B. Regulation of the Fatty Acid Synthetase Complex by Dietary Lipid

Fatty acid synthetase is a very large dimer, and each monomeric subunit catalyzes all the intervening reactions of adding one two-carbon unit to the growing fatty acid. When the fatty acid reaches the length of 16 carbons, it is cleaved off. This is an excellent example of concerted catalysis. During pregnancy, lactation, and weaning, the activity of the enzyme varies widely (Gimenez et al., 1984). Newly synthesized monomeric units may be inserted one by one (Strawser and Larrabee, 1976). The enzyme is induced by the feeding of carbohydrate [especially sucrose; Bruckdorfer et al. (1972)] and is decreased by a high-fat diet (Sabine et al., 1969). The effect of dietary fat is due to the polyunsaturated fats in the diet (Clarke et al., 1977; Flick et al., 1977), such as linoleic acid.

C. Regulation of G6PDH by Dietary Lipid

Rat liver G6PDH has been extensively studied for a number of reasons. The human gene for the enzyme is involved in a number of mutations (Szabo et al., 1984), and liver G6PDH is believed to be an important factor in the control of lipogenesis and hence blood lipids. The importance of the enzyme is underscored by the fact that its control parallels the nature of dietary and biological factors (Szepesi, 1976; Szepesi and Michaelis, 1986): Factors that tend to increase the level of liver G6PDH are believed to increase the risk of disorders in lipid metabolism, whereas factors that reduce G6PDH levels tend to reduce disorders in lipid metabolism and the health risks associated with them. Rat (Matsuda and Yugari, 1967) and mouse (Hizi and Yagil, 1974) liver enzymes have

been purified, and the amino acid sequence of the human enzyme (Persico et al., 1986; Takizawa et al., 1986), the sequence of G6PDH from fruit fly (Fouts et al., 1988), and a partial sequence of the rat liver enzyme (Jeffery et al., 1988) have been published. A cDNA clone for the rat liver enzyme was reported (Kletzien et al., 1985). This study indicated only pretranslational control (Kletzien et al., 1985). Antibody precipitation of the enzyme gave data that failed to indicate the existence of an inactive to active enzyme conversion with either G6PDH (Peavy and Hansen, 1975) or 6PGDH (Hutchison and Holten, 1978). Levels of these enzymes undergo adaptive changes with age (Wang and Mays, 1977), as do those of a number of other enzymes (Greengard and Jamdar, 1971). The possible role of Iysosomal fragility in regulating enzyme levels has been suggested (Schroeder et al., 1976).

Dimeric and tetrameric forms of G6PDH from human red blood cells were prepared and were found to show a different pattern of binding to NADP (Bonsignore et al., 1970). The existence of the many variants of human G6PDH gave rise to a vigorous effort to identify possible isozymes of rat liver G6PDH (Schmukler, 1970; Holten, 1972; Watanabe et al., 1972; Martins et al., 1985; Angel and Back, 1986). At least six bands were found in electrophoresis of the native enzyme (Holten, 1972). A glutathione-mediated conversion (Watanabe et al., 1972) of the electrophoretic bands, a preferential induction of certain isozymes (Martins et al., 1985), and a possible role of the isoenzymes in the turnover of the enzyme (Grigor, 1984) were suggested. The identity and role of these isoenzymes, however, might be a more difficult problem than was first believed. There was early evidence of enzymes that inactivate G6PDH by removing NADP plus a third enzyme that may also inactivate G6PDH *in vitro* (Bonsignore et al., 1968). A low molecular weight inactivator of G6PDH has been found in some leukemic cells (Kahn et al., 1976). And the isolation of a nascent form of G6PDH suggests processing of the enzyme (Cummings and Barker, 1986). Experiments in our laboratory indicated that G6PDH prepared from starved rats refed a high-fat diet was less stable *in vitro* than rats refed a low-fat diet (Thimaya and Szepesi, 1986). Calculations of molecular weight from electrophoretic mobility showed that most of the isoenzymes had a molecular weight between 58,000 and 62,000 (monomeric), whereas one to three bands had a molecular weight of 122,000 (dimeric) (Thimaya and Szepesi, 1986). In spite of our taking numerous precautions to repeat the experiment in exactly the same way, the number of isoenzymes we found varied from three to seven; at times bands split into closely spaced doublets, and at other times bands may have been missing altogether, although a minimum of three bands could always be found. Molecular exclusion with a Sephadex 100 column indicated that almost all of the freshly prepared enzyme was at least in the dimeric form (Thimaya and Szepesi, 1986). This would suggest that the production of monomeric units is an artifact of the electrophoretic process. This was also suggested by the fact that when the electrophoresis gel was turned 90° and current was applied, the dimeric band split into monomers (Thimaya and Szepesi, 1986). Finally, in starved rats, we found an odd-sized G6PDH band that moved more slowly than the dimer and may have been a precursor G6PDH (Thimaya and Szepesi, 1986).

The control of G6PDH has been studied in great detail. Much of the work involved the use of the starvation-refeeding regimen (Tepperman and Tepperman, 1958). Most of the early work was previously reviewed (Szepesi, 1976). Starvation-refeeding produces a profound change in the activities of NADP-linked dehydrogenases of rat liver. It was noted that G6PDH, 6PGDH, and ME seemed to vary together (Glock and McLean, 1955; Tepperman and Tepperman, 1958; Fitch and Chaikoff, 1960; Weber and MacDonald, 1961; Potter and Ono, 1962) under a wide variety of conditions; therefore, it was proposed that these changes were "coordinate" (Pette et al., 1962). It was shown, however, that G6PDH and ME respond differentially to thyroxine (Tepperman and Tepperman, 1964); ME is induced to a greater extent than G6PDH, especially in rats fed a high fat diet. In hypophysectomized rats, the starvation-refeeding episode failed to produce the expected coordinate induction; this was restored if the animals were injected with somatotropin, thyroxine, and cortisone (Tepperman and Tepperman, 1962). Later work showed that the actual hormone requirement was insulin and glucocorticoid (Williams and Berdanier, 1982), with a possible interaction between the glucocorticoid and thyroxine (Nessmith et al., 1983). Glucagon inhibits the induction (Hahn and

Kirby, 1974; Rudack and Holten, 1975). The role of thyroxine was suggested to be an antagonizing effect of dietary PUFA (Szepesi and Thimaya, 1989). The PUFA effect will be examined shortly. The induction of the enzyme was shown to be due to an increase in the rate of synthesis (rather than activation of an inactive form) in both the liver (Rudack and Holten, 1975; Winberry and Holten, 1977) and free hepatocytes (Morikawa et al., 1984). Free hepatocytes in culture were shown to have a 12-fold higher G6PDH mRNA from refed rats than free cells from fasted rats (Stumpo and Kletzien, 1984). These same studies suggested that glucocorticoid alone can elevate the level of mRNA without increased synthesis of the enzyme; hence the role of insulin is presumed to be in translation (Stumpo and Kletzien, 1984). Glucose and ethanol also increased G6PDH synthesis in free cells (Kelley and Kletzien, 1984) by increasing specific mRNA levels (Stumpo and Kletzien, 1985). In these studies, it was concluded that the role of glucocorticoid is permissive and amplifies the induction produced by insulin.

The picture that emerges from the work cited in the previous paragraph explains the fundamentals of G6PDH induction, but it may be incomplete. The question that can be raised is this: Is there another factor essential for the induction of G6PDH by the starvation-refeeding regimen? Previously published work indicates that there is (Szepesi, 1976). One possibility, the substrate induction hypothesis (Sassoon et al., 1973), proposed that carbohydrate per se was the inducer. This hypothesis was later elaborated as follows: Upon refeeding, a very large increase in liver glycogen occurs during the first day of refeeding. Figure 25.1 shows the time course of events in a typical starve-refeed experiment (figure drawn from previously published data; see Szepesi, 1976). When liver glycogen reaches a high enough level, glycogenolysis is triggered, which in turn elevates the level of hepatic glucose-6-phosphate. This in turn induces G6PDH synthesis and fat synthesis. Both the enzyme activity and total liver lipid overshoot normal levels (enzyme overshoot). As the level of hepatic lipid reaches a triggering concentration, enzyme synthesis and lipid synthesis begin to fall until normal levels of hepatic glycogen (2 days), lipid, and G6PDH are established (the latter two in about a week). To establish such a cause and effect relationship, one has to show two things: (1) that the accumulation of a large amount of liver glycogen will trigger the enzyme overshoot and (2) that the enzyme overshoot can occur only with (and subsequent to) an overshoot of the normal level of liver glycogen (such as occurs on day 1 or refeeding; see Figure 25.1). The first condition is violated

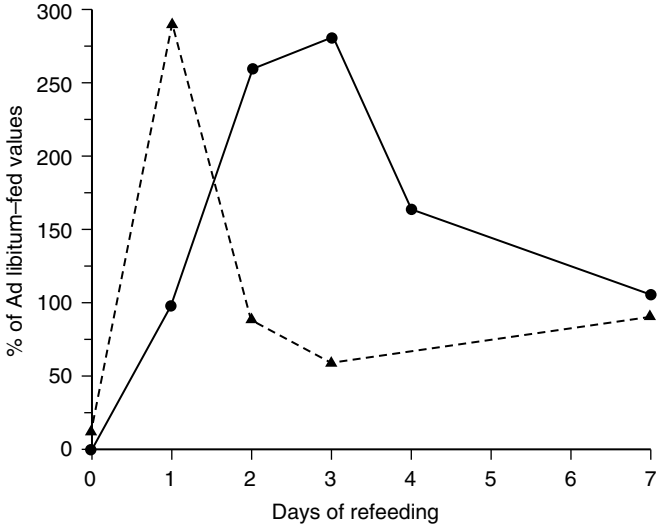

FIGURE 25.1 Time course of changes in liver glycogen and glucose-6-phosphate dehydrogenase. Rats were starved 2 days and refed a 5% corn oil diet (65% glucose + 25% casein) for the number of days indicated. (•) G6PDH; (▲) liver glycogen.

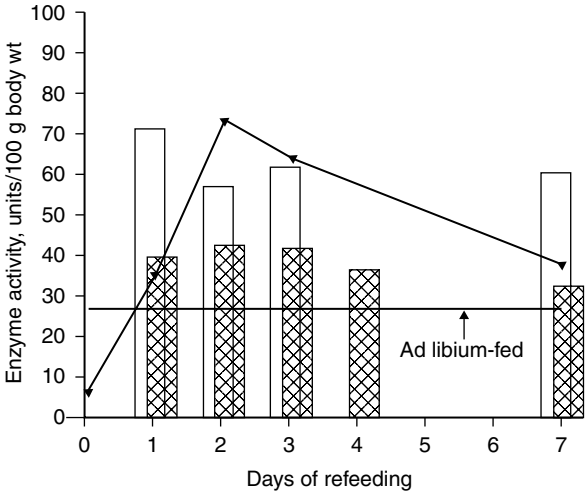

FIGURE 25.2 Requirement for starvation per se as the inducing (potentiating) stimulus for the enzyme "overshoot" of G6PDH upon refeeding an inducer diet. Three experiments are contrasted. Experiment 1 (▼): Rats were starved 2 days and refed the inducer diet (65% glucose, 25% casein, 5% corn oil) for the number of days indicated. Experiment 2 (▼): Rats were starved 2 days, refed a 90% casein, 5% corn oil diet for the number of days, then given the induced diet for 3 days. Experiment 3 (▼): Rats were given the high-protein diet for the number of days indicated (without prior starvation) and then fed the inducer diet for 3 days. The difference between Experiments 2 and 3 shows that starvation is required to potentiate the overshoot. An abnormally high level of liver glycogen was observed on the first day of feeding the inducer diet in all three experiments.

by data shown in Figure 25.2 (Szepesi and Moser, 1971). If starvation is followed by refeeding, a high-protein diet, G6PDH only returns to normal; when such rats are fed an inducer diet, the overshoot occurs even if the high-protein regimen is interposed for up to a week (Szepesi and Moser, 1971). No such overshoot occurs if rats fed ad libitum are fed a high-protein diet and then the inducer diet; yet the glycogen overshoot on day 1 of feeding the inducer diet is the same (Szepesi and Moser, 1971). Therefore, the enzyme overshoot is not a direct consequence of the glycogen accumulation. The second condition is violated by the presence of a G6PDH overshoot in starved-refed rats that are made hyperthyroid by the injection of thyroxine (Liao and Szepesi, 1980). What may happen is that the influx of extra carbohydrate during day 1 is deposited as excess glycogen, which later is converted to lipid when lipogenesis is driven by excess capacity to make NADPH. The isotope data confirm this (Chang and Johnson, 1976). Equally important is the fact that it is starvation that potentiates the overshoot, and that even if the G6PDH level is normalized (by a 90% protein diet), the overshoot occurs after the inducer diet is fed even after the interposition of the high-protein diet for as long as 7 days (Szepesi and Moser, 1971). When starved-refed rats are starved and refed a second time, the level of G6PDH climbs even higher (Szepesi et al., 1973). This extra induction has been referred to as an "induction increment" (Szepesi, 1976). It can be shown even after the G6PDH level returns to normal following the first refeeding. In fact, even if 21 days are interposed between the first and second refeeding, the induction increment is still present (Szepesi, 1976). The nature of this potentiating effect of starvation is not known, but it is not due to the sudden withholding of a single dietary component but to the drop in caloric intake (Szepesi, 1973). The "metabolic memory" of starvation can be erased by feeding a high-fat diet (Szepesi et al., 1973). In this case, if the high-fat diet is fed during the first refeeding, no overshoot occurs. And if the high-fat diet is interposed between two starvations, the rat responds to the second starvation-refeeding as if it were starved-refed for the first time (Szepesi et al., 1973) (i.e., no induction increment). Interestingly, this latter effect of a high-fat diet is inhibited by injections of 8-azaguanine, indicating that the effect of

the fat diet itself (like the enzyme induction) requires de novo RNA synthesis (Szepesi et al., 1973). The effect of dietary fat (i.e., the erasure of the metabolic memory of starvation) occurs during day 2 of refeeding (Szepesi et al., 1974b).

The role of dietary fat in controlling the activity of G6PDH and ME has long been recognized (Hill et al., 1958; Niemeyer et al., 1962; Tepperman and Tepperman, 1963, 1965; Vaughn and Winder, 1964; Leveille, 1967a,b; Novello et al., 1969; Bartley and Abraham, 1972; Century, 1972; Gozukara et al., 1972; Slayton and Szepesi, 1973; Wiley and Leveille, 1973; Szepesi et al., 1974a; Nace and Szepesi, 1975, 1976, 1983; Williams et al., 1977a,b). These studies included work with the liver (Niemeyer et al., 1962; Tepperman and Tepperman, 1963, 1965; Vaughn and Winders, 1964; Novello et al., 1969; Bartley and Abraham, 1972; Century, 1972; Gozukara et al., 1972; Slayton and Szepesi, 1973; Wiley and Leveille, 1973; Szepesi et al., 1974a; Nace and Szepesi, 1975, 1976, 1983; Williams et al., 1977a,b; Berdanier et al., 1989), adipose tissue (Leveille, 1967a,b; Wiley and Leveille, 1973), starvation-refeeding (Niemeyer et al., 1962; Tepperman and Tepperman, 1963; Vaughn and Winders, 1964; Novello et al., 1969; Bartley and Abraham, 1972; Slayton and Szepesi, 1973; Szepesi et al., 1974a; Nace and Szepesi, 1975, 1976), ad libitum feeding (Tepperman and Tepperman, 1965; Leveille, 1967a,b; Century, 1972; Gozukara et al., 1972; Wiley and Leveille, 1973), and meal feeding (Leveille, 1967a,b). In all cases, the levels of liver G6PDH and ME were reduced by the inclusion of dietary fat. Although in a number of cases the fat used was derived from natural sources, it was nonetheless clear (or at least strongly indicated) that the fats responsible for this effect were polyunsaturates (Tepperman and Tepperman, 1965; Bartley and Abraham, 1972; Century, 1972; Gozukara et al., 1972; Wiley and Leveille, 1973; Nace and Szepesi, 1975, 1976; Williams et al., 1977a,b). Our own studies indicated that (1) synthetic triglycerides containing only saturated fats were very poorly absorbed and (2) even when absorbed, they were ineffective in reducing G6PDH and ME levels (Nace and Szepesi, 1975). MCTs (C_8 and C_{10}) acted like LCTs and actually increased adipose tissue enzymes (Wiley and Leveille, 1973). Triglycerides containing single fatty acids (8:0, 10:0, 16:0, 18:0) had no lowering effect on rat liver G6PDH and ME, whereas triglycerides containing the single fatty acids 18:2 and 18:1 did lower both enzymes (Nace and Szepesi, 1977). Linoleic acid was more effective in this than oleic acid (Musch et al., 1974; Nace and Szepaesi, 1977). In starved-refed rats, trilinolein was found to decrease liver G6PDH exponentially and ME linearly (Nace et al., 1979). When these enzymes were increased by feeding a fat-free diet for 7 days, the trilinolein given was not effective in lowering liver enzymes during the first 2 days (Nace et al., 1979). Adipose tissue enzymes were slightly reduced in starved-refed rats (Nace et al., 1979). Linolenic acid and linoleic acid were equally effective in preventing an overshoot (Szepesi et al., 1989). Comparison of menhaden oil to corn oil in Sprague-Dawley and BHE rats indicates that the PUFAs of fish oils may be even more effective in lowering G6PDH and ME levels than linoleic acid, although this effect is strain dependent and is reduced in sucrose-fed rats (Berdanier et al., 1989).

It was already pointed out that starvation itself may be the potentiating stimulus for the enzyme induction that occurs during refeeding (Szepesi, 1973). As the length of starvation increases, so does the subsequent enzyme induction (Szepesi et al., 1971). Maximum enzyme overshoot can be produced if starved rats are refed a fat-free diet (Szepesi and Kamara, 1986). This would indicate that more than one effect of dietary PUFAs may be at work and that some endproduct of PUFA metabolism, or some product that contains PUFA, may be destroyed during starvation and resynthesized during refeeding (Szepesi, 1976). There have been efforts to ascertain the identity of such a possible compound. It was found that eicosa-5,8,11,14-tetraynoic acid inhibited the induction of fatty acid synthetase, G6PDH, and ME (Szepesi, 1976; Clarke and Clarke, 1983). From this it was inferred that conversion of 18:2 to 20:4 was required. However, since both linoleic and linolenic acid do equally well in reducing the starve-refeed response of G6PDH and ME (Szepesi et al., 1989), a single specific metabolic product as the effector is unlikely. In addition, some metabolic inhibitors of arahcidonic acid metabolism failed to prevent the PUFA effect (Szepesi et al., 1989).

There are also indications that dietary PUFAs may have a specific effect on G6PDH to destabilize the enzyme and perhaps even interfere with its processing (Nace, 1979). We had purified

G6PDH and ME and prepared specific rabbit antibodies against each enzyme. (In cooperation with R.H. Hansen, Department of Physiological Sciences, School of Veterinary Medicine, University of California, Davis.) Precipitation of ^{14}C-Leu-labeled enzyme from liver of rats refed high-fat or low-fat diets was carried out, and the resultant precipitates were electrophoresed with sodium dodecylsulfate (SDS); the gels were sliced into 2-mm pieces and counted. Figure 25.3 shows the labeling pattern of G6PDH obtained from several treatments. It is clear from this figure that in groups that are starved and refed a low-fat diet, most of the label is recovered in a narrow band in the gel that represents the approximately 62-kDa monomer of G6PDH, as expected. However, in groups refed the high-fat diet, a great deal of the label is found in areas outside of the monomeric G6PDH. Furthermore, the counts show up not only to the right of the monomeirc peak (which represents fragments smaller than the 62-kDa subunit) but also to the left of this peak. This would imply two things: (1) the high fat somehow destabilizes the enzyme and (2) the high-fat diet somehow interferes with the processing of a pre-G6PDH peptide larger than 62 kDa. Incubations of homogenates prepared from rat liver (obtained from identical treatments) indicated a much faster disappearance of G6PDH activity from rats fed a high-fat diet (Szepesi and Safir, 1983). Since the double-antibody precipitation technique employed when these experiments were done required 2- to 3-day incubation periods (Nace, 1979), it cannot be determined now if the presence of counts obtained outside of the monomeric subunit in the SDS gel were due to degradation *in vivo* or *in vitro*. However, there is little doubt that G6PDH obtained from rats fed the high-fat diet was less stable. This conclusion is bolstered by data shown in Figure 25.4. ME, when treated in a manner identical to the procedure used with G6PDH, did not significantly fragment, nor did it show a significant fraction of counts in fragments larger than the monomeric subunit.

More recent attempts to unravel to control of liver G6PDH have used rat hepatocyte monolayers (Salati et al., 1988) or a primary culture of mouse hepatocytes (Hillyard et al., 1988). The usefulness of such data depends on how much of the *in vivo* influences can be reproduced *in vitro*. What recommends such a procedure is the relative ease with which substrate and hormone levels can be changed independently of each other and the absence of secondary adaptations to such changes that could confound the response. The drawback is that *in vitro* simulation of the transport of lipid molecules to individual cells is chancy at best. In addition, the modifying effects of various tissues on the nature and amount of lipoproteins that may reach a particular cell (such as a liver cell) may be significant. In rat hepatocyte monolayers, inclusion of glucose caused a 500-fold increase in G6PDH activity (Salati et al., 1988). There was an additional twofold increase in the enzyme level when insulin as well as glucose was added to the medium. Dexamethasone or T_3 had no additional effect when added with insulin Linoleate added to the medium had no effect on enzyme induction when glucose, dexamethasone, or insulin was added singly. However, linoleate reduced enzyme induction (by about 30%) when both dexamethasone and insulin and glucose were added. With insulin and glucose both added, arachidonate caused an almost complete inhibition in the increase of G6PDH activity (Salati et al., 1988). The *in vitro* system appears to reproduce a number of features of G6PDH inductions (Szepesi, 1976).

The requirement for carbohydrate, the portion of the induction that cannot be blocked by dietary fat (i.e., the reaching of enzyme levels comparable to rats fed ad libitum a low-fat, high carbohydrate diet), and the partial inhibition of induction by linoleic acid (i.e., the inhibition of the enzyme overshoot) are all features that are qualitatively similar between the *in vitro* work (Salati et al., 1988) and the *in vivo* changes (Szepesi, 1976). The requirement for dietary protein was not demonstrated, and the effect of glucocorticoid and T_3 were not as important in the *in vitro* system as reported for the *in vivo* induction (Williams and Berdanier, 1982).

The report with adult mouse hepatocytes is even more puzzling (Hillyard et al., 1988). In these studies, G6PDH activity declined steadily during the experiment, and this decline was not affected by the addition of 18:1, 18:2, or 20:4. Although the authors reported an inhibition of the Δ9-desaturase activity, their conclusion was that the mechanism for long-term regulation of lipogenic enzymes may not be contained entirely in the liver (Hillyard et al., 1988). Another explanation may be that

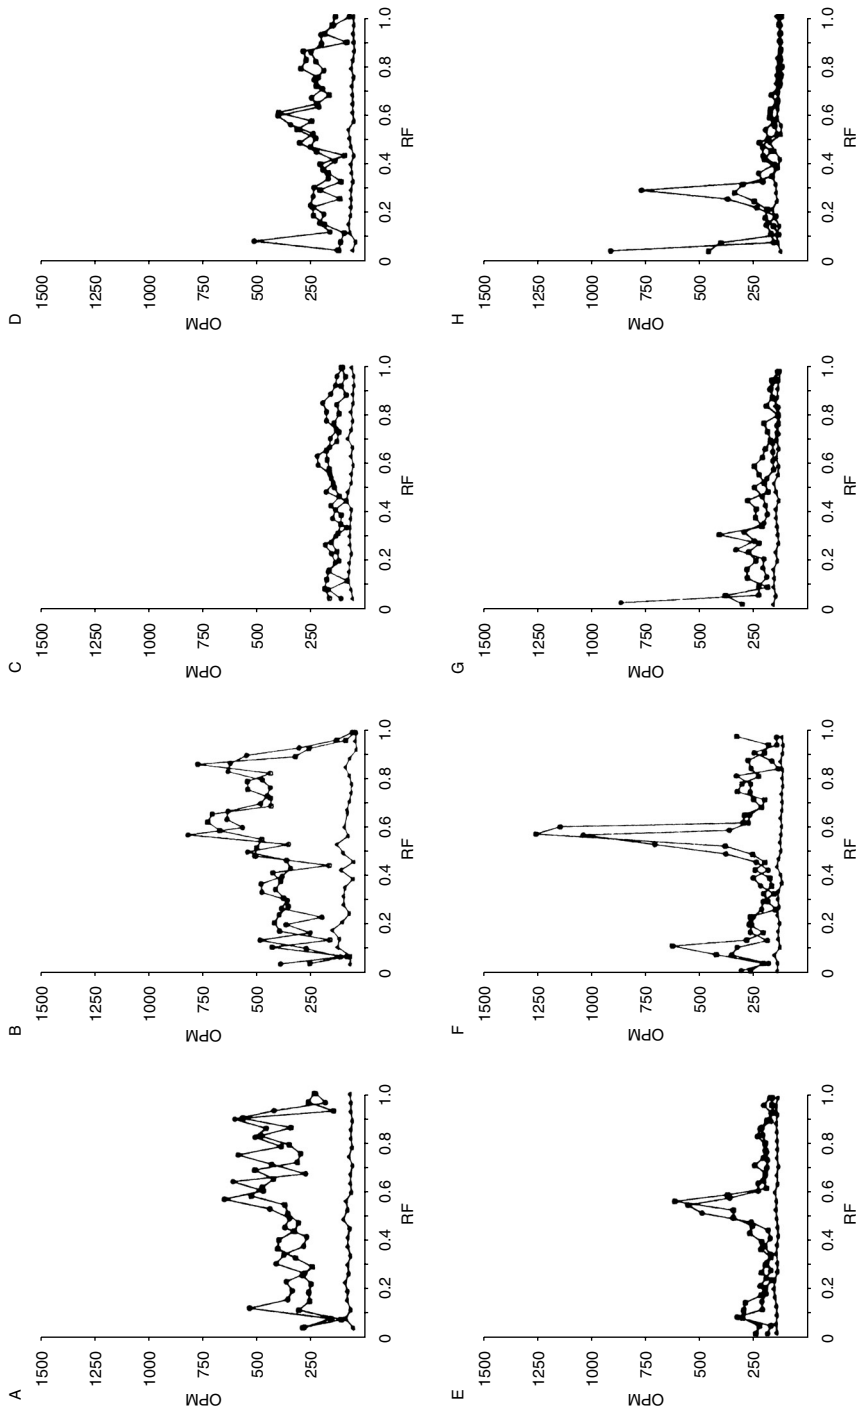

FIGURE 25.3 SDS-gel electrophoresis of rat liver glucose-6-phosphate dehydrogenase. Precipitates of rat liver homogenates with control serum (triangles) or duplicate samples using serum from immunized rabbits (squares and octagons) were treated with SDS and electrophoresed; the gel was cut into 2-mm sections and counted. The capital letters refer to treatments: A–D, starved-refed; E–H, ad libitum fed. Groups A, B, E, and F were fed the high-fat diet; C, D, G, and H, the fat-free diet. Glucagon was injected in groups A, C, E, and G.

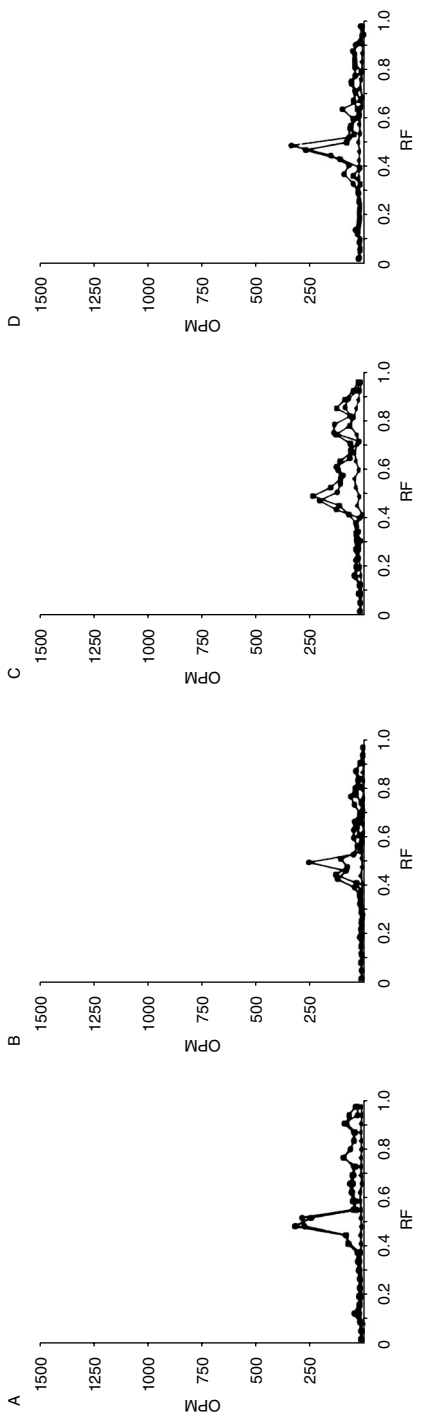

FIGURE 25.4 SDS-gel electrophoresis of rat liver malic enzyme. Precipitates of rat liver homogenates with control serum (triangles) or duplicates samples using serum from immunized rabbits (squares and octagons) were treated with SDS and electrophoresed, and the gel was cut into 2-mm sections and counted. The capital letters refer to treatments: A–D, starved-refed; E–H, ad libitum fed. Groups A, B, E, and F were fed the high-fat diet; C, D, G, and H, the fat-free diet. Glucagon was injected in groups A, C, E, and G. (From Nace, C.S. (1979). Dietary and Hormonal Regulation of Glucose-6-Phosphate Dehydrogenase and Malic Enzyme in Rat Liver and Adipose Tissue, PhD dissertation, University of Maryland, College Park, MD.)

when cultured *in vitro* the mouse liver cells lose their *in vivo* control functions or that elements necessary for the expression of the controls are missing. It is quite clear, however, that the influx of carbohydrate into the liver is a major regulator of hepatic lipogenesis and that this regulation is strongly affected by the amount and type of dietary lipid.

The control of G6PDH may respond to different stimuli in different organs. Adipose tissue G6PDH is not induced by starvation-refeeding, nor is it inhibited by dietary PUFAs (Szepesi, 1976). Uterine G6PDH may even have entirely different controls: Estrogens and NADP may be inducers (Smith and Barker, 1974), and some estrogens act as translational and posttranslational modulators (Donohue and Barker, 1983).

D. Regulation of Malic Enzyme by Dietary Lipid

As with G6PDH, there have been waves and cycles of interest related to ME. Of the *Escherichia coli* mitochondrial enzymes, only the NADP-linked enzyme has a role in lipogenesis (Murai et al., 1971). ME (NADP-linked) has been isolated not only from rat liver (Isohashi et al., 1971; Stark et al., 1975; Yeung and Carrico, 1976) but also from adrenal cortex (Sauer, 1973; Mandella and Sauer, 1975; Pfeiffer and Tchen, 1975), bovine brain (Frenkel and Cobo-Frenkel, 1973), bovine heart (Frenkel, 1971), rabbit heart (Lin and Davis, 1974), pigeon liver (Hsu and Lardy, 1967; Hsu et al., 1976), and other tissues. Other than the production of NADPH, the bacterial enzyme has a physiological role in the production of acetyl CoA (Murai et al., 1971), and it has been suggested that the rat liver enzyme may participate in glutathione-dependent dehydrogenases (via producing NADPH) (Stark et al., 1975). The NAD-dependent enzyme is involved in the oxidation of malate in both the liver and the adrenal (Sauer, 1973). The earliest studies indicated that Ca^{2+}, Mg^{2+}, or Mn^{2+} is required in the adrenal enzyme (Lin and Davis, 1974). Mg^{2+} and Mn^{2+} were also identified as cofactors for pigeon liver (Hsu, 1970; Hsu et al., 1976). Eventually, it came to be recognized that the decarboxylating-reductive function of rat liver ME is dependent on Mn^{2+}. The ability of thyroxine (T_4) and T_3 (Wise and Ball, 1964) to induce ME was recognized relatively early (Tepperman and Tepperman, 1964; Hemon, 1968). The isoenzymes of ME have not been of as much interest as that of G6PDH. However, mouse ME from the heart is mitochondrial, whereas that from the liver is cytosolic, and mutations are more likely to affect the liver enzyme than the heart enzyme (Henderson, 1966). Numerous laboratories (including our own) purified the enzyme and were able to show that (1) rat liver enzyme level changes are accompanied by changes of titratable protein (Isohashi et al., 1971; Frenkel, 1974; Le et al., 1975) and (2) the liver enzyme is immunologically different from the mitochondrial enzyme (Isohashi et al., 1971).

The control of rat liver ME is similar to the control of rat liver G6PDH with some differences (Tepperman and Tepperman, 1964; Frenkel et al., 1972). The ME level is increased by T_4 (Tepperman and Tepperman, 1964; Reed and Tarver, 1976) and by a low-protein diet (Frenkel et al., 1972) and is reduced by a high-fat diet (Tepperman and Tepperman, 1964). Premature weaning increases rat liver ME (Back et al., 1985). This increase is not suppressed by dietary fat (Angel and Back, 1985; Back et al., 1985), but glucagon inhibits the ME increase due to premature weaning. Hydrocortisone or insulin alone or together failed to invoke the adaptive increase in ME before weaning (Back et al., 1985). Diabetes (one dose streptozotocin) greatly reduces the enzyme's response to T_3, although the rats respond better when fed fructose (Kaiser et al., 1980).

Significant efforts have been expended to study the control of ME in several species using antibody precipitation and sometimes free cells. Some of the earliest of these studies were preformed using *in vivo* labeling of ME in chick liver (Silpananta and Goodridge, 1971). This study showed that the level of this enzyme was decreased by starvation and increased by refeeding and that all the changes in enzyme activity were paralleled by equal changes in antibody-precipitable protein (Silpananta and Goodridge, 1971). During starvation in a chick less than 1-week-old enzyme synthesis decreased along with the rate of ME degradation; both tendencies were reversed during refeeding (Silpananta and Goodridge, 1971). The controls of ME synthesis and degradation, therefore, impose

some limits on the magnitude of the changes. The enzyme's half-life varied with the age of the chicks: in 8- and 11-day-old chicks, $t_{1/2}$ was 55 h in the fed and 28 h in the fasted animals (Silpanata and Goodridge, 1971). Increased fatty acid synthesis upon refeeding precedes changes in ME activity by 1.5–3.0 hr (Silpanata and Goodridge, 1971). Messenger RNA is reduced by starvation and increases following refeeding in ducklings (Goldman et al., 1985). The half-life of ME-specific mRNA was 3–5 h in the fed and 1 h in the starved animals (Goldman et al., 1985). Measurement of the nuclear accumulation of mRNA showed that starvation actually reduced ME–specific mRNA transcription in a specific manner without affecting the transcription of the albumin gene (Goldman et al., 1985).

Whereas starvation-refeeding seems to increase transcription of the ME gene, one of the effects of dietary fat may operate by a different mechanism. Replacement of polyunsaturated fat with saturated fat in the diet of mice was shown to increase the amount of immunologically titratable ME without increasing the mRNA (Schwartz and Abraham, 1983). This effect of PUFA, therefore, seems to be a translational effect. The effect of a high-carbohydrate diet fed ad libitum is to elevate the level of translatable ME–specific mRNA without increased transcription by reducing mRNA degradation (Dozin et al., 1986).

IV. CONCLUSION

The interactions of dietary lipids and carbohydrates can be divided into two types: (1) those interactions that are observable on lipogenesis, the control of lipogenesis and lipogenic enzymes; and (2) the effects on blood lipids. Within this context, there is interaction with age, sex, and genetic predisposition. Animal experiments *in vivo* and *in vitro* have produced a relatively uniform conclusion, but the results of human studies are controversial. Considering the number of interactions possible, it is expected that some effects may tend to be masked by interactions and vice versa. In this light, the conclusion of the FDA report that, because dietary sucrose consumption is not an independent risk factor (Sugar Task Force, 1986). It need not be regarded as an important risk factor, is simply not valid. There is no statistical justification for the idea that only independent risk factors should be recognized.

It is true in a number of areas of nutrition that genetic predisposition is an important factor in determining the risk of various diseases that have a nutritional vector. It is therefore incumbent on those who conduct human studies to identify subpopulations in high-risk groups. The lumping together of a group of healthy human beings (such as healthy college students) for the purpose of studying the effects of dietary carbohydrates does not and cannot yield results that are useful for determining metabolic risk in other groups such as those with impaired glucose tolerance. In addition, claims that groups with already proven arterial damage (such as diabetic individuals) no longer suffer demonstrable problems from the consumption of simple sugars are disingenuous, because they ignore the basic nature of carbohydrate effects, which are long term and interactive. The purpose of this chapter is not to reignite the controversy or revisit the battleground, but to emphasize the interactive nature of the effects of dietary lipids and carbohydrate and lipid metabolism.

The nature of these interactions is becoming clear. Dietary fat in general tends to limit the production of lipid from carbohydrate, probably by affecting acetyl CoA carboxylase. Polyunsaturated fat, on the other hand, affects the synthesis of the enzymes necessary for lipogenesis, notably G6PDH and ME. I suggested years ago that the PUFA effect is partly transcriptional and partly translational (Szepesi, 1976); this has been clearly demonstrated by others. The requirement for dietary carbohydrate and protein in the starvation-refeeding experiment to induce G6PDH remains to be explained. The precise role of glucose and insulin likewise remains to be explored. As the *in vitro* methods are refined and validated, this will undoubtedly be accomplished. Although the role of PUFAs in helping to prevent arterial disease has been generally accepted (Dyerberg, 1986), the opposite role of the consumption of simple sugars remains in doubt. A new effort is necessary, therefore, to reexamine this problem. Hopefully, with recent advances in methodology, we shall get some more definitive answers.

26 Reappraisal of the Essential Fatty Acids

Robert S. Chapkin

CONTENTS

I. INTRODUCTION

The essentiality of fat in the diet has been known since 1929 (Burr and Burr, 1929, 1930), when it was first recognized that linoleic acid (Δ9,12-octadecadienoic acid, 18:2n-6), and possibly other acids, is an essential fatty acid (EFA). Since this initial observation, there have been numerous published studies documenting the fact that certain polyunsaturated fatty acids (PUFAs) cannot be synthesized de novo from endogenous precursors and are, therefore, essential dietary elements (Alfin-Slater and Aftergood, 1968; Holman, 1971; Rivers and Frankel, 1981). Indeed, it is now recognized that there are two EFAs, 18:2n-6 and α-linolenic acid (Δ9,12,15-octadecatrienoic acid, 18:3n-3). Although the volume of literature associated with the biological significance of PUFAs in laboratory animals is immense, relatively few studies have focused on the essentiality of 18:2n-6 and 18:3n-3 with respect to humans. In fact, the critical issues related to EFA physiological functions and requirements in humans are still being investigated. The results of some of these recent investigations are discussed in this review.

II. ESSENTIAL FATTY ACIDS

A. Linoleic Acid Requirement

The physiological effects of 18:2n-6 deficiency has been very well characterized, particularly in rodent species (Burr and Burr, 1929, 1930; Alfin-Slater and Aftergood, 1968; Holman, 1971; Rivers and Frankel, 1981). The various deficiency symptoms include depressed growth, scaly dermatoses, increased permeability of skin, fatty liver, kidney damage, and impaired reproduction (Burr and Burr, 1929, 1930; Alfin-Slater and Aftergood, 1968; Holman, 1971; Rivers and Frankel, 1981) (refer to Table 26.1). The classical biochemical method of establishing EFA deficiency is to calculate the ratio of the "Mead acid," Δ5,8,11-eicosatrienoic acid (20:3n-9), to arachidonic acid (Δ5,8,11,14-eicosatetraenoic acid, 20:4n-6) (Holman, 1960). Although the validity of this index has

TABLE 26.1
Symptoms of Linoleic Acid Deficiency in Mammals

Diminished growth	Alopecia
Scaly dermatoses	Fatty liver
Inflamed epidermis	Kidney degeneration
Diminished skin pigmentation	Impaired reproduction and sterility
Increased transepidermal water loss	Increased basal metabolic rate
Increased water consumption	Impaired protein utilization
Impaired wound healing	Electrocardiographic aberrations
Increased susceptibility to infection	Increased fragility and permeability of cellular membranes
Caudal necrosis	
Loss of muscle tone

been questioned (Horrobin and Cunnane, 1981; Yamanaka et al., 1981), ratios above 0.2 and 0.4 are considered the upper limit of normalcy in the rat (Alfin-Slater and Aftergood, 1968) and human (Holman et al., 1979), respectively.

Ingestion of approximately 1%–2% of daily calories as 18:2n-6 is widely accepted as the amount needed to meet the EFA requirement of rodent species and humans (Holman, 1977). However, it is important to note that the 1%–2% figure is only an approximation of 18:2n-6 dietary requirement for humans. Although many attempts have been made to determine the human 18:2n-6 requirement, most studies have met with a plethora of problems regarding the considerable recycling of PUFAs (Sprecher et al., 1995; Sheaff et al., 1996) and the physiological criteria to use for normality. For example, reports that dietary oleic acid (18:1n-9) spares 18:2n-6 oxidation, and that 16:2n-6 can be elongated to 18:2n-6, indicates that the 18:2n-6 requirement may have been overestimated by feeding diets deficient in all unsaturated fatty acids (Cunnane, 1996). In addition, the quantity and type of dietary PUFA (Pawlosky et al., 2003) as well as body composition, that is, adiposity (Villalpando et al., 2001), can alter EFA metabolism in humans.

Human infants and children are generally thought to require 1%–2% of total dietary energy as 18:2n-6 to prevent EFA deficiency (Rivers and Frankel, 1981). However, it has been argued that the minimum requirement has been set "far too high" for infants, and should be changed to less than 0.5% of calories (Cuthbertson, 1976; Naismith et al., 1978). This value is consistent with the findings of Hansen et al. (1963) who demonstrated that growing infants developed deficiency symptoms only when receiving less than 0.1% of their calories as 18:2n-6. The scientific response to these data remains mixed primarily because it is believed that children require more 18:2n-6 as a percentage of total daily calories than adults because growth increases the demand for cell membrane constituents (Holman et al., 1979). In a study on premature infants (Farrell et al., 1988), the average amount of 18:2n-6 required to achieve normal fatty acid nutrition was 1.19 g/kg/day or approximately 10% of total caloric intake. The prodigious requirement for 18:2n-6 was attributed to the premature infants' small amount of adipose tissue and the great need for energy production from fat (Farrell et al., 1988). There is growing evidence that additional long-chain n-6 PUFAs may be conditionally essential for preterm and possibly full-term infants. This is based on the limited efficiency of conversion of 18:2n-6 to 20:4n-6 and 18:3n-3 to 22:6n-3 (Carlson et al., 1993; Demmelmair et al., 1995). Carlson and coworkers (Carlson et al., 1993; Carlson, 2001) have hypothesized that dietary 20:4n-6 could improve first year growth of preterm infants. It is uncertain, however, whether growth is a biomarker that accurately reflects "optimal nutrition" (Lapillonne and Carlson, 2001). It is also

unclear whether 20:4n-6 has a significant effect on infant development (Fleith and Clandinin, 2005; Wright et al., 2006).

With respect to factors affecting EFA requirement, a higher requirement for 18:2n-6 during pregnancy (4.5% of calories) has been suggested (Mendy et al., 1986). In addition, an FAO/WHO expert committee has advised increased intakes of 18:2n-6 (5%–7% of calories) during lactation (Mendy et al., 1986). Other examples of physiological conditions that may alter the 18:2n-6 requirement are protein malnutrition (Hill and Holman, 1980; Holman et al., 1981), genetic disorders that affect the relative activity of unsaturated fatty acid metabolic pathways (Holman, 1977; Dyck et al., 1981; Hernell et al., 1982), intestinal malabsorption (Gourley et al., 1982), cystic fibrosis (van Egmond et al., 1996), anorexia nervosa (Holman et al., 1995), and n-3 fatty acid intake (Bourre et al., 1989a; Lands, 1989). Not surprisingly, EFA abnormalities may be the single most important nutritional deficiency in patients with gastrointestinal disorders (Siguel and Lerman, 1996; Jeppesen et al., 1997). Since the metabolic pathways for the biosynthesis of long-chain PUFAs consist of a series of desaturation and elongation enzymatic steps (Brenner, 1981), dietary 18:3n-6 and 20:4n-6 may have superior biopotency with respect to 18:2n-6 (Rivers and Frankel, 1981).

Attempts to determine the 18:2n-6 requirement of isolated mammalian cells in culture have created an interesting paradox. Although the phenotype of some cell lines is altered under EFA-deficient conditions (Garner et al., 1995; Lerner et al., 1995; Stoll and Spector, 1995), many studies (Bailey, 1980; Spector et al., 1981; Rosenthal, 1987; Grammatikos et al., 1994) indicate that most "normal" human cells do not require 18:2n-6 or any PUFAs for growth or metabolism. The reason for this is unknown.

Current adequate intakes for infants, children, and adults range from 4.4 to 17 g/day of n-6 PUFA (Institute of Medicine, 2005). This corresponds to approximately 2 energy percent as 18:2n-6. Modest adjustments are made for pregnancy and lactation. It is generally agreed that there may be a tolerable upper intake level of 18:2n-6, however, insufficient data exist at present to set a precise value for the upper limit.

B. Linolenic Acid Requirement

The essentiality of 18:3n-3 in higher animals and humans has been debated for many years. Although, similar to 18:2n-6, it cannot be synthesized *in vivo* (Brenner, 1981), initial attempts to elicit 18:3n-3 deficiency in mammals produced equivocal results (Tinoco et al., 1979; Tinoco, 1982). During the early 1970s (Fiennes et al., 1973; Lamptey and Walker, 1976) and again in the 1980s, cogent evidence in support of the role of 18:3n-3 in the brain and retina was presented (Holman et al., 1982; Rivers, 1984; Yamamoto et al., 1987, 1988; Bourre et al., 1989b; Neuringer et al., 1994). Estimates for the 18:3n-3 requirement of humans have been listed at 0.4% (Bjerve et al., 1989), 0.54% (Holman et al., 1982), and 0.2%–0.3% of calories (Bjerve et al., 1987a,b). In addition, numerous recommendations that the diet provide an adequate amount of n-3 fatty acids and a PUFA n-6/n-3 ratio of 4:1–10:1 (Neuringer et al., 1994), 6:1 (Bourre et al., 1989a), 4:1 (Simopoulos, 1989a), and 2:1 (Okuyama et al., 1997), particularly during infancy, pregnancy, and lactation, have been made. The current estimate of the PUFA n-6/n-3 ratio in the Western diet is 10–11:1 (Simopoulos, 1996) and 4–5:1 in the Japanese diet (Okuyama et al., 1997) (refer to Table 26.2).

The very limited ability of 18:3n-3 to substitute for 18:2n-6 (or its metabolic derivatives) and to reverse classical EFA deficiency signs, that is, growth, reproduction, or dermal symptoms (Mohrhauer and Holman, 1963; Houtsmuller, 1975; Tinoco, 1982; Bivins et al., 1983; Crawford, 1992), is a major reason why the essentiality of 18:3n-3 has remained controversial (Rivers, 1984; Koletzko, 1987) and why the requirement remains ill defined. However, substantial evidence now indicates that 18:3n-3 and its metabolic fatty acid derivatives (Δ5,8,11,14,17-eicosapentaenoic acid, 20:5n-3 and Δ4,7,10,13,16,19-docosahexaenoic acid, 22:6n-3) have their own specialized and distinct functions in the retina and central nervous system (Wheeler et al., 1975; Bivins et al., 1983; Hoffman et al., 1993; Neuringer et al., 1994; Ikemoto et al., 2001; Lauritzen et al., 2001). Indeed, precisely

TABLE 26.2
Recommendations for Dietary PUFA Intake

(For *normal healthy adults* free of genetic disorders, medical disorders, etc.)
Polyunsaturated fatty acids
18:2n-6 = 12–17 g/day (4%–5% of calories, perhaps as low as 2%)
18:3n-3 = 1.1–1.6 g/day (0.7% of calories)
20:5n-3 (EPA) plus 22:6n-3 (DHA) = 0.5–0.85 g/day (0.27% of calories)
Total PUFA = 18 g/day (6%–7% of calories)
(n-6/n-3 ratio) = (4/1 or perhaps as low as 2 or below), *note:* there is no scientific evidence to support a recommendation of 5–10
(n-3 as 18:3/n-3 as EPA plus DHA ratio) = (4/1)
*Estimated Current Japanese vs. U.S. Fatty Acid Intake (as energy percentage)

	Japan	United States
n-6 PUFA	6.4	7.1
n-3 PUFA	1.6	0.8
n-6/n-3	3.9	8.3

because long-chain fatty acids are required for the development and function of the brain and retina (Ikemoto et al., 2001; Lauritzen et al., 2001), there is a consensus that bottle-fed healthy term infants should be supplemented with long-chain n-3 PUFA (Bouwstra et al., 2003; Birch et al., 2005). This may in part be related to the neuroprotective properties of 18:3n-3 and its metabolic product, 22:6n-3 (Lauritzen et al., 2000; Akbar et al., 2005). In addition, because preterm infants do not receive the third trimester intrauterine supply of 22:6n-3 and full-term infants are at risk of 22:6n-3 deficiency since some formulas are devoid of this fatty acid, 22:6n-3 is considered provisionally essential for infant nutrition (Hoffman et al., 1993; Agostoni et al., 1995; Uauy et al., 1996). Therefore, infant foods should contain a level of n-3 fatty acids (ratio of 10:1 n-6:n-3 fatty acids, 20:4n-6 at ~0.5% and 22:6n-3 at 0.1%–1.5% of energy) similar to human milk (Anonymous, 1995). Historically, U.S. infant formulas contained >4% of energy as 18:2n-6 and 0.75% of energy as 18:3n-3 (up to a (16:1) n-6:n-3 ratio), and none contained 20:4n-6 or 22:6n-3 (Innis et al., 1996; Ratnayake et al., 1997). In February 2002, infant formulas with added 20:4n-6 and 22:6n-3 for infants born to term became commercially available in the United States and Canada. Additional concerns related to the nutritional adequacy of infant formulas have focused on the presence of *trans* geometrical fatty acid isomers in powdered and liquid infant formulas (Ratnayake et al., 1997). Therefore, infants should be fed breast milk if at all possible (Anonymous, 1995). Further studies are required to determine whether *trans* acids adversely affect fetal and infant n-6 and n-3 fatty acid metabolism, neurodevelopment, and growth (Carlson et al., 1997). The potential for an excessive or imbalanced intake of long-chain PUFA exists with the increasing fortification of n-6 and n-3 fatty acids into infant foods other than formulas (Koo, 2003).

Dietary estimates to prevent n-3 PUFA depletion of liver and brain phospholipids are 800–1100 mg/day of 18:3n-3 and 300–400 mg/day of 20:5n-3 and 22:6n-3 combined (Simopoulos, 1989b). It has been estimated that 1–2 g/day of 18:3n-3 is consumed by the U.S. population, which provides approximately 75%–85% of the 400–500 mg/day of long-chain n-3 fatty acids that are required by

adults (Emken et al., 1994; Kris-Etherton et al., 2000). Current adequate intakes for infants, children, and adults range from 0.5 to 1.6 g/day of n-3 PUFA (Institute of Medicine, 2005). This corresponds to approximately 0.7 energy percent as 18:3n-3. Modest adjustments are made for pregnancy and lactation. It is recommended that up to 10% of the total n-6 and n-3 PUFA requirements can come from long-chain PUFA. It is highly likely that a minimum intake level of 20:5n-3 and 22:6n-3 (500 mg/day) will be adopted in the near future (ISSFAL, 2004).

III. METABOLIC FATES OF LINOLEIC AND LINOLENIC ACIDS

Once ingested, 18:2n-6 and 18:3n-3 can be desaturated and elongated, primarily in the liver, in most mammals including humans (DeGomez Dumm and Brenner, 1975; Brenner, 1981; Biagi et al., 1990) in a manner such that the methylene-interrupted pattern of unsaturated double bonds is maintained (Brenner, 1981). The microsomal enzymatic reactions do not permit crossover between fatty acid metabolites from the 18:2n-6 and 18:3n-3 sequences (Brenner, 1981; Sprecher, 1981, 2000). It is also likely that considerable recycling of fatty acids occurs between peroxisomes and microsomes (Sprecher et al., 1995). This implies that individuals with peroxisomal disorders could suffer from defects in long-chain PUFA metabolism (Martinez, 1990). The desaturation and elongation steps are influenced by numerous nutritional and hormonal factors, possibly involving obesity and lifestyle variables (Brenner, 1981; Brenner et al., 1981; Naughton, 1981; Cho et al., 1999a,b; Warensjo et al., 2006). A competitive interaction between 18:2n-6 and 18:3n-3 exists, such that n-3 PUFA suppress the metabolism of n-6 PUFA and n-6 PUFA suppress the metabolism of n-3 PUFA less strongly (Rahm and Holman, 1964; Brenner and Peluffo, 1969). It is generally believed that the capacity to convert 18:2n-6 and 18:3n-3 into 20- and 22-carbon fatty acids in humans is very limited (Nichaman et al., 1967; Stone et al., 1979; Dyerberg, 1986; Mark and Saunders, 1994; Burdge et al., 2002a,b). Interestingly, in an investigation using deuterated 18:2n-6 (Emken et al., 1987), desaturation/elongation products were not detected in plasma lipids. The authors concluded that 18:2-$^{2}H_4$ to 20:4-$^{2}H_4$ conversion is extremely low in normal subjects. In a separate series of studies using mixtures of triglycerides containing deuterium-labeled fatty acids, Emken et al. (1988, 1990) demonstrated the conversion of 18:3n-3 to 20:5n-3 and 22:6n-3, but were again unable to detect conversion of 18:2n-6 to 20:4n-6. The exclusive conversion of 18:3n-3, but not 18:2n-6, in these studies is most intriguing. It is possible that the 18:2n-6 conversion products were sequestered in tissues following ingestion and, therefore, could not be released into the plasma lipid pool, which was subsequently analyzed. In comparative studies, Siguel and Maclure (1987), using derivative precursor ratios, and El Boustani et al. (1989), using 20:3n-$^{2}H_4$, have demonstrated that desaturase activity operates in humans and that the desaturation/elongation enzymes have a preference for n-3 vs. n-6 fatty acids. The conversion (Siguel and Maclure, 1987) of 18:3n-3 suggests that vegetarians can accumulate 20:5n-3 and 22:6n-3 and need not alter their diets to include fish products (which are rich in 20:5n-3 and 22:6n-3). Recently, a number of human studies (Pawlosky et al., 2001; Burdge et al., 2002a,b; Hussein et al., 2005) have demonstrated that 22:6n-3 synthesis from 18:3n-3 is generally low. However, these tracer kinetic studies are complicated, and overall, the regulation of 22:6n-3 studies remains an enigma. Currently, there is consensus that 22:6n-3 can be formed from 18:3n-3 *in vivo*, albeit at a low rate, but cannot be readily increased by dietary 18:3n-3. In addition, dietary 20:5n-3 is well utilized in the biosynthesis of 22:6n-3. With respect to the influence of dietary 20:4n-6 on metabolism of 20:3n-6, although the conversion of 20:3n-6 to 20:4n-6 (Δ5 desaturase activity) is low in humans, it can be enhanced by feeding 20:4n-6 (Emken et al., 1997).

The recent cloning and expression of Δ6,Δ5 desaturases (Cho et al., 1999a,b) and the long-chain PUFA elongases (Leonard et al., 2002, 2004) provide direct evidence of the position-specific enzymes responsible for the interconversion of 18:2n-6 and 18:3n-3 to 20-carbon fatty acids. Structure–function studies of mammalian desaturases indicate that combinations of multiple transcription

factors, for example, sterol regulatory binding protein-1c (SREBP-1c), peroxisome proliferator-activated receptor-α (PPAR-α), carbohydrate response element binding protein (ChREBP), and liver X receptor response element (LXR), regulate 20:4n-6, 20:5n-3, and 22:6n-3 levels in tissues (Tang et al., 2003; Nakamura and Nara, 2004; Li et al., 2005).

Many epidemiological and clinical studies have demonstrated that long-chain n-3 PUFAs are bioactive food components, and attenuate diseases with an immune-mediated inflammatory component such as heart disease, arthritis, and certain forms of cancer. Since new studies are raising serious concerns about the long-term safety of many popular pain-relief anti-inflammatory drugs, it is important to recognize that there are dietary alternatives to these pharmaceutical agents. At present, sources of n-3 fatty acids include vegetable and nut oils, which can contain up to 50% 18:3n-3, and marine oils and single cell oils derived from the fermentation of microalgae, which contain 20:5n-3 and/or 22:6n-3 in varying amounts. However, there are limitations to each of these sources. Yields from global fisheries have been reported to be stagnant and there is concern regarding the levels of methyl mercury in a number of species (Ursin, 2003). Aquaculture requires fish meal and fish oil, and microalgae is currently not being produced in sufficient quantities for wide scale impact. As already noted, with respect to vegetable oils, the bioconversion of 18:3n-3 to long-chain n-3 PUFA, which is necessary for the therapeutic and preventive benefits, is extremely inefficient. In contrast, it has been recently shown that stearidonic acid (Δ6,9,12,15-octadecatrienoic acid, 18:4n-3), a metabolic intermediate between 18:3n-3 and 20:5n-3, is efficiently converted in humans to 20:5n-3 (James et al., 2003). Therefore, the use of 18:4n-3-containing land-based plant oils could become a valuable tool for increasing tissue concentrations. Along these lines, in an attempt to generate n-3 PUFA-enriched foods, Kang and coworkers (Kang, 2005; Lai et al., 2006) have successfully cloned n-3 fatty acid desaturase into pigs in an attempt to produce high tissue levels of n-3 fatty acids from n-6 analogs. This genetic approach may very well prove to be an effective and sustainable way to produce n-3 PUFA-enriched bioactive foods.

IV. PHYSIOLOGICAL FUNCTIONS

The broad array of deficiency symptoms suggests that EFAs play a prominent physiological role in different organs. For example, 18:2n-6 and 18:3n-3 and their desaturation/elongation products (20:4n-6, 20:5n-3, and 22:6n-3) were historically recognized in the homoviscous control of the membrane lipid bilayers of most cells (Burr and Burr, 1930; Bernsohn and Spitz, 1974; Mead, 1984). The identification of 18:2n-6 as a constituent of epidermal sphingolipids is an example of the regulation of membrane barrier function by an EFA (Hansen et al., 1986).

The molecular mechanisms of cellular uptake and intracellular translocation of EFAs have been extensively studied. In general, this is a multistep process that involves various membrane-associated proteins utilizing both passive and carrier-mediated transmembrane translocation (Glatz and vand der Vusse, 1996; Hamilton et al., 2002; Daleke, 2003). Upon incorporation into structural lipids, long-chain PUFAs can modify membrane fluidity, membrane thickness, and alter specific interactions with membrane proteins (Carrillo-Tripp and Feller, 2005). Of relevance to membrane biology, it has been demonstrated that dietary PUFAs are capable of altering reversible fatty acylation of membrane-anchored proteins in platelets (Laposata and Muszbek, 1996). Complimentary studies have shown that both n-3 and n-6 PUFAs are capable of inhibiting fatty acylation, plasma membrane localization, and intracellular signaling in T-cells (Webb et al., 2000; Liang et al., 2001). These data suggest that dietary PUFAs may alter the hydrophobic contribution of lipid groups responsible for membrane localization of lipidated proteins. This represents a putative mechanism by which dietary PUFAs can alter intracellular signal transduction pathways.

Our view of biological membranes has evolved dramatically over the past 5 years (Helms and Zurzolo, 2004; Ma et al., 2004a,b). Within the cell membranes, there are specific detergent-resistant domains in which key signal transduction proteins are localized. These regions are classified as "lipid rafts" (Xavier et al., 1998; Viola et al., 1999). Rafts are composed mostly of cholesterol and

sphingolipids and therefore do not integrate well into the fluid phospholipid bilayers causing them to form microdomains that influence protein–protein interactions (Hancock, 2006). The emerging role of n-3 PUFAs in maintaining the fluid microenvironment of membranes was originally supported by studies showing an altered electroretinogram, decreased visual activity, and impaired learning ability in animals deprived of 18:3n-3 (Menon and Dhopeshwarkar, 1982; Neuringer et al., 1994). Deprivation of 18:3n-3 and its major fatty acid metabolite, 22:6n-3, eventually results in decreased brain and retina 22:6n-3 membrane content (Hoffman et al., 1993; Uauy et al., 1996). It is generally believed that 22:6n-3 is synthesized from 18:3n-3 by the liver (Emken et al., 1988, 1990), secreted into the bloodstream in lipoprotein form and taken up by the brain and retina, possibly by a 22:6n-3 receptor (Scott and Bazan, 1989).

22:6n-3 is the most unsaturated membrane fatty acid commonly found in biological systems and can be obtained by dietary consumption of cold-water fatty fish. Long-chain n-3 PUFAs present in dietary fish oil, such as 20:5n-3 and 22:6n-3, affect diverse physiological processes including cognitive functions, visual acuity, eicosanoid signaling, and whole body glucose and lipid metabolism (Jump, 2002), thereby providing significant protection against a variety of apparently unrelated human diseases (Kris-Etherton et al., 2002; Hu et al., 2003; Stulnig, 2003; Terry et al., 2003; Lupton and Chapkin, 2004). 22:6n-3 is rapidly incorporated into cells, primarily into membrane phospholipids at the *sn*-2 position (Anderson and Sperling, 1971), and in general, the cellular level is readily influenced by diet (Katan et al., 1997; Vidgren et al., 1997). The presence of 22:6n-3 in membrane phospholipids imparts unique physicochemical properties to cellular membranes and 22:6n-3-induced alterations in membrane structure and function have been proposed to underlie its pleiotropic salutary effects (Ma et al., 2004a,b; Seo et al., 2006; Stillwell et al., 2006).

The EFAs are also the precursors for prostaglandins, hydroxy fatty acids, sulfidopeptide-leukotrienes, and lipoxins, collectively referred to as eicosanoids (Lands, 1979; Samuelsson et al., 1991). These oxygenated metabolites are formed rapidly on stimulus and, acting as autacoids, exert a profound influence on many cellular reactions. A flurry of interest focusing on the dietary modulation of eicosanoid formation in humans has surfaced (von Schacky et al., 1985; Knapp et al., 1986; Kinsella et al., 1990; Zhou and Nilsson, 2001). For example, diets rich in select n-3 and n-6 PUFAs are capable of influencing *in vivo* levels of 13-hydroxyoctadecadienoic acid (13-HODE) (Miller et al., 1990). This is significant because 13-HODE, a 15-lipoxygenase-1 metabolite of 18:2n-6, is capable of inhibiting diacylglycerol-activated protein kinase C (PKC) activity, which may have relevance in modulating epidermal hyperproliferation (Cho and Ziboh, 1994). Curiously, 13-HODE may play a promoting role in the development of prostate (Kelavkar et al., 2004) and a protective role in colorectal cancer (Zuo et al., 2006). In addition, increased 20:5n-3/20:4n-6 ratios can inhibit cyclooxygenase I and thus thromboxane formation. Cyclooxygenase II-mediated signaling is also modulated via the reduction of PGE_2 and the increase in PGE_3 (Smith, 2005). This is significant because recent evidence indicates that PGE_2 induces angiogenesis at the earliest stage of tumor development (Wang and DuBois, 2004), while PGE_3 is antiproliferative/chemoprotective (Bagga et al., 2003; Yang et al., 2004). Results from several laboratories indicate that a number of cell types are capable of generating novel oxygenase products from n-3 PUFA (Lukiw et al., 2005; Serhan, 2005). These findings have implications for neurogenerative diseases (Calon et al., 2004) and for the resolution of inflammatory processes (Serhan and Savill, 2005).

Dietary PUFA manipulations are highly significant because many diseases are associated with an overproduction of eicosanoids from 20:4n-6 (derived from 18:2n-6), and the formation of n-6 eicosanoids can be antagonized by dietary n-3 PUFA (Lands, 1989; Kinsella et al., 1990; Kremer et al., 1995). In humans who ingest 0.2–0.5 g of 20:4n-6 and 10–20 g of 18:2n-6 per day on the typical Western diet, the formation of 20:4n-6 from 18:2n-6 exceeds the dietary supply of 20:4n-6 (Zhou and Nilsson, 2001). As a point of reference, 20:4n-6 intakes are in the range of 100–200 mg/day (Innis and Elias, 2003). In contrast, obligate carnivores do not produce 20:4n-6 by desaturation–elongation and depend on the supply of 20:4n-6 in the diet. Recent studies on interactions between n-3 and n-6 PUFAs indicate that cycles of deacylation/reacylation of 20:4n-6 and 22:6n-3 operate

independently from each other (Contreras and Rapoport, 2002; Marszalek et al., 2005; Murphy et al., 2005). Interestingly, the 20:4n-6 pool(s) for prostaglandins in humans is not quickly influenced by dietary 18:2n-6 and 20:4n-6 because of a large pool(s) size of 20:4n-6 and a low conversion of 18:2n-6 to 20:4n-6, whereas the n-3 PUFA pool(s), which is considerably smaller, is immediately influenced by n-3 PUFA supplementation (Hamazaki et al., 1989). The relationship between dietary 18:3n-3 and its respective long-chain metabolites was also examined in humans by Mantzioris et al. (1995), who demonstrated that increasing dietary 18:3n-3 levels will elevate tissue 20:5n-3 levels in a predictable manner whereas no relationship was observed between dietary 18:2n-6 and its metabolite, 20:4n-6. There is, however, growing evidence to indicate that although the average intake of 20:4n-6 in the diet (~100 mg/day) is approximately 100 times lower than 18:2n-6 (Mantzioris et al., 1995), its consumption may have physiological relevance (Mann et al., 1995). Since dietary 20:4n-6 bypasses some of the normal regulatory rate-limiting enzymatic ($\Delta 6$ and $\Delta 5$ desaturase) steps that control membrane 20:4n-6 content, it can abrogate the salutary effects of n-3 PUFAs (Li et al., 1994; German et al., 1995; Whelan and McEntee, 2004).

Additional insight into the mechanisms by which dietary PUFAs modulate gene expression was provided by the identification of several nuclear receptors (e.g., PPARs), which are activated at micromolar concentrations by a variety of fatty acids (Kliewer et al., 1997). This class of nuclear receptor binds n-3 and n-6 PUFAs with equal affinity and lacks fatty acid class (n-3 vs. n-6) specificity (Kliewer et al., 1997; Xu et al., 1999; Fan et al., 2003). Therefore, the unique effects of n-3 PUFA are likely not mediated via PPARs. Other molecular pathways that do not require PPARs are also involved in the PUFA-mediated regulation of gene expression (Ren et al., 1997; Fan et al., 2003; Jump et al., 2005). With regard to alternative pathways of intracellular signaling, Brown and Goldstein (1997) have documented how cells sense the level of a membrane embedded lipid, and how this information is transmitted to the nucleus to regulate gene transcription. Data are emerging from studies which demonstrate that families of membrane-bound transcription factors (e.g., SREBPs) coordinate the synthesis of the two major constituents of membranes, fatty acids and cholesterol (Anderson, 2003; Jump et al., 2005; Botolin et al., 2006). These data offer insight into mechanisms by which dietary PUFAs can modify risk of disease development.

V. CONCLUSION

It is evident that large gaps exist in our present understanding of EFA requirements and 18:3n-3 functions in humans. Specific issues related to n-6/n-3 PUFA balancing, quantitative dose-response to dietary n-3 PUFA and mechanisms involved in defining the essentiality of n-3 PUFA in growth, development, and disease resistance require further investigation. In addition, because North Americans consume greater than ten times the amount of n-6 PUFA required to meet minimal requirements (Lands, 1989; Simopoulos, 1989a), the significance of the question "when does enough (18:2n-6) become more than enough" (Lands, 1979) must now be evaluated. The excesses in n-6 PUFA (18:2n-6 and 20:4n-6) consumption are creating an overall imbalance in long-chain fatty acid metabolism. This issue is of particular importance in view of the relative n-3 PUFA deficiency syndrome seen in Japan, where an increase in the n-6/n-3 ratio from 2.8 to 4 during the past 40 years is associated with the rising incidence of cancer of the colon, breast, prostate, and pancreas (Okuyama et al., 1997). In addition, provocative data related to cognitive function in the elderly also reinforces the concept that an elevated dietary n-6/n-3 PUFA ratio is creating a health risk (Moriguchi and Salem, 2003; Calon et al., 2005; Lukiw et al., 2005; McCann and Ames, 2005). Kalmijn et al. (1997) have demonstrated that in men, aged 69–89 years, high 18:2n-6 intake was positively associated with cognitive impairment. In contrast, fish consumption (containing 20:5n-3 and 22:6n-3) was inversely associated with cognitive impairment, and no protective effect of any dietary antioxidants was observed. Although the complexity of this issue precludes any conclusions, it can be argued that more attention must be paid to promoting the consumption of n-3 PUFA-rich foods while reducing the intake of n-6 PUFA (Burchfiel et al., 1996; Connor, 1997; Daviglus et al., 1997; Okuyama et al., 1997).

In conclusion, effective public intervention to encourage the consumption of foods with an appropriate n-6/n-3 PUFA ratio is needed. As well, new food and agriculture policies are needed in order to expand federal efforts to disseminate relevant nutrition information. It is also important to recognize the inaccuracies of the dietary instruments used in epidemiological studies and the databases used to translate foods into nutrients. Finally, future efforts should concentrate on defining single nucleotide polymorphisms that influence EFA metabolism. Several loci are providing proof-of-principle for the potential application of genetics and diet (nutrigenomics) in the context of personalized nutritional recommendations for chronic disease prevention (Corella and Ordovas, 2005).

CONTENTS

I. INTRODUCTION

Within and around all living cells are membranes. These structures have been studied intensely over the past 75 years as scientists have become increasingly aware of their importance in metabolic regulation as well as in the regulation of the cell's life cycle. Membranes serve as biological boundaries to the various cell compartments and to the cell itself. If these boundaries altered, cell function is affected. Every organelle within each cell, and each cell type has this boundary. Some of the functions of these membranes are unique to the particular organelle or cell under study while other functions may be common to all cells or all similar organelles. In general, the plasma membrane (the membrane surrounding the cell) serves to exclude certain toxic ions and molecules from the cell. The plasma membranes also accumulate cell nutrients and serves in energy and signal transduction. To a limited extent in the mammal, the plasma membrane has a role of cell locomotion and cell division. This chapter focuses on the lipid components of membranes and discusses how changes in these lipids can affect the functions of membranes and hence the function of the cell. Indeed, the metabolism of the whole body may be affected if the membrane lipids are drastically altered.

II. MEMBRANE LIPID COMPOSITION AND STRUCTURE

A. Fluid Mosaic Model

Biological membranes contain a large number of lipids, proteins, lipid–protein complexes, glycolipids, and glycoproteins. The arrangement of these many compounds within the membrane structure has been studied extensively.

In the early twentieth century, Gortner and Grendel (1925) studied the composition and function of the lipids in the erythrocyte membrane. These lipids were primarily phospholipids.

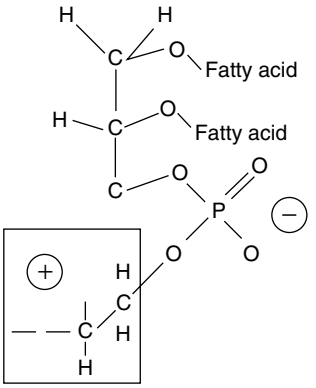

FIGURE 27.1 Structure of the major phospholipids. Head group can be ethanolamine, serine, glycerol, choline, or inositol.

Phospholipids can be thought of as substituted triacylglycerols. Attached to the glycerol backbone (Figure 27.1) are two fatty acids at carbons 1 and 2, respectively, and a charged moiety connected to carbon 3 via a phosphate group. Ethanolamine, inositol, choline, serine, or another glycerol can also be connected. Hence, one can find phosphatidylethanolamine, phosphatidylcholine (also known as lecithin), phosphatidylinositol, phosphatidylserine, and phosphatidylglycerol in the plasma membrane. In the mitochondrial membrane cardiolipin can be found. Cardiolipin has two phosphatidylglycerol groups (diphosphatidylglycerol) attached to the glycerol backbone. This structure has some unique properties as will be described in Section III. Cardiolipin serves as the signature for the mitochondrial membrane. Biochemists separating the various membranes for study use this signature to determine what membrane fraction they have. Cholesterol and cholesterol esters can also be found in the lipid portion of the plasma membrane. There is less cholesterol in the mitochondrial membrane than in the plasma membrane.

Gortner and Grendel extracted the lipids from the erythrocyte membrane and found that they covered more surface area than they had expected considering their calculations of the cell surface area of the erythrocyte. They concluded that these lipids must exist as a bilayer rather than as a monolayer around the cell contents. A decade later, Danielli and Dawson (1935) proposed that this lipid bilayer wore a protein coat. Then, in 1972, Singer and Nicholson, in their now classic paper, proposed that biological membranes exist as lipid bilayers and have a number of different proteins distributed throughout them. Some of these proteins might extend entirely through the layer, whereas others might rest on either aspect of the layer or be partially drawn into the layer. Singer and Nicholson thus proposed that biological membranes exist as fluid mosaics with regional differences in composition, structure, and function.

The reason the membrane exists as a lipid bilayer has to do with the amphipathic character of the phospholipids. They have both polar (the phosphorylated substituent at carbon 3) and nonpolar (the fatty acids) regions. The polar region is hydrophilic and is positioned such that it is in contact with the aqueous media around and within the cells. The nonpolar or fatty acid region is hydrophobic and is oriented toward the center of the bilayer so that it is protected from contact with the contents of cell and the fluids that surround it.

The ability of these amphipathic compounds to self-assemble into a bilayer can be demonstrated *in vitro*. Lipid vesicles can be made by the addition of these phospholipids to water. A lipid bilayer will form just as described above. This feature of the phospholipids is consistent with one of the many roles a membrane serves: that of a permeability barrier for the cell and cell compartments. The lipid bilayer forms the matrix into which specific proteins are placed. Each of the individual phospholipids and the cholesterol provide specific regional characteristics that satisfy the insertion

requirements of each of the many membrane proteins. The lipid bilayer serves as a seal around these membrane proteins and thus prevents nonspecific leakage. The lipids also serve to maintain the proteins in their most appropriate functional conformations. The polar position of the phospholipids satisfies the requirements for the electrostatic charge that is needed for the surface associations of specific cell surface proteins. All of the characteristics are needed and are critical to normal cell function. For example, an intact permeability barrier to sodium, potassium, calcium, and hydrogen ions is needed so that electrochemical gradients, which in turn drive other membrane transport process, are maintained.

The phospholipids are distributed asymmetrically depending on the cell type and the membrane in question. In the erythrocyte, for example, phosphatidylcholine is distributed such that 76% of it is located in the outer aspect of the membrane while the remainder can be found in the inner aspect. Asymmetric distribution of membrane components applies not only to the phospholipids as just mentioned but also to proteins and other membrane components. The glycolipids, for example, are almost exclusively found on the outer aspect with their carbohydrate moiety extending beyond the outer aspect. There they can participate in the cell recognition process.

Cell membranes usually work best when their lipids are in the liquid crystal state. This means that there are regional differences in the physical state of the lipid. Some portions may be fairly fluid, whereas other regions may be fairly solid. The localized difference in physical state or fluidity has to do with the chain length and saturation of the fatty acids attached at carbons 1 and 2 of the phospholipid; it is this portion of the molecule that extends into the center of the bilayer. Membranes whose phospholipid fatty acids are saturated are less fluid than those membranes containing polyunsaturated fatty acids in their phospholipids. Even within a membrane there can be regional differences in fluidity due to the nature of the fatty acids in the phospholipids of that region and in the amount of cholesterol. Although there can be local regions which differ in fluidity, the overall fluidity of the plasma membrane is usually constant in normal individuals despite drastic dietary change. This has been shown in human erythrocytes (Popp-Snijders et al., 1986), rat brush-border membranes (Stenson et al., 1989; Wahnon et al., 1992), and myocardial plasma membranes (Abeywardena et al., 1984). Differences in fluidity are not only due to the ratio of saturated fatty acids to unsaturated fatty acids but also due to the ratio of cholesterol to fatty acids (Naito, 1978a,b; Shinitzky, 1984). This ratio varies according to the location of the membrane within the cell and the tissue or cell type. Plasma membranes, for example, contain more cholesterol than do mitochondrial membranes. Hence, dietary fatty acid variation could have a greater influence on mitochondrial membrane fluidity than on plasma membrane fluidity. Indeed such has been shown (McMurchie and Raison, 1979; McMurchie et al., 1983a,b,c; Kim and Berdanier, 1988, 1998). When diets differing in the degree of unsaturation, that is, hydrogenated coconut oil vs. fish oil, mitochondrial membrane fluidity as well as the activity of certain mitochondrial membrane-embedded enzymes and transporters is affected. Clouet et al. (1995) reported that altering the outer mitochondrial membrane fatty acid content through diet affected carnitine palmitoyltransferase I, but had no effect on monoamine oxidase, glutamine dehydrogenase, and acylester hydrolase activities. Carnitine palmitoyltransferase I activity was reduced in outer membranes when rats were fed an arachidonic acid-enriched diet, whereas this membrane-bound enzyme was less sensitive to malonyl coenzymes A (CoA) inhibition when rats were fed a fish oil-enriched diet. Enzymes of the respiratory chain, particularly those in complexes III and IV, were less active in hepatic mitochondria isolated from rats fed highly saturated fats, for example, hydrogenated coconut oil, than in hepatic mitochondria isolated from rats fed polyunsaturated fat diets (McMurchie and Raison, 1979; Blomstrand and Svenson, 1983; McMurchie et al., 1983a,b; Deaver et al., 1986; Stillwell et al., 1997; Kim and Berdanier, 1998). Furthermore, in instances where there are small genetically determined differences in one or more of the proteins involved in mitochondrial oxidative phosphorylation, dietary effects on mitochondrial fluidity and function are more pronounced (Deaver et al., 1986; Kim and Berdanier, 1998; Mathews et al., 1999).

Microsomal membranes likewise have been examined. Through manipulating the cholesterol content and the fatty acid composition of the dietary lipid, the microsomal fatty acid profile as well as the Δ5 desaturase activity was affected. Rats fed a beef tallow diet had less desaturase activity than rats fed a linseed oil diet but more activity than rats fed a fish oil diet. When these diets were enriched with cholesterol, desaturase activity was reduced but the dietary fat effect on membrane lipid was unchanged (Garg et al., 1988). These observations suggest that the cells of these rats could adjust microsomal membrane fluidity not only through adjusting the ratio of saturated to unsaturated fatty acids but also through adjusting the ratio of membrane cholesterol to unsaturated fatty acids. Such adjustments have not been reported to occur in the mitochondrial membranes or the nuclear membranes. In these organelles, fluidity apparently is solely responsive to the ratio of saturated to unsaturated fatty acids.

B. Phospholipid Composition

As mentioned earlier, there are three major classes of lipids in membranes: glycolipids, cholesterol, and phospholipids. The glycolipids have a role in the cell surface-associated antigens, whereas the cholesterol serves to regulate fluidity. The phospholipids have fatty acids attached at carbons 1 and 2. It is usual to find a saturated fatty acid attached at carbon 1 and an unsaturated fatty acid at carbon 2. In addition, phosphatidylethanolamine and phosphatidylserine usually have fatty acids that are more unsaturated than phosphatidylinositol and phosphatidylcholine. Shown in Table 27.1 are some observations of the fatty acid composition of phospholipids extracted from normal human erythrocytes (van Deenen and de Gier, 1974) and rat hepatic mitochondrial membranes (Sire et al., 1986). Note the diversity in fatty acids, both in amount and kind, in these two types of membranes. Note too that the plasma membrane of the erythrocyte has no cardiolipin, whereas the rat mitochondrial membrane contains very little phosphatidylserine. Less than 10% of the membrane phospholipid is phosphatidylinositol. The fatty acid pattern shown in Table 27.1 for the erythrocyte membrane phospholipids can be altered. Similarly, the fatty acid composition as well as phospholipid composition of the B and T cells of the immune system can be influenced by the fatty acid

composition of the diet (Tiwari et al., 1987). Other cell types have also been studied, and again dietary fat composition affects the fatty acid array of the phospholipid. Mention should be made here of the role that fatty acids as well as the phosphatidylinositol play in the regulation of metabolism that occurs through the inositol cascade and through eicosanoid production. The arachidonic acid that is often attached to carbon 2 of the phospholipid can be released via the activity of phospholipase B. Diet can influence the amount of arachidonic acid present in the plasma membrane, and this arachidonic acid can then serve as a precursor for the eicosanoids, particularly those of the prostaglandin 2 (PG_2) series (see Chapters 29 and 31). These eicosanoids act as localized hormones to stimulate one or more metabolic processes such as uterine contraction ($PGF_2\alpha$). In this instance, arachidonic acid serves not only in the maintenance of membrane fluidity and function but also as a substrate for the synthesis of a number of metabolic regulators.

In the second instance, the phospholipid, phosphatidylinositol, serves as substrate for phospholipase C that stimulates the release of phosphatidylinositol and diacylglycerol (DAG) from the membrane. Phosphatidylinositol (PIP_2) is further phosphorylated to PIP_3 and PIP_4. Both PIP_3 and PIP_4 and DAG are second messengers for a number of hormone-mediated cellular processes and thus can be included in the list of lipids that are metabolic controllers. Fatty acids and eicosanoids are covered in detail in Chapter 29 and signal transduction is discussed in Chapter 31.

C. Disease Effects on Membrane Lipids

Holman (1986) reviewed the literature on the effects of essential fatty acids and disease on the fatty acid content of membrane fatty acids. Goldberg and Riordan (1986) reviewed the literature on the role of membranes in the pathophysiology of a number of genetic diseases as well as contagious and degenerative diseases. Although these authors focused primarily on the abnormalities of the proteins in the membrane lipid bilayer, they indicated a role for the lipid in some of these disorders. For example, muscular dystrophy and multiple sclerosis are characterized by changes in the lipid structure of the membrane. In the former, the change consists of an increase in the amount of lysophosphatidylcholine and cardiolipin (Kalofoutis et al., 1977). In multiple sclerosis, there is a degeneration of the myelin of both central and peripheral nerves. The myelin is 75% lipid and 25% protein. Although the disease could be attributed to a specific abnormality in either component, there are reports that the protein contains about 27% fatty acid (palmitate and oleate) in a covalent linkage (Wood et al., 1971) and that multiple sclerosis is associated with a derangement in this association (Boggs and Moscarello, 1978) and a reduction in the amount of phosphatidylserine (Winterfield and Debuch, 1977). Another example is diabetes. Cardiolipin depletion in the myocardial tissues occurs in diabetes (Han et al., 2005). Diabetes is also characterized by excessive utilization of fatty acids as metabolic substrates as well as by diminished glucose transport into cells and mitochondrial dysfunction. Some of these dysfunctions could be due to the effects of the disease on the cardiolipin content of the inner mitochondrial membrane.

There have been many reports of secondary rather than primary differences in the lipid portion of the membrane. In these situations, it is the specific membrane protein(s) that somehow become abnormal. Other diseases—for example, heart arrhythmias coupled with sudden death, renal disease, ethanol intoxication, spur cell anemia, and diabetes—likewise result in secondary effects on the membrane lipids. These changes can, however, make the disease state worse by compromising the functionality of the membrane and its role in metabolic regulation. Alvaro et al. (1982) reported that the erythrocyte membrane fatty acids change in humans with liver disease (cirrhosis). In cirrhotic subjects, the membranes contain less phosphatidylethanolamine and more phosphatidylcholine than membranes from normal subjects. Although the membrane cholesterol content remained unchanged, the ratio of cholesterol to phospholipid increased. The fatty acid content of the phospholipid remained unchanged. Finally, cardiolipin, the mitochondrial membrane phospholipid, has an atypical fatty acid profile. The other phospholipids can have a number of different fatty acids attached to the glycerol backbone at positions 1 and 2 and thus be quite diverse in

this respect. Although there could be enormous combinational diversity among cardiolipin species in normal individuals there is not. Using sophisticated analytical tools, Schlame et al. (2005) reported that cardiolipin contained only one or two types of fatty acids and this generated a high degree of structural uniformity and molecular symmetry. The exception was found in patients with Barth's syndrome. Barth's syndrome is characterized by a loss in activity of acyltransferase. With this loss there is a wide diversity of fatty acids found in the cardiolipins of mitochondrial membranes from these patients. Since cardiolipin plays such an important role in mitochondrial physiology and cell viability (Hatch, 2004; Webster et al., 2005), these changes explain some of the features of this syndrome (Zhong and Greenberg, 2005). Additional concerns with respect to fatty acids and disease states are discussed in Chapters 39–53.

D. Diet Effects on Membrane Fatty Acids

Diet can alter the fatty acid content of the membrane phospholipid fatty acids both directly and indirectly (Valentine and Valentine, 2004; Hulbert et al., 2005; Leaf et al., 2005; Cury-Boaventura et al., 2006). Listed in Table 27.2 are some examples of reports in the literature of how the dietary fatty acids can affect the kinds and mounts of fatty acids in the membranes. Although this list is incomplete with respect to many published works in the literature, one can readily realize that the kind of dietary lipid and the lipid in the diet can affect the membrane phospholipid fatty acids. This is especially apparent from those fatty acids deemed essential because of inadequate synthesis (18:2, 20:4). Most animals can synthesize arachidonic acid (20:4) from linoleate (18:2) by desaturation and chain elongation (Sprecher, 1981; Holman, 1986). Felines cannot do this (MacDonald et al., 1984a,b); for this reason, felines must have both the 18:2 and 20:4 fatty acids in their diets. As detailed in Chapter 25 in this volume, palmitate, stearate, and oleate are the main fatty acids

TABLE 27.2
Effects of Dietary Fats on Selected Membrane Fatty Acids[a]

[a] Only the major fatty acids are listed here. Membrane phospholipids also contain a variety of other fatty acids in small amounts.

[b] Significant amounts of *trans* 18:1 fatty acid were also found.

synthesized de novo. Monounsaturated as well as polyunsaturated fatty acids can be synthesized from the saturated fatty acids via the activity of the microsomal desaturases. The dietary fat effect on desaturase activity is influenced by the genotype of the consumer. Park et al. (1997) studied two different strains of mice-fed diets containing 4% or 20% coconut or corn oil. The BALB/cByJ mice had significantly less desaturase activity and mRNA than normal C57BL/6J mice. Mice fed the 20% fat (corn oil) diet had less desaturase activity than those fed the 4% fat or the hydrogenated coconut oil diets. The desaturase enzymes (as well as the enzymes for fatty synthesis—acetyl CoA carboxylase, fatty acid synthase complex, for example) can be altered by the nature of the diet and by hormonal status. Note in Table 27.2 that rats fed a high-carbohydrate, fat-free diet have significant quantities of 16:0 and 18:1 fatty acids. Rats fed high-carbohydrate, low-fat diets where the carbohydrate is either sucrose of starch will evidence differences in their fatty acid profiles. Those fed sucrose will have more saturated fatty acids in their membrane phospholipids than those fed starch (Wander and Berdanier, 1985). The large amount of carbohydrate in the diets of these rats stimulated the activity of the enzymes for both de novo synthesis and fatty acid desaturation. This activation was probably due in part of the stimulatory effect of the diet on insulin release. Insulin is a potent stimulant of the desaturase and lipogenic enzymes. In addition, certain of the fatty acids (18:2, 20:4) are involved in the regulation of transcription of the mRNA for the lipogenic enzymes (see Chapter 29). Stearic acid (18:0) serves in a similar fashion for the Δ5 desaturase.

Note in Table 27.2 that within the same dietary treatment, membrane phospholipid fatty acid differs depending on the cell type from which the membrane was extracted. McMurchie et al. (1983a) studied mitochondrial membranes from the heart and liver and found significant differences in the fatty acid profiles between these tissues in rats fed the same diet as well as the aforementioned differences in the profiles of these mitochondria from rats fed different fats. Although it might appear from Table 27.2 that only a few tissues have been studied, this is not the case. The literature is vast. Many cell types have been studied. What can be concluded from Table 27.2 is that the type of dietary fat (degree of saturation), the amount of fat in the diet, and the tissue and organelle examined all contribute to what may be observed with respect to the fatty acid profile of the membrane phospholipids.

E. Hormones and Their Effects on Membrane Lipids

As mentioned above, the hormone insulin can affect the fatty acid profile of the membrane phospholipids through its effect on glucose conversion to fatty acids and through its effect on the desaturases. Other hormones can influence the profile as well. Examples of this influence are shown in Table 27.3. Daily injections of the synthetic glucocorticoid, dexamethasone, resulted in an increase in the mol.% of linoleic acid (18:2) and a decrease in arachidonic acid (20:4). Thyroidectomy resulted in a small increase in rat liver mitochondrial levels of 18:2 and 20:4. Hypophysectomy, which causes a decrease in growth hormone levels, resulted in an increase in 18:2 and a decrease in 20:4 in hepatic mitochondria. Studies on the influence of all the many hormones that affect fatty acid synthesis, phospholipid synthesis, and membrane phospholipid fatty acid levels are not as readily available as are reports on the dietary fat effects on these parameters. However, they are of interest, because these hormones may also have a large influence on the function of the protein components that are embedded in the various membranes. These hormones may act directly on the synthesis and activation of these proteins or indirectly through their effects on the membrane lipids that surround the proteins. Some of these hormones affect desaturase activity and thereby affect the fatty acid profile of the membrane. As mentioned, this could affect the activity of the membrane-embedded enzymes (Hoch et al., 1980, 1981; Withers and Hulbert, 1987). For example, microsomal cytochrome b_5 activity is dependent on the lipid environment. This is, it must be surrounded by a very fluid lipid, and this lipid must have a number of unsaturated fatty acids in it (Hoch et al., 1980). Just as thyroidectomy results in a decrease in membrane phospholipid fatty acid unsaturation, hyperthyroidism has the reverse effect (Mak et al., 1983; Berdanier, 1988a; Raederstorff et al., 1991). The thyroid hormones

[a] Streptozotocin-induced diabetes.

also affect fatty acid elongation by inducing an increase in the activity of the microsomal fatty acid elongation system, whereas they have little effect on mitochondrial elongation (Landriscina et al., 1976). Thyroxine also affects the synthesis of phospholipids. Pasquini et al. (1980) reported that the incorporation of labeled choline into brain and liver phosphatidylcholine was less in thyrotoxic rats than in normal rats. In turn, the type of dietary fat affects triiodothyronine (T_3) production (Takeuchi et al., 1995; Kim and Berdanier, 1998). Rats fed a lard diet had lower serum T_3 levels and Na^+, K^+-ATPase activity in liver and muscle than did rats fed a safflower oil diet (Takeuchi et al., 1995). Diabetes-prone BHE/cdb rats fed a hydrogenated coconut oil diet had higher levels of thyroxine and T_3 than rats fed a corn oil or menhaden oil diet. Sprague-Dawley rats fed these same diets had no difference in T_3 levels, and the difference in thyroxine was significant only between the coconut oil and corn oil groups not between the corn and menhaden oil groups (Kim and Berdanier, 1998). In this same study, there were similar strain differences in the effects of these fats on mitochondrial fluidity and function.

Nuclear T_3 receptor number (but not binding affinity) on the other hand is affected by the type of dietary fat (Knopp et al., 1992). Rats fed a saturated fat diet had decreased T_3 receptor binding in the nucleus. Hypothyroidism is characterized by reduced phosphate transport (Paradies and Ruggiero, 1990; Paradies et al., 1991) as well as by a reduction in mitochondrial respiratory activity and ATP synthesis efficiency (Hoch, 1968; Hulbert et al., 1976; Sugiyama et al., 1991). Essential fatty acid deficiency mimics many of these same effects both with respect to mitochondrial fatty acid composition, fluidity, and function (Levin et al., 1957; Hayashida and Portman, 1963; Ito and Johnson, 1964; Stancliff et al., 1969; Williams et al., 1972; Divakaran and Venkataraman, 1977; Rafael et al., 1984).

F. Age Effects on Membrane Lipids

As animals age, their hormonal status changes, as does the lipid component of their membranes (Pepe, 2005a,b). With age, there is a decrease in growth hormone production, an increase followed by a decrease in the hormones for reproduction, and, as the animal develops, larger fat stores. There may develop peripheral resistance of the action of insulin, and insulin levels may rise as a result of increased fat cell size. As mentioned in the preceding section, these hormones can affect the lipid portion of the membranes within and around the cells and hence affect how these cells regulate their metabolism. Yechiel and Barenholz (1985) studied aging myocytes isolated from newborn rats. As these cells aged *in vitro*, sphingomyelin and cholesterol levels increased by 100% and 50%, respectively, whereas phosphatidylcholine fell by 15%–20%. There were no changes in total

phospholipids. These myocytes were grown in vitro in a defined medium without the influences of the many factors that, in the aging whole body, can affect membrane lipids. Hegner (1980) studied rats as they aged. He found that with age, the degree of unsaturation of the plasma membrane fatty acids decreased and the cholesterol level rose. He also reported that with age, there was an increase in the number of superoxide radicals and proposed that this increase led to the degradation of the membrane lipids, which in turn might explain the age-related changes in membrane function. Others (Wahnon et al., 1989; Yen et al., 1989) have reported that membranes from aging animals are less fluid and have reduced transport capacities. Yen et al. (1989) reported that, as human's age, there is a decline in hepatic mitochondrial respiratory rate and a decrease in the respiratory rate and a decrease in the respiratory ratio and the ADP/O ratio. Wei and Kao (1996) have also shown that free radicals rise with age as does the number of mitochondrial DNA mutations. This might explain the age-related decline in mitochondrial respiratory function as reported to occur in aging rats as well as humans. Since mitochondrial membranes are rich in unsaturated fatty acids, free radicals could readily form and damage mitochondrial DNA which in turn would result in malfunctioning respiratory proteins (Chen et al., 1972; Murfitt and Sanadi, 1978; Berdanier and McNamara, 1980; Kim and Berdanier, 1988). In addition, there are reports of an age-related decrease in membrane fatty acid unsaturation coupled with a decrease in membrane fluidity and a decrease in the exchange of ATP for ADP across the mitochondrial membrane (Nohl and Kramer, 1980), a decrease in ATP synthesis (Clandinin and Innis, 1983), and an amelioration of these age-related decreased mitochondrial function by restricted feeding (caloric intake reduced by 50% over the lifetime of the animals) (Weindrach et al., 1980).

III. MEMBRANE FUNCTION

In the previous section, the importance of diet, age, and hormonal status was described in terms of their influence on the composition of the membrane lipids. Although not emphasized, these compositional differences have important effects on metabolic regulation. This regulation consists of the control of the flux of nutrients, substrates, and/or products into, out of, and between compartments of the cell.

The terms metabolic regulation implies that metabolic flux is controlled such that there is an interdigitation of the pathways within cellular compartments, between compartments, between cells or tissues, and between tissues within the body and that this is closely regulated. The mechanisms that control metabolism at all of these levels are various. Both genetic and dietary factors may influence these mechanisms, and individuals within a population group may vary in the activity of given reactions or pathways. Hence, we have genotypes for obesity and/or diabetes whose controls of lipid metabolism and/or glucose metabolism are aberrant regardless of diet, and we have other genotypes whose phenotypic expression of their genotype is inhibited or enhanced by the composition of the diet they consume. Still other genotypes will express normal phenotypic features of tight control of energy balance, fat synthesis, fat storage, glucose use, glycogen synthesis, and so forth. In normal individuals, metabolic control mechanisms include redox state, calcium ion flux, phosphorylation state, substrate and product levels, enzyme amount and activity, concentrations of cofactors, coenzymes, hormones, second messengers such as cAMP, and probably a whole host of other factors as yet not identified or described. Some of these are listed in Table 27.4.

Although the cellular membranes serve as geographical boundaries of the cell and its compartments, these structures have metabolic control properties as well. They are the "gatekeepers" of the cells and their compartments. They regulate the influx and efflux of nutrients, substrates, hormones, and metabolic products produced or used by the cell or compartment in the course of its metabolic activity. For example, the mitochondrial membrane through its transport of two- and four-carbon intermediates and though its exchange of ADP of ATP regulates the activity of the respiratory chain and ATP synthesis. If too little ADP enters the mitochondria because of decreased ADP transport across the mitochondrial membrane, respiratory chain activity will decrease, less ATP will be

TABLE 27.4
Dietary Effects on Membrane-Embedded Enzyme or Transporter or Receptor Function

Diet Treatment	Effect	Comment	Reference
Coconut vs. safflower oil (20% w/w diet)	↑ Δ5 Desaturase activity	↑ mRNA for stearoyl CoA	Dang et al. (1989); Park et al. (1997)
Coconut vs. soybean oil (15% w/w)	↑ Alkaline phosphatase activity	No effect on enterocyte plasma membrane fluidity	Wahnon et al. (1992); Stenson et al. (1989)
Mackeral vs. soybean oil (15% w/w)	↓ Alkaline phosphate activity	No effect on enterocyte plasma membrane fluidity	Wahnon et al. (1992); Stenson et al. (1989)
Fish vs. vegetable oil in a fat mixture (50% w/w diet)	↓ Sensitivity of carnitine palmitoyl transferase I to inhibition	Increase in hepatic outer mitochondrial membrane fluidity	Clouet et al. (1995)
n-6 vs. n-3 deficiency (60% fat w diet)	↓ Secretagogue effect of prolactin on mammary cells	Plasma membrane fatty acids reflected dietary fatty acids	Ollivier-Bousquet et al. (1993)
Lard vs. safflower oil	↓ Hepatic and muscle Na^+K^+ATPase activity No difference in lipoprotein lipase activity ↓ Serum T_3 levels	Rats were fatter when fed the lard diet	Takeuchi et al. (1995)
Coconut vs. corn oil (5%–6% w/w) or a fat-free diet	↑ Activity of soluble and microsomal phosphatidate phosphatase ↑ α-Glycerol-P shuttle ↓ Coupling of mitochondrial respiration to ATP synthesis	↑ Mitochondrial membrane fluidity ↓ 18:2 and 20:4 content of membrane lipid	Deaver et al. (1986); McMurchie et al. (1983a–c); Stillwell et al. (1997); McMurchie and Raison (1979); Kim and Berdanier (1998)
Sheep vs. safflower oil	No change in ion transporting ATPases	No change in plasma membrane fluidity; membrane fatty acid profile reflects diet fat	Abeywardena et al. (1984)

synthesized, and there may be a decrease in other mitochondrial reactions that are either driven by ADP influx or dependent on ATP availability. Through its export of citrate from the matrix of the mitochondria, it regulates the availability of citrate to the cytosol for cleavage into oxaloacetate and acetyl CoA, the beginning of fatty acid synthesis. If more citrate is exported from the mitochondria than can be split to oxaloacetate and acetyl CoA, this citrate will feed back onto the phosphofructokinase reaction and glycolysis will be inhibited. Thus, the activity of the mitochondrial membrane tricarboxylate transporter has a role in the control of cytosolic metabolism. Other transporters such as the dicarboxylate transporter or the adenine nucleotide translocase have similar responsibilities vis-á-vis the control of cytosolic and mitochondrial metabolic activity. Receptors embedded in the plasma membrane have a similar function; that is, they control the entry of nutrients or hormones into the cell. Further, the plasma membrane hormone receptor may bind a given hormone, and, with binding, elicit a cascade of reaction characteristic of the hormone effect without permitting the entry of the hormone itself into the cystosolic compartment. An example here is the hormone insulin. Insulin binds to its receptor and in so doing elicits the cascade of events that include the transport and metabolism of glucose by the cell. The insulin, bound to the receptor site, is inactivated and is brought into the cell by pinocytosis for further degradation. Other hormones, notably the nonprotein steroids and the low-molecular weight hormones such as epinephrine and thyroxine, pass through the plasma membrane and attach to receptors in the cytosol and/or nuclear membrane or on the endoplasmic reticulum. Once attached to their respective biding sites, they also elicit a metabolic response.

These examples illustrate the importance of the cellular and intracellular membranes in the regulation of metabolism. They also illustrate the fact that the gatekeeping property of the membrane is vested in the structure and function of the various transporters and receptors or binding proteins embedded in the membrane. Whereas the genetic heritage of an individual determines the amino acid sequence of the proteins and hence their function, this function can be modified by the lipid milieu in which they exist. An example of a diet–genetic interaction with respect to membranes is seen in the function of the mitochondrial $F_1 \cdot F_0$ ATPase. This enzyme complex consists of two parts. The base, the F_0 is embedded in the inner mitochondrial membrane while the stem and head projects out into the mitochondrial matrix. Both parts must be mobile. They rotate around the stem as the F_0 captures the energy generated by the respiratory chain and transmits it to the head which traps it in the high-energy bond of the ATP. Rotation of the F_0 proton is hindered when the inner mitochondrial membrane contains more then the usual amounts of saturated fatty acids. This occurs when the animal is fed hydrogenated coconut oil or an essential fatty acid-deficient diet. Indeed, essential fatty acid deficiency is characterized by a reduction in ATP synthesis. In the diabetes-prone BHE/cdb rat (a rat with a mutation in the mitochondrial ATPase 6 gene), ATP synthesis efficiency is reduced. When this rat is fed a highly saturated fat, the combined effects of the diet and the genetic defect are additive: that is, there is a considerable loss in ATP synthesis efficiency (Deaver et al., 1986; Kim and Berdanier, 1998). Thus, diet as in a fatty acid deficiency, or genetics, or an interaction of both these factors can result in mitochondrial malfunction. Fatty acid deficiency affects other cell types as well. Ollivier-Bousquet et al. (1993) showed that a deficiency of n-6 fatty acids but not n-3 fatty acids inhibited the secretagogue effect of prolactin on lactating rat mammary epithelial cells. This is due to inadequate supplies of arachidonic acid in the mammary cell plasma membrane. Arachidonic acid is an essential component of the signal cascade that is elicited when the hormone prolactin is bound to its cognate receptor. This cascade involves the conversion of arachidonic acid to the E series of eicosanoids. Diet, hormonal state, and genetics in turn control the lipid milieu in terms of the kinds and amounts of the different lipids that are synthesized within the cell and incorporated into the membrane.

In the membranes are a variety of closely packed proteins and lipids. The membrane-bound proteins have extensive hydrophobic regions and usually require lipids for the maintenance of their activity. Adenylate cyclase (Engelhard et al., 1978), Cytochrome b_5 (Holloway et al., 1982), and cytochrome c oxidase (Robinson, 1982) have all been shown to have phospholipid affinities. Cytochrome c oxidase (E.C.1.9.3.1) from mitochondria has tightly bound aldehyde lipid that cannot be removed without destroying its activity as the enzyme that transfers electrons to molecular oxygen in the final step of respiration (McMillen et al., 1986). Marinetti and Cattieu (1982) found a number of membrane proteins that have tightly bound fatty acids as part of their structures. These fatty acids are covalently bound to their proteins as a post-translational event and act of direct, insert, and anchor the proteins in the cell membranes. Alkaline phosphatase in the enterocyte is an example of one such enzyme. This enzyme increases in activity as the membrane increases in eicosapentaenoic acid (20:5) without any change in membrane fluidity (Stenson et al., 1989; Wahnon et al., 1992). Alkaline phosphatase is an integral enzyme known to be intimately associated with the hydrophobic core of the intestinal microvillus plasma membrane. Other lipids are bound differently to membrane proteins. Some are acylated acids with fatty acids during their passage from their site of synthesis on the rough endoplasmic reticulum to the membrane, whereas others acquire their lipid component during their placement in the membrane. β-Hydroxybutyrate dehydrogenase (E.C.1.1.1.30), for example, requires the choline head of phosphatidylcholine for its activity (Isaacson et al., 1979). If hepatocytes are caused to increase their synthesis of phosphatidylmethylethanolamine, which substitutes for phosphatidylcholine in the membrane, β-hydroxybutyrate dehydrogenase activity is reduced (Clancy et al., 1983).

On the other hand, low membrane levels of phosphatidylethanolamine are related to low levels of calcium pump activity in the muscle and high levels of calcium pump activity in reconstituted membrane systems (Hui et al., 1981; Hidalgo et al., 1982; Navarro et al., 1984). The difference

between the activity of the calcium pump in the reconstituted system and in the muscle preparation probably has to do with the conformation of the phospholipid in the two preparations. In the reconstituted system, the phosphatidylethanolamine assumes a form that allows for a lipid bilayer to surround the pump and stimulate it. If in a monolayer (or prevented from surrounding the pump to hold it in its active form), then the pump is less active (Yeagle, 1989).

Cholesterol also modulates the ion pumps in the plasma membrane. Two of these, the Na^+,K^+-ATPase and the Ca-ATPase, have been studied (Yeagle, 1989). The Na^+,K^+-ATPase is responsible for pumping sodium out of the cell and potassium into the cell against their respective gradients. The ratio of Na^+ to K^+ is 3:2, so the pump is electrogenic. Thus, this enzyme has a central role in metabolic regulation. High levels of membrane cholesterol are associated with low levels of Na^+,K^+-ATPase activity (Kimelberg and Paphadjopoulus, 1974; Giraud et al., 1981; Yeagle, 1983). Decreased plasma membrane fluidity, due, not only to increase cholesterol content but also to an increase in the amount of saturated fatty acids in the phospholipids, also results in decreased Na^+,K^+-ATPase activity (Solomonson et al., 1976; Storch and Schachter, 1984). Adenine nucleotide exchange via adenine nucleotide translocase is also affected by the mitochondrial membrane lipid. It is less active in less fluid membranes (Mak et al., 1983). Mg^{2+} ATPase is 18 times as active in the presence of lysolecithin and to a smaller extent in the presence of cardiolipin, phosphatidylinositol, and phosphatidylethanolamine as in the presence of lecithin or in a lipid-free environment (Swanljung et al., 1973). If ATP synthesis is less due to less active Mg^{2+} ATPase, and if ADP influx and ATP efflux from the mitochondria are decreased, respiration (which is dependent on ADP influx) will also decrease. Cytosolic reactions that are affected by phosphorylation state (ATP:ADP) will be decreased or increased depending on the reaction in question. Lipogenesis is favored by an increase in the phosphorylation state, whereas gluconeogenesis is favored by a decrease.

Microsomal HMG CoA reductase, the rate-limiting enzyme in cholesterol synthesis, is similarly affected (Wulfert et al., 1981), as are the plasma receptor proteins for insulin, glucagon (Liepnieks et al., 1983), prolactin (Knazek and Liu, 1979), epidermal growth factor (Shoyab and Todaro, 1981), and the enkephalins (Deber and Behnam, 1984).

The hepatic mitochondrial membrane fatty acid composition in relation to the activities of the enzymes embedded in this membrane has been particularly well studied. This tissue is very responsive to dietary changes and has received considerable attention, because the mitochondria manifest a number of functional changes as part of the animal's response to a diet deficient in essential fatty acids. The uncoupling of mitochondrial respiration to ATP synthesis has been reported, as has the increased activity of the α-glycerol phosphate shuttle (Levin et al., 1957; Divakaran and Venkataraman, 1977; Deaver et al., 1986). Increased respiratory chain activity and increased succinate dehydrogenase activity in rats fed an essential fatty acid–deficient diet has also been reported (Hayashida and Portman, 1963; Ito and Johnson, 1964; Williams et al., 1972; Rafael et al., 1984; Royce and Holmes, 1984). When these findings are coupled with the reports on the effects of diet, particularly the effects of low-fat or no-fat diets, on the membrane phospholipid fatty acid composition and function, one can readily appreciate the importance of these membranes in the regulation of metabolism throughout the body. One can also appreciate the fact that Mother Nature has designed a number of systems that, under normal conditions of diet, exercise, growth, and health, ensure the maintenance of the most appropriate fluidity in each and every cell membrane. Only those conditions that cause severe perturbations in metabolism will affect cell membrane fluidity. If highly saturated fats are produced de novo, the cell increases the activity of the microsomal desaturases; the ratio of unsaturated fatty acids to saturated fatty acids to cholesterol is thus carefully controlled. On top of this is the maintenance and positioning of amounts of the different phospholipids. There is an asymmetrical distribution of these phospholipids (Krebs et al., 1979) just as there is an asymmetrical distribution of the membrane proteins. As mentioned, certain of these proteins require certain phospholipids for their activity. Fortunately, these molecules are arranged according to need. This asymmetry may be due in part of the action of the different phopholipases (Fujii and Tamura, 1979) although these lipases may be found on either side of a given membrane, activation may not be

equal of the two sides, thus leaving some phospholipids degraded, whereas others are left in place. Also, certain of the phospholipids may be protected by the proteins that are closely associated with them. The membrane phospholipids do turn over rapidly, and they exchange their fatty acids rapidly with their neighbors and with the fatty acids present in the media surrounding them. Thus, there is ample opportunity to maintain a steady state with respect to membrane lipid composition and function.

There is one further consideration where membrane lipid has a profound effect on cell function and that is the role of lipid particularly cardiolipin in programmed cell death, apoptosis. This is the process whereby the body regulates cell number (cell turnover). Cell turnover has two parts: cell replacement and cell death. Cell death is either a concerted, all at once, event (necrosis) or a programmed, gradual process. Necrotic cell death is preceded by cell enlargement and a swelling of all the organelles within the cell. The DNA disintegrates and its nucleotides are degraded. In contrast, programmed cell death or apoptosis involves a shrinkage of the cell and enzyme catalyzed DNA fragmentation. This fragmentation can be detected as a laddering when the DNA is extracted from the cell and separated by electrophoresis. Apoptosis is viewed as a defense mechanism to remove unwanted and potentially dangerous cells such as virally infected cells or tumor cells. The process involves the mitochondria as the "central executioner." The mitochondria produce reactive oxygen (free radicals) as well as other materials that participate in apoptosis. Alterations in mitochondrial function have been observed to occur prior to any other feature of apoptosis. A decrease in mitochondrial membrane potential that in turn affects membrane permiability is an early event. The increase in permiability is followed by a release of cytochrome c. Cytochrome c acts as a cardiolipin oxygenase required for the release of proapoptoctic factors (Kagan et al., 2005; Orrenius and Zhivotovsky, 2005). In turn, cytochrome c regulates the caspases, which are cysteine proteases. These caspaces stimulate the proteolysis of key cell proteins in various parts of the cell. Altogether the fragmentation of the DNA and the destruction of cell proteins result in the death of the cell via a very orderly process.

Apoptosis is the mechanism used in the thymus to eliminate thymocytes that are self-reactive. By doing so the development of autoimmune disease is suppressed. Figure 27.2 illustrates the process of apoptosis and Table 27.5 lists some of the factors that influence apoptosis.

Many cells can be stimulated to become apoptotic. The p53 protein, for example, can induce apoptosis as one of its modes of protecting the body against tumor cells. The p53 protein is a DNA-binding protein. Mutations in tumor cells have been found that inactivate p53. The result of such mutation is that tumor cells grow and multiply. The gene for p53 likewise can mutate and this mutation has been associated with tumor development and growth. Apparently, this gene has several "hot spots" (likely places for mutation to occur), which explains its role in carcinogenesis and its

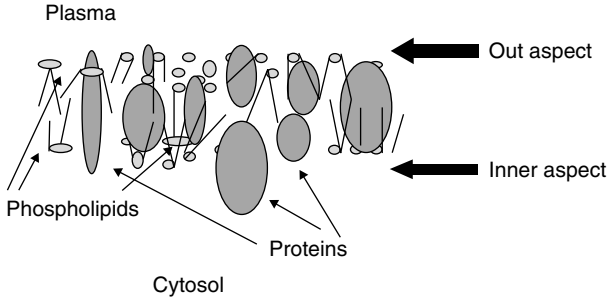

FIGURE 27.2 Cartoon representation of the membrane structure showing that some proteins extend through the lipid bilayer while others can be found on either aspect of the membrane. The phospholipids are shown as having their fatty acids (the straight lines) extending into the center of the bilayer while the phosphatidyl component is on either aspect of the membrane.

loss in normal function. The bcl-2 protein, a membrane bound cytoplasmic protein, is another player in this regulation of apoptosis. It is a member of the family of proteins called protooncogenes. Its normal function is to protect valuable cells against apoptosis. It is down regulated when cells are stimulated to die. Inappropriately, high bcl-2 protein levels can provoke cell overgrowth. The cell regulates bcl-2 protein so as to maintain a normal homeostatic state. Bcl-2 and its homologue, Bcl-x_L, blocks apoptosis. Both Bcl-2 and Bcl-x_L can heterodimerize with Bax or Bcl-x_s and when Bcl-2 or Bcl-x_L is over expressed an enhancement of oxidative stress mutagenesis can be observed. This occurs because these proteins suppress the apototic process allowing more exposure of the cell to DNA damage by mutagens. As an example, if there is a deficiency of respiratory complex I as happens in several of the mitochondrial genetic diseases, this deficiency primes BAX-dependent apoptosis through mitochondrial oxidative damage (Perier et al., 2005).

Nutrients play a role in apoptosis. Intakes of highly peroxidized lipids or lipids that are easily peroxidized, that is, fish oils, can stimulate apoptosis. High levels of zinc (500 μm) have been found to block apoptosis in cultured thymocytes. The zinc blocks the action of glucocorticoids in stimulating apoptosis. Zinc also interferes with tumor necrosis factor (TNF) induced apoptosis as well as heat-induced death. In contrast, low levels of zinc (0.3–200 μm) have the reverse effect. That is, at low levels of zinc, apoptosis could be stimulated by TNF, glucocorticoid and heat exposure. TNF induces apoptosis through an alteration of membrane lipid (Sandra et al., 2005). Manganese, another essential nutrient, also is involved as a cofactor for superoxide dismutase (SOD). In instances where SOD is less active than normal, apoptosis is stimulated coincident with an increase in C2-ceramide,

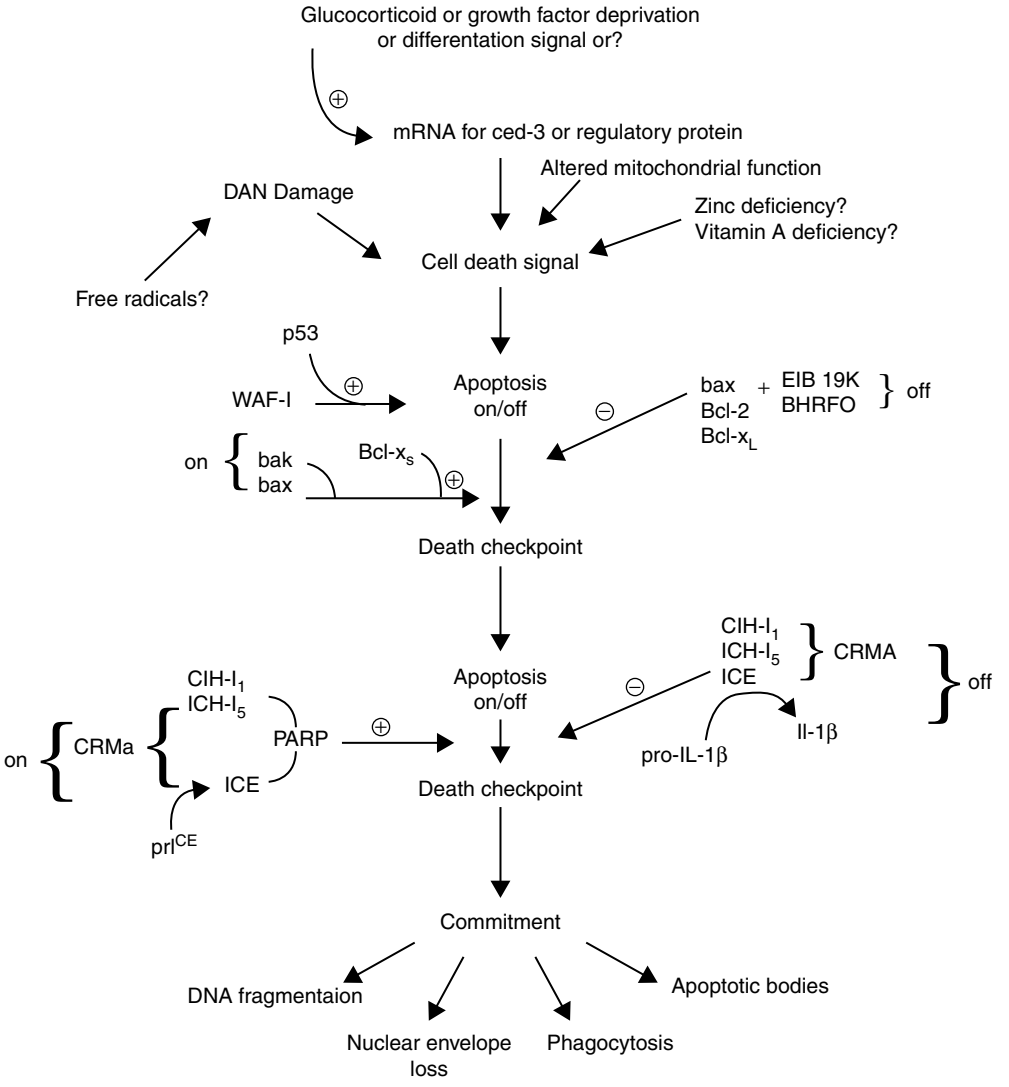

FIGURE 27.3 Roles of fatty acids in gene expression and cell signaling.

TNFα, and hydrogen peroxide. Ceramide displaces cholesterol from lipid rafts and decreases the association of the cholesterol-binding protein caveolin-1 (Yu etal., 2005). Ceramide is a positively charged molecule that induces mitochondrial permeabilization (Novgorodov et al., 2005). Ceramide induces nonapoptotic death as well (Kim et al., 2005). Peroxides form from unsaturated fatty acids as well as certain of the amino acids. There may be a link therefore between the fatty acid intake of the individual and apoptosis of certain cell types. In one study of genetically obese diabetic rats, an increase in fatty acid intake was associated with an increase in β cell apoptosis.

Retinoic acid (and dietary vitamin A) deficiency stimulates apoptosis. The well known feature of vitamin A deficiency (suppressed immune function) suggests that vitamin A and its metabolite, retinoic acid, serve to influence the sequence of events leading to cell death. This link is made because it is known that T cell apoptosis is an important defense mechanism and T cells are part of the immune system. Vitamin A is also an antiproliferative agent so its effect on abnormal cell growth is two pronged. One, it stimulates apoptosis and two, it suppresses proliferation.

Genetic regulation of apoptosis involves not only the transcription factors mentioned above but also specific genes. Already described are the p53 and bcl-2 DNA-binding proteins that (like zinc, retinoic acid, and fatty acids) affect gene expression. Add to this list the mitogen activated protein kinases (p42/44) Erk1 and Erk2 and mitochondrial p38 mitogen-activated protein kinase (Kong et al., 2005). When phosphorylated these proteins suppress apoptosis in brown adipocytes. Apoptosis is also suppressed by certain of the cytokines (IL6, IL3, and interferon γ) and stimulated by others (leptin). Lastly, the gene Nedd 2 encodes a protein similar to the nematode cell death gene ced-3 and the mammalian interleukin 1β converting enzyme. Overexpression of this gene induces apoptosis.

With the understanding of apoptosis comes the understanding of how and why the body changes in its composition as it ages from conception to death. The young animal has little fat while the older one has gained fat sometimes at the expense of body protein. Clearly, the body is continually being remodeled and quite clearly this remodeling is the result of a combination of many factors including the apoptotic process.

IV. CONCLUSION

This chapter presents an overview of the many factors that affect the fatty acid composition of the membrane phospholipids. These membrane lipids under normal circumstances are carefully balanced so as to maintain optimal function of the membrane as an important determinant of metabolic function of the cell. Not included in this chapter is a summary of the signaling properties of some of the complex lipids, eicosanoid formation, or the roles of specific fatty acids in gene expression (Figure 27.3). This information is covered in the chapters that follow.

28 Dietary Fatty Acids and Eicosanoids

Joo Y. Lee and Daniel H. Hwang

CONTENTS

I. INTRODUCTION

One of the important functions of dietary fat is to provide essential fatty acids (EFAs). However, the requirement for EFAs as linoleic acid (18:2n-6) is only 1%–2% of the total caloric intake. Thus, EFA deficiency seldom occurs in the general population consuming ordinary diets. In spite of this, much greater amounts of intake for dietary polyunsaturated fatty acids (PUFAs) are generally recommended. This recommendation is primarily based on the cholesterol-lowering action of dietary PUFAs, and this, in part, resulted in changes in trends in the consumption of dietary fat in the United States (Stephen and Wald, 1990).

Dietary PUFAs has been generally used as an entity without differentiating the type of PUFA. Epidemiological, clinical, and biochemical studies conducted during the past 20 years suggest that dietary n-3 PUFA is beneficial in reducing certain risks of chronic diseases. Revelation of the difference existing between n-6 and n-3 fatty acids in metabolic pathways leading to the formation of eicosanoids and their precursor acids suggests that not only the level of PUFAs but also the types of PUFAs need to be defined for recommendation of dietary PUFAs in dietary guidelines in the future.

In this chapter, discussion is focused on how different dietary fatty acids affect the capacity of tissues to synthesize eicosanoids with diverse physiological actions and their nutritional implications.

II. DIETARY PUFAs AS A SOURCE OF ESSENTIAL FATTY ACIDS

In 1929, Burr and Burr first reported the essentiality of dietary fat (Burr and Burr, 1929). Later, it became clear that the essentiality of dietary fat is due to the requirement of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), which cannot be synthesized by mammals. The requirement for linoleic acid is known to be only 1%–2% of the total daily caloric intake (Holman, 1970). This requirement is based on the amounts of linoleic acid that can clear the dermal lesion resulting from EFA deficiency or the amounts that normalize the triene/tetraene ratio (Mohrhauer and Holman, 1963). Ordinary American diets can provide linoleic acid at amounts much higher than required. Thus, EFA deficiency (based on overt symptoms and an increased triene/tetraene ratio) rarely occurs in the general population. However, it should be noted that the amount of EFAs required to prevent the deficiency symptoms may not represent the amount needed for optimal functioning of the body.

The major PUFAs in our diets are the n-6 fatty acids including linoleic acid, which is the predominant PUFA in most edible vegetable oils consumed in the United States. The major vegetable oils consumed in the United States are soybean, corn, and cottonseed oils, which comprise more than 82% of the total fats and oils used in foods (ISEO, 1988). More than 50% of the total fatty acids of these vegetable oils are linoleic acid.

Although a wide range of symptoms was ascribed to the deficiency of EFAs, their biological functions were unknown until early 1964, when Van et al. (1964) and Bergstroem et al. (1964) demonstrated that prostaglandins (PGs) are synthesized from PUFAs derived from dietary EFAs in animal tissues. It is now generally recognized that EFAs have both a structural role in maintaining the integrity of cell membranes and a functional role in serving as precursors of eicosanoids.

III. DIETARY ESSENTIAL FATTY ACIDS AS PRECURSORS OF EICOSANOIDS

Long-chain PUFAs, which are the precursors of eicosanoids, can be generated by the desaturation and elongation of dietary fatty acids in tissues, as shown in Figure 28.1.

Oleic acid (18:1n-9), which is the most abundant fatty acid in our food system, can be converted to 20:3n-9. This fatty acid cannot serve as a substrate for cyclooxygenase (COX). Therefore, no PGs is synthesized from 20:3n-9. However, 20:3n-9 is a substrate for 5-lipoxygenase (5-LOX) from rat RBL-1 cells leading to the formation of leukotriene A_3 (LTA_3) (Stenson et al., 1984).

There is an indication that 20:3n-7 derived from palmitoleic acid can be converted to PGs (Lands et al., 1977). However, 20:3n-7 does not accumulate in animal tissues in significant amounts. It has been shown that the 5- LOX in RBL-1 cells requires double bonds at C-5 and C-8 for catalysis to occur. This structural requirement suggests that 20:3n-7 is not a substrate for 5-LOX (Jakschik et al., 1980).

Linoleic acid (18:2n-6) can be desaturated and elongated to arachidonic acid (20:4n-6) in animal tissues. Arachidonic acid is the predominant 20-carbon PUFA present in most tissues of terrestrial animals. Thus, eicosanoids synthesized in animal tissues are mostly derived from arachidonic acid. The metabolic map for the arachidonic acid cascade is shown in Figure 28.2. Arachidonic acid is a precursor of "2-series" PGs and thromboxanes and 4-series leukotrienes. The biosynthesis and physiological actions of various eicosanoids have been reviewed extensively (Nicosia and Patrono, 1989; Samuelsson, 1983; Samuelsson et al., 1987; Smith et al., 1991).

α-Linolenic acid (18:3n-3) can be converted to longer-chain n-3 PUFAs by the same desaturases used for n-6 or n-9 fatty acids. The extent to which α-linolenic acid is converted to longer-chain PUFAs is not known. Dyerberg et al. (1980) suggested that α-linolenic acid is not converted to 20:5n-3 in humans on the basis of their observations that insignificant amounts of 20:5n-3 in plasma lipids were found in human subjects who consumed linseed oil. Similarly, Adam et al. (1986) showed

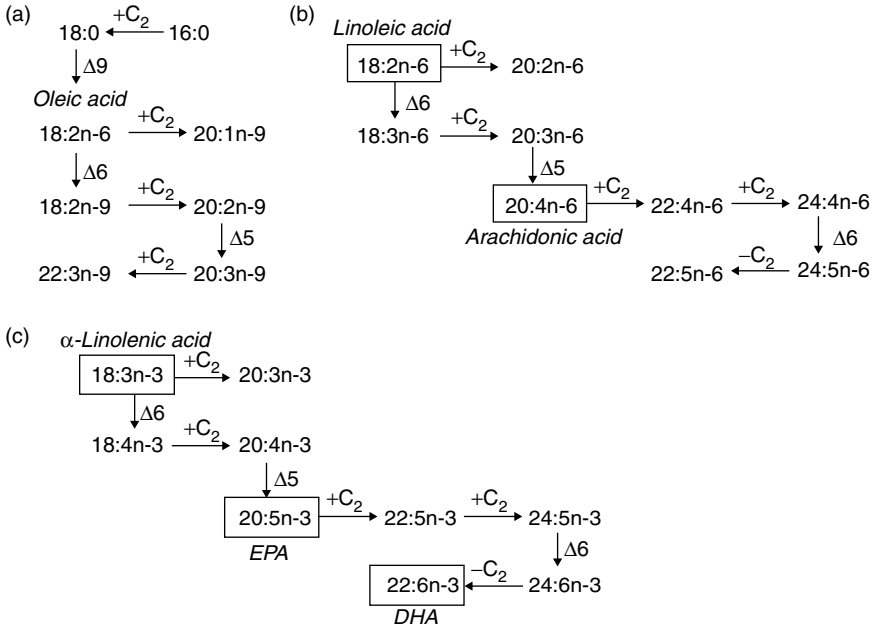

FIGURE 28.1 Conversion of dietary fatty acids to longer-chain polyunsaturated fatty acids and precursor acids for eicosanoids. The first number denotes the number of carbon atoms, the number after the colon denotes the number of double bonds, and the number after n denotes the position of the last double bond from the methyl end of fatty acids. EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

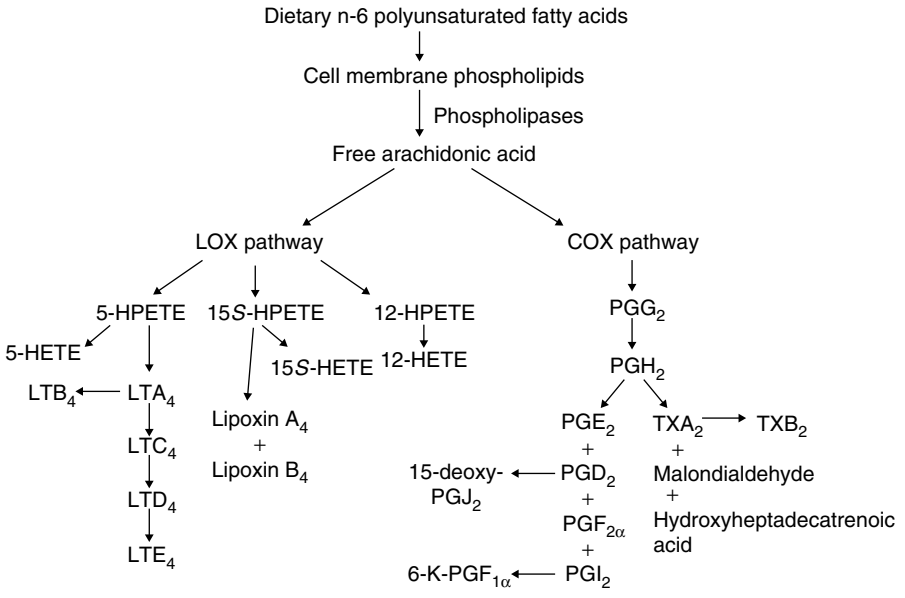

FIGURE 28.2 Eicosanoid formation from arachidonic acid via the cyclooxygenase and lipoxygenase pathways. LOX, lipoxygenase; COX-2, cyclooxygenase; LTA_4, leukotriene A_4; TXA_2, thromboxane A_2; PGH_2, prostaglandin H_2; HPETE, hydroperoxyeicosatetraenoic acid; HETE, hydroxyeicosatetraenoic acid.

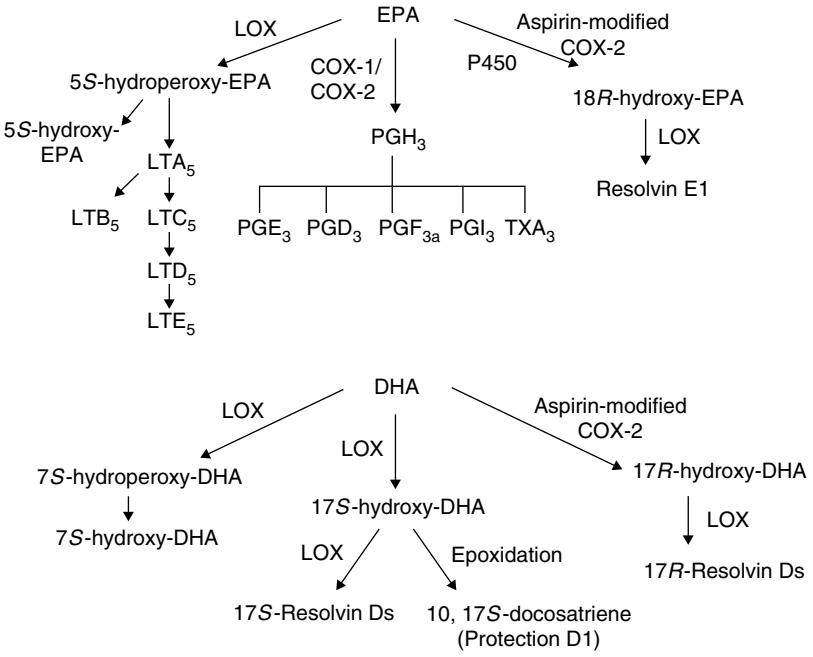

FIGURE 28.3 The biosynthesis of prostanoids, resolvins, and protectins from eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The metabolism of EPA by cyclooxygenase (COX) leads to the formation of the "3-series" of prostanoids. The acetylated COX-2 by aspirin produces 18*R*-hydroxy-EPA in endothelial cells that are sequentially metabolized to Resolvin E1 by LOX in neutrophils.

that ingestion of α-linolenic acid did not affect levels of 18:3n-6 or 20:4n-6 in plasma and platelet phospholipids in human volunteers. However, levels of PGE_2 in urine samples were reduced by dietary α-linolenic acid in a dose-dependent fashion. Thus, the possibility that dietary α-linolenic acid can be desaturated and elongated to longer-chain n-3 fatty acids in other tissues cannot be ruled out on the basis of fatty acid composition of plasma and platelet lipids alone. Furthermore, the results of these studies were derived from relatively short-term feeding trials (less than 2 weeks).

Eicosapentaenoic acid (EPA, 20:5n-3) can be metabolized by both COX and 5-LOX leading to the formation of "3-series" PGs, thromboxane A_3 (TXA_3), and "5-series" leukotrienes (Figure 28.3) (Dyerberg et al., 1978; Fischer and Weber, 1983; Gryglewski et al., 1979; Needleman et al., 1979). EPA is a poorer substrate for COX than arachidonic acid (Culp et al., 1979). Thus, it acts as a competitive inhibitor. Since EPA is a poor substrate, tissues of animals fed fish oil diets synthesized *in vitro* very small amounts of triene PGs and TXA_3. However, it has been shown that urine samples of human subjects consuming fish oil contain greater amounts of metabolites of triene PGs than those of diene PGs derived from arachidonic acid (Fischer and Weber, 1983; FitzGerald et al., 1984). The reason for the discrepancy between the *in vivo* and *in vitro* results has not been resolved. Overall, these studies appear to have established the cause and effect relationships among dietary fatty acids, eicosanoid formation, their cellular responses, and perhaps certain chronic diseases. Aspirin-treated COX-2 converts EPA to 18*R*-hydroxy-EPA (18-HEPE) in vascular endothelial cells, which is further metabolized to resolvin E1 (5*S*,12*R*,18*R*-trihydroxy-6Z,8E,10E,14Z,16E-EPA) by 5-LOX in neutrophils (Serhan et al., 2000). EPA was shown to be a preferred substrate for 5-LOX as compared to arachidonic acid (Ochi et al., 1983). Thus, increasing dietary n-3 PUFAs suppressed LTB_4 formation and increased formation of LTB_5 in human neutrophils.

Docosahexaenoic acid (DHA, 22:6n-3) can be converted to 7*S*- or 17*S*-hydroperoxy-DHA by LOX. 17*S*-hydroxyDHA is further metabolized to 17*S*-Resolvin D by LOX or converted to 10,

TABLE 28.1
Physiological Actions of Eicosanoids

Eicosanoid	Effect
PGE_1	Inhibits platelet aggregation
PGE_2	Vasodilation; increases cAMP levels; decreases gastric acid secretion; suppresses immune response; luteotropic action
PGI_2	Relaxes smooth muscle; vasodilation; inhibits platelet aggregation; raises cAMP levels
TXA_2	Contracts smooth muscle; causes platelet aggregation; bronchoconstriction
PGD_2	Inhibits platelet aggregation; raises cAMP levels; causes peripheral vasodilation
LTB_4	Neutrophil and eosinophil chemotaxis; leakage in micro circulation; raises cAMP levels; causes neutrophil aggregation
LTC_4–LTD_4	Contracts smooth muscle; constricts peripheral airways; leakage in microcirculation; decreases cAMP levels
12-HETE–12-HPETE	Neutrophil chemotaxis; stimulates glucose-induced insulin secretion
15-HETE	Inhibits 5- and 12-lipoxygenases
Lipoxin A	Superoxide anion generation; chemotaxis; activates protein cell activity
Lipoxin B	Inhibits NK cell activity
Resolvins	Block PMN transmigration and infiltration; inhibit microglial cell cytokine expression
Protectins	Block PMN recruitment and activation; inhibit TNF-α secretion

Abbreviations: PG, prostaglandin; TX, thromboxane; LT, leukotrine; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; NK, natural killer.

17*S*-docosatriene called neuroprotectin D1 through epoxidation process (Hong et al., 2003). DHA is a poor substrate for COX. However, DHA can be converted to 17*R*-hydroxyDHA by aspirin-treated COX-2 and subsequently, to 17*R*-resolvin D series by 5-LOX (Serhan et al., 2002).

IV. PHYSIOLOGICAL ACTIONS OF EICOSANOIDS

The eicosanoids exert diverse actions on the cardiovascular, reproductive, respiratory, renal, endocrine, skin, nervous, and immune systems (Table 28.1). Many of the actions are due to their capacity to change vascular tone and cAMP concentrations in the tissues. The kinds of eicosanoids synthesized vary with the type of tissue. As an example, thromboxane A_2 (TXA_2), which is a potent platelet-aggregating agent, is mainly synthesized in platelets (Hamberg et al., 1975), whereas prostaglandin I_2 (PGI_2), which is a potent inhibitor of platelet aggregation, is formed by endothelial cells (Bunting et al., 1976). Eicosanoids are synthesized when and where cells are stimulated. Eicosanoids are not stored in cells, and they are rapidly metabolized. Thus, the effects of eicosanoids are locally expressed.

A. Prostaglandins and Thromboxanes

Prostanoids, PGs, and TXA_2 are produced by the action of COX, or PGHS (prostaglandin G/H synthase). The series 2 PGs and thromboxanes derived from arachidonic acid generally promote inflammation with potent chemotactic activity, serve as vasoconstrictors, and stimulate platelet aggregation. In contrast, the "3-series" PGs and thromboxanes from EPA act as vasodilators and antiaggregators. Prostanoids act as autacoids by activating specific G-protein coupled receptors (GPCRs). Prostacyclin, the IP; $PGF_{2\alpha}$, the FP; TXA_2, the TP; PGE_2, EP1-4; PGD_2, DP1, and DP2; EP2, EP4, IP, and DP1 are the relaxant receptors that increase cAMP levels, whereas EP1, FP, and TP are the contractile receptors that increase intracellular calcium levels. EP3 increases intracellular calcium, but decreases cAMP level.

TXA_2 is a potent vasoconstrictor and platelet agonist. TXA_2 is produced by platelet COX-1 and macrophage COX-2. The protective effect of aspirin on cardiovascular system is considered to be attributed to the inhibition of platelet COX-1. PGI_2 is a potent vasodilator and inhibitor of platelet aggregation. Increase of PGI_2 production suppresses the proliferation and migration of vascular smooth muscle cells in response to injury. PGD_2 is the major product released from mast cells during allergic responses and asthma. PGE_2 is involved in a variety of biological processes including cell growth and proliferation, contraction and dilation of smooth muscle, reproduction, and inflammation. There are four PGE_2 receptors, EP1–4. The differential expression of four receptors and PGE_2 level dictate the outcome of PGE_2 action in the specific cell type. EP4 activation leads to platelet inhibition at low-PGE_2 concentration while high concentration of PGE_2 activates EP3 resulting in platelet aggregation. $PGF_{2\alpha}$ induces smooth muscle contraction. The activation of FP is known to lead to vaso- and bronchoconstriction and cell proliferation. TXA_3 is much less potent than TXA_2 in inducing platelet aggregation (Needleman et al., 1979). However, PGI_3 is as effective as PGI_2 in inhibiting platelet aggregation. For this reason, dietary EPA is implicated to reduce the risk of thrombosis.

B. Leukotrienes

4-Series leukotrienes are generated from arachidonic acid by 5-LOX in leukocytes. Leukotriene A_4 (LTA_4) is an unstable intermediate that is metabolized to leukotriene B_4 (LTB_4). LTB_4 increases the adhesion of leukocytes and the recruitment of $CD8^+$ cytotoxic T lymphocytes at sites of inflammation. LTA_4 is also converted to LTC_4, LTD_4, and LTE_4 that are slow-reacting substances of anaphylaxis and promote endothelial cell permeability and airway smooth-muscle constriction during anaphylactic reactions. LTB_4 activates BLT_1 and BLT_2 while LTC_4, LTD_4, and LTE_4 activate $CysLT_1$ or $CysLT_2$ to exert proinflammatory activities (Funk, 2005).

LTB_5 that is generated from EPA is less potent than LTB_4 in chemotactic and aggregating activities for human neutrophils (Lee et al., 1984, 1985). However, the efficacy of 5-series leukotrienes compared with that of 4-series leukotrienes on other physiological responses is not known.

C. Lipoxins

5*S*,6*R*,15*S*-trihydroxy-7,9,13-*trans*-11-*cis*-eicosatetraenoic acid (LXA_4) and its positional isomer 5*S*,14*R*,15*S*-trihydroxy-6,10,12-*trans*-8-*cis*-eicosatetraenoic acid (LXB_4) are the major lipoxins found in mammals. The 15-epi-lipoxins are endogenous 15*R*-enantiomers of LXA_4 and LXB_4 and also called as the aspirin-triggered lipoxins. Lipoxins can be generated from arachidonic acid through three different enzymatic pathways. First, arachidonic acid is converted to LTA_4 by 5-LOX in polymorphonuclear leukocytes (PMNs). LTA_4 is subsequently metabolized to LXA_4 and LXB_4 by platelet 12-LOX. Second, arachidonic acid is also a substrate of 15-LOX to generate 15*S*-HPETE that is subsequently converted to 5,6-epoxytetraene by 5-LOX in PMNs. Then LXA_4 and LXB_4 are generated by epoxide hydrolases in leukocytes. Third, 15-epi-LXA_4 and 15-epi-LXB_4 can be generated by 5-LOX in leukocytes from 15*R*-HETE that is converted from arachidonic acid by aspirin-acetylated COX-2. Lipoxins are known to be expressed during the resolution phase of inflammation. Lipoxins are anti-inflammatory mediators that inhibit leukocyte migration, NF-κB activation, and the expression of chemokines, cytokines, and adhesion molecules (Gilroy et al., 2004). Lipoxin A_4 (LXA_4) activates two receptors, a G-protein-coupled receptor, LXAR (or FPRL1, formylpeptide receptor-like 1), and a nuclear receptor, AhR (Devchand et al., 2003; Maddox et al., 1997; Schaldach et al., 1999). LXA_4 decreases LTB_4- and fMLP-induced Ca^{2+} mobilization in PMNs resulting in the suppression of neutrophil chemotaxis, adhesion, and superoxide generation. LXA_4 stimulates clearance and phagocytosis of apoptotic PMNs, which is associated with increased production of TGF-β1 and decreased release of IL-8 and monocyte chemotactic protein-1 (MCP-1). A recent report has shown that the stimulation of denderitic cells with lipoxins resulted in the expression of suppressor of cytokine signaling (SOCS)-2 (Machado et al., 2006).

D. Resolvins

Whereas arachidonic acid is metabolized to epi-lipoxins by consecutive action of aspirin-aceylated COX-2 and LOX, resolvins can be generated from n-3 PUFAs, DHA, and EPA by COX-2 and LOX. Aspirin-acetylated COX-2 in vascular endothelial cells and LOX in leukocytes synthesize 18*R*-Resolvin E1 from EPA and 17*R*-Resolvin D series from DHA, respectively. 17*S*-Resolvin D series and protectin D1 are generated from DHA by LOX (Schwab and Serhan, 2006). The resolvins and protectins are endogenously found during the resolution phase of inflammation. The resolvins and protectins showed potent anti-inflammatory activities through the inhibitory effects on the leukocytes activation and the proinflammatory mediator synthesis (Serhan and Savill, 2005). Resolvin E1 showed the protective effect on inflammatory responses in periodontitis and 2,4, 6-trinitrobenzene sulfonic acid-induced colitis by decreasing PMN recruitment (Arita et al., 2005b; Hasturk et al., 2006). Resolvin E1 acts on a specific GPCR, ChemR23 to downregulate NF-κB activation (Arita et al., 2005a). Resolvin D series inhibits infiltration of leukocytes and IL-1β production in microglial cells (Hong et al., 2003). Both 17*S*-resolvin Ds and 17*R*-resolvin Ds have similar activity in inhibiting PMN infiltration. Protectin D1, 10,17*S*-docosatriene, possess potent neuroprotective activity by inhibiting NF-κB activation, COX-2 expression, and PMN infiltration in cultured neuronal cells and ischemic stroke animal model (Marcheselli et al., 2003).

Excessive and/or imbalanced synthesis of eicosanoids has been implicated in various pathological conditions, including thrombosis, inflammation, asthma, ulcers, and kidney disease. Specific inhibitors of enzymes in COX and LOX pathways and receptor antagonists for specific eicosanoids have been tried and used as therapeutic agents for many of the disorders mentioned above. Accumulated evidence suggests that the amounts and types of eicosanoids synthesized in tissues can also be modulated by manipulating dietary fatty acids. Thus, it may be possible that risk factors of certain chronic diseases can be reduced by modulating eicosanoid biosynthesis through changes in the composition of dietary fatty acids.

V. REGULATION OF EICOSANOID BIOSYNTHESIS

There are many factors that can regulate eicosanoid biosynthesis in tissues. First, substrate availability is an important limiting factor in the biosynthesis of eicosanoids. The immediate substrate for eicosanoid biosynthesis is free arachidonic acid (Lands and Samuelsson, 1968). Arachidonic acid is incorporated into tissue phospholipids. Cellular concentration of free arachidonic acid is extremely low. Thus, arachidonic acid has to be released by the action of phospholipases to initiate the synthesis of eicosanoids.

Second, pharmacological agents, which can inhibit activities of phospholipases or key enzymes in the arachidomic acid cascade, suppress the formation of eicosanoids. Corticosteroid and mepacrine, which inhibit phospholipase A_2, can inhibit release of the immediate precursor acids of eicosanoids (Flower et al., 1989; Hirata, 1989). Thus, they can suppress the formation of both COX- and LOX-derived eicosanoids. Many nonsteroidal anti-inflammatory drugs inhibit COX, resulting in preferential suppression of the formation of eicosanoids derived from the COX pathway (Nelson, 1989). COX requires peroxides, particularly lipid hydroperoxides, as activators (Lands et al., 1984). Thus, agents that affect peroxide levels would modulate the COX activity. Phenolic antioxidants are known to inhibit PG synthesis as a result of reduced lipid peroxide levels. Glutathione peroxidase also suppresses PG biosynthesis by removing lipid hydroperoxides (Lands et al., 1977).

The studies (Raz et al., 1988; Wu et al., 1988) indicate that the synthesis of COX enzyme itself is another important factor affecting PG biosynthesis. COX is irreversibly inactivated by the substrate (Hemler and Lands, 1980). This may be due to the oxidizing equivalent released during the reduction of PGG_2 to PGH_2 by PGH synthase, an enzyme that possesses both COX and peroxidase activity (Gale and Egan, 1984). If purified enzyme is incubated with the substrate, oxygen consumption ceases before the substrate is depleted. The reaction can be started again only if the fresh enzyme

is added. This suggests that the synthesis of new enzyme would be required to maintain the biosynthesis of PGs in tissues.

VI. MODULATION OF EICOSANOID BIOSYNTHESIS BY DIFFERENT DIETARY FATTY ACIDS

The immediate precursor acid of eicosanoids is nonesterified free fatty acid (Lands and Samuelsson, 1968). Since most PUFAs are esterified mainly in the *sn*-2 position of phospholipids, the amounts of precursor acid released from phospholipids can limit the rate and amounts of eicosanoid synthesis. The amounts and types of precursor acid released from phospholipids depend on the composition of fatty acids in tissue phospholipids, which in turn is influenced by the composition of dietary fatty acids.

There are two steps in which dietary fatty acids can modulate eicosanoid biosynthesis from arachidonic acid. The first step is in the desaturation and elongation. There is a competitive inhibition among linoleic acid and linolenic acid families for the conversion of the fatty acids to longer-chain PUFAs. The observation that n-3 PUFAs can decrease the conversion of linoleic acid to arachidonic acid was first made by Machlin (1962) and subsequently by Mohrhauer and Holman (1963).

Although these observations were made even before the discovery that PGs are synthesized from 20:3n-6 and arachidonic acid derived from EFAs, they provided a predictable basis for the modulation of eicosanoid biosynthesis by modifying dietary fatty acid composition. The far-reaching nutritional significance of this is that modification of the composition of dietary fatty acids can be used to modulate the biosynthesis of eicosanoids and consequent physiological responses. Furthermore, it can be used as a new strategy to prevent and/or ameliorate certain chronic diseases for which modulation of eicosanoid biosynthesis is desirable.

The second step in which dietary fatty acids can modulate the biosynthesis of eicosanoids is at the formation of endoperoxide intermediate. The n-3 fatty acids competitively inhibit the oxygenation of arachidonic acid by COX (Lands et al., 1973). The competitive inhibition between n-3 and n-6 PUFAs for desaturases and COX suggests that increasing n-3 PUFAs in diets would reduce arachidonic acid levels in tissue lipids and, consequently, would decrease the formation of eicosanoids derived from arachidonic acid. It has been suggested that the bleeding tendency and low incidence of coronary heart disease among native Greenland Eskimos, whose diets consist mainly of cold water marine animals, is attributed to enhanced levels of n-3 PUFAs in their blood lipids (Dyerberg and Bang, 1979; Dyerberg et al., 1978).

It has been shown that α-linolenic acid can suppress arachidonic acid levels in tissue lipids and eicosanoid biosynthesis from arachidonic acid, although it is less effective than longer-chain n-3 PUFAs, which are abundant in marine lipids (Hwang et al., 1988). α-Linolenic acid is not a substrate for COX or 5-LOX; thus, no thromboxanes or leukotrienes can be formed from it.

In addition to competitive inhibitory effects, another mechanism through which PUFAs reduce eicosanoid biosynthesis has been recently proposed. The expression of COX-2, which is a rate-limiting enzyme to generate PGs from arachidonic acid released from plasma membrane, is upregulated in response to proinflammatory stimuli. The activation of Toll-like receptors in response to microbial infection or endogenous agonists leads to enhanced expression of inflammatory gene products including COX-2 and cytokines (Beutler, 2004; Lee et al., 2001, 2003). Various PUFAs (n-6 and n-3) suppress the expression of COX-2 induced by bacterial components mediated through the inhibition of Toll-like receptor activation (Lee et al., 2001, 2003). n-3 PUFAs (EPA and DHA) showed the highest potency in inhibiting the activation of Toll-like receptors 2 and 4 resulting in the reduced PGE_2 synthesis (Lee et al., 2003, 2004). This provides a novel mechanism as to how dietary PUFAs regulate the level of eicosanoids at inflammatory sites.

If inclusion of n-3 PUFAs in diets is desirable to suppress eicosanoid synthesis, an important practical question would be how much of them should be added into the diet. It has been shown that when rats were fed graded amounts of n-3 fatty acids (trilinolein and fish oil) in the presence of a

constant amount of linoleic acid, the levels of arachidonic acid in tissue lipids and the formation of eicosanoids derived from arachidonic acid were suppressed in a dose-dependent fashion (Hwang et al., 1988). However, if rats were fed graded amounts of the n-3 fatty acids with constant ratios of n-3/n-6 fatty acids (0.62 for linolenate and 0.3 for menhaden oil groups) by concomitant increases in n-6 fatty acid, then there was no dose response within groups fed different levels of the same dietary fat at a constant n-3/n-6 ratio (Boudreau et al., 1991). These results indicate that the ratio of n-3/n-6 fatty acids in the diet, rather than the absolute amount of n-3 fatty acids, is the determining factor in inhibiting eicosanoid biosynthesis from arachidonic acid. Thus, in assessing desirable levels of dietary n-3 fatty acids, not only the absolute amounts of n-3 fatty acids but also the amounts of dietary n-6 fatty acids may have to be adjusted.

However, the results from human studies demonstrated that absolute amounts of fish oil, and not the relative amounts of fish and vegetable oil (ratios of n-3 and n-6 PUFAs), determined the magnitude of the reduction of arachidonic acid and increase in eicosapentaenoic in phospholipids of plasma and platelets (Hwang et al., 1997). The suppression of plasma triglycerides by fish oil was also not affected by varying amounts of dietary n-6 PUFAs (Hwang et al., 1997).

VII. INCORPORATION OF n-3 FATTY ACIDS INTO FOOD SYSTEMS

If incorporation of n-3 fatty acids into processed foods is desired in the future, plant oils containing α-linolenic acid as a major PUFA would have certain advantages over fish oil. α-Linolenic acid is abundant in certain plant seed oils, and it is the major PUFA in chloroplast lipids, as shown in Table 28.2. In spite of the suggested beneficial effect of n-3 PUFAs in reducing certain risks of coronary heart disease, there would be a limitation for the direct incorporation of fish oil into food systems owing to its undesirable flavor and the greater susceptibility of EPA and DHA to autoxidation compared to α-linolenic acid.

Fish oil or plant seed oils containing α-linolenic acid can be added as supplements to feeds for poultry or aquacultured fish to increase the n-3/n-6 fatty acid ratios. Feeding linseed oil or menhaden oil at the 1.0%, 2.5%, or 5.0% level to broiler chickens resulted in a significant increase in n-3 PUFAs and a decrease in n-6 PUFAs, with a consequent increase in the n-3/n-6 fatty acid ratio in thigh muscle lipids compared to the control group, which was fed a corn oil diet (Chanmugam et al., 1992). The increase in the n-3/n-6 fatty acid ratio by linseed oil was much greater than by menhaden oil.

It has been demonstrated that the lipids from pond-reared prawn and catfish have considerably lower amounts of n-3 fatty acids compared with lipids of their wild counterparts (Chanmugam et al., 1986). This difference is due to the diet used for commercial aquaculture, which contains soybean meal in which n-6 PUFAs predominate, whereas marine animals consume diets derived from plankton, which are rich in n-3 fatty acids. The content of n-3 fatty acid in aquacultured fish

TABLE 28.2
Fatty Acid Composition of Total Lipids from Selected Vegetables and Nuts (wt. %)

Fatty Acid	Frozen Spinach	Green Bell Pepper	Green Cabbage	Broccoli	Romaine Lettuce	Walnut	Linseed Oil
16:0	16.22	23.79	16.42	18.90	12.75	2.05	7.33
16:1n-7	3.82	0.09	3.66	2.72	3.76	8.45	—

can also be increased by supplementing their feeds with fish oil or plant oil containing a high level of α-linolenic acid.

VIII. DIETARY γ-LINOLENIC ACID (18:3n-6)

Certain plant oils such as primrose seed and borage seed oil contain considerable amounts of γ-linolenic acid. Approximately 8% of the total fatty acids of primrose oil is 18:3n-6. Some studies suggested that primrose oil suppresses acute and chronic inflammation in rats (Kunkel et al., 1988; Tate et al., 1988). It was speculated that this anti-inflammatory effect of primrose oil is due to accumulation of dihomo-γ-linolenic acid (20:3n-6) derived from γ-linolenic acid, and dihomo-γ-linolenic acid competes with arachidonic acid for COX, resulting in suppressing the formation of diene PGs derived from arachidonic acid. Furthermore, dihomo-γ-linolenic acid cannot be converted to leukotrienes. However, dihomo-γ-linolenic acid does not normally accumulate in animal tissues in significant amounts. Dietary γ-linolenic acid would be converted mostly to arachidonic acid. The ratio of dihomo-γ-linolenic acid (20:3n-6) to arachidonic acid (20:4n-6) is normally less than 1:30 in rat tissue lipids. In fact, one of the studies (Tate et al., 1988) suggesting the beneficial effect of primrose oil on acute inflammation showed that arachidonic acid levels in serum lipids of rats fed primrose oil were much higher than those of rats fed chow or a safflower oil diet. Some studies (Kernoff et al., 1977) also suggested that the oral administration of dihomo-γ-linolenic acid is beneficial in the treatment of thromboembolic diseases. This suggestion may be based on the fact that, unlike PGE_2, PGE_1 derived from dihomo-γ-linolenic acid inhibits platelet aggregation. However, since dihomo-γ-linolenic acid can be converted to TXA_1 but cannot be converted to prostacyclin, the beneficial effects of long-term administration of dihomo-γ-linolenic acid are questionable. Furthermore, dihomo-γ-linolenic acid can be readily converted to arachidonic acid in tissues.

IX. DIETARY *TRANS* FATTY ACIDS

Geometrical and positional isomers of octadecenoate (18:1) comprise the major portion of fatty acid isomers present in partially hydrogenated vegetable oil. Various positional isomers of *trans*-octadecenoate can be desaturated *in vitro* by Δ9, Δ6, or Δ5 desaturases (Mahfouz et al., 1980). Some of them may be further elongated to longer-chain PUFAs (Kameda et al., 1980). However, the presence of 20-carbon PUFAs derived from *trans*-octadecenoate in significant amounts in tissue lipids has not been reported. Possible effects of geometrical and positional isomers of octadecenoate and longer-chain PUFAs derived from the isomers on eicosanoid formation have not been reported.

Three different kinds of geometrical isomers of linoleic acid are present in hydrogenated vegetable oil: 9-*trans*-, 12-*trans*-; 9-*trans*; 12-*cis*; and 9-*cis*, 12-*trans*-linoleic acid. 9-*cis*, 12-*trans*-linoleic acid is present in most vegetable shortenings in much greater quantities than 9-*trans*, 12-*trans*-linoleic acid (Lanza and Slovar, 1981). Unlike 9-*trans*, 12-*trans*-linoleic acid, 9-*cis*, 12-*trans*-linoleic acid can be converted to arachidonic acid containing a *trans* double bond (Privett et al., 1967). It was shown that *trans* isomers of arachidonic acid inhibited the formation of PGs from all-*cis*-20:4n-6 (Nugteren, 1970). Some *trans* isomers (9-*trans*, 12-*cis* and 9-*trans*, 12-*trans*) of linoleate inhibit the conversion of *cis*-linoleate to arachidonic acid (Privett and Blank, 1964; Privett et al., 1977). It was demonstrated that dietary *trans* (9-*trans*, 12-*trans*)-linoleate at levels equal to or greater than that of *cis*-linoleate suppresses arachidonic acid levels in tissue lipids and the formation of eicosanoid by platelets in rats (Hwang and Kinsella, 1979; Hwang et al., 1982). However, the level of 9-*trans*, 12-*trans*-linoleate does not exceed 0.5% of total fatty acids of partially hydrogenated vegetable oils (Lanza and Slovar, 1981). Such a level does not appear to be enough to suppress the formation of eicosanoids derived from arachidonic acid.

X. CONCLUSION

The level of intake of dietary PUFA recommended by the American Heart Association is based on the lowering effect of dietary PUFA on the blood cholesterol level, which is one of the important risk factors of coronary heart disease, the leading cause of death in the United States. Dietary PUFA has been used as an entity without differentiating the kind of PUFA. There are two types of dietary PUFA: n-3 and n-6 fatty acids. Linoleic acid (18:2n-6) is the predominant PUFA in the major vegetable oils consumed in the United States. Thus, linoleic acid is the major dietary PUFA in the diet. Among n-3 PUFA, α-linolenic acid (18:3n-3) is abundant in certain plant seed oils and is the major PUFA in chloroplast lipids. Longer-chain n-3 PUFAs such as EPA (20:5n-3) and DHA (22:6n-3) are abundant in marine lipids.

Twenty-carbon PUFAs derived from EFA are precursors of eicosanoids with diverse pathophysiological actions in the cardiovascular system and inflammatory processes. It has been implied that excessive and/or imbalanced synthesis of eicosanoids in tissues can lead to the development of certain pathological conditions. It is now well documented that the amounts and types of eiocosanoids synthesized in tissues can be modulated by manipulating the composition of dietary fatty acids. Epidemiological, clinical, and biochemical studies performed during the past two decades suggest that replacing dietary n-6 PUFA with n-3 PUFA to some extent is beneficial in reducing risks of certain chronic diseases. It has been revealed that dietary n-3 PUFA suppresses tissue levels of arachidonic acid, the biosynthesis of eicosanoids derived from arachidonic acid and the expression of inflammatory gene products including COX-2. Furthermore, eicosanoids derived from EPA possess a different potency with respect to various cellular responses as compared with those derived from arachidonic acid. This suggests that biosynthesis of eicosanoids and their cellular responses can be modulated by modifying the relative amounts of n-3 and n-6 PUFA in the diet. For this reason, types of PUFA may have to be defined in recommendations of dietary PUFA levels in the future dietary guidelines.

29 Polyunsaturated Fatty Acids and Regulation of Gene Expression

Harini Sampath and James M. Ntambi

CONTENTS

I. INTRODUCTION

It has now long been understood that lipids not only serve as important stores of energy, but also function as fine modulators of cellular signaling and metabolism. Fatty acids and especially polyunsaturated fatty acids (PUFAs) of the n-3 and n-6 series have been implicated in the modulation of various biochemical pathways. PUFAs decrease plasma lipid levels (Rambjor et al., 1996; Harris et al., 1997), improve the immune response (Hwang, 2000; Ntambi et al., 2002a), and increase insulin sensitivity (Storlien et al., 1998; Suresh and Das, 2003). The n-3 PUFAs are also preventive in several chronic diseases including coronary heart disease and stroke (Siscovick et al., 2000; von Schacky, 2000; Skerrett and Hennekens, 2003), inflammatory bowel disease (Kremer, 1996; Beluzzi et al., 2003), lung disease (Schwartz, 2000) as well as certain kinds of cancer such as breast, prostate, and colorectal cancers (Rose, 1997; de Deckere, 1999). Although the beneficial effects of n-3 PUFAs are clear, there is also some concern about possible detrimental effects of n-6 PUFAs due to their known roles in inflammatory and aggregatory pathways. Thus, better understanding of the mechanisms by which these fatty acids affect cellular metabolism will be invaluable in establishing a valid dietary n-3/n-6 fatty acid ratio for optimal health (Sampath and Ntambi, 2004).

Once fatty acids are taken up into the cell, they are rapidly converted to fatty acyl CoA thioesters (Figure 29.1) by one of six characterized acyl CoA synthetases (Coleman et al., 2000). These fatty acyl CoAs can then be shunted toward incorporation into complex lipids such as triglycerides (TG) and phospholipids, thereby decreasing the availability of fatty acyl CoAs within the cell (Figure 29.1). Alternately, they can be elongated/desaturated or oxidized through various pathways to give rise to second messengers such as prostaglandins and leukotrienes (Figure 29.1). Furthermore, the generation of fatty acyl CoAs is an energy requiring process that increases the cellular AMP/ATP ratio. This leads to secondary effects such as activation of AMP activated protein kinase (AMPK), which in turn can lead to changes in cellular and nuclear signaling (Kawaguchi et al., 2002). Thus, the

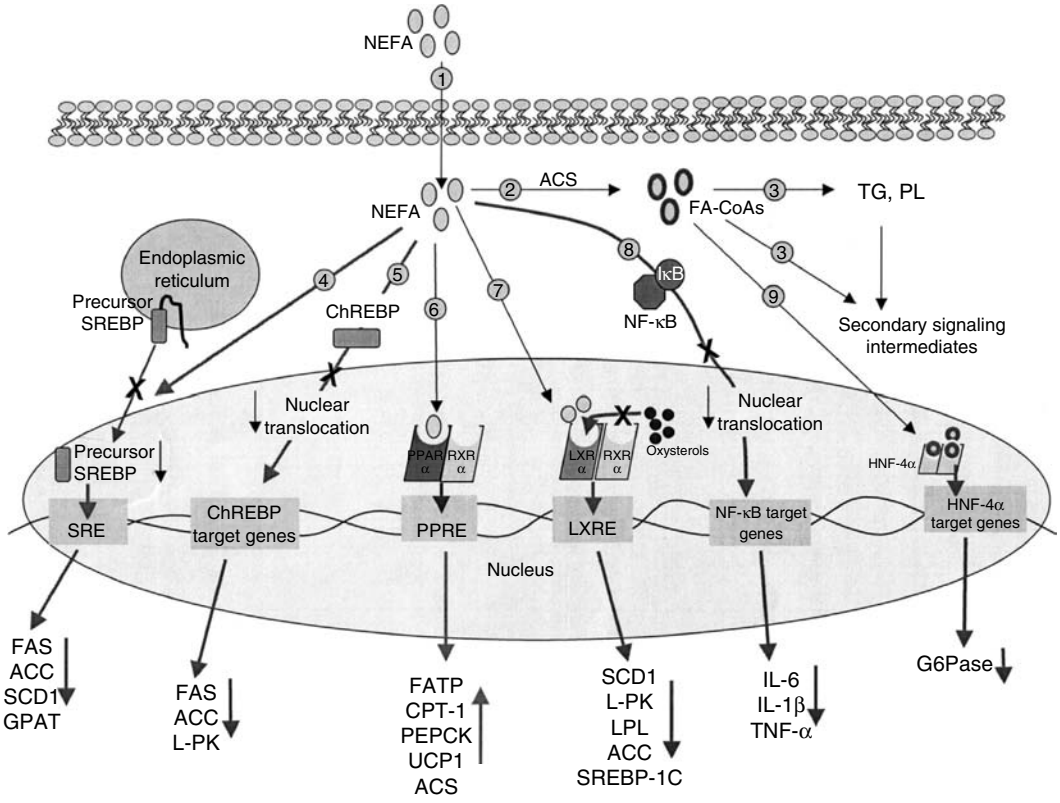

FIGURE 29.1 Once nonesterified fatty acids (NEFA) enter the cell (1), they can be rapidly converted to fatty acyl CoAs (2) by acyl CoA synthetases (ACS). Fatty acyl CoAs can then be esterified to complex lipids or give rise to secondary signaling intermediates (3). Alternately, NEFA or fatty acyl CoAs themselves can affect cellular signaling. Polyunsaturated fatty acids (PUFAs) can reduce lipogenic gene expression by decreasing the maturation of SREBP (4) as well as by reducing its expression and mRNA stability. PUFAs can also decrease the half-life and activity of ChREBP (5). On the other hand, PUFAs can serve as endogenous ligands for PPARa (6), thereby increasing oxidative gene expression. PUFAs can compete with oxysterols for binding to LXR and can also LXR binding to LXREs (7). PUFAs are also thought to inhibit NF-κB nuclear translocation (8). Fatty acyl CoAs can modulate the activity of HNF-4α (9). *Abbreviations:* ACC, acetyl CoA carboxylase; ChREBP, carbohydrate responsive element binding protein; CPT-1, carnitine palmitoyl transferase-1; FAS, fatty acid synthase; FATP, fatty acid transport protein; GPAT, glycerol phosphate acyl transferase; HNF-4α, hepatocyte nuclear factor-4α; IκB, inhibitor κB; IL, interleukin; L-PK, L-type pyruvate kinase; LPL, lipoprotein lipase; LXR, liver X receptor; NF-κB, nuclear factor κB; PEPCK, phosphoenolpyruvate carboxykinase; PPAR, peroxisome proliferator-activated receptor; PPRE, PPAR response element; RXR, retinoid X receptor; SCD1, stearoyl CoA desaturase-1; SRE, sterol response element; SREBP, sterol regulatory element binding protein; TNF, tumor necrosis factor; UCP1, uncoupling protein-1.

cellular and nuclear effects of fatty acids can be modulated not only by the site-specific metabolism and availability of the fatty acids, but also from the production of secondary signaling intermediates and activation of alternate pathways (Sampath and Ntambi, 2005).

II. SITE-SPECIFIC GENE REGULATION BY PUFAs

The ability of fatty acids to affect gene expression has been best characterized in the case of PUFAs. PUFAs regulate gene expression not only in liver and primary hepatocytes but also in many other

cell types including adipose tissue (Mater et al., 1998), small intestine (Niot et al., 1997), pancreas (Brun et al., 1997), the immune system (Tebbey and Buttke, 1993), and the neonatal mouse brain (DeWille and Farmer, 1993). In rodents, PUFA-rich diets repress various hepatic lipogenic genes including stearoyl CoA desaturase-1 (SCD1), acetyl CoA carboxylase (ACC), fatty acid synthase (FAS), and glucose-6-phosphate dehydrogenase (G6PDH) in the liver (Salati and Clarke, 1986; Clarke et al., 1990; Tebbey et al., 1994; Sessler et al., 1996; Cho et al., 1999; Jump et al., 1999a; Ntambi et al., 2002b; Wahle et al., 2003). In adipose tissue, PUFAs inhibit genes such as FAS in retroperitoneal fat but not in subcutaneous fat (Raclot et al., 1997), suggesting site-specific differences in fatty acid availability (Sessler and Ntambi, 1998). In addition, while hepatic genes respond to both n-3 and n-6 PUFAs in a similar manner, adipose genes are most responsive to n-3 PUFAs (Raclot et al., 1997), except for the SCD1 gene that is similarly regulated by both n-3 and n-6 fatty acids in adipose tissue (Sessler and Ntambi, 1998). Another difference between hepatic and adipose repression of lipogenic genes by PUFAs is the fact that in liver, PUFAs act directly to inhibit gene expression, while in adipose tissue, this effect may be mediated by eicosanoid intermediates (Mater et al., 1998; Jump et al., 1999).

Apart from repressing the expression of genes encoding enzymes involved in lipid synthesis, there is recent evidence that PUFAs also repress transcription of the leptin gene (Reseland et al., 2001). Leptin is an adipose-derived hormone that regulates appetite, body weight, and adiposity. Increased plasma leptin levels have been correlated with increased adiposity and obesity in humans, while weight loss results in decreased plasma leptin levels. High-fat diets increase plasma leptin levels in humans, but substitution of PUFAs for saturated fat in the diet causes a decrease in plasma leptin levels without effecting changes in body mass (Reseland et al., 2001). The effect on leptin gene expression is accompanied by decreased levels of transactivating factors such as peroxisome proliferator activated receptor-γ (PPAR-γ) and sterol regulatory element binding protein-1 (SREBP-1), discussed further below.

Conversely, PUFAs are involved in upregulation of genes of fatty acid oxidation and adipocyte differentiation. In the liver, PUFAs induce the expression of various genes including acyl CoA synthetase (Duplus et al., 2000), acyl CoA oxidase (Berthou et al., 1995), liver fatty acid binding protein (Meunier-Durmort et al., 1996), carnitine palmitoyl transferase-1 (Chatelain et al., 1996), and cytochrome P450 A1 (Duplus et al., 2000). In adipose tissue, both saturated as well as unsaturated long-chain fatty acids upregulate adipogenic genes (Duplus et al., 2000) in a direct manner (Grimaldi et al., 1992). For example, the gene encoding phosphoenolpyruvate carboxykinase (PEPCK), which in adipose tissue plays a role in TG synthesis, is upregulated in response to PUFAs; however, the same effect is not observed in the liver, where PEPCK serves as a gluconeogenic enzyme (Forest et al., 1997).

III. NUCLEAR RECEPTORS AND TRANSCRIPTION FACTORS

It was initially thought that fatty acids affect cellular metabolism solely through indirect mechanisms such as changing membrane phospholipid concentrations or producing signaling intermediates such as the eicosanoids. However, the actions of fatty acids on gene regulation occur within hours of feeding animals diets rich in PUFAs (Jump et al., 1993, 1994; Kim et al., 1999), suggesting a more direct mode of action. The discovery by Gottlicher et al. (1992) of nuclear receptors capable of binding fatty acids to modulate gene expression established a direct role for fatty acids at the nuclear level.

Nuclear receptors are found in metazoan organisms and contain two major domains (Beato, 1991). The ligand binding domain interacts with a ligand in order to induce binding of the DNA-binding domain to specific DNA sequences on target genes. These nuclear receptor specific DNA sequences are termed nuclear receptor response elements. Binding of the nuclear receptor to this sequence affects transcription of the target gene. DNA response elements can be direct repeat sequences such as AGGTCA-*Nx*-AGGTCA, where *N* can be any nucleotide and *x* refers to the number of residues

between the two direct repeats. Thus, a direct repeat sequence with a single nucleotide spacer is denoted as a DR1 element. Nuclear response elements can also exist as inverted repeats (IR) such as AGGTCA-*Nx*-ACTGGA or everted repeats (ER) such as ACTGGA-*Nx*-AGGTCA. Nuclear receptors that do not have a known ligand are termed orphan nuclear receptors (Forman and Evans, 1995). Unlike classical hormone receptors such as the thyroid hormone receptor or the retinoic acid receptor, some nuclear receptors do not bind a single compound with great specificity but rather a broad range of compounds, such as fatty acids and eicosanoids, with varying sensitivities. It has therefore been suggested that these nuclear receptors be classified as metabolic sensors rather than as classical nuclear receptors (Desvergne et al., 2006).

Transcription factors are proteins that bind to selected DNA sequences in the promoter or enhancer regions of target genes, often in conjunction with other proteins and in response to changes in cellular signaling. This binding leads to changes in the transcription of the target gene.

Our current understanding of the mechanisms whereby PUFAs affect gene expression is far from complete; however, several possible mechanisms for PUFA action have been well characterized. These include interactions of PUFAs with nuclear receptors such as peroxisome proliferators-activated receptors (PPARs), liver X receptors (LXRs), and hepatocyte nuclear factor-4α (HNF-4α), as well as regulation of the transcription factor, sterol regulatory element binding protein (SREBP), and carbohydrate response element binding protein (ChREBP).

IV. PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS

PPARs were the first nuclear receptors to be identified as possible mediators of fatty acid regulation of gene expression. Isseman and Green (1990) first characterized these nuclear receptors as transcription factors that belong to the superfamily of steroid nuclear receptors and include three different isoforms, α, β/δ, and γ. These three isoforms of PPARs are encoded by separate genes. PPARα is mainly expressed in brown adipose tissue and liver, as well as in the heart, skeletal muscle, kidneys, and enterocytes and is a key regulator of energy balance. PPARα regulates fatty acid uptake and oxidation in rodent liver and is activated by an array of fatty acids, eicosanoids as well as the hypolipidemic fibrate class of drugs (Desvergne et al., 2006). The prooxidative phenotype associated with PUFA feeding seems to be mainly regulated by the PPARα isoform and is reviewed further below. PPARγ is mainly expressed in adipose tissue and is shown to be a key regulator of adipocyte differentiation, energy storage and energy dissipation in white and brown adipose tissues. PPARγ is also expressed in monocytes/macrophages, endothelial cells, and vascular smooth muscle cells where its activation is associated with decreased monocyte expression and decreased production of proinflammatory cytokines (Ricote et al., 2004). PPARγ activation also results in improved insulin sensitivity, making this transcription factor the target of the thiazolidinedione class of drugs used in the clinical management of type II diabetes (Desvergne et al., 2006). Similar to PPARα, PPARγ binds fatty acids and eicosanoids as endogenous ligands. PPAR β/δ, which remains as the least characterized of the three isoforms, is ubiquitously expressed and binds fatty acids and eicosanoids without much specificity (Michalik et al., 2003).

Upon ligand activation, PPARs dimerize with the orphan nuclear receptor, RXR, and bind to DR1 elements termed peroxisome proliferator response elements (PPREs) (Desvergne and Wahli, 1999). Gottlicher et al. (1992) used a chimeric receptor of the putative PPAR ligand binding domain fused to the glucocorticoid receptor to show that linolenic and arachidonic acids activated the chimeric receptor, while cholesterol and DHEA did not. This led to PUFAs being established as the endogenous ligands of PPARs (Figure 29.1). It has since been shown that binding of PUFAs to PPARα causes rapid upregulation of target genes such as acyl CoA oxidase and CYP4A2 that are involved in peroxisomal β-oxidation (Berthou et al., 1995; Jump et al., 1999b). *In vitro* studies suggest that PPARs are capable of binding many different fatty acids. However, *in vivo*, PUFAs differentially regulate gene expression in various tissues and at different developmental stages possibly due to

differences in rates of fatty acid elongation, desaturation, and oxidation that result in alterations in fatty acid availability. The physiological significance of PUFA activation of PPARα has been established through the development of the PPARα-null mouse. Bing et al. (1997) showed that supplementation of the diet with fish oil, which is enriched in PUFAs, resulted in upregulation of genes of β-oxidation in wild-type mice. This effect was not observed in PPARα-null mice. However, fish oil feeding also resulted in repression of lipogenic genes such as S14 and FAS not only in wild-type animals, but also in PPARα knockout animals. This suggested that while the induction of oxidative genes by PUFAs occurs through a PPARα-dependent mechanism, the PUFA-induced repression of lipogenic genes is unlikely to involve PPARα (Bing et al., 1997). Overall, PUFA activation of PPARα results in increased expression of fatty acid oxidation genes (Figure 29.1), causing a decrease in hepatic and plasma TG.

V. STEROL REGULATORY ELEMENT BINDING PROTEINS

SREBPs were first identified due to their ability to regulate cholesterolgenesis by binding to specific sterol response elements (SREs) on target genes in response to fluctuations in cellular sterol concentrations. SREBPs belong to the family of helix–loop–helix family of transactivators (Osborne, 2000). Thus far, three SREBP isoforms have been identified that include SREBPs-1a and -1c and SREBP-2. SREBP-1c is the predominant isoform in rodent and human liver and is of immense physiological importance in the regulation of lipogenesis. SREBP-1a is encoded by the same gene as SREBP-1c and differs from the SREBP-1c isoform only at the N-terminus. SREBP-1a is highly expressed in cell culture models. SREBP-2 is encoded by a separate gene and regulates the expression of genes involved in cholesterol synthesis (Osborne, 2000).

The activation of SREBPs is regulated not only at the level of transcription, but also at the level of mRNA stability and protein maturation. The precursor SREBP proteins are inserted into the membrane of the endoplasmic reticulum with the COOH domain bound to the COOH domain of an escort protein, SREBP cleavage-activating protein (SCAP). When cellular sterol levels drop, SCAP escorts SREBP to the Golgi apparatus where it undergoes a two-step proteolytic cleavage through the actions of a site 1 and site 2 protease. The resultant smaller mature protein subsequently transits to the nucleus (Figure 29.1). Here, the SREBP protein binds to SREs in the promoter regions of target genes to affect transcription of genes involved in fatty acid and TG synthesis as well as cholesterolgenesis (Horton et al., 2002).

There is ample evidence, both *in vitro* and *in vivo*, suggesting that PUFAs repress lipogenic gene expression by affecting SREBP maturation in a posttranslational manner (Worgall et al., 1998; Kim et al., 1999). Incubation of CHO, HepG2, and CV-1 cells with PUFAs decreases expression of SRE containing genes in a dose-dependent manner. However, this regulation by PUFAs is lost in a cell line that has lost sterol regulation of SREBP, suggesting that the regulation of SREBP by PUFAs occurs upstream of SREBP binding to SREs on target genes (Worgall et al., 1998). Furthermore, *in vivo* studies have established that SREBP nuclear content is repressed by fasting and is greatly increased upon refeeding; this pattern corresponds to the expression pattern of various lipogenic SREBP-target genes such as ACC and FAS (Horton et al., 1998). However, the expression of these target genes as well as the nuclear abundance of SREBP-1c protein are greatly decreased by n-3 or n-6 PUFA supplementation in rats (Yahagi et al., 1999). In addition, rats overexpressing SREBP in liver do not display as great a reduction in lipogenic gene expression upon PUFA supplementation. These results suggest that PUFAs inhibit maturation of SREBP, possibly through increasing cellular cholesterol levels (Worgall et al., 2002).

In addition to affecting protein maturation, PUFAs, especially eicosapentanoate and arachidonate, decrease hepatic mRNA abundance of SREBP-1a and -1c, but not of SREBP-2. This reduction in SREBP mRNA has been attributed to changes in both mRNA stability as well as decreased SREBP transcription (Jump, 2002). Overall, the net effect of PUFA action on SREBPs is a reduction in

expression of lipogenic genes (Figure 29.1). This reduction in lipogenesis, along with the increase in fatty acid oxidation via PPARs, synergistically contributes to the hypolipidemic effect of PUFAs.

SREBP-1c is a very weak transactivator on its own and requires the presence of coactivators for maximal induction of gene expression (Magaña et al., 2000). One such coactivator is the transcription factor, PPARγ coactivator-1β (PGC-1β). Lin et al. (2004) have recently shown that treatment of cells with a variety of fatty acids, both saturated and unsaturated, results in increased expression and activation of PGC-1β. PGC-1β then functions as a coactivator of SREBP-1c, consequently activating downstream target genes such as FAS. However, treatment of these cells with a saturated fatty acid such as stearic acid also results in activation of the coactivator PGC-1α (Lin et al., 2004), which has been shown to be linked to pathways associated with the fasting response in liver (Puigserver, 2005). Hence, the physiological significance of the coordinate induction of both PGC-1α as well as PGC-1β by saturated fatty acids, and its consequent effect on SREBP-1c activity, is not yet clear.

Although the regulation of SREBP by PUFAs and expression of target lipogenic genes are closely correlated, there are also some emerging examples of SREBP-independent regulation of lipogenic genes. For example, Teran-Garcia et al. (2002) demonstrated that while dietary PUFAs reduce both hepatic SREBP as well as FAS content, mutation of the SRE in the promoter region of FAS results in only a 25% loss of PUFA regulation of FAS. On the other hand, mutating a region corresponding to the nuclear factor-Y (NF-Y) responsive site in the FAS promoter resulted in a 50% loss of PUFA repression of FAS and an 85% reduction in promoter activity, suggesting that PUFA regulation of FAS may be mediated more by NF-Y than by SREBP as previously assumed (Teran-Garcia et al., 2002).

Another example of SREBP-independent regulation of a lipogenic gene is seen in the regulation of the delta-9 desaturase, SCD1. SCD1 contains an SRE in its promoter region and is induced by SREBP-1. Treatment of HepG2 cells with PUFAs such as arachidonic, linoleic, and eicosapentanoic acids results in inhibition of transcription of SCD1, as predicted. However, overexpression of a mature SREBP protein does not circumvent this inhibition of SCD1 by PUFA treatment. These results suggest that the regulation of SCD1 by PUFAs is independent of SREBP maturation (Ntambi, 1992; Ntambi and Bene, 2001), and possibly mediated through another nuclear receptor such as LXR.

VI. LIVER X RECEPTORS

Similar to PPARs, LXRs belong to the superfamily of steroid nuclear receptors and include two isoforms, LXRα and LXRβ (Hannah et al., 2001; Ou et al., 2001). LXRs have been well characterized for their ability to bind oxysterols and consequently regulate genes involved in fatty acid and cholesterol transport and metabolism as well as bile acid synthesis. Similar to the PPARs, the LXRs function by heterodimerizing with RXRα and then bind DR4 elements in the promoters of target genes. LXRs have been shown to induce expression of genes such as Cyp7α, FAS, ACC, SCD1, lipoprotein lipase, as well as SREBP-1c (Repa et al., 2000; Lu et al., 2001).

PUFAs are thought to exert an inhibitory effect on LXR activation (Figure 29.1). For example, it has been proposed that PUFAs compete with oxysterols for binding to LXRs and that PUFA binding inhibits LXR activation of target genes (Hannah et al., 2001; Yoshikawa et al., 2001). Although it had previously been suggested that regulation of SREBPs by PUFAs was dependent on LXR inhibition by PUFAs (Yoshikawa et al., 2002), there is also some evidence suggesting that PUFAs can inhibit SREBP-1c expression independent of LXRs (Pawar et al., 2003).

Another proposed mechanism of PUFA regulation of LXR involves activation of PPARs α and γ by PUFAs (Yoshikawa et al., 2003). As discussed above, the PPARs are activated by PUFAs and dimerize with RXRα to bind to PPREs on target genes. Since LXRs also heterodimerize with RXRα, it has been proposed that inhibition of LXR activity by PUFAs occurs due to activation of PPARs and sequestration of RXRα away from LXR. In these studies, supplementation of PUFA-treated cells with RXRα decreased the level of PUFA-repression of LXR, suggesting that PPARs and LXRs may in fact compete for RXRα and therefore be reciprocally regulated by PUFAs (Yoshikawa et al., 2003).

VII. HEPATOCYTE NUCLEAR FACTOR-4α

Another player in PUFA regulation of gene expression is an orphan member of the hepatocyte nuclear factor family, HNF-4α (Hayhurst et al., 2001). This nuclear receptor binds DR1 sequences on target genes as a homodimer (Figure 29.1) and is involved in regulating hepatocyte differentiation as well as key hepatic functions such as lipoprotein secretion and cholesterol efflux (Hayhurst et al., 2001). Studies in cell culture models have demonstrated that HNF-4α is important for transcription of a variety of genes including apolipoprotein A-1 (ApoA-I), ApoA-II, ApoB, ApoC-II, ApoE, and ApoC-III, as well as CYP7A1. HNF-4α has also been shown to be important in iron metabolism through regulation of transferrin, and carbohydrate metabolism through regulation of PEPCK, glucose-6-phosphatase, and L-type pyruvate kinase (L-PK) (Hayhurst et al., 2001). Fatty acyl CoAs modulate HNF-4α activity through changes in phosphorylation via protein kinase A (Hayhurst et al., 2001). Fatty acyl CoAs can also bind directly to the ligand-binding domain (Figure 29.1) of HNF-4α (Hertz et al., 1998; Hertz et al., 2001), but the result of this binding varies depending on the specific fatty acid. For example, binding of 16:0-CoA seems to increase HNF-4α activity, while binding of 18:0-CoA and 18:3-CoA seem to have the opposite effect (Hertz et al., 1998). The regulation of the gluconeogenic gene, glucose-6-phosphatase by PUFAs via HNF-4α suggests yet another mechanism of regulation. PUFAs inhibit HNF-4α binding to its DNA recognition sites on the promoter of glucose-6-phosphatase (Figure 29.1), thereby decreasing transcription of this gene (Rajas et al., 2002). Another putative mechanism of action for PUFA regulation of HNF-4α is through activation of PPARα, which then competes with HNF-4α for binding to DNA recognition sites (Hertz et al., 2001). Xu et al. (2006) have shown in a recent study that while n-3 PUFA treatment of rat primary hepatocytes has no effect on transactivation of HNF-4α, treatment with WY14643, a PPARα activator, represses HNF4α. These results suggest that fatty acids and PPAR agonists may regulate gene expression through divergent mechanisms (Xu et al., 2006).

VIII. AMP-ACTIVATED PROTEIN KINASE AND CARBOHYDRATE RESPONSE ELEMENT BINDING PROTEIN

AMP-activated protein kinase (AMPK) is a heterotrimeric protein consisting of catalytic α-subunits and regulatory β- and γ-subunits. In recent years, AMPK has emerged as a key sensor and regulator of cellular energy status. AMPK is activated in response to increased AMP:ATP ratios. Activation of AMPK results in increased flux through catabolic processes such as glucose uptake, glycolysis, and fatty acid oxidation in order to generate ATP. This is accompanied by a downregulation of anabolic processes such as fatty acid and cholesterol synthesis (Kahn et al., 2005). AMPK can be activated in the presence of dietary fat due to increased cellular AMP concentrations generated by the synthesis of fatty acyl CoAs. In addition, both PUFA feeding and AMPK activation result in a favorable hypolipidemic phenotype, making it tempting to speculate that the cellular effects of PUFAs may be mediated by AMPK activation.

However, the topic of AMPK activation by PUFAs remains controversial at best. A study by Suchankova et al. (2005) showed that while refeeding after a fasting period results in inactivation of AMPK, addition of PUFAs to the diet stunts this inhibition, albeit not completely. The authors therefore suggest that PUFAs enhance AMPK activity *in vivo*. In contrast to these results, Dobrzyn et al. (2005) have reported that while feeding mice a high-PUFA diet causes decreased lipogenesis and increased oxidation as expected, this is not accompanied by increased AMPK activity. Furthermore, Dentin et al. (2005) also observed that the presence of PUFAs does not alter AMPK activity *in vivo* or *in vitro*. Thus, while a role for AMPK as a sensor of energy status has been firmly cemented, the issue of its regulation by PUFAs and the physiological significance of any such regulation remain to be ironed out.

Although regulation of AMPK by PUFAs remains questionable, one of the transcription factors known to be regulated by both AMPK and PUFAs is ChREBP. ChREBP is a recently identified

transcription factor belonging to the helix–loop–helix family of transcription factors and is expressed in liver. ChREBP is responsive to nutritional status in that its expression and nuclear translocation are both induced by glucose and insulin. Using ChREBP–/– mice, Iizuka et al. (2004) have shown that ChREBP is a transcription factor essential in regulating the expression of key glycolytic and lipogenic genes, especially in response to high-carbohydrate feeding. Deficiency of ChREBP has been shown to decrease adiposity as well as plasma glucose levels in leptin-deficient ob/ob mice that are normally obese and hyperglycemic (Iizuka et al., 2006). Dentin et al. (2005) have suggested that this transcription factor may also be the missing link in PUFA regulation of genes such as L-PK that are repressed by PUFAs (Figure 29.1) but do not contain any putative SREs in their promoter regions. These authors show that addition of linoleic acid to cultured hepatocytes results not only in SREBP-1c mRNA decay, as expected, but also in decreased half-life of ChREBP mRNA (Dentin et al., 2005). Furthermore, linoleate treatment also prevents nuclear translocation of ChREBP in response to glucose and insulin (Dentin et al., 2005). This is at least partly mediated by decreased expression of genes, encoding rate-limiting enzymes of the glycolytic and pentose phosphate pathways, which are required for promoting nuclear translocation of ChREBP (Dentin et al., 2005). Conversely, the decreased translocation of ChREBP in response to PUFAs is not mediated by AMPK, as neither the presence of the AMPK inhibitor AICAR, nor the genetic deletion of the α1 or α2 AMPK subunits abolishes the repressive effect of PUFAs on ChREBP (Dentin et al., 2005).

Overall, these studies indicate that ChREBP, at least partially, mediates the effect of PUFAs on genes such as L-PK (Dentin et al., 2005, 2006), albeit in an AMPK-independent manner. It remains to be determined whether this SREBP-independent regulation by PUFAs extends to other genes that are regulated by both PUFAs and ChREBP, notably SCD1.

IX. NUCLEAR FACTOR-κB

Although the nuclear receptors and transcription factors outlined above remain the best characterized mechanisms for fatty acid regulation of gene expression, there are several other potential players that are being identified. One such candidate is the transcription factor, nuclear factor-κB (NF-κB). NF-κB regulation of target genes is mainly regulated by sequestering it in the cytoplasm through association with the protein, inhibitor-κB (I-κB). Phosphorylation of I-κB in response to cellular signals results in its degradation, leaving NF-κB free to translocate to the nucleus, where it can regulate transcription of various genes including Cox-2 and interleukin-6 (Calder, 1997; Khalfoun et al., 1997). PUFAs have been shown to both increase (arachidonate) as well as decrease (arachidonate and eicosapentanoate) nuclear translocation of NF-κB (Camandola et al., 1996; Stuhlmeier et al., 1997; Zhao et al., 2004). In humans, fish-oil supplementation seems to decrease transcription of NF-κB target genes such as tumour necrosis factor-α (Zhao et al., 2004). More recently, it has been shown that this decrease in target gene expression (Figure 29.1) is mediated by decreased NF-κB DNA-binding activity. In addition to docosahexanoic and α-linolenic acids, linoleic acid has also an anti-inflammatory effect in human monocytic cells, suggesting a role for both n-3 and n-6 fatty acids in this pathway (Zhao et al., 2005). It is likely that PUFAs function synergistically with NF-κB as well as certain PPAR isoforms such as α and γ to decrease the inflammatory response (Lehmann et al., 1997; Ricote et al., 1998; Delerive et al., 1999; Jump and Clarke, 1999a; Zhao et al., 2005). Activation of the NF-κB pathway is involved in the formation of atherosclerotic lesions. PUFAs as well as some other fatty acids such as CLA and oleic acid blunt NF-κB activation and thereby reduce the inflammatory response in atherosclerotic lesions. These effects are similar to those achieved by the statin drugs and could therefore be of therapeutic importance in reducing inflammation and consequently, the risk for cardiovascular disease (Zhao et al., 2005).

X. CONCLUSION

Although certainly far from complete, our understanding of how fatty acids affect gene expression has progressed by leaps and bounds over the past decade. This research has not only provided

a clearer understanding of the roles of specific fatty acids, but also helped unravel some of the mechanisms involved in nutrient regulation of gene expression. Some of the better characterized mechanisms of fatty acid action remain modulation of gene expression via numerous transactivating factors including PPARs, LXRs, SREBP, ChREBP, HNF-4α, and NF-κB. The emergence of new players such as PGC-1α and PGC-1β have opened up further avenues for exploring the physiological significance of fatty acid mediated gene regulation.

Given that fatty acids represent an integral part of our diets, it is imperative that we continue to increase our understanding of how various fatty acids are capable of differentially modulating cellular metabolism. In the face of looming public health crises such as obesity and lipid-related disorders including diabetes and cardiovascular disease, understanding the molecular mechanisms that can lead to or prevent such conditions has no doubt become a scientific priority.

30 Fatty Acids, Lipids, and Cellular Signaling

Geza Bruckner

CONTENTS

I. INTRODUCTION/BACKGROUND

Fatty acids are important constituents of membrane phospholipids and when fatty acids are released by cellular phospholipases and lipases, or made available to the cell from the extracellular environment, they serve as important cellular signaling molecules. These released fatty acids can serve as second messengers for transduction of internal and external signals. Furthermore, they function as cellular modulators, because their action can be reversed at a precise intra- and extracellular location; they can serve to amplify, attenuate, or alter a cellular signal. Among their many actions fatty acids can modify the action of protein kinases, G-proteins, adenylate and guanylate cyclases, and phospholipases, as well as modulate ion channels and events involved in stimulus-response coupling mechanisms. Many of the cellular signaling events related to fatty acids are via their conversion to eicosanoids, which are potent bioactive lipid molecules and these are reviewed in Chapter 28. Furthermore, the recently discovered lipid mediators lipoxins (LPX) and the two new families of lipid mediators, resolvins (resolution phase interaction products) and protectins, which derive from omega-3 polyunsaturated fatty acid (PUFA) provide for better understanding of the cellular signaling in the inflammatory process (see Chapter 28) (Schwab and Serhan, 2006). These resolution-active lipid mediators are small molecules that derive from essential n-6 and n-3 eicosapentaenoic acid and docosahexaenoic acid (EPA and DHA) PUFAs in the diet. Among the n-6 PUFAs, arachidonic acid (AA)-derived LXA_4 and aspirin-triggered LXA_4 (ATL) evoke anti-inflammatory protective actions in physiologic and pathophysiologic processes. These two molecular series have emerged as prototypic members of the first class of endogenous lipid/chemical mediators that are "switched on" in the resolution phase of an inflammatory response, thus acting as "braking signals" in inflammation (see Chapter 28).

In addition to their direct effects, fatty acids are also messenger and modulator molecules to extracellular signals. The generation and release of extracellular lipid mediators are generally cell

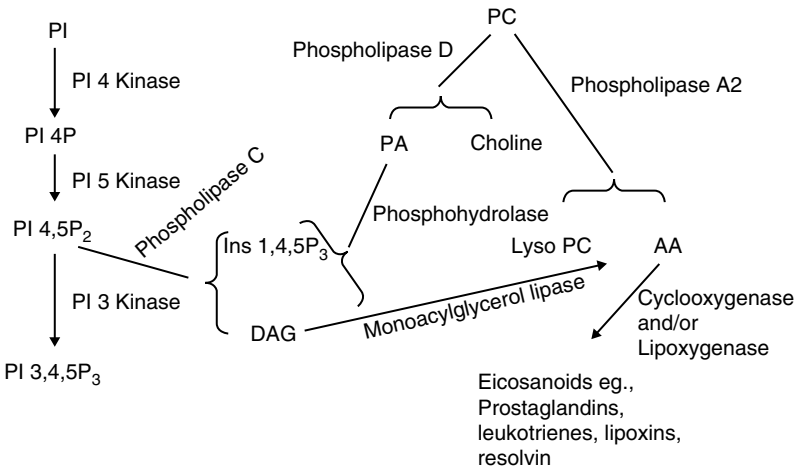

FIGURE 30.1 Signaling molecules include the protein kinase C regulator diacylglycerol (DAG), the calcium signal inositol 1,4,5-trisphosphate (Isn 1,4,5P3), and phosphorylated forms of phosphatidylinositol. The phospholipase C system depicted shows generation of DAG and Isn 1,4,5P3, from phosphatidylinositol 4,5-bisphosphate (PI 4,5P2) whereas phospholipase D catalyzes the hydrolysis of phosphatidylcholine to form phosphatidic acid and choline. The phosphatidic acid may itself act as a signal molecule or it can be hydrolyzed to form DAG by the enzyme PA phosphohydrolase. DAG when acted on by monoacylglycerol lipase can also release arachidonic acid (AA).

and receptor specific, whereas the intracellular lipid mediators appear to be ubiquitous regarding cellular transduction. These lipid mediators are involved in a wide range of processes involving cell-to-cell communication. The activation of specific phospholipases within individual cell types, via extracellular signals, that is, eicosanoids, cytokines, is critical in the biosynthesis of multiple cellular lipid mediators (Serhan et al., 1996; Chiang and Serhan, 2006). Lipid and nonlipid molecules can be divided into two groups regarding their second messenger function: (1) a group of molecules dedicated to signal transduction, that is, cyclic AMP, inositol triphosphate, various eicosanoids; and (2) a group of molecules that may function either as second messengers or lipid metabolic intermediates, that is, diacylglycerol (DAG), phosphatidic acid (PA), AA, and so forth (see Figures 30.1 and 30.2). The distinction between these groups as previously stated is difficult to make since many serve in both roles. Most likely intercellular compartments, concentrations, and receptors play a role as to their given function at any given time. For example, the role of AA, both as an eicosanoid or as a constituent of DAG in cellular signaling mechanisms illustrates this complexity.

Another example of signaling complexity is the phosphatidylinositol-cycle (PtdIns-cycle), an intracellular signaling pathway, which includes the receptor-mediated activation of GTP-binding protein (G-protein) that is associated with (PtdIns(4,5)P_2) specific phospholipase C-β (PLC-β) and tyrosine phosphorylation-regulated PLC-γ. Activation of PLC-β and PLC-γ results in the formation of the inositol-1,4,5-trisphosphate (Ins(1,4,5)P_3) and the activator of the protein kinase C (PKC) isoenzymes and 1,2-diacylglycerol (1,2-DAG) (deJonge et al., 1996; Heilmeyer et al., 2003). This signaling pathway of the PtdIns-cycle links various stimuli, such as hormone, growth factor, and mechanical stretch to their final responses at the transcriptional level through formation of the PKC and Ca^{2+}-calmodulin-dependent PKC activators: 1,2-DAG, Ca^{2+}, and Ca^{2+}-calmodulin (Straub et al., 2004). Many processes, believed to be involved in atherogenesis, such as expression of leukocyte adhesion molecules, adhesion and infiltration of blood cells to the vasculature, platelet aggregation, mechanical stress effects on the endothelium, secretion of endothelium-derived factors, and mitogenic responses of vascular smooth muscle cells are partially mediated by activation of the PtdIns-cycle. The PtdIns-cycle activity could be affected by the modification of the fatty acyl composition of the membrane phospholipids at several steps of the signaling cascade.

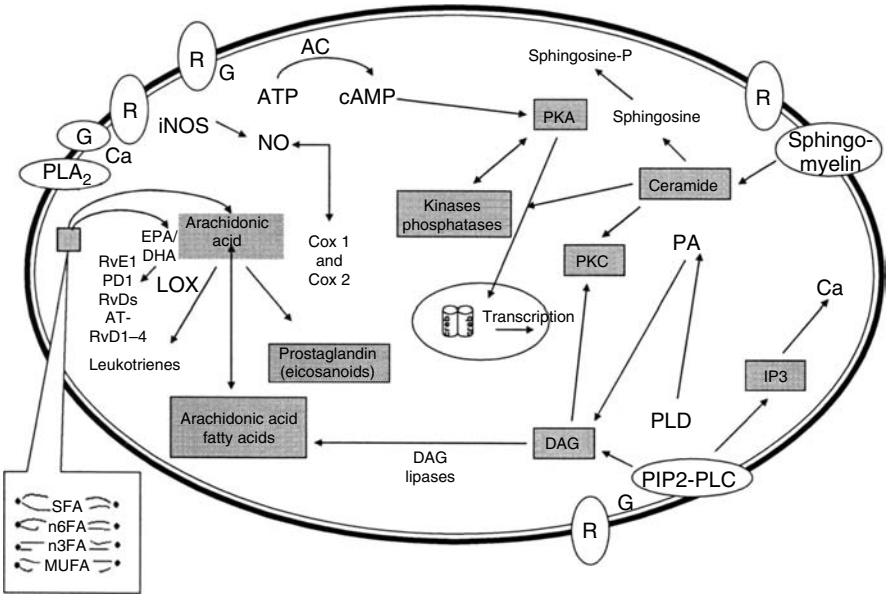

FIGURE 30.2 Cellular fatty acid and lipid signaling. iNOS, nitric oxide synthase; NO, nitric oxide; PK, protein kinase; PA, phosphatidic acid; DAG, diacylglycerol; PLD, phospholipase D; PLC, phospholipase C; LOX, lipoxygenase; COX, cyclooxygenase; PLA2, phospholipase A2; PIP2, phosphotidylinositol-4,5-bisphosphate; RvE1, resolvin E1; PD1, protectin D1; AT-RvD1–4, aspirin triggered resolvin 1–4; CERB, c-AMP receptor element binding protein; SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; R, receptor.

The minimum requirements for a lipid to function as a direct second messenger, as stated by Khan et al. (1995) are as follows: (1) the demonstration of changes in concentration of the lipid in response to physiologic stimulation, (2) the demonstration of a direct *in vitro* or *in vivo* target (receptor) for this lipid, (3) the ability of this lipid to activate the target, and (4) establishing a true biological role for this lipid in mediating a biochemical and/or physiological response. Two characteristics are generally attributed to modulator molecules: (1) a reversible modification of the action of signaling molecules at a precise location and (2) a very short action that amplifies, attenuates, or deviates a signal.

For AA, the regulation of its intracellular concentrations and activation of cellular targets, that is, PKC, have been clearly demonstrated; however, whether these effects are direct or mediated via other cellular signaling is less clear. For example, the intracellular concentrations of AA have been reported to be in the range of 50–100 μM following stimulation of pancreatic cells or platelets (McPhail et al., 1984; Wolf et al., 1986; Nishikawa et al., 1988); however, the range of concentration for free fatty acids *in vivo* is less clear and the resulting effect on cellular signaling will certainly require further study. It has been widely accepted that AA and lysophospholipid generated by calcium-independent phospholipase A2 (iPLA2) act as a signaling molecule in cellular functions. These include eicosanoid production, glucose-induced insulin secretion, Fas-induced apoptosis, cellular proliferation, membrane trafficking in fusion, contribution to myocardial ischemia, and others. The functional role of iPLA2 in cellular responses upon stimulation has been recently reviewed by Akiba and Sato (2004).

Transmembrane mechanisms may be involved in the transduction of external signals (agonists that bind to plasma membrane receptors) and thus mediate the rapid production of intracellular second messengers (Berridge, 1987; Rana and Hokin, 1990). Two of these mechanisms, as mentioned, are the inositide phospholipid pathway that generates inositol 1,4,5-trisphosphate (IP3) and sn-1, 2-DAG (Berridge, 1984) and the cyclic AMP (cAMP) pathway that produces cAMP. Via these second messengers, the initial signal can be delivered to the nucleus to regulate a specific physiological

cell process. Perhaps the best examined nuclear lipid pathway is the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PI4,5P(2)) by PLC resulting in activation of nuclear PKC and the subsequent production of inositol polyphosphates. However, phosphoinositides appear to function not only as precursors for soluble inositol phosphates and DAG, but may also act as second messengers themselves. In this role, as recently reviewed by Bunce et al. (2006), they modulate important nuclear signaling events such as cell cycle progression, apoptosis, chromatin remodeling, transcriptional regulation, and mRNA processing.

A number of studies have shown that fatty acids (particularly unsaturated fatty acids) act as second messengers and modulators, as defined above, through their capacity to modulate protein kinases, phospholipases, G-proteins, adenylate, guanylate cyclases, and ion channels activities (Khan et al., 1991, 1995; Zhu et al., 2006).

II. PHOSPHOLIPASES AND FATTY ACID MODULATION

The *in vivo* fatty acid composition of membrane phospholipids can be modified by dietary means and by alteration of cellular desaturation and acylation reactions. Most cellular membranes appear to reflect the dietary fatty acid constituents, including the endoplasmic reticulum, plasma, and mitochondrial membranes (King et al., 1977; Hammer and Wills, 1979). Cell signaling is accompanied by rapid remodeling of the membrane lipids following activation of the various lipases. This remodeling can occur on both the inner and outer membranes but affects different membrane lipid domains in these membranes. Sphingolipids are located primarily in the outer leaflet of the plasma membrane bilayer, while glycerophospholipids such as phosphatidylserine, phosphatidylinositol, and phosphatidylethanolamine occur mainly in the inner membrane. Cholesterol is believed to occur in roughly equal proportions in both leaflets. Cholesterol with sphingomyelin and other sphingolipids are located in an intimate association in specific sub-domains or "rafts" of membranes. These are segregated regions that form between sphingolipids and membrane proteins, which act to compartmentalize the latter and thereby separate different biochemical functions. Lipid "rafts" are defined as small (10–200 nm), heterogeneous, highly dynamic, sterol- and sphingolipid-enriched domains that compartmentalize cellular processes. Small rafts can sometimes be stabilized to form larger platforms through protein–protein and protein–lipid interactions. These sphingolipid rafts contain primarily long-chain saturated fatty acids (Zeyda and Stulnig, 2006).

Fatty acids can be released from membrane phospholipids by cellular lipases and phospholipases, producing nonesterified free fatty acids (NFFA) (Irvine, 1982; Burgoyne and Morgan, 1990; Jenkins and Frohman, 2005). Agonists that stimulate these lipases and/or phospholipases appear to release endogenous fatty acids that then act directly as second messengers (Irvine, 1982; Akiba and Sato, 2004). As the regulation of membrane fatty acid composition appears to be tightly controlled, cellular function is therefore closely associated with membrane lipid form. Although the overall contents of the different phospholipid classes are mostly unchanged, a dynamic distribution of the different molecular species of the phospholipids or the lipid rafts embedded in the lipid bilayer are needed for enzymatic activity (Stubbs and Smith, 1984; Lamers et al., 1992; Rajendran and Simons, 2005). The rate of conversion of membrane lipids, for example, phosphatidylethanolamine methylation to phosphatidylcholine and PtdIns into PtdIns (4,5)P, may be indirectly stimulated by α_1- and β-adrenergic receptor stimulation of the methylating or phosphorylating membrane-associated enzymes. Phospholipids contain information in addition to their important structural role in membrane function. For example, the hydrolysis of phosphatidylethanolamine by PLA_2 from rat brain synaptosomes released primarily 20:4n6 despite the high abundance of 22:6n3 in these membrane lipids, suggesting that the role of 22:6n3 in neuronal membranes is required more as part of the structure and not as the free fatty acid (Kim et al., 1996). However, the release of other fatty acids, in other phospholipid molecules may be mediated by receptor-G-protein- and receptor nonG-protein-coupled activation of phospholipases A, C, and D (Zhu et al., 2006). Therefore, the hydrolysis of phospholipids remains a major contributor to transmembrane signaling; as slight changes

in phospholipid fatty acid composition are induced, membrane function, for example, fluidity and transport, might be altered in either a positive or negative sense. Membrane lipid composition has been shown to influence functions as diverse as insulin receptor sensitivity, phenylalanine transport, succinate oxidase activity, transport of hexose sugars, sodium and potassium transport, and Ca ATPase activity (Im et al., 1979; McMurchie and Raison, 1979; Legendre et al., 1980; Innis and Clandinin, 1981; Ginsberg et al., 1982; Spector and Yorek, 1985; Poling et al., 1996; Haugaard et al., 2006; Turner et al., 2006).

Not only the enzyme activities but also membrane receptor affinities may be altered by dietary fatty acids and thus affect cellular signaling; differences in fatty acid distribution have been demonstrated in native acetylcholine receptor-rich membranes with significantly more 24:1 found in the outer vs. the inner membrane (Bonini et al., 2002). Upon appropriate stimuli, the fatty acids are released from phospholipid membranes, and the levels of free fatty acids, for most tissues, thus reflect the nature of the membrane composition. It is in large part the amount of free fatty acid released that determines the final concentration of the eicosanoids produced. Thus, the rate-limiting step for eicosanoid production and other lipid signaling molecules appears to be PLA_2, C, or D activity. The free fatty acids that are released have different binding affinities for the cyclooxygenase (COX) and lipoxygenase enzymes, and the n-3 series (20:5n3, 22:6n3) are especially potent competitive inhibitors (Lands et al., 1973). For this reason, the fish oil fatty acids can alter eicosanoid biosynthesis and thus alter cellular response by increasing the 3-series eicosanoids (TXA_3, PGI_3) and decreasing the amount of n-6 products formed (TXA2, PGE2, etc.). The 3-series eicosanoids appear to have different biopotencies than the 2-series products. For example, TXA_2 is a more potent platelet aggregatory agent than TXA_3. The eicosanoid-mediated functions, via the release of fatty acids by phospholipases, may be enhanced by several agonists (thrombin, growth factors, adenosine, cholinergic agonists, α-adrenergic agonists, serotonin, vasopressin, angiotensin, bradykinin, etc.) that generally bind to plasma membrane receptors.

The cellular phospholipases that are triggered by various agonists are classified according to the bond cleaved in the phospholipid molecule. Thus, PLA_1 and PLA_2 selectively remove fatty acids from the sn-1 and sn-2 positions, respectively. Phospholipase B (PLB) cleaves both the 1- and 2-lysophospholipids produced by PLA_1 and PLA_2, respectively. Phospholipase C (PLC) cleaves the bond between glycerol and a phosphate, while phospholipase D (PLD) hydrolyzes the amino alcohol moiety from a phospholipid (see Figures 30.1 and 30.2).

PLA_2 is primarily responsible for the direct release of AA, which is predominately esterified in the sn-2 position of membrane phospholipids. However, highly unsaturated fatty acids such as DHA and EPA fatty acids can displace AA from the sn-2 position (Glaser et al., 1993; Murakami et al., 1997). AA can also be released by the activation of (see Figures 30.1 and 30.2) (1) PLC, followed by DAG and monoacylglycerol (MAG) lipase; or (2) PLD, followed by PA phosphohydrolase, DAG and MAG lipase; or (3) PLA_1, followed by PLB (less common). Other *cis*-unsaturated fatty acids such as oleic, linoleic, linolenic, eicosapentaenoic, and docosahexaenoic acids can also be liberated from phospholipids by lipases; therefore, the dietary fatty acid intake can influence membrane composition and, thus, the ratios and types of second messengers formed (Mitchell et al., 2003).

III. FATTY ACIDS AND PHOSPHOLIPASE MODULATION

A. Phospholipase A_2

PLA_2 plays a crucial role in diverse cellular responses and provides precursors for the generation of eicosanoids, platelet-activating factor (PAF), when the sn-1 position of the phosphatidylcholine contains an alkyl ether linkage, and some bioactive lysophospholipids, such as lysophosphatidic acid (LPA). As overproduction of these lipid mediators causes inflammation and tissue disorders, it is extremely important to understand the mechanisms regulating the expression and functions of PLA_2. PLA_2 isozymes that are regulated independently and exert distinct functions are classified

into four broad categories: (1) the group IV cytosolic PLA_2 ($cPLA_2$) and its paralogues; (2) the low molecular weight, secretory enzymes ($sPLA_2$); (3) the Ca^{2+}-independent, group VI enzymes $iPLA_2$; and (4) the selective acetyl hydrolases of PAF, groups VII and VIII PLA_2. These groups of PLA_2 enzymes differ in their Ca^{2+} requirements, overall structure, pH optima, substrate specificity, and susceptibility to pharmacologic inhibition (Dennis, 1997). One of the putative actions of group VI PLA_2 is the regulation of membrane remodeling to control the pool of available AA (Winstead et al., 2000). Groups VII and VIII PLA_2 degrade PAF and oxidized lipids, thereby downregulating oxidative injury and inflammation.

Most importantly, the $sPLA_2$ family is composed of a group of calcium-dependent lipolytic enzymes containing a conserved calcium-binding loop. To date, the following ten $sPLA_2$ isozymes have been identified in mammals: groups IB, IIA, IIC, IID, IIE, IIF, V, X, III, and XII. $sPLA_2$ isozymes generally exhibit tissue-specific and species-specific expression, suggesting that their cellular behaviors and functions differ. $sPLA_2$-IB is abundant in pancreatic secretions, and its main function is thought to be the digestion of dietary phospholipids. $sPLA_2$-IIA is the prototypic inflammatory PLA_2, found in inflammatory rheumatoid arthritic fluids; the two groups can be distinguished by the distribution of disulfide bonds and differences in primary structure. Since the genes for $sPLA_2$-IIA, -IIC, -IID, -IIE, -IIF, and -V are found at the same chromosomal locus, they are often referred to as the group II subfamily. Not only $sPLA_2$-IIA, but also the other group II subfamily $sPLA_2$ isozymes (i.e., IID, IIE, IIF, and V) are stimulus inducible (Murakami and Kudo, 2003).

Cytokines such as tumor necrosis factor (TNF), interleukin-1 and -6 (IL-1, IL-6) cause increases in expression of the group II $sPLA_2$s in a variety of cells that result in greater eicosanoid production; glucocorticoids via macrocortin suppress these effects.

$cPLA_2$ is an 85 kDa molecule and is the first arachidonic selective PLA_2 identified (Clark et al., 1995). $cPLA_2$ also exhibits relatively high-lysophospholipase activity and can completely diacylate diacylphospholipids and thus prevent toxic accumulation of lysophospholipids. A Ser228 site is essential for both PLA_2 and lysophospholipase activity and the N-terminal, Ca^{2+}, and phospholipid-binding domain is needed for the Ca^{2+}-dependent membrane association (Sharp et al., 1994), $cPLA_2$ is regulated by both transcriptional and posttranscriptional mechanisms (Shimizu et al., 2006). The ability of individual cytokines to induce different forms of PLA_2 and second messenger lipids demonstrates the complexity of the mechanisms involved. Posttranscriptional regulation depends on both serine phosphorylation and Ca^{2+}. In a variety of cells, phosphorylation occurs from a diverse group of agonists among that are thrombin, mitogens, zymosan, endotoxin, TNFα, Il-1, calcium ionophore, acetic acid, and phorbol esters; these resulted in increased PLA_2 activity and a gel shift on SDS gels (Serhan et al., 1996). The mechanisms involved in specific targeting of $cPLA_2$ to the nuclear membrane and exclusion from the plasma or other membranes are not clearly understood, however, it seems that colocalization of $cPLA_2$, 5-lipoxygenase activating protein (FLAP), and PGHS-II on the nuclear envelope represents a coordinated regulation of enzymes that are involved in fatty acid release and subsequent eicosanoid synthesis (Shimizu et al., 2006).

Membrane-bound PLA_2 can be inhibited by oleic, arachidonic, linoleic, linolenic, and eicosapentaenoic acids depending on the concentration of the fatty acid. AA has been found to be the most inhibitory fatty acid and behaves kinetically as a competitive inhibitor (K_I of about 5 μM). However, the saturated fatty acid palmitate causes no enzyme inhibition (Lister et al., 1988).

Calcium-dependent PLA_2, purified from snake venom was strongly inhibited *in vitro* by micromolar concentrations of *cis*-unsaturated fatty acids (oleic and arachidonic acid) and to a much lesser extent by *trans*-unsaturated or saturated fatty acids (Raghupathi and Franson, 1992); *cis*-unsaturated fatty acids bound directly to the isolated enzyme but did not affect the enzyme–substrate interaction. This suggests that the inhibition of PLA_2 activity *in vitro* may be mediated by the formation of an enzymatically inactive enzyme–substrate–fatty acid complex that represents a negative feedback regulation for PLA_2 activity. On the other hand, there is ample evidence that nonesterified fatty acids, particularly AA, can increase the activity of various phospholipases. For example, AA was shown to stimulate the hydrolysis of membrane PI by soluble PLC and oleic acid-activated cytosolic PIP2-PLC in human

peripheral monocytes (Irvine et al., 1979; Guan, 1994; Sternfeld et al., 2000); in addition, unsaturated fatty acids can stimulate PLD which in turn leads to other lipid mediators (Jackson, 1997).

Little attention has been given to understanding how modification of the membrane phospholipid fatty acid composition may modulate the membrane-bound PLA_2 activity and conversely how $cPLA_2$ plays a role in maintaining membrane fatty acid composition (Asai et al., 2003).

It has been reported that the catalytic activity of pancreatic PLA_2 was altered by small changes in the interfacial lipid architecture, such as incorporation of unsaturated fatty acids, and that these changes modulate the intensity of the hydrophobic interactions at the active site of the enzyme (Vergal et al., 1972). Ventricular myocytes treated with n6 fatty acid exhibited 34% greater PLA_2 activity than n3 fatty acid supplemented cells and it was concluded in these studies that it was the membrane alteration that brought about the change in enzyme activity (Grynberg et al., 1992). Other studies using n3 vs. n6 fatty acids, both *in vivo* and *in vitro*, indicate that marked changes in eicosanoid production can be brought about by n3 fatty acids, but it is unclear whether these changes are a result of altered PLA_2 activity, decreased COX, or lipoxygenase substrate availability or fatty acid binding affinity for the enzymes. Recently, Asai et al. (2003) showed that overexpression of cPLA(2)γ increased the proportion of PUFAs in phosphatidylethanolamine, suggesting that the enzyme modulates the phospholipid composition. They propose that cPLA(2)γ is constitutively expressed in the endoplasmic reticulum and plays an important role in remodeling and maintaining membrane phospholipids under various conditions, including during oxidative stress.

B. Phospholipase C and D

Several studies support that dietary PUFAs affect the receptor mediated activation of PLC as reviewed by deJonge et al. (1996). Phosphoinositide-specific phospholipase C is a key enzyme involved in inositide metabolism, leading to the formation of the second messengers IP_3, and DAG after binding of agonists to the cell surface (see Figure 30.2) (Berridge, 1984; deJonge, 1996). Numerous studies have reported on the modulating effects of fatty acids on PLC activity. Irvine et al. (1979) demonstrated that oleic acid or AA markedly activated the hydrolysis of membrane-bound phosphatidylinositol in rat liver microsomal fraction. The effect of AA on PLC activity appears to be indirectly mediated by some of its eicosanoid metabolites. In intact human platelets, the AA-induced stimulation of phosphatidylinositol-specific PLC is due in part to endoperoxides or thromboxane A_2, and this effect could be blocked by COX inhibitors (Siess et al., 1983). Other studies have shown that α_1-adrenergically stimulated PLC-β in ventricular myocytes was reduced in n3 fatty acid pretreated cells while the PLC-β in the same cells was stimulated by endothelin-1 (deJonge, 1996). *Cis*-unsaturated free fatty acids (oleic and palmitoleic acids at 10–100 μM), but not *trans*-unsaturated or saturated fatty acids, blocked the stimulatory effect of epidermal growth factor (EGF), bradykinin and bombesin on elevating cytosolic calcium concentration in diverse cell lines (Casabiell et al., 1991). It appears that unsaturated *cis* fatty acids block signal transduction by interfering with the PLC receptor but do not alter PKC-mediated mechanisms. These effects appear to be related to their chemical configuration rather than chain length or the hydrophobicity of the fatty acid.

PLC-β hydrolysis of $PtdIns(4,5)P_2$ results in two messengers: $Ins(1,4,5)P_3$ which is known to release calcium from intracellular stores (Berridge, 1993) and 1,2-DAG which is known to activate members of the PKC family, some of which are also dependent on calcium (Mori et al., 1982; Berridge, 1984). Pretreatment of rat submandibular acinar cells with 100 μM AA produced a 75% inhibition of IP3 (Chung and Fleming, 1992). The AA effect on the carbachol-IP_3 response was not mediated by eicosanoid metabolites and did not involve PKC. As suggested by these authors the action of AA was most likely due to an inhibition of phosphoinositide synthesis and not due to PLC inactivation. AA (10–100 μM) induced a dose-dependent inhibition of inositol incorporation into phosphoinositide of rat pancreatic acinar cells (Chaudry et al., 1987). It is therefore suggested that in these tissues, AA might act as a negative feedback regulator of phosphoinositide turnover via inhibition of inositol phospholipid synthesis.

Evidence has accumulated over the past decade, and as cited above, that there is a distinct nuclear phosphatidylinositol pathway. Nuclear lipid pathways showing the hydrolysis of PI4,5P(2) by PLC results in activation of nuclear PKC and production of inositol polyphosphates. Recent findings suggest that not only are they precursors for soluble inositol phosphates and DAG, instead they can act as second messengers themselves. They have been implicated to play a role in different important nuclear signaling events such as cell cycle progression, apoptosis, chromatin remodeling, transcriptional regulation, and mRNA processing. This has been reviewed by Bunce et al. (2006) with a focus on the role of PI4,5P(2) in the nucleus as a second messenger as well as a precursor for PI3,4,5P3, inositol polyphosphates, and DAG.

By changing the PUFA composition of membrane phospholipids, the endogenous substrates for the membrane-associated phospholipase C-β and A_2 are changed. It appears that the hydrolytic action of the phospholipases on these substrates is also changed and thus results in altered products (1,2-DAGs and nonesterified PUFAs) which in turn evoke changes downstream in the signaling cascades such as activation of distinct PKC isoenzymes, formation of distinct eicosanoids, and regulation of Ca^{2+} channels. Membrane physicochemical properties, in terms of fluidity and cholesterol content of the bilayer, might also undergo changes due to altered PUFA incorporation into membrane phospholipids. As mentioned previously, these changes could alter receptor function, receptor-GTP-coupling, and GTP-binding protein-phospholipase C-β or A_2 coupling as well (deJonge et al., 1996).

It has been suggested that high-dietary fat might enhance colon carcinogenesis through the modulation of colonic mucosal PLA_2 and phosphatidylinositol-specific phospholipase C (PI-PLC). These authors state that colon carcinogen treatment increased the activities of colonic mucosal PLA_2 and PI-PLC and the formation of prostaglandins and thromboxane A_2 from AA through COX compared to saline-treated rats fed on similar diets. The activities of PLA_2, PI-PLC, and COX were significantly higher in colon tumors compared to colonic mucosa and this effect was related to the amount of corn oil (Rao et al., 1996).

PLC activation generates primarily polyunsaturated species while PLD activation generates saturated/monounsaturated species. In endothelial cells, PLD when activated by LPA independent of PLC showed no activation of PKC. These authors also suggest that only polyunsaturated DAGs and saturated/monounsaturated phosphatidates function as intracellular messengers and that their interconversion products are inactive (Pettitt et al., 1997). PLC- γ isozymes when activated involve various agonists resulting in tyrosine phosphorylation of the effector enzymes. Further PLC-γ isozymes are also activated by PA, (PI3,4,5P(3)), and AA in the absence of PLC γ tyrosine phosphorylation. These lipid-derived messengers are the products of phosphatidylinositol 3-kinase, phospholipase D, and phospholipase A_2, enzymes that are often stimulated along with PLC-γ in response to an agonist. Additionally, PI4,5P(2) may act as a substrate for both PLC-γ and phosphatidylinositol 3-kinase and can activate PLD and PLA_2. Sekiya et al. (1999) have shown that there is an elaborate mechanism of cross-talk and mutual regulation between four effector enzymes that participate in receptor signaling by acting on phospholipids.

It has been shown by several investigators that PLD activity is stimulated by PKC and PKCα, small G-protein ADP-ribosylation factor (ARF), small G-proteins of the Rho family, $PtdIns(4,5)P_2$ (and as cofactor) and by fatty acids, particularly by oleic acid (Hattori and Kanfer, 1984; Shukla and Halenda, 1991; Cockcroft, 1997). To this effect, PLD activity was shown to be dependent on the concentration of oleate (4 mM giving maximal activity) in rat brain microsomal fraction (Gustavsson and Alling, 1987).

Chalifour and Kanfer (1982) reported that monounsaturated fatty acids were the most effective activators of rat brain microsomal PLD; PUFAs stimulated it to a lesser degree, while SATs were ineffective. A consequence of PLD activation by FAs is that PA is mainly formed by the hydrolysis of phosphatidylcholine due to the activation of PLD; PA can be further degraded by PA phosphohydrolase to DAG (Dhalla et al., 1997). PA is also generated by phosphorylation of DAG due to the action of DAG kinase and is converted to DAG under the action of PA phosphohydrolase. PA has

been implicated in the regulation of protein kinases, GTPase activating proteins, PI kinases, adenylate cyclase, and other signaling proteins. The growth factor-like effect of PA has been recognized in a wide variety of tissues and the positive inotropic agents that are known to stimulate cardiac hypertrophy have been shown to increase the level of PA in cardiac sarcolemma. Thus, the signaling of PLD by FAs can induce other second messengers. Some of the mechanisms by which unsaturated fatty acids can exert their effects on signal pathways are best demonstrated by their effects on PKC.

IV. PROTEIN KINASE C

PKC has been implicated in the regulation of a variety of physiological and pathological cellular processes, including proliferation, differentiation, and release of hormones and neurotransmitters. PKC isozymes constitute a family of ubiquitous phosphotransferases and to date, at least 11 different PKC isotypes have been identified. Lipid cofactors play a key role in the activation of PKC isoforms and this area has been recently reviewed by Martelli et al. (2006). PKC appears to reside in the cytoplasm in an inactive form and to translocate to the plasma membrane or cytoplasmic organelles upon cell activation. However, PKC is also capable of translocating to the nucleus and several PKC isoforms actually resident within the nucleus.

PKC normally requires phosphtidylserine and either DAG and/or Ca^{2+} depending on the isoform of PKC. DAG generally increases the affinity for Ca^{2+} and thus facilitates full PKC expression. Unsaturated fatty acids may activate PKC directly, independently of DAG, phosphtidylserine or Ca^{2+} or enhance its DAG-dependent activation at relatively low-Ca^{2+} concentrations. Thus, *cis* linoleic acid, but not the *trans* linoleate isomer or oleic or stearic acids, activated PKC in human platelets (Seifert et al., 1987; Jackson, 1997).

Incorporation of linoleic and AA into lymphocyte plasma membranes phospholipids resulted in long-term activation of PKC that was linked to IL-2 release; the incorporation of palmitic, oleic, or *trans* linoleic did not induce a PKC response. In T-helper cells, linoleic but not AA activated PKC (Jackson, 1997).

Diacylglycerol must have the 1,2-sn-configuration to act as an activator of PKC and the various fatty acyl moieties determine the kinetic characteristics of PKC activation (Go et al., 1987). This implies that the molecular species of 1,2-DAG may be of importance for its potency to activate PKC. In most tissues the sn-2 position of the PtdIns is mainly occupied by 20:4n-6, which as mentioned previously appears to play a significant role in signal transduction processes. The α, β, and γ isoforms of PKC were synergistically activated by the simultaneous addition of DAG and AA (50 mM). Activation did not require Ca^{2+}, but micromolar concentrations of Ca^{2+} enhanced activity. Synergistic activation of PKC by unsaturated fatty acids, and not the saturated fatty acids, was most evident for the PKC isoenzyme (Graber et al., 1994).

Both monounsaturated and PUFAs may promote a time- and dose-dependent redistribution of PKC activity. In rat hepatocytes, oleate or arachidonate (in the presence of Ca^{2+}) caused a translocation of cytosolic PKC toward the plasma membrane. Oleate-induced translocation was dose-dependent (between 0.5 and 0.75 mM oleate) for PKC activity found in the plasma membrane.

PKC could also be activated by other 18 and 20 carbon PUFAs with either n3 or n6 configuration in the absence of other lipid activators. However, when PKC was in its activated state in the presence of phosphatidylserine and DAG, the n3 or n6 fatty acids inhibited phosphatidylserine/DAG-stimulated PKC activity. DHA acid was noted an exception as it did not stimulate PKC activity in the absence of phosphatidylserine and DAG but was the most potent inhibitor of phosphatidylserine/DAG-stimulated activity. These observations indicate that the fatty acids of fish oil behave differently from other long chain PUFAs with respect to PKC.

The impact of FFA on activating novel PKCs (nPKC) has received a great deal of interest regarding their major role in inducing insulin resistance in insulin target cells. FFAs are also found to be involved in activating nPKCs associated with the impairment of insulin sensitivity (Dey et al., 2006).

V. PLATELET-ACTIVATING FACTOR AND LPA

Eicosanoids, PAF, and LPA are ubiquitous lipid mediators that play important roles in inflammation, cardiovascular regulation, and immunity and also modulate gene expression of specific proinflammatory genes. These lipids are dependent on their specific plasma membrane receptors belonging to the superfamily of G-protein-coupled receptors (GPCR).

PAF and LPA fall into a subclass of intercellular lipid messengers that are released from cells and transmit signals via these GPCR. Increasing evidence suggests the existence of a functional intracellular GPCR population. PAF, similar to LPA, can activate a variety of cells by binding to the membrane receptor. It has been proposed that the immediate effects of these bioactive lipids are mediated via cell surface receptors whereas long-term responses are dependent on intracellular receptor effects. It has recently been reviewed by Zhu et al. (2006) that receptors for PAF, LPA, and PGE (2) (specifically EP(1), EP(3), and EP(4)) localize at the cell nucleus of cerebral microvascular endothelial cells of newborn pigs, rat hepatocytes, and cells overexpressing each receptor. Stimulation of isolated nuclei with these lipids reveals biological functions including transcriptional regulation of major genes, namely c-fos, COX-2, and endothelial as well as inducible nitric oxide synthase. It has been shown that certain oxidized phospholipids can elicit a response similar to PAF, suggesting that oxidized phospholipids are mediators of inflammation in a mechanistic manner similar to that of PAF (Liscovitch and Cantley, 1994).

LPA binds to GPCR of the EDG family, inducing proliferation and migration in many cell lines. The characterization and purification of lysophospholipase D (lysoPLDs) have been recently reviewed by Xie and Meier (2004). Some proposed routes for LPA production involve the sequential actions of PLD and PLA_2. Another route involves the sequential actions of PLA_2 and lysoPLD. LysoPLD is defined as an enzyme that hydrolyzes lysophospholipids to produce LPA and both microsomal and extracellular forms of lysoPLD have been reported. The microsomal lysoPLD plays an important role in the metabolism of PAF since it has a preference for alkyl-phospholipids and shows a close linkage between these two active lipid molecules.

PAF activity is also markedly altered by fatty acids. It has been shown that the phosphoinositide (PI)-signaling pathway through the activation of G-proteins, stimulated a higher Ca^{2+} mobilization in macrophages from mice fed n-3 compared to n-6 fatty acids. In addition, the response of macrophages from n-3 fed mice to PAF was less sensitive to PLC inhibition than that of macrophages from those fed n-6 diets. The activity of PLC in macrophages from mice fed n-3 diets was significantly higher than that of macrophages from mice fed diets containing n-6 fatty acids. These results show that n-3 fatty acids can enhance the PAF-signaling pathway in macrophages by increasing the activation potential of PLC, without affecting PAF receptor number and affinity (Chakrabarti et al., 1997). For an excellent review on the effects of fatty acids of PKC and PAF see Graber et al. (1994) and Jackson (1997).

VI. OTHER FATTY ACID SIGNALING MECHANISMS

A. Involvement in Ion Channel Regulation

It has been shown by many investigators that certain fatty acids may be regulators of ion channels. This may involve direct interaction of the fatty acid with the ion channel itself or by altering the interaction of channels with the lipid bilayer.

1. *Potassium channels* Ordway et al. (1989, 1991) have shown that *cis*-mono and polyunsaturated, *trans*-polyunsaturated and saturated fatty acids are capable of directly activating K^+ channels in gastric smooth muscle cells. Others have noted similar effects in cardiac atrial cells (Kim and Clapham, 1989) and in aortic or pulmonary artery smooth muscle cells (Bregestovski et al., 1989; Kirber et al., 1992). In membrane patches from toad smooth muscle cells, both myristic and AAs at micromolar concentrations promptly activated a K^+ selective channel (Ordway et al., 1991). Poling et al. (1995, 1996) showed

that DHA produced a concentration-dependent inhibition of the sustained outward current in isolated neocortical neurons. These authors suggest that the fatty acid interacts directly with an external domain of the ion channel and serves to selectively modulate certain voltage-gated K^+ channels in a zinc-dependent fashion. However, concentrations of 5 μM, unsaturated and medium chain length saturated fatty acids accelerated the inactivation of voltage-dependent K^+ channels in neuroblastoma cells (Rouzaire-Dubois et al., 1991).

As recently reviewed by Besana et al. (2005), two-pore domain K^+ channels make up the newest branch of the K^+ channel super-family and modulation of these channels is thought to underlie the function of physiological processes as diverse as the sedation of anesthesia, regulation of normal cardiac rhythm and synaptic plasticity associated with simple forms of learning. Lipids, including arachidonate and its lipoxygenase metabolites (12(S)-HPETE) as well as PAF have been identified as important mediators of these channels.

2. *Calcium channels* It has been shown that AA-induced Ca^{2+} mobilization from pancreatic islets that occurred rapidly, within 2 min, was not due to the metabolites of AA (Wolf et al., 1986). A similar effect of AA on intracellular Ca^{2+} efflux was also observed in T and B human lymphocytes and in MA-lO cultured Leydig tumor cells (Graber et al., 1994).

   On the whole, as suggested by Graber et al. (1994) AA and other unsaturated fatty acids play the role of second messengers in transducing activation signals by inducing Ca^{2+} mobilization from intracellular stores or by modulating plasma membrane Ca^{2+} channels. However, many of the Ca^{2+} channel regulatory effects of AA appear due to eicosanoid metabolites.
3. *Sodium and chloride channels* AA and other *cis*-unsaturated fatty acids (including oleic and linoleic acids) in human fetal tracheal epithelial cells has been shown to block secretory chloride (CV) channels in a dose-dependent manner (1–25 μM), whereas *trans*-unsaturated and saturated fatty acids do not inhibit the channel.

   The effects of fatty acids on sodium channels in muscle cells depend on the side of the membrane exposed to the fatty acids. It appears that fatty acids are modulators of skeletal muscle sodium channels by two different pathways. Extracellular fatty acid could be interacting with specific sodium channel receptors and intracellular fatty acid could be modulating PKC activity, but the mechanism of excitatory and inhibitory modulation of sodium channels by fatty acids remains to be elucidated. These mechanisms as they relate to Na-K-ATPase activity modulation are reviewed by Graber et al. (1994).

VII. CONCLUSIONS

This review has focused on some of the roles fatty acids contribute to cellular signaling directly as free fatty acids and indirectly as structural analogues to other lipid signaling molecules. Our understanding of these fatty acid–lipid signaling molecules has advanced tremendously in the past decade but much work still remains. It appears that many of the studies reviewed cite contradictory effects for many of the fatty acids depending on the cell type used and other co-factors needed (e.g., zinc). Furthermore, the studies cited are predominately *in vitro* studies and the *in vivo* conditions and concentrations are most likely very different and thus great care should be exercised in extrapolating these fatty acid effects to *in vivo* conditions. However, the study of lipid signaling molecules is growing exponentially and as more is understood new doors are opened and seemingly never ending new pathways revealed.

31 Safety and Health Effects of *Trans* Fatty Acids

J. Edward Hunter

CONTENTS

I. INTRODUCTION

In recent years, *trans* fatty acids in foods have raised health concerns largely from reports that high levels in the diet, compared to high levels of *cis* fatty acids, have resulted in unfavorable effects on both low-density lipoprotein cholesterol (LDL-cholesterol) and high-density lipoprotein cholesterol (HDL-cholesterol). In response, many health professional organizations have recommended reduced consumption of foods containing *trans* fatty acids, and the U.S. Food and Drug

Administration (FDA) issued regulations requiring the labeling of *trans* fatty acids on packaged foods effective from January 1, 2006. In addition, many food manufacturers, who have used partially hydrogenated oils in their products, have developed or are considering ways to reduce or eliminate *trans* fatty acids from these products.

This chapter updates that of Hunter (2000) and covers the following topics: (1) occurrence of *trans* fatty acids in the U.S. food supply; (2) review of human studies relating dietary *trans* fatty acids to risk of coronary heart disease (CHD); (3) review of studies relating dietary *trans* fatty acids to other health conditions, such as cancer, maternal and child health, type 2 diabetes, and macular degeneration; (4) dietary recommendations regarding *trans* and saturated fatty acids by health professional organizations; and (5) alternatives for replacing or reducing *trans* fatty acids in foods.

II. OCCURRENCE OF *TRANS* FATTY ACIDS IN THE U.S. FOOD SUPPLY

Unsaturated fatty acids in foods can exist in either the *cis* or *trans* configuration (Figure 31.1). In the *cis* form, the hydrogen atoms are on the same side of the double bond. In the *trans* form they are opposite. As a result of these orientations around the double bond, the *cis* fatty acid has a bend in the carbon chain, whereas the *trans* fatty acid has a straight carbon chain resembling that of a saturated fatty acid. The term "positional isomer" is commonly used to refer to *cis* or *trans* fatty acids if one or more of the double bonds has migrated to a new position in the fatty acid chain. *Trans* fatty acids (with double bonds at various positions in the fatty acid chain) and *cis* positional isomers are formed during partial hydrogenation of fats and oils, a process used to impart desirable stability and physical properties to food products such as margarines and spreads, shortenings, frying fats, and specialty fats (e.g., for fillings, toppings, and candy). In addition, small amounts of *trans* fatty acids occur naturally in foods such as milk, butter, and tallow as a result of biohydrogenation in ruminants.

Widespread use of partially hydrogenated vegetable oils in the United States during the past four or five decades has raised questions about the health effects resulting from the consumption of *trans* fatty acids present in these products. Among isomeric fatty acids, interest has focused on *trans* fatty acids rather than on positional isomers of *cis* fatty acids. Accordingly, this chapter deals with effects of *trans* fatty acids rather than positional isomers of *cis* fatty acids.

Typical levels of *trans* fatty acids in food products containing partially hydrogenated oils are shown in Table 31.1. Frying oils used by restaurants and food service operations range in *trans* fatty acid content from 0% to about 35% of total fatty acids. Some restaurants and food service operations currently use unhydrogenated oils (such as those used as salad oils) for frying, and such oils are *trans*-free. Until a few years ago, the fats used in the manufacture of retail margarines and spreads contained, on average, about 15%–25% *trans* fatty acids. Currently, most tub, liquid, and spray products contain no *trans* fat. The total fat content of many retail spreads, both tub and stick

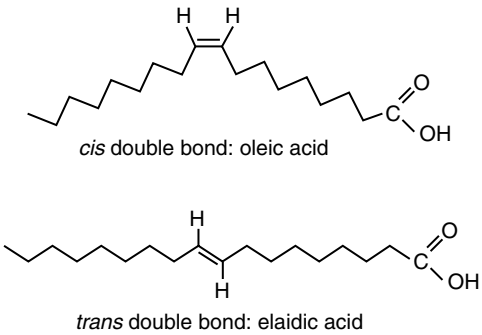

FIGURE 31.1 Structural formulas for the *cis* fatty acid, oleic acid, and its *trans* isomer, elaidic acid.

TABLE 31.1
Typical Levels of *Trans* Fatty Acids in Food Fats/Products

Food Fat/Product	*Trans* Fatty Acid Content
Frying fats	0%–35% of fatty acids
Margarines/spreads	Fat: 0%–25% of fatty acids Product: 0%–15% by weight
Shortenings	0%–30% of fatty acids
Beef and dairy fat	3% of fatty acids

The levels of *trans* fatty acids in various food products are expressed as a percentage of total fatty acids.

varieties, now averages about 55%–60%. Thus, these spread products contain between 0% and 15% *trans* fatty acids by weight. True margarines contain at least 80% fat (required by the FDA's standard of identity for margarines), but such products now represent only a small market share of the category of margarines and spreads. Most currently available baking shortenings typically contain about 15%–30% *trans* fatty acids, expressed as a percentage of total fatty acids. In 2005, at least one marketed shortening was *trans*-free. Beef and dairy fat typically contain about 3% *trans* fatty acids, also expressed as a percentage of total fatty acids.

With regard to levels of consumption, Allison et al. (1999) reported a mean intake of *trans* fatty acids by the U.S. population of 2.6% of energy, or 5.3 g/person/day. This estimate was based on 24-h recalls and 2-day food records by over 11,200 subjects as part of the USDA's Continuing Survey of Food Intakes by Individuals. Consistent with these results, Harnack et al. (2003) reported that the mean intake of *trans* fatty acids in a population of adult subjects in the Minneapolis–St. Paul, MN, metropolitan area decreased from 3.0% of total energy in 1980–1982 to 2.2% of total energy in 1995–1997. The estimates of Harnack et al. (2003) were based on 24-h dietary recalls by more than 7900 subjects participating in the Minnesota Heart Study, an ongoing observational epidemiologic study. These estimated intakes of *trans* fatty acids by Allison et al. (1999) and by Harnack et al. (2003) of 2%–3% of total energy are smaller than those of saturated fatty acids, which contribute 12%–14% of energy intake (Grundy and Denke, 1990; Kris-Etherton and Nicolosi, 1995; American Society for Clinical Nutrition/American Institute of Nutrition Task Force on *Trans* Fatty Acids, 1996; Ahuja et al., 1997). The intake of *trans* fatty acids in 14 European countries has been reported to range from 0.5% to 2.1% of energy (Hulshof et al., 1999), somewhat less than the intake reported for the United States. This intake of *trans* fatty acids in Europe also is considerably less than the intake of saturated fatty acids in Europe, estimated to be 10%–19% of energy (Hulshof et al., 1999).

The estimates of intake of *trans* fatty acids based on reported consumption of foods (Allison et al., 1999; Hulshof et al., 1999; Harnack et al., 2003) are considerably lower than estimates based on the availability from foods. The latter estimates consider market size, market share, and composition of various products made from partially hydrogenated fats and oils, and thus represent reasonable approximations of intake. Such estimates, however, do not take into account fats that are wasted or deliberately discarded. In 1986, Hunter and Applewhite (1986) reported an estimate of *trans* fatty acids available for consumption in the U.S. diet for 1984 of 7.6 g/person/day. A similar value, 8.3 g/person/day, was obtained independently by a *Federation of American Societies for Experimental Biology* (FASEB) Review Panel on *Trans* Fatty Acids (Senti, 1985). Hunter and Applewhite (1991) updated their estimate of *trans* fatty acid availability in the U.S. diet for 1989 to be 8.1 g/person/day. Current efforts by many food manufacturers to eliminate or drastically reduce levels of *trans* fatty acids in their products (to be discussed in Section VI of this chapter), are expected to reduce the intake of *trans* fatty acids to levels well below those reported to date.

III. HUMAN STUDIES RELATING DIETARY *TRANS* FATTY ACIDS TO RISK OF CORONARY HEART DISEASE

A. Review Articles

a. Reviews of Studies Reported Prior to 1990

The year 1990 marked a period of renewed interest by many health professionals in effects of dietary *trans* fatty acids. That year a study by Mensink and Katan (1990) reported that high levels of *trans* fatty acids in the diet increased the level of LDL-cholesterol and decreased the level of HDL-cholesterol compared to high levels of *cis* fatty acids. Details of this study will be discussed subsequently.

Prior to the study by Mensink and Katan (1990), there were numerous reviews and comprehensive studies on the nutritional and biological effects of *trans* fatty acids (e.g., Mattson, 1960; Alfin-Slater and Aftergood, 1979; Applewhite, 1981; Beare-Rogers, 1983; Kritchevsky, 1983; Emken, 1984; Hunter, 1987) that focused on whether or not *trans* fatty acids play a role in the development of atherosclerosis. In general, these studies showed that diets high in 18-carbon *trans* monoenes but adequate in essential fatty acids were not uniquely atherogenic. Many of these reviews and studies were considered in a comprehensive literature review by a special FASEB committee (Senti, 1985). This report concluded that there is "little reason for concern with the safety of dietary *trans* fatty acids *both* at their present and expected levels of consumption *and* at the present and expected levels of consumption of dietary linoleic acid … ." A 1987 British Nutrition Foundation report on the safety of *trans* fatty acids reached the same conclusion (British Nutrition Foundation, 1987).

b. Reviews of Studies Reported Since 1990

Reviews published after 1990 discussed the Mensink and Katan study (1990) and subsequent studies, suggesting that high dietary levels of *trans* fatty acids increased CHD risk. A review by Kris-Etherton and Nicolosi (1995, before much of the *trans* fat literature was published) suggested that the association between *trans* fatty acid intake and CHD risk is weak and inconsistent compared with the large body of evidence from epidemiologic observations and animal and human studies that support a direct effect of saturated fat on CHD risk. These authors commented that some clinical studies were difficult to interpret because it was unclear whether the reported responses were due to the addition of *trans* fatty acids to the diet or to a decrease in dietary unsaturated (i.e., cholesterol-reducing) fatty acids. Kris-Etherton and Nicolosi (1995) considered the current level of intake of *trans* fatty acids to be safe; however, they supported the reduction of total fat intake (including reduced intake of *trans* and cholesterol-raising saturated fatty acids) as part of national dietary guidelines to promote health and well-being.

Katan et al. (1995) concluded that the effects of *trans* fatty acids on raising plasma LDL-cholesterol levels were similar to those of saturated fatty acids. These authors recommended that diets aimed at reducing the risk of CHD be low in both *trans* and saturated fatty acids.

A comprehensive review by the American Society for Clinical Nutrition/American Institute of Nutrition Task Force on *Trans* Fatty Acids (1996) concluded that "compared with saturated fatty acids, the issue of *trans* fatty acids is less significant because the U.S. diet provides a smaller proportion of *trans* fatty acids and the data on their biological effects are limited." The Task Force recommended that data be obtained on the intake of *trans* fatty acids, their biological effects, mechanisms of action, and relation to disease that are comparable to those of saturated fatty acids.

Zock and Katan (1997) reviewed 20 dietary trials comparing effects of butter and margarine on blood lipids. The authors reported that replacing butter by soft, low-*trans* margarines favorably affected the blood lipoprotein profile, which in turn might reduce the risk of CHD. Replacing butter by hard, high-*trans* margarines appeared to offer no benefit over butter.

Ascherio et al. (1999) reported a linear relationship between the change in LDL/HDL ratio (a measure of CHD risk) vs. the percentage of energy from either *trans* fatty acids or saturated fatty acids in the diet. These authors also concluded that the adverse effect on LDL/HDL ratio of *trans* fatty acids appeared to be stronger than that of saturated fatty acids.

A subsequent review by Katan (2000) indicated that since around 1990, *trans* fatty acids went from a type of fat generally regarded as safe and possibly beneficial to one considered by many to be unfavorable for CHD risk. Katan felt that *trans* fatty acids were at least as unfavorable as cholesterol-raising saturated fatty acids.

A review by Schaefer (2002) suggested that hydrogenated margarines and butter should be avoided, and that either oil or soft margarine low in *trans* fatty acids should be used as a spread. Schaefer noted that in addition to having unfavorable effects on LDL- and HDL-cholesterol concentrations, there is evidence that increased *trans* fatty acid consumption, in contrast with consumption of saturated fat, increases plasma concentrations of lipoprotein(a) [Lp(a)], an independent risk factor for CHD.

Mensink et al. (2003) reported a meta-analysis of 60 controlled trials focusing on the effect of individual dietary fatty acids on the ratio of total cholesterol to HDL-cholesterol and on serum lipoproteins. These authors determined that this ratio was decreased most effectively (corresponding to decreased risk of CHD) when *trans* fatty acids and saturated fatty acids were replaced with *cis* unsaturated fatty acids.

In contrast to the above reviews, Wilson et al. (2001) concluded that the intake of *trans* fatty acids does not pose as much of a health concern for Americans as does the intake of cholesterol-raising saturated fatty acids. Although Wilson et al. (2001) encouraged efforts to minimize increased amounts of *trans* fatty acids in the diet, they felt that *trans* fatty acids at the current level of intake are a safe component of the diet. Wilson et al. (2001) suggested that consumers limit their intake of *trans* fatty acids by lowering their intake of total fat within the context of a varied and healthful diet.

The Institute of Medicine (IOM) of the National Academy of Sciences (2002) reviewed effects of dietary *trans* fatty acids as part of a report on reference intake levels of macronutrients. Referring to the article by Ascherio et al. (1999), the IOM report stated that similar to saturated fatty acids, there is a positive linear trend between *trans* fatty acid intake and increased risk of CHD. The IOM report did not establish a "Tolerable Upper Intake Level" above which long-term consumption might be undesirable for some individuals. The IOM noted that *trans* fatty acids are unavoidable in ordinary diets, and that eliminating them from the diet might result in inadequate intakes of certain nutrients and increase certain health risks. The report recommended that consumption of *trans* fatty acids as well as saturated fatty acids and cholesterol be as low as possible from a nutritionally adequate diet.

The most recent review, by Mozaffarian et al. (2006), considers evidence for physiological and cellular effects of *trans* fatty acids as well as the feasibility and potential implications of reducing or eliminating the consumption of *trans* fatty acids in the United States. Consistent with other reviews, this article conveys risks associated with consumption of high levels of *trans* fatty acids. In contrast to other reviews, the authors state that even low levels of consumption (1%–3% of total energy intake) confer "a substantially increased risk … ." However, the references cited to support this statement were epidemiological and prospective studies and not controlled dietary trials in which the investigators fed *trans* fatty acids at such levels. A controlled study by Lichtenstein et al. (1999) found no significant effect on either LDL- or HDL-cholesterol when a diet containing *trans* fatty acids at 3.3% of energy was fed for 35 days and compared to a control diet with *trans* fatty acids at only 0.6% of energy. Mozaffarian et al. (2006) expressed their view that consumption of *trans* fatty acids at less than 0.5% of total energy may be necessary to avoid adverse effects. This would mean complete or near-complete avoidance of dietary *trans* fatty acids, an extreme position compared to that expressed in the IOM report (2002) and probably unlikely in the near future to meet with significant consumer acceptance.

B. Human Trials Reporting Changes in Blood Lipid and Lipoprotein Levels with Dietary *Trans* Fatty Acids

a. Experimental Studies

Prior to 1990, two comprehensive literature reviews (Senti, 1985; British Nutrition Foundation, 1987) had concluded that there was little basis for concern about the consumption of *trans* fatty acids at present and expected dietary levels. One study (of many) on which this conclusion was based was that of Mattson et al. (1975). This study was particularly significant because it was the first to control carefully the fatty acid composition of the diets. In this study, subjects were fed liquid formula diets high in *cis* or *trans* fatty acids for 28 days. The fatty acid intakes of both groups were the same except for the presence or absence of *trans* fatty acids. The key result was that the subjects fed the high-*trans* diet had the same blood total cholesterol and triglyceride levels as subjects fed the high-*cis* diet. At the time this study was conducted, methodology for measuring HDL- and LDL-cholesterol and their apoproteins was not well established.

In a subsequent study by Mensink and Katan (1990), blood lipoprotein levels were measured in young adult human subjects (mean age 26 years) fed conventional food diets high in either *cis*, *trans*, or saturated fatty acids. The study design resembled that used by Mattson et al. (1975) in that the diets containing *cis* and *trans* fatty acids had similar fatty acid compositions except for the presence or absence of *trans* fatty acids. In this study, the high-*trans* diet (10.9% of energy as *trans* fatty acids) raised total and LDL-cholesterol and lowered HDL-cholesterol compared to the high-*cis* diet after 3 weeks. Although the level of *trans* fatty acids in the high-*trans* diet was unrealistically high (nearly 11% of energy), the authors concluded that the effect of *trans* fatty acids on serum lipoprotein profiles was similar to that of cholesterol-raising saturated fatty acids.

Since the Mensink and Katan study (1990), numerous other human trials have been conducted, which included measurement of LDL- and HDL-cholesterol [and occasionally Lp(a)], after feeding diets moderate or high in *trans* fatty acids. These studies include Mensink et al. (1992), Nestel et al. (1992), Zock and Katan (1992), Lichtenstein et al. (1993, 1999), Wood et al. (1993a,b), Judd et al. (1994, 1998, 2002), Almendingen et al. (1995), Cuchel et al. (1996), Aro et al. (1997), Clevidence et al. (1997), Sundram et al. (1997), Muller et al. (1998a,b), Noakes and Clifton (1998), Tholstrup et al. (1998, 2006), Vidgren (1998), Louheranta et al. (1999), Denke et al. (2000), de Roos et al. (2001a,b), French et al. (2002), Han et al. (2002), Lovejoy et al. (2002), and Sanders et al. (2003). Key study design parameters and results are summarized in Table 31.2. In essence, these studies demonstrated that diets high in *trans* fatty acids raised LDL-cholesterol and lowered HDL-cholesterol compared to diets low in *trans* fatty acids.

Three noteworthy studies (Zock and Katan, 1992; Judd et al., 1994, 2002) are discussed in more detail below. Zock and Katan (1992) compared effects on blood lipoproteins of diets high in linoleic acid, *trans* fatty acids, and stearic acid. In this study, the intake of *trans* fatty acids was lower than that of the Mensink and Katan (1990) study (7.7% of energy vs. 10.9% of energy). The lower level of *trans* fatty acids raised total cholesterol and LDL-cholesterol and lowered HDL-cholesterol compared to the linoleic acid diet. The stearic acid diet similarly raised total and LDL-cholesterol and reduced HDL-cholesterol compared to the linoleic acid diet. Subsequently, Mensink et al. (1992) reported that this *trans* fatty acid diet raised Lp(a) levels compared to the linoleic acid and stearic acid diets.

In the first study by Judd et al. (1994), moderate- and high-*trans* diets (3.8% and 6.6% of energy, respectively) resulted in increased plasma LDL-cholesterol levels compared to an oleic acid diet. These increases, however, were less than those observed with a saturated fatty acid diet. The high-*trans* diet, but not the moderate-*trans* diet, resulted in a minor (statistically significant) reduction in HDL-cholesterol. The saturated diet, however, led to a slight increase in HDL-cholesterol.

Lp(a) levels were reported in a subsequent publication (Clevidence et al., 1997). Compared to the oleic diet, the *trans* diets had no effect on Lp(a) levels when all subjects were considered collectively.

TABLE 31.2
Human Trials Reporting Changes in LDL-Cholesterol, HDL-Cholesterol, and Lipoprotein(a) with Dietary *Trans* Fatty Acids (TFA)

Reference	Study Population	Period (Days)	TFA (% en) Treatment and Control Diets	Change in LDL-C vs. Control[a]	Change in HDL-C vs. Control[a]	Change in Lp(a) vs. Control[a]

[a] Changes indicated were significant at $p \leq 0.05$ unless otherwise indicated.

[b] Based on 3-day food records.

Abbreviations: TFA, *trans* fatty acids; % en, % of energy; LDL-C, low-density lipoprotein-cholesterol; HDL-C, high-density lipoprotein-cholesterol; Lp(a), lipoprotein(a); mM, millimoles/liter; OL, oleic acid; LA, linoleic acid; STE, stearic acid; SFA, saturated fatty acids; PUFA, polyunsaturated fatty acids; CO, corn oil; SBO, soybean oil; SO, sunflower oil; PHSBO, partially hydrogenated soybean oil; PHFO, partially hydrogenated fish oil; min, minimum (i.e., values apply only to test fat, not to total fat in diet); NS, not significant; NR, not reported.

However, a subset with initially high levels of Lp(a) (≥30 mg/dL) responded to the high-*trans* diet with a slight (5%) increase in Lp(a) levels relative to the oleic and moderate-*trans* diets. Thus, the unfavorable effects on Lp(a) of replacing *cis* with *trans* fatty acids were restricted to high-*trans* intakes in subjects with high levels of Lp(a).

The second study by Judd et al. (2002) included a high-carbohydrate diet to assess whether direct addition of *trans* fatty acids to the diet had an independent cholesterol-raising effect. In addition, a high-stearate diet was included to determine whether stearate and *trans* fatty acids were neutral with regard to their effects on blood lipoproteins. Compared to a high-oleic diet, a high-*trans* (8% of energy) diet raised LDL-cholesterol to a greater extent than a high-saturated diet despite similar levels of *trans* plus saturated fatty acids. In contrast, in the previous study (Judd et al., 1994), the increase in LDL-cholesterol after the high-*trans* diet was directionally (but not significantly) less than that observed after the high-saturated diet. Compared to the high-carbohydrate diet, both the moderate-*trans* (4% of energy) and high-*trans* diets and the saturated diet resulted in increased LDL-cholesterol levels. Both *trans* diets lowered HDL-cholesterol compared to the oleic diet but not compared to the carbohydrate diet. Also compared to the carbohydrate diet, the stearic acid diet had no effect on LDL-cholesterol but lowered HDL-cholesterol. The oleic acid diet had no effect on LDL-cholesterol but raised HDL-cholesterol.

The studies by Mensink and Katan (1990) and Zock and Katan (1992) and the two studies by Judd et al. (1994, 2002) were consistent in that in all four studies, the *trans* and saturated fatty acid treatments raised LDL-cholesterol levels compared to the control diet. The changes in LDL-cholesterol levels by *trans* fatty acids and by saturated fatty acids were similar. HDL-cholesterol levels in these studies were reduced consistently when the level of *trans* fatty acids in the diet was 6.6% of energy or higher. In the second study by Judd et al. (2002), the moderate-*trans* diet showed a reduction in HDL-cholesterol, which was not seen in the first study (Judd et al., 1994).

b. Collective Consideration of Human Trials

Other human studies (Nestel et al., 1992; Lichtenstein et al., 1993, 1999; Aro et al., 1997; Sundram et al., 1997) have also reported increases in LDL-cholesterol levels and decreases in HDL-cholesterol levels when diets high in *trans* fatty acids were compared to diets high in either oleic acid or linoleic acid (Table 31.2). Either of these control diets contained only small levels of *trans* fatty acids (from 0% to 0.7% of energy).

Nine such studies (Mensink and Katan, 1990; Nestel et al., 1992; Zock and Katan, 1992; Lichtenstein et al., 1993, 1999; Judd et al., 1994, 2002; Aro et al., 1997; Sundram et al., 1997) have been compared collectively by Ascherio et al. (1999). The latter investigators graphed the changes in LDL/HDL ratio reported in these studies against the percentage of energy from either *trans* fatty acids or saturated fatty acids (Figure 31.2). Two best-fit regression lines were plotted through the origin, one line representing the percentage of energy from *trans* fatty acids and the other line, the percentage of energy from saturated fatty acids. Six of the nine studies (Mensink and Katan, 1990; Nestel et al., 1992; Zock and Katan, 1992; Judd et al., 1994, 2002; Sundram et al., 1997) allowed a comparison between *trans* and saturated fatty acids. Both regression lines had positive slopes, indicating a positive association between intake of either category of fatty acids and CHD risk. However, the slope of the regression line for *trans* fatty acids was larger (by about twofold) than that for saturated fatty acids. This difference in slopes led to the conclusion that *trans* fatty acids have a more adverse effect on CHD risk than saturated fatty acids (Ascherio et al., 1999). The conclusion was supported further by the greater effect on LDL/HDL ratio of *trans* fatty acids compared to saturated fatty acids in the six studies that allowed such a comparison.

Another way to look at these studies collectively is to consider the relationship between simply the change in LDL-cholesterol level or the change in HDL-cholesterol level (rather than the change in their ratio) with increasing level of *trans* fatty acids in the diet (Hunter, 2005). This is reasonable because changes in the LDL/HDL ratio do not permit determination of whether LDL, or HDL, or

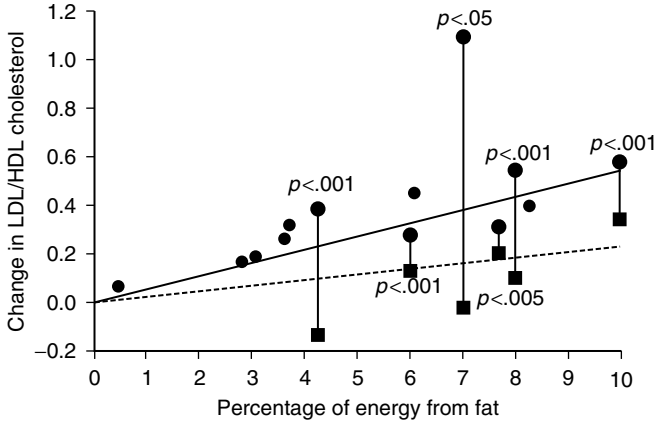

FIGURE 31.2 Change in LDL/HDL ratio with level of dietary *trans* fatty acids or saturated fatty acids. This graph was reported by Ascherio et al. (1999) and compares collectively the LDL/HDL ratios against the percentage of energy as either *trans* fat (solid circles, solid line) or saturated fat (solid squares, dashed line) for nine studies (see text).

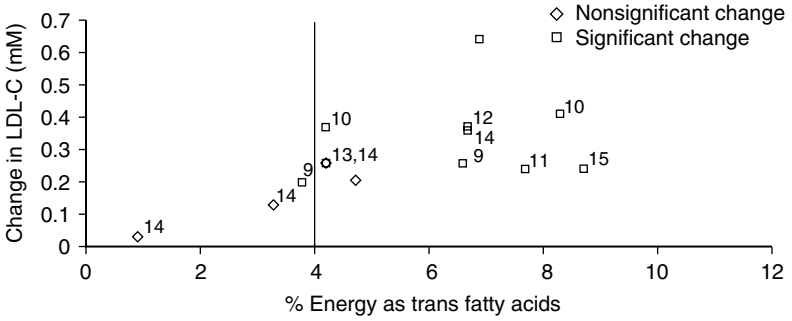

FIGURE 31.3 Scatter diagram of the change in LDL-cholesterol (expressed as mM) with dietary level of *trans* fatty acids (expressed as % energy) using data from the nine studies compared collectively by Ascherio et al. (1999). Changes in LDL-cholesterol were calculated from the difference between a *trans* fatty acid treatment and its corresponding control treatment. Open diamonds (◊) represent changes in LDL-cholesterol that were reported NOT to be statistically significant. Open squares (□) represent changes in LDL-cholesterol that were reported to be statistically significant. The number to the right of each point indicates the reference from which the data were taken (see Hunter, 2005).

both were changing at a particular dietary level of *trans* fatty acids. In addition, considering the ratio, saturated fatty acids tend to increase both LDL- and HDL-cholesterol, thus appearing to be "healthy" compared to *trans* fatty acids.

Using data from the same nine studies, Figure 31.3 is a scatter diagram of the change in LDL-cholesterol with dietary level of *trans* fatty acids. The relationship is directionally similar to that seen when the LDL/HDL ratio was plotted (Figure 31.2). Importantly, however, considering these nine studies, the change in LDL-cholesterol was not statistically significant unless the dietary level of *trans* fatty acids was around 4% of energy or higher. The change in HDL-cholesterol with increasing level of *trans* fatty acids in the diet (Figure 31.4), with the exception of one study, was not statistically significant unless the dietary level of *trans* fatty acids was higher than about 5%–6% of energy. [*Note:* Numerous other human studies (Table 31.2) that have evaluated effects of *trans* fatty acids on LDL- and HDL-cholesterol levels were excluded from consideration here because they did not compare effects of *trans* fatty acids with those of isocaloric amounts of *cis* fatty acids.]

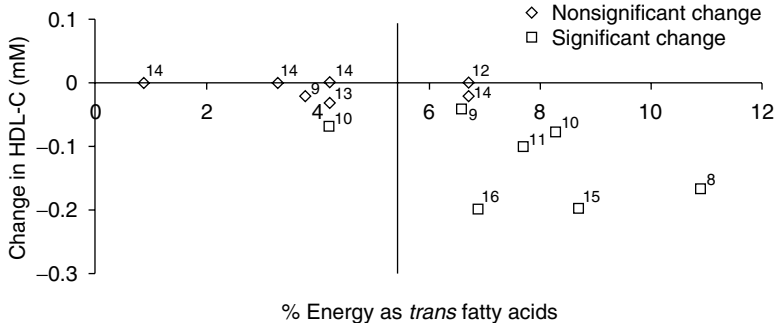

FIGURE 31.4 Scatter diagram of the change in HDL-cholesterol (expressed as mM) with dietary level of *trans* fatty acids (expressed as % energy) using data from the nine studies compared collectively by Ascherio et al. (1999). Changes in HDL-cholesterol were calculated from the difference between a *trans* fatty acid treatment and its corresponding control treatment. Open diamonds (◊) represent changes in HDL-cholesterol that were reported NOT to be statistically significant. Open squares (□) represent changes in HDL-cholesterol that were reported to be statistically significant. The number to the right of each point indicates the reference from which the data were taken (see Hunter, 2005).

In an effort to better define the dietary level of *trans* fatty acids that raises LDL-cholesterol and lowers HDL-cholesterol, weighted regression break point analysis and chi-squared analysis have been considered (Hunter, 2005). For LDL-cholesterol, a visual break point (the minimum level of *trans* fatty acids resulting in a significant increase in LDL) appeared to exist at or below about 4% of energy as *trans* fatty acids (Figure 31.3). Weighted regression analysis, however, did not show quantitatively that 4% of energy is the break point, probably in part because there were only two data points below 3.8% of energy. Nevertheless, it seemed reasonable to expect that a break point might exist in the range of 3.3%–4.2% of energy, where the difference between treatment and control LDL values was greatest. This range is consistent with a possible visual break point at or below 4% of energy.

In the case of HDL-cholesterol, more data were available below a visual break point estimated to be between 5% and 6% of energy (Figure 31.4). However, the absence of data in the range of 4.2%–6.6% of energy did not permit more precise estimation of a break point other than to suggest that it might fall in the 5%–6% of energy range.

Chi-squared analyses indicated reasonable break points for LDL and HDL to be about 3.5% and 7.0% of energy, respectively (Hunter, 2005). These latter values are similar to the visual break point estimates of 4% of energy for LDL and 5%–6% of energy for HDL. It is recognized that the confidence in these visual and estimated break points is limited because of the small amount of data (14 treatments) available from the nine studies considered. In particular from Figure 31.3, there were only two dietary treatments below 4% of energy as *trans* fatty acids. This is an insufficient amount of evidence at present to say whether or not *trans* fatty acids at less than 4% of energy are harmful to humans, and possible biological effects below 4% of energy cannot be ruled out.

An additional way to consider the same studies is to compare the levels of *trans* fatty acids and of linoleic acid used in the *trans* fatty acid diet treatments (Hunter, 2005). A scatter diagram (Figure 31.5) indicates that higher dietary levels of *trans* fatty acids were associated with lower levels of linoleic acid and vice versa. In some cases where high levels of *trans* fatty acids (i.e., more than 6% of energy) were fed, the corresponding levels of linoleic acid (2%–4% of energy) may have been nutritionally inadequate. For example, an adequate intake of linoleic acid for men 31–50 years old is 17 g/day (Institute of Medicine, 2002). For men in this age range consuming 2800 kcal/day, an adequate intake of linoleic acid would be 5.5% of energy, well above the 2%–4% of energy used in several studies.

Figure 31.6 plots the change in LDL/HDL ratio from the *trans* fatty acid diet treatments (Ascherio et al., 1999) against the percentage of energy as linoleic acid instead of against the percentage of

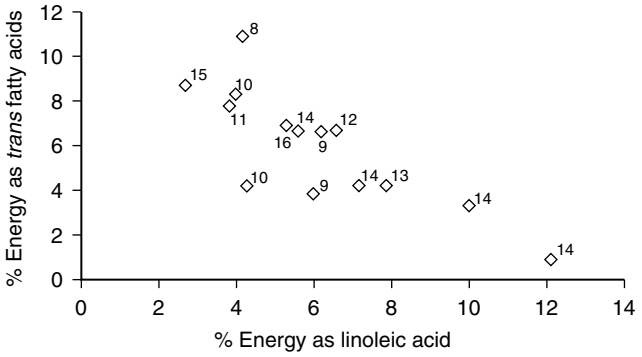

FIGURE 31.5 Scatter diagram comparing the levels of *trans* fatty acids and of linoleic acid used in the *trans* fatty acid diet treatments of the nine studies compared collectively by Ascherio et al. (1999). Each open diamond represents the level of dietary *trans* fatty acids and the corresponding level of linoleic acid used in that same treatment. The number to the right of each point indicates the reference from which the data were taken (see Hunter, 2005).

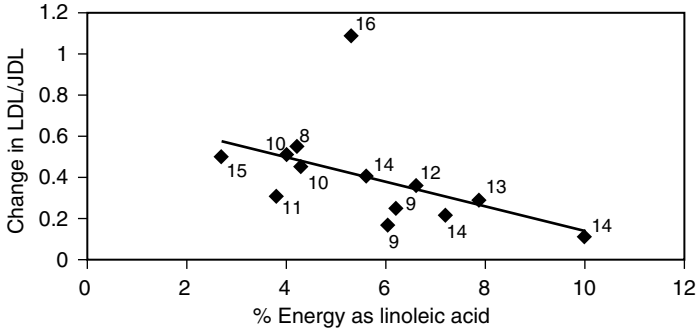

FIGURE 31.6 Change in the ratio of LDL-cholesterol/HDL-cholesterol vs. the dietary level of linoleic acid using data from the nine studies compared collectively by Ascherio et al. (1999). The slope for the best-fit regression line is –0.059, similar in magnitude (0.056) to that determined for the graph presented by Ascherio et al. (1999) (LDL/HDL ratio vs. % energy as *trans* fatty acids) but opposite in sign. The number to the right of each point indicates the reference from which the data were taken (see Hunter, 2005).

energy as *trans* fatty acids (Hunter, 2005). The regression line obtained is opposite in direction compared to that for the percentage of energy as *trans* fatty acids (Ascherio et al., 1999). One interpretation of this difference in direction of the regression lines is that at a sufficient level of linoleic acid in the diet (i.e., 5%–6% of energy or higher), *trans* fatty acids may be less effective in increasing the LDL/HDL ratio. Alternatively, increasing dietary linoleic acid may lower the LDL/HDL ratio through the well-known effect of lowering LDL-cholesterol. Thus, at sufficiently high levels of linoleic acid, there may be little effect on the LDL/HDL ratio due to *trans* fatty acids.

In summary, it appears that at a sufficiently high dietary level, *trans* fatty acids indeed raise LDL-cholesterol and reduce HDL-cholesterol levels compared to a diet essentially free of *trans* fatty acids. The dietary levels of *trans* fatty acids necessary to increase LDL-cholesterol appear to be around 4% of energy and higher and to decrease HDL-cholesterol, around 5%–6% of energy or higher compared to control diets. Statistically, based on limited available data, it was not possible to estimate precise break points for LDL or for HDL. Nevertheless, it appears that high dietary levels of *trans* fatty acids indeed increase CHD risk.

C. Studies on Clotting Tendency, Blood Pressure, and LDL Oxidation

Results of studies assessing the effect of dietary *trans* fatty acids on blood clotting tendency have been inconsistent. Wood et al. (1993a) reported that blood levels of thromboxane B_2, an indicator of increased platelet aggregation (i.e., a measure of increased clotting tendency), were unchanged in a group of human subjects fed high levels of hard margarine compared to subjects fed a baseline diet. On the other hand, blood levels of 6-keto-prostaglandin $F_{1\alpha}$, an indicator of antiaggregatory activity, were reduced in the margarine group compared to the baseline group, suggesting that *trans* fatty acids might have increased clotting tendency. Almendingen et al. (1996) found that a diet containing 8.5% energy from a margarine made from partially hydrogenated soybean oil resulted in higher levels of plasminogen activator inhibitor type 1 than a diet containing 8.0% energy from a margarine made from partially hydrogenated fish oil. This finding suggested that partially hydrogenated soybean oil had unfavorable antifibrinolytic effects compared to partially hydrogenated fish oil. There were no differences between the diets in levels of factor VII, fibrinogen peptide A, β-thromboglobulin, D-dimer, or tissue plasminogen activator.

In other studies, Mutanen and Aro (1997) reported no differences in coagulation and fibrinolysis between a high-stearic acid diet (0.4% of energy as *trans* fatty acids) and a high-*trans* fatty acid diet (8.7% of energy as *trans* fatty acids). The same high-stearic acid and *trans* fatty acid diets also produced similar effects on platelet aggregation and endothelial prostaglandin I_2 production (Turpeinen et al., 1998). Sanders et al. (2000), saw no significant differences in factor VII coagulation activity after feeding single meals high in either oleic acid (0.07% of energy as *trans* fatty acids) or elaidic acid (24.7% of energy as *trans* fatty acids). A subsequent study (Sanders et al., 2003) in which normocholesterolemic men were fed a high-oleic acid diet (0.1% of energy as *trans* fatty acids) or a high-*trans* fatty acid diet (9.6% of energy as *trans* fatty acids) for 2 weeks resulted in no differences in known hemostatic risk markers (fibrinogen and D-dimer concentrations, factor VII coagulant, plasminogen activator inhibitor type 1, and tissue plasminogen activity) for cardiovascular disease. Feeding a diet high in the ruminant *trans* fatty acid, vaccenic acid (1.1% of energy), similarly had no effect on the hemostatic variables factor VII coagulant activity and plasminogen activator inhibitor type 1 (Tholstrup et al., 2006).

With regard to blood pressure, two studies with normotensive subjects showed no effect of *trans* fatty acids (fed at up to 10.9% of energy) compared to oleic acid on either systolic or diastolic blood pressure (Mensink et al., 1991; Zock et al., 1993). Similarly, high-*trans* diets containing up to 8.5% of energy as *trans* fatty acids, consistently have reported little or no effect on the susceptibility of LDL to oxidation (Nestel et al., 1992; Cuchel et al., 1996; Halvorsen et al., 1996; Sorensen et al., 1998).

In summary, a limited number of studies to date have reported no consistent effects of dietary *trans* fatty acids on blood clotting tendency and no significant effects on blood pressure or LDL oxidation compared to dietary *cis* fatty acids.

D. Epidemiologic and Case–Control Studies

Several epidemiologic and case–control studies have reported associations between the intake of *trans* fatty acids and the risk of developing CHD. These studies include Troisi et al. (1992), Willett et al. (1993), Ascherio et al. (1994, 1996), Kromhout et al. (1995), Hu et al. (1997), Pietinen et al. (1997), Tavani et al. (1997), Oomen et al. (2001), and Lemaitre et al. (2002). Key study design aspects and results of these studies are summarized in Table 31.3. Results of the studies were consistent in that *trans* fatty acid intake was positively associated with risk of CHD or with a major coronary event, particularly when relative risks between the highest and lowest quintiles of intake were considered.

On the other hand, in at least one study (Ascherio et al., 1994), individuals consuming intermediate levels of *trans* fatty acids had a lower risk of CHD compared to individuals consuming the *lowest*

TABLE 31.3
Epidemiological/Case–Control Studies Relating Dietary *Trans* Fatty Acids and Risk of CHD

Reference	Study Design	Subjects	TFA Intake	Results	Comments
Troisi et al. (1992)	Cross-sectional	748 men, aged 43–85 years	Food frequency questionnaire; for entire sample, mean TFA intake was 1.6% of total energy	TFA intake directly related to total serum ($r = 0.07$, $p = 0.04$) and LDL-C ($r = 0.09$, $p = 0.01$)	Authors suggested increasing TFA intake from 2.1 to 4.9 g/d would correspond to a 27% increase in risk of MI
Willett et al. (1993)	Prospective cohort study among 85,095 women	431 women experiencing new CHD (nonfatal MI or death from CHD) over 8 year follow-up period	Food frequency questionnaire; quintiles of mean TFA intakes: 1.3, 1.8, 2.2, 2.6, and 3.2% of energy (2.4, 3.2, 3.9, 4.5, and 5.7 g/d)	TFA intake directly related to risk of CHD (relative risk for highest vs. lowest quintile was 1.50 ($p = 0.001$ for trend)	Authors suggested consumption of partially hydrogenated vegetable oils may contribute to occurrence of CHD
Ascherio et al. (1994)	Case–control	239 MI patients, 282 population controls	Food frequency questionnaire; quintiles of mean TFA intake: 1.69, 2.48, 3.35, 4.52, 6.51 g/d	TFA intake directly related to risk of MI (relative risk for highest vs. lowest quintile was 2.44 ($p < 0.0001$ for trend). Increased risk evident only among individuals in top quintile of intake	Patients not asked whether they changed their dietary intakes after their MI. LDL-C in this group may reflect recent dietary intakes rather than diet before MI
Kromhout et al. (1995)	Cohort study among men from seven countries	12,763 men, aged 40–59 years, over 25-year follow-up period	Food composites collected and analyzed for TFA. Average TFA intakes: 0.05% to 1.84% of energy	Strong positive associations between 25-year death rates from CHD and average intake of TFA (elaidic acid, $r = 0.78$, $p < .001$)	Authors suggested dietary TFA (also SFA and cholesterol) are important determinants of differences in population rates of CHD death
Ascherio et al. (1996)	Cohort study	43,757 men, aged 40–75, over 6 year follow-up period	Food frequency questionnaire; median intakes (g/d) of quintiles: 1.5, 2.2, 2.7, 3.3, 4.3 (0.8% to 1.6% of energy, lowest to highest quintiles)	TFA intake directly associated with risk of MI (nonfatal and fatal). Relative risk for quintiles: 1.0, 1.20, 1.24, 1.27, 1.40, $p = 0.01$	The association was attenuated after adjustment for dietary fiber
Hu et al. (1997)	Prospective cohort study	939 women with MI, aged 34–59 years	Food frequency questionnaire; median intakes of quintiles (% of energy): 1.3, 1.7, 2.0, 2.4, 2.9	TFA intake directly associated with risk of CHD. Relative risk for quintiles: 1.0, 1.07, 1.10, 1.13, 1.27 ($p = 0.02$ for trend)	Authors reported that replacing 2% of energy intake from TFA with unhydrogenated, unsaturated fats would reduce CHD risk by 53%

Pietinen et al. (1997)	Cohort study	21,390 male smokers, aged 50–69 years, over 6.1 year follow-up period	Food frequency questionnaire; median intakes (g/d) of quintiles: 1.3, 1.7, 2.0, 2.7, 6.2	TFA intake significantly associated with risk of major coronary event. Relative risk for quintiles: 1.00, 1.10, 0.97, 1.07, 1.14 (p = 0.158 for trend)	Authors also reported positive association between TFA intake and risk of coronary death (p for trend = 0.004)
Tavani et al. (1997)	Case–control	Italian women, aged 18–74 years, 429 MI cases, 866 controls	Margarine intakes reported as no or low, medium or high	Medium or high intake of margarine associated with increased risk of MI (multivariate odds ratio [OR] = 1.5) vs. no or low intake). Association stronger for women aged 60–74 years (OR = 2.4) and in current smokers (OR = 2.3)	Authors suggested the association with margarine could explain about 6% of MI in this population. Major limitation of this study: low intake of margarine by these Italian women
Oomen et al. (2001)	Prospective study	667 elderly Dutch men, aged 64–84 years	Dietary surveys; average TFA intakes fell from 10.9 to 6.9 to 4.4 g/d from 1985 to 1990 to 1995 (4.3%, 2.9%, and 1.9% of energy)	TFA intake positively associated with 10-year risk of CHD. Relative risk for a difference of 2% of energy in TFA intake at baseline was 1.28	Authors suggested that high intake of TFA contributes to risk of CHD
Lemaitre et al. (2002)	Case–control	174 cardiac arrest patients, 285 controls, aged 25–74 years	TFA levels in RBC membranes used as indicator of intake	Higher TFA levels in RBC membranes associated with increased risk of primary cardiac arrest (relative risk = 1.47). *Trans* isomers of oleic acid not associated with risk, but those of linoleic acid associated with threefold increase in risk	It seems unlikely that *trans* 18:2 isomers are present at sufficient levels in typical U.S. diets to contribute significantly to risk of primary cardiac arrest

Abbreviations: CHD, coronary heart disease; MI, myocardial infarction; TFA, *trans* fatty acids; SFA, saturated fatty acids; LDL-C, LDL-cholesterol; g/d, grams per day; r = partial correlation coefficient (adjusted for various parameters including energy intake, age, BMI, waist-to-hip ratio, smoking status, and alcohol intake); RBC, red blood cell.

level of *trans* fatty acids. This study did not support a dose–response relationship. A limitation of epidemiologic studies is that they may show associations between two variables but do not prove cause and effect relationships. The relatively low risk values reported for associations of *trans* fatty acid intake and CHD risk (typically around 1.2–1.5, Table 31.3) are considered weak associations by many epidemiologists (Lilienfeld and Stolley, 1994; Rothman and Greenland, 1998).

The study by Lemaitre et al. (2002) reported that *trans* isomers of oleic acid were not associated with CHD risk, whereas higher levels of *trans* isomers of linoleic acid were associated with a three-fold increase in risk. It seems doubtful, however, that *trans* 18:2 isomers are present at sufficient levels in typical U.S. diets to contribute uniquely and significantly to the risk of primary cardiac arrest (Expert Panel on *Trans* Fatty Acids and Coronary Heart Disease, 1995).

A further limitation of epidemiologic studies is that self-reported dietary intake data are likely inaccurate. Mertz et al. (1991) found that recall and food record data usually underestimate intake. A further complicating factor is that the *trans* fatty acid contents of similar appearing foods, such as tub margarines, can be highly variable among brands and even with the same brand over time. Thus, an assumed *trans* fatty acid level for the category of "tub margarines" may not result in accurate calculation of *trans* fatty acid intake levels over time.

In addition, a recent report by Schatzkin et al. (2003) does *not* recommend use of a food frequency questionnaire for evaluating relationships between absolute intake values and disease. This is because repeated applications of the questionnaire did not lead to improvement in proposed relationships being considered. The study by Schatzkin et al. (2003) was part of the National Cancer Institute's "Observing Protein and Energy Nutrition" (OPEN) Study designed to assess dietary measurement error by comparing results from self-reported dietary intake data with four dietary biomarkers: doubly labeled water and urinary nitrogen, sodium, and potassium. The study was conducted from July 1999 to March 2000 among 484 men and women, aged 40–69 years old. A key finding was the significant underreporting of energy and protein intakes by both men and women. While the study by Schatzkin et al. (2003) did not assess fatty acid intake, this study nevertheless would raise questions about the strength of the proposed relationship between CHD risk and *trans* fatty acid intake because most of the studies reporting such a relationship used a food frequency questionnaire to assess *trans* fatty acid intake. (Further information about the OPEN study may be found at the NCI website: http://riskfactor.cancer.gov/studies/open/status.html)

E. Other Studies

Muller et al. (2001) developed regression equations to predict effects on serum total and LDL-cholesterol levels of dietary *trans* fatty acids as well as individual saturated fatty acids. The regression equations were based on consideration of four controlled studies. The food sources of *trans* fatty acids were partially hydrogenated soybean oil and partially hydrogenated fish oil. *Trans* fatty acids from these two sources differ with respect to chain length and number of *trans* bonds. The authors concluded that myristic acid (C14:0) is the most hypercholesterolemic fatty acid and that *trans* fatty acids are less hypercholesterolemic than the saturated fatty acids, myristic and palmitic (C16:0) acids. Hydrogenated fish oil was felt to be slightly more hypercholesterolemic than hydrogenated soybean oil.

Kritchevsky (1999) cited human data indicating that if the diet contains a high level of linoleic acid (e.g., 22%–37% of total dietary fatty acids) and a relatively low level of *trans* fatty acids (e.g., 8%–18% of total dietary fatty acids), the change in total serum cholesterol is much smaller than if the diet contains a low level of linoleic acid and a high level of *trans* fatty acids. Such a relationship would be predicted according to equations presented by Muller et al. (2001). The relationship is supported by data cited in Figures 31.5 and 31.6 (see also Hunter, 2005).

The *trans* fats used in studies considered thus far have contained principally *trans* 18:1 isomers as well as low levels of *trans* 18:2 isomers. These fats have been essentially free of *trans* 18:3 isomers. Vermunt et al. (2001) recently investigated the effect of *trans* α-linolenic acid formed by deodorization

of canola oil (Sebedio et al., 2000) on plasma lipids and lipoproteins. Eighty-five healthy men from three European countries consumed a *trans* fatty acid-free diet for 6 weeks followed by either a diet "high" or "low" in *trans* α-linolenic acid for 6 weeks. Daily mean total *trans* α-linolenic acid intake was 1410 mg in the high *trans* group and 60 mg in the low *trans* group. The high *trans* α-linolenic acid diet did not change total, LDL-, or HDL-cholesterol, but it significantly increased the plasma LDL/HDL ratio by 8.1% and the total/HDL ratio by 5.1% compared to the low-*trans* diet. The authors commented that whether the diet-induced changes in these ratios truly affects CHD risk remains to be established. These results, however, suggest the importance of selecting conditions for deodorization that minimize formation of *trans* α-linolenic acid isomers. A parallel study by Armstrong et al. (2000) using the same high dietary level of *trans* α-linolenic acid found no effect on platelet aggregation and blood coagulation factors, including platelet thromboxane production, fibrinogen levels, factor VII, activated factor VIIa, or plasminogen activator inhibitor activity.

The level of *trans* α-linolenic acid produced by deodorization of canola or soybean oil depends on the time and temperature of the deodorization process (Kellens and De Greyt, 2000). The canola oil used in the studies by Vermunt et al. (2001) and Armstrong et al. (2000) contained 4.5% *trans* α-linolenic acid and was produced by batch deodorization for 52.5 h at 205°C (Sebedio et al., 2000). In contrast, most canola oil produced in the United States has a *trans* α-linolenic acid level ranging from about 1.0% to 2.5% (personal communication, David Volker, J.M. Smucker Co., Cincinnati, OH). The lower (1.0%) level of *trans* α-linolenic acid is typically produced by a continuous deodorization process lasting up to about 5 min at about 240°C–270°C. The higher (2.5%) level is typically produced by batch deodorization for up to 2 h also at 240°C–270°C. Canola oil containing 2.5% *trans* α-linolenic acid would qualify for a label claim of zero *trans* fatty acids in the United States, because a 14 g (1 tablespoon) serving of the oil would provide 0.35 g of *trans* fatty acids. The U.S. FDA permits a label claim of zero *trans* fatty acids if the food product contains less than 0.5 g of *trans* fatty acids per serving.

In summary, since 1990, controlled human studies have found that sufficiently high levels of dietary *trans* fatty acids increase LDL-cholesterol and decrease HDL-cholesterol compared with diets high in *cis* monounsaturated or polyunsaturated fatty acids. The dietary levels of *trans* fatty acids necessary to do this appear to be approximately 4% of energy or higher to increase LDL-cholesterol and approximately 5%–6% of energy or higher to decrease HDL-cholesterol, compared with control diets essentially *trans*-free. There are very limited data at lower levels of intake (less than 4% of energy). In the United States, the intake of saturated fatty acids is reported to be substantially higher (about 10%–12% of energy) than the intake of *trans* fatty acids (about 2%–3% of energy). In addition, since 1992, several epidemiologic and case–control studies have reported a positive association between dietary *trans* fatty acids and the risk of CHD. A major limitation of the epidemiologic studies may be inaccurate *trans* fatty acid intake data. To date, no consistent effects of dietary *trans* fatty acids compared to *cis* fatty acids have been reported on blood clotting tendency, blood pressure, or LDL oxidation.

IV. STUDIES RELATING DIETARY *TRANS* FATTY ACIDS TO CANCER, MATERNAL AND CHILD HEALTH, TYPE 2 DIABETES, AND MACULAR DEGENERATION

A. *Trans* Fatty Acids in Relation to Cancer

In contrast to the extensive literature on *trans* fatty acids in relation to CHD, relatively few investigators have studied *trans* fatty acids with respect to cancer. Ip and Marshall (1996) published a comprehensive review of more than 30 reports addressing the strength and consistency of available scientific data on *trans* fatty acids and cancer. One reviewed study (Sugano et al., 1989) involved the treatment of a colon cancer-sensitive strain of rats with the colon carcinogen dimethylhydrazine and then compared tumor development after feeding diets containing either partially hydrogenated corn

oil or high-oleic safflower oil. Overall, there was no evidence that cancer of the intestinal tract was differentially affected by fat type given to animals of either sex.

Ip and Marshall (1996) also evaluated epidemiologic studies since around 1990 that have considered the intake of various types of fatty acids on the development of cancer at different sites. For breast cancer, Ip and Marshall noted that the epidemiologic evidence shows only a slight to negligible effect of fat intake in general on breast cancer risk and no strong evidence that the intake of *trans* fatty acids is related to increased risk. For colon cancer, evidence exists of increasing risk with the intake of saturated fat or animal fat and decreasing risk with increased intake of fiber and vegetable products. However, no evidence indicated that the intake of *trans* fatty acids is related to an increased risk of colon cancer or rectal cancer. For prostate cancer, Ip and Marshall noted evidence that fat intake might be related to risk. Most of this evidence has focused on the consumption of saturated and animal fats. The intake of *trans* fatty acids has not been correlated with prostate cancer risk.

Since the review by Ip and Marshall (1996), two case–control studies have investigated an association between dietary *trans* fatty acids and the development of cancer. Kohlmeier et al. (1997) investigated the relationship between adipose tissue levels of *trans* fatty acids and postmenopausal breast cancer in European populations in 209 cases and 407 controls. Adipose tissue levels of *trans* fatty acids were used as a biomarker of dietary exposure. The adipose concentration of *trans* fatty acids showed a positive association with breast cancer, suggesting a relationship between adipose stores of *trans* fatty acids and postmenopausal breast cancer risk in European women. Dietary fatty acid data, however, were not provided to relate to adipose tissue stores.

The other case–control study was conducted by Slattery et al. (2001) to examine a possible association between dietary *trans* fatty acids and colon cancer incidence in 1993 cases and 2410 control subjects. Dietary data were collected using a diet history questionnaire. The authors found a weak association between dietary *trans* fatty acids and colon cancer risk in women (odds ratio = 1.5) but not in men (odds ratio = 1.2). Slightly stronger associations were observed in subjects aged 67 years or older (odds ratios = 1.4 for men, 1.6 for women). The authors concluded that it seems prudent to avoid consuming partially hydrogenated fats, because no increased risk was observed for *cis* fatty acids.

In recent years, a specific category of *trans* fatty acids, conjugated linoleic acid (CLA), has been reported to have human health benefits, including controlling body fat gain, enhancing immunity, and reducing inflammation (reviewed by Pariza, 2004). These and other health effects associated with CLA are covered by a separate chapter in this book.

In summary, current scientific evidence does not support a convincing relationship between *trans* fatty acid intake and the risk of cancer at specific sites. Two recent case–control studies have reported an association between the intake of *trans* fatty acids and breast cancer or colon cancer risk. However, the accuracy of the intake values is subject to question.

B. *Trans* Fatty Acids in Relation to Maternal and Child Health

Concerns about a possible relationship between dietary *trans* fatty acids and maternal and child health have focused on whether or not *trans* fatty acids may affect human fetal growth and infant development. It is well established that n-6 and n-3 long-chain polyunsaturated fatty acids play significant roles in growth and development. Linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3) are essential fatty acids (i.e., they cannot be synthesized by humans) that are precursors of other important long-chain polyunsaturated fatty acids. Specifically, arachidonic acid (20:4n-6) is derived from linoleic acid by desaturation and chain elongation reactions and is a component of membrane phospholipids, a precursor for eicosanoids, and a stimulant of growth and cell division. Docosahexaenoic acid (22:6n-3) is obtained in the diet (e.g., from fish oils) or synthesized from α-linolenic acid (also by desaturation and chain elongation) and is a component of retinal and neural membrane phospholipids. As such, it is involved in visual and central nervous system functions.

According to Carlson et al. (1997), concerns have been expressed that *trans* fatty acids could decrease fetal and neonatal tissue concentrations of n-6 and n-3 long-chain polyunsaturated fatty acids, thereby interfering with normal growth and development. Carlson et al. (1997) concluded that a definitive answer to the question of whether *trans* fatty acids affect fetal development is not possible because there are few studies in this area, observed effects have been small, results have been inconsistent, and confounding factors have not been excluded.

Noting that *trans* fatty acids from the maternal diet can cross the placenta or be secreted into human milk, Craig-Schmidt (2001) indicated that developing fetuses and nursing infants in the United States and Canada generally would be exposed to larger amounts of *trans* fatty acids than would infants in other parts of the world. This is supported by larger amounts of *trans* isomers in human milk samples from the United States and Canada compared to human milk samples from various countries of Europe, Asia, or Africa.

Craig-Schmidt (2001) also cited studies in which plasma *trans* fatty acid levels were inversely related to birth weight and head circumference. She added that the hypothesis that dietary *trans* fatty acids could inhibit the biosynthesis of long-chain polyunsaturated fatty acids with 20- or 22-carbon atoms and thus affect infant development is supported by studies demonstrating an inverse correlation between plasma *trans* fatty acids and n-3 and n-6 long-chain polyunsaturated fatty acids in infants. However, no such relationship has been observed in human milk. Craig-Schmidt (2001) concluded that the evidence supporting an unfavorable effect of *trans* fatty acids on infant development is correlational and that the physiological implications of the reported relationships are largely unknown.

Larque et al. (2001) also reviewed studies on the effects of dietary *trans* fatty acids in early life. These authors added that multigenerational studies using animals have shown no correlation between birth weight or growth and dietary *trans* fatty acids. Citing reports of inverse relationships between plasma *trans* fatty acids and arachidonic and docosahexaenoic acids, Larque et al. (2001) suggested that such results may indicate an inhibitory effect of *trans* fatty acids on liver Δ-6 fatty acid desaturase activity. In contrast to blood and liver, the brain appears to be protected from *trans* fatty acid accumulation in experimental animals, but no data have been reported for human infants.

Decsi et al. (2001) evaluated previously reported inverse correlations between values of *trans* fatty acids and long-chain polyunsaturated fatty acids in plasma lipids of full-term infants. In this study, the fatty acid composition of venous cord blood lipids was determined in 42 healthy full-term infants. The investigators found significant inverse correlations between total *trans* fatty acids and both arachidonic and docosahexaenoic acids in phospholipids, cholesterol esters, and nonesterified fatty acids, but not in triglycerides. Because *trans* fatty acids in the fetal circulation originate from the maternal diet, the authors suggested that maternal exposure to *trans* fatty acids may inversely influence long-chain polyunsaturated fatty acid status in full-term infants at birth.

The IOM report (2002) recognized concerns that *trans* fatty acids have been suggested to have adverse effects on growth and development through inhibition of the desaturation of linoleic acid and α-linolenic acid to arachidonic acid and docosahexaenoic acid, respectively. However, considering available evidence, including experimental work showing that inhibition of the Δ6 desaturation of linoleic acid is not of concern with linoleic acid intakes above about 2% of energy, the IOM concluded that inhibition of essential fatty acid metabolism by *trans* fatty acids is unlikely to be of concern for practical human diets.

In summary, it appears unlikely that current average dietary levels of *trans* fatty acids in the United States and Europe will have unfavorable effects on growth and development, reproduction, or gross aspects of fetal development.

C. *Trans* Fatty Acids in Relation to Type 2 Diabetes

Salmeron et al. (2001) suggested that an increase in polyunsaturated fatty acid intake and a decrease in *trans* fatty acid intake would substantially reduce the risk of women developing type 2 diabetes. During a 14-year follow-up of 84,204 women with no diabetes, cardiovascular disease, or

cancer, the investigators documented 2507 new cases of type 2 diabetes. Dietary information was assessed by food frequency questionnaires. Total fat intake, compared to equivalent energy intake from carbohydrates, was not associated with risk of type 2 diabetes. In contrast, polyunsaturated fatty acid intake was inversely associated and *trans* fatty acid intake positively associated with risk. The authors estimated that replacing 2% of the energy from *trans* fatty acids with polyunsaturated fatty acids would reduce the risk of type 2 diabetes by 40%.

Commenting on this study, Clandinin and Wilke (2001) noted that the influence of dietary *trans* fatty acids on insulin resistance has not been studied, and epidemiologic evidence relating *trans* fatty acid intake to diabetes is lacking. There is no known functional or physiological relation to connect *trans* fatty acids to disease mechanisms involved with type 2 diabetes. Clandinin and Wilke also questioned the reliability of estimates of intake of *trans* fatty acids from food frequency questionnaires.

An additional complication is that some processed foods containing *trans* fatty acids also contain large amounts of refined carbohydrates (e.g., certain baked goods), which could exacerbate the insulin-resistant state in diabetes and/or contribute to increases in serum triglyceride levels. This association of *trans* fatty acids with simple and complex carbohydrates does not permit distinction about whether *trans* fatty acids alone, *trans* fatty acids plus carbohydrates, or carbohydrates alone in certain products would contribute to the risk of type 2 diabetes. Thus, the conclusions of Salmeron et al. (2001) still represent a hypothesis to be tested.

A follow-up study by Hu et al. (2001) looked at combined effects of dietary and lifestyle factors in relation to type 2 diabetes. Considering essentially the same subject population studied by Salmeron et al. (2001), Hu et al. (2001) documented 3300 new cases of type 2 diabetes during 16 years of follow-up. Overweight or obesity was the single most important predictor of diabetes. Lack of exercise, a poor diet, current smoking, and abstinence from alcohol use were all associated with increased risk of diabetes, even after adjusting for body mass index. In addition, the combination of an appropriate diet, moderate amount of exercise, and abstinence from smoking, even in overweight and obese subjects, resulted in reduced risk of type 2 diabetes. A "poor diet" was described as being high in *trans* fat and glycemic load, low in cereal fiber, and having a low ratio of polyunsaturated to saturated fat. Quantitative levels of *trans* fatty acids, sugars, cereal fiber, and polyunsaturated and saturated fatty acids associated with the "poor diet" were not specified, and *trans* fatty acids were not singled out as an individual risk factor.

A similar study by van Dam et al. (2002) examined dietary fat and meat intake in relation to risk of type 2 diabetes in 42,504 male subjects initially free of diabetes, cardiovascular disease, and cancer. Diet was assessed by food frequency questionnaire. During 12 years of follow-up, 1321 new cases of type 2 diabetes were observed. Intakes of total fat and saturated fat were associated with a higher risk of type 2 diabetes. However, these associations disappeared after adjustment for body mass index. In addition, intakes of oleic acid, *trans* fatty acids, long-chain n-3 fatty acids, and α-linolenic acid were not associated with diabetes risk after multivariate adjustment. Results of this study with men were not consistent with the Salmeron et al. (2001) study reporting that *trans* fatty acids were positively associated and polyunsaturated fatty acids negatively associated with risk of type 2 diabetes in women.

D. *Trans* Fatty Acids in Relation to Macular Degeneration

Age-related macular degeneration (AMD) is the leading cause of irreversible visual impairment and blindness in the United States and other developed countries. Two recent studies from the same institution that evaluated a possible connection between dietary *trans* fatty acids and type 2 diabetes also addressed whether dietary fat, including *trans* fatty acids, is related to risk of AMD.

One of these studies, by Seddon et al. (2001), evaluated the relationship between intake of total fat and of specific fatty acids, including *trans* fatty acids, and risk of AMD in a case–control study at five U.S. clinical ophthalmology centers. Case subjects included 349 individuals (aged 55–80 years) with the advanced neovascular stage of AMD diagnosed within 1 year of their enrollment into the study. Control subjects included 504 individuals without AMD but with other

ocular diseases. Higher consumption of vegetable fat, monounsaturated fatty acids, polyunsaturated fatty acids, or linoleic acid was associated with an elevated risk of AMD. In contrast, higher consumption of saturated or *trans* fatty acids was not associated with higher risk of AMD.

The association between AMD and higher intake of vegetable, monounsaturated, and polyunsaturated fats and linoleic acid was suggested to be related to snack foods containing products that adversely affect the blood vessels of the choroids or retina. The authors felt that such foods might also increase oxidative damage in the macula, which is susceptible to oxidation because of high oxygen tension in the presence of light exposure. Thus, some individual dietary fats, but not necessarily total fat consumption, might increase or decrease the risk for AMD.

Cho et al. (2001) assessed a possible association between total fat and specific types of fat and AMD. This was a prospective study that at baseline included 42,743 women and 29,746 men, aged 50 years or older with no diagnosis of AMD. During the 12-year follow-up period, 567 subjects were diagnosed with AMD. The pooled (women and men) multivariate relative risk for the highest compared to the lowest quintile of total fat intake was 1.54, a value considered statistically significant. Unexplained was why the fourth quintile for fat intake had a relative risk equal to that of the first quintile and lower than that of the second and third quintiles. *Trans* fat intake was not related to risk of AMD, whereas α-linolenic acid intake was positively associated with risk of AMD. Docosahexaenoic acid, on the other hand, showed a slight inverse relationship with AMD, and more than four servings of fish per week was associated with a 35% lower risk of AMD compared with three or fewer servings per month.

In summary, one study has reported an association between *trans* fatty acid intake and type 2 diabetes, however, a follow-up study found no such association. In view of no known functional or physiological connection between *trans* fatty acids and type 2 diabetes, the reported association requires further testing. In the case of AMD, neither of the two studies reported an association between dietary *trans* fatty acids and risk of developing the condition. Considering the difficulty of conducting meaningful studies on effects of dietary fat on specific human disorders, such as type 2 diabetes and AMD, it is not surprising that no adverse effects were found in the few studies reported in these areas.

V. DIETARY RECOMMENDATIONS REGARDING SATURATED AND *TRANS* FATTY ACIDS

Current dietary recommendations by health professional organizations within and outside the United States (Anon, 2001a,b, 2003, 2005; Krawczyk, 2001; Institute of Medicine, 2002; Lichtenstein et al., 2006) address intake of cholesterol-raising saturated and *trans* fatty acids. These organizations are consistent in their recommendations of an upper limit of intake of saturated fatty acids of 10% of

TABLE 31.4
Dietary Recommendations for Saturated and *Trans* Fatty Acids: U.S. Organizations

Organization	Saturated Fatty Acids	*Trans* Fatty Acids
American Heart Association	<7% Energy (population) <7% Energy (those at risk)	<1% Energy (population)
Adult Treatment Panel III of the National Cholesterol Education Program	<7% Energy (those at risk)	Keep intake low
Health and Human Services/U.S. Department of Agriculture	<10% Energy (population)	Low as possible
Institute of Medicine of the National Academy of Sciences	Low as possible	Low as possible

Current dietary recommendations of U.S. health professional organizations for saturated and *trans* fatty acids.

TABLE 31.5
Dietary Recommendations for Saturated and *Trans* Fatty Acids: Non-U.S. Organizations

Organization	Saturated Fatty Acids	*Trans* Fatty Acids
Health Council of The Netherlands	Low as possible UL 10% energy	Low as possible UL 1% energy
Health Canada	<10% Energy	
Ministry of Agriculture, U.K.	<10% Energy	<2% Energy
Austria, Germany, Switzerland	<10% Energy	
Japan	6%–8% Energy	
World Health Organization/Food and Agricultural Organization of the United Nations	<10% Energy; <7% energy for high-risk groups	<1% Energy

Current dietary recommendations of non-U.S. health professional organizations for saturated and *trans* fatty acids.

energy and reduced intake of *trans* fatty acids. Recommendations from U.S. organizations are summarized in Table 31.4, and those from organizations in Europe and Japan, in Table 31.5. The consistency of these recommendations provides the basis for food manufacturers in the United States and globally to consider ways to decrease or eliminate *trans* fatty acids from their food products.

VI. ALTERNATIVES FOR REPLACING OR REDUCING *TRANS* FATTY ACIDS IN FOODS

Food manufacturers are using or developing basically four technological options to reduce or eliminate *trans* fatty acids in their products. These options include (1) modification of the hydrogenation process; (2) use of interesterification; (3) use of fractions high in solids from natural oils; and (4) use of trait-enhanced oils. Information on each of these topics was presented at a recent *AOCS* symposium on *trans* fat (Watkins, 2004). Frequently, some approaches are used in combination with others. Discussion of each option follows.

A. Modification of the Hydrogenation Process

Certain food products, such as spreads, margarines, and shortenings, require oils with specific levels of solids at different temperatures to achieve desired functionality. Solids normally come from either *trans* fatty acids (resulting from hydrogenation) or saturated fatty acids. Modifying the conditions of hydrogenation (e.g., pressure, temperature, and catalyst) affects the fatty acid composition of the resulting oil, including the amount of *trans* fatty acids formed, and properties such as melting point and solid fat content of the oil. It is possible to make equivalently performing low-*trans* fats by increasing the degree of hydrogenation, which reduces the level of *trans* fatty acids but increases the level of saturated fatty acids. Such fats will differ analytically from fats hydrogenated to a lesser degree because saturates now contribute most of the solids. This is illustrated in Figure 31.7 indicating that with progressive hydrogenation (decreasing iodine value) of soybean oil, the content of *trans* fatty acids increases to a maximum and then decreases essentially to zero. The corresponding level of saturated fatty acids increases gradually until the content of *trans* fatty acids is maximized and then increases rapidly.

Modification of the hydrogenation process can be used to prepare low-*trans* baking shortenings. The simple substitution of unhydrogenated (*trans*-free) fats for hydrogenated fats does not work well in baking applications. Some recipes for baked foods require a greater amount of saturated fat to replace a given amount of *trans* fat for the recipe to work (i.e., one-to-one substitution of saturated fat for *trans* fat often does not produce foods of equivalent consumer acceptability).

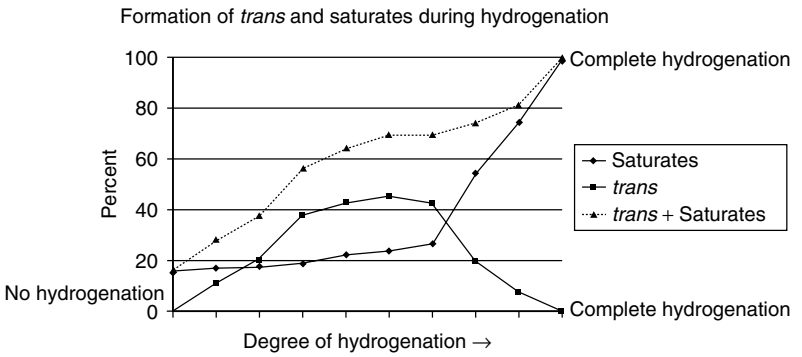

FIGURE 31.7 Changes in percentages of *trans* and saturated fatty acids with progressive hydrogenation of soybean oil. Progressive hydrogenation is indicated by decreasing iodine value. Corresponding levels of *trans* and saturated fatty acids, expressed as percent of total fatty acids, are shown. The graph was provided by Bob Wainwright, Cargill, Inc.

Low- or zero-*trans* baking fats may have increased levels of stearic acid from the hydrogenation of α-linolenic, linoleic, and oleic acids, and also significant levels of palmitic acid for functionality. Palmitic acid may be provided by incorporating a high palmitic acid fat, such as cottonseed oil, into the shortening.

B. Use of Interesterification

The interesterification process involves the rearrangement (randomization) of the fatty acids on the glycerol backbone of the fat (i.e., triglyceride) in the presence of a chemical catalyst or an enzyme. Interesterification modifies the melting and crystallization behavior of the fat, and the resulting fat is very low in *trans* fatty acids. One current application of this process is in the production of *trans*-free or low-*trans* fats for margarine, spread, and shortening applications. Several human studies have shown no significant effects of interesterified fats on blood lipid parameters (Nestel et al., 1995, 1998; Zock et al., 1995; Meijer and Weststrate, 1997; summarized in Hunter, 2001).

In chemical interesterification, an unhydrogenated liquid vegetable oil (such as a salad oil) and a fully hydrogenated vegetable oil (called a "hardstock," which has a low iodine value and a low amount of *trans* fatty acids) are mixed and heated. A typical blend may contain about 85% unhydrogenated oil and about 15% hardstock. Both components of the blend are essentially *trans*-free. A catalyst, commonly sodium methoxide, is added, and the interesterification process causes a random rearrangement of the fatty acids on the glycerol backbone. It is important to note that in such blended fat products, the term "hydrogenated fat" or "partially hydrogenated oil" would appear on the ingredient statement, but the product would be very low in *trans* fatty acids. Therefore, the listing of "hydrogenated fat" or "partially hydrogenated oil" on an ingredient statement does not always mean that the product contains a significant level of *trans* fat, as has been erroneously indicated by the popular press.

A recently modified interesterification process uses an enzyme instead of sodium methoxide to catalyze the reaction. The enzyme is a heat-stable, 1,3-specific lipase derived from a microorganism and immobilized on a granulated silica matrix. Because the lipase is specific for the 1- and 3-positions of the triglycerides, its use results in a fat that is partially randomized rather than being completely randomized, as occurs with use of sodium methoxide. One advantage of enzymatic interesterification is that there are no waste or by-product issues, for example, no catalyst residues that could be released into the environment.

Table 31.6 compares the fatty acid composition of a typical shortening fat prepared by partial hydrogenation with a newly developed product made by enzymatic interesterification. The interesterified fat is low in *trans* fatty acids and has a lower oleic acid content and higher levels of stearic,

TABLE 31.6
Fatty Acid Composition (Percentages) and Melting Points of Shortenings Made by Partial Hydrogenation and by Enzymatic Interesterification

Fatty Acid or Melting Point	Partial Hydrogenation (PHSBO, PHCSO)	Enzymatic Interesterification (SBO, FHSBO)
% C16:0	10.4	10.8
% C18:0	15.5	21.9
% C18:1 *cis*9	37.5	21.9
% C18:2 *cis*9,12	4.80	39.8
% C18:3 *cis*9,12,15	0.30	5.6
% Total *trans*	30.0	2.5–3.5 typical 5.0 max
% Total saturates	25.9	32.7
Melting point (°F)	117.5	110.0

Fatty acid compositions and melting points are shown for two shortening products, one made by conventional partial hydrogenation (using a blend of partially hydrogenated soybean oil [PHSBO] and partially hydrogenated cottonseed oil [PHCSO]) and one made by enzymatic interesterification (using a blend of unhydrogenated soybean oil [SBO] and fully hydrogenated soybean oil [FHSBO]).

Source: Data were provided by Tom Tiffany, Archer Daniels Midland Co.

linoleic, and α-linolenic acids compared to the partially hydrogenated fat. Although the fatty acid compositions of the two products differ from each other, the functional characteristics for shortening applications (e.g., melting points) of the two products are very similar. The low level of *trans* fatty acids (typically 2.5%–3.5%, with a maximum of 5.0%) in this interesterified fat may have resulted in part from deodorization and/or incomplete hydrogenation of the component hydrogenated oil. Nevertheless, considering the normal 12 g serving size for shortening, the product made by interesterification would qualify for a declaration of 0.5 g of *trans* fat per serving according to the FDA's final labeling rule. If this shortening were incorporated into a baked product, depending on the amount of fat per serving, the product may be able to declare 0 g of *trans* fat per serving.

C. Use of Fractions High in Solids

Fractions high in solids derived from natural oils, namely coconut, palm, and palm kernel oils, are not new to the food industry and have been components of functional ingredients for years. Many commercially available fractions come from palm and palm kernel oils. They can be used successfully either as single fractions or in combination with other fractions to meet specific needs. Examples of fractions from palm oil that can be used in preparing *trans*-free or low-*trans* shortenings and margarines include palm olein, palm mid-fractions, and palm kernel stearin. Such fractions can be blended with liquid oils, such as soybean and canola oils, to create either no-*trans* shortenings and margarines or low-*trans*, low-saturate shortenings and margarines.

Fractions high in solids usually are prepared by reducing the temperature of an oil sample so that a more saturated fraction solidifies and a more unsaturated fraction remains liquid. The solid fraction is then physically separated from the liquid fraction by filtration or centrifugation. Liquid fractions, sometimes referred to as "olein fractions," are high in oleic acid and also are good sources of antioxidants, such as tocopherols and tocotrienols. Olein fractions frequently are used in Pacific-rim countries as salad oils and frying oils. Fractions with higher solids content may be incorporated into margarine or shortening fats.

TABLE 31.7
Fatty Acid Composition (Percentages) and Melting Points of No-*Trans* Shortening and Margarine Oils Made with Fractions from Palm and/or Palm Kernel Oils

	No-*Trans* Shortening	No-*Trans* Shortening	No-*Trans* Margarine Oil
Label declaration	Safflower, palm, and/or palm kernel oils	Canola, palm, and/or palm kernel oils	Canola, palm, and/or palm kernel oils
% TFA	0	0	0
% SFA	35	23	26
% MUFA	55	53	35
% PUFA	10	24	39
Melting point (°F)	109	101	97

All products were made with either safflower or canola oil plus fractions of palm and/or palm kernel oils. Partial hydrogenation was not used in making these products. One shortening was made with safflower oil, and the other, with canola oil.

Abbreviations: TFA, *trans* fatty acids; SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

Source: Data were provided by Carl Heckel, Aarhus United, USA, Inc.

Table 31.7 compares fatty acid compositions of two no-*trans* shortenings and a no-*trans* margarine oil made with specific fractions from naturally solid vegetable oils such as palm or palm kernel oil. All the products are *trans*-free, although there are differences in the levels of saturated, monounsaturated, and polyunsaturated fatty acids.

D. Use of Trait-Enhanced Oils

Trait-enhanced oils generally fall into three categories: high-oleic acid oils, such as high-oleic sunflower and canola oils; mid-range oleic acid oils, such as mid-oleic sunflower and soybean oils; and low-linolenic acid oils, such as low-linolenic canola and soybean oils. (The term "low linolenic" commonly refers to an oil containing about 1%–3% α-linolenic acid. Soybean oil typically contains about 7%, and canola oil, about 10% α-linolenic acid.) These types of oils are derived through traditional plant breeding or biotechnological methods. The high- and mid-range oleic acid oils are more stable oxidatively than traditional oils high in linoleic acid, such as soybean, corn, and sunflower oils. Low-linolenic acid oils have significantly reduced levels of oxidatively unstable α-linolenic acid. All these trait-enhanced oils have good oxidative stability (i.e., a relatively high content of oleic acid and comparatively low levels of linoleic and α-linolenic acids) making them suitable for frying, spraying, beverages, and some bakery applications.

At present, the plant varieties that produce high-oleic and low-linolenic as well as some mid-oleic oils are not widely cultivated, and these oils are more expensive to produce than the corresponding polyunsaturated oils. In addition, the high-oleic oils are liquid at room temperature, and thus would not be particularly useful in spread and baking applications that require a relatively high solids content.

Table 31.8 shows typical fatty acid compositions of several trait-enhanced oils. All have significant levels of oleic acid and comparatively lower levels of linoleic and α-linolenic acids. For salad oil and frying applications, these oils would not require hydrogenation and therefore would be *trans*-free.

The United Soybean Board (USB) has projected the future availability of low-linolenic soybean oil (having less than 3% α-linolenic acid) (Reeves, 2006). Seed for low-linolenic soybeans has been developed by duPont, Monsanto, and Iowa State University. For 2006, the USB expected 800,000 acres to be planted, which likely would have yielded about 32 million bushels of soybeans and 320 million

TABLE 31.8
Typical Fatty Acid Composition (Percentages) of Trait-Enhanced Oils

Fatty Acid	Canola	High-Oleic Canola	Sunflower	Mid-Oleic Sunflower	High-Oleic Sunflower	Soybean	Low-Linolenic Soybean
% C16:0	5	4	7	5	4	11	10
% C18:0	2	2	4	4	4	4.5	5
% C18:1 *cis*9	61	74	14	58	79	25	28
% C18:2 *cis*9,12	21	12	74	32	11	51	56
% C18:3 *cis*9,12,15	10	4	<0.5	<0.5	<0.5	8	1

Typical fatty acid compositions of high-oleic canola oil, mid-oleic and high-oleic sunflower oils, and low-linolenic soybean oil (low in α-linolenic acid) are compared to their respective conventional oils.

Source: Data were provided by Bob Wainwright, Cargill, Inc.

TABLE 31.9
Projected Availability of Low-Linolenic Soybean Oil

Year	Acres to be Planted	Production (Bushels)	Oil Production (Pounds)
2006	800,000	32 M	320 M
2008	4 M	160 M	1.6 B

Abbreviations: M, million; B, billion.

Source: Data were provided by the United Soybean Board.

pounds of oil (Table 31.9). By 2008, these totals are projected to be 4 million acres, 160 million bushels of soybeans, and 1.6 billion pounds of oil.

VII. CURRENT STATUS OF USAGE OF ZERO- AND LOW-*TRANS* FATS

There is considerable interest in zero- and low-*trans* fats among food manufacturers, and current usage of such products is increasing. For example, in frying applications, some restaurants and food service operations currently use unhydrogenated, *trans*-free oils. The use of such oils for frying is likely to increase as greater quantities of trait-enhanced oils, such as high-oleic and mid-range-oleic oils, become available in the future. With regard to spreads and margarines, low-*trans* and *trans*-free products are currently marketed. Considering shortenings, in 2005 at least one *trans*-free product was being marketed. Key challenges to manufacturers of zero- or low-*trans* fat products are to provide equivalent functionality at reasonable cost but without drastic increases in saturated fatty acid content.

VIII. SUMMARY AND CONCLUSIONS

In summary, dietary *trans* fatty acids at sufficiently high levels have been found to increase LDL- and decrease HDL-cholesterol levels compared to diets high in *cis* monounsaturated or polyunsaturated fatty acids. On the other hand, dietary *trans* fatty acids have not been strongly related to cancer risk at specific sites or to other health conditions, including fetal growth and development,

type 2 diabetes, and AMD. As a result of the effects of dietary *trans* fatty acids on LDL- and HDL-cholesterol, most health professional groups have recommended reduced consumption of *trans* as well as saturated fatty acids. Current efforts to replace or reduce *trans* fatty acids in food products focus on (1) modification of the hydrogenation process; (2) use of interesterification; (3) use of fractions high in solids from natural oils; and (4) use of trait-enhanced oils.

ACKNOWLEDGMENTS

The author thanks the following individuals who provided information presented in this chapter: Frank Kincs (Bunge Foods Corp.), Tom Tiffany (Archer Daniels Midland Co.), Carl Heckel (Aarhus United USA Inc.), Bob Wainwright (Cargill Inc.), and Robert Reeves (Institute of Shortening and Edible Oils, Inc.). Appreciation is extended to Dr James Deddens, Professor of Mathematics, and Manager of the Statistical Consulting Laboratory at the University of Cincinnati, Cincinnati, OH, for assistance with statistical analyses.

32 Significance of Dietary γ-Linolenate in Biological Systems: Attenuation of Inflammatory and Proliferative Processes

Vincent A. Ziboh

CONTENTS

I. INTRODUCTION AND HISTORICAL PERSPECTIVES

A. Essential Fatty Acids

The first indication that dietary fat may be essential for healthy growing animals was presented in 1918 by Aron (1918) who proposed that butter has a nutrient value that cannot be provided by other dietary components. This report suggested that there was a special nutritive value inherent in fat apart from its caloric contribution and that this possibly was related to the presence of certain lipids. In 1929, Burr and Burr (1929) presented the first series of articles outlining a "new deficiency disease produced by the rigid exclusion of fat from the diet." In the series of conclusions put forth, they developed the hypothesis that warm-blooded animals, in general, cannot synthesize appreciable quantities of certain fatty acids. In 1930, both investigators significantly added to their earlier work by presenting evidence that the dietary inclusion of linoleic acid alone could reverse all deficiency symptoms resulting from a fat-free diet and thus linoleic acid (LA or 18:2n-6)[1] was heralded as an essential fatty acid (EFA) (Burr and Burr, 1930; Burr et al., 1940). The recognition that some unsaturated fatty acids could not be synthesized from endogenous precursors by mammals and were essential dietary elements led to the designation of essential and nonessential fatty acids. It was originally thought that there are only two EFAs, linoleic acid (9,12-octadecadienoic acid, LA, 18:2n-6) and γ-linolenic acid (9,12,15-octadecatrienoic acid, GLA, 18:3n-6), but continued nutritional studies revealed positive essential growth responses not only for linoleic acid and GLA, but also for arachidonic acid (AA) as well as the long-chain highly unsaturated fatty acids in fish oil [eicosapentaenoic acid (EPA), 20:5n-3 and docosahexaenoic acid (DHA), 22:6n-3]. More recent reports on the biological significance of the longer-chain n-3 polyunsaturated fatty acids (PUFAs) do qualify these long-chain fatty acids as essential PUFAs.

[1]Fatty acids and acyl groups are denoted 18:2n-6, 18:3n-3, and so on, with the first number representing the number of carbons in a straight chain and the number following the colon indicating the number of methylene interrupted *cis* double bonds. The number after "n" indicates the number of carbon atoms from the methyl end of the acyl chain to the nearest double bond.

B. Deficiency Symptoms

With the discovery of the EFAs came the recognition of their deficiencies (Burr and Burr, 1929; Burr et al., 1940; Griffith, 1958; Marcel et al., 1968). The various deficiency symptoms apparent in the response to diets low or free from EFAs were first described by Bur and Burr (Burr and Burr, 1929; Burr et al., 1940). A salient feature of this syndrome is decreased growth rate, particularly in the male-fed animals. The most visible and striking feature of EFA-deficiency (EFAD) is scaly skin dermatosis, hair loss, tail necrosis with histological section of the skin revealing epidermal thickness or acanthosis as well as hyperproliferation of the stratum corneum. Other organs also undergo alterations such as fatty liver, kidney damage, impaired reproduction, fetal resorption in females, testicular degeneration in males, and reduced ability to form and maintain cell membrane integrity.

Interest to explore the mechanisms that produced these EFAD symptoms have prompted examination of the roles they play in (1) the homeoviscious control of the membrane bilayers of most cells (Rance et al., 1980; Esfahani and Devlin, 1982); (2) providing a controlling influence in processes by which small molecules are translocated in either direction across cell membranes via protein channel or pore (Read and McElhaney, 1976; Schindler and Nelson, 1982; Solomon et al., 1983); (3) providing lipid–protein interactions that affect membrane enzyme activity; and (4) serving as vital precursors for the biosynthesis of eicosanoids, prostaglandins, leukotrienes, and biologically active hydroxy fatty acids (Dunham et al., 1978; Hansen, 1981).

C. Desaturation/Elongation of EFA

The shorter-chain EFA, linoleic acid (LA, 18:2n-6), serves as the initial unsaturated precursor for the *in vivo* biosynthesis of the longer-chain PUFAs. Metabolism of the LA in most tissues involves an alternating sequence of Δ^6-desaturation, chain elongation, and Δ^5-desaturation in which two hydrogen atoms are removed to create a new double bond followed by the addition of two carbon atoms from glucose metabolism to lengthen the fatty acid chain (Marcel et al., 1968) (Figure 32.1). The desaturations are catalyzed by two separate enzymes: the Δ^6-desaturase catalyzing the transformation of 18:2n-6 (LA) to 18:3n-6 (GLA) and the Δ^5-desaturase catalyzing the transformation of 20:3n-6 dihomo-γ-linolenic acid (DGLA) to 20:4n-6 (AA). The elongase enzyme catalyzes the elongation of GLA to DGLA (Fujiwara et al., 1983). It is believed that the same enzyme catalyzes equivalent steps in the n-3 and n-9 pathways (Brenner, 1974). The PUFA families interact in such a manner that the n-3 PUFAs competitively suppress the bioconversion of the n-6 PUFAs. Both the n-6 and the n-3 PUFAs respectively do suppress the formation of the nonessential long-chain n-9 fatty acids, hence the negligible formation of the long-chain n-9 PUFA (20:3n-9) in the EFA-fed animals.

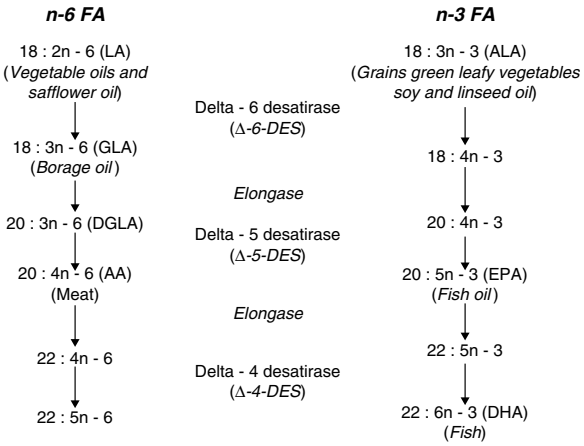

Figure 32.1 Oxidative desaturation/elongation of n-6 and n-3 PUFAs.

II. THE BIOLOGICAL SIGNIFICANCE OF γ-LINOLENIC ACID

A. Sources of γ-Linolenic Acid

γ-Linolenic acid (18:3n-6) is an important n-6 PUFA and a Δ^6-desaturase product of linoleic acid (18:2n-6). Most of the GLA currently being used in a variety of reported studies is extracted from three major sources:

1. *Evening Primrose* (*Oenothera biennis* L.), of the *Onagraceae family*, is a biennial crop with yellow flowers that blooms in the evening. It grows widely in North America. The seed oil contains GLA (7%–14%), LA (65%–80%), and negligible amounts of n-3 fatty acids (Wolf et al., 1983; Hudson, 1984).
2. *Borage* (*Borago Officianalis* L.), of the *Boraginaceae family*, is a herbaceous hardy annual crop with starlike bright blue flowers. It is found commonly in the Mediterranean region in North Africa. The seed oil contains high levels of GLA (20%–27% of total fatty acids), low levels of LA (35%–40%), and no n-3 fatty acids (Kleiman et al., 1964; Miller et al., 1968). Interestingly, the leaf lipids of Borage (Jamieson and Reid, 1969) contain high levels of α-linolenic acid (ALA, 18:3n-3) and stearidonic acid (STA, 18:4n-3).
3. *Blackcurrant* (*Ribes nigrum*), of the *Saxifragaceae family*, is a shrub that grows mainly in Europe. Its seed oil, unlike Evening Primrose and Borage contains high levels of GLA (15%–19%) (Traitler et al., 1984) and n-3 fatty acids ALA (12%–14%) and STA (2%–4%) (Gunstone, 1992).
4. *Others*: Although several *microorganisms* and *fungi* have been reported to contain GLA (Shaw, 1965; Hiruta et al., 1989; Shimitzu et al., 1989; Nakajima and Izu, 1992), these oils have not been used as much as those from plant sources in the conduct of dietary experiments.

B. Metabolism and Generation of Potent Biological Modulators

The metabolism of linoleic acid derived from corn oil and GLA derived from dietary Borage or Evening Primrose is illustrated in Figure 32.2. Specifically, GLA derived from LA (18:2n-6) by Δ^6-desaturase and directly ingested as GLA from the dietary oil is rapidly elongated to DGLA by the DGLA elongase enzyme. DGLA occupies a pivotal position in this cascade. On the one hand, DGLA is modestly metabolized into AA by the rate-limited enzyme Δ^5-desaturase. The Δ^5-desaturase

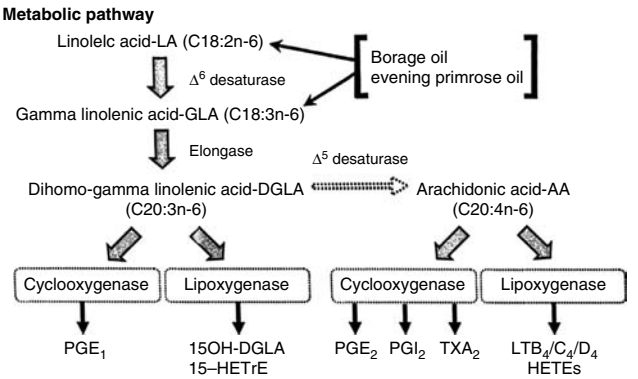

Figure 32.2 Metabolism of linoleic acid (LA)/γ-linolenic acid (GLA) into cyclooxygenase and lipoxygenase metabolites. *Abbreviations:* DGLA, dihomo-γ-linolenic acid; AA, arachidonic acid; PGE_1, prostaglandin E_1; 15-OH-DGLA, 15-hydroxyeicosatrienoic acid; PGE_2, prostaglandin E_2; PGI_2, prostacyclin; TXA, thromboxane A; $LTB_4/C_4/D_4$, leukotrienes; HETEs, hydroxyeicosatetraenoic acid.

enzyme (as shown in Figure 32.2) is known to elicit significant species and tissue differences in enzyme activity. For instance, the rodent exhibits a striking active Δ^5-desaturase enzyme system whereas in both guinea pig and liver, the enzyme is less active and lower (Marcel et al., 1968). Thus, in any of the metabolic pathway of unsaturated fatty acids, the rates of desaturation are generally lower than those of chain elongation (Crawford et al., 1977).

In addition, the rate-limiting steps associated with the bioconversion of LA to AA are Δ^6-desaturation and Δ^5-desaturation. The AA (20:4n-6) that is biosynthesized by Δ^5-desaturation catalyzes and then undergoes oxygenation reactions catalyzed by oxygenase 1 and 2 (COX-1/COX-2) to generate (1) prostaglandins of the two series: PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2, and TXA_2; (2) via the lipoxygenase enzymes to generate leukotrienes (leukotriene B_4 or LTB_4, C_4, D_4); and (3) three major monohydroxy acids [5-, 12-, and 15-hydroxyeicosatetraenoic acids (HETEs)]. The DGLA (20:3n-6), which is derived from the dietary GLA-containing oils, is rapidly bioconverted by COX-1 either via the cyclooxygenase pathway to prostaglandin of the 1-series (PGE_1) as well as via the 15-lipoxygenase (15-LOX) pathway into 15-hydroxy-8,11,13-eicosatrienoic acid (15-HETrE). The latter metabolites derived from DGLA are known to exert anti-inflammatory/anti-proliferative properties.

III. GENERALIZED FUNCTIONAL ROLES OF γ-LINOLENIC ACID

The triacylglycerol stereospecific position of GLA varies with the source of the oils, and this is important in establishing their relative efficacies. For instance, GLA is concentrated in the *sn*-3 position of the glycerol bridge of the triacylglycerol in the Evening Primrose and Blackcurrant seed oil. In contrast, GLA is concentrated in the *sn*-2 position of the glycerol bridge in Borage oil and in the *sn*-2/*sn*-3 positions of fungal oil. Following ingestion of the triacylglycerol structures of Borage and Evening Primrose GLA in both humans and rodents, only a small fraction of the DGLA resulting from the elongation of GLA is converted by the Δ^5-desaturase to AA. This minor conversion (as shown in Figure 32.2) is due to the low activity of Δ^5-desaturase in most tissues. This metabolic consequence therefore argues against the often raised concerns that the ingestion of dietary GLA/DGLA does contribute to the excessive accumulation of AA and thus result in the excessive generation of proinflammatory AA metabolites such as PGE_2, LTB_4, LTC_4, and LTD_4. Indeed, in many tissues and cell types, DGLA, but not AA, is what accumulates in the tissues and cells after GLA supplementation in the diet. The accumulated DGLA is oxygenated via the COX-1 pathway to PGE_1 and via the 15-LOX pathway to 15-hydroxyeicosatrienoic acid (15-HETrE) as shown in Figure 32.2. These two major oxidative metabolites of DGLA (PGE_1 and 15-HETrE) have been reported to exert biological and clinical effects and notably the suppression of acute and chronic inflammation as well as hyperproliferation in a variety of systems and disease conditions. In addition, DGLA can compete with AA for COX-2 enzyme to decrease the production of PGE_2. In addition, DGLA is metabolized by the lipoxygenase enzyme 15-LOX to generate 15-HETrE (a potent inhibitor of the 5-LOX pathway and the suppression of synthesis of the proinflammatory mediators: LTB_4, LTC_4, and LTD_4 from AA) via the inhibition of 5-LOX activity (Vanderhoek et al., 1980; Miller et al., 1988).

IV. NUTRITIONAL/BIOLOGICAL SIGNIFICANCE OF γ-LINOLENIC ACID

The rationale for the dietary ingestion of GLA can be summarized as follows: (1) GLA will bypass the Δ^6 desaturation step in the n-6 EFA metabolism and be rapidly elongated to increase the *in vivo* level of DGLA; (2) the formed DGLA does compete to diminish the amount of AA for incorporation into membrane phospholipids for maintenance of the normal fluidity of the cell membrane; and (3) the DGLA most importantly serves as the precursor and substrate for the biosynthesis of potent oxidative metabolites via the COX-1 pathway to form most importantly, PGE_1 and via the 15-LOX pathway to form 15-HETrE as illustrated in Figure 32.2. These metabolites function *in vivo* to attenuate inflammatory and proliferative processes.

A. Significance of Dose of Dietary Intake of γ-Linolenic Acid

The results from a number of dietary studies of GLA [content of Evening Primrose oil (EPO) and/or Borage oil] have been variable resulting in contentious results and controversies as to whether or not the reported beneficial effects of GLA are valid. One likely reason for these controversies is the use of varying dietary doses presumably inadequate to elicit the biological effects being investigated. To address this concern, it is prudent to establish as a first step whether varying doses of dietary GLA can elicit selected biological effect in healthy normal individuals. Thus, in one study, one group of healthy normal human volunteers ingested Borage oil as capsules containing a total of 480 mg GLA/day as dietary supplement for 12 weeks. The second group in a parallel experiment received approximately threefold (a total of 1300 mg GLA/day) for 12 weeks. Using isolated polymorphonuclear (PMN) cells as the model to evaluate the effect of the dietary GLA, the *ex vivo* generation of proinflammatory LTB_4 by isolated PMNS after challenge with calcium ionophore was evaluated. The findings revealed that ingestion of the lower concentration of 480 mg GLA/day only moderately suppressed the *ex vivo* PMN-biosynthesis of LTB_4 (46%). In contrast, the group that ingested the higher concentration of 1300 mg GLA/day significantly exerted higher suppression of *ex vivo* PMN-induced biosynthesis of LTB_4 (65%) (Ziboh and Fletcher, 1992). These findings clearly demonstrated the relationship of the ingested dose of GLA and its biological efficacy. Although the trial of 1300 mg GLA/day was not maximal, the data support the view that the efficacy of GLA was dose-dependent; hence, it must be ascertained in any given study.

B. *In Vivo* Role of γ-Linolenic Acid in Normal Skin

Two PUFAs, linoleic acid (LA, 8:2n-6) and GLA (18:3n-6), are known to play important roles in the physiology and pathophysiology of the skin. For instance, the 18-carbon linoleic acid is the most abundant PUFA in human skin epidermis (Chapkin and Ziboh, 1984). A major functional role of LA in the skin is its involvement in the maintenance of the epidermal water barrier (Hansen and Jensen, 1985), which is one of the major abnormalities of cutaneous EFAD. This significant effect of linoleic acid (LA) was reported early in a series of studies by Prottey and coworkers who demonstrated that increased transepidermal water loss (TEWL) occurred in EFAD animals (Hartop and Prottey, 1976). Information derived from these findings supported the special role of LA in restoring the defect of skin epidermal water barrier, which has been induced by EFAD.

In humans, although deficiency of GLA has been associated with clinical disorders of the skin, information on its role in the normal physiology of skin is limited. This prompted an earlier study, which reported that intake of dietary Borage oil (containing GLA) by humans decreased skin roughness, TEWL, as well as increased the moisture in normal skin (Nissen et al., 1995). This, presumably, is a physiological effect of GLA. However, in a recent report of a randomized double-blind, placebo-controlled study of oral capsules of EPO (containing a total of 345 mg GLA/day) given to healthy human adults with normal skin for 12 weeks, the data revealed that significant skin moisture, firmness, and roughness were all improved as determined by biophysical techniques (Muggli, 2005). Taken together, these findings indicate that GLA does function as an EFA and can contribute to maintaining the normalcy of human skin. Further studies are, however, warranted, which will reveal its mechanism of action.

C. *In Vivo* Role of γ-Linolenic Acid-Enriched Diet in the Induction of the Biosynthesis of Potent Biologically Active Mediators

In an earlier study, it was shown that *in vitro* preparations from skin epidermis are active in the *in vitro* metabolism of GLA/DGLA (Miller et al., 1988). Using the guinea pig skin epidermis as a model, which is functionally similar to that of human epidermis, it was demonstrated that

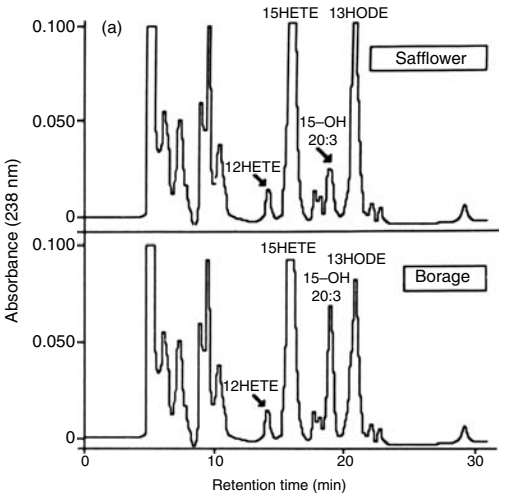

Figure 32.3 Reverse phase (RP)-HPLC profile of the effect of GLA-enriched diets on the *in vivo* generation of epidermal monohydroxy fatty acids by normal guinea pigs. 15-OH-(20:3), 15-HETrE (derived from dietary GLA); 15-OH-(20:4), 15-HETE (derived from dietary AA); and 15-OH-(18:2), 13-HODE (derived from dietary LA). (From Miller, C.C., and Ziboh, V.A. (1998). *Biochem Biophys Res Commun*. 154:3. With permission.)

supplementation of the guinea pig diet with GLA-containing Borage oil resulted in the major generation of PGE_1 and a 15-LOX metabolite (15-HETrE) from DGLA (Miller and Ziboh, 1988). A chromatographic representation of the skin epidermal extract from Borage oil-fed guinea pigs is shown in Figure 32.3. These *in vivo* findings were consistent with the *in vitro* metabolic results (Miller et al., 1988). Since the prostanoid (PGE_1) and monohydroxy acid (15-HETrE) have been reported to exhibit both anti-inflammatory/antiproliferative properties *in vitro* (Miller et al., 1988), supplementation of diets with appropriate amounts of Borage/Primrose or Blackcurrant could generate local *in vivo* anti-inflammatory/anti-proliferative modulators that can serve as adjuncts to standard therapy to attenuate inflammatory/proliferative skin disorders.

V. DIETARY ROLE OF γ-LINOLENIC ACID IN DISEASE SITUATIONS: MODULATION OF INFLAMMATORY/ IMMUNOLOGICAL DISORDERS

A. *In Vivo* Dietary Role in Rheumatoid Arthritis

Chronic disorders of inflammation are often associated with immunological activities and so it is appropriate to group these disorders together in evaluating the role of dietary GLA in the clinical course of the diseases. Rheumatoid Arthritis (RA) is a chronic systemic inflammatory disorder of unknown etiology. It is a human disease characterized by symmetrical polyarthritis and it is prototypical, immunologically induced, inflammatory arthritis. In an early clinical study of 20 patients given a relatively low dose of 360 mg GLA/day (as EPO) for 12 weeks, the observed beneficial effects were mixed due in part to administration of low concentrations of total GLA (360 mg/day) (Mork-Hansen et al., 1983). In a subsequent study, the dietary intake of patients with a higher concentration of Borage oil (equivalent to 1400 mg of GLA/day) for 24 weeks resulted in clinically significant reductions in signs and symptoms of rheumatoid disease activity (Leventhal et al., 1993), suggesting that responses to GLA were dose-dependent in contrast to placebo, which showed no change or worsening of disease. This finding is consistent with earlier *in vitro* findings in other systems, which demonstrated the dose-dependent effect of GLA. In a larger double-blind, placebo-controlled study, with the administration of higher total GLA content (2.8 g/day) for

6 months, the data revealed significant clinically relevant reductions in signs and symptoms of the disease activity (Zurier et al., 1996). Furthermore, patients who remained for an entire 12 months on the 2.8 g/day dietary GLA protocol exhibited continued improvement in symptoms with minimal deleterious effects. Indeed, the use of GLA at the above higher dose was reported to be well tolerated and effective in the treatment of active RA. In addition, it has been reported that GLA can be used as an adjunct with nonsteroidal anti-inflammatory drug (NSAID) in controlled clinical trial (Zurier, 1993) in the treatment of RA. Taken together, the data derived from these studies demonstrate that the amount of total GLA/day intake and the duration of GLA intake do correlate with the clinical efficacy. Both factors must therefore be considered in any dietary protocol.

B. *In Vivo* Dietary Role in a Model of Lupus Erythematosus

Since GLA has not been given to patients with systemic lupus erythematosus (SLE) in any elaborate study, the mechanism of efficacy is unknown. However, it has been reported that using the murine model of lupus, leukotrienes do contribute to the renal disease in MRL/lpr/lpr mouse model (Spurney et al., 1991). Since GLA has been reported to suppress leukotriene generation via the inhibition of 5-LOX pathway, it is likely that GLA can exert efficacy in this mouse model. In addition, dietary administration of GLA was also reported to enhance the generation of the renal protective COX-1 catalyzed metabolite from AA (prostacyclin, PGI_2), which has been shown to attenuate inflammatory effects in patients with RA and to suppress acute and chronic inflammation of joint tissue injury in several experimental animals (Zurier, 1993). These findings imply that GLA, which exerts anti-inflammatory and immune modulatory effects in patients with RA, may also be useful in the treatment of SLE patients. Thus, well-controlled human studies seem warranted in this disease.

C. *In Vivo* Dietary Role in Cardiovascular Disorders

Hypertension is considered as one of the major risk factors in cardiovascular disease because it has been associated with heredity, obesity, smoking, and diet. The interest in its control has triggered numerous studies involving pharmacological and nonpharmacological agents. Although pharmacological agents have been shown to exert beneficial effect by reducing blood pressure (BP), the downside of the protracted use of these agents has been associated with deleterious side effects, thus, diminishing the therapeutic potential of these chemical agents. For this reason, the use of nonpharmacological agents such as nutritional manipulation in recent years has seemed attractive. In particular, the role of dietary PUFAs has come to the forefront of dietary manipulation because of lesser tendency to toxicity.

Much of the evidence for the relationship between dietary intake of various levels and types of fatty acids and systemic BP has been derived from the work conducted on rats. Much of that work, in turn, has been derived from studies comparing the effects of different dietary fatty acids on BP development in the genetically spontaneously hypertensive rat (SHR), a commonly used animal model for human hypertension. In these animals, consistent differences in tissue fatty acid metabolism exist during hypertension (Watanabe et al., 1989). Numerous membrane abnormalities have been reported in SHR (Montenay-Garestier et al., 1981; Devynck et al., 1982; Tsuda et al., 1988). Consequently, the hypertension observed in SHR could be related to fundamental changes in lipid metabolism, affecting long-chain PUFA (LCPUFA) in cell membranes. For instance, it has been reported that Δ^{-6} and Δ^{-5} enzymes that catalyze the transformation of LA to AA activities are lower in the SHR when compared to normotensive rats (Narce and Poisson, 1995, 1996).

Another major contributor to BP regulation is the Renin–Angiotensin System (RAS) that has also been a focus of hypertension research. The determinants of arterial BP are cardiac output and systemic vascular resistance (Creager and Gerhard, 1999). The RAS plays a central role in BP regulation by increasing vascular resistance while promoting renal retention. Although various pharmacological agents have been developed to antagonize the RAS, their beneficial effects have often been limited by side effects. Thus the thrust to evaluate the role of PUFAs, particularly GLA, is prudent and attractive (Engler, 1993, 2000).

In the studies evaluating the role of PUFAs, the dietary administration of GLA-enriched diets to normotensive and hypertensive SHRs, GLA was reported to reduce BP in both animal groups, although, greater effect was exerted on the hypertensive animals. A suggested attractive and interesting mode of action is that dietary GLA does interfere with the RAS, which would lead to the production of angiotensin II (Creager and Gerhard, 1999). GLA is purported to alter the properties of the vascular smooth muscle cell (SMC) membrane, resulting in the inhibition of angiotensin II receptor binding to the adrenal glomerulosa cells (Goodfriend and Ball, 1986). This finding implies that dietary GLA blocks the primary effect of angiotensin II, which stimulates the synthesis and secretion of aldosterone by the adrenal cortex. This blockade prevents aldosterone's action on the kidney tubules that contribute to elevated sodium reabsorption and arterial BP. This suggested mechanism seems plausible and it implies that dietary GLA may function *in vivo* as a nonpharmacologic angiotensin II receptor antagonist or as a membrane modifier on the angiotensin II receptor-binding activity to suppress aldosterone's contribution to elevated BP.

Another possibility in the ability of dietary GLA to lower BP is the elongation metabolite (DGLA) and its tissue elevation. The elevated DGLA is then incorporated into vascular tissue membrane phospholipids. The DGLA–phospholipid complex undergoes phospholipase A_2 cleavage to release DGLA that is transformed by COX-1 to yield PGE_1. This prostanoid is biologically known to induce vascular smooth-muscle relaxation. This latter possibility is consistent with the *in vitro* findings that PUFAs incorporated into vascular tissue cell membrane phospholipids do influence signal transduction, ionic fluxes, and enzyme activities (Goodfriend and Ball, 1986; Oishi et al., 1990; Ordway et al., 1991).

D. *In Vivo* Dietary Role in Bleomycin-Induced Lung Fibrosis

Interstitial lung fibrosis (ILF) is a potentially lethal, chronic response of the lung to injury resulting from a wide range of processes. ILF is invariably associated with fibrosing alveolitis characterized by inflammation, fibroblast proliferation, and accumulation of extracellular matrix proteins. The hamster is a fitting animal model for the study of induced lung fibrosis (Snider et al., 1978). Although Bleomycin (BLM) is a glycopeptide known to cause pulmonary injury via the generation of reactive oxygen species and various inflammatory mediators, it is pharmacologically widely used as an antineoplastic drug in the treatment of human lymphoma, testicular and squamous cell tumor, which is often complicated by a dose-dependent induction of ILF (Crooke and Bradner, 1976). The possible efficacy of dietary GLA-containing oil (EPO) was tested in an animal model of BLM-induced lung fibrosis (Ziboh et al., 1997) since alterations in the levels of certain fatty acid metabolites had been associated with BLM-induced lung injury. The findings, after 14 days of dietary supplementation with GLA, revealed an increase in (1) GLA metabolite (DGLA) in the lung tissue, (2) enhanced COX-1 catalyzed generation of PGE_1, and (3) its 15-LOX catalyzed generation of 15-HETrE. The latter two metabolites are known to exert anti-inflammatory/antiproliferative properties. Associated with these biochemical events are the suppression of BLM-induced increase in tissue hydroxyproline (a marker for collagen synthesis) as well as the inhibition of LTB_4 (a proinflammatory mediator). These biochemical alterations parallel the attenuation of the lung fibrosis. Taken together, GLA-enriched diet may serve as an adjunct to diminish toxicity of standard therapy and for the management of interstitial lung fibrosis and the suppression of the peripheral inflammatory mediators induced by BLM.

E. *In Vivo* Dietary Role in the Management of Type I and Type II Diabetes

One of the major complications of diabetes mellitus is peripheral neuropathy characterized by reduction of nerve conduction velocity (NCV). Strict control of the hyperglycemia may delay the development of clinical diabetic neuropathy (Pirart, 1977) or improve nerve function in patients with clinical neuropathy (Brown and Asbury, 1984), but a complete cure has not been found. To explore the role of GLA in this serious disorder, the rat animal model of experimental diabetes was

used (Julu, 1988). Using this model of streptozotocin-induced insulin-dependent diabetic rats, the animals were administered GLA-enriched EPO orally to ascertain whether any efficacy would occur in this model of the gross lipid abnormality in the diabetic nerve. Interestingly, the results revealed marked increase of GLA in the diabetic plasma reflecting mostly the dietary intake. This increase paralleled the depletion of excess cholesterol in the diabetic nerve. Improvement of the NCV after EPO/GLA ingestion (Julu, 1988; Kuruvilla et al., 1998) correlated with conservation of AA in the nerve phospholipids.

Although human trials of GLA in the form of EPO in patients with neuropathy due to Type I or Type II diabetes are consistent with those of the animal studies, the effects after GLA ingestion did not attain complete normalization as seen in the animals (Jamal and Carmichael, 1990; Keen et al., 1993). These limited results in the human patients may be due, at least in part, to the fact that most of the human disease was Type II diabetes and not Type I, which predominantly occurs in the animal model. Furthermore, the dose of GLA administered to the humans may have been too low to elicit major beneficial effects. Thus, the administration of higher doses of GLA would be a prudent first step to establish the efficacy of dietary GLA in human diabetes. This investigation warrants further explorations.

F. *In Vivo* Dietary Role in the Management of Bronchial Asthma

In a previous study, the administration of EPO-containing GLA and fish oil-containing EPA/DHA was reported to be ineffective in the treatment of bronchial asthma (Stenius-Aarniala et al., 1989). Notably in that study, the amounts of GLA and EPA/DHA, which were contained in 15–20 mL and administered to patients, were not quantitated; thus, the actual amounts of GLA or EPA/DHA ingested were not known. The authors even concluded that the lack of detectable response in the patients could be attributed to insufficient amounts of EPO or fish oil administered.

However, in a recent trial with dietary GLA in asthma patients, the study design was based on the recognition that both humans and rodents exhibit no serious deleterious effects of the GLA-enriched oil had been described. Metabolically, only a small fraction of the DGLA derived from the elongation of GLA is converted by the Δ^5-desaturase to AA. This minor conversion has been demonstrated to be due to the low activity of Δ^5-desaturase in most tissues. This low metabolic desaturation of dietary GLA therefore does not support the often suggested concerns that dietary ingestion of GLA poses an undesirable risk because of its further elongation and Δ^5-desaturation to excessive generation and accumulation of AA, which in turn would result in the excessive generation of proinflammatory metabolites such as prostanoid (PGE_2) and lipoxygenase products such as LTB_4, LTC_4, and LTD_4. Indeed, in many tissues and cell types, this concern has not materialized; rather, it is DGLA that accumulates while AA shows a decrease after GLA supplementation in the diet. The accumulated DGLA becomes the substrate that is oxygenated via the COX-1 pathway to produce PGE_1 and via the 15-LOX pathway to produce 15-HETrE as shown in Figure 32.4. These two oxidative metabolites of DGLA (PGE_1 and 15-HETrE) have been reported *in vitro* to inhibit the generation of proinflammatory leukotrienes and *in vivo* to suppress acute and chronic inflammation in a variety of disease conditions. In addition, DGLA *in vitro* has been reported to compete with AA for the cyclooxygenase, thus, inhibiting the production of proinflammatory PGE_2. DGLA is additionally metabolized by 15-LOX to 15-HETrE (which is a potent inhibitor of the 5-LOX), the enzyme that catalyzes the synthesis of the proinflammatory LTB_4, LTC_4, and LTD_4. The inhibitory potential of 15-HETrE has been shown *in vitro* to markedly inhibit 5-LOX pathway and LTB_4 generation from AA by basophilic leukemia (RBL-I) cells (Vanderhoek et al., 1980; Miller et al., 1988; Ziboh and Fletcher, 1992). Also *in vivo*, the feeding of a diet supplemented with GLA-containing oil to hamsters revealed significantly elevated levels of DGLA and 15-HETrE biosynthesized *in vivo* in the hamster lung. This elevated 15-HETrE paralleled reduced LTB_4 generation by PMN-infiltrated hamster lung (Ziboh et al., 1997).

Because asthma is characterized by variable and reversible airflow obstruction and by bronchial hyperresponsiveness, as well as excessive airway narrowing in response to a variety of apparently

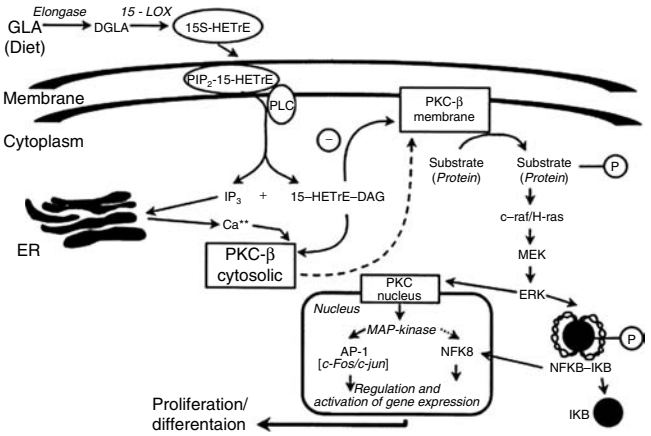

Figure 32.4 Speculative scenario of dietary GLA modulation of epidermal nuclear transcription factor. *Abbreviations*: 15-LOX, 15-lipoxygenase; 15-HETrE, 15-hydroxyeicosatrienoic acid; PIP, phosphatidylinositol phosphate; PKC, protein kinase C; DAG, diacylglycerol; MAPK, mitogen activated protein kinase; AP-1, activator protein 1. (From Ziboh, V.A., et al. (2002). *Arch Pharm Res*. 25:6. With permission.)

unrelated stimuli, contraction of the airway smooth muscle has been emphasized as an important mechanism contributing to asthmatic airway obstruction. Inflammation in the airway wall is therefore a prominent feature of fatal asthma attack (Dunnill, 1960; Glynn and Michaels, 1960). There is abundant experimental evidence that inflammation is also present in mild asthma and is related to bronchial hyperresponsiveness (Chung, 1986), a characteristic feature of asthma (Boushey et al., 1980). Taken together, the pathological changes are therefore likely to include the release of inflammatory mediators such as leukotrienes. Thus, in a randomized, double-blind comparison of dietary supplementation of GLA-containing Borage oil equivalent to the total of 2 g GLA/day and a placebo control receiving corn oil, in patients with asthma, the data revealed that the patients receiving dietary supplementation of the total of 2 g GLA/day for 52 weeks significantly suppressed the capability of their PMNs to generate LTB_4 (an inflammatory response characteristic of asthma) (Ziboh et al., 2004). The degree of beneficial clinical response by the patients, although moderate, was variable and not as highly correlated with the biochemical data. This variability is probably due to the multifactorial disease nature of asthma, which likely contributed other unknown mediators to the pathogenesis of asthma. Alternatively, and perhaps more importantly, the dose of γ-linolenate (2 g/day) given to patients with chronic moderate to severe asthma was inadequate in view of the severity of the disease and the need to generate sufficiently high *in vivo* inhibitor such as 15-HETrE to strongly inhibit 5-LOX pathway, diminish the inflammatory mediators, and attenuate the clinical course of asthma. Further higher dose-dependent study is therefore warranted.

VI. ROLE OF γ-LINOLENIC ACID-ENRICHED DIET IN HYPERPROLIFERATIVE PROCESSES

A. *In Vivo* Dietary Role in a Guinea Pig Model of Normal Skin Epidermis: Generation of Biologically Potent Metabolites

The excitement generated by reports of clinical improvement of patients with atopic eczema after oral administration of Primrose oil (Kunkel et al., 1981; Zurier, 1982) signaled a possible role for GLA-containing oil in cutaneous biology. To ascertain what form of GLA-containing oil could exert the beneficial effects of dietary GLA, the study included dietary supplementation of Safflower oil (containing predominantly 18:2n-6, LA) and Borage oil (containing predominantly 18:3n-6, GLA) to normal

guinea pigs for 8 weeks. The results revealed the generation of oxidative metabolites of the constituent LA/GLA/DGLA as shown graphically in Figure 32.4 (Miller et al., 1988). Extracts of the epidermis from the guinea pigs fed Safflower oil and Borage oil revealed no significant differences in AA-derived monohydroxy fatty acids such as 12- and 15-HETE in the two diets. In contrast, the epidermis of the Borage oil-fed animals revealed a significant increase in the DGLA-derived monohydroxy fatty acid (15-HETrE), indicating the *in vivo* metabolism of DGLA into 15-HETrE by epidermal 15-LOX. The skin epidermal tissue therefore generates significant 15-HETrE after dietary supplementation with GLA-enriched diet, which can contribute to maintain normal cutaneous homeostatis.

B. *In Vivo* Dietary Role in a Rodent Hyperproliferative Skin Model

The exclusion of EFA in guinea pig diet is known to result in a model of EFAD. This is associated with epidermal hyperplasia and scaling dermatosis of the skin. Replenishment of the diet of the EFAD animals with GLA-containing Borage oil resulted in reversal of the scaly dermatoses and suppression of hyperproliferation (Chung, 1986). Interestingly, the accumulation of DGLA and 15-HETrE (a potent antiproliferative metabolite derived from DGLA) was elevated in the EFAD-Borage oil-fed animals, suggesting that the antiproliferative effect of dietary GLA is due, at least in part, to the *in vivo* generation of 15-HETrE. This study further supports the view that metabolites of GLA are biosynthesized *in vivo* after dietary GLA-containing oils.

VII. ROLE OF γ-LINOLENIC ACID-ENRICHED DIET IN CARCINOGENESIS: MODELS, MECHANISMS, AND SPECULATIVE PATHWAYS

In vitro studies have been reported, which indicate that GLA exerts varying effects on a variety of malignant cells. For instance, the addition of GLA *in vitro* to malignant cell lines induced cytotoxity on the cells in a dose- and time-dependent manner (Begin et al., 1985, 1986), whereas normal cell lines are resistant to cytotoxity of GLA at low concentrations. Furthermore, it has been reported that the coculture of normal fibroblasts with human malignant cells results in the cancer cells completely overgrowing the normal fibroblasts. However, the coculture of the normal and malignant cells in the presence of GLA (10^{-4} M) resulted in the death of the malignant cells and being outgrown by the normal cells (Begin et al., 1986). These experiments indicate that *in vitro*, GLA/DGLA were presumably incorporated into the cellular membrane phospholipids and then alter the activity of malignant cells in culture. Although these *in vitro* findings are interesting, ultimately, it is the *in vivo* findings in animal models of carcinogenesis and in humans that will establish the beneficial effects of GLA-enriched diet in the management of hyperproliferative/carcinogenic disorders.

A. *In Vivo* Role in Animal Models of Human Breast Cancer

In vivo studies on the nutritional role of GLA-enriched diet in human breast carcinogenesis are sparse. A major problem has been, and is still, to develop a suitable animal model that mimics the biological and biochemical events in human breast cancer. As a consequence, many animal studies have been used, which yielded information that is either confusing or contrary to *in vitro* observations. For instance, in some animal observations it has been suggested that linoleic acid (an EFA) may be a tumor promoter in experimental cancer systems, notably, in rodent breast cancer models. The interpretation of some of these findings has been flawed because the amount of LA fed to these animals is excessively high, and there is no information of the normal level of LA in the animals and the dose-dependent effect of linoleic acid in normal breast tissue development and carcinogenesis.

Nevertheless, the use of athymic mouse model has found a niche in the study of human tumors because these animals lack T-cell mediated immunity and thus fail to reject foreign species xenografts. Using this type of model for transplantation of human breast cancer and melanoma, it has

been reported that dietary administration of adequate amounts of GLA (4–8 g/day) per day inhibited cancer growth (Pritchard et al., 1989). In a similar study with high dietary doses of GLA given as Evening Primrose to a small group of humans (21 patients) with advanced cancer stages of mainly liver, brain, and mesothelioma, GLA was reported to exert clinical improvement by reducing tumor bulk and pain (Van der Merwe et al., 1987, 1990). On the basis of these limited studies, there seems a valid rationale for investigating the role of GLA as a possible antitumor agent in a wide spectrum of human cancers. Although, the place of nutritional intervention at large in the management of human cancer still remains controversial, it is nonetheless an exciting prospect to consider that dietary EFA such as GLA, which has been reported to exert negligible *in vivo* toxicity, could serve at least in part, as an adjunct therapy to standard chemotherapeutic agents in the management of human cancers.

B. *In Vivo* Role of γ-Linolenic Acid as an Adjunct to Tamoxifen in Chemotherapeutic Management of Human Breast Cancer

Tamoxifen is a synthetic nonsteroidal antiestrogen. It is used extensively in the treatment of human breast cancer. The mechanisms of action are complex. However, the main mechanism is that it acts as a competitive antagonist to estrogen for binding with the estrogen receptor (ER). The resultant tamoxifen/ER complex prevents estrogen-induced effects on growth factors and proliferation (Kenny et al., 2000).

Because GLA has been proposed as a valuable adjunct in cancer therapy due to its *in vitro* selective antitumor properties with negligible systemic toxicity (Begin et al., 1985), orally administered GLA was investigated as an adjunct along with tamoxifen (a primary hormone therapy) in an endocrine-sensitive breast carcinogenesis. Specifically, the oral intake of capsules containing GLA along with tamoxifen (as primary therapy) by elderly patients (with primary, locally advanced, and metastatic breast cancer) significantly accelerated positive beneficial clinical response when compared to the group that was treated with tamoxifen alone (Kenny et al., 2000). Although the mechanism of action of the orally administered GLA in tamoxifen trial remains unclear, the dietary study revealed a significant suppression of ER expression in the patients treated with tamoxifen plus GLA than in patients treated with tamoxifen alone. This finding suggests that the biological actions of GLA in ER-breast cancer may be via the modulation of the ER pathway. Consistent with this finding, the suppression of ER binding by fatty acids has been reported in other studies (Borras and Leclercq, 1992). Specifically, GLA has been reported to induce apoptosis in human cervical carcinoma (HeLA) cells (de Kock et al., 1996). The important finding from this limited study is that the biological action of GLA in the human ER-driven breast cancer is mediated via the ER pathway. The modulatory effects of GLA on ER function and the possibility that GLA ingested with tamoxifen may be synergistic and can attenuate the growth of breast cancer via the enhanced downregulation of ER warrants further investigation.

C. Peroxisome Proliferator-Activated Receptor-γ: A Possible Target for γ-Linolenic Acid Mode of Action

Consistent with the biological effect of oral GLA plus tamoxifen in the attenuation of ER-driven breast cancer growth (Kenny et al., 2000), extensive *in vitro* studies of PUFAs on breast cancer cells have revealed that the activation of peroxisome proliferator-activated receptor-γ (PPAR-γ) by GLA and other PUFAs may function to suppress growth of breast cancer cells (Xu et al., 1999). This family of nuclear receptors has been reported to regulate gene-encoding enzymes for lipid metabolism (Schoonjans et al., 1996; Kilgore et al., 1997). In particular, ligands that activate PPAR-γ have been demonstrated to inhibit the proliferation of breast cancer cells *in vitro* (Elstner et al., 1998; Mueller et al., 1998; Yee et al., 1999). Among the several fatty acids studied, GLA was shown to induce the highest activation. Interestingly, this action of GLA was higher than ciglitazone (a known ligand for

PPAR) (Xu et al., 1999). In addition, *in vitro* studies revealed that GLA (derived from Borage oil), EPA (derived from fish oil), and ciglitazone (a pharmacological agent) significantly inhibited proliferation of all the human breast cancer cells tested. Interestingly, among the fatty acids tested, GLA exerted the highest activation of the reporter gene, which was higher than EPA (Xu et al., 1999). Taken together, the possibility exists that adequate oral intake of GLA or oil containing GLA could serve as a nontoxic dietary adjunct to standard chemotherapeutic agents to diminish toxicity during the management of breast cancer.

VIII. DIETARY ROLE OF γ-LINOLENIC ACID IN PROSTATE CARCINOGENESIS

A. *In Vivo* Role in a Rodent Model of Prostate Adenocarcinoma

Prostate cancer poses considerable threat to the aging male population as it has become a leading cause of cancer death to this group (Carter and Coffey, 1990). Due to the complexity of this age-related disease, the mechanism(s) and factors resulting in prostate cancer remain unclear. Reports associating the increased risk in prostatic cancer with increasing dietary fat have been contrasted by other studies suggesting that beneficial effects of certain PUFAs in the modulation of tumor development do exist. Similar to problems associated with the development of appropriate animal models for breast cancer, attempts to establish a fitting animal model for the different stages of prostate cancer development have been limiting. However, the animal model that best represents human prostate cancer disease is the Lobund–Wistar (L–W) rat model of prostatic adenocarcinoma. This experimental animal model of prostatic adenocarcinoma, which exhibits androgen dependency as in human beings, exhibits high disease spontaneity, with high incidences of clinically evident induced tumors, with long latency periods, and with the development of additional neoplasms in tissue other than the prostate, was developed in the L–W rats (Pollard, 1992). Experimentally, the induction of prostatic adenocarcinomas with high incidence (70%–90%) in these rats was accomplished within 10 months by the initial injection of *N*-nitroso-*N*-methylurea (NMU) (which serves as the initiator), followed by the implantation of testosterone propionate (TP) (which serves as the promoter) (Pollard and Luckert, 1987).

Although GLA has been reported to suppress tumor growth *in vitro* using androgen-primed prostatic hyperplastic and tumorigenic cells, which were derived from the L–W rats (Pham et al., 2003), the efficacy of GLA-enriched diet to attenuate prostatic carcinogenesis *in vivo* has not been demonstrated. Thus, using the L–W rat model of prostate carcinogenesis, Borage oil (highly enriched with GLA) was added to the diet of tumorigenic rodent (NMU/TP) group for 54 weeks. Result from this long study revealed (1) a significant reduction of prostate tumor size in the tumorigenic (NMU/TP) group when compared with the non-GLA-fed control (NMU/TP) group; (2) the dietary GLA-induced reduction of the tumor size and growth was accompanied by a significant suppression of the elevated biosynthesized PGE_2 and 5-HETE in the tumorigenic (NMU/TP) group (Pham et al., 2006). Both elevated PGE_2 and 5-HETE have previously been reported in human prostate cancer. This first long-range GLA dietary supplementation therefore revealed that dietary GLA can attenuate both the prostate tumor growth and the suppression of the dysregulated eicosanoid metabolism in the rodent model. This finding raises the possibility that dietary supplementation with highly GLA-enriched diet could serve as a nontoxic adjunct to standard therapy in the management of human prostate cancer. This possibility warrants testing in well-designed trials in human prostate carcinogenesis.

B. *In Vitro* Modulatory Role of GLA and 15-HETrE on Rodent Prostatic Carcinoma Cells in Culture

The excitement generated from the *in vivo* dietary efficacy of GLA in the L–W rodent model of prostate carcinogenesis prompted *in vitro* experiments of GLA and its 15-LOX metabolite (15-HETrE)

on the rodent prostatic cells in culture to delineate a possible mechanism (Pham et al., 2003). The preincubation of the isolated rodent (androgen-dependent prostatic) adenocarcinoma cells with GLA or 15-HETrE prior to incubation in culture revealed that 15-HETrE markedly inhibited growth of the prostatic cells in a dose-dependent manner. The *in vitro* inhibitory effect of precursor GLA was moderate on the mitogenic cells in culture, while 15-HETrE at the same concentration was markedly suppressive. This finding underscores the capacity of the *in vivo* generated 15-HETrE to suppress prostatic carcinogenesis. Further cellular exploration of growth of the prostatic tumor cells in culture paralleled the activation of PPAR-γ. The results from these *in vitro* studies support the *in vivo* observations that dietary GLA via its *in vivo* endogenous generation of 15-HETrE metabolite can attenuate prostatic adenocarcinoma in the L–W rodent model. It is therefore reasonable to speculate that dietary supplementation with sources containing GLA could serve as a nontoxic adjuvant to reduce toxic doses of standard chemotherapeutic agents to attenuate human prostatic carcinogenesis.

C. Comparison of the *In Vitro* Modulatory Roles of 15-LOX Metabolites of GLA/DGLA and EPA on Human Androgen-Dependent and Nonandrogen-Dependent Prostate Carcinoma Cells in Culture

The observed capability of dietary GLA to suppress growth of prostatic adenocarcinoma in the rodent model (Pham et al., 2006) prompted another experimental design to compare the effects of 15-HETrE (15-LOX metabolite of GLA/DGLA) and 15-HEPE (15-LOX metabolite of fish oil EPA), respectively, on the growth and AA metabolism of the human androgen-dependent (LNCaP) and nonandrogen-dependent (PC-3) prostatic cancer cells in culture. Both human prostatic cancer cells have been reported to have increased capability to biosynthesize PGE_2 and 5-HETE from AA. This capability is similar to the results observed in the L–W rodent prostatic cell model that also had an increased capability to biosynthesize PGE_2 and 5-HETE. Preincubation of both human prostatic cells with 15-HETrE or 15-HEPE revealed differential degrees of growth suppression by the cells as well as the decreased biosynthesis of PGE_2 and 5-HETE from AA, respectively (Ziboh et al., 2004). Notably, 15-HETrE exerted greater suppression of PGE_2 and 5-HETE biosynthesis than 15-HEPE. The parallel *in vitro* studies of the effects of GLA/15-HETrE and EPA/15-HEPE on the androgen-driven (LNCaP) and nonandrogen-driven (PC-3) cancer cells clearly suggest that dietary GLA derived from Borage oil may be more efficacious than dietary EPA derived from fish oil. This *in vitro* finding answers, in part, the often asked question as to which of the two PUFAs (GLA or EPA) is more beneficial in proliferative disorders. In addition, these findings imply that nutritional management of prostatic cancer via nontoxic dietary supplementation with GLA-containing oil, which *in vivo* could generate antiproliferative 15-HETrE, is a possibility and deserves to be explored.

IX. ATTENUATION OF CUTANEOUS HYPERPROLIFERATION BY GLA–15-LOX METABOLITE (15-HETrE): MODULATION OF EPIDERMAL CELL SIGNALING

A. *In Vitro* Role of 15-HETrE in Cutaneous Signal Transduction

In pursuit for possible mechanisms of action of dietary GLA and its metabolite on skin homeostasis, it was reported that incubation of 15-HETrE *in vitro* with skin epidermal homogenate resulted in its incorporation into phosphatidylinositol 4,5-bisphosphate (Ptd 4,5-P_2). When the Ptd 4,5-P_2 undergoes a catalytic cleavage by phospholipase-C (PLC) it yields novel 15-HETrE-containing diacylglycerol [1-acyl-2-15-HETrE-glycerol (15-HETrE-DAG)] and inositol trisphosphate (Ins-1,4,5-P_3)

(Schoonjans et al., 1996). Interestingly, 15-HETrE-DAG selectively inhibited membrane associated protein kinase C-β (PKC-β), a mediator of cell cycle proliferation in various cells. This finding raises the interesting speculation that the dietary GLA (from EPO or Borage oil) could elicit the *in vivo* generation of second messenger: 15-HETrE-substituted DAG that in turn could attenuate skin inflammation/proliferation.

B. Attenuation of Proliferation by 15-HETrE via Modulation of Downstream Signaling Transduction

Since cell growth and proliferation are regulated by biochemical events in the nuclear compartment of the cell, the modulatory role of 15-HETrE on cytoplasmic and nuclear signaling molecules was evaluated in an animal model of skin hyperproliferation (Xi et al., 2000a). Specifically, using this guinea pig skin model, topical application of DHA on guinea pig normal skin elicited severe hyperplasia and hyperproliferation in the skin epidermis. This skin lesion was accompanied by the suppression of the expression of activated protein-1 (AP-1) (Xi et al., 2000b). AP-1 has been associated with cell proliferation and apoptosis (Welter and Eckert, 1995). Furthermore, topical DHA application was also found to increase the expression of Bcl-2 (an antiapoptotic protein) while the expression of caspase-3 was found to decrease (an apoptotic protein). Interestingly, the topical application of 15-HETrE to the skin lesion did suppress the DHA-induced expression of Bcl-2 while enhancing the expression of caspase-3. Taken together, the reversal of DHA-induced suppression of AP-1 expression by 15-HETrE, which is derived from dietary GLA, does provide information of how to investigate the activity of new antiproliferative agents. Since 15-HETrE is a metabolite derived from dietary GLA, it is possible that increased dietary intake of this PUFA may result in the *in vivo* generation of biologically active metabolite (15-HETrE) that could alleviate the hyperproliferative skin conditions via the modulation of the transcription factor AP-1. A speculative scenario of how dietary GLA could modulate skin hyperproliferation is illustrated in Figure 32.4.

X. GLA/DGLA CATALYZED GENERATION OF PROSTAGLANDIN E_1 (PGE_1)

A. *In Vivo* Oral Intake of Natural PGE_1 or PGE_1 Analog

A plausible rationale for the dietary intake of GLA or GLA-containing oil is its rapid elongation to DGLA followed by the latter's oxygenation and catalyzed transformation by COX-1 to PGE_1 and 15-LOX transformation to 15-HETrE as illustrated in Figure 32.2. Interestingly, it is now evident that dietary content of fatty acids can alter/modulate membrane-bound receptors, enzyme activities, and eicosanoid biosynthesis (Brenner, 1974; Chapkin and Ziboh, 1984; Nakahara et al., 1990). The dietary modulation of eicosanoid generation has been well demonstrated in the following reports (Chapkin and Ziboh, 1984; Miller and Ziboh, 1988; Miller et al., 1990; Ziboh and Fletcher, 1992; Ziboh et al., 1997, 2004).

Biologically, PGE_1 (the prostanoid metabolite derived from dietary GLA) has been reported to exert a wide range of effects *in vivo*. For instance, PGE_1 has been reported to inhibit platelet aggregation via cyclic AMP (cAMP)-dependent mechanism. This in turn inhibits thrombus formation in the mesenteric microvessels as well as dilates the coronary arteries and lowers BP (Simmet and Peskar, 1988; Watanabe et al., 1989). Furthermore, PGE_1 infusion into humans after angioplasty has been shown to inhibit abrupt occlusion and early restenosis. Because of the systemic short half-life of natural PGE_1 in the body due to its *in vivo* metabolism into less biologically active products, the use of stable analogs of PGE_1 to circumvent the problem of short half-life of the natural PGE_1 has been studied. For example, PGE_1 analog (misoprostol) has been used to prevent acute Graft-Rejection in Renal-Transplant Recipients treated with cyclosporine and prednisone (Moran et al., 1990). These desirable effects of PGE_1 and/or analogs have considerable therapeutic potential. However, despite the promising use of the analogs of PGE_1, the possibility of their long-term use and side effects has

remained unresolved. Alternatively, a reasonable, nontoxic modality to counteract the drawbacks of exogenous use of natural or analog of PGE_1 for therapeutic purposes, particularly in the treatment of vascular diseases, is to enhance the endogenous biosynthesis of PGE_1 via the dietary intake of GLA.

PGE_1 analog has also been used in an interesting clinical disorder (Mork et al., 2004). Erythromelalgia (EM) is a rare condition characterized by red, hot, and painful extremities. Warmth, exercise, tight shoes, and gloves intensify discomfort (Thompson et al., 1979). The condition may be primary or secondary to another disease (Rance et al., 1980). Local skin cooling provides relief. The hypothesis to test oral PGE_1 analog (misoprostol) was based on previous reports of parenteral use of prostanoids (Kalgaard et al., 2003). In this trial, oral administration of misoprostol PGE_1 analog (0.4–0.8 mg/day) for 6 weeks to patients with symptoms, resulted in reduced EM symptoms such as microvascular arterionevous shunting in the affected skin. Although no major side effects were observed, the long-term oral effect of misoprostol has not been determined. Although the use of analogs of PGE_1 as a strategy to administer PGE_1 has shown promise, the possibility of side effects has remained unresolved. Therefore, a reasonable, nontoxic therapeutic modality to counteract any drawbacks of oral use of PGE_1 for therapeutic purposes, particularly in the treatment of vascular diseases, is to administer dietary GLA in order to enhance endogenous biosynthesis of PGE_1.

B. *In Vitro* Modulatory Role of PGE_1: A Speculative Scenario of *In Vivo* Mechanism of Action

The biological actions of the prostaglandins in tissues are known to be associated with changes in adenyl cyclase activity (Dayal et al., 1983). For instance, the binding of PGE_1 to its receptor (EP) on the cell surface modifies cyclase activity, depending on the nature of the regulatory G-proteins, which couple the receptor to the adenyl cyclase. The association of dietary GLA with the generation of PGE_1; the latter's modulation of cAMP and SMC proliferation are illustrated in Figure 32.5 in the investigation of the modulatory role of macrophage on SMCs that were harvested from mice previously fed GLA-enriched oil and the control of non-GLA-fed animals (Fan and Chapkin, 1998). Interestingly, exogenous PGE_1 restored the antiproliferative effect of GLA-enriched macrophages on SMC that were previously treated with cyclooxygenase inhibitor (indomethacin). These findings suggest that PGE_1 (derived from dietary GLA) is the primary mediator of macrophage–SMC interaction that involves the cAMP signaling cascade. A speculative scenario of dietary GLA-modulated macrophage/SMC interaction via G-protein coupled PG receptor (EP_2, EP_4, IP), which results in the elevation of intracellular cAMP/activation of PKA and ultimately modulation of nuclear transcription factor is illustrated in Figure 32.5 (Fan and Chapkin, 1998). The proposed model delineates that dietary GLA is elongated to DGLA and then incorporated into macrophage membrane phospholipids. Release of DGLA and metabolism by COX-1 results in the generation of PGE_1. The secreted PGE_1 binds to G-protein coupled prostaglandin receptor (EP_2/EP_4) or prostacyclin receptor (IP) on the SMCs. The binding results in stimulation of the adenyl cyclase resulting in the elevation of intracellular cAMP. The cAMP seemingly activates the PKA causing the phosphorylation of the nuclear cAMP response element-binding protein (CREB). CREB proteins do subsequently dimerize with other transcription factors to downregulate proliferation. This speculative scenario is nicely illustrated in Figure 32.5. Since PGE_1 is derived from GLA, the biological significance of dietary GLA as an EFA is further enhanced.

XI. CONCLUSION AND FUTURE PERSPECTIVES

γ-Linolenic acid (18:3n-6), although a Δ^6-desaturase product of linoleic acid, is normally found in great abundance in some plant seed oils, notably Evening Primrose, Borage, and Blackcurrant seed oils. It is also present in some storage oils of algae and various species of fungi. A notable metabolic feature of GLA is its rapid *in vivo* elongation to DGLA, followed by the latter's oxidative metabolism either via the cyclooxygenase (COX-1) pathway to PGE_1 or via the 15-LOX pathway into 15-HETrE. An increasing number of reports continue to emerge indicating that dietary GLA is

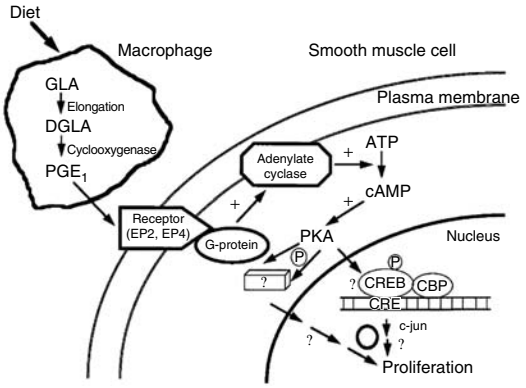

Figure 32.5 Speculative scenario of dietary GLA induced macrophage-DGLA derived PGE_1: Modulation of SMC nuclear transcription factor/gene expression. *Abbreviations:* cAMP, cyclic 3,5-adenosine monophosphate; CREB, cAMP response element-binding protein; CBP, CREB-binding protein. (From Fan, Y.Y., and Chapkin, R.S. (1998). *J Nutr*. 128:9. With permission.)

capable of modulating membrane bound receptors, enzyme activities, and *in vivo* eicosanoid biosynthesis. For instance, PGE_1 (the prostanoid metabolite of DGLA) does elicit an array of intracellular responses by binding to select G-protein coupled surface PGE receptors (EP) and the prostacylin receptor (IP). The receptors couple to adenyl cyclase resulting in increases in intracelluclar cAMP. Elevation of cAMP stimulates the expression of numerous genes via the PKA-mediated phosphorylation of the nuclear CREB. Through this mechanism, PGE_1 has been shown to inhibit vascular SMC proliferation *in vitro*. This modulatory effect *in vivo* would reduce the migration and proliferation of vascular SMC and retard development of the atherosclerotic plaque. In addition, PGE_1 has been associated with retarding platelet aggregation and lowering BP. PGE_1 has also been implicated with the inhibition of cancer cell growth. On the other hand, 15-HETrE the major 15-LOX metabolite derived from DGLA has been demonstrated to suppress both inflammation and cell growth, particularly in epithelial cells. A notable feature of this metabolite is its incorporation into epidermal phosphatidyl 4,5-bisphosphate (PtdIns 4,5-P_2) followed by its PLC catalyzed hydrolytic bifurcation into 15-HETrE-substituted diacylglycerol (15-HETrE-DAG) and the inositol trisphosphate (Ins-P_3). These GLA/DGLA metabolites exert anti-inflammatory/anti-proliferative effects via signal transduction pathways.

Taken together, dietary GLA, although a member of the n-6 PUFA family that is inappropriately deemed deleterious, serves as an important essential dietary fatty acid nutrient with the capacity to be transformed into potent metabolites that modulate pathways that enhance the excessive generation of proinflammatory prostanoids and leukotrienes as well as provide a nontoxic therapeutic adjunct to standard chemotherapy for the management of human inflammatory/proliferative disorders.

33 Biological Effects of Alpha-Linolenic Acid

Luc Djoussé

CONTENTS

I. INTRODUCTION

Alpha-linolenic acid (ALA) belongs to the N-3 family of essential fatty acids for humans. ALA contains 18 carbons and 3 double bonds and may play an important role in human physiology. Long-chain omega-3 fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) that are mainly found in fish have been shown to have health benefits (Burr et al., 1989; Siscovick et al., 1995; Valaugussa et al., 1999). For example EPA and DHA have been reported to possess antiarrhythmic effects (Kang and Leaf, 1996a; Billman et al., 1999; Leaf et al., 1999; Leaf et al., 2005) and to lower triglycerides in humans (Harris, 1989; Roche and Gibney, 1996, 2000). On the other hand, taste preference, vegetarian diet, and possibly mercury contamination are factors that influence the frequency of fish consumption—a major source of EPA and DHA. In contrast, since plants are major sources of ALA and a small amount of ALA can be converted to EPA *in vivo*, ALA may provide an alternative to obtaining adequate amounts of non-animal omega-3 fatty acids. Of note is that the conversion of ALA to EPA and DHA may be affected by the concentration of linoleic acid (18:2 n-6) because linoleic acid and ALA use the same set of enzymes for desaturation and chain elongation (Gerster, 1988). Americans consume on an average 0.8 g of ALA per day (Djousse et al., 2001; Koralek et al., 2006).

The physiologic effects of ALA are poorly understood as the majority of research has focused on long-chain omega-3 fatty acids (EPA and DHA). The current chapter will describe the sources of ALA and discuss current epidemiological evidence on biological effects of ALA as well as future directions in ALA research.

II. SOURCES OF ALA

ALA is provided in the food chain mostly by plants. Major sources of ALA are flaxseed oil (51% by weight), canola and soy oils (9% and 7% by weight, respectively), and walnuts (6% by weight)

(Connor, 1999; Kris-Etherton et al., 2000). ALA content of processed foods can be variable depending on the oil used for processing. ALA is found in lesser concentration in green leafy vegetables, corn oil, almonds, and hazelnuts (Connor, 1999; Kris-Etherton et al., 2000). Variable amounts of ALA are also available in red meat, poultry, eggs, and dairy products (Bourre, 2005; Koralek et al., 2006).

III. *IN VIVO* CONVERSION OF ALA TO EPA AND DHA

Because other chapters of this book are devoted to the metabolism of fatty acids including ALA, this section will only provide a brief overview of the ALA metabolism *in vivo* and refers the reader to appropriate chapters for further details. Theoretically, it is possible for humans to convert ALA into long-chain omega-3 fatty acids EPA and DHA. This process utilizes elongase and desaturase enzymes to transform 18:3 (n-3) into 20:5 (n-3) and to a lesser extent 22:6 (n-3). However, this path does not appear to be effective in humans to make ALA a substitute for EPA and DHA. Only a small portion of ALA is metabolized to EPA (Sanders and Roshanai, 1983; Gerster, 1988; Nettleton, 1991; Mantzioris et al., 1994; Karvonen et al., 2002; Wilkinson et al., 2005). The major rate-limiting step in the conversion of ALA to EPA and other long-chain n-3 is the first delta-6 desaturation. It is thus possible that some of the physiological effects of ALA are mediated through EPA. The reader is referred to Chapter 36 for details on biological effects of EPA and DHA.

IV. ALA AND ARRHYTHMIA

Epidemiological evidence suggests that ALA may play an important role in protecting against cardiac arrhythmia. ALA may raise the threshold for arrhythmia in cardiac muscle cells, thereby making it more difficult to develop and sustain severe arrhythmia. In an experimental model, intravenous infusion of ALA over 90 min just before the exercise and ischemia test resulted in a significant reduction of the incidence of ventricular flutter/fibrillation (Billman et al., 1999); in that study, six out of eight mongrel dogs failed to develop ventricular flutter/fibrillation after the induced ischemia ($p = .004$) while infusion of a control substance (soybean oil) did not protect any animal from severe arrhythmias. In another animal model, rats fed with an ALA-rich diet showed a reduced incidence of ventricular fibrillation and cardiac mortality (McLennan and Dallimore, 1995).

It is not clear whether observed antiarrhythmic effects of ALA are direct or are indirect through its conversion to EPA. However, the relatively short period of time between ALA infusion and observed antiarrythmic effects lends support to the hypothesis of a direct effect of ALA on cardiac myocytes. What is known at the molecular level to support antiarrhythmic effects of omega-3?

It has been suggested that ALA and other long-chain omega-3 fatty acids may prevent arrhythmia through inhibition of sodium and calcium channels (Kang and Leaf, 1995; Xiao et al., 1997, 1998). In an animal study using neonatal cardiac myocytes, it was shown that ALA as well as EPA and DHA inhibited the binding of [*benzoyl*-2,5-^{3}H]batrachotoxinin A 20α-benzoate (a toxin that binds to voltage-sensitive Na^+ channels) to Na^+ channels in a dose-response fashion (Kang and Leaf, 1996b). Sodium channels represent the major class of ion channels that predict cardiac excitability. In addition, ALA and other omega-3 fatty acids may prevent arrhythmia by modulating the conduction of the L-type Ca^{2+} channels (Xiao et al., 1997). The inhibition of calcium channel prevents excessive cytosolic calcium fluctuation (Kang and Leaf, 1996b; Xiao et al., 1997) that is responsible for triggered arrhythmias. It is thought that the inhibition of sodium channels by omega-3 fatty acids results in an prolongation of the inactivated state of the Na^+ channel, and thus to more negative potentials (Xiao et al., 1995).

Nevertheless, data on antiarrhythmic effects of ALA, EPA, and DHA remain inconsistent. Animal experiments have shown that both long-chain and short-chain omega-3 fatty acids can protect against ventricular fibrillation (McLennan et al., 1993; Billman et al., 1994; Billman et al., 1999). In a meta-analysis of 27 animal studies, intervention with fish oil, EPA, and DHA showed protective effects

on ventricular tachycardia and fibrillation, whereas ALA had no antiarrhythmic effects (Matthan et al., 2005). Similarly, studies examining the effects of omega-3 including ALA on sudden cardiac death and fatal myocardial infarction—diseases associated with ventricular fibrillation—have been inconsistent (Burr et al., 1989; Ascherio et al., 1995; Hu et al., 2001; Whelton et al., 2004; Iso et al., 2006). An earlier meta-analysis of randomized trials reported a 30% lower risk of fatal myocardial infarction, 30% lower risk of sudden death, 20% lower risk of total mortality, but only a statistically nonsignificant 20% lower risk of nonfatal myocardial infarction with omega-3 fatty acids compared with placebo (Bucher et al., 2002). These findings were corroborated by another meta-analysis of randomized control trials of omega-3 fatty acids (Yzebe and Lievre, 2004).

In contrast, other randomized control trials of EPA and DHA showed no significant effects of these fatty acids on ventricular premature complexes (Geelen et al., 2005; Matthan et al., 2005) or ventricular fibrillation (Raitt et al., 2005; Brouwer et al., 2006). Similarly, the effects of omega-3 fatty acids on heart rate (Geelen et al., 2005; Mozaffarian et al., 2005) or heart rate variability have been inconsistent (Christensen and Vaupel, 1996; Christensen et al., 1997, 2000, 2001, 2005; Christensen, 2003). These negative studies cast doubt on the validity of the antiarrhythmic hypothesis underlying a lower risk of sudden death and fatal coronary events supposedly conferred by intake of omega-3 fatty acids.

In light of current gaps in physiological mechanisms by which ALA and other long-chain omega-3 fatty acids may influence cardiac arrhythmias, additional studies are needed not only to help understand biological mechanisms of ALA, but also to clarify its effects in humans as a potential antiarrhythmic agent.

V. ALA AND INFLAMMATION

Inflammation plays an important role in the pathogenesis of coronary artery disease and other chronic diseases (Gimbrone et al., 2000; Libby et al., 2002). Activation of the vascular endothelium is an early event in the development of atherosclerosis (Cybulsky and Gimbrone, 1991). Increased expression of proinflammatory cytokines has been found in atherosclerotic lesions, and both macrophages and activated endothelium produce proinflammatory cytokines (Seino et al., 1994; Plutzky, 2001). The circulating cytokines stimulate endothelial expression of cell adhesion molecules—such as vascular cell adhesion molecule-1 (VCAM-1), intercellular cell adhesion molecule-1 (ICAM-1), and E-selectin. These adhesion molecules mediate monocyte attachment to the endothelium and transmigration into the subendothelial space.

ALA is a precursor of EPA, which can displace arachidonic acid (20:4n-6) and reduce the production of proinflammatory eicosanoids prostaglandin E_2 (PGE_2) and leukotriene B_4. Epidemiologic data from animal and human trials suggest that ALA may indeed exhibit anti-inflammatory properties. In an animal experiment, a diet rich in ALA was shown to decrease PGE_2 and arachidonic acid in the hepatocyte membrane phospholipids and to increase circulating levels of tumor necrosis factor-alpha (TNF-α) (Chavali et al., 1998). In a study of healthy volunteers, the use of flaxseed oil in domestic food preparation for 4 weeks inhibited TNF-α and interleukin (IL)-1 beta production by approximately 30% (Caughey et al., 1996). An average daily intake of 9 g/day of ALA was associated with 36% decrease in thromboxane B_2, 26% decrease in PGE_2, and 20% decrease in IL-1 beta synthesis after 4 weeks of intervention (Mantzioris et al., 2000). In a randomized clinical trial of 76 dyslipidemic men, daily intervention with 15 mL of linseed oil was associated with a statistically significant decrease of C-reactive protein (CRP), serum amyloid A (SAA), and IL-6 concentrations after 3 months of intervention; the corresponding magnitude of decrease was 38% ($p = .0008$), 23.1% ($p = .0001$), and 10.5% ($p = .01$), for CRP, SAA, and IL-6, respectively (Rallidis et al., 2003). Contrary to linseed oil, safflower oil had no effects on inflammatory markers (Rallidis et al., 2003). Other studies have reported a decreased production of inflammatory markers that was attributable to long-chain omega-3 fatty acids (Endres et al., 1989; Kremer et al., 1990; Endres et al., 1993). In addition, other investigators have documented beneficial effects of ALA on inflammatory markers.

Supplementation with 15 mL of flaxseed oil per day for 12 weeks resulted in a statistically significant decrease in SAA, CRP, macrophage colony-stimulating factor, and IL-6 among 50 dyslipidemic men (Paschos et al., 2005). In a randomized crossover design, ALA-rich diet was associated with a significant decrease in CRP, ICAM-1, VCAM-1, and E-selectin compared with an average American diet after 6 weeks of intervention (Zhao et al., 2004). Compared with a control diet, ALA diet was associated with a decrease in CRP levels but had no effects on soluble ICAM-1, IL-6, or IL-10 levels in another randomized double-blind placebo controlled trial of 103 subjects over 2 years (Bemelmans et al., 2004).

Overall, there is sufficient data supporting anti-inflammatory effects of ALA in well-controlled trials, suggesting a favorable role of ALA on coronary heart disease (CHD), possibly mediated through an improved cytokine profile.

VI. ALA AND LIPIDS

Dyslipidemia is a major risk factor for CHD. Elevated low-density lipoprotein (LDL) cholesterol and triglycerides, low-levels of high-density lipoprotein (HDL) cholesterol individually or in combination are established risk factors for CHD (Kannel et al., 1965; Castelli, 1993; Kannel, 1995). Although it is possible that some of the reported effects of ALA on CHD might be mediated through lipid metabolism, limited and inconsistent data are available on the effects of ALA on lipids. Several studies did not find an effect of ALA on triglycerides (Annuzzi et al., 1991; Layne et al., 1996; McManus et al., 1996; Goh et al., 1997; Li et al., 1999; Rallidis et al., 2003; Goyens and Mensink, 2005), HDL (Layne et al., 1996; Li et al., 1999; Goyens and Mensink, 2005), and LDL or total cholesterol (Layne et al., 1996; Li et al., 1999; Bemelmans et al., 2002; Rallidis et al., 2003). In a randomized controlled trial, ALA-rich diet was associated with a significant increase in triglycerides and the ratio of total-to-HDL cholesterol compared with a controlled diet after 2 years of intervention (Bemelmans et al., 2002); in that study, ALA had no effects on total and LDL cholesterol.

In contrast, compared with the control diet, while an ALA-rich diet showed a significant reduction of total and LDL cholesterol, ALA had no effects on HDL and triglycerides after 6 weeks of intervention (Goyens and Mensink, 2005). In another trial, flaxseed oil was associated with a decrease in triglycerides, total, and LDL cholesterol (Wilkinson et al., 2005). Rallidis et al. (2003) reported a significant decrease in HDL-cholesterol; however, the magnitude of effect (1.3 mg/L) was not clinically meaningful. In a randomized crossover trial, an ALA-rich diet was shown to reduce total and LDL cholesterol by 11% each, triglycerides by 18%, HDL by 6%, and apolipoprotein B by 10% compared with an average American diet (Zhao et al., 2004). Data from the National Heart, Lung, and Blood Institute (NHLBI) Family Heart Study showed an inverse association between ALA and triglycerides (Djousse et al., 2003b).

In sum, despite inconsistent data on the effects of ALA on major lipids, there is enough support for favorable effects of ALA on triglycerides. Given the partial conversion of ALA to EPA *in vivo* (Li et al., 1999; Karvonen et al., 2002; Wilkinson et al., 2005), the well-established triglycerides lowering effects of fish oil or EPA/DHA lends additional support to possible beneficial effects of ALA on triglycerides. Whether ALA influences total and/or LDL cholesterol awaits confirmation in future studies.

VII. ALA AND BLOOD PRESSURE

Hypertension is highly prevalent in the United States and is a major cause of stroke, kidney failure, and CHD. Though the effects of ALA on CHD have been widely investigated, limited data are available on its effects on blood pressure or hypertension in humans. Existing data on the association between ALA and blood pressure remain inconclusive. In a trial of 33 normotensive men with slightly elevated cholesterol, a diet supplemented with 9.2 g/day of ALA did not influence systolic blood pressure (SBP) after 6 weeks of intervention (Kestin et al., 1990). Similarly, consumption of

a diet rich in ALA for 42 days did not influence SBP or diastolic blood pressure (DBP) among 17 male vegetarians (Li et al., 1999). In a randomized trial, a diet rich in ALA was not associated with SBP or DBP compared with linoleic-rich diet after 2 years of intervention (Bemelmans et al., 2002).

In contrast, other investigators found evidence for an effect of ALA on blood pressure. In a cross-sectional study of 399 male subjects aged 20–78 years, a 1% higher adipose tissue ALA was associated with a 5 mm Hg lower SBP and DBP (Berry and Hirsch, 1986). In the Kuopio Ischemic Heart Disease Risk Factor Study (Salonen et al., 1988), dietary intake of ALA—assessed by a 4-day food record—was inversely associated with SBP and mean blood pressure but not with DBP (Salonen et al., 1988). Rupp et al. (1996) showed that a diet supplemented with ALA lowered SBP by 6 mm Hg after 7 weeks in 28 spontaneous hypertensive rats. Similarly, data from the NHLBI Family Heart Study showed that ALA was inversely associated with SBP but not DBP (Djousse et al., 2005b).

Metabolites of ALA could favorably influence blood pressure. In particular, PGI_3—a metabolite of ALA—is a vasodilator and can influence vascular tone. It is also possible that an increased dietary intake of ALA could decrease the ratio of n-3/n-6 and thus decrease the synthesis of thromboxane A_2 from n-6 fatty acids. Thromboxane A_2 is a vasoconstrictor that could help sustain elevated blood pressure. In animal models, production of $PGF_{2\alpha}$—which stimulates vascular constriction and smooth muscle contraction—was significantly reduced in animals fed diets rich in ALA (Hoffmann et al., 1986). Alternatively, ALA could lower blood pressure through its anti-inflammatory effects (Rallidis et al., 2003; Zhao et al., 2004). Since inflammation plays an important role in the development of atherosclerosis, prevention of such process would preserve the elasticity of arterial walls and prevent an increase in vascular resistance. The anti-inflammatory hypothesis of ALA is consistent with data showing that dietary ALA is inversely related with intima-media thickness of the carotid arteries (Djousse et al., 2003a) as well as calcified atherosclerotic plaque in the coronary arteries (Djousse et al., 2005a). Although the evidence is weak, there is a strong possibility that ALA may favorably influence blood pressure. Additional controlled studies are warranted for confirmation.

VIII. ALA AND CLOTTING SYSTEM

Although an earlier report suggested antithrombotic effects of ALA (Owren, 1965), the majority of existing data provide little evidence to support such hypothesis. Epidemiologic studies have consistently reported no direct effects of ALA on hemostatic factors. In an intervention study, consumption of a diet rich in ALA for 28 days had no effects on plasma fibrinogen, factors VII, prothrombin time, activated partial thromboplastin time, antithrombin III, and plasminogen (Li et al., 1999). In a randomized trial, ALA had no significant effects on fibrinogen or von Willebrand factor after 2 years of intervention (Bemelmans et al., 2002). Others did not find beneficial effects of ALA on hemostatic factors (Freese and Mutanen, 1997; Archer et al., 1998; Allman-Farinelli et al., 1999).

Data on the effects of ALA on platelet aggregation have been inconsistent. Kwon et al. (1991) reported a reduction of collagen-induced platelet aggregation in whole-blood after a 3-week intervention with canola oil. A decreased collagen-induced platelet aggregation was also seen with an increased ratio of ALA to LA (Freese et al., 1994; Allman et al., 1995). However, other investigators could not replicate these effects of ALA on platelet aggregation (Mutanen et al., 1992; Li et al., 1999). Additional data are needed to determine whether ALA has a meaningful influence on hemostatic factors. However, the most promising hypothesis is a direct influence of ALA on platelet aggregation.

IX. ALA AND PROSTATE CANCER

Since 1975, when it was suggested that dietary fat might be associated with death from prostate cancer (Armstrong and Doll, 1975), several studies have examined the role of dietary fats and the risk of prostate cancer. However, results from those studies have been inconsistent (Graham et al., 1983;

Ohno et al., 1988; Mettlin et al., 1989; Giovannucci et al., 1993). Among polyunsaturated fats, ALA has received a lot of attention since the publication of the data from the Health Professionals' Follow-up Study in 1993 suggesting a modest 25% increased risk of prostate cancer with higher intake of ALA (95% CI: 0.82–1.92) (Giovannucci et al., 1993). Current literature on the role of ALA in the development of prostate cancer in not conclusive, as reported findings ranged from suggestive protection to a substantial increased risk of prostate cancer with ALA. Specifically, data on 58,279 subjects from the Netherlands found that higher consumption of ALA derived from food-frequency questionnaire was associated with 24% reduction in risk of prostate cancer; however, this finding was only borderline significant (95% CI: 0.66–1.04; $p = .09$) (Schuurman et al., 1999). In contrast, other cohort studies reported no increased risk of prostate cancer with ALA (Mannisto et al., 2003; Laaksonen et al., 2004; Koralek et al., 2006) or a significant increased risk of prostate cancer with ALA (Harvei et al., 1997; Leitzmann et al., 2004). Results of other observational studies assessing the effects of ALA on prostate cancer have been inconsistent (Andersson et al., 1996; Godley et al., 1996; Meyer et al., 1997; Bairati et al., 1998; Yang et al., 1999; De Stefani et al., 2000; Ramon et al., 2000; Newcomer et al., 2001; Mamalakis et al., 2002). A meta-analysis summarizing 9 of these findings reported a 70% increased risk of prostate cancer with higher ALA (RR = 1.70; 95% CI: 1.12–2.58) (Brouwer et al., 2004). Of note is that this meta-analysis does not include findings from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening trial that found no association between total or food-specific ALA and total, organ-confined, or advanced prostate cancer in nearly 30,000 subjects (Koralek et al., 2006).

What are possible sources of heterogeneity across studies? Is there a clear biological mechanism by which ALA may increase the risk of prostate cancer? In the absence of a large randomized and placebo-controlled trial of ALA on prostate cancer, shortcomings of noninterventional studies could influence the results and subsequent conclusions. Although many of the published studies controlled for measured confounding, there is no guarantee that unmeasured confounding does not partially or completely account for the heterogeneity across studies. In addition, several studies used food frequency questionnaires to assess ALA intake. Recall bias and/or inaccuracy in reporting consumed foods could lead to biased estimate of ALA. Similarly, studies using plasma or tissue levels of ALA are not exempted from inaccuracy in ALA estimation. ALA content in processed foods is variable, and the ALA sources could be correlated with dietary or lifestyle factors associated with prostate cancer risk. As to the biology, limited experimental studies are available. Perilla oil has been reported to decrease the rate of prostatic intraepithelial cancer in the presence of testosterone (Mori et al., 2001). In contrast, another animal model showed that linseed oil diet did not prevent prostate cancer growth in mice compared with corn oil diet (Connolly et al., 1997). Furthermore, results from *in vitro* studies using prostate cell lines have been inconsistent. Although one study reported an increased growth of the PC-3, LNCaP, and TSU cell lines (Pandalai et al., 1996), others found an inhibition of DU-1145 cells proliferation (du Toit et al., 1996) and increased cell deaths (Motaung et al., 1999) with ALA.

It is possible that reported beneficial effects of ALA on CHD might be offset by its detrimental effects on the development of prostate cancer. However, based on the current level of evidence, we do not have enough data to confirm a major role of ALA on the risk of prostate cancer or to exclude a modest increased risk of prostate cancer. Because CHD remains the leading cause of death and there are enough data to support beneficial effects of ALA on CHD, additional studies to clarify the role of ALA on prostate cancer are necessary before dismissing strategies using ALA to prevent CHD.

X. CONCLUSIONS

Plant-based omega-3 may have beneficial health effects. However, limited data are available to understand underlying biological mechanisms. Specifically, biological effects of ALA are not completely understood. Based on current evidence, there is enough data to support possible antiarrhythmic effects of ALA either directly or through its metabolite EPA. Accumulating evidence also

supports anti-inflammatory role and blood pressure lowering effect of ALA in humans. In addition, ALA may possibly exert beneficial effects on triglycerides either directly or through its metabolite EPA. Currently, there is limited support for a meaningful role of ALA on hemostatic factors. In addition, current data are insufficient to confirm an increased risk of prostate cancer with ALA. Given some of the shortcomings of fish consumption including costs, availability, and taste preference, ALA provides an alternative source of essential omega-3 fatty acids at a relatively low costs. However, because of the slow and limited conversion of ALA to EPA and the limited dada on direct benefits of ALA, it would be premature to recommend the replacement of EPA/DHA with ALA or to assign both types of n-3 fatty acids equivalent roles. Additional studies (particularly randomized placebo-controlled trials where applicable) are needed to confirm biological mechanisms of ALA in humans.

34 Biological Effects of Conjugated Linoleic Acid

Yung-Sheng Huang, Teruyoshi Yanagita, Koji Nagao, and Kazunori Koba

CONTENTS

I. INTRODUCTION

Conjugated linoleic acid (CLA) is a group of positional and geometric isomers of linoleic acid with conjugated double bonds located at positions 8 and 10, 9 and 11, 10 and 12, or 11 and 13, and these double bonds may be of *cis* and *trans* configuration (Eulitz et al., 1999) (Figure 34.1). This group of isomers is synthesized by microbial fermentation (bacteria, *Butyrinvibrio fibrisolvens*) occurring in the gut of ruminant animals (such as sheep and cattle) (Kepler et al., 1966). Thus, CLAs are predominantly found in dairy products and meat from ruminants (Chin et al., 1992). The concentration of CLA in these foods can be as high as 30 mg/g depending on the diet of the ruminant animal, and are generally higher if the animal is grazing on fresh, green pasture than feeding a grain (Dhiman et al., 1999). Interestingly, the highest concentration of CLA when compared with other foods is found in Kangaroo meat (Engelke et al., 2004). Kangaroos are not true ruminant animals, but like ruminants, they ferment feed in their foregut. Other foods including vegetable oils, eggs, seafood, poultry, and pork may also contain CLA but at very low levels. The most abundant isomer in food is *cis* 9, *trans* 11-18:2 (*c*9,*t*11-18:2), followed by *t*10, *c*12-18:2. Evidence indicates that different CLA isomers exert different health effects (Ip et al., 1999; Pariza et al., 2001; Li et al., 2006).

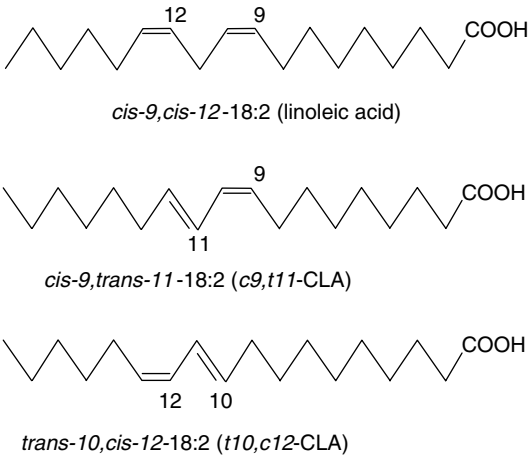

FIGURE 34.1 Chemical structure of conjugated linoleic acids.

II. CLA AND HUMAN HEALTH

Interest in the beneficial effects of CLA on human health started from the original findings by Pariza and his coworkers that red meat contains a component exhibiting the cancer-fighting properties (Ha et al., 1987). Since then, CLA has been the subject of a variety of research, and findings also suggest that CLA possesses other benefits such as increased metabolic rate, decreased abdominal fat, enhanced muscle growth, lowered cholesterol and triglycerides, lowered insulin resistance, reduced food-induced allergic reactions, and enhanced immune system.

A. CLA and Cancer

Early research with animal models demonstrated that CLA found in red meat could interfere with the growth of breast and prostate tumors (Ip et al., 1991, 1994). Since then, more studies have further shown the cancer-fighting potential of CLA. However, most of the evidence on breast as well as skin, liver, and colon cancers has come from animal and human cancer cell lines *in vitro*. Clinical studies were scarce. Nevertheless, recent results from a large French study have indicated that dietary CLA could protect against breast cancer in humans (Chajes et al., 2003).

Evidence indicates that CLA inhibits the initiation and incidence of mammary tumors in rodents. It also had a significant effect on the latency, metastasis, and pulmonary tumor burden of transplantable murine mammary tumors grown in mice (Hubbard et al., 2000). Recently, Ohtsua et al. (2005) demonstrated that CLA decreases cellular proliferation and inhibits NF-κB and activator protein-1 activation in PC3 cancerous prostate epithelial cells.

B. CLA and Weight Management

Obesity has become a major health issue in the affluent societies. In the United States, over 30% of the adult population is obese. During the past decade, the percent of obese people has doubled (Flegal et al., 2002). CLA is one of nutrients that has been shown to be able to reduce body fat and to increase lean body mass (LBM) in pigs (Dugan et al., 1997), mice (Park et al., 1997; DeLany et al., 1999; Pariza et al., 2000), and rats and chicks (Martin et al., 2000; Pariza et al., 2000; Wang et al., 2003). In humans, CLA shows a tendency to reduce body fat, particularly abdominal fat, change serum total lipids, and decrease whole body glucose uptake (Blankson et al., 2000; Smedman and Vessby, 2001; Thom et al., 2001).

On the other hand, there are studies failed to confirm this benefit (West et al., 1998; Blankson et al., 2000; Riserus et al., 2001; Smedman and Vessby, 2001; Thom et al., 2001; Kreider et al., 2002; Kamphuis et al., 2003; Larsen et al., 2003; Gaullier et al., 2004; Malpuech-Brugere et al., 2004; Wang and Jones, 2004). Atkinson (1999) did not find any differences between the CLA group (2.7 g/day) and the placebo group in a 6 months placebo-controlled, randomized, double-lind study in obese volunteers. Zambell et al. (2000) have found that CLA supplementation (3 g/day) had no effect on body composition and energy expenditure in 17 healthy, adult women for 64 days following a baseline period of 30 days.

C. CLA and Heart Health and Arteriosclerosis

One of the major risk factors for coronary heart disease is high levels of cholesterol, particularly low-density lipoproteins (LDL) cholesterol (or "bad" cholesterol); because cholesterol over time can form plaque in arteries, narrowing them, reducing heart's blood supply. Animals fed a CLA-containing diet had a significantly reduced LDL and total cholesterol and triglyceride levels in blood (Kritchevsky et al., 2000), and reduced cholesterol concentration in liver (Sakono et al., 1999). Results from studies with rabbits and hamsters have indicated that CLA can lower plasma lipoproteins and early aortic atherosclerosis in rabbits and hamsters (Lee et al., 1994; Nicolosi et al., 1997). In human, a small double-blind trial has also found that CLA could reduce blood cholesterol levels in healthy human subjects (Noone et al., 2002). Among different CLA isomers, the *t*10,*c*12-CLA as compared to linoleic acid has been shown to be more effective in lowering the concentration of total cholesterol and triglyceride, whereas raising the concentration of serum HDL-cholesterol (Akahoshi et al., 2003).

The hypotensive properties of CLA have also been reported. Feeding of CLA mixture and the *t*10,*c*12-CLA isomer has been shown to prevent the development of obesity-induced hypertension in obese, diabetic Zucker rats and obese OLETF rats (Nagao et al., 2003a,b), and prevent the development of essential hypertension in nonobese spontaneously hypertensive rats (Inoue et al., 2004).

In addition, CLAs (both *c*9,*t*11- and *t*10,*c*12-isomers) have been shown to inhibit the arachidonic acid- and collagen-induced platelet aggregation, and the formation of proaggregatory cyclooxygenase product, TXA_2 (Truitt et al., 1999).

D. CLA and Diabetes

The incidence of type II diabetes in the affluent societies is increasing dramatically. There is evidence that CLA may have the ability to normalize glucose metabolism. In studies with obese, diabetic rats, feeding of CLA diet normalized impaired glucose tolerance, and the effect of CLA was similar to that of the pharmaceutical agent troglitazone (Houseknecht et al., 1998; Belury et al., 2003). In another study, dietary supplementation with CLA also lowered body mass, levels of blood sugar, triglycerides, and insulin, and improved glucose utilization in diabetes (Belury et al., 2003).

The beneficial effect of CLA are attributable to the specific action of the *t*10,*c*12-isomer (Ryder et al., 2001). *In vitro* studies showed that the *t*10,*c*12-isomer but not the *c*9,*t*11-isomer lowered body weight but stimulated peroxisome proliferator-activated receptor-γ (PPAR-γ)-mediated reporter gene activity. The activation of PPAR-γ may play some role in the putative antidiabetic activity of CLA (Houseknecht et al., 1998).

However, there is also growing evidence that CLA may *worsen* blood sugar control. In overweight people without diabetes, CLA might promote insulin resistance and thus decrease insulin sensitivity, creating a prediabetic state (Riserus et al., 2002; Larsen et al., 2003; Moloney et al., 2004; Riserus et al., 2004).

E. CLA and Immune Function and Inflammatory Response

The immune system protects the body by fighting disease. CLA can enhance the immune system. Feeding CLA to chicks provided partial protection against the catabolic effects of endotoxin

(Cook et al., 1993). CLA also supports the production of key immune system cells and the inflammation response system. When the immune system is challenged by antigen or polyclonal T cell mitogens, such as concanavalin A and phytohemagglutinin, and their production of interleukin-2, feeding CLA could improve the age-related decrease in the ability of T cells to proliferation in mouse (Hayek et al., 1999). More, feeding CLA could significantly increase the splenic levels of immunoglobulin A (IgA), IgG, and IgM in mice (Sugano et al., 1997; Yamasaki et al., 2000).

F. CLA and Bone Health

Recently, effects of CLA on bone have been investigated (Cook et al., 1997; Watkins and Seifert, 2000; Thiel-Cooper et al., 2001; Doyle et al., 2005; Banu et al., 2006). *In vitro* studies using MC3T3-E1 osteoblast-like cells showed that CLA increased levels of osteocalcin, alkaline phosphatase activity, and calcium absorption (Fernandes et al., 1986). *In vivo* studies using young chicken, mice, and pigs have shown that in the presence of CLA there is an increase in bone mass. However, in young rats, CLA decreased bone formation rates (Ammann et al., 1992; Griffin et al., 1993), but when CLA was given along with n-6 PUFA, bone formation rates increased (Lu et al., 1994). In humans, a study that tested the effects of CLA supplementation on the biochemical markers of bone metabolism has reported that in adult men CLA supplementation did not affect markers of bone metabolism (Rahman et al., 2003). A recent study on the effects of CLA on postmenopausal women has concluded that dietary intake of CLA may benefit bone mineral density (Brownbill et al., 2005).

The mechanism by which CLA exerts its effect on bone is still not very clear, although a few theories have been reported recently. CLA has been shown to enhance bone mineralization (Kelly et al., 2003; Kelly and Cashman, 2004). In the presence of PUFA, CLA has been shown to modulate the action and expression of COX-2 enzyme, thereby alter the prostaglandin-dependent bone resorption (Li and Watkins, 1998; Li et al., 1999). Dietary CLA is also known to reduce both proinflammatory IL-1 (Thomas and Burguera, 2002) and IL-6 production (Burguera et al., 2001). Studies have reported that IL-1 and IL-6 induce bone resorption by stimulating the recruitment and formation of osteoclasts, and thereby releasing calcium from bone (Kang and Pariza, 2001; Reseland and Gordeladze, 2002).

III. POSSIBLE MECHANISMS OF CLA EFFECTS

A. Effect of CLA on Fatty Acid Oxidation Related Enzymes

The mechanism that underlines the CLA-induced changes on body fat content has been related to two aspects: (1) expedite the body's fat metabolism by increasing lipolysis in adipocyte and (2) enhance fatty acid oxidation in both adipocytes and skeletal muscle cells (Park et al., 1999; Pariza et al., 2000).

In mice, dietary CLA significantly increased total carnitine palmitoyl transferase activity in both fat pad and skeletal muscle (Park et al., 1999), and the hormone sensitive lipase activity in adipocytes (Park et al., 1997). In 3T3-L1 adipocytes, CLA inhibited the heparin-releasable lipoprotein lipase (LPL) activity and intracellular concentration on triacylglycerol and glycerol (Park et al., 1997).

B. Effect of CLA on Fatty Acid and Eicosanoid Synthesis

CLA is known to affect fatty acid and eicosanoid metabolism (Figure 34.2). As CLA can be readily incorporated into membrane phospholipids, the effect can be exerted through replacing arachidonic acid by CLA in cell membrane and reducing the availability of arachidonic acid for eicosanoid synthesis (Liu and Belury, 1998; Sugano et al., 1998; Banni et al., 1999). Belury and Kempa-Steczko (1997) have demonstrated decreased arachidonic acid levels in hepatic neutral lipids of rats fed CLA. CLA can also compete with fatty acid metabolic enzymes and thus affect the synthesis of arachidonic acid (Sebedo et al., 1997; Sugano et al., 1999). Feeding CLA has been shown to increase

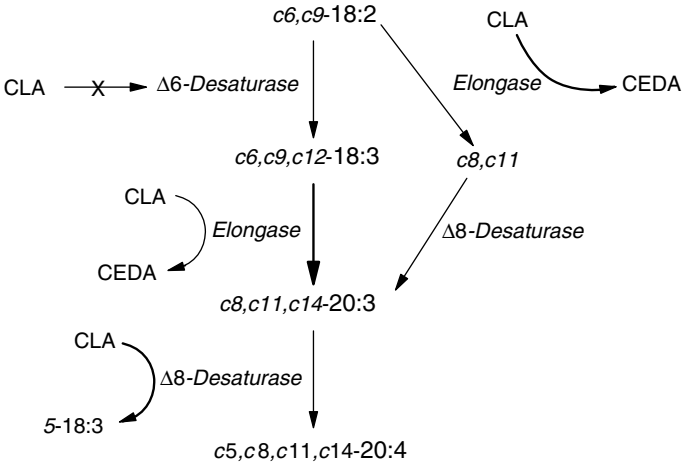

FIGURE 34.2 Effect of CLA on n-6 fatty acid metabolism. CLA: conjugated linoleic acid; CEDA: conjugated eicosadienoic acid; Δ5-18:3: *c*5,*c*9,*c*12-18:3.

the proportions of stearic, docosatetraenoic, and docosapentaenoic acids in serum lipids and thrombocytes, while proportions of palmitic, oleic, and dihomo-gamma-linolenic acids decreased, suggesting a decrease in the estimated Δ-6 and Δ-9 and an increase in the Δ-5 desaturase activities (Smedman and Vessby, 2001). Recently in a transformed yeast system, Chuang et al. (2001a,b, 2004) have demonstrated that CLA inhibited essential fatty acid metabolic enzymes such as Δ-6-desaturase, Δ-5-desaturase, and elongase. Eder et al. (2002) have demonstrated that *t*10,*c*12-CLA suppressed the Δ6-desaturase in HepG2 cell.

C. CLA as Antioxidant

It has been shown in *in vitro* and *in vivo* studies that CLA is an effective antioxidant (Ha et al., 1987; Ip et al., 1991). Indeed, comparative studies have shown that CLA is as effective as butylated hydroxytoluene (BHT), more potent than α-tocopherol, and approximately two times more powerful an antioxidant than beta-carotene (Ha et al., 1990; MacDonald, 2000). In the body CLA can be taken up by phospholipids, where CLA serves as one of the structural components of cell membranes and protect cell from the detrimental effect of peroxides. Because numerous studies have demonstrated that oxidative reactions are associated with the development of cancer and atherosclerosis, the ability of CLA to reduce the harmful effects of these oxidative reactions could be attributed to its health beneficial effect.

D. Effect of CLA on Gene Expression

CLA interacts with dozens of genes, but not all consequences are known. The ability of CLA to modulate lipid metabolism appears to be a pivotal mechanism of CLA's beneficial effects in mice and rats. The effect of CLA on body composition changes observed in animals seems to be associated mainly with the *t*10,*c*12-CLA isomer (Park et al., 1999). The *t*10,*c*12-isomer decreased the expression of stearoyl-CoA desaturase mRNA in mouse liver and adipocytes (Lee et al., 1998; Choi et al., 2000). Stearoyl-CoA desaturase activity is a key enzyme in lipogenesis, and inhibition of this enzyme activity depresses fat synthesis.

Dietary CLA induces the expression of genes dependent in part on the transcription factor, peroxisome proliferator-activated receptor (PPAR). Several CLA isomers are high-affinity ligands and activators for PPAR (Moya-Camarena and Belury, 1999).

IV. OTHER CONJUGATED FATTY ACIDS

There are also other types of conjugated fatty acids in some plant seed oils. Punicic acid (*c*9,*t*11, *c*13-conjugated linolenic acid, CLN) in pomegranate seed oil, α-eleostearic acid (*c*9,*t*11,*t*13-CLN) in bitter gourd oil and tung seed oil, catalpic acid (*t*8,*t*10,*c*12-CLN) in pot marigold seed oil (Suzuki et al., 2001; Kohno et al., 2002). It has been reported that several seaweeds contain conjugated trienoic and tetraenoic fatty acids. *Ptilota filicna* contains *t*5,*t*7,*t*9,*c*14,*c*17-conjugated eicosapentaenoic acid (CEPA) and *c*5,*t*7,*t*9,*c*14,*c*17-CEPA (Lopez and Gerwick, 1987). *Bossiella orbigniana* contains *c*5,*c*8,*t*10,*t*12,*c*14-CEPA (Burgess et al., 1991). Green seaweed *Anadyomene stellata* contains stella-heptaenoic acid, *c*4,*c*7,*t*9,*t*11,*c*13,*c*16,*c*19-conjugated docosaheptaenoic acid (Mikhailoba et al., 1995).

A. Anticarcinogenic Effect

Results from the *in vivo* study indicate that dietary CLN inhibits azoxymethane-induced colonic aberrant crypt foci in rats (Kohno et al., 2002). There are also several reports indicating the cytotoxic effects of CLN on various human cancer cell lines suggesting that conjugated trienes are stronger anticarcinogens than conjugated dienes (Igarashi and Miyazawa, 2000a; Suzuki et al., 2001). The cytotoxic actions of conjugated EPA and conjugated DHA were demonstrated in several cancer cell lines including colorectal, hepatoma, lung, breast, and stomach (Igarashi and Miyagawa, 2000b; Tsujita-Kyutoku etal., 2004; Tsuzuki et al., 2004).

B. Antiobese Effect

The antiobese effects of CLN have also been demonstrated. Dietary supplementation of CLN reduced perirenal adipose tissue weight by increasing triglyceride lipolysis, enhancing hepatic fatty acid beta-oxidation and reducing hepatic fatty acid synthesis in rats (Koba et al., 2002, 2006), in chickens, obese rats, and human liver-derived cells (Lee et al., 2002; Arao et al., 2004a,b).

V. SAFETY AND DOSAGE OF CLA

Evidence shows that for an individual with a body weight of 70 kg to reduce body fat mass is about 3.4 g (Blankson et al., 2000). Results from a randomized, double-blind, placebo-controlled trial shows that CLA supplementation (3.4 g/day in triglyceride form) for 24 months in healthy, overweight adults was well tolerated, and that CLA decreases body fat mass in overweight humans, and may help maintain initial reductions in body fat mass and weight in the long term (Gaullier et al., 2004). Thus, all evidence indicates that dietary supplementation of CLA at this dosage does not have any adverse effects. There are concerns regarding the use of CLA by nursing mothers. Results from a double-blind, placebo-controlled study indicates that use of CLA by the lactating women reduces the fat content of breast milk (Masters et al., 2002). Since infants require the fat in breast milk for energy and proper growth and development, one should be prudent to recommend CLA supplement to the nursing mothers (Bee, 2000).

CLA occurs naturally in foods such as milk, cheese, beef, and lamb as well as many processed foods (Chin et al., 1992), and whole milk usually contains less than 2 mg/g of CLA in milk fat, most people consume less than 1 g/day from these food sources (Ip et al., 1994; Parodi, 1994; Herbal et al., 1998). In order to get enough CLA from the diet one would require considerable intake of these types of foods. This approach is not only impractical, but also having a seriously negative impact on one's metabolism due to the high intake of calories. Supplemental CLA is usually derived from synthesis.

VI. CONCLUSION

CLA appears to be a generally safe nutritional substance (Whigham et al., 2004). CLA exerts many beneficial effects, such as anticarcinogenic, antiobese, antiatherogenic, anti-inflammatory, and so forth.

However, not all CLA isomers are equal; since specific CLA isomers exhibit different functions (Yotsumoto et al., 1999; Evans et al., 2002; Hargrave et al., 2002; Rodriguez et al., 2002; Nagao et al., 2003c; Yanagita et al., 2003; Jaudszus et al., 2005). The availability of different isomer-specific CLA products may provide a more efficient approach to the CLA supplementation.

35 The Role of Omega-3 Polyunsaturated Fatty Acids in Food Intake and Energy Homeostasis

Richard S. Weisinger, Denovan P. Begg, Lauren Stahl, Harrison S. Weisinger, Andrew J. Sinclair, and Markandeya Jois

CONTENTS

I. INTRODUCTION

Obesity, the excess accumulation of adipose tissue, is a major health problem worldwide. It is associated with more than 30 medical conditions, including type 2 diabetes and cardiovascular disease, and is a leading cause of unnecessary deaths. The control of body energy homeostasis is fundamental to mammalian life as well as to the problem of obesity. This chapter will describe the role of the omega-3 polyunsaturated fatty acids (n-3 PUFAs) in modulating some of the mechanisms that control body energy homeostasis. The chapter is divided into three major sections. The first section is dedicated to the dietary intake and metabolism of the n-3 PUFAs, as well as the interrelated n-6 PUFAs. The second section describes the major mechanisms responsible for the maintenance of body energy homeostasis. Then, in the third section, evidence regarding the role of n-3 PUFAs in these homeostatic mechanisms will be described, including evidence regarding the role of n-3 PUFAs in obesity and cancer cachexia.

II. OMEGA-3 POLYUNSATURATED FATTY ACIDS

A. Supply and Metabolism of Polyunsaturated Fatty Acids

Mammals do not produce Δ12 and Δ15 desaturase enzymes and therefore cannot produce either linoleic acid (LA) or α-linolenic acid (ALA), precursors of the n-6 and n-3 families, respectively, *de novo*. ALA is metabolized, in a series of desaturation and elongation reactions, to produce long-chain n-3 PUFA, the most prevalent of which are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). This metabolism occurs primarily in the liver and cerebral microvasculature of the blood brain barrier, but also by astrocytes and the cerebral endothelium (Moore et al., 1990). EPA is further metabolized by the cyclooxygenase and lipoxygenase pathways to produce the eicosanoids (prostaglandins, thromboxanes, and leukotrienes) that are potent, short-acting, local hormones, or second messengers. The eicosanoids are derived from EPA as well as from arachidonic acid (20:4n-6). These fatty acids are liberated from the cell membrane by the phospholipase-A_2. Phospholipase-A_2 has equal affinity for both EPA and arachidonic acid, therefore, the proportion of n-3:n-6 hydrolyzed by phospholipase-A_2 is determined by the tissue n-3:n-6 profile (Calder, 1996). DHA is primarily sequestered into the phospholipid membranes of cells within the brain and central nervous system. The predominant PUFA in the brain is DHA that comprises up to 30% of the phospholipid fatty acids in the grey matter (Sinclair, 1975). DHA is a determinant in the regulation of synaptic transmission, ultrastructural changes in neural synapses and changes in dopamine and NMDA receptor function (for reviews, see Fenton et al., 2000; Kurlack and Stephenson, 1999). Furthermore, n-3 PUFA deficiency early in life may result in irreversible damage to biochemical processes in the central nervous system (Uauy et al., 2000).

The metabolism of n-3 and n-6 PUFA is interlinked as they compete for enzymes and metabolic substrates at all levels. Therefore, relative as well as absolute dietary intake is relevant in the determination of tissue n-3 and n-6 fatty acid levels. The Western diet typically contains high levels of n-6 fatty acids, as these are components of most animal and vegetable fats. Dietary sources of n-3 PUFA are varied. The most plentiful sources are fish, shellfish, and marine products, which contain large amounts of EPA and DHA. Certain plant oils, such as rapeseed (canola), soybean, and perilla contain large amounts of ALA. Although beef and lamb do contain n-3 PUFAs, both the absolute content and the n-3:n-6 ratio of PUFAs within these meats is low (Crawford and Sinclair, 1972; Sinclair, 1975).

Burr and Burr highlighted the importance of certain fats in the human diet and demonstrated that dietary deprivation of the essential fatty acids was deleterious to health (Burr and Burr, 1929). They concluded that the n-6 PUFAs were most important to function in mammals because their omission resulted in overt systemic dysfunction. Conversely, it has been shown that deprivation of n-3 PUFAs results in subtle dysfunction across a range of behavioral and physiological modalities.

The n-3 PUFAs are important components of cell membranes throughout the body, as they are incorporated into the phospholipids that form cell membranes. Each phospholipid molecule is composed of a headgroup to which fatty acid esters are bound. There are two binding positions, termed as *sn*-1 and *sn*-2. The acyl chains that bind to these headgroups interact with other chains in neighboring phospholipid molecules within the bilayer and the level of chain interaction determines the biophysical properties of the membrane. The *sn*-1 position is usually occupied by a saturated fatty acid; the *sn*-2 position is usually occupied by a relatively unsaturated fatty acid chain.

Fleischer and Rouser (1965) suggested that lipid bilayers composed mainly of saturated fat (such as cholesterol) are relatively stable due to low acyl chain interactions. These stable membranes have higher viscosity and produce rigid cell membranes. An example of cells with this type of membrane is myelinated nerve fibers. Conversely, membranes composed of phospholipids with highly unsaturated acyl chains are less rigid, owing to interactions between such bulky acyl chains. This state of membrane disorder produces a physical fluidity and it is proposed that such membranes offer minimal hindrance to the function of proteins (e.g., receptors or channels) that lie within the membrane. Thus, Fleischer and Rouser (1965) suggest that metabolically active membranes,

such as those found in neuron cell bodies, are composed of phospholipids-containing unsaturated *sn*-2 chains. Work by Brown, Dratz, and Litman supports this notion, as recombinant membranes that comprise higher levels of DHA mimic biological activity more closely when studied *in vitro* (Brown, 1994; Dratz and Holte, 1993; Littman and Mitchell, 1996).

Western diets typically contain low levels of n-3 PUFAs (Simopoulos et al., 2000). Furthermore, relative to the diet of early man, today's diet is not only higher in saturated fats but has an altered ratio of the two major groups of PUFAs. Modern-day humans are, most probably, descendants of coastal dwelling hunter-gatherers, with a primary diet of fish, shellfish, and plant matter. This omnivorous, and opportunistic, diet was varied and most probably low in saturated fat. The ratio of n-6 to n-3 fatty acids during the early part of human evolution was close to 1, whereas today the ratio is 10:1 or more (Eaton et al., 1998; Simopoulos, 1998). A recent study in Australia (A. J. Sinclair, unpublished data) indicates that DHA intake is 0.1% of fat intake or about 100 mg/day. The recommended intake is 0.5%–1% (Simopoulos et al., 2000). Furthermore, recent data from our group (A. J. Sinclair, unpublished data) has shown that reduced DHA levels in neural tissue occur in animals that are maintained on high saturated fat diets similar to that of a Western diet.

B. Omega-3 PUFA in the Brain and Central Nervous System

A significant proportion of neural development occurs postnatally, hence, early nutrition is vital to support optimal neural development (Connor et al., 1992). The large demand for DHA during pregnancy and early development is usually met via the placenta and then by maternal milk (Neuringer et al., 1986; van Houwelingen et al., 1996). Maternal dietary LA and ALA serve as precursors for n-3 and n-6 long-chain PUFAs by the maternal liver. The ability to obtain sufficient amounts of DHA to ensure normal growth and development, however, may be compromised by the decreased ability to transform precursor into DHA during pregnancy and lactation (van Houwelingen et al., 1996). There is a progressive enrichment of DHA within circulating lipids of the fetus during the third trimester, a time when fetal demands for vascular and neural growth are greatest (Clandinin et al., 1980; van Houwelingen et al., 1996). DHA is concentrated in synapses and most synaptogenesis occurs during perinatal life.

III. BODY ENERGY HOMEOSTASIS

Many factors are involved in the control of food intake. Some of the most important factors controlling the amount of food that we eat include environmental factors such as food availability, the characteristics of the food itself, for example, smell, taste, our eating habits, learned preferences and aversions, as well as other psychological and social factors including our lifestyle. Although these psychosocial factors are extremely important to the food intake patterns of humans, this review will concentrate only on the physiological factors, primarily, the role of fat in food intake.

The regulation of body energy homeostasis, the balance between energy input and expenditure, is crucial to an animal's growth and survival. Complex central nervous system mechanisms have evolved to ensure that the animal's needs and its behavioral and physiological responses are coordinated. A starving animal, motivated by hunger, seeks out and ingests food it encounters. Simultaneously, mechanisms act to conserve body energy when possible, for example, body temperature and activity may be decreased. In the long term, the interplay between the various environmental and physiological factors controlling energy input and expenditure determines the individual's body weight.

The importance of the hypothalamic brain area to the control of food intake and body weight has been known for at least 50–60 years (Anand and Brobeck, 1951; Hetherington and Ranson, 1940). Initially, evidence demonstrated the importance of the lateral hypothalamus (LH) and the ventromedial nucleus (VMN) of the hypothalamus. Lesion of the LH causes animals to lose body weight through decreased food intake and increased body temperature. Experiments suggested that the lesion of the LH reduced the animal's body weight "set point." That is, when the animal's body

weight was decreased by food deprivation prior to lesion of the LH, the normally observed under-eating did not occur after the lesion but rather the new low body weight was maintained. In contrast, lesion of the VMN causes animals to increase food intake and gain body weight. When an animal's body weight was increased prior to lesion of the VMN, the normally observed over-eating did not occur after lesion but rather the new elevated body weight was maintained. These results suggest that the "set point" is determined, at least in part, by hypothalamic mechanisms (Friedman and Stricker, 1976; Hoebel and Teitelbaum, 1966; Keesey and Hirvonen, 1997; Keesey and Powley, 1975; Keesey et al., 1979; Mrosovsky and Powley, 1977). Clearly, however, the "set point" can be influenced by various environmental and physiological factors, as evidenced by obesity. Interestingly, even "obese" humans appear to have a body weight set point, for example, following a weight loss regimen, most obese patients regain all of their lost weight within 9 years (Johnson and Drenick, 1977).

Evidence consistent with the idea of a body weight "set point" is observed in animals with normal body weight as well. For example, like others (Keesey and Hirvonen, 1997), we have observed that when animals are given free access to food after a period of food restriction, the loss in body weight is restored. Interestingly, over-eating may only be evident during the first week following the return of free food access.

Today, other brain areas are known to be important to the control of food intake and body weight. Lesion of the arcuate nucleus (ARC) or PVN result in obesity (Bray, 1993; Dallman et al., 1993; Holzwarth-McBride et al., 1976; Kirchgessner and Sclafani, 1988; Rothwell, 1990). One of the important factors contributing to obesity appears to be an increase in the activity of the hypothalamic-pituitary-adrenal axis. Adrenalectomy inhibits or prevents the development of obesity subsequent to lesion of the ARC or PVN (Dallman et al., 1993). Other brain areas, such as the amygdala, area postrema (AP), NTS, parabrachial nucleus (PBN), DMV, and frontal cortex are also involved (Bray and York, 1998; Dallman et al., 1993; Holzwarth-McBride et al., 1976; King et al., 1999; Kirchgessner and Sclafani, 1988; Ritter and Hutton, 1995; Woods et al., 1998). Disruption of the neural pathways between PVN, NTS, and DMV simulate aspects of the obesity caused by lesion of the VMN (Kirchgessner and Sclafani, 1988). Thus, these results are consistent with neural networks rather than neural centres controlling food intake and body weight. Of course, although many key brain areas have been identified, there is much to be elucidated in terms of determining the relevant pathways.

Glucose and fat are the two major sources of energy for the body. Early theories proposed that food intake was controlled by central mechanisms sensing changes in the level or utilization of these fuels. Mayer (1952, 1955) suggested that food intake was controlled by blood glucose levels or, by levels of glucose utilization. Glucostats in the hypothalamus were thought to sense the changes in glucose levels. Some evidence suggests that a small decrease in plasma glucose precedes hunger and food intake in humans (Campfield and Smith, 1986).

Another theory, the "lipostatic" theory, proposed by Kennedy (1950), suggested that food intake varied so as to maintain body fat stores, that is, the "set point." Changes in body fat stores, reflected in signals dependent on the size of those stores (e.g., blood levels of fatty acids), controlled food intake. Indeed, it has been shown that animals with lesion of the LH and VMN have pronounced disturbances in fat metabolism (Friedman and Stricker, 1976). Animals with a VMN lesion show increased fat storage such that circulating levels of the metabolic products of fat metabolism are decreased. It has been proposed (Friedman and Stricker, 1976) that this decreased availability of the metabolic products of fat metabolism stimulates food intake.

Presently, in line with the idea that fat metabolism is crucial to body energy homeostasis, evidence suggests that peptides produced in the body and correlated with body fat mass, are essential to the long-term control of food intake and body weight. Leptin is one such peptide. Leptin is the protein product of the *ob* gene. It is primarily produced in white adipose tissue and the plasma level of leptin accurately reflects total body adiposity (Friedman, 1997; Porte et al., 1998). It enters the brain from the circulation by a saturable transport mechanism (Friedman, 1997; Seeley and

Schwartz, 1999; Woods et al., 1998). Leptin expression is stimulated by cortisol, insulin, and fasting, and is attenuated by long-chain fatty acids (Houseknecht et al., 1998; Trayhurn et al., 1999). It has been shown that central administration of leptin decreases body weight, primarily by causing the loss of fat (Chen et al., 1996; Halaas et al., 1997). Interestingly, while decreased food intake normally causes a reduction in energy utilization, this does not occur during administration of leptin. Indeed, body weight decreases during administration of leptin even when food intake has returned to normal (Halaas et al., 1997).

The decrease in food intake caused by leptin is mediated by its actions on central peptidergic systems involved in food intake. For example, leptin stimulates peptidergic systems that inhibit food intake. Leptin stimulates corticotropin releasing factor (CRF) release in the PVN. CRF and urocortin, a newly discovered member of the CRF family, decrease food intake and increase energy expenditure (Richard, 1993; Rothwell, 1990; Weisinger et al., 2000). The decreased food intake caused by CRF/urocortin is mediated by CRF-R2 receptors (Smagin et al., 1998; Spina et al., 1996), found in the VMN, amygdala, and PVN (Baram et al., 1997; Eghbal-Ahmadi et al., 1997; Gray and Bingaman, 1996). It has been shown that the influence of leptin on food intake is blocked by a CRF receptor antagonist (Gardner et al., 1998). CRF is thought to decrease food intake by its influence on the release of another peptide that inhibits food intake, that is, oxytocin (Olson et al., 1991), or by its ability to decrease gastric emptying (Tache et al., 1987). The increase in energy expenditure caused by CRF/urocortin has been attributed to their activation of the sympathetic nervous system (Arase et al., 1988; Rothwell, 1990; Smagin et al., 1998; Spina et al., 1996). The influences of leptin and CRF on food intake and body weight are clearly very similar and it seems likely that the actions of leptin are, at least in part, mediated via a system involving CRF and its receptors.

In addition, leptin acts to inhibit the activity of peptidergic systems that stimulate food intake. Leptin receptors have been found on many of the peptidergic neurons thought to increase food intake and body weight. Such neurons are found throughout the brain and include the melanin concentrating hormone (MCH)-containing neurons of the LH; the neuropeptide Y (NPY)-containing neurons of the ARC and VMN, and the galanin-containing neurons of the PVN (Hakansson et al., 1999; Meister, 2000). MCH is synthesized in the LH- and MCH-containing neurons project to various brain areas involved in energy balance. Stimulation of MCH pathways causes increased food intake (Chambers et al., 1999). NPY is found in neurons in the ARC that project to the PVN, LH, and NTS. Stimulation of NPY pathways is followed by increased food intake, lipogenesis, and decreased sympathetic nervous system activity, and energy expenditure in brown fat (Billington and Levine, 1992; Grundemar and Hakanson, 1994; Levine and Billington, 1997; Richard, 1995; White, 1993). Stimulation of food intake by NPY is thought to be mediated by neurons expressing MCH, via an ARC-LH pathway (Broberger et al., 1998). NPY neurons appear to be more responsive to changes in carbohydrate metabolism than to fat metabolism (Leibowitz, 1995). Galanin-expressing neurons and neurons with galanin receptors are found in many brain areas involved in food intake such as LH, PVN, and amygdala (Merchenthaler et al., 1993). Activation of galaninergic neurons that project from the anterior PVN to the median eminence (ME) causes increased intake and accumulation of fat (Leibowitz, 1995; Leibowitz and Alexander, 1998). Interestingly, not only does leptin prevent food intake caused by NPY, MCH, and galanin but also leptin appears to block the formation of these peptides, that is, leptin decreases hypothalamic NPY, MCH, and galanin gene expression (Sahu, 1998). The decrease in MCH caused by leptin is, at least in part, mediated by α-melanocyte stimulating hormone (αMSH). Leptin increases expression of αMSH, a peptide that acts on neurons with melanocortin-4 (MC-4) receptors, and stimulation of these receptors decreases MCH (Broberger, 1999; Hanada et al., 2000). αMSH may also be involved in the decrease in food intake caused by CRF (Rothwell, 1990).

Leptin also influences body weight by interacting with peptides that control short-term food intake, that is, peptides that affect meal size and/or meal frequency. Secretion of the gut-peptide cholecystokinin (CCK) produces short-term satiety. However, while CCK can decrease meal size, meal frequency is increased such that body weight is not altered (West et al., 1984). One of the

mechanisms by which CCK decreases food intake is by decreasing gastric emptying (Moran and McHugh, 1982). Interestingly, it has been shown that when leptin (given centrally) and CCK (given peripherally) are administered simultaneously, body weight loss is greater than that observed when leptin is given alone (Matson et al., 2000). The synergy between leptin and CCK cannot be explained by decreased food intake alone. Presumably, increased energy expenditure is involved. It should be noted that most of the peptides that influence food intake also influence, inversely, the activity of the sympathetic nervous system controlling thermogenesis in the brown adipose tissue. For example, NPY increases food intake and decreases activity of the sympathetic nervous system while CRF decreases food intake and increases activity of the sympathetic nervous system (Bray, 1993).

IV. INFLUENCE OF n-3 PUFAS ON BODY ENERGY HOMEOSTASIS

A. Food Intake, Body Weight, and Body Fat (Figure 35.1)

Several studies have reported that diets containing n-3 PUFAs can decrease body weight or body weight gain. McGahon et al. (1999) reported that after 22 months on a long-chain n-3 PUFA (DHA) or short-chain n-6 diet (corn oil), male Wistar rats maintained on the DHA diet were significantly lighter. Long-chain n-3 PUFA diets were also observed to decrease body weight (but not food intake) of diabetic (streptozotocin-treated) rats. Such diets increased responsiveness of muscle glucose transport to insulin (Sohal et al., 1992). Cunnane compared a diet high in n-6 PUFA (evening primrose oil = 18:2n-6 and 18:3n-6) with a diet high in n-3 PUFA (cod liver oil, EPA, and DHA). The diets were matched for caloric content whereby fat provided 20% of energy. No differences in food intake was observed in either lean (ln/ln) or obese (ob/ob) mice. However, body weight of obese mice on the n-3 PUFA diet was less than those obese mice on the n-6 PUFA diet (Cunnane et al., 1986). After 6 weeks of treatment, body weight and body fat of Swiss albino mice maintained on a high-fat diet (40.8% of energy) that contained canola oil, a good source of ALA, was less than that of mice maintained on the high-fat diet that contained beef fat and was similar to that of mice maintained on a low-fat diet (Bell et al., 1997). In C57 mice that received 60% of their total calories from fat, body weight after 19 weeks was lowest when the fat source was fish oil while diets containing perilla or canola oil were less effective (Ikemoto et al., 1996). In a study where C57 mice

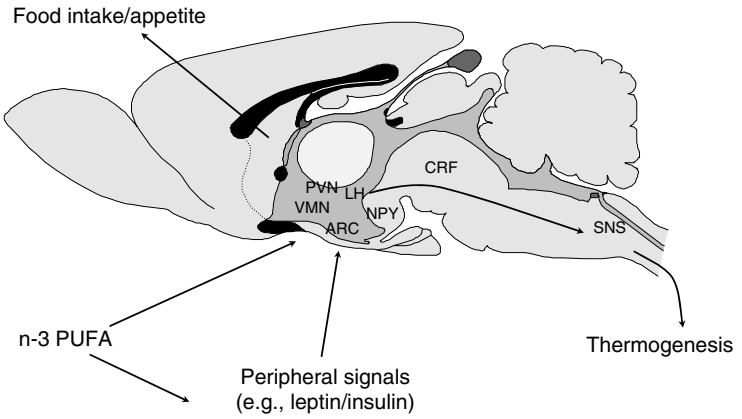

FIGURE 35.1 Model showing mechanisms controlling body energy homeostasis. Major brain nuclei and central and peripheral pathways are shown. LH, lateral hypothalamus; VMN, ventromedial nucleus of the hypothalamus; ARC, arcuate nucleus; PVN, paraventricular nucleus of the hypothalamus; SNS, sympathetic nervous system; n-3 PUFAs, omega-3 polyunsaturated fatty acids; CRF, corticotropin releasing factor; NPY, neuropeptide Y.

received 58% of calories as either saturated fat or long-chain n-3 PUFA (Wang et al., 1999), animals maintained on the high saturated fat diet gained the most body weight. In animals fed the high saturated fat diet, neural activity, as measured by an increase in fos immunoreactivity, was observed to be increased in the LH ("hunger" area) and decreased in the VMN ("satiety" area). Conversely, the activity in the VMN but not the LH was increased in the fish oil fed group. These results are consistent with the proposition that relative to diets with long-chain n-3 PUFAs, diets high in saturated fats cause obesity not only because they are less satiating but also because they act to increase activity in brain areas associated with increasing food intake and body weight.

However, not all studies have shown that the addition of n-3 PUFAs (long or short chain) to the diet of normal rats, mice, or human subjects has an influence on food/energy intake or body weight (e.g., Awad et al., 1990; Belzung et al., 1993; Chicco et al., 1996; Cunnane et al., 1986; Hill et al., 1993; Parrish et al., 1991; Raclot et al., 1997; Russell et al., 1991; Rustan et al., 1993; Sohal et al., 1992). Interestingly, Reseland et al. (2001) found that although supplementation with n-3 PUFAs did not alter either body weight or plasma leptin level in humans or rats, n-3 PUFAs did reduce leptin mRNA expression in rat epididymal fat tissue. Clearly, further work needs to be done to establish the influence on body weight of addition of long-chain n-3 PUFA to the diet. In particular, physiologically relevant amounts (e.g., 0.5%–1.0% of fat intake) of the n-3 PUFA have to be examined.

In the absence of changes in food intake and body weight, however, addition of long-chain n-3 PUFAs to the diet has been shown to significantly reduce body adiposity and increase lean body mass. For example, in a long-term study, 3–4-month-old rats were maintained on semisynthetic diets where the fat content of the diet comprised 45% of the energy. Relative to the rats maintained on a diet containing lard (high in saturated fats) or corn oil, rats maintained on a diet containing n-3 PUFA rich fish oil had less adipose tissue in epididymal, inguinal, mesenteric, and retroperitoneal stores (Hill et al., 1993). In male Wistar rats, maintained on a lard or MaxEPA (high in long-chain n-3 PUFA) diet where the fat content of the diet comprised 40% of the energy, by 5 weeks, fat in epididymal and perirenal tissues, as well as plasma triglycerides, was lower in the MaxEPA group (Parrish et al., 1991). It was suggested that n-3 PUFAs restrict adipose tissue growth by limiting the amount of triglyceride in each cell (Parrish et al., 1991). Inclusion of fish oil (7%, w/w) in the diet markedly reduced fat pad mass of sucrose fed rats (Soria et al., 2002). In KK-A^y mice, addition of fish oil to diet was shown to decrease abdominal fat (Hun et al., 1999). In humans, Couet et al. (1997) substituted 6 g of dietary fat by 6 g of fish oil in healthy adults. Body fat mass decreased by 0.88 kg ($p < .05$) in 3 weeks following substitution.

Several studies have suggested that the reduction in body fat mass is not universal but rather some adipose tissue stores are more susceptible than others. For example, Raclot offered 50-day-old male Wistar rats diets containing n-3 PUFA rich fish oil, purified DHA, purified EPA, a mixture of DHA and EPA, or a diet containing lard and olive oil (control). These semisynthetic diets were formulated so that the caloric content was matched and that 40% of caloric content was derived from fat. Diets containing n-3 fatty acids produced a site-specific antiadipogenic effect. Decreased retroperitoneal fat was noted, but subcutaneous adipose tissue remained constant (Raclot et al., 1997). Belzung obtained a similar result. In this latter study, the addition of n-3 PUFA to a diet high in saturated fat limited hypertrophy of retroperitoneal and epididymal adipose tissues, but had no effect on subcutaneous or mesenteric fat stores (Belzung et al., 1993). In humans on a diet containing 52% carbohydrates, 16% protein, and 32% fat (PUFA:SFA ratio 0.2), replacing visible fat with fish oil (6 g/day for 3 weeks) caused a reduction in body fat without altering energy intake. Although basal metabolic rate was unchanged, lipid oxidation rate was increased (Couet et al., 1997). Further work will be needed to establish the factors responsible for reduction of fat in the specific adipose tissues.

B. Fat Metabolism: Oxidation and Thermogenesis (Figure 35.2)

Given that nearly 100% of the cell volume of adipose tissue is triglycerides, factors that influence their synthesis and breakdown are crucial. Jones and Schoeller (1988) showed that when added to a

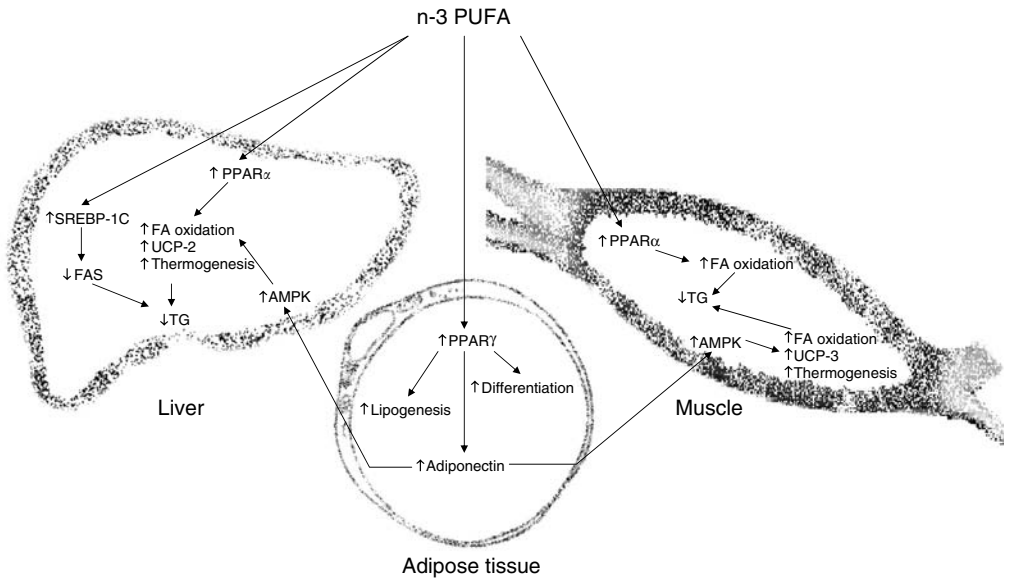

FIGURE 35.2 Model showing pathways by which n-3 PUFAs can influence body energy homeostasis. n-3 PUFAs, omega-3 polyunsaturated fatty acids; PPAR, peroxisome proliferators-activated receptor; SREBP, sterol regulatory element binding protein; FAS, fatty acid synthase; FA, fatty acid; UCP, uncoupling protein; AMPK, AMP-activated protein kinase; TG, triglycerides.

saturated fat diet, n-3 PUFA increased basal metabolic rate and total energy expenditure. Subsequent to ingestion, n-3 PUFAs rapidly cause an upregulation of genes involved in lipid oxidation and a downregulation of genes involved in lipogenesis in the liver and muscle. Hepatic oxidation of fatty acids increases within 3 days when the diet contains 12%–15% fish oil, but does not increase for several weeks when the diet contains n-6 PUFAs. Evidence suggests that unlike intake of a high-fat diet, intake of a diet rich in n-3 PUFAs may promote fat utilization rather than storage (Price et al., 2000). Dietary fish oil protected rats from visceral fat hypertrophy by increasing lipid mobilization from adipose tissue and inhibiting lipid synthesis in the liver (Peyron-Caso et al., 2003). In a study in which rats were fed diets containing 15% fat for 15 days, mitochondrial and peroxisomal fatty acid oxidation rates, many of the enzymes involved in fatty acid oxidation and carnitine palmitoyl transferase I activity were greatly increased in animals that were given perilla and fish oil compared to animals given palm or safflower oils (Ide et al., 2000; Neschen et al., 2002). Relative to rats with LA as their sole source of PUFA, animals with n-3 PUFA had lower fatty acid synthase activity (Ikeda et al., 1998). n-3 PUFA suppresses fatty acid synthesis by suppressing SREBP-1c in the liver (Jump et al., 2005). Mono- and polyunsaturated fatty acids bind directly to PPARα and PPARγ at physiological concentrations, thereby providing other mechanisms by which fatty acids modulate lipid homeostasis (Kliewer et al., 1997). Activation of PPARα increases oxidation of fatty acids in liver and muscle (Evans et al., 2004; Jump et al., 2005; Lefebvre et al., 2006; Neschen et al., 2002); activation of PPARγ, on the other hand, increases adipogenesis (differentiation of preadipocytes to adipocytes) and increases lipogenesis and lipid storage in adipose tissue (Evans et al., 2004; Forman et al., 1997). However, fish oil, via PPARγ-dependent mechanisms, also appears to increase secretion of adiponectin, a peptide produced and secreted by adipocytes, implicated in the reduction of body fat (Neschen et al., 2006). On the basis of body composition analysis and RQ, Sanz Sampelayo et al. (2006) concluded that consumption of fish oil leads to decreased oxidation of protein but increased oxidation of fat. Altered expression of genes encoding lipogenic (fatty acid synthase and lipoprotein lipase), lipolytic (hormone sensitive lipase), and glyceroneogenic enzymes due to ingestion of n-3 PUFAs appear to be important in reducing body fat stores.

Thermogenesis, the production of body heat, is one of the major components of energy expenditure and therefore a major aspect of body weight control. Uncoupling proteins (UCPs) uncouple oxidation of substrates from phosphorylation (synthesis of ATP) in mitochondria and are implicated in the regulation of thermogenesis (Ricquier, 2005). Evidence suggests that in rats fed a high-fat diet, addition of n-3 PUFA enhances expression of UCP1 mRNA in brown adipose tissue (Takahashi and Ide, 2000). Adiponectin, has been shown to reduce visceral adiposity via upregulation of uncoupling protein (UCP) genes in skeletal muscle and adipose tissue (Masaki et al., 2003). The upregulation of UCP genes is mediated by AMP-activated protein kinase (Stoppani et al., 2002). Armstrong and Towle showed that PUFAs stimulate hepatic thermogenesis by increasing hepatic UCP2 expression via a PPARα-mediated pathway (Armstrong and Towle, 2001). In addition, thermogenesis in brown adipose tissue is regulated by the sympathetic nervous system. Increased thermogenesis can be due to increased responsiveness to noradrenaline or increased release of noradrenaline. Thus, n-3 PUFAs could influence the effectiveness of the sympathetic nervous system because they increase the sensitivity of brown adipose tissue to noradrenaline (Ohno et al., 1996). In summary, the influence of n-3 PUFA on enhancing pathways involved in the metabolism of fat seems to be crucial to the changes in body composition.

C. High-Fat Diets and Obesity

Obesity is one of the major health risks for a number of diseases, particularly heart disease and diabetes. It is well known that ingestion of a diet high in saturated fats is one of the major causes of obesity. There are two explanations for this observation. First, diets high in saturated fats do not seem to be as satiating as either high-carbohydrate or high-protein diets (Doucet et al., 1998), even when the high-fat diet is less palatable (Warwick, 1996). Second, whereas increased intake of either carbohydrate or protein causes a concomitant increase in energy expenditure, for example, nonshivering thermogenesis, increased intake of saturated fat does not cause a similar increase in energy expenditure. Individuals maintained for 1 week on a high-carbohydrate or high-protein diet have increased body temperature, whereas individuals maintained on a diet high in saturated fat do not, furthermore, ingested fat is mostly sequestered to adipose tissue. That is, increased intake of saturated fat does not promote the use of fat as a metabolic fuel (Schutz et al., 1989; Thomas et al., 1992). Thus, diets high in saturated fats are more obesity producing than diets high in carbohydrate or protein because of their lesser ability to satiate appetite and to increase fat oxidation. With the ingestion of more energy than expended, storage of fat is increased and obesity results (Tremblay et al., 1989).

The peptide hormone insulin is produced in the pancreas and secreted in proportion to the degree of adiposity. Similar to leptin, insulin levels are correlated with the amount of abdominal fat (Porte et al., 1998; Woods et al., 1990, 1996, 1998). It is transported into the brain where it acts to decrease food intake and body weight (Schwartz et al., 1992; Woods et al., 1996). High insulin resistance is a characteristic of obesity, hypertension, and noninsulin dependent diabetes mellitus. There is an inverse relationship between insulin action and triglyceride content. With the ingestion of fat, insulin secretion is increased. Insulin stimulates fatty acid synthase, an enzyme that catalyzes all reactions involved in lipogenesis, and thereby results in the accumulation of triglycerides (Sul et al., 2000). Monounsaturated fatty acids (such as oleate) and saturated fatty acids (such as palmitate), have little or no influence on fatty acid synthase, are incorporated into triglycerides in adipose tissue (Parrish et al., 1990, 1991; Su and Jones, 1993), and increase insulin resistance. In contrast, n-3 PUFAs markedly inhibit fatty acid synthase, and are therefore preferentially incorporated into phospholipids for cell membrane remodeling. That is, n-3 PUFAs decrease triglyceride production, resulting in low levels of tissue and plasma triglycerides, and thereby decrease insulin resistance (Awad et al., 1990; Chicco et al., 1996; Hill et al., 1993; Parrish et al., 1991; Russell et al., 1991; Rustan et al., 1993; Sohal et al., 1992). It is clear that ingestion of diets high in n-3 PUFAs can be beneficial in the treatment of obesity and diabetes. However, this is effected by numerous factors including the

amount and type of n-3 PUFA ingested, the stage of development when n-3 PUFA is supplied and the duration that n-3 PUFA is available for. For maximal benefit, ingestion of n-3 PUFAs should begin at an early age.

D. Cancer Cachexia

In patients with cancer, weight loss indicates a poor prognosis and a shorter survival time. Cancer cachexia involves a massive loss of body weight, with extensive breakdown of both body fat and skeletal muscle, often, but not always, accompanied by anorexia (DeWys, 1985). Metabolic studies have shown that increased free fatty acid mobilization occurs prior to weight loss in cancer patients (Costa et al., 1981) and weight loss is not reversed by parenteral nutrition, thus, the weight loss associated with cancer cachexia is different from simple starvation (Brennan, 1977).

Although not fully understood, it appears that the most likely model for the development of cancer cachexia is based on increased cytokine production. Interleukin (IL)-1β, an endogenous pyrogen, is a cytokine released by activated macrophages and monocytes that mediates local and systemic responses to inflammation. Peripheral or central administration of IL-1β produces decreased food and water intake and increased body temperature. Such a decrease in food intake caused by IL-1β can be attenuated by an MC-4 receptor antagonist (Huang et al., 1999) or by depletion of neuronal histamine (Sakata et al., 1995). Activation of the MC-4 receptor (Broberger, 1999; Hanada et al., 2000) as noted earlier, and the release of histamine (Morimoto et al., 2000) contribute to the decrease in food intake caused by leptin.

In a mouse model of cancer (MAC16 mice), cachexia was reversed by a semisynthetic diet in which a high proportion of the calories were derived from n-3 PUFA rich fish oil (19% EPA; 13% DHA (Tisdale and Dhesi, 1990)), suggesting that EPA and DHA interfered with catabolic activity. Fish oil supplementation also elevated the normally reduced blood glucose levels observed in MAC16 mice suggesting a decrease in glucose utilization by the tumor. Free fatty acids were unaltered. An n-6 PUFA rich diet had no effect on weight loss or tumor growth and none of the diets influenced food intake. The weight gain by fish oil treated mice was shown to be due to reduction in loss of fat and muscle, and not due to increased water retention (Tisdale and Dhesi, 1990).

In a subsequent study, Tisdale and Beck (1991) investigated the inhibition of lipid mobilization by PUFAs in MAC16 mice. Ingestion (by gavage) of EPA, but not of DHA or ALA, prevented weight loss and minimized tumor growth. None of the n-6 PUFAs (e.g., LA, arachidonic acid) was effective in inhibiting the mobilization of lipid. EPA was also effective in inhibiting the lipolytic effect of salbutamol (β-adrenergic agonist) or adrenocorticotrophin. In combination with cytotoxic drugs used to treat cancer, it was shown that neither DHA nor EPA interfered with treatment and, in many cases, potentiated the anticancer effects of the drugs (Wynter et al., 2004). In another mouse model of cancer (C57 mice, Lewis lung carcinoma), treatment with either DHA or EPA prevented the decrease in body weight (Ohira et al., 1996), but did not alter food or water intake or tumor size.

In a rat model of cancer cachexia (Walker 256 tumor), fish oil reduced tumor growth, increased food intake and body weight, partially restored renal function and increased survival time (Fernandez et al., 2004; Togni et al., 2003). Furthermore, providing a high-fat diet containing fish oil in combination with sunflower oil, an n-6:n-3 ratio of 6:1 was able to prevent the decrease in food intake and body weight caused by the cancer (Pizato et al., 2005).

Given that weight loss in cancer patients occurs prior to a reduction in food intake, the problem appears to be due, at least initially, to disruption of the sympathetic nervous system and the regulation of energy expenditure. It is possible that some by-product of the cancer causes damage to the LH. A cachectic individual with multiple sclerosis was shown to have damage to the LH (Kamalian et al., 1975). Another possibility is that the factors that mediate the cachectic process stimulate inhibitory factors such as leptin or inhibit stimulatory factors such as NPY (Inui, 1999). Furthermore, it has been shown that patients with surgically inoperable pancreatic adenocarcinoma normally lose body weight but this is reversed by eating n-3 PUFA rich fish oil. This reversal is due to an increase

in appetite and a decrease in energy expenditure (Barber et al., 1999) and possibly reducing the demand for amino acids caused by hepatic protein synthesis (Barber et al., 2004). Weight loss is generally a potent stimulus to food intake, therefore, the failure of patients with cancer to increase their intake of food and the reversal of this by n-3 PUFA requires further investigation.

V. CONCLUSION

The evidence presented in this review shows that n-3 PUFAs can influence body energy homeostasis. With respect to the intake of food and regulation of body weight, the possibility that a critical period exists is minimal. Clearly, n-3 PUFAs can influence the accumulation and utilization of fat, both crucial to the regulation of body weight. Ingestion of n-3 PUFAs have been shown to reduce the size of adipose tissue, increase thermogenesis, and in some instances reduce body weight. In this regard, ingestion of n-3 PUFAs as a replacement for saturated fat or monounsaturated fatty acids might be important in overweight individuals. Ingestion of the n-3 PUFAs could facilitate the loss of body fat via its effect on increasing fat metabolism and thermogenesis. n-3 PUFAs could also improve glucose utilization by reducing cellular triglycerides and thus increasing insulin sensitivity. Interestingly, in animal models of cancer cachexia and in patients with cancer cachexia, n-3 PUFAs can act to increase body weight. The mechanism appears to involve interference with the catabolic influence of toxins produced by the tumor. This is clearly different to the mechanisms by which the n-3 PUFAs act to reduce body fat in individuals without cancer. Thus, the ingestion of n-3 PUFAs can influence fat mass and body weight via several different mechanisms.

Although our current understanding of the role of n-3 PUFAs in food intake and body weight maintenance requires further work, evidence suggest that these metabolites might be important in a multitude of cellular functions. Certainly, n-3 PUFAs are crucial for normal neural function and deprivation may alter cell membrane properties in crucial areas of the brain that monitor appetite. Perhaps coincidentally, there seems to be a commonality in the neural functions altered by n-3 PUFA deprivation. More often than not, affected processes are mediated by receptors belonging to the seven-transmembrane domain, G-protein-coupled receptor family. G-protein-coupled receptors are essential in the integration of feeding and drinking control mechanisms (Plata-Salaman et al., 1998). For example, with respect to feeding, NPY receptors (Blomqvist and Herzog, 1997; Du et al., 1997), galanin receptors (Kask et al., 1997), and MC-4 receptors (Huszar et al., 1997) belong to G-protein-coupled receptor superfamily. With respect to drinking, angiotensin II (ANG II) receptors (Lenkei et al., 1998), OT receptors (Barberis et al., 1998), and somatostatin receptors (Raulf et al., 1994) belong to G-protein-coupled receptor superfamily. The function of this receptor superfamily may be more susceptible to alteration by decreased n-3 PUFA because of their morphology. These large and complex membrane-bound proteins alter conformation after ligand binding and, it is possible, that a decrease in membrane fluidity would hamper conformational change such that the active conformation is no longer energetically favorable, following binding of the ligand.

Over the past 50 years, there has been an increase in diabetes, heart disease, and cancer, thought to be due, in part, to changes in environmental factors. The nutrients we eat may be the most influential environmental stimuli, and fat is a strong determinant of cell differentiation, growth, and metabolism. Although the effects of n-3 PUFAs on several behavioral indices have been widely reported, there is still much work to be done if we are to understand the mechanism by which this family of fatty acids exerts its many actions.

36 Biological Effects of Oxidized Fatty Acids

Ching Kuang Chow

CONTENTS

I. INTRODUCTION

Good-quality edible fats and oils are bland, odorless, and free of impurities and are oxidatively stable. However, fats and oils may become oxidized and develop objectionable tastes and odors during processing, storage, and culinary practices. Oil processing is designed partly to remove oxidized oils and free fatty acids, as well as contaminants that may initiate oxidative reactions. However, some processing steps such as bleaching and caustic refining, if not done properly, may promote oxidation. During storage and culinary practice, fatty acid oxidation may occur in the presence of a free radical initiator. Oxidized fatty acids formed may catalyze further oxidation and/or break down to form compounds that give the rancid odor and flavor that characterize oxidized fats and oils. Hydrolysis is another main degradation process for oils during culinary practice. In deep-frying, the fatty acids are hydrolyzed off the triglycerides at high temperatures in the presence of water, yielding free fatty acids, monoglycerides, diglycerides, and glycerol. These breakdown products may speed up oxidation and degradation of the remaining triglycerides as they enhance emulsification of water from the food into the oil. In addition to polymerized fatty acids, prolonged oxidation may result in the formation of aldehydes, ketones, alcohols, short-chain fatty acids, and other compounds. Oxidized oils and their secondary products when consumed exert varying biological effects depending on the conditions of oxidation.

II. FATTY ACID OXIDATION

Oxidation is a major problem associated with storage and use of fats and oils. Mechanisms of fat and oil oxidation include enzymic oxidation, photooxidation, autoxidation, and thermal oxidation

(see Chapter 2). Lipoxygenases are primarily responsible for the increased oxidation of unsaturated fatty acids in seeds during storage (Suzuki et al., 1996). However, since enzymes are labile to heat denaturation, lipoxygenase activity is normally absent in a refined oil. Oxidation catalyzed by enzymes, therefore, does not present a problem during the storage and use of fats and oils. In the presence of oxygen and a photosensitizer, fatty acids can be peroxidized directly after exposure to light. Initial formation of fatty acid hydroperoxides by photooxidation may involve the generation of highly reactive singlet oxygen (Frankel et al., 1985). As potential photosensitizers, such as chlorophyll, dyes, heme compounds, and flavonoids, are normally removed from fats and oils during processing, photooxidation does not present a serious problem in the storage and utilization of fats and oils, either. Autoxidation and thermal oxidation reactions, on the other hand, are more directly involved in the oxidation of fatty acids during storage and use than are enzymatic oxidation and photooxidation.

Autoxidation is the process of fat/oil oxidation induced by air at room temperature. The oxidative stability of unsaturated lipids generally decreases with the increased degree of unsaturation in air. Saturated fatty acids have very low reactivity. Autoxidation behavior is different between complex lipids and simple lipids. For example, at 30°C in the dark, phospholipid is the most oxidatively stable molecular form of the fatty acids, followed by triglycerides, then fatty acid methylesters, and then free fatty acids (Ogawa et al., 1995). In addition, the position of fatty acids on triglycerides plays a role in determining the relative rate of autoxidation (Neff and El-Agimy, 1996).

Autoxidation of fatty acids occurs in a series of steps involving the generation of free radicals and can be divided into three phases: initiation, propagation, and termination. In the initiation phase, hydrogen is abstracted from the α-methylenic carbon of fatty acids to yield a free radical (Equation 36.1). Once a free radical is formed, it may form peroxyl radicals through reaction with atmospheric oxygen (Equation 36.2). In addition, free radicals can abstract hydrogen from another unsaturated molecule to form a hydroperoxide and a new free radical, thus propagating reaction (Equation 36.3). Initial formation of fatty acid hydroperoxides from fatty acids may involve the generation of singlet oxygen via photooxidation (Frankel et al., 1985) and/or free radicals formed from the breakdown of the hydroperoxides catalyzed by transition metal ions (Aust et al., 1985).

$$RH \rightarrow R^{\cdot} \tag{36.1}$$

$$R^{\cdot} + O_2 \rightarrow ROO^{\cdot} \tag{36.2}$$

$$ROO^{\cdot} + R'H \rightarrow ROOH + R^{\cdot\prime} \tag{36.3}$$

The free radical-initiated chain reaction has one critically important feature. Once initiated, the reaction is self-sustaining and is capable of oxidizing large amounts of lipids. Although hydroperoxides are the primary oxidation products formed during the propagation phase, the reaction is accelerated via chain branching or free radical multiplication (Equation 36.4 and 36.5). The free radical chain reaction may be terminated by antioxidants (AH) such as vitamin E (tocopherols) that competitively react with a peroxyl radical and remove a free radical from the system reaction (Equation 36.6). In addition, the chain reaction may be terminated by self-quenching or polymerization of free radicals (Equation 36.7). During autoxidation, the hydroperoxides formed may be split, or break down into free radicals and smaller organic compounds such as aldehydes, alcohols, and acids (Frankel et al., 1961; Schultz et al., 1962; Artman, 1969; Frankel, 1980, 1985; Weiss, 1983; Aust et al., 1985).

$$ROOH \rightarrow RO^{\cdot} + OH^{\cdot} \tag{36.4}$$

$$2ROOH \rightarrow ROO^{\cdot} + RO^{\cdot} + H_2O \tag{36.5}$$

$$ROO^{\cdot}\ (\text{or } R^{\cdot}) + AH \rightarrow ROOH\ (\text{or } RH) + A^{\cdot} \tag{36.6}$$

$$ROO^{\cdot}\ (\text{or } R^{\cdot}) + R^{\cdot\prime} \rightarrow ROOR'\ (\text{or } RR') \tag{36.7}$$

TABLE 36.1
Oxidation Products of Fatty Acids

Aliphatic hydrocarbons	Alcohols
Aldehydes	Aliphatic acids
Cyclic dimeric acids	Cyclic hydrocarbons
Cyclic ethers	Cyclic monomeric acids
Dibasic acids	Epoxides
Hydroperoxy fatty acids	Hydroxy fatty esters
Hydroxy fatty acids	Keto hydroxy fatty esters
Keto fatty esters	Ketones
Lactones	Polymeric fatty acids

Oxidation reactions are accelerated at higher temperature. The oxidation of fats and oils at high temperature is termed *thermal oxidation*. A number of free radicals, including peroxylalkoxy- and carbon-centered radicals, are formed during heating of various fatty acids or their esters in air, and the amount of free radicals generated is inversely related to the number of double bonds in the fatty acids (Vicente et al., 1995). During deep-fat cooking, baking, and frying of fats and oils, oxidation reactions are greatly accelerated. A large number of end compounds, including hydroperoxides, short-chain fatty acids, dimeric and polymeric compounds, cyclic dimmers and monomers, polar lipids, volatile hydrocarbons, and other secondary products (Table 36.1), have been detected in heated or fried oils (Frankel et al., 1961; Schultz et al., 1962; Artman, 1969; Yoshioka and Kaneda, 1972, 1974; Weiss, 1983; Hansen et al., 1994; Vicente et al., 1995; Arroyo et al., 1996; Kajimoto et al., 1996; Marquez-Ruiz and Dobarganes, 1996; Velasco et al., 2004). These compounds are generated through oxidation, hydrolysis, degradation, and/or polymerization reactions.

The type of products generated by thermal oxidation reactions is modulated by heating conditions, the lipid phase (e.g., temperature, duration, and oil type), and the presence of antioxidant(s) and prooxidant(s). For example, Fujioka and Shibamoto (2004) have shown that more glyoxal is found from salmon and cod liver oils when heated at 60°C for 3 days than for 7 days, that when oils are treated under cooking conditions at 200°C for 1 h, the aldehydes formed are comparable to those formed under accelerated storage conditions at 60°C for 3–7 day, and that fish oils produced more malondialdehyde (MDA), glyoxal, and methylglyoxal than do vegetable oils because the fish oils contained higher levels of long-chain polyunsaturated fatty acids than the vegetable oils. Prolonged heating of oils usually leads to increased formation of polymeric materials and secondary products. Used oils may contain as much as 25%–30% of polymeric materials at the end of their usable frying capability (Poling et al., 1970; Nolen, 1973). The formation of polymers darkens the color and increases foaming of the oil, and can lead to an increase in viscosity and solidification of the oil.

During deep-fat cooking, baking, and frying of fat and oil, in which oxidative reactions are greatly accelerated, a stream blanket may be formed. However, the steam blanket over the oil by water in the foodstuff does not exclude contact with air, and the presence of water increases the extent of oxidation. Since absorption of oil by the frying food is extensive, it is often necessary to replenish the fryer with fresh oil. The replenishment with fresh oil tends to dilute overall compositional changes of the oil during prolonged frying, and fairly steady-state conditions are often maintained in a normal continuous operation. As flavor and odor are very sensitive indicators of the oxidative deterioration of fats and oils, before oil has undergone a significant alteration in nutritive value, it has normally become organeleptically unacceptable.

Important parameters determining the characteristics of oils include chemical measures, such as the degree of unsaturation (iodine value), average fatty acid chain length (saponification value), and flash, smoke, and fire point, as well as physical parameters, such as melting point, refractive index, and solid fat index (Chapter 2). Methods for estimating the oxidation state of lipids include sensory

analyses, measurement of oxygen consumption, active oxygen (accelerated shelf life measurements) and free fatty acids, and analysis of hydroperoxides, peroxide value, and secondary products of lipid oxidation (Berset and Cuvelier, 1996; Kajimoto et al., 1996). These parameters are all important in determining the stability and shelf life of an oil.

III. BIOLOGICAL EFFECTS OF OXIDIZED FATTY ACIDS

Triglycerols represent over 95% of the weight of most food fats and oils. The minor components of fats and oils include monoglycerides, diglycerides, free fatty acids, sterols, phosphatides, fatty alcohols, carotenoids, and tocopherols. Although free fatty acids account for only a minute portion of the total fatty acids in fresh edible fats and oils, their content may greatly rise during processing, storage, and certain culinary practices. Free fatty acids are more labile to oxidation than the esterified ones (Schultz et al., 1962; Artman, 1969; Frankel, 1980, 1985; see Chapter 2). The oxidation reaction and products derived from fats and oils are more complicated and less well defined than those of free fatty acids. When consumed, oxidized fats/oils and their secondary products exert different biological effects depending on the levels and types of oxidation products present (Nolen, 1973; Kubow, 1990).

A number of reports dealing with the absorption and deposition of oxidized oils and their secondary products, when given at a large quantity in their diet, are available, but with inconsistent results (Kaunitz et al., 1956; Glavind and Tryding, 1960; Perkins et al., 1961; Glavind and Sylven, 1970; Glavind, 1972). As expected, the extent of oil absorption is adversely affected by heating. For example, Porsgaard et al. (1999) have shown that the transport of fatty acids is significantly lower in lymph-cannulated rats receiving heated oil (180°C for 15 min) compared to those receiving the corresponding unheated oil, that the absorption of sunflower oil is more affected by heating than the absorption of soybean or rapeseed oil, and that the largest decrease in total activity of tocopherols following heating is observed in sunflower oil. Using [U-^{13}C]-labeled hydroxy or dihydroxy triglycerides, Wilson et al. (2002) have shown that dietary hydroxy fatty acids are absorbed in humans, with plasma peak levels being reached between 4 and 6 h, and the amount of ^{13}C-labeled oxidized fat absorbed is related to that of plasma triglycerides. In addition, ^{13}C monohydroxy triglycerides are absorbed to a greater extent than those of ^{13}C dihydroxy triglycerides.

Consumption of oxidized oils is associated with an increase in lipid peroxidation products. The levels of thiobarbituric acid reactants (TBARs), for example, are increased in liver microsomes and mitochondria of male Wistar rats fed 4 weeks with a diet containing 2% oxidized corn oil (Iritani et al., 1980). Triglyceride molecules with a hydroxy, an epoxy, or a keto group attached to fatty acids, as well as triglyceride core aldehydes, are detected in pig lipoproteins after a diet rich in oxidized sunflower seed oil (Suomela et al., 2005). In addition, the lipoprotein triglycerides and total lipids are more oxidized in the pigs fed on oxidized oil than those fed on nonoxidized oil. Similarly, ingestion of oxidized sunflower oil (heated at 98°C for 48 h) that contained 262 mmol/kg of hydroperoxides, 5.7% of the oxidized esters, and 50.4% polymerized oil, results in increased levels of TBARS and *trans* fatty acid (18:1) in rat liver (Ammouche et al., 2002). As at least portions of the oxidized oils and their secondary products are absorbed and incorporated into the lipoproteins and tissues, these compounds are expected to exert various adverse effects when consumed. Studies on the toxicological and biological effects of oxidized fats and oils can be roughly classified into three types: (1) oxidized fats and oils, (2) oxidized fatty acids, and (3) degradation products of lipid hydroperoxides.

A. Oxidized Fats and Oils

Male broilers fed with 3.5% oxidized fat for 7 weeks reduce feed efficiency and growth rates as compared to those receiving normal fat (Wang et al., 1997). Broiler hens fed a diet containing oxidized oil exhibit growth depression and reduced plasma levels of fat, energy, α-tocopherol, lutein, β-carotene, and retinol than those receiving fresh oil (Enberg et al., 1996). In addition, rats fed

heated oils (175°C for 24 h) for 16 weeks have significant pathological changes in heart muscle (Rupcikova et al., 1992). In addition, hepatic injury is associated with the treatment of oxidized lipids, and intubation of oxidized lipids (0.15 mL oxidized trilinolein or 1.05 mL oxidized butter per rat) at 12 h intervals results in increased incorporation of thymidine in hepatic DNA during the early stage of intoxication and severe liver cirrhosis (Fouad et al., 1995).

As oxidized fatty acids can be absorbed and incorporated, increased consumption of oxidized oils may alter tissue lipid composition. Administration of 15% thermally oxidized sunflower oil to rats for 45 days, for example, significantly increases the concentrations of hepatic phospholipids 16:0, 16:1, 18:0, 18:1, and 18:2, whereas the concentration of 20:4 is significantly decreased (Kode et al., 2005). Similarly, feeding of oxidized oil (50°C for 16 days) reduces the milk triglyceride concentration and long-chain fatty acids (Brandsch et al., 2004). In addition, feeding of moderately heated oils (175°C for 24 h) to rats for 16 weeks results in the presence of fatty acid *trans* isomers in body fats and lung (Rupcikova et al., 1992), and feeding of the oil heated at 190°C–195°C for 28 h to broilers results in increased geometrical and positional fatty acid isomers in dark meat (Bou et al., 2005). Rats ingested oxidized soybean oil have reduced content of free thiols in the erythrocyte membrane and an increased level of reactive carbonyl group in eh proteins of the ghosts and of the muscle than the controls (Hayam et al., 1997).

Dietary fat has profound effects on gene expression, leading to changes in metabolism, growth, and cell differentiation. The effects of dietary fat on gene expression reflect an adaptive response to changes in the quantity and type of fat ingested (Jump and Clarke, 1999). In mammals, specific fatty acid-regulated transcription factors, such as peroxisome proliferator-activated receptors (PPAR-α, -β, and -γ), HNF4α, NF-κB, and SREBP1c, are regulated by (1) direct binding of fatty acids, fatty acyl-coenzyme A, or oxidized fatty acids; (2) oxidized fatty acid (eicosanoid) regulation of G-protein-linked cell surface receptors and activation of signaling cascades targeting the nucleus; or (3) oxidized fatty acid regulation of intracellular calcium levels, which affect cell signaling cascades targeting the nucleus (Jump and Clarke, 1999). The effects of fatty acids on the genome provide new insight into how dietary fat might play a role in health and disease.

The activities of hepatic aminopyrine N-demethylase, aniline hydroxylase, NADPH-cytochrome *c* reductase, UDP-glucuronyl transferase, and GSH *S*-transferase, as well as cytochrome P-450 content are significantly increased in rats fed a diet containing 15% deteriorated soybean frying oil (Huang et al., 1988). Similarly, oxidized frying oil has been shown to upregulate hepatic acyl-CoA oxidase and cytochrome P-450 4 A1 genes in rats and activates PPAR-α (Chao et al., 2001). In addition, feeding the diets with oxidized fats leads to a significant overall reduction of the relative mRNA concentrations and the activities of fatty acid synthase and glucose-6-phosphate dehydrogenase in rats (Eder et al., 2003a). The study suggests that oxidized fats contain substances that suppress gene expression of lipogenic enzymes in the liver. However, feeding male Wistar rats for 4 weeks with a diet containing 2% oxidized corn oil does not alter the levels and the activities of glucose-6-phosphate dehydrogenase, malic enzyme, and acetyl-CoA-carboxylase in the liver (Iritani et al., 1980), and feeding of thermally oxidized oil (50°C for 16 days) does not affect the activities or expression of lipogenic enzymes (fatty acid synthase and acetyl-CoA-carboxylase) in mammary glands of lactating rats (Brandsch et al., 2004).

As the levels of oxidized lipoproteins in the circulation are directly correlated to the quantity of oxidized lipid in the diet, it is suggestive that in humans dietary oxidized lipids are absorbed by the small intestine, incorporated into chylomicrons, and appear in the bloodstream where they contribute to the total body pool of oxidized lipid (Staprans et al., 1994). Thus, oxidized fats and lipid oxidation products in the diet ingested may exert deleterious cardiovascular effects and contribute to the pathogenesis of atherosclerosis (Cohn, 2002). Oxidative modification of lipoproteins, particularly low-density lipoprotein (LDL), increases its atherogenicity by altering receptor-mediated uptake by cells in the intima of blood vessels (Westhuyzen, 1997). Oxidized lipoproteins may be taken up by scavenger receptors on monocytes, smooth muscle cells, and macrophages in an uncontrolled process leading to the accumulation of lipid and the formation of foam cells, an early feature

of atherosclerotic plaque. Loading with oxidized LDL alters the endocytic and secretory activities of murine macrophages (Bolton et al., 1997), and oxidized lipoproteins, including high-density lipoprotein (HDL) and their lipid peroxidation products inhibit tumor necrosis factor α secretion by THP-1 human macrophages (Girona et al., 1997). In addition, rabbits fed a diet rich in oxidized lipid have a significant increase in fatty streak lesions in the aorta and cholesterol in the pulmonary artery (Staprans et al., 1996).

To determine the effect of dietary oxidized lipids on lipoproteins, Suomela et al. (2004) studied the effects of three sunflower seed oil diets differing in oxidation levels (PV in oils 1, 84, and 223 mEq O_2/kg) on lipoprotein lipid oxidation in growing pigs, and found that the lipoprotein lipids were more oxidized in the pigs fed on the most oxidized oil compared with those fed on nonoxidized oil, reflecting oxidation of dietary fat in the lipoprotein. In addition, rats fed oil heated at 50°C, 105°C, or 190°C have higher concentrations of HDL cholesterol and lower ratios between plasma and HDL cholesterol than rats fed the diet containing the fresh fat (Eder et al., 2003b). However, the composition of LDL apolipoproteins and uptake of LDL by macrophages are not different between rats fed the fresh fat diet and those fed the oxidized fat diet. The findings suggest that ingestion of oxidized fats does not adversely affect the lipoprotein profile in the rat model used, and does not cause modifications of apolipoproteins that would lead to enhanced uptake of LDL via macrophage scavenger receptors.

Oxidized fats and oils may promote or initiate carcinogenesis or mutagenesis. Sugai et al. (1962), for example, have shown that feeding of heated oil to rats promotes the carcinogenicity of 2-acetylaminofluorene, a substance that can cause neoplasia in a varirty of tissues. The ability of vitamin E to partially protect against experimentally induced carcinogenesis (Haber and Wissler, 1962; Wattenberg, 1972) suggests that lipid peroxidation may play a role in carcinogenesis or mutagenesis by damaging genetic materials. The percentage of embryo malformations and reabsorptions is 21.7% in pregnant Wistar rats treated *per os* (0.30 mL/day) with thermally stressed safflower oil for 12 days, compared with 5.6% in the group receiving nonheated oil (Indart et al., 2002). As vitamin E supplementation decreases malformations to 7% in the heated oil group, it is suggestive that the potent teratogenic actions of lipid peroxidation products in the heated cooking oils are partially circumventable by the vitamin. In addition, rats fed the deteriorated fat and oil with at least 107.2 mEq/kg peroxide value significantly decrease locomotor activity compared to control rats (Gotoh et al., 2006). The findings suggest that oxidized fat and oil may induce neurotoxicity, and that it is important to evaluate the toxicity of oxidized fats and oils by using other measures, in addition to using general toxicity tests.

B. Oxidized Fatty Acids

There are a large number of oxidation products of fatty acids. Autoxidation of U-^{14}C-labeled methyl linoleate, for example, results in the formation of methyl linoleate hydroperoxides, as well as their polymeric and low molecular weight fractions (Oarada et al., 1986). The polymeric fraction consists mainly of dimers of methyl linoleate hydroperoxides. 4-Hydroxy-2-nonenal (HNE), 8-hydroxy methyl octanoate, and 10-formyl methyl-9-decenoate are identified as major constituents in the low molecular weight fraction. As is shown in Table 36.2, the distribution of radioactivities in the digestive contents and feces of rats 12 h after intubation averaged 41% for methyl linoleate hydroperoxides, 53% for the polymeric fraction, and less than 3% for low molecular weight compounds. On the other hand, approximately 73% of the total radioactivity is found in the urine and as expired CO_2 of rats treated with the low molecular weight fraction compared to 25% in animals receiving methyl linoleate hydroperoxides and 23% in the polymeric fraction-treated group (Oarada et al., 1986). The findings suggest that small molecular weight compounds of oxidized fatty acids are more readily absorbable and metabolizable than the polymeric materials.

Although some fatty acid hydroperoxides are absorbed from the gut, they may not survive the transfer and exert their effects on distant organs (Glavind and Tryding, 1960; Bhalerao et al., 1963).

TABLE 36.2
Distribution of Oxidation Products of Methyl Linoleate[a]

	Polymers	Hydroperoxides	Small Compounds
Digestive contents			
Stomach	7.13	33.54	0.09
Small intestine	3.58	2.46	0.88
Cecum and large intestine	32.35	4.56	1.44
Feces	9.60	0.67	0.70
Digestive tract			
Stomach	1.17	2.50	0.22
Small intestine	0.44	0.49	0.30
Cecum and large intestine	1.24	0.21	0.25
Organs			
Brain	0.04	0.03	0.07
Lung	0.06	0.08	0.13
Heart	0.03	0.05	0.03
Liver	1.93	3.71	0.86
Kidney	0.19	0.24	0.27
CO_2	9.73	10.61	27.46
Urine	12.79	13.98	46.87

[a] Percentage (%) of radioactivity administered observed 12 h after male Wistar rats received oral administration of U-^{14}C-labeled methyl linoleate hydroperoxide, polymeric fraction, or low molecular weight fraction.

Source: Adapted from Oarada, M., et al. (1986). *Lipids 21*: 150–154.

After oral administration of methyl linoleate 1-^{14}C-hydroperoxides to rats, only labeled hydroxy acids, and not unchanged hydroperoxides of linoleate 1-^{14}C-hydroperoxides are detected in the lymph (Bergan and Draper, 1970). Kanazawa et al. (1985) have shown that 13.4% of orally administered ^{14}C-labeled linoleate hydroperoxides is detected in the feces of rats compared to 45.3% of the secondary oxidation products 90 h after treatment, and that 51.9% of the radioactivity absorbed by the rats treated with secondary oxidation products is recovered from the urine and 22.9% as CO_2 90 h after administration compared to 29.3% from urine and 23.9% as CO_2 in the linoleate hydroperoxide-treated group. The secondary product fraction employed consists of approximately 35% polymers, 25% endoperoxide-rich components, and 40% low molecular weight compounds. Approximately 2.6% of the total orally administered secondary products are found in rat liver 12–24 h after administration. The significant presence of those compounds, coupled with the observed increase in hepatic TBARS, elevation of serum transaminase activities, and slight hepatic hypertrophy suggest that the secondary products of linoleate hydroperoxides may be absorbed and deposited in distant organs. Similarly, male growing rats fed a diet containing 10% oxidized linoleic acid-rich preparation for 4 weeks result in profound alterations in membrane composition, fluidity, and function of liver microsomes, as well as higher levels of fluorescent compounds and TBARS, higher activities of aldehyde dehydrogenase (ADH) and NADPH cytochrome reductase, and enhanced cholesterol turnover than the control animals (Hochgraf et al., 1997).

Oxidative damage in biomembranes may be induced by dietary oxidized oils. When added at the initial stage or at the early logarithmic phase, linoleate hydroperoxides at 1 mM concentration completely inhibit the growth of *Escherichia coli* (Gamage et al., 1971). Linoleic acid hydroperoxides (LOOH) and/or oxidized oils with different hydroperoxide contents induce lipid peroxidation in erythrocyte ghosts and colon cells (Udilova et al., 2003). LOOH incorporated into the lipid bilayer decreases membrane fluidity and initiates lipid peroxidation in the lipid phase. In addition, exposure

of LOOH to cultured cells (IEC18 intestinal epithelial cells, SW480 and HT29/HI1 colon carcinoma cells) causes cell death both via apoptosis and necrosis. Cells with higher degree of membrane unsaturation are more susceptible and antioxidants (vitamin E and selenite) are protective indicating the involvement of oxidative stress. Similarly, vitamin E deficiency symptoms such as encephalomalacia in chicks (Nishida et al., 1960) and creatinuria and erythrocyte hemolysis in rabbits (Kokatnur et al., 1966) have been observed in animals infused with methyl linoleate hydroperoxides.

Martin et al. (2000) have shown that feeding of cyclic fatty acid monomers (0.1%–1.0%) from heated oil for 2 weeks increases some characteristic enzyme activities, such as peroxisomal acyl-CoA oxidase, and the microsomal omega- but also (omega-1)-laurate hydroxylase (CYP4A1 and CYP2E1, respectively) in rat liver. Dietary cyclic fatty acids induce a coordinated regulation between the activities of the lipogenic enzymes studied (Δ9-desaturase, phosphatidate phosphohydrolase) and peroxisomal oxidation, but not with mitochondrial β-oxidation. The dose-dependent decrease of Δ9-desaturase activity with cyclic fatty acid monomer intake is accompanied by a similar decrease of the monounsaturated fatty acid level in liver. The increase in the γ-linolenic acid level with cyclic fatty acid intake suggests an increase in Δ6-desaturase activity, and decreased liver glycogen concentration suggests an effect on the carbohydrate metabolism. The findings also suggest that the altered liver levels of eicosapentaenoic and arachidonic acids are due to the peroxisomal retroconversion process in rats fed cyclic acids.

Consumption of a small amount of linoleate hydroperoxide causes an increase in the formation of oxidatively modified LDL with a high content of conjugated dienes in plasma and liver (Machira, 1994). In addition, both acid and neutral cholesteryl esterases are suppressed in mononuclear leukocytes, liver, and aorta of the oxidized linoleate hydroperoxide-fed rats. A specific polyclonal antibody against 13-hydroperoxyoctadecadienoic acid-modified protein: formation of lipid hydroperoxide-mediated apoB-100 in oxidized LDL has been characterized (Kato et al., 1997). Oxidatively modified lipoproteins may exert an atherosclerotic effect by altering receptor-mediated uptake by cells in the intima of blood vessels (Westhuyzen, 1997). Dietary 13-hydroxylinoleic acid promotes atherosclerosis (increased aortic lesion areas, and plasma total cholesterol and LDL cholesterol, as well as oxidatively modified proteins) and plasma cholesterol concentrations in LDL receptor knockout mice in the presence of dietary cholesterol (Khan-Merchant et al., 2002). Apolipoprotein (apo) A-I, the major protein component of HDL, synthesized principally in the small intestine and liver, is increased in plasma apoA-I level in humans treated with an oxidized fat diet. Rong et al. (2002) have shown that oxidized linoleic acid causes a dose-dependent increase in the levels of apoA-I, but not apoB, protein in both differentiated and undifferentiated Caco-2 cells, that the mRNA expression for apoA-I paralleled the protein expression, and that Caco-2 cells did express PPAR-γ. As mRNA and PPAR-gamma ligand could increase apoA-I secretion in these cells, the mechanism for the induction of apoA-I might include PPAR-γ for which oxidized fatty acid is a ligand. The findings suggest that fatty acid hydroperoxides may play a role in the oxidation of lipoproteins and the development of atherosclerotic lesions.

Daily intubation of oxidized ethyl linoleate (peroxide value 700 or 1400; the major oxidized compounds are 9-hydroperoxy-*cis*, *trans*- and 13-hydroperoxy-*trans*, *cis*-octadecadienote) to rats (2.5 g/kg body weight) for 16 days results in mucosal hypertrophy of the large intestine and affected the fecal fermentation of dietary fiber (Hara et al., 1996). The data suggest that dietary oxidized fatty acids may influence cecal metabolism and play a role in the etiology of colon cancer.

C. Degradation Products of Lipid Hydroperoxides

Prolonged heating of fats and oils may result in the degradation of peroxidized fatty acids formed initially. Depending on the type of fatty acids and oxidation conditions, different secondary products of fatty acids are formed. For example, major compounds found in the low molecular weight fraction obtained from peroxidized methyl linoleate are 8-hydroxy methyl octanoate, HNE, and 10-formyl methyl-9-decanoate (Oarada et al., 1986), and azelaldehydoc acid, hexanal, azelaic acid, monocarboxylic acids (mainly hexanoic, hepatanoic, and octanoic acids), and suberladehydic

acid are found in the low molecular weight fraction of autoxidized linoleic acid (Kanazawa et al., 1985). In addition, 2-hydroxy heptabal and HNE are the major aldehydic compounds resulting from the oxidation of arachidonic acid by iron ascorbate, whereas MDA, glyoxal, and 2-hydroxy-4-decenal are the minor products (Mlakar and Spiteller, 1997). Owing to their shorter carbon chain lengths, low molecular compounds are more easily absorbed than fatty acid hydroperoxides or polymerized materials into the intestinal wall. Among a diverse array of low molecular weight compounds, MDA and HNE, the principal α,β-unsaturated aldehydic products of lipid peroxidation, have received the most research interest.

a. Malondialdehyde

Malondialdehyde (MDA), a three-carbon dialdehyde, is produced during autoxidation of polyunsaturated fatty acids. Much more MDA is produced from autoxidized linolenate than from autoxidized linoleate, whereas autoxidized oleate produces essentially no MDA (Kenaston et al., 1955). Dahle et al. (1962) proposed that only polyunsaturated fatty acids containing three or more double bonds can undergo autoxidation and form peroxyl radicals with a β,γ-unsaturation to the carbon that bears the hydroperoxide group. This peroxyl radical then cyclizes to form a five-member ring compound. Peroxyl radicals can either abstract a hydrogen atom from an alkyl group or undergo ring closure to form cyclic endoperoxide radicals (Pryor et al., 1976a,b). The resulting compounds can then generate MDA when exposed to heat or acid.

The LD_{50} levels of MDA in rats are 632 mg/kg of body weight for its enolic solium salt and 527 mg/kg for its acetate form (Crawford et al., 1965); considerably more toxic than formaldehyde or glyoxal. MDA can react with the mitochondrial membrane (Balcavage and Alvager, 1982), disrupt red blood cell membranes (Jain, 1984), and decrease erythrocyte survival (Jain et al., 1983). MDA can also form a conjugated Schiff base product by reacting with the amino group of proteins or phospholipid (Tappel, 1972). Major MDA adducts found in rat and human urine include amino acid–MDA adduct *N*-(2-propenal), lysine and its acetylated derivative (McGirr et al., 1985), and *N*-(2-propenal) serine (Hadley and Draper, 1988). Under conditions of oxidative stress (vitamin E deficiency or administration of iron nitrilotriacetate or carbon tetrachloride), increased excretion of *N*-(2-propenal) lysine, its ester, and free MDA is observed in rat urine (Mahmoodi et al., 1995). These studies suggest an accelerated rate of proteolysis by MDA. In isolated rat hepatocytes, MDA has been shown to modify proteins through covalent alkylation of lysine, histidine, and cysteine residues (Hartley et al., 1997). Increased levels of aldehyde-modified proteins are associated with oxidative stress conditions but not with cell death, suggesting that these proteins may also function to sequester electrophilic molecules during oxidative injury.

MDA is capable of reacting with DNA (Tappel, 1972; Summerfield and Tappel, 1984) and produce chromosomal aberrations in cultured fibroblasts (Bird et al., 1982). The preferential reaction sites on the DNA molecule for the MDA are the bases guanine and cytosine (Brooks and Klamerth, 1968). Increased formation of cross-link products by MDA is correlated with the loss of DNA template activity and structural changes (Reiss et al., 1972). In addition, MDA may inactive DNA polymerase and thus restrict cell proliferation in culture (Wawra et al., 1986). Increased formation of a deoxyguanosine–MDA adduct was found in the liver and kidney of aged rats (Draper et al., 1995). High-dietary polyunsaturated fat is associated with increased formation of DNA ethano–DNA base adducts of MDA in white blood cells of healthy individuals (Fang et al., 1997; Nair et al., 1997).

The amounts of MDA present in foods vary widely depending on the structure composition and conditions of processing, storage (duration and temperature), and culinary practices (Papavergou et al., 1995; Abdel-Kader, 1996; Liu et al., 1996). In addition to those originating from foods, MDA can be formed nonenzymatically in the tissues by peroxidative decomposition of polyunsaturated fatty acids and enzymatically as a by-product of the cyclooxygenase reaction in prostaglandin synthesis. Increased formation of lipid peroxidation products, including MDA, in serum and tissues of experimental animals and humans is associated with increased oxidative stress. The concentration of

MDA in the urine is a useful index of the amount of lipid peroxidation consumed in the diet (Brown et al., 1995).

The mutagenicity/carcinogenicity of MDA has been demonstrated in a variety of test systems (Shamberger et al., 1974; Mukai and Goldstein, 1976; Yau, 1979). The mutagenicity of MDA in several strains of bacteria tested is reduced by coincubation with antioxidants (Shamberger et al., 1979). As MDA may catalyze the formation of *N*-nitrosoamines from secondary amines and nitrite (Kikugawa et al., 1980; Kurechi et al., 1980), MDA may play a role in regulating tumor metastasis, host immune mechanisms, and proliferation and differentiation of tumor cells (Begin, 1987). Higher levels of MDA and other aldehydic products are found in the blood of cancer patients (Torun et al., 1995; Yazdanpanah et al., 1997) and in noninsulin-dependent diabetic patients with or without microalbuminuria (Nacitarhan et al., 1995; Ozben et al., 1995).

However, the mutagenicity of MDA may be attributable to the presence of other compounds (Marnett and Tuttle, 1980). Enzymatically synthesized MDA lacks mutagenicity in a standard *Salmonella*/microsome assay and has weak mutagenic activity in a new *Salmonella* strain that reverts by frameshift mutation in a repeating sequence of adenine residues (National Academy of Sciences, 1982). In addition, administration of MDA in drinking water fails to demonstrate the carcinogenicity of MDA in random-bred Swiss mice (Apaja, 1980). Thus, the significance of MDA to human risk of cancer remains to be determined.

b. 4-Hydroxyalkenals

4-Hydroxyalkenal is formed in relatively high quantities during lipid peroxidation (Benedetti et al., 1986; Jurgens et al., 1986, 1987; Oarada et al., 1986; Esterbauer, 1993). A range of 14–150 nmol/g of HNE is found in pork and 1–152 nmol/g in beef, and the content of HNE is linearly correlated with the content of total omega-6 fatty acids, linoleic acid, or arachidonic acid in pork (Sakai et al., 1996). HNEs are very toxic to mice and rats. The lethal dose of HNE, when given intraperitoneally, is 68 mg/kg of body weight (Schauenstein et al., 1977). HNE causes severe liver damage in rats when administered intravenously as a phospholipid emulsion at the dose of 13–18 mg/kg of body weight (Segall et al., 1985). The symptoms are very similar to those seen after CCl_4 administration.

HNE may inactivate liver microsomal P-450 cytochromes (Kuo et al., 1997); upregulate transforming growth factor β1 expression in the macrophage lineage (Leonarduzzi et al., 1997); impair signal transduction associated with muscarinic acetylcholine and metabotropic glutamate receptors (Blanc et al., 1997); mediate oxidative stress-induced neuronal apoptosis (Kruman et al., 1997); inhibit interleukin-1 β converting enzyme (Davis et al., 1997); inactivate glutathione reductase (Vander Jagt et al., 1997); interact with rhodopsin (van Kuijk, 1997); inhibit Na,K-ATPase (Siems et al., 1996); induce transcription and expression of aldose reductase in rat vascular smooth muscle cells (Spycher et al., 1996); cause cell death in murine alveolar macrophages (Li et al., 1996); modify proteins through covalent alkylation of lysine, histidine, and cysteine residues (Hartley et al., 1997); inhibit poly(ADP-ribose) formation in primary cultures of rabbit synovial fibroblasts (Ullrich et al., 1996); induce mitochondrial permeability transition (Kristal et al., 1996); inactivate ethanol-inducible cytochrome P-450 and other microsomal P-450 isozymes (Bestervelt et al., 1995); disrupt iron homeostasis and cause cell degeneration (Mark et al., 1997); inhibit hepatic DNA polymerases and O^6-methylquanine-DNA methyltransferase (Krokan et al., 1985; Wawra et al., 1986); modify glucose-6-phosphate dehydrogenase (Esterbauer et al., 1988; Grace et al., 1996); and induce coronary vasodilation in perfused rat heart (Van der Kraaij et al., 1990). In addition, HNE cross-linked protein inhibits multicatalytic proteinase (proteasome) noncompetitively and inhibits the degradation of oxidatively modified glutamine synthetase by the proteinase (Friguet and Szweda, 1997).

Oxidative stress has been implicated in the pathogenesis of many neurodegenerative conditions that involve degeneration of synapses and neurons in glutamatergic pathways, including strokes, Alzheimer's disease, and Huntington's disease. In Alzheimer's disease, the microtubule-associated protein tau is excessively phosphorylated in degenerative neurons. The ability of HNE to inhibit

dephosphorylation of the microtubule-associated protein tau suggests a role for HNE in altered tau phosphorylation and neurofibrillary degeneration (Mattson et al., 1997). Increased HNE-derived advanced lipid peroxidation endproducts, lysine-derived pyrrole adducts, are found in the neurofibrillary tangles of patients with Alzheimer's disease (Sayre et al., 1997). Removal of extracellular glutamate at synapses by specific high-affinity glutamate transporter is critical to prevent excitotoxic injury to neurons. As 4-HNE may mediate oxidation-induced impairment of glutamate transport and mitochondrial function in synapses, it is suggestive that HNE plays important roles in oxidative impairment of synaptic functions that may promote excitotoxic cascade (Keller et al., 1997). In addition, excretion of 4-HNE is increased in the bile of patients with biliary tract and pancreatic disorders (Leo et al., 1997).

4-Hydroxyalkenals can cause severe disturbance of cell functions at the biochemical and genetic levels (Esterbauer et al., 1988), and Chinese hamster ovary cells exposed to HNE show an increased frequency of sister chromatid exchange (Brambilla et al., 1986). Exposure of HNE and other 2-alkenals increases the number of revertants in bacteria (Marnett et al., 1985). Both HNE and MDA are chemotactic for neutrophils (Curzio et al., 1986, 1990), toxic to many cells (Benedetti et al., 1980, 1986), and play a role in cell-mediated oxidation of lipoproteins in cell-free systems (Andreis et al., 1981; Gavino et al., 1981). Kumagai et al. (2000) have shown that among the oxidized fatty acid metabolites tested, only HNE, a highly mutagenic and genotoxic aldehyde generated during oxidative stress, dramatically induced cyclooxygenase-2 (COX-2) gene expression in rat liver epithelial RL34 cells, and that intracellular GSH status was strictly related to HNE-induced COX-2 expression. These findings suggest the presence of a signaling pathway in the cellular response mediated by locally produced lipid peroxidation products under oxidative stress. Tumor necrosis factor α secretion by human macrophages is inhibited by 2,4-hepatadienal, hexanal, 2-nonenal, 2-octenal, and 2,4-decadienal, but not by linoleic acid hydroperoxides (Girona et al., 1997), suggesting a role of aldehydic compounds in the modulation of the inflammatory response by macrophages. Another lipid peroxidation product, 12-oxo-*cis*-9-octadecenoic acid (12-keto-oleic acid), can bind covalently to protein and amino acids and form fluorescent pigments (Kanazawa et al., 1985). In addition, the methanolic extract of cooking oil fumes contain *trans–trans*-2,4-decadienal (*t–t*-2,4-DDE), which induces genotoxicity and oxidative stress in human lung carcinoma (A-549) cells (Wu and Yen, 2004).

IV. FACTORS AFFECTING THE BIOLOGICAL EFFECTS OF OXIDIZED FATTY ACIDS

There is a general agreement that undesirable or harmful materials are generated during prolonged oxidation or high-temperature treatment. However, there is considerable disagreement regarding the biological significance of such materials formed in experimental studies. This is mainly due to differences in experimental designs and approaches, especially the extent of oxidation of oils used, and adequacy of dietary nutrients, employed for each study.

A. Extent of Fatty Acid Oxidation

As discussed previously, the types and amounts of oxidation products of fats and oils vary greatly, depending on the oxidation conditions. Studies on the biological effects of heated and oxidized oils conducted can be divided into two categories. The first involves extensively used oils and the second involves oils that have been heated or oxidized under normal-use conditions approximating current culinary practices. The first type is usually prepared form experimental oils under unrealistic conditions. The problem with this type of study is the failure to remove used oil (with a fried product) and add new (makeup) oil continuously. Since steady-state conditions are not attained, such oils continuously deteriorate, and the amount of oxidation products formed is expected to be directly proportional to heating time (Poling et al., 1960, 1962, 1970; Nolen, 1973).

The biological effects resulting from ingestion of heated oils is closely related to both the levels of oil used in the diet and the conditions of their heating treatment. Highly deteriorated frying oils are generally poorly digested and absorbed. Approximately one-half of orally administered [^{14}C] linoleate autoxidation products, for example, is found in the feces of rats (Kanazawa et al., 1985). This can be attributed to the presence of cyclic dimmers and polymeric materials in the extensively oxidized oils (Nolen et al., 1967; Kajimoto and Makai, 1970; Poling et al., 1970). Consumption of large amounts of polymeric fatty acids may result in diarrhea, and cyclic monomers, when fed at high levels (15% of the diet), cause an increase in the fat content of the liver (Poling et al., 1960; Weil, 1970). Badly abused oils also produce adverse effects such as mild enlargement of the liver, spleen, and adrenals in experimental animals (Poling et al., 1960; Weil, 1970). Consumption of oils that have undergone prolonged heating in the presence of air depresses appetite and growth and causes depression, diarrhea, histological changes in various tissues, tissue enlargement, interference with reproduction, and even death in some instances (Poling et al., 1970). Although the feed intake of male Wistar rats fed a diet containing 15% thermally oxidized sunflower oil with 19% polar materials for 27 days is similar to those receiving 15% used oil with 5.1% polar materials, final body weight, feed efficiency ratio, and protein efficiency ratio are significantly lower (Lopez-Varela et al., 1995). In addition, the liver of nine of ten animals that received high-polymeric materials exhibits moderate fibrotic degenerative areas with severe vaculization together with regenerative areas containing eosinophilic binuclear hepatocytes.

On the other hand, experimental animals are rather resistant to the effects of oils that have not been subjected to prolonged heating or abuse. The growth rate of rats maintained on a diet using heated partially hydrogenated soybean oil prepared under conditions that simulated intermittent frying in a restaurant as the sole source of dietary lipid is only somewhat lower than that of rats fed unheated oil (Nolen et al., 1967). The heated oil has a slight decrease in digestibility or absorbability, but does not adversely affect the rate of animal survival or incidence of tissue lesions during the 24-month period (Table 36.3), and the overall mortality rate and incidence of tumors and other pathological changes or disease conditions are not correlated with the extent of heating for up to 216 h. In addition, rats grow well on a diet that contains 60% ricinoleic acid-rich castor oil (Stewart and Sinclair, 1945) and are relatively insensitive to the ingestion of oxidized fats containing hydroxy or carbonyl groups (Kaunitz and Johnson, 1964). In humans, a cathartic action probably protects against absorption of significant quantities of oxidized fat. More importantly, the presence of a number of metabolic systems, such as glutathione peroxidase (GPx) and AD (Figure 36.1), in the body reduces the potentially harmful effects of oxidized fats and oils and their degradation products (Chow, 1979; Antonenkov et al., 1987).

B. Adequacy of Dietary Nutrients

As essential fatty acids and tocopherols present in fats and oils are readily oxidized during autoxidation or thermal oxidation, the levels of these nutrients remaining in the oxidized oil are important in determining its biological effect. If oxidized fats and oils are used as the only source of dietary lipid and vitamin E, deficiencies of essential fatty acids, vitamin E, or both may result. For example, using 15% autoxidized cottonseed oil as the sole source of dietary lipid, Kaunitz et al. (1956) have observed a marked inhibition of growth in growing rats, and when fresh cottonseed oil was added to the diet, normal growth resumed. These findings suggest a deficiency of essential fatty acids, vitamin E, or both in the autoxidized oil used in the diet. In a study to determine if the antioxidant status alters the adverse effects of oxidized oils, Giani et al. (1985) have shown that supplementation with vitamin E at 300 mg/kg diet neutralized the adverse effects of heated oils on vascular eicosanoid production compared to the values found in rats fed a diet containing fresh oil. The body and organ weights of animals treated with heated oil and given vitamin E supplements did not differ from those of the controls after 8 weeks. Similarly, growth depression in rats following ingestion of oxidized oils is prevented by vitamin E supplementation (Privett and Cortesi, 1972), and supplementation

of α-tocopherol to chicks fed thermally oxidized sunflower oil reduces their tissue susceptibility to oxidation (Sheehy et al., 1994). In addition, dietary oxidized frying oil compromises α-tocopherol retention and enhances tissue depletion and excretion of α-tocopherol in vitamin E-deficient rats (Liu and Huang, 1995, 1996). The study suggests that chronic ingestion of oxidized lipids compromises free radical scavenging activity *in vivo*.

Besides essential fatty acids and vitamin E, dietary protein levels have been shown to play a role in the toxicity of oxidized fats and oils. Witting et al. (1957), for example, observed an almost

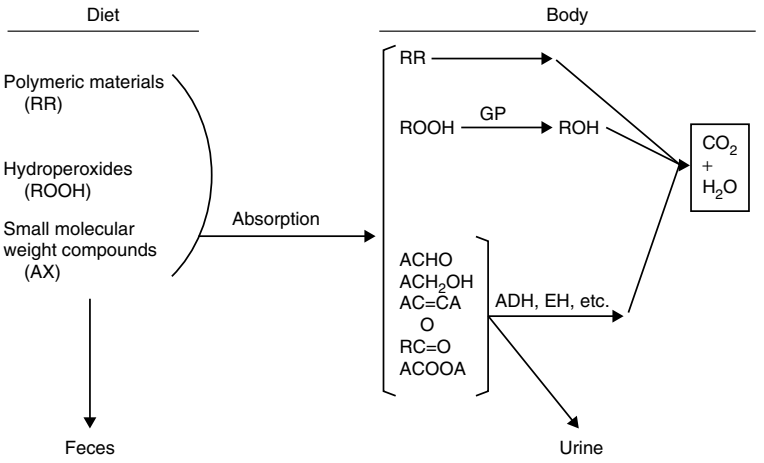

FIGURE 36.1 Possible fate of dietary oxidized fatty acids and secondary products. total lack of growth in rats fed a diet containing laboratory-prepared heated corn oil and 10% casein. With 20% casein in the diet, severe growth depression was still seen, but at 30% or more protein in the diet, only a mild effect was observed. Similarly, long-term feeding of thermally oxidized fats induces hepatic microsomal enzymes, and the levels of hepatic microsomal enzyme induced by oxidized oil are influenced by dietary protein levels (Andia and Street, 1975). However, the extent of enzyme induction is much higher in the animal group receiving 27% protein than when dietary protein was 8%. On the other hand, animals fed the low protein diet have elevated serum glutamate-oxaloacetate transaminase and glutamate-pyruvate transaminase values, suggesting injury to the heart or liver. These findings agree with reports that the toxicity of used frying oil is much less severe when rats are fed a high protein diet (Hermans et al., 1973).

Although the mechanism of the protective effects of high-dietary protein is not yet clear, it may be linked to an enhanced detoxification capability.

V. METABOLIC FATE OF OXIDIZED FATS AND OILS

Pure fatty acid hydroperoxides are very toxic to experimental animals when administered intravenously (IV) (Horgan et al., 1957; Olcott and Dolev, 1963; Findlay et al., 1970). The 24-h lethal IV dose of a high-purity preparation of methyl linoleate hydroperoxides in adult male rats is approximately 0.07 mmol/100 g body weight (Cortesi and Privett, 1972). The major effect of injected linoleate hydroperoxides was on the lungs, which became enlarged from edema, and the animals died of lung congestion and injury similar to that observed in acute oxidant toxicity (Stockinger, 1965; Haugarard, 1968). However, lipid hydroxides are not that toxic when given orally (Dubouloz and Laurent, 1950; Dubouloz et al., 1951). In addition, only very small amounts of hydroperoxides and TBARS are detected in the lung and serum, indicating that most of the injected hydroperoxides are destroyed in the tissue. The findings suggest that the peroxidized fatty acids ingested/absorbed are metabolized. This view is supported by the observation that no deaths are seen in rabbits during a 24-h period after a single oral dose of methyl linoleate hydroperoxides of about ten times the amount that causes death by the intravenous route (Cortesi and Privett, 1972).

A metalloprotein capable of metabolizing peroxidized fatty acids has long been suggested (Dubouloz and Laurent, 1950; Dubouloz et al., 1951). The presence of an active metabolic system for lipid hydroperoxides is supported by the finding that within 24 h after intraperitoneal injection of ^{14}C-labeled linoleate hydroperoxides in rabbits, the majority of the radioactivity was collected as carbon dioxide (Findlay et al., 1970). Similarly, after giving oxidized corn oil orally to rats with thoracic lymph fistula, Iritani et al. (1980) fail to detect the presence of hydroperoxides per se in the lymph or tissues in the next 24 h. The findings suggest that peroxidized lipids absorbed are metabolized. Subsequent studies show the metalloprotein is the seleno-enzyme GPx, which utilizes the reducing equivalents of glutathione (GSH) to reduce hydrogen peroxide as well as lipid hydroperoxides (Little and O'Brien, 1968; Ursini et al., 1982, 1985) (Figure 36.1).

After feeding 7% oxidized stripped corn oil (peroxide value 1000 mEq/kg) in a diet adequate in selenium and vitamin E to weanling rats for 14 weeks, Vilas et al. (1976) observed an increase in the specific activity of GPx in stomach mucosa but not in the plasma or in perirenal and paraepididymal adipose tissues. In addition, consumption of peroxidized oils does not significantly affect GPx activity of the mucosa of the gastrointestinal tract of selenium-supplemented rats, but the enzyme activity in both the stomach and intestine declined more slowly than in other organs as a result of consuming peroxidized oil during selenium depletion (Reddy and Tappel, 1974).

Ingestion of oxidized sunflower oil (heated at 98°C for 48 h) resulted in increased levels of TBARS and activities of GPx and GSSG reductase in rat liver (Ammouche et al., 2002). As the activities of GPx and metabolically related enzymes are increased in tissues of animals fed oxidized oils and other oxidatively stressed animals (Chow and Tappel, 1972; Chow et al., 1973; Negishi et al., 1980), the enzymic system is an important mechanism protecting against the deleterious effects of hydroperoxides (Chow, 1979, 1988). Similarly, significantly higher lipase activities observed in the exocrine pancreatic juice of growing pigs fed oxidized canola oil suggests that the exocrine pancreas is able to adapt to variations in the levels and quantity of oxidized lipids in the diet (Ozimek et al., 1995). In addition, the metabolic response to the consumption of oxidized oils is supported by the findings that the activities of hepatic aminopyrine *N*-demethylase, aniline hydroxylase, NADPH-cytochrome *c* reductase, UDP-glucuronyl transferase, and GSH *S*-transferase, as well as cytochrome P-450 content are significantly increased in rats fed a diet containing 15% deteriorated soybean frying oil (Huang et al., 1988).

Although MDA is very reactive, the compound originated from foods or generated *in vivo* is normally eliminated or metabolized rapidly. Hepatic ADH is the major enzymic system responsible for MDA metabolism (Chow, 1988; Esterbauer et al., 1988; Esterbauer, 1993) (Figure 36.1). Multiple, forms of ADH isozymes exist in mitochondria, cytosol, and microsomes (Mitchell and Peterson, 1989). In addition, alcohol dehydrogenase (ALH) and GSH conjugation catalyzed by GSH *S*-transferases plays a role in the elimination of MDA (Esterbauer et al., 1991). An age-associated decline in mitochondrial detoxification of aldehydic compounds by ALH and GSH *S*-transferase may cause mitochondrial dysfunction during aging (Chen and Yu, 1996). The increased activities of microsomal ADH and NADPH cytochrome *c* reductase of rats fed a diet containing 10% oxidized linoleic acid rich preparation for 4 weeks (Hochgraf et al., 1997) also suggest a metabolic adaptation of rats to metabolize absorbed aldehydic compounds from the diet.

Although HNE is toxic to biological systems, it is also eliminated or metabolized rapidly under normal conditions (Esterbauer, 1993). For example, over 80% of infused HNE is metabolized in the perfused kidney during the first 3 min (Grune et al., 1997). GSH–HNE conjugate (35%), the corresponding alcohol 1,4-dihydroxynonene (14%), HNE–mercapturic acid conjugate (4%), 4-hydroxynonenoic acid (7%), and water (32%) are identified as primary and secondary metabolites. The formation of a HNE–mercapturic acid conjugate in the kidney and its selective excretion may be of central importance in the detoxification of a number of lipid peroxidation products. Similarly, following intravenous administration of treated HNE to rats, no unchanged HNE is detected in urine, whereas at least four mercapturic acid conjugates (HNE–mecapturic acid, 1,4-dihydroxynonene mercapturic acid, 4-hydroxynonenoic mercapturic acid, and the corresponding lactones) are

identified as HNE metabolites (Alary et al., 1995). These findings obtained suggest that two pathways are involved in the biotransformation of HNE: (1) reduction/oxidation of the aldehyde group and (2) conjugation to endogenous GSH leading to mercapturic acid conjugates in urine.

In hepatocytes, the primary metabolites of HNE are the GSH–HNE adduct, hydroxynonenoic acids, and the corresponding alcohol of HNE, 1,4-dihydroxynon-2-ene (Siems et al., 1997). The sum of these products accounts for about two-thirds of the total HNE degradation after 3 min of incubation. The fast metabolism of HNE underlines the importance of this metabolic pathway as an important part of the antioxidant defense against protein modification by aldehydic compounds. Metabolism by the alcohol/ADH pathways account for approximately 10% of the HNE elimination, whereas bioconversion by GSH *S*-transferases represent 50%–60% of the total HNE removal by hepatocytes and the pathway for the remaining 40% HNE metabolism remains to be identified (Hartley et al., 1995). Murine mGSTA4-4, a GSH *S*-transferase, possesses high activity and specificity for lipid peroxidation products, including HNE. Amino acid residue M104 is important in determining the recognition and binding of HNE to the active center of mGSTA4-4 (Nanduri et al., 1996). GSH *S*-transferase isozyme rGST8-8 in rat lens epithelium, which utilizes 4-HNE as a preferred substrate, is induced by curcumin, an antioxidant present in spice turmeric (Awasthi et al., 1996). Another GSH *S*-transferase isozyme, bGST 5.8, localized in bovine lens epithelium is also involved in the metabolism of HNE (Srivastava et al., 1996). Another enzyme, aldose reductase, which catalyzes the reduction of glucose to sorbital as part of the polyol pathway, also exhibits broad specificity for both hydrophilic and hydrophobic aldehydes, including HNE (Vander Jagt et al., 1995).

VI. SUMMARY AND CONCLUSION

Unsaturated fatty acids are susceptible to oxidation during processing, storage, and culinary use. In addition to hydroperoxides, secondary products of fatty acids, including polymerized materials and small molecular weight compounds, are formed during prolonged heating at high temperature. The adverse effects of oxidized fats and oils differ considerably depending on oxidation/heating conditions, as well as whether the heated oil is used as the sole source of dietary lipid. Feeding of oils that are extensively heated as the sole source of dietary lipids can cause diarrhea, growth retardation, organ enlargement, and even death. The adverse effects observed can be partly attributable to the loss of essential fatty acids and vitamin E. Peroxidized fatty acids and their small molecular weight products, such as MDA and HNE, are very toxic to biological systems. On the other hand, lipid hydroperoxides when ingested or absorbed can be readily metabolized by the GPx and related enzyme systems. Similarly, the aldehydic compounds, including MDA and HNE, can be rapidly metabolized by ADH or eliminated through urine following conjugation with GSH or other compounds. Thus, if oxidized or heated oils are not used as the sole source of dietary lipids, or oils are heated at conditions normally used in food preparation for periods that do not severely affect the taste of the oils of foods, they are generally considered safe and nontoxic despite the presence of many reactive oxidation products.

37 Satiating Effects of Fat

Zoe S. Warwick, Colleen M. McGuire, and Christina Revelle

CONTENTS

I. INTRODUCTION

Consumption of a diet high in dietary fat typically promotes greater weight gain than a diet high in carbohydrates. This pattern has been revealed in experimental research in both human and animal subjects, as well as in epidemiological studies (for reviews, see Warwick and Schiffman, 1992; Weststrate, 1995; Bray et al., 2004). This greater weight gain is usually (although not invariably) attributable to greater daily kcal intake ("hyperphagia") evoked by the high-fat diet. Researchers studying high-fat diet hyperphagia have examined the attribute(s) of high-fat foods that promote overeating, as well as individual differences in response to high-fat diets. High-fat foods are often more palatable and more calorically dense than high-carbohydrate foods; however, while both taste and caloric density may contribute to high-fat diet hyperphagia, high-fat foods need not be more palatable (Lissner et al., 1987; Warwick and Weingarten, 1995) or more calorically dense (Warwick and Weingarten, 1995) than high-carbohydrate foods in order to elicit overeating.

Since 24-h intake reflects the cumulative intake over many meals, it follows that high-fat hyperphagia must reflect larger meals (in terms of kcal consumed) and/or more frequent meals. One way of conceptualizing the behavioral difference(s) elicited by high-fat and high-carbohydrate foods is in terms of their "satiating effect." The satiating effect of a food is the reduced willingness to eat associated with ingestion of the food. Satiating effects occur *during* a meal (since all meals eventually cease), and also *after* a meal (hunger/subsequent food intake is less than that would be observed

had the food not been consumed). Blundell et al. (1992) have cogently delineated the conceptual distinctions between "satiation" (processes exerting their effects during a meal that contribute to meal termination) and postprandial "satiety" (observed after the meal has ended).

This chapter will review the evidence regarding the relative satiating effects of fats vs. carbohydrates, and will also compare the satiating potency of various types of fats. The satiating effects during, and after, a meal will be considered separately, and the evidence regarding the peripheral anatomical site(s) and signals mediating these effects will be presented. Also discussed will be individual differences in response to fats, long-term body weight regulation as a function of dietary fat content, and the role of learning in the control of fat intake.

II. SATIATION DURING A MEAL

Consumption of a meal produces stimulation of oronasal receptors that produce sensations of taste, aroma, and texture; mechanical stimulation of stomach receptors by food's bulk in the stomach; and chemical stimulation of gastrointestinal receptors. Afferent signals from each of these sites contribute to a reduced willingness to eat, which will ultimately result in the cessation of eating (meal termination). This has been demonstrated in studies in which either oral (e.g., Swithers and Hall, 1992), stomach (e.g., Phillips and Powley, 1996), or duodenal (e.g., Greenberg et al., 1990) stimulation alone elicited behavioral indices of satiety. During normal feeding, of course, all of these signals are experienced and may interact; for example, oral stimulation potentiates the satiating effect of intestinally administered nutrient (Antin et al., 1977).

A. Fats vs. Carbohydrates

Meals consisting primarily of high-fat food(s) are often (but not always; see Table 37.1) larger, in terms of kcal consumed, than meals consisting of high-carbohydrate, low-fat foods. Since high-fat foods are almost always more calorically dense than high-carbohydrate foods, intake of high-fat foods on a weight basis may be equal or even less than intake of high-carbohydrate foods. Both obese (Blundell et al., 1993) and normal weight (Lawton et al., 1994) humans consumed more calories when the meal consisted of high-fat foods than when a high-carbohydrate meal was provided. Because neither the caloric density nor the palatability of the meals was equated, the larger meal size of high-fat foods in these studies cannot be specifically attributed to a unique effect of fat independent of its taste and/or density. When energy density and fat content were independently

TABLE 37.1
Comparisons of Meal Size of High-Fat (HF) and High-Carbohydrate (HC) Foods

Reference	Subjects	Gram Intake	kcal Intake	
Blundell et al. (1993)	Obese humans	HF>HC	HF>HC	Density, taste not controlled
Lawton et al. (1994)	Normal-weight adults	HF>HC	HF>HC	Density, taste not controlled
Louis-Sylvestre et al. (1989)	Teenage boys	HF<HC	HF>HC	Density not controlled
Warwick et al. (2000)	Rats	HF>HC	HF>HC	Observed across two levels of diet density (1.15; 2.3 kcal/mL)
Warwick et al. (2003)	Rats	HF>HC	HF>HC	Observed in self-regulated intragastric infusion
Synowski et al. (2005)	Rats	HF>HC	HF>HC	Observed in long-term spontaneous feeding
Sclafani et al. (1993)	Rats	HF=HC	HF=HC	Equal density (0.08 kcal/mL)
Tordoff et al. (1987)	Rats	HF=HC	HF=HC	Equal density (1.33 kcal/mL)

manipulated across separate test sessions, both lean and obese subjects consumed fewer daily kcal when offered a low-energy density menu relative to a high-density menu (Bell and Rolls, 2001).

Animal studies have also compared meal size of high-fat and high-carbohydrate foods. A larger meal (in kcal) was eaten of a high-fat (HF) liquid diet than of a high-carbohydrate (HC) liquid diet (see Table 37.2 for formulation) even when both diets had equivalent caloric density of 2.3 kcal/mL; this pattern was also observed when both diets were diluted to 1.15 kcal/mL (Warwick et al., 2000). Since the caloric density of the diets was equated, this finding demonstrates that a high-fat food need not be more dense than a high-carbohydrate food to elicit greater intake. Interestingly, the relationship between fat:carbohydrate ratio and meal size is not linear. This was determined by formulating five liquid diets representing graded ratios of HF:HC, which were 100:0 (pure HF), 75:25, 50:50, 25:75, and 0:100 (pure HC). Nondeprived rats consumed each of five liquid diets on separate test days, with counterbalanced presentation order. Consistent with the previous finding (Table 37.3), meal size of pure HF was greater than meal size of pure HC. However, the decrease in meal size associated with increased carbohydrate content of the liquid diet was only evident when the carbohydrate content reached 66% of total kcal (HF:HC 25:75) (Figure 37.1). This may reflect a threshold effect for the relatively greater satiating potency of carbohydrate, and/or a nonlinear increment in the palatability of the liquid diet as a function of HF:HC ratio. Additional tests in which oral and postingestive influences on meal size are isolated are required to discriminate among these possibilities.

Other studies have demonstrated that the relative meal size of fat and carbohydrate depends on the type and/or concentration of nutrients used. When meal size of solutions of glucose or sucrose was compared to intake of corn oil emulsion of equivalent caloric density in nondeprived rats, no difference in meal size was found (Tordoff et al., 1987; Sclafani and Ackroff, 1993). However, meal

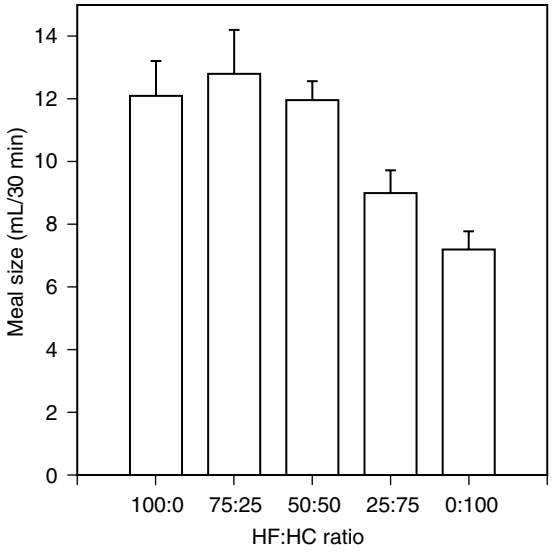

FIGURE 37.1 Meal size of liquid diets varying in HF:HC ratio. All diets 2.3 kcal/mL.

size of Polycose (a complex carbohydrate) solution was greater than intake of corn oil emulsion (Sclafani and Ackroff, 1993). Taken together, these inconsistent findings regarding relative meal size of high-fat and high-carbohydrate foods can be understood by recognizing that intake reflects the summation of stimulatory effects of the food's orosensory properties (taste, aroma, texture) and the inhibitory effects of the food's postingestive effects (stomach fill, contact with gastrointestinal chemoreceptors, postabsorptive effects). Fats differ from one another in their palatability (Naim et al., 1987) as do carbohydrates (Sclafani, 1987); within each macronutrient type there are also differences in postingestive effects under certain conditions (Maggio et al., 1987, but see Warwick and Weingarten, 1994b; Moran and McHugh, 1981; Ackroff and Sclafani, 1991). Thus meal size—the behavioral expression of the summation of food's orosensory and postingestive effects—would be expected to differ across various types of fats and carbohydrates.

In order to investigate the contribution of postingestive influences to relative meal size of high-fat and high-carbohydrate foods, it is necessary to equate or eliminate the foods' sensory properties. When high-fat and low-fat mousses were formulated so as to be equally palatable, teenage boys consumed more calories when eating the high-fat mousse compared to their intake of the low-fat mousse (Louis-Sylvestre et al., 1989). In rats, the orosensory stimulation produced by food can be eliminated by training rats to self-infuse a liquid diet directly into their stomach. Rats accustomed to infusing a high-fat liquid diet self-infused larger "meals" than did rats infusing a high-carbohydrate liquid diet of equivalent caloric density (Warwick and Weingarten, 1995; Lucas and Sclafani, 1999). Both these findings demonstrate that the postingestive effects of fats have a less potent intake-terminating (satiating) effect than carbohydrates. A recent study (Warwick et al., 2003) independently manipulated orosensory influences (highly palatable, moderately palatable) and macronutrient-specific postingestive influences (high-fat, high-carbohydrate) to investigate their independent and interactive effects on eating in a between-subjects design using self-regulated intragastric infusion. The highly palatable solution stimulated larger meals for both diet groups, but the reduced satiating effect (i.e., bigger meals) of high-fat relative to high-carbohydrate was robust across both palatability levels.

B. Hunger and Satiation

As mentioned above, nondeprived rats consumed a larger meal of a high-fat liquid diet than of a high-carbohydrate liquid diet (Table 37.3). To determine whether hunger level would differentially affect meal size, another group of rats was tested in a study in which meal size (30-min intake) of

HF and HC was measured under two conditions: 0-h food deprivation (chow removed just prior to the test session) and 24-h food deprivation (chow, but not water, removed 24 h before the test session). Order of deprivation and diet presentation were counterbalanced across rats. Consistent with the previous finding (Table 37.3), 0-h food-deprived rats consumed a bigger meal of HF than of HC. When hungry (24-h food deprived), rats consumed larger meals overall, but the intake-enhancing effect of deprivation was equivalent across HF and HC (Warwick and Synowski, 1999). However, it should be noted that the effect of deprivation on relative meal size of fat and carbohydrate apparently depends on the type of nutrients used and/or the deprivation conditions. Sclafani and Ackroff (1993) found that chronic food deprivation (body weight maintained at 85% of baseline) increased meal intake of a corn oil emulsion relative to sucrose or Polycose solution.

Another strategy for investigating the effect of deprivation on macronutrient intake is to offer two (or more) macronutrient sources simultaneously ("two-bottle" or "two-jar" test). A number of reports indicate that deprivation selectively enhances preferential intake of fat relative to other macronutrients (Piquard et al., 1978; Bligh et al., 1990; Bernardini et al., 1993; Sclafani and Ackroff, 1993; Warwick and Synowski, 1999).

C. Fatty Acid-Specific Effects

Greenberg and coworkers have utilized a novel approach to assessing the effects of fats on meal size. Instead of comparing oral intake of various fats—which would preclude isolation of the postingestive effects of the fats since their tastes would also vary—they infuse fats directly into the duodenum while allowing the rat to sham-feed. In sham-feeding, ingested food spills out of a surgically implanted hole in the stomach and thus exerts little or no postingestive activity. The type of food sham-fed is held constant across various types of infusions, and sham-feeding intake provides a measure of the satiating effect of the infusion. They observed that the reduction of sham- feeding produced by duodenal infusion of fat was dose dependent (Greenberg et al., 1990). Duodenal infusion of oleic fatty acids was more satiating than an infusion in which these fatty acids were in triglyceride form, and infusion of linoleic acid reduced sham-intake more potently than either oleic or linolenic acid (Greenberg and Smith, 1996). The satiating effect of medium-chain fatty acids differs as a function of chain length; duodenal infusion of lauric acid (C-12) produced a greater reduction of sham-feeding intake than infusion of capric acid (C-10). Caprylic acid (C-8) did not suppress sham-feeding (McCaffery et al., 1994).

D. Individual Differences

The obese Zucker rat differs from its lean counterpart by exhibiting hyperphagia when a high-fat diet is provided, in addition to other physiological differences that contribute to the obesity. Greenberg et al. (1986) found that this hyperphagia could not be explained by a blunted response to the satiating effect of fat, as lean and obese animals showed similar behavioral sensitivity to the satiating effect of duodenally infused fat. However, Greenberg et al. (1996) found that Osborne–Mendel rats, a strain of rats that is susceptible to dietary-induced obesity, were less sensitive to the satiating effect of duodenally infused fat than were S5B/PL rats, a strain that is resistant to dietary obesity. This difference was observed across two types of fat infusions: intralipid (a mixture of long-chain triglycerides [LCTs]) and linoleic acid. In addition to genetic differences in sensitivity to the satiating effect of fat, environmental influences can also play a role. Covasa and Ritter (2000) found that a high-fat maintenance diet blunted the satiating effect of intestinally infused fat.

III. SATIETY AFTER A MEAL

A frequently used strategy for evaluating the satiety produced by a food is the "preload-test meal" paradigm. In this paradigm, the subject first consumes a fixed amount of food, the "preload." Following an intermeal interval (typically <60 min), the subject consumes a "test meal," which is

a premeasured large quantity of food (or foods). The amount of test meal consumed serves as an index of satiety and is negatively correlated with the satiety value of the preload. Although preloads are most commonly consumed orally, they can also be delivered intragastricallyor intravenously, in order to eliminate sensory differences.

A. Fats vs. Carbohydrates

Overall, results from the animal literature have indicated that fat is less satiating than carbohydrate (Table 37.4). In comparisons of test meal intake following oral ingestion of either oil emulsion or an isocaloric glucose or sucrose solution (e.g., Tordoff et al., 1987; Warwick and Weingarten, 1994b; Lucas and Sclafani, 1999; Warwick et al., 2000), rats ate more following the fat preload across a variety of methodological manipulations. One study (Burggraf et al., 1997) compared intragastric and intravenous preloads. Rats were infused with either a lipid emulsion or an isocaloric glucose solution for 30 min before and during the 30-min test meal presentation. The fat infusion was less satiating under both conditions of site of infusion; site of infusion did not affect test meal intake. Although other studies have also found intragastric high-fat loads to be less satiating than isocaloric high-carbohydrate loads (e.g., Geliebter, 1979; Warwick, 1996, 2003), some (e.g., Maggio and Koopmans, 1982; Maggio et al., 1983) have found intragastric fat and carbohydrate to be equally satiating. The inconsistent results could be due to a variety of procedural differences including deprivation level, intermeal interval, rate of preload delivery, and method of preload delivery (intubation vs. catheter delivery).

Results from the human literature comparing the satiety produced by fat and carbohydrate, reviewed by Rolls and Hammer (1995), have been mixed. Although some of these studies have found a fat preload to be less satiating than a high-carbohydrate preload, others have found the preloads to be equally satiating (Table 37.5). In general, studies in which the weight or volume of the preload was held equal found no difference between the satiety produced by a high-fat and high-carbohydrate preload. However, relative responses to fat and carbohydrate differed across various subject types, as discussed below (“individual differences”).

B. Fatty Acid-Specific Effects

Studies conducted in humans have found that foods containing medium-chain triglycerides (MCTs) administered as preloads were more satiating than isocaloric foods containing LCTs (Rolls et al., 1988a). However, in rats, Maggio et al. (1983) found no difference in the relative satiating effect of corn oil and MCT oil. Another study found that relative to water-loaded controls, rats loaded with MCT showed greater satiety than did rats loaded with LCT during the first 3 h after the load. However, this effect was transient as 24-h intake did not differ as a function of fat type (Satabin et al., 1991).

Recent work has compared the satiating effects of three common dietary fats: olive oil, corn oil, and safflower oil in rat. Emulsions at 15% wt./vol. of each fat were prepared using the emulsifier sodium steroyl lactylate (Emplex, American Ingredients, Inc.) as described previously (Warwick and Weingarten, 1995). Fifteen rats consumed a 6 mL preload of emulsion, followed 20 min later by a 10% sucrose test meal. Each rat was tested with all emulsions. Both corn and safflower oil emulsions produced a significant suppression of test meal intake; the suppression of intake produced by olive oil just failed ($p = .08$) to attain statistical significance (Figure 37.2).

The within-subjects design of this study allowed investigation of whether the satiating effects of corn, olive, and safflower oils are mediated by similar or different mechanisms. Correlation coefficients were calculated among test meal intakes following these three fats: the rationale behind this strategy being that if two oils elicit satiety through the same physiological mechanism (e.g., receptor site), then the satiating effects of these two oils (as indexed by test meal intake) should be correlated. However, if the oils elicit satiety through different mechanisms (e.g., different receptor sites), then the satiating effects of these oils would not correlate. The satiating effects of corn and olive

TABLE 37.4
Comparisons of the Satiety Produced by Preloads High in Fat or Carbohydrate: Animal Studies*

Reference	Preload Volume	Nutrient Sources	Finding	Notes
Burggraf et al. (1997)	1.6 mL for 30 min before and during 30-min intake test	*Fat:* microlipid emulsion *CHO:* glucose	Fat less satiating	Loads delivered IV or IG between groups design
Geliebter (1979)	Two daily loads of 10 mL	*Fat:* corn oil *CHO:* corn starch or sucrose	Fat less satiating	Loads delivered IG
Maggio et al. (1983)	8 mL	*Fat:* corn oil emulsion *CHO:* glucose	*Obese rats:* fat less satiating at 10, 30 min. *Lean rats:* equal satiety	Loads delivered IG
Tordoff et al. (1987)	10 mL	*Fat:* corn oil emulsion *CHO:* glucose solution	Fat less satiating at 1 and 24 h, not 23 h	Loads consumed orally. Entire preload not always consumed
Warwick and Weingarten (1994b)	3 mL	*Fat:* corn oil emulsion *CHO:* sucrose solution	Fat less satiating	Loads consumed orally
McGuire and Warwick (1997)	2–8 mL	*Fat:* corn oil emulsion *CHO:* sucrose solution	*Sucrose testmeal:* oil less satiating *Oil testmeal:* oil and sucrose equally satiating. No compensation for increasing preload size	Loads consumed orally
Maggio and Koopmans (1982)	8 mL	*Fat:* emulsions of either SCT, MCT, or LCT *CHO:* glucose solution	Equal satiety produced by triglycerides and glucose	Loads delivered IG
Warwick (1996)	5 mL	*Fat:* corn oil *CHO:* sucrose	Fat less satiating	Loads delivered IG
Warwick et al. (2000)	2–8 mL	*Fat:* HF mixed diet *CHO:* HC mixed diet	Fat less satiating	Loads consumed orally

*CHO, carbohydrate; IV, intravenous; IG, intragastric; LCT, long-chain triglycerides; MCT, medium-chain triglycerides. All preloads isocaloric except as noted.

TABLE 37.5
Comparisons of the Satiety Produced by Preloads High in Fat or Carbohydrate: Human Studies

Reference	Weight or Volume Equal (HF vs. HC)?	Nutrient Sources	Finding	Notes
Rolls et al. (1988)	Yes	*Fat:* either LCT or MCT + 6% LCT	MCT more satiating at all preload levels for nondieters	Female dieters vs. nondieters
Shide et al. (1995)	Yes	*Fat:* intralipid *CHO:* dextrose	No difference in satiety	15- or 210-min nasogastric or IV infusion Males
Blundell et al. (1993)	No	Mixed meals	At some (not all) time points fat less satiating than CHO	Males
Caputo and Mattes (1992)	No	Mixed meals	Mean daily intake higher with high fat meal	Males and females. Fat preload contained 14% or 22.5% more kcal than the CHO preload
Van Amelsvoort et al. (1990)	No	Mixed meals	CHO more satiating	Males
Van Amelsvoort et al. (1989)	No	Mixed meals	Reduced hunger ratings 4 h after CHO compared to fat preload	Males
Driver (1988)	Yes	Skim milk, Skim milk + lactose, or full cream milk powder	No difference in satiety	Males and females. Information on calories not provided
Rolls et al. (1991)	Yes	Yogurts with either *CHO:* maltose or *Fat:* corn oil and cream emulsion	No difference in satiety	Males and females
Rolls et al. (1994)	Yes	Yogurts with either *CHO:* maltose or *Fat:* corn oil and cream emulsion	No difference for nondieting males; all others fat less satiating	Subjects varied in dieting status and body weight

de Graaf et al. (1992)	Yes	Drink with either *CHO:* maltodextrine maltose or glucose *Fat:* cream	No difference in satiety	Females
Foltin et al. (1992)	No	Range of fat levels	Effect of fat on satiety depends on fat level in preloads	Males. Protein content higher in fat meals. Fat preload contained 1%–5% more kcal than CHO preload
Foltin et al. (1990)	No	Mixed meals	No difference in satiety	Males
Geliebter (1979)	Yes	*Fat:* corn oil *CHO:* corn starch	No difference in satiety	Males
Warwick et al. (1993)	Yes	Drink with either *Fat:* corn oil or *CHO:* glucose polymer	No difference in satiety	Males and females
Rolls et al. (1988b)	No	Various foods	CHO more satiating	Females
Johnson and Vickers (1993)	No	*CHO:* pasta *Fat:* whipped cream	CHO more satiating	Females and males. Protein content higher in CHO
Westerterp-Plantenga et al. (1997)	No	High fat and high CHO versions of the same lunch	HF less satiating than HC lunch	Males and females
Cotton et al. (1994)	No	Mixed breakfasts	CHO more satiating	Males
Woodend and Anderson (2001)	Yes	*CHO:* sucrose in water *Fat:* safflower oil emulsion	CHO more satiating	Males
Robinson et al. (2005)	Yes	*CHO:* high-maltodextrin soup *Fat:* high-olive oil soup	Fat more satiating	Males; soup delivered IG

* CHO, carbohydrate; IG, intragastric; LCT, long-chain triglycerides; MCT, medium-chain triglycerides. All preloads isocaloric except as noted. All subjects normal weight, nonrestrained eaters except as noted.

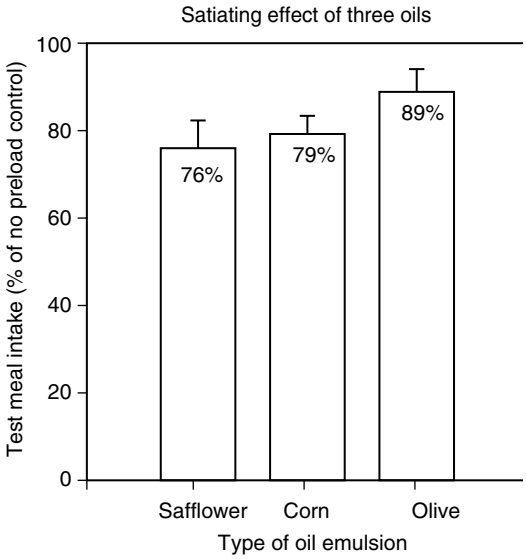

FIGURE 37.2 Test meal intake following preloads of three types of dietary fat.

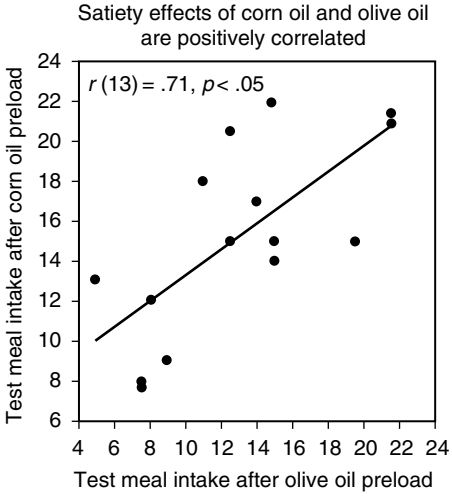

FIGURE 37.3 Correlation of test meal intake following preloads of corn and olive oil.

oils were significantly correlated $r(13) = .71$, $p < .05$ (Figure 37.3), but no other correlations were significant. This suggests that corn and olive oils produce satiety through a similar mechanism, whereas safflower oil exerts its satiating effect though a different mechanism.

Woltman et al. (1995) compared effects of intraduodenal infusions of triolein, oleic acid, and oleic acid + monoolein (2:1 ratio) on subsequent 4-h intake. The three infusions were equivalent with regard to oleic acid content. Infusions of oliec acid and 2:1 oleic:monoolein were equally satiating, and the satiating effect was dose dependent. In contrast, triolein infusion was markedly less satiating. These findings demonstrate that the breakdown products of triglyceride (monoglyceride and free fatty acids) are more satiating than the intact triglyceride, and are consistent with the finding cited previously (Greenberg and Smith, 1996) in which infusion of fatty acids into the duodenum reduced sham-feeding intake more potently than infusion of triglyceride. However, Maggio

and Koopmans (1982) found intragastric triolein and oleic acid + glycerol to be equally satiating. Methodological differences between these studies, which in addition to infusion site included the animals' degree of deprivation and the type of food consumed during the test meal, may explain these inconsistent findings.

C. Individual Differences

The satiety produced by intragastric nutrient infusion has been compared in lean and genetically obese rats. In lean rats, corn oil, MCT, and glucose were equally satiating as measured by test meal intake given 20 min after the preload, whereas in obese rats corn oil was the less satiating nutrient (Maggio et al., 1983). In humans, Rolls et al. (1994) compared the satiating effects of a fat preload and a carbohydrate preload in subjects who differed in their degree of concern about food intake and body weight ("eating restraint"). In normal-weight unrestrained males, fat and carbohydrate were equally satiating. In normal-weight restrained males and in females (lean and obese, restrained and unrestrained) fat was less satiating than carbohydrate. Thus, there are individual differences, in both humans and animals, in the potency of the satiety produced by fat.

To investigate the relationship between individual differences in sensitivity to the postprandial satiety effect of fat and spontaneous daily intake, outbred Long–Evans rats consumed chow ad lib. for 3 baseline days, and then for further 3 days ate a supplement of 48 kcal/day of fat (corn oil emulsion) plus ad lib. chow. Each rat's sensitivity to the satiating effect of fat was indexed by chow intake during the fat supplement phase as a percent of baseline chow intake (thus a lower percent indicated greater sensitivity). Individual differences in sensitivity were reliable across two replications and predicted spontaneous daily kcal intake when animals were allowed to consume a high-fat food ad lib. for 16 days: animals with the least sensitivity to the satiating effect of fat had the highest ad lib. intake (Warwick and Rice, 2003). In humans, Blundell et al. (2005) found that individuals who habitually consumed a high-fat diet and were overweight (termed susceptible) showed a weaker satiety response (suppression of hunger) to a high-fat preload than did individuals who also consumed a high-fat diet but remained lean (termed resistant).

IV. PHYSIOLOGICAL MECHANISM(S) MEDIATING THE SATIATING EFFECT OF FAT

A preabsorptive locus for the anatomical site mediating the satiety produced by LCT (corn oil, intralipid) in rat is indicated by a series of studies by Greenberg and colleagues. In these studies, the satiety produced by fat infusion was indexed by sham-feeding intake. Duodenal infusion of intralipid (LCT) suppressed sham-feeding, whereas intravenous (i.v.) infusion had no effect on sham-feeding (Greenberg et al., 1990, 1993). Although this earlier work used an infusion rate that may have exceeded the physiological rate of delivery of fat into the duodenum, recent data (Greenberg and Strohmeyer, 1997) confirm that a slower rate of intraduodenal infusion of intralipid is satiating. This is consistent with findings from a recent study (Burggraf et al., 1997) in which rats received lipid infusions intragastrically or intravenously continuously during a 17-h period of food access. Intragastric infusion reduced spontaneous food intake to a greater extent than isocaloric infusion of lipid given intravenously.

Researchers have also compared different intestinal sites for their sensitivity to fat's satiating effect. Welch et al. (1988) found that corn oil emulsion infused directly into the jejunum reduced food intake in healthy human volunteers; a less pronounced reduction of food intake was also noted when lipid was infused into the ileum. In rat, duodenal infusion of oleic acid was more inhibitory of food intake than was ileal infusion, whereas glucose infusion showed the opposite pattern (Woltman and Reidelberger, 1995).

Observations (Rolls et al., 1988; Satabin et al., 1991) that MCTs and carbohydrate were more satiating than LCTs implicate the liver as mediating the satiety effects of nutrients. MCTs, similar

to carbohydrates, are absorbed from the intestine into the portal vein and thus flow through the liver, whereas long-chain fats are secreted into the lacteals and bypass the liver. The liver, as a source of satiety signals, has also been indicated by other findings (Friedman, 1991). Afferent signals mediating the satiety produced by at least one fat, oleic acid, are transmitted vagally, since total subdiaphragmatic vagotomy produces insensitivity to the satiating effect of intraduodenal oleic acid infusion (Yox et al., 1991).

The role of the duodenal peptide cholecystokinin (CCK) in the satiating effect of fat is demonstrated by multiple lines of evidence. Administration of the CCK-A antagonist lorglumide attenuated the satiating effect of intraduodenal intralipid (Greenberg et al., 1989) and intraduodenal oleic acid (Yox et al., 1992). Another CCK-A antagonist, devazepide, reversed the satiating effect elicited by intraduodenal oleic acid, but only when relatively small loads of oleic acid were given (Woltman et al., 1995). This suggests that additional, CCK-independent mechanisms mediate the satiating effect of oleic acid, and that these additional mechanisms were more potently stimulated by the higher doses of oleic acid. Measurement of endogenous systemic CCK levels associated with infusion of various nutrients revealed no correlation between the nutrient's satiating effect and plasma CCK levels, suggesting that CCK receptors mediating satiety are not stimulated by bloodborne CCK (Brenner et al., 1993).

V. LONG-TERM BODY WEIGHT REGULATION

A. Fats vs. Carbohydrates

As stated at the beginning of this chapter, a high-fat diet often elicits hyperphagia, a caloric intake that exceeds energy expenditure. If this hyperphagia is sustained, as it typically (although not inevitably, see Boozer, 1997) is, weight gain will result. A dose–response relationship between dietary fat content and spontaneous daily kcal intake has been observed (Warwick, 2003). It is notable that high-fat foods need not be the sole nutrient source in order to promote greater weight gain than high-carbohydrate foods. Rats consuming 30 mL (69 kcal) per day of high-fat liquid diet (HF, Table 37.2) in addition to ad lib. chow gained more weight over 16 days than rats consuming an identical number of calories from a high-carbohydrate liquid diet (HC). A similar finding was noted when the daily ration was smaller (32 kcal) and consisted of pure fat (corn oil emulsion) or pure carbohydrate (sucrose solution) (Z. S. Warwick, unpublished data). Previous studies in which intake of dietary supplements of fat or carbohydrate were not equated had similar findings (Sclafani et al., 1993). Earlier studies compared the effects of fixed daily loads of various macronutrients delivered intragastrically on spontaneous food intake and weight gain. Geliebter et al. (1984) gave rats daily intragastric loads of either fat (corn oil) or carbohydrate (sucrose) for 6 weeks, while Liu and Yin (1974) gave intragastric loads of either fat (shortening) or carbohydrate (glucose) for 5 weeks. In both studies the fat- and carbohydrate-loaded groups had similar ad lib. kcal intake and weight gain. The inconsistent findings from studies in which dietary supplements were consumed orally (Sclafani et al., 1993; Warwick et al., 2000) compared with studies in which supplements were intubated may reflect the different route of nutrient delivery and/or other methodological differences.

B. Fatty Acid-Specific Effects

Medium-chain fatty acids are less obesogenic than long-chain fatty acids. Rats fed diets rich in MCT gained less weight than animals consuming a diet containing LCT (Bray et al., 1980; Geliebter et al., 1983). The lesser weight gain associated with MCT can be due to lower daily kcal intake (Edens and Friedman, 1984), greater energy expenditure via postprandial thermogenesis (Seaton et al., 1986), or a combination of these factors.

A diet high in saturated fat (from beef tallow) promoted greater daily kcal intake than a diet high in polyunsaturated fat (corn oil), an effect observed across two levels (5% and 34%) of dietary fat

(Mullen and Martin, 1990). Weight gain was greatest in rats fed a 34% tallow diet. In one study, a diet high (45% of kcal) in safflower oil produced less weight gain than a diet containing the same proportion of kcal from tallow (Shimomura, cited in Hill et al., 1993), while another comparison of these two fat sources, at slightly lower levels (32%) of dietary kcal failed to reveal differential weight gain (Awad, cited in Hill et al., 1993). A comparison of diets formulated with either safflower or flaxseed oil found no difference in energy intake over 34 days, at two levels of fat content (Rice and Corwin, 2002). Hill et al. (1993) fed rats with diets containing fish oil, corn oil, lard, or MCT oil as 45% of kcal for 6 months; no differences in body weight gains were noted, although across the entire study, average kcal intake by fish-oil fed rats tended to be lower than lard- and MCT-fed rats.

Lucas et al. (1989) gave rats ad lib. access to either pure corn oil or pure vegetable shortening in addition to ad lib. chow for 36 days. The shortening group ate more total kcal (fat + chow) and gained more weight than the corn oil group. However, when the diet options were presented as emulsified gels, no differences in intake or body weight were observed. Taken together, these findings indicate that differential responding to various fats is attributable not only to differences in fatty acid composition, but also to other factors such as physical form.

C. Individual Differences

In rats, differences in the obesity-promoting effects of high-fat diets have been found both across (Schemmel et al., 1970) and within (Levin et al., 1997) strains. Rats susceptible to diet-induced obesity differ metabolically from rats that do not gain excess weight when put on a high-fat diet (Boozer, 1997; Levin et al., 1997). In a group of ten rats fed a high-fat liquid diet (Table 37.2), a significant correlation was found between kcal intake and weight gain (Figure 37.4). However, the proportion of variance in weight gain accounted for (r^2) by kcal intake was .37, indicating that 63% of the variance in weight gain was attributable not only to kcal intake but also to other factors such as individual differences in metabolic rate and/or activity.

VI. LEARNED CONTROLS OF SATIETY: FATS VS. CARBOHYDRATE

Rats and humans can learn to associate a food's flavor (the composite of its taste/smell/texture) with its postingestive effects (e.g., satiety, relief from nutritional deficiency), a process called

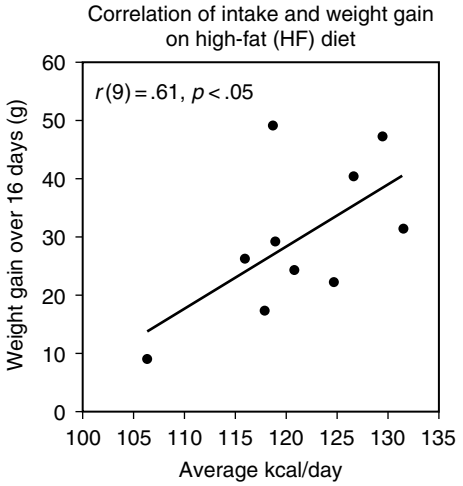

FIGURE 37.4 Relationship between caloric intake and weight gain on a high-fat diet.

flavor-postingestive consequence (or calorie-based learning). The behavioral evidence of such learning is modification of intake in response to the flavor, independent of the unique postingestive effects of the food. This is illustrated by the following example (from Warwick et al., 1997): rats repeatedly consumed a fixed amount (e.g., 30 mL) of a concentrated nutrient solution (1.6 kcal/mL) containing a distinctive flavor such as grape, and had an equal number of trials consuming 30 mL of dilute nutrient solution (0.2 kcal/mL) containing a different flavor such as cherry. Then a "two-bottle test" was conducted, in which cherry- and grape-flavored solutions were offered simultaneously. Importantly, in this test both solutions had identical nutrient density (0.9 kcal/mL), which was midway between the densities used in the initial training. When the nutrient used was carbohydrate (sucrose, glucose, fructose, maltodextrine), in two-bottle test rats consumed *less* of the flavor previously paired with the more concentrated nutrient solution (grape in the example given). This is interpreted as indicating a learned control of satiety: rats had learned during training that grape was associated with strong satiety signals elicited by the concentrated nutrient, while cherry was associated with weak or no satiety signals. When given a choice in the two-bottle test, rats consumed less of the grape-flavored solution since they anticipated its greater satiating effect (which was, however, not realized since in the two-bottle test the nutrient density of grape and cherry solutions were equated).

In contrast, when fat (corn oil) was used as the nutrient, rats did not exhibit learned satiety in the two-bottle test. However, when these same corn oil emulsions that failed to entrain learned satiety were sweetened with noncaloric saccharin during training, rats did exhibit learned satiety by consuming less of the flavor previously paired with the more concentrated fat emulsion (Figure 37.5).

This is consistent with earlier work by Booth (1972), who reported that the acquisition of conditioned satiety to solid foods differing in fat content depend on the particular taste–odor cues used. Lucas and Sclafani (1989) found that saccharin facilitated acquisition for a flavor paired with intragastrically administered fat, probably because it increased the quantity of fat infused. Differential intake can be ruled out as an explanation of saccharin's facilitation of learned satiety in the Warwick et al. (1997) study, since intake was equated at 30 mL per trial during training. There are a number of

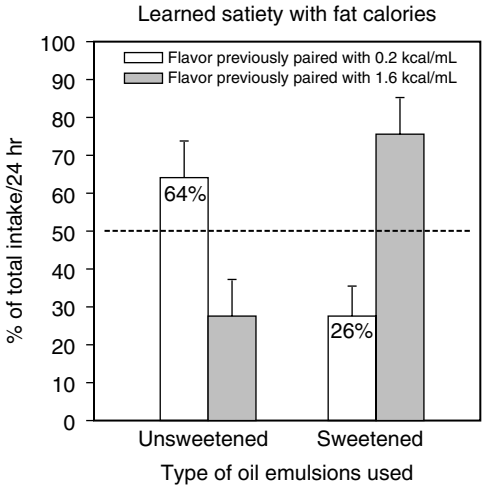

FIGURE 37.5 Two-bottle test intake in rats trained with unsweetened (left bars) or sweetened (right bars) distinctively flavored corn oil emulsions at 0.2 kcal/mL and 1.6 kcal/mL. Both flavors presented in 0.9 kcal/mL emulsion in two-bottle test. Dashed line indicates 50% intake (no preference). Percentages within bars indicate intake of the 0.2 kcal/mL-paired flavor as a percent of total two-bottle test intake.

possible explanations, not mutually exclusive, for the finding that saccharin enhanced conditioned satiety entrained by fat. Tasting saccharin alters the digestive profile of intragastrically administered corn oil (Ramirez, 1985), which may under certain conditions enhance its satiating effect. A human study comparing nutritionally identical preloads differing in sweetness found the sweeter preload to be more satiating (Warwick et al., 1993). Another possibility relates to the observation that rats trained with sweetened oil emulsions appeared to consume the 30 mL of training solution more rapidly than rats trained with unsweetened emulsions, although consumption time was not directly measured. More rapid consumption would produce a bigger calorie bolus that would presumably increase satiety. Finally, "flavor–flavor" conditioning may also have been a factor; although both concentrations of emulsion contained equal amounts of saccharin (0.4%), the more concentrated oil emulsion may have partially masked saccharin's sweetness with the result that the less-concentrated emulsion had greater sweetness intensity. Since association of a flavor with sweetness is sufficient to condition a preference (Warwick and Weingarten, 1994a), preferential intake of the flavor previously paired with the dilute fat emulsion in two-bottle testing may have been due to this flavor's previous association with greater sweetness.

Additional evidence that fat-entrained flavor-cued conditioned satiety is less readily acquired comes from recent work in which the number of training trials was varied. Separate groups of rats were trained with two distinctively flavored concentrations (0.2 and 3.6 kcal/mL) of either sucrose solution or corn oil emulsion. Learned satiety (i.e., lesser intake of the flavor previously paired with the higher concentration) was evident after only two training trials with each concentration for sucrose-trained animals, but required at least twice as many trials for fat-trained animals (C. Revelle, unpublished data).

Although flavor-cued learned satiety represents an inhibitory effect on meal size (negative feedback); calorie-based learning can also exert a stimulatory effect on meal size (positive feedback) by increasing the acceptance and/or preference of an associated flavor. "Flavor preference learning" is observed when a flavor previously paired with calories is preferred, in two-bottle testing, to a flavor paired with fewer or no calories. All energy-yielding substances (fat, carbohydrate, protein, alcohol) can reinforce such flavor preference learning (e.g., Mehiel and Bolles, 1988; Perez et al., 1995); the energy must be metabolically available since diabetic rats did not learn to acquire a preference for a flavor paired with carbohydrate, although they did acquire a fat-based preference (Tordoff et al., 1987). In a recent study comparing the reinforcing effect of various fat sources in flavor preference learning (Ackroff et al., 2005), safflower and corn oils tend to condition stronger preferences (relative to a water-paired flavor) than did beef tallow and vegetable shortening. (For discussion of the interaction of the behaviorally opposing effects of learned flavor preference and learned satiety on the control of meal size, see Warwick, 1996; Lucas et al., 1998; Ackroff and Sclafani, 2006.)

VII. SUMMARY AND CONCLUSIONS

When compared to an isocaloric quantity of carbohydrate, dietary fat is often observed to exert a less potent satiating effect during a meal and also after a meal. The higher caloric density of fat plays a role: per kcal, fat produces less stomach distention, which is known to generate potent satiety signals. However, even when the caloric density of high-fat and high-carbohydrate foods is equated, fat is often less satiating. Individual differences in sensitivity to the fat-induced satiety have been found, and various fats and their constituent fatty acids differ in their satiating effects. Learned orosensory control of intake is less readily acquired when the calorie source is fat, although experimental conditions such as the composition of the maintenance diet and whether or not the fat is associated with a sweet taste moderate this effect. Further research is needed to clarify the variables—such as taste, density, subject characteristics—that mediate the relative satiating effects of fat and carbohydrate, and the mechanisms by which these variables exert their effect.

38 Fatty Acids and Growth and Development

Margit Hamosh

CONTENTS

I. INTRODUCTION

This chapter will address several aspects of fatty acid requirements specific to the perinatal and neonatal period. It is not intended to cover all aspects of fatty acid needs and metabolism during development, since these topics have been reviewed extensively (Hamosh, 1987, 1988, 1991a; Innis, 1991, 1993; Giovannini et al., 1995; Koletzko, 1997). The supply of fatty acids to the newborn is in great measure dependent on the digestive and absorptive maturity of the gastrointestinal system (Hamosh, 1996; Hamosh and Hamosh, 1999); therefore, this aspect of neonatal function will be briefly reviewed.

II. FETAL PERIOD

During fetal development, fatty acids are transferred from mother to fetus through the placenta (Soderhjelm, 1953; Koren and Shafrir, 1964). The magnitude of the transfer, depending on species (Koren and Shafrir, 1964; Hershfield and Nemeth, 1968), is a function of maternal–fetal gradient (Nobel et al., 1979; Knopp, 1986), fetal blood albumin concentration (Hershfield and Nemeth, 1968; Dancis et al., 1977; Elphick and Hull, 1977b; Thomas and Lowy, 1983; Hendrickse et al., 1985), occurs rapidly (within minutes) (Portman et al., 1969), and is subject to maternal metabolic regulation (higher in fasted animals or after heparin administration to the mother) (Muller et al., 1964; Edison et al., 1975).

TABLE 38.1
Fatty Acids in the Fetus

Placental transfer from mother; magnitude depends upon species and is a function of
Maternal–fetal gradient
Fetal blood albumin concentration
Possibly fatty acid chain length subject to maternal metabolic regulation
De novo synthesis
High fetal hepatic lipogenesis in late gestation precursors are
Glucose, glycogen, lactic acid, ketone bodies

The controversy whether fatty acid chain length affects the placental free fatty acid (FFA) transfer rate is still not settled (Dancis et al., 1974; Elphick and Hull, 1977b). Uptake of FFAs by the placenta and synthesis of triglycerides suggest that the placenta may protect the fetus from excessive fatty acid transfer (Freinkel, 1965; Diamant et al., 1980). The significance of FFA transport to the fetus is supported by a relationship between maternal fatty acid levels and infant birth weight (Knopp et al., 1991). Triglyceride fatty acids are transferred to the fetus only after release of the fatty acids by placental lipoprotein lipase (Mallov and Alousi, 1965; Elphick and Hull, 1977a; Clegg, 1981; Thomas et al., 1984). Estimates of the significance of placental transfer of lipids vary from 20% of the amount required for the accumulation of fetal adipose tissue during the last trimester of pregnancy (Dancis et al., 1973) to 50%–100% of fetal needs (Elphick et al., 1977; Coleman, 1986) and vary according to species (Kimura, 1991). Because placental transfer of fatty acids cannot account for all fetal needs, endogenous synthesis of fatty acids by the fetus may be important (Kimura, 1991). Indeed, fetal hepatic lipogenesis is high in late gestation at a time of rapid adipose tissue accumulation and is higher than in the adult (Villee and Hagerman, 1958; Roux, 1966; Ballard and Hanson, 1967; Taylor et al., 1967). Precursors of fatty acid synthesis in the fetus are glycogen, glucose, lactate (especially in the lung), and ketone bodies (mainly in liver and brain) (Ville and Hagerman, 1958; Roux, 1966; Ballard and Hanson, 1967; Taylor et al., 1967; Edwards, 1974; Seccombe et al., 1977; Maniscalco et al., 1982; Farrell and Bourbon, 1986). Increased lipogenesis in hyperglycemic fetuses suggests that availability of glucose controls fetal lipogenesis (Ktorza et al., 1983; Williamson, 1988) (Table 38.1).

III. NEONATAL PERIOD

At birth, there is a sudden change from a high-carbohydrate to a high-fat diet. Fatty acids in milk or formula are, however, present almost exclusively as triglycerides rather than as fetal FFAs transferred through the placenta to the fetus. Although classic (colipase-dependent) pancreatic lipase is poorly developed at birth, the newborn is able to digest milk and formula triglyceride with the aid of gastric lipase and probably also pancreatic carboxyl ester lipase and, in the case of the breast-fed infant, the bile salt-dependent lipase of human milk (Hamosh et al., 1985; Hamosh, 1994a,b, 1996; Hamosh and Hamosh, 1999). Fatty acids of animal origin are usually unbranched, monocarboxylic acids containing an even number of carbon atoms varying from 2 to 24 in chain length.

The fatty acid chains may be either saturated or unsaturated (Table 38.2). Most biologically important fatty acids are esterified with glycerol, whereas a small portion are linked with other compounds or are free. Fatty acids are generally classified according to chain length (short C_2C_6; medium C_8–C_{10}; intermediate C_{12}–C_{I4}, and long chain = C_{16}) and degree of desaturation; that is, saturated (no double bond), monounsaturated (one double bond), and polyunsaturated (two or more double bonds). The double bonds occur in two isomeric forms: *cis* and *trans.* Most plants and mammals contain fatty acids of the *cis* configuration, which is more flexible and has greater fluidity than

TABLE 38.2
Structure of Fatty Acids

Descriptive Name	Systematic Name	Carbon Atoms (Chain Length)	Double Bonds	Position of Double Bonds[a]	Position and Terminal Double Bond	Formula
Short-Chain FA						
Acetic		2	0			C_2:0
Butyric		4	0			C_4:0
Caproic	Hexanoic	6	0			C_6:0
Medium-Chain FA						
Caprilic	Octanoic	8	0			C_8:0
Capric	Decanoic	10	0			C_{10}:0
Intermediate-Chain FA						
Lauric	Dodecanoic	12	0			C_{12}:0
Myristic	Tetradecanoic	14	0			C_{14}:0
Long-Chain FA						
Palmitic	Hexadecanoic	16	0			C_{16}:0
Palmitoleic	Hexadecaenoic	16	1	9	n-7	C_{16}:1n7
Stearic	Octadecanoic	18	0			C_{18}:0
Oleic	Octadecaenoic	18	1	9	n-9	C_{18}:1n9
Linoleic[b]	Octadecadienoic	18	2	9,12	n-6	C_{18}:2n6
alpha-Linolenic[b]	Octadecatrienoic	18	3	9,12,15	n-3	C_{18}:3n3
gamma-Linolenic[b]	Octadecatrienoic	18	3	6,9,12	n-6	C_{18}:3n6
Homolinolenic[b]	Eicosatrienoic	20	3	8,11,14	n-6	C_{20}:3n6
Arachidonic[b,c]	Eicosatetraenoic	20	4	5,8,11,14	n-6	C_{20}:4n6
	Eicosapentaenoic	20	5	5,8,11,14,17	n-3	C_{20}:5n3
Cervonic[b,d]	Docosahexaenoic	22	6	4,7,10,12,15,19	n-3	C_{22}:6n3

[a] Position of the one or more double bonds listed according to the D numbering system. In this numbering system, only the first carbon of the pair is listed; that is, 9 means position 9, 10, starting from the carboxyl end.
[b] Essential fatty acids.
[c] No commonly used descriptive name.
[d] In the n numbering system, only the first double bond from the methyl end is listed and, as above, only the first carbon of the pair is written.

Source: From Hamosh, M. (1998b). *Biochem. Soc. Trans.* 26:96–103.

the *trans* isomeric form formed in ruminants' stomach by bacteria or by the technical hydrogenation of fat. *Trans* fatty acids have lower melting points, are less fluid than their *cis* isomers, and are structurally and functionally similar to saturated fatty acids. Polyunsaturated fatty acids (PUFAs) of the n-3 and n-6 families are not synthesized by humans and higher animal species and have to be added to the diet. Because of their important physiological functions, they are considered essential fatty acids (EFA). In general, stored lipid contains higher amounts of saturated fatty acids than do structural lipids, which contain a higher percentage of PUFAs (Figure 38.1). The function of lipids in mammals is listed in Table 38.3.

Over 95% of the fat in human milk is present in eight major fatty acids (C_{10}–C_{22}:6n-3) (Table 38.4). The fatty acids in human milk (and in the milk of other species) are present mainly (98%–99%) as triglycerides (Bitman et al., 1983b) (Table 38.5). FFAs in human milk are an indicator of poor collection and storage techniques and are a sign of lipolysis after collection (Bitman et al., 1983a).

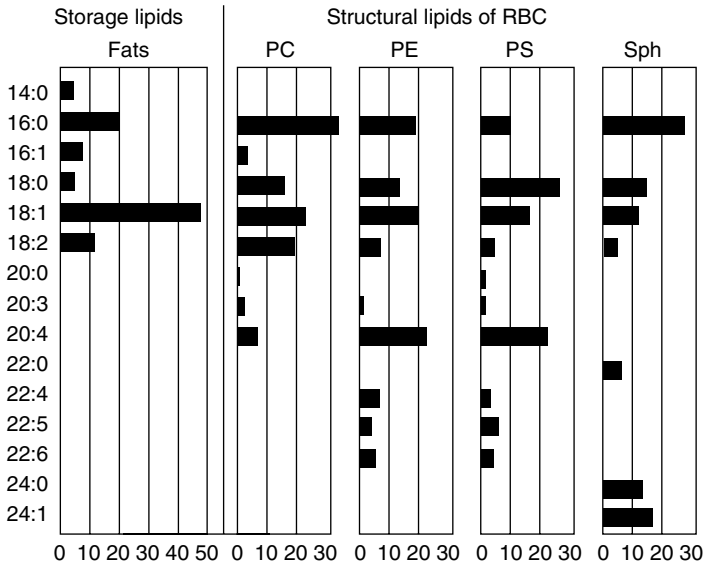

FIGURE 38.1 Fatty acid composition of storage and structural lipids. Storage lipid is triglyceride, whereas structural red blood cells (RBC) lipids are phospholipids and sphingomyelin: PC, PE, PS are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine, respectively, Sph is sphingomyelin. *(*From R.W. McGilvery and G.W. Goldstein (1983). *Biochemistry: A Functional Approach*, Philadelphia, Saunders.)

TABLE 38.3
Function of Lipids in Mammals

Lipid Class	Function
Glycerides	Fatty acid storage, metabolic intermediates
Phospholipids	Membrane structure, lung surfactant
Sterols	
Cholesterol	Membranes and lipoprotein structure; precursor of steroid hormones; degradation products are bile salts important in fat digestion and absorption
Cholesteryl ester	Storage and transport
Fatty acids	Major energy source, components of most lipids, precursors of prostaglandins, essential for normal brain development (long-chain polyunsaturated fatty acids)

Source: From Hamosh, M. (1998b). *Biochem. Soc. Trans.* 26:96–103.

Medium- and intermediate-chain fatty acids amount to 10% of total fatty acids in mature milk of mothers of term infants but contribute 17% of total fatty acids in milk produced by mothers of preterm infants (Bitman et al., 1983b).

Saturated fatty acids constitute 42% and unsaturated fatty acids account for 57% of total lipid in human milk. Linoleic acid concentrations are higher in recent studies (Bitman et al., 1983b) than in earlier reports (Jensen et al., 1980) and reflect the higher intake of polyunsaturated fats by the American population. EFA contents are higher in colostrum and transitional milk than in mature milk (Bitman et al., 1983b). Long-chain PUFAs (LCPUFAs) derived from linoleic acid (20:2n-6, 20:3, 20:4, 22:5n-6) and from linolenic acid (20:5, 22:5n-3, 22:6n-3) show a similar decrease throughout lactation. The level of these fatty acids is significantly higher in colostrum and milk of mothers of preterm infants than mothers of full-term infants (Bitman et al., 1983b). Thus, human milk provides the essential long-chain unsaturated fatty acids linoleic (C18:2n-6) and linolenic (C18:3n-3), as well

TABLE 38.4
Fatty Acid Composition (%) of Human Milk (Comparison of Milk[a] from Mothers Who Delivered at 26–30 Weeks [VPT], 31–36 Weeks [PT], and 37–40 Weeks [T] of Pregnancy)

	Fatty Acid	VPT[b] 26–30 Weeks	PT 31–36 Weeks	T 37–40 Weeks
Capric	10:0	1.37 ± 0.17	1.27 ± 0.18	0.97 ± 0.28
Lauric	12:0	7.47 ± 0.72	6.55 ± 0.77	4.46 ± 1.17

as their longer chain elongation and desaturation derivatives, such as arachidonic acid (AA, C20: 4n-6) and docoshexaenoic acid (DHA, C22:6n-3).

Although EFA deficiency is rare, it might occur (Holman et al., 1972). EFA deficiency is assessed by the triene:tetraene ratio. The n-9, n-6, and n-3 unsaturated FAs compete for the same desaturase enzymes in their metabolic pathways. Desaturation of n-9 FAs leads to the formation of trienes, whereas desaturation of n-6 FAs leads to formation of tetraenes. The n-6 and n-3 families have greater affinity for these desaturases than does the n-9 structure (oleic acid), resulting in competitive inhibition of the production of trienes. Deficiency in linoleic acid (18: 2n 6) leads to lower production of tetraenes, whereas the production of trienes is increased. A triene:tetraene ratio of >0.4 was considered to be indicative of EFA deficiency (Holman, 1979); however, currently a ratio of 0.2 is considered a mere accurate indicator of the presence of mead acid (eicosatrienoic acid, C20: 3n-9). The above ratio is, however, not an indicator of deficiency of only n-6 or only n-3 fatty acids or of their supply to the infant (Innis, 1991). Furthermore, this ratio is not an indicator of deficiency or sufficiency of DHA or AA.

Infants fed parenterally have to be given lipid, since EFA deficiency interferes with normal lung surfactant synthesis (essential for pulmonary function) (Friedman and Rosenberg, 1979) and platelet function (Friedman et al., 1977).

The fatty acid profile of human milk is generally used as the "gold standard" for the composition of the fat in infant formulas. It has to be taken into account, however, that the fatty acid composition of milk fat changes in the course of lactation and that it is highly dependent on maternal diet. Thus, although the amount of fat in milk seems to be constant throughout lactation and is typical of each woman (Bitman et al., 1983b), the composition of fat (i.e., the fatty acid profile of milk triglyceride) is highly variable and dependent on diet (Insull et al., 1959; Craig-Smith et al., 1984; Harris et al., 1984; Michaelsen et al., 1994). Indeed, dietary effects on milk fatty acid composition are detectable within several hours after consuming a meal (i.e., the time necessary for fat absorption and digestion) and, after incorporation of the circulating triglyceride fatty acids into mammary gland triglyceride (Hamosh et al., 1970; Hamosh and Hamosh, 1983), the time necessary for the formation of milk fat globules and their secretion into milk (Stemberger and Patton, 1981; Hachey et al., 1987). Table 38.6 lists the factors that affect milk fat content and composition. Length of gestation and length of lactation affect especially the content of the lipids that constitute the milk fat globule membrane, phospholipids, and cholesterol (Bitman et al., 1983b). The latter are higher in the early stages of lactation (colostrum and transitional milk), because the milk fat globules are much smaller than in mature human milk. It has long been known that the milk fat content changes drastically during each feed (Macy et al., 1931; Hytten, 1954). More recent studies have shown that the mechanism for endogenous synthesis of fatty acids seems to be exhausted in women of very high parity (Prentice et al., 1989), that infants who receive low-fat containing milk tend to nurse more frequently and for longer periods, thereby causing an increase in milk volume (Tyson et al., 1992), and that there is a strong positive relationship between weight gain during pregnancy and milk fat content (Michaelsen et al., 1994).

IV. *TRANS* FATTY ACIDS

The relationship between increased maternal consumption of industrially hydrogenated unsaturated vegetable oils (margarine) (Senti, 1985), which is high in *trans* fatty acids and an increase in these fatty acids in mother's milk has led to an evaluation of these fatty acids during development. *Trans* fatty acids are not natural components (most unsaturated fatty acids have the *cis* configuration) and are formed during hydrogenation in the process of the manufacture of margarine. The common *trans* fatty acids are the monounsaturated elaidic (*cis*: 1n-9t) and *trans* vaccenic (*cis*: 1n-7t) acids and the *trans* polyunsaturated linolelaidic (*cis*: 2n-6t) acid (Putnam et al., 1982; Dotson et al., 1992; Koletzko, 1997). Recent studies suggest that *trans* fatty acids impair the conversion of linoleic acid to its long-chain metabolites *in vivo* in animals and *in vitro* in animal cells and human fibroblasts,

TABLE 38.6
Factors That Affect Milk Fat Content and Composition

Variable	Change	Reference
Gestation	LCPUFAs higher in preterm[a] and transitional[b] milk	Bitman et al. (1983b)
Lactation stage	Phospholipid, cholesterol higher in colostrums (preterm[a] > term[a])	Bitman et al. (1983b)
Parity	P 10+: lower endogenous synthesis of FAs (C_6–C_{16})	Prentice et al. (1989)
Volume	Low milk fat concentration associated with high volume	Tyson et al. (1992)
Feed	Fat: fore < mid < hind milk	Macy et al. (1931); Hytten (1954)
Diet		
High-CHO intake	Increase in endogenous synthesis of FA (C_6–C_{16})	Insull et al. (1959)
Low-caloric intake	Increase in palmitic acid (C_{16})	Insull et al. (1959)
Hydrogenated fat	Increase in *trans* fatty acids	Chappell et al. (1985); Craig-Smith et al. (1984)
High LCPUFAs	Increase in LCPUFAs	Harris et al. (1984)
Pregnancy weight gain	Positively associated with milk fat content	Michaelsen et al. (1994)

[a] FA, fatty acids; CHO, carbohydrate; LCPUFAs, long-chain polyunsaturated fatty acids. *Preterm, term* refer to milk or colostrums of women who deliver prematurely (26–37 weeks gestation) or at term (37–40 weeks gestation).
[b] *Transitional* refers to the period between secretion of colostrums and mature milk (week 2–3 of lactation).

apparently caused by competitive inhibition of desaturation enzymes (Mahfouz et al., 1980, 1981; Koletzko, 1992, 1997). Indeed, inverse correlations between *trans* fatty acids and LCPUFAs have been reported in human premature infants and in healthy children (Koletzko, 1992, 1997; Decsi and Koletzko, 1995b). Koletzko (l997) suggests that these findings are compatible with impairment of LCPUFA synthesis in humans, which is a potentially serious side effect of *trans* fatty acids in view of the importance of LCPUFA availability for infant growth and development. An impairment of growth has also been attributed to *trans* fatty acids as seen in pre- and postnatal studies in animals (Koletzko, 1991) and in premature infants studied at birth (Koletzko, 1992).

The potential sources of *trans* fatty acids in infant formulas are partially hydrogenated vegetable oils or *trans* fatty acids formed during the formula manufacturing process (Carrol, 1989).

Current regulatory bodies restrict the upper limit of *trans* fatty acid content of infant formulas to 4% of total fat (Scientific Committee for Food, 1993) or to none (Life Sciences Research Office, 1998).

Since the human milk fat composition reflects the composition of the fat consumed by the mother, general consumption of fatty acids as well as transfer through milk to the infant can be assessed. In general, consumption of Western diets that contain higher levels of *trans* fatty acids leads to higher *trans* fatty acids in maternal milk. Table 38.7 summarizes some of the data on *trans* fatty acids in human milk and compares them with the concentrations in bovine milk. Consumption of a diet low in animal fat and high in carbohydrate and fiber leads to lower levels of *trans* fatty acids in the milk of Nigerian women.

In Western countries where consumption of olive oil is high (France, Spain, and Italy), the human milk *trans* fatty acid concentration tends to be lower (Billeaud et al., 1997). Data on *trans* fatty acid consumption in the United States across ages 2–70 years have recently been published for a cohort of 11,258 subjects (Allison et al., 1999). It is interesting that identical levels of *trans* fatty acids (2.6% of total energy, 7.4% of fat energy) are consumed irrespective of age (Allison et al., 1999). Furthermore, consumption of *trans* fatty acids in the United States has not changed markedly in the past decade (Hunter and Applewhite, 1991).

Eur. J. Nutr*. 30:289–297; (4) From Jensen, R.G. (1995). *Handbook of Milk Composition*, Academic Press, San Diego, CA, p. 566.

In view of the recent (October 2006) voluntary elimination of *trans* fatty acids by several fast food chains in the United States, it can be assumed that the food industry will follow suit and the general content of *trans* fatty acids will be lowered in the United States. This will also affect the newborn, since maternal milk FA content reflects maternal intake, and thus also the level of *trans* fatty acids.

About 20%–25% of *trans* fatty acids in the American diet are naturally occurring and that value, 1.1–1.34 g/day (total *trans* fatty acid consumption of 5.3 g/day), has remained quite constant during the past decade (Hunter and Applewhite, 1991; Allison et al., 1999).

Recent studies show that *trans* fatty acids have decreased in human milk in Canada, where their amount in food has to be listed. The relatively low content of *trans* fatty acids in bovine milk suggests that *cow* milk-based formulas might provide lower *trans* fatty acid amounts to infants than does mother's milk (Tomarelli, 1988; Jensen, 1995; Life Sciences Research Office, 1998).

V. MEDIUM-CHAIN FATTY ACIDS

Medium-chain triglyceride (MCT) oil is normally prepared from coconut oil and contains a *mixture of* fatty acids from C6 to C12 (C6:0-1-2%; C8:0-65-75%; C10:0-25-35%; C12:0-1-2%) (Bach and Babayan, 1982). Although human milk, usually contains less than 10% medium-chain fatty acids (MCFAs) (Bitman et al., 1983b) except for certain maternal diseases (Hamosh and Bitman, 1992), such as hypobetalipoproteinemia, diabetes, cystic fibrosis (Bitman et al., 1987; Hamosh and Bitman 1992), or consumption of a high-carbohydrate diet (Insull et al., 1959), some infant formulas for premature infants contain up to 50% MCFAs. Standard formulas for healthy term infants contain only little MCFAs. Because of the frequent use of MCT formula for preterm infants, we will discuss aspects of their synthesis and levels in human milk as well as their digestion and absorption in infants.

The human mammary gland is able to synthesize de novo MCFAs as well as to elongate and desaturate *some* long-chain fatty acids (LCFAs) shortly after parturition. Prepartum mammary secretions (collected between 1 and 70 days before full-term delivery) contain lower amounts of fat than colostrum and mature milk (1.15 and 1.28 g/dL at an average of 42 and 9 days before delivery, respectively), and have a markedly different lipid composition than postpartum secretion (Bitman et al., 1986). The data presented in Table 38.8 show that prepartum secretions contain considerably lower concentrations of C10, C12, and C14 than postpartum colostrum or mature milk. As prepartum secretions collected at an average of 42–70 days before term delivery correspond to secretions collected at 6–10 weeks prepartum, the MCFA composition of total lipids in these secretions

TABLE 38.8
Medium-Chain Fatty Acids in Human Mammary Prepartum Secretion, in Colostrum, and in Milk Secreted after Premature of Full-Term Delivery

		Fatty Acid (%)		
Specimen	***n***	**10:0**	**12:0**	**14:0**
Prepartum secretion[a]	10	0.10 ± 0	1.7 ± 0.4	4.9 ± 0.6
Postpartum colostrum[b]				
Premature delivery				
26–30 weeks	15	0.26 ± 0.14	3.09 ± 0.59	5.52 ± 0.68
31–37 weeks	23	0.31 ± 0.10	3.14 ± 0.43	5.87 ± 0.50
Full-term delivery	6	0.27 ± 0.22	3.10 ± 0.91	6.81 ± 1.06
Mature milk[c]				
Premature delivery				
26–30 weeks	15	1.37 ± 0.17	7.47 ± 0.72	8.41 ± 0.83
31–37 weeks	23	1.27 ± 0.18	6.56 ± 0.77	7.55 ± 0.89
Full-term delivery	6	0.97 ± 0.28	4.46 ± 1.17	5.68 ± 1.36

[a] Prepartum secretion collected from women 1–70 days before full-term delivery (Bitman et al., 1986).
[b] Data for colostrums and milk fatty acid composition after preterm and full-term delivery (Bitman et al., 1983b).
[c] Mature milk collected at 6 weeks lactation (Bitman et al., 1983b).

were compared with those in the colostrum secreted by women who delivered at similar periods of prematurity. As can be seen from the data presented in Table 38.8, there was no difference in the MCFA level between the colostrum of women who delivered prematurely and colostrum of women who delivered after a full-term pregnancy (Bitman et al., 1983b, 1986). Thus, parturition, irrespective of length of pregnancy, seems to be the trigger for the increase in de novo fatty acid synthesis within the mammary gland. It is also possible that milk removal, whether by the newborn's suckling or by milk expression, after full-term or premature delivery, respectively, is an important factor in the increase of lipogenesis within the human mammary gland. Animal studies have shown that a marked increase in the lipogenic enzymes acetyl-coenzyme A (acetyl-CoA) carboxylase, ATP citrate lyase and fatty acid synthetase occurs immediately after parturition and that milk removal is essential for this increase (Martyn and Hansen, 1981). Whether the presence of long-chain fatty acyl-CoA, which is a potent inhibitor of the two former enzymes in the mammary gland (Romsos et al., 1978; Grigor and Warren, 1980), or other factors (Wilde et al., 1988) that might contribute to the lower concentration of MCFAs in prepartum secretions is not known. The absence of lipoprotein lipase from prepartum secretions (Bitman et al., 1986) suggests low activity in the mammary gland before term delivery, as previously shown in the rat (Hamosh et al., 1970). This would indicate that the LCFAs present in these secretions might originate mainly from the albumin-bound FFAs in the circulation. The absence of tight junctions between mammary epithelial cells before parturition would facilitate this transfer of fatty acids into the mammary gland.

Synthesis of MCFAs is specific to the mammary gland, because only this tissue contains a specific enzyme, thioesterase II, which terminates chain elongation at 6–14 carbon atoms (Chivers et al., 1977; Libertini and Smith, 1978). In all other tissues, lipogenesis results in LCFAs associated with the enzyme thioesterase I, which terminates chain elongation at or above 16-carbon atoms (Lin and Smith, 1978). One could, therefore, use the milk/serum fatty acid ratio to assess the origin of milk fatty acids (Spear et al., 1992b). Indeed, the serum concentration of fatty acids shorter than C14 was extremely low. Concentrations were, however, considerably higher in colostrum, resulting in very high-milk/serum fatty acid ratios for C10:0 and C12:0 at 16.23 and 17.11, respectively (Table 38.9) as compared to milk/serum fatty acid ratios of 0.18–2.0 for all other major long-chain saturated, monounsaturated, and polyunsaturated fatty acids (Spear et al., 1992b).

TABLE 38.9
Medium-Chain Fatty Acid Composition of Colostrum and Serum after Full-Term Delivery[a]

Medium-Chain Fatty Acid	Colostrum[b]	Serum[b]	Milk/Serum Ratio
8:0	0.05 ± 0.01	0.02 ± 0.01	3:18
10:0	0.32 ± 0.04	0.02 ± 0.00	16:23
12:0	2.53 ± 0.20	0.15 ± 0.02	17:11
14:0	5.68 ± 0.25	1.31 ± 0.06	4:35

[a]Data are from 31 healthy women who delivered full-term infants. There were no statistically significant differences in colostrum fatty acid composition as function of weight gain during pregnancy or parity except that myristic acid (14:0) concentration was significantly higher in primipara than in multipara (6.60 ± 0.38 vs. 5.19 ± 0.46% $p < .05$).
[b]Percentage of total fatty acids.

Fatty acid synthetase has been characterized (Thompson et al., 1981; Thompson and Smith, 1982) in a permanent human mammary epithelial cell line, SkBr 3 (Weber and Osborn, 1969), and the production of MCFAs in *in vitro* studies has been reported (Thompson and Smith, 1985). The onset of fatty acid synthetase and thioesterase I activity in the human mammary gland is, however, unknown. Because the human lactating mammary gland cannot be studied for ethical reasons, one depends on indirect observations such as those described above. Based on these studies, which include colostrum (see Table 38.8), milk, and serum as well as prepartum mammary secretion, one can conclude that, in the human, as in other species, parturition, irrespective of length of pregnancy, is the trigger for the synthesis of MCFAs (Spear et al., 1992b).

Whether this is dependent on hormonal changes associated with delivery and the onset of lactation or with the removal of milk from the mammary gland (by suckling or pumping), or a combination of both, remains to be determined. As in other species, in the human, the rate of synthesis of MCFAs increases with length of lactation (see Table 38.3) (Roy et al., 1975; Tantibhendyangkul, 1975; Bitman et al., 1983b).

At birth, the digestive function of premature infants is not fully developed (Hamosh, 1994b, 1996; Hamosh and Hamosh, 1999; Hamosh, 2006). The physiological immaturity of pancreatic and hepatic function results in reduced levels of pancreatic lipase (Zoppy et al., 1972; Sbarra et al., 1996) and bile salts (Watkins, 1975), both necessary for the digestion of dietary fat (Hamosh, 1996). To reduce the fat malabsorption of premature infants, fat blends have been adjusted to contain relatively high levels of MCFAs; that is, chain length of 6–10 carbons (Roy et al., 1975; Tantibhendyangkul and Hashim, 1975; Shenai et al., 1980). Although MCFAs have certain advantages, such as absorption through the gastric mucosa (Aw and Grigor, 1980; Fernando-Warnakulasuriya et al., 1981; Bitman et al., 1985), direct transport from the intestine to the liver via the portal vein (Patton, 1981; Bach and Babayan, 1982; Carey et al., 1983), and efficient oxidation without the need for carnitine-mediated transport through mitochondrial membranes (Innis et al., 1996b), they also have certain drawbacks (Watkins, 1975), such as ketosis and acidosis, the production of dicarboxylic acids (Henderson and Dear, 1986; Whyte, 1986; DuPont et al., 1987), and the fact that they are not used as building blocks for cell membranes and are only minimally incorporated into adipose tissue (Sarda et al., 1987).

However, several studies have shown that fat blends containing almost exclusively long-chain triglycerides (LCTs) (86%–100%) or 40%–50% MCTs are absorbed to the same extent by preterm infants (Okamoto et al., 1982; Whyte et al., 1986a; Hamosh et al., 1989, 1991b) even in crossover studies in which each infant was randomly fed for 1 week the LCT and for 1 week the MCT formula

(Hamosh et al., 1989, 1991b). The data for fat absorption and infant growth on these different types of formulas are shown in Tables 38.10 through 38.12 and Figures 38.2 and 38.3. Thus, the only advantage of MCTs in formula fat might be that octanoic acid (C8:O) is absorbed through the gastric mucosa (Hamosh et al., 1989) and might provide a readily available energy source. Figures 38.2 and 38.3 present the individual data for each infant while being fed either MCT- or LCT-containing formula as well as for a group of nine preterm infants fed a full-term infant formula (S26). It is clear that only one infant in the SMA formula (Wyeth) and one in the Enfamil formula (Mead-Johnson) groups benefited from MCT, which was absorbed at a better rate. It seems, therefore, that with the exception of a small number of very premature infants with poorly developed digestive ability who might benefit from MCT, fat absorption in most preterm infants is a function of development of digestive potential rather than the fat blend (MCT or LCT) of the formula (Hamosh et al., 1989, 1991a). It is, therefore, advisable not to include MCT in fat blends of formulas for full-term infants, whereas in formulas for preterm infants, MCT should not exceed the level in the milk of women who deliver prematurely (15% fatty acids C6:O-C:14).

TABLE 38.10
Fat Absorption and Growth Rate in Preterm Infants Fed Medium-Chain Triglyceride or Long-Chain Triglyceride Formula

Formula	Dietary Fat (g/kg/day)	Fat Excretion (g/kg/day)	Fat Absorption (%)	Wt Gain (g/day)
Medium-chain triglycerides	6.04 ± 0.54	1.04 ± 0.24	84.63 ± 3.14	23.0 ± 1.50
(n = 12)	(4.18–8.38)	(0.15–1.87)	(60.21–97.05)	(15.71–34.28)
Long-chain triglycerides (n = 12)	5.88 ± 0.48	1.02 ± 0.26	82.81 ± 4.01	20.85 ± 1.80
	(3.63–7.60)	(0.18–2.29)	(49.34–97.50)	(22.42–32.85)

Data are mean ± SEM and ranges (in parentheses). Fat excretion and absorption were determined during a 3-day balance study. Weight gain was determined during 1 week when infants were fed either medium-chain or long-chain triglyceride formula. Each infant was fed each formula for 1 week. Infants were randomly assigned to start with either formula. The formulas were Enfamil (Mead-Johnson).

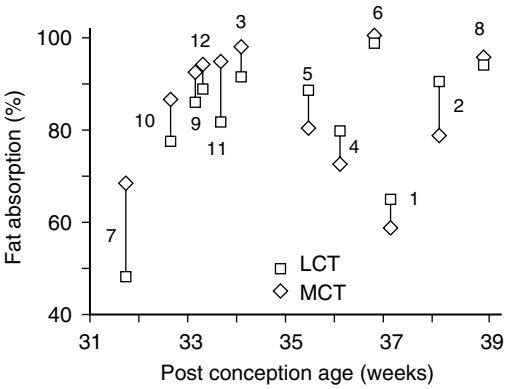

FIGURE 38.2 Comparison of fat absorption in premature infants fed alternately medium-chain (MCT) and long-chain triglyceride (LCT) formula. Numbers next to symbols designate individual infant numbers. *(*From Hamosh, M., et al. (1989). *Pediatrics* 83:83–92.)

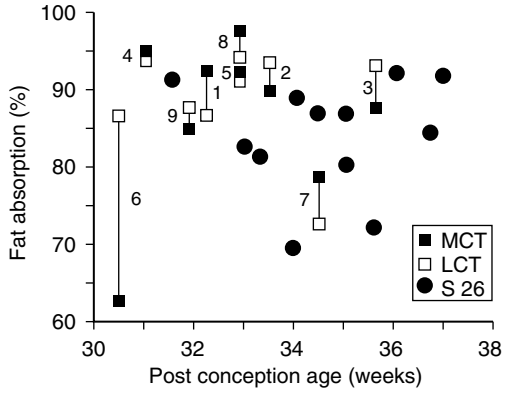

FIGURE 38.3 Comparison of fat absorption in premature infants fed SMA or S-26 formulas. The SMA formula contained two different fat blends: 50% medium-chain triglyceride (MCT) or 86% long-chain triglyceride (LCT). Each formula was fed alternately for 1 week to a group of nine infants. A second group of 11 infants was fed S-26 formula containing 98% LCT for 1 week. Fat absorption studies were conducted during a 3-day balance study. Numbers next to symbols designate individual infant numbers. (From Hamosh, M., et al. (1991a). *J. Pediatr. Gastroenterol. Nutr*. 13:143–149.)

It is interesting that within formulas fat blends containing up to 40% MCT, the latter do not adhere to feeding tubes (Mehta et al., 1991). The same is true of human milk fat with a content of 5% C8:0 and C10:0 (Mehta et al., 1988). However, the addition of MCT oil and feeding through gastric gavage tubes after mixing with formula or human milk leads to separation of the MCT oil and preferential adherence of C8:0 and C10:0 to the tubing (Figures 38.4 and 38.5). Given the tendency of MCT to adhere to feeding tubes of gastric gavage-fed infants (Mehta et al., 1988, 1991), caution should be exercised in the addition of MCT oil to either formula or human milk with the aim to increase the caloric content of feeds for low-birth weight infants.

Because increasing the proportion of MCT in formulas might lower the availability of long-chain mono- and polyunsaturated fatty acids essential for the infant's normal growth and development, it might not be advisable to prepare infant formulas with a high content of MCT.

VI. LONG-CHAIN POLYUNSATURATED FATTY ACIDS

LCPUFAs are essential for normal growth and development. There are two families of LCPUFAs, one derived from linoleic acid (C18:2n-6) and the other from linolenic acid (C18:3n-3) (Figure 38.6).

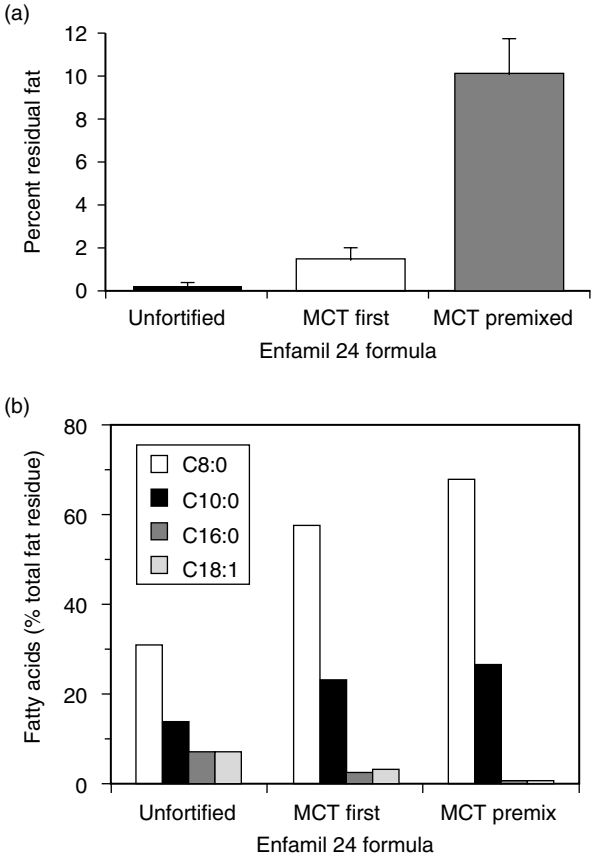

FIGURE 38.4 (a) Amount of fat adhering to feeding sets during intermittent feeding to Enfamil formula fortified with MCT oil. Data are percentage (means ± SEM) of total fat adhering to feeding sets during three feeding regimens. (b) Fatty acid composition of fat adhering to feeding sets during gavage feeding of Enfamil formula with MCT fortified with MCT oil. Enfamil premature formula contains 18% C8:0, 11.3% C10:0, 7% C16:0, and 11.7% C18:1. (From Mehta, N.R., et al. (1991). *J. Pediatr. Gastroenterol. Nutr*. 13:267–269.)

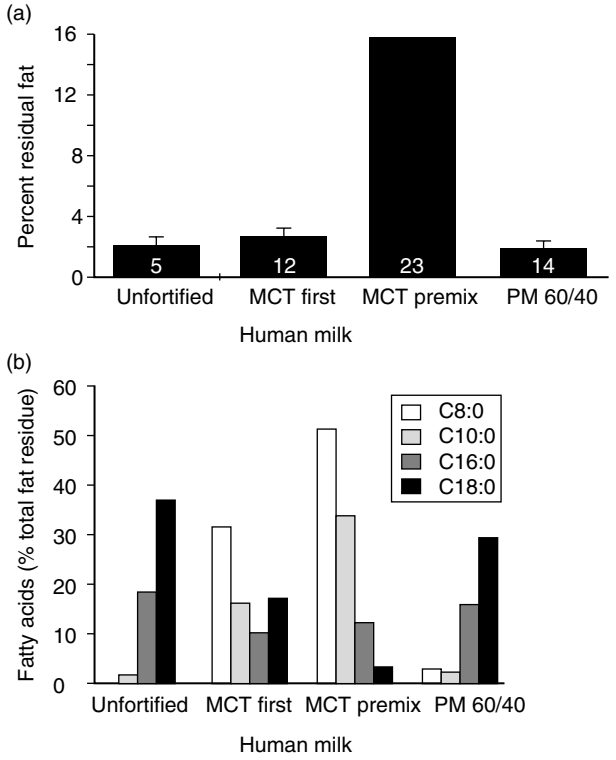

FIGURE 38.5 (a) Amount of fat adhering to feeding sets during intermittent feeding of fresh human milk fortified with MCT oil. Numbers in each bar represent number of experiments. Data are mean ± SEM. (b) Fatty acid composition of fat adhering to feeding sets during gavage feeding of human milk fortified with MCT oil in four feeding regimens: unfortified human milk, MCT oil delivered first, followed by milk, MCT oil premixed with milk before gavage feeding and milk fortified with PM 60/40. C8:0 and C10:0 are major components of MCT oil, C16:0 and C18:1 are major components of human milk fat. (From Mehta, N.R., et al. (1988). *J. Pediatr.* 112:474–476.)

FIGURE 38.6 Synthesis of LCPUFA from 18 carbon precursors. (From Hamosh, M., and Salem, N., Jr. (1998). *Biol. Neonate* 74:106–120.)

Among the derivatives of linolenic acid, DHA (C22:6n-3) is essential for normal brain development and visual function, whereas the elongation and desaturation product of linoleic acid, AA (C20:4n-6) is the precursor of prostaglandins and leukotrienes and is essential for neonatal growth. These highly unsaturated fatty acids affect many aspects of membrane function such as membrane order, permeability, lipid–lipid, as well as lipid–protein interaction. These specific interactions may in turn affect receptor function, enzyme activities, signal transduction, and membrane excitability (Uauy et al., 1996). For the developing infant, DHA is of major importance, because it amounts to a major part of the total fatty acids in cerebral cortex and retina phospholipids. The photoreceptor outer segments of the retina contain very high concentrations of DHA, which is important for normal photochemical activity of the visual pigment rhodopsin (Litman and Mitchell, 1996; Uauy et al., 1996; Innis, 2004). We and others have reviewed the topic recently and present here several aspects from these reviews (Hamosh, 1998; Hamosh and Salem, 1998; Innis, 2004; Heird and Lapillone, 2005; Uauy and Dangour, 2006).

Fatty acids with double bonds at the n6 and n3 positions (i.e., linoleic and linolenic acids) have to be provided by the diet because humans cannot synthesize them. Both types of fatty acids are elongated and further desaturated by the same enzymes (desaturases and elongases) to produce AA and DHA. Figure 38.6 shows the steps involved in this process (Voss et al., 2001), which occurs in adults (Hoffman et al., 2001) as well as in infants (Sauerwald et al., 1997).

LCPUFA requirements of the newborn have been a major focus of research for the past two decades. The reason for this intense interest is based on several observations: (1) accretion of LCPUFAs occurs primarily during the last trimester of pregnancy (Kneebone et al., 1985), making the preterm infant especially vulnerable to LCPUFA deficiency; (2) plasma levels of LCPUFAs decrease markedly after birth in formula-fed preterm infants as compared to almost constant levels in breast-fed infants of comparable gestational age; (3) maternal LCPUFA status does not seem optimal during both pregnancy and lactation in well-nourished women in the United States (Koletzko, 1997) and The Netherlands (Koletzko et al., 1988; Koletzko, 1992); (4) the level of LCPUFAs in human milk is not constant as a function of length of lactation or geographical distribution (i.e., nutrition) (Hamosh, 1998; Hamosh and Salem, 1998), and therefore to what extend can human milk be the "gold standard?"; and (5) studies that evaluate the effect of formula supplementation with LCPUFAs provide only partial answers as to benefit of such supplementation to preterm or full-term infants (Hamosh, 1998; Hamosh and Salem, 1998).

Although accretion occurs prenatally through preferential transfer of LCPUFAs from mother to fetus, possibly as a result of the high-LCPUFA affinity of α-fetoprotein (Koletzko et al., 1991a,b), postnatal accretion of these fatty acids is also important, because myelination and synaptogenesis occur during the postnatal brain growth spurt.

The above points assume that LCPUFAs are conditionally essential nutrients in the newborn; that is, although adults have the capacity to synthesize these fatty acids by elongation and desaturation from their 18-carbon EFA precursors, infants are unable or may have only a limited capacity to accomplish this and therefore have to receive LCPUFAs, especially DHA and possibly AA, in their diet. This assumption is currently questioned as a result of several studies that show that stable isotope-enriched 18-carbon precursors can be incorporated into LCPUFAs by newborn infants (Carnielli et al., 1996; Salem et al., 1996; Sauerwald et al., 1997). Furthermore, these studies (Ktorza et al., 1983) also show that newborn premature and full-term infants use the recently described Δ4 desaturase independent pathway (Voss et al., 1991) in the endogenous synthesis of DHA (Sauerwald et al., 1997) and that this ability is similar in preterm and full term infants (Uauy et al., 2000). The question, therefore, now is to what extent does endogenous LCPUFA synthesis cover the DHA and AA needs of the newborn? Salem et al. (1996) made an order of magnitude estimate and concluded that AA might be produced in adequate amounts, whereas the amount of DHA produced is inadequate.

A. LCPUFAs in Human Milk: Effect of Diet and Length of Lactation

The sufficiency of breast milk LCPUFAs for the full-term infant is worth examination. Although milk AA concentrations are relatively uniform and do not seem to vary with maternal nutrition, DHA levels in milk show great variability among populations, being lowest in countries with a relatively high-meat intake (e.g., United States) and highest in populations where most animal foods are provided as fish (Far East, Nigeria, Canadian Inuits) (Table 38.13) (Sanders et al., 1978; Hall, 1979; Jensen et al., 1981; Putnam et al., 1981; Villacampa et al., 1982; Bitman et al., 1983b; Harzer et al., 1983; Kneebone et al., 1985; Sas et al., 1986; Muskiet et al., 1987; de Lucchi et al., 1988; Innis and Kuhnlein, 1988; Koletzko et al., 1988, 1991b; Tomarelli, 1988; Van der Westhuizen et al., 1988; Prentice et al., 1989; Boersma et al., 1991; Dotson et al., 1992; Jackson et al., 1994; de la Presa-Owens et al., 1996; Hamosh, 1998; Hamosh and Salem, 1998). Furthermore, milk LCPUFA levels change as a function of length of lactation and decrease markedly after the first 3 months postpartum (Nobel et al., 1979; Bitman et al., 1983b; Boersma et al., 1991; Spear et al., 1992a,b; Luukkainen et al., 1994; Henderson et al., 1996; Hamosh, 1998). Again, as discussed above, AA levels seem relatively constant, whereas DHA shows the greatest change (Table 38.14). The decline

in DHA levels is more pronounced in the milk of mothers of full-term infants (Bitman et al., 1983b; Luukkainen et al., 1994; Henderson et al., 1996), possibly because LCPUFA reserves are greater in women who deliver prematurely. However, infants who are breast-fed for 1 year and receive milk with only traces of DHA have adequate plasma DHA levels (Henderson et al., 1996), suggesting that at 6 and 12 months of age, endogenous synthesis of LCPUFAs is well developed. Cell culture studies indicate that astrocytes convert C20:5n3 and C22:5n3 to DHA that is then transferred to neurons (Bernoud et al., 1988; Moore et al., 1991; Moore, 1993).

B. Effect of LCPUFA Supplementation on Blood Levels of DHA and AA of Formula-Fed Infants

The effect of low n-3 fatty acid diets on neural functions of rodents (mice and rats) and primates has been reviewed (Salem et al., 1986; Salem, 1989; Hamosh and Salem, 1998). Earlier reports of irreversible changes in *Rhesus* monkey brain function associated with temporary DHA deficiency during pregnancy and lactation (Neuringer et al., 1984, 1986) were the trigger for studies on the LCPUFA status of the newborn infant with special emphasis on the premature infant. Indeed, a number of studies have evaluated the LCPUFA status of the newborn by measurement of DHA and AA in cord blood vessels, a potentially more sensitive indicator of EFA status than cord blood composition. These studies have shown a close relationship between the maternal and fetal LCPUFA status and the lower neonatal EFA status in successive pregnancies and in multiple pregnancies (Muller et al., 1964). A marked decrease in plasma and red blood cell (RBC), DHA and AA in formula as compared to breast-fed infants (Putnam et al., 1982) was taken as further indication of rapid postnatal deterioration of the LCPUFA status in the absence of dietary supplementation. LCPUFA supplementation of formula-fed infants has received much attention lately. Supplementing pregnant women with fish oil (that provides DHA and EPA) during the last trimester of pregnancy (Van Houwelingen et al., 1995) has improved fetal DHA reserves.

Improvement in the DHA status was achieved without impairing the AA status, although the supplementation was with n-3 fatty acids only (Van Houwelingen et al., 1995). However, the preterm infant cannot be helped by maternal supplementation, because birth often occurs before the LCPUFA accretion of the last trimester of pregnancy. Postnatal supplementation seems therefore the correct approach to solve this problem. The initial studies carried out by Carlson et al. (1991) supplemented preterm formula with marine oil, which provides a mixture of DHA and EPA. This supplementation led to higher EPA and DHA levels in plasma and RBCs, but concomitantly there was a decrease in AA (Carlson et al., 1991). Supplementation with marine oil also led to impaired growth, resulting in lower weight, length, and head circumference in the supplemented compared to the regular formula-fed group. Subsequent studies by Carlson et al. (1992, 1993) showed that the depressed growth was evident at 1 year of age, that it was related to the lower AA levels, and that it was due to the EPA present in marine oil. Subsequent studies in the United States, Canada, Europe, and South America reported similar findings (Clandinin et al., 1992; Hoffman and Uauy, 1992; Hoffman et al., 1993; Uauy-Dagach et al., 1994; Carnielli et al., 1995; Koletzko et al., 1995). In order to avoid the growth-depressing effects of EPA in fish oil preparations, studies were carried out with other sources of DHA and AA. LCPUFA derived from egg yolk phospholipids, evening primrose oil, and single-cell organisms (algae and fungi) have been used successfully to increase plasma and RBC concentrations of DHA and AA in preterm infants. The rationale for quantifying LCPUFA levels in RBC membranes is the assumption that they reflect tissue (including brain) DHA and AA concentrations. Although this has been reported to be true in the rat (Carlson et al., 1986), studies in *Rhesus* monkeys show that diet-induced differences in RBC DHA can greatly overestimate differences in retinal and cerebral cortex DHA (Riesbich et al., 1986).

Brain lipid (Farquhrson et al., 1992; Makrides et al., 1994) and phospholipid (Farquhrson et al., 1995a), liver (Farquhrson et al., 1995b), and subcutaneous adipose tissue (Farquhrson et al., 1993) DHA and AA were lower in formula-fed than in breast-fed full-term infants who died of SIDS (sudden infant death syndrome), suggesting that the full-term infant might also benefit from DHA supplementation. Within the past few years, studies have been carried out to assess whether LCPUFA supplementation changes the DHA and AA profile of blood (plasma and RBC lipids) in full-term infants. Most of these studies have used varied sources of DHA and AA and have shown that supplementation results in plasma and DHA levels that are similar to those of breast-fed infants and higher than in unsupplemented formula-fed infants (Agostoni et al., 1994; Decsi and Koletzko, 1995b; Makrides et al., 1995; Carlson et al., 1996; Hoffman et al., 1996; Innis et al., 1996a; Auestad et al., 1997).

C. Effect of LCPUFA Supplementation on Visual and Cognitive Functions of Formula-Fed Infants

Studies have also been carried out to assess whether improving LCPUFA status, as measured by plasma and RBC-phospholipid concentrations of DHA and AA, affects visual and cognitive function in preterm and full-term infants. These studies have used a number of different tests such as forced-choice preferential looking (FPL), which evaluates the infant's tendency to gaze at a pattern rather than a blank field (Dobson and Teller, 1978; McDonald et al., 1985); visual evoked potential (VEP), which measures the electrical potential at the occipital visual cortex in response to patterns of contrast and is expressed as $1\log_{10}$ of minimum angle of resolution (MAR): the smaller log MAR the better visual acuity (Sokol et al., 1983; Norcia and Tyler, 1985); electroretinogram (ERG), which measures the summed activity of the retina in response to a flash of light (Naka and Rushton, 1966; Hood and Birch, 1990); the novel preference test (NPT), also known as the Fagan test of infant intelligence (FTII), which tests the preference of infants to look at new images (Fagan and McGrath, 1981; Rose and Wallace, 1985), or the Brunet–Lezine test (a modification of the Gesell test), which evaluates psychomotor development by testing posture and gross motor function, adaptation, and fine motor function, social reaction, and language. Results of studies in preterm infants

showed improved visual and cognitive function associated with LCPUFA supplementation, but in most cases the effect was of short duration and, generally, after 2–6 months of age there was no difference in performance among formula-fed, supplemented formula-fed, or breast-fed infants (Uauy et al., 1990; Birch et al., 1992a,b, 1993; Carlson et al., 1993, 1994; Hoffman et al., 1993; Uauy-Dagach et al., 1994; Carlson and Werkman, 1996). Only in one study was the functional benefit of supplementation still evident at the age of 1 year (Werkman and Carlson, 1996).

Functional studies of the effect of DHA and AA supplementation have also been carried out in full-term infants. Although some of these studies clearly show improvement of visual and cognitive function, other studies fail to show effects (Makrides et al., 1993; Innis et al., 1994, 1996b; Agostoni et al., 1995; Carlson et al., 1996; Jorgensen et al., 1996; Hamosh, 1998; Hamosh and Salem, 1998). The reason for the great variation in the results obtained in the functional studies in preterm and full-term infants is not clear. Potential causes of variability could be sample size, infrequent testing, and differences in infant age at testing as well as an insufficiently long follow-up for meaningful evaluation. More recent studies on large numbers of preterm and full-term infants show benefits of supplementation in the former, but not in the latter (Auestad et al., 2001; O'Connor et al., 2001; Makrides et al., 2005).

Studies to change DHA concentrations of blood lipids, and thereby to affect the functional development of infants, by changing the ratio of the precursor α-linolenic and linoleic acids have also been carried out. Although low linoleic to α-linolenic acid ratios improve DHA status, they tend to decrease AA levels (Clark et al., 1992; Innis et al., 1997; Jensen et al., 1997) as well as growth (Jensen et al., 1997; Hamosh, 1998; Hamosh and Salem, 1998).

It seems, therefore, that maternal supplementation during pregnancy (Van Hauwelingen et al., 1995), or during lactation (Makrides et al., 1996), or eventually during both pregnancy and lactation might be an acceptable way of ensuring optimal LCPUFA supply to the newborn. The former form of supplementation would, of course, benefit only full-term breast-fed infants and the latter preterm infants. As far as formula-fed infants are concerned, the need for supplementation of the full-term infant is not clearly evident, whereas supplementation of the preterm infant might have temporary beneficial effects.

In view of the fact that humans evolved on and are likely to be best adapted to a diet much richer in LCPUFAs than the modem American diet (Sinclair and O'Dea, 1990), it would be prudent to increase the dietary intake of AA and DHA, particularly during times of dietary stress such as pregnancy and lactation.

Although much attention has been given to maternal nutrition as the determinant of milk LCPUFAs, especially DHA levels, very little or no consideration has been given to the possible regulation of milk LCPUFAs at the mammary gland level. To gain insight into this aspect, we have quantified tissue and milk LCPUFAs in the lactating ferret, a species with an adequate and constant intake of LCPUFAs (Pereira et al., 1994; Henderson et al., 1998). Concomitantly, we have quantified LCPUFA accretion in the late fetal and suckling ferret offspring (kits). Figure 38.7 summarizes these studies.

Ferrets were studied at 5 weeks of pregnancy and throughout 4 weeks of lactation. Duration of pregnancy and lactation is 6 weeks each in this species. Because the kits start to nibble on the mother's food after the first 4 weeks after birth, no studies was conducted beyond the first 4 weeks of age. Data from pregnant or lactating females were compared to those from virgin animals who served as control (Henderson et al., 1998).

Maternal adipose tissue LCPUFAs (total n-3 and n-6 fatty acids as well as DHA and AA) were virtually constant during pregnancy and lactation and were identical to those of the virgin control females (see Figure 38.7a). Four different adipose tissues were sampled for analysis—omentum, perirenal, periovarian, and subcutaneous at all study times. LCPUFAs as well as total (saturated, monoene, polyene, DHA, and AA) fatty acid profiles were identical at the different anatomical sites (Hamosh, 1998) (Table 38.15). We have, therefore, presented the mean values of the different fat depots at each study point in Figure 38.7b. Although the dietary intake of DHA and AA remained

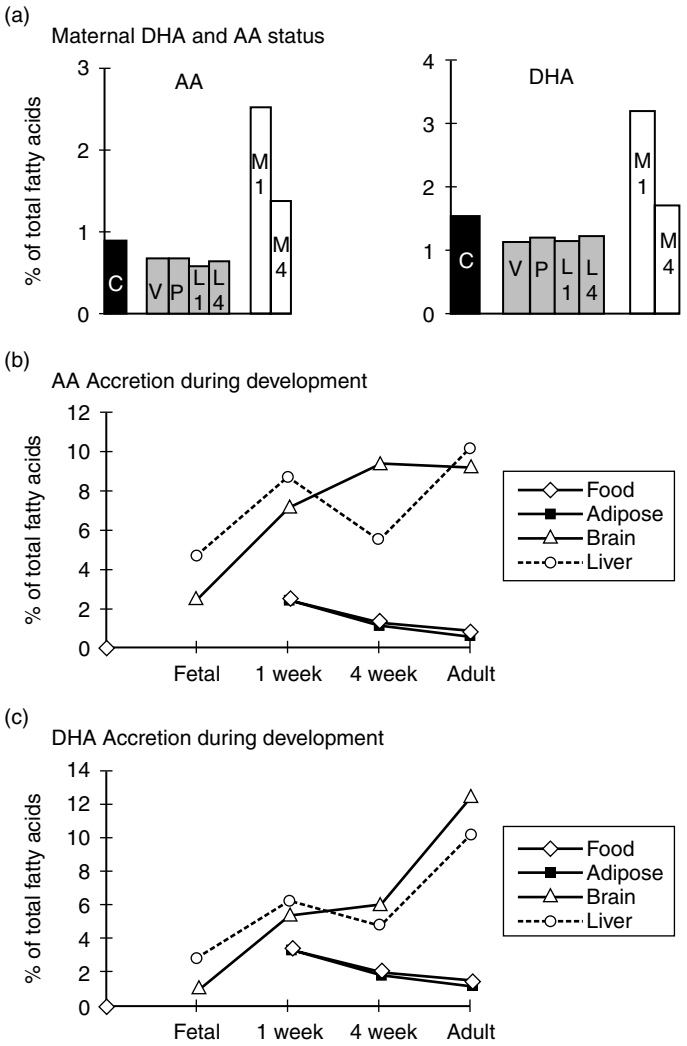

FIGURE 38.7 Maternal arachidonic acid (AA) and docosahexaenoic acid (DHA) status during pregnancy and lactation. (a) Adipose tissue AA and DHA levels of virgin (V), pregnant (P), and lactating 1 weeks (L1) and 4 weeks (L4) ferrets are compared to ferret chow levels (C) and to milk levels in early (M1) and advanced (M4) lactation. (b) Arachidonic acid (AA) and (c) docosahexaenoic acid (DHA) accretion during late fetal and postnatal development in ferret kit brain, liver and adipose tissue. Values are compared to food (i.e., milk or chow) values. (From Hamosh, M., and Salem, N., Jr. (1998). *Biol. Neonate* 74:106–120.)

constant during pregnancy and lactation, as did the concentration of these fatty acids in maternal adipose tissues, milk DHA and AA levels decreased throughout lactation. The data suggest that milk LCPUFA levels are intrinsically regulated within the lactating mammary gland, the concentration of DHA and AA in milk secreted during early lactation being twofold and threefold higher than dietary content and threefold and fourfold higher than adipose tissue content. The pattern of decrease of milk DHA and AA in advanced lactation is very similar in the ferret and in the human (Luukkainen et al., 1994; Henderson et al., 1996), although absolute values are higher in the ferret.

D. LCPUFA Accretion in the Newborn

Although we have quantified the individual fatty acids in all classes (saturates, monoenes, polyenes, and LCPUFAs), because of space constraints, we present only the data for DHA and AA here. No

TABLE 38.15
Effect of Formula Supplementation with DHA or DHA and AA on Blood Lipid Levels of DHA and AA in Preterm Infants

Reference	Outcome Tested Plasma and RBC DHA and AA	Results	Age
Carlson et al. (1991)	Marine oil suppl. (DHA + EPA)	DHA suppl. lowers AA levels	
Carlson et al. (1992)	Marine oil suppl. (DHA + EPA)	DHA > 0.5% suppl. lowers AA levels

Hoffman et al. (1990, 1992, 1993)	Plasma DHA, AA	SF > F, SF = BF	1,6 months
Koletzko et al. (1995)	Plasma DHA, AA	SF > F, SF = BF	3 weeks
Carnielli et al. (1996)	Plasma DHA, AA	SF > F, SF = BF	1 month

DHA, docosahexaenoic acid, 22:6n-3; AA, arachidonic acid, 20:4n-6. Comparison made between supplemented formula (SF) and regular formula (F) and, in most studies, also with breast milk (BF). (From Hamosh, M., and Salem, N., Jr. (1998). *Biol. Neonate* 74:106–120.)

adipose tissues were detectable in the fetus at the start of the last week of gestation; however, 1 week after birth (i.e., within an interval of 2 weeks) the newborn had well-developed adipose deposits at all sites examined. As in the adult, there was no difference in LCPUFA profiles among various adipose tissues examined. DHA and AA were highest in adipose tissue in the first week after birth (see Figure 38.7b and 38.7c). Kit adipose tissue DHA and AA were identical to milk DHA and AA levels, indicating rapid deposition of milk LCPUFAs into adipose depots during early postnatal development. The rapid postnatal development of adipose tissue and the rapid accretion of DHA and AA in fat depots suggests that these might serve as reservoir for the LCPUFA accretion in other tissues during later periods when milk supply of DHA and AA decreases. Analysis of fatty acid profiles in brain and liver showed a very different developmental pattern from that in adipose tissue. Brain DHA levels increased sixfold from the late fetus to the first week after birth, and at 4 weeks after birth, they had only reached 50% of the DHA level of the adult brain. The percentage of DHA was much higher in brain than in adipose tissue. AA levels were higher than DHA levels in fetal brain. AA increased threefold from the late fetal period to 1 week after birth and reached adult levels 4 weeks after birth. Accretion of DHA and AA in the liver closely parallels that of the brain. DHA levels increased more than twofold from the late fetal period to the early neonatal period, but amounted to only 50% of adult levels 4 weeks after birth, whereas AA levels were much higher in fetal liver than DHA levels, and by 1 week after birth, they had reached adult levels (see Figure 38.7). The study shows marked differences in LCPUFA accretion rates among different organs and suggests that tissues with rapid growth and LCPUFA accretion such as adipose tissue might act as subsequent reservoirs of LCPUFA when the dietary supply (milk LCPUFAs) decreases. An additional conclusion that can be reached from the data presented for brain and liver LCPUFA accretion is that more rapid accretion of n-6 LCPUFAs might be due to earlier development of endogenous synthesis of the n-6 than the n-3 LCPUFA series, rendering the latter more dependent on dietary supplementation than the former. Similar conclusions have recently been reached in studies of conversion of stable isotope-labeled precursors to DHA and AA in premature and full-term infants (Salem et al., 1996). Accretion of DHA and AA in brain and liver occurs mainly postnatally, emphasizing the need of adequate levels of LCPUFAs during neonatal development. In the ferret, this might be achieved by a combination of dietary (milk) and reserve (adipose tissue) sources as well as endogenous synthesis. Whether the human infant uses similar resources is yet to be established.

Because LCPUFAs contain a large number of double bonds, they might be especially vulnerable to oxidation. Recently, studies were conducted to assess whether pasteurization of banked human milk (heating at 62.5°C for 30 min, without precautions to prevent oxidation) might cause a measurable decrease in milk LCPUFAs. Pasteurization is mandatory to prevent passage of microorganisms through donor milk to the recipient infant. The data of this study show that all fatty acids in milk, including LCPUFA (DHA and AA), are not affected by pasteurization (Henderson et al., 1998).

Another interesting aspect of the role of lipid in the nutrition of preterm infants was recently explored in preterm infants with bronchopulmonary displasia (BPD). These infants have significant pulmonary disease combined with higher metabolic rates. Feeding a high-fat diet rather than a high-carbohydrate diet resulted in significantly lower CO_2 production (6.6 ± 0.3 vs. 7.4 ± 0.4 mL/kg/min) and, therefore, lower respiratory quotients (0.80 ± 0.02 vs. 0.94 ± 0.01 mL/kg/min, $p < .005$) whi1e maintaining adequate growth and nutritional status (Pereira et al., 1994).

VII. PROTECTIVE FUNCTIONS OF FATTY ACIDS

Fatty acids (especially lauric acid, Cl2:0) and monoglycerides have antiprotozoan, antibacterial, and antiviral activity, specifically against lipid-enveloped viruses (Kabara, 1980; Thormar et al., 1987; Isaacs and Thormar, 1991). These fatty acids and monoglycerides are produced during the intragastric digestion of either human milk or formula fat (Hamosh, 1991; Armand et al., 1996). The fatty acids with highest anti-infective activity (Cl2:0, C18:1, C18:2) are also preferentially released during gastric lipolysis, suggesting that release of these fatty acids in the stomach might provide maximal protection along the gastrointestinal tract.

Conjugated linoleic acid (CLA, C18:9c, 11t) was recently shown to have anticarcinogenic activity (Pariza, 1997; Parodi, 1997). This fatty acid is found in grilled ground beef and dairy products and was also shown to have antioxidant activity and to be antiatherogenic. Its presence in human milk in amounts varying from 3.64 to 11.8 mg/g fat, depending on geographical location and maternal nutrition, was reported by several investigators (Fogarty, 1988; McGuire et al., 1997; Jensen et al., 1998). Although studies in animals have shown that CLA prevents endotoxin-induced growth suppression, improves weight gain, and feed eficiency, and enhances select immune functions, there is no information about its potential function in the newborn infant.

A. LCPUFA and Atopic Disease

In addition to their role in development, EFAs, among them LCPUFAs may also play a role in atopic disease. It is interesting that the observation of a disturbance in EFA metabolism in atopic disease (Hansen, 1937) is almost as old as the discovery of EFAs (Burr and Burr, 1930). It is quite amazing that by the rather primitive analytical techniques available 60 years ago, Hansen was able to find lower AA levels in the blood of atopic disease patients (Brown and Hansen, 1937) and to ascertain that a high supply of EFAs will ameliorate this condition (Hansen et al., 1947). Evidence of disturbances of EFA metabolism, specifically of impaired conversion of 18-carbon precursors to their LCPUFA products, is present in cord blood and may be predictive of atopic disease (Stranngard et al., 1987; Galli et al., 1994; Yu et al., 1996).

Similar changes in EFA and LCPUFA profiles in the milk of mothers of infants with atopic eczema, indicative of a defect in the conversion of linoleic acid to its long-chain products (Wright and Bolton, 1989), might explain why breast-feeding may not alleviate the infant's symptoms. A significant difference in the ratio of linoleic acid to the sum of its metabolites, γ-linolenic, dihomogammalinolenic, and arachidonic acids, in the milk of mothers of infants with newly developed atopic disease as compared to mothers of healthy infants (11.78 vs. 9.02, respectively) has been reported (Businco et al., 1993). The recent study of Yu et al. (1998) advances our understanding of this condition further by reporting that not only are the levels of the products of linoleic acid lower in the milk of atopic mothers but also that, in addition, the ratio of n-6 to n-3 LCPUFAs is higher than

in healthy women. Furthermore, the decline in milk n-3 LCPUFAs during lactation occurred more rapidly in the milk of atopic mothers. This imbalance could result in higher levels of mediators of inflammatory responses and lower anti-inflammatory mediators.

The fatty acid profiles in atopic disease suggest a lower activity of Δ6 desaturase (Manku et al., 1982; Harrobin, 1993; Yu et al., 1998). The recent identification of two candidate clones for mammalian Δ6 desaturase (an 820-bp mouse and 1500-bp human cDNA) with 75% nucleotide and 58% amino acid homologies between the two species (Cho et al., 1998) suggests the possibility for direct measurement of Δ6 desaturase expression and activity rather than inference on activity potential by means of LCPUFA metabolites. Such studies will provide the needed evidence for the link between Δ6 desaturase and atopic disease and might clarify the basis for the genetic predisposition to this condition.

B. Breast-Feeding and Development of Cognitive Function

The effect of breast-feeding, that is, providing the infant mother's milk that contains the LCPUFA's DHA and AA is based on numerous studies in infants as well as studies that have shown that 80% of the FAs in retinal photoreceptors is DHA. Furthermore, recent studies have shown that DHA may affect photoreceptor signal transduction (Litman et al., 2001). The beneficial effect of breast-feeding on visual function has led to supplementation of infant formulas with both DHA and AA. The role of DHA in brain function is much less understood. It is known that DHA is present in high concentration in neural gray matter, that is, it regulates genes involved in synaptic plasticity and the functions derived from the latter (Innis, 2004). Low brain DHA is associated with lower cytochrome *c* oxidase activity and glucose uptake (Ximenes da Silva et al., 2002), the latter could have important functional consequences because of the high-metabolic activity of the developing brain (Innis, 2004). Low-DHA in the developing brain has also been shown to affect dopamine and serotonin metabolism (de la Presa Owens and Innis, 1999; Zimmer et al., 2002), which in turn can affect cognitive function during early development.

TABLE 38.16
Effect of Breast-Feeding or DHA Supplementation on Cognitive Function

Author	Year	Breast-Feeding Months[a]	Effect (IQ Points)	Age of Assessment
Hoefer and Hardy[b]	1929	4–9	Higher IQ	7–13 years
Menkes	1977	Less breast-feeding in children with learning disability	Higher IQ (small difference)	
Fergusson et al.	1982		Higher IQ (small difference)	5–7 years
Rodgers	1978		Higher IQ (small difference)	8–15 years
Morrow-Tlucak and Hande	1988	4 months	Higher IQ (small difference)	1–2 years
Florey et al.	1995		Higher IQ (small difference)	18 months
Rogan and Gladen	1993		Higher IQ (small difference)	
Lucas et al.[c]	1992		Higher IQ (7–8 point diff.)	7.5–8 years
Lanting et al.	1994		Higher IQ	9 years
Harwood and Ferguson[d]	1998		Higher IQ	18 years
Gale and Martyn[d]	1996		Higher IQ	
Mortensen et al.[a]	2002	1–9 months	Higher IQ (7 points)	Adults
Helland et al.	2003		Higher IQ (4 points)	4 years

[a] Where breast-feeding duration is not indicated, it lasted for several months.

[b] Breast-feeding longer than 9 months was associated with the poorest cognitive development.

[c] Preterm infants, gavage fed expressed human milk.

[d] Increase in IQ related to length of breast-feeding attributed to exposure to higher n3 LCP level during pregnancy.

The effect of mode of infant feeding on subsequent cognitive function has been investigated for the past 80 years. IQ and motor development measured either during infancy, early or later childhood, or even in adults showed that feeding breast milk rather than formula has beneficial effects on the infant. The effects were, however, small, especially when correcting for confounding factors such as maternal age and education, socioeconomic status, and birth order. More recent studies indicate a relationship between duration of breast-feeding and IQ in teenagers and adults. It is interesting that breast-feeding for more than 9 months is associated with a decrease in IQ levels (Table 38.16). Whether this is due to lack of proper nutritional complementation during prolonged breast-feeding is not known.

While cognitive benefits might be associated with DHA in human milk, the latter might affect the former by additional factors such as growth factors, especially nerve growth factor (NGF) in human milk and with other components. Furthermore, breast-feeding might also be an indicator of maternal involvement in the infant's well-being and development not only during infancy, but also well beyond it. Well-designed, prospective studies are needed to ascertain the exact role of human milk and its components on cognitive development and function.

39 Fatty Acids, Cognition, Behavior, Brain Development, and Mood Diseases

Jean-Marie Edouard Bourre

CONTENTS

I. INTRODUCTION

Fatty acids control the structure and function of biological membranes, including membranes in the nervous system. The brain has higher lipid content than any other of the body's organs, except adipose tissue itself. All its lipids, which are mostly phospholipids, are found in cell membranes, and they are almost never sources of energy. Position 2 of the glycerol molecules in phospholipids generally bears a polyunsaturated fatty acid such as docosahexanoic acid (DHA; 22:6(n-3), 22:6ω3, cervonic acid), or arachidonic acid (ARA; 20:4(n-6), 20:4ω6). There may well be smaller amounts of adrenic acid (22:4ω6) and eicosapentanoic acid (EPA; 20:5(n-3), 20:5ω3) or docosapentaenoic acid (22:5ω3). The brain contains very little alpha-linolenic acid (ALA; 18:3(n-3), 18:3ω3) although this fatty acid is the precursor of all the other omega-3 fatty acids. The families of fatty acids are shown in Figure 39.1. A major component of brain membrane phospholipids is the omega-3 fatty acid DHA, and high concentrations of this fatty acid are found in the more metabolically active area of the brain, including the frontal cerebral cortex, which is involved in cognition, mitochondria, nerve endings, and synaptic vesicles. Most studies on cognition have focused on omega-3 fatty acids, or the

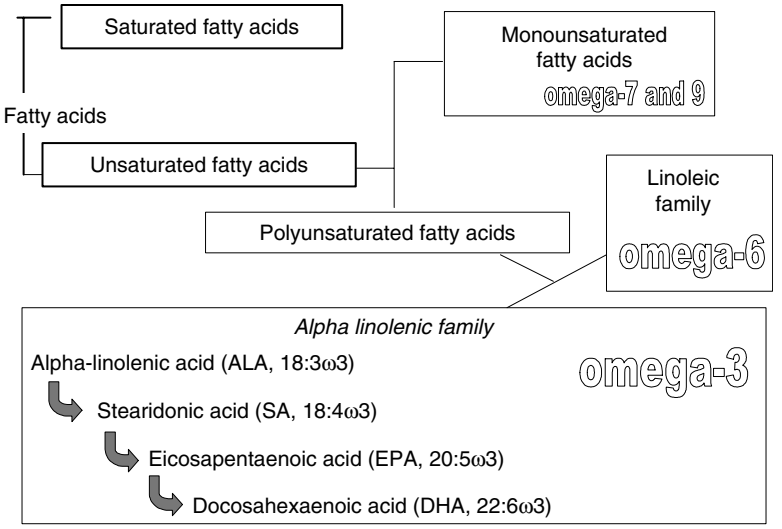

FIGURE 39.1 Omega-3 and other fatty acids. Quite possibly, at least part of the body's oleic acid requirement must come from the diet (Bourre et al., 1997), including that for the peripheral nerves (but not the brain) (Bourre and Dumont, 2003). Saturated fatty acids are synthesized in the cell cytosol and endoplasmic reticulum and in the process of myelinization (Bourre et al., 1976). Most lignoceric and nervonic acids are synthesized in the brain, but some may come from the diet (Bourre et al., 1977).

balance between these fatty acids and omega-6 fatty acids. However, one review has examined the role of the ARA cascade in affective disorders (Sublette and Trappler, 2000).

The importance of the omega-3 fatty acids (ω3) for brain development is based on three findings. First, the brain is exceptionally rich in polyunsaturated fatty acids, including omega-3 fatty acids. They account for 15%–20% of cerebral fatty acids, and for as much as 40% in the neurons and nerve terminals (Bourre et al., 1984). Second, a lack of dietary ALA results in a reduced cerebral DHA content, which is offset by increase in 22:6 omega-6 (Bourre et al., 1984; Galli et al., 1972). Finally, human mother's milk is particularly rich in ALA, but the cow's milk used to prepare baby formula in the early 1980s is not. This was because many formula producers used sunflower oil (without any omega-3 fatty acids) in the 1980s rather than rapeseed oil (9% ALA). The effect of such a deficiency on brain structure and functions, including cognition was first examined in animal studies and later in human newborns. Human fetuses and newborns accumulate considerable quantities of omega-3 fatty acids, mainly DHA (Cunnane et al., 2000).

Experimental studies showed that the differentiation (Bourre et al., 1983) of brain cells in culture requires omega-3 fatty acids as well as omega-6 fatty acids. A lack of dietary ALA disturbs the composition of brain cell membranes (Bourre et al., 1984). Chemical, physicochemical, biochemical, and enzymological analyses, plus toxicological, physiological, electrophysiological, and behavioral studies on ALA-deficient animals provided the first experimental evidence that a dietary component could influence the structure and function of the brain (Bourre et al., 1989b). There is a dose–effect relationship between the amount of ALA in a nursing rat's diet and its accumulation in the pup's brain, a minimum must be added to the diet: 0.4% of the dietary calories in a rat, thus 0.8% in humans, taking into account the brain/body weight ratio and the energy need per unit of surface area (Bourre et al., 1989b). It was subsequently shown that the omega-3 fatty acids in modified baby formula influence the visual and cerebral (including intellectual) capacities of the child, as measured by its neurological development, intellectual quotient, and motor index (Uauy et al., 2003). Hence, all baby formulas now contain at least ALA, in quantities equivalent to those in mother's milk.

Omega-3 fatty acids have both long-term and short-term actions in the brain. Long-term, they influence the production and maintenance of brain structures, and hence their function. Many studies

have shown their effects on the development of the brain. Their short-term effects are on the physiology of signal transduction. These are biochemical pathways that have no direct link with the diet, except that the molecules involved are of dietary origin. Several reports have claimed that these reactions underlie such disorders as autism, dyslexia, or even schizophrenia. And of course, both long-term and short-term influences can be present at the same time, such as when membrane alterations are accompanied by neuroinflammation (Bourre, 2005a).

Several studies have examined the effects of omega-3 fatty acid on brain biochemistry, membrane physical chemistry, enzyme activities and carrier function, neuromediators, electrophysiological parameters, behavior, and cognition. Others have looked at how these and other fatty acids are implicated in the nervous systems of animals and humans during life, particularly during development and aging. They have been covered in recent reviews (Bourre, 2004a,b); there have even been popular books written about them (Bourre, 1990, 2004c), including a recent one on omega-3 fatty acids (Bourre, 2004c).

Psychiatrists are interested in omega-3 fatty acids for several reasons. The high content of these fatty acids in the brain is one reason. Another reason is the experimental demonstration that a lack of dietary ALA results in behavioral and cognitive defects, particularly problems of learning, memory and habits, and reactions to toxins such as morphine. A lack of ALA also results in the abnormal metabolism of neuromediators.

The main feature of the omega-3 and omega-6 fatty acids is that they are both essential and strictly complementary, but they compete for the desaturase enzymes. The human diet usually contains enough omega-6 fatty acid, but the diets of people in occidental countries may contain insufficient ALA and DHA for pregnant women, mainly because of an insufficient intake of rapeseed oil (canola oil), walnut oil, and oily fish.

II. BRAIN DEVELOPMENT: EVIDENCE FROM ANIMAL MODELS AND STUDIES ON HUMANS

A. Experimental Evidence

Animal studies have provided convincing and consistent evidence linking a decrease in brain concentrations of DHA to altered performance in cognitive and behavioral tests. ALA deficiency affects the cognition/behavior of animals. For example, a lack of dietary ALA does not severely alter the neuromuscular function of rats (Frances et al., 1995), but it does affect learning (Bourre et al., 1989b) and behavior in humans (Frances et al., 1996a; Wainwright et al., 1994). Those activities that are associated with memory and habituation are particularly affected (Frances et al., 1996b, 2000), as has been confirmed in studies (Carlson, 2000; Coscina et al., 1986; Heird and Lapillonne, 2005; McCann and Ames, 2005; Salem et al., 2001; Wainwright, 2002; Yamamoto et al., 1988) using other tests. The effects on rodent cognition were shown in tests that involved sensory pathways other than the visual pathway.

The suggested relationship between the changes in learning performance and the composition of the microsomal membrane (Yoshida et al., 1997) seems to correlate well with the cognitive and behavioral deficits seen in rats fed a low-ALA diet and the defects in their monoaminergic nerve transmission, particularly in the frontal cortex (Chalon et al., 2001; Levant et al., 2004). A lack of dietary omega-3 influences specific neurotransmitter systems, particularly the dopamine systems of the frontal cortex, which is involved in cognition, but restoring dietary ALA does not completely restore dopaminergic neurotransmission in the frontal cortex and other areas (Kodas et al., 2002). Thus, the slow incorporation of fatty acids into the brain (Bourre et al., 1989a) is correlated with a slow improvement in learning (Lim and Suzuki, 2001). There is a clear relationship between polyunsaturated fatty acids and neurotransmission, and so between them and behavior (Chalon et al., 2001). Cholinergic and serotoninergic neurotransmission (Aid et al., 2003; Kodas et al., 2004) are also influenced by a lack of dietary ALA.

The most commonly used developmental outcomes examined in human infants are visual function and general neurodevelopment. Neurodevelopment is assessed by the Bayley Scale of Infant Development (BSID), first or second edition. It includes both the mental developmental index (MDI) and psychomotor developmental index (PDI). Other developmental assessments include the clinical Adaptative test (CAT); clinical Linguistic and Auditory Mileston Scale (CLAMS) and Gross Motor Scale (GMS) of the revised Gesell Developmental Inventory. Developmental quotients (DQ) are determined for language development (CLAMS DQ), visual problem solving ability (CAT DQ) in overall cognition (the mean of CLAMS and CAT DQ). A meta-analysis showed that infants fed ALA-supplemented formula had significantly higher concentrations of DHA in plasma and erythrocyte phospholipids, but further studies are needed to provide convincing evidence of the effect of ALA itself on growth and development (Udell et al., 2005).

ALA alone does not seem to be sufficient to ensure that the brain has an optimal concentration of DHA (Bowen and Clandinin, 2000), although an adequate equilibrium between linoleic acid (LA, 18:2(n-6), 18:2ω6) and ALA could ensure the optimal synthesis of DHA (Cheon et al., 2000). The brain seems to use preformed very long-chain omega-3 polyunsaturated (and omega-6) fatty acids most effectively under normal circumstances (Cunnane et al., 2001), which implies that they are synthesized in the liver from ALA (and LA, respectively) or are not obtained directly from the diet. DHA injected into the blood stream is taken up by the brain (Bazan and Scott, 1990). Supplementing the diet of animals with DHA (and EPA) improves certain aspects of their cognitive performance (Carlson, 2000). This has led to a comparison of diets without ALA and those containing either ALA (rapeseed and linseed oils), or DHA (seaweed extracts, fish oils, and purified products), or ALA plus DHA (algae, brain or egg extracts, and mixtures of vegetable and fish oils). There is a clear relationship between omega long-chain polyunsaturated fatty acid status during infancy and the neurodevelopmental status of babies at 1 year of age (Table 39.1) (Voigt et al., 2002).

Diets containing only very long-chain omega-3 fatty acids (EPA and DHA) are not satisfactory: a diet very rich in fish oil alters the composition of brain membranes by increasing the DHA content and considerably reducing the ARA content (Bourre et al., 1990). This favors arousal and learning in young mice, but reduces motor activity and learning in older mice (Carrie et al., 2000). The omega-6 fatty acids must therefore be in balance and accompanied by omega-3 fatty acids. Consequently, a diet supplemented with DHA and ARA prevents the decrease in dopaminergic and serotoninergic neurotransmitters in the frontal cortex of piglets caused by a lack of ALA (de la Presa and Innis, 1999).

Nearly all studies on cognition have concentrated on mammals; we have found no studies on birds and fish.

TABLE 39.1
Effect of ALA Concentration on Blood Parameters and the Mental Performance of Newborn Infants

ALA in milk	0.40	0.95	1.70	3.20
Plasma phospholipid ALA	0.10	0.16	0.23	0.46
Erythrocyte phospholipid ALA	0.05	0.09	0.12	0.23
Erythrocyte phospholipid DHA	0.83	1.55	1.72	2.52
Bayley PDI	88.80	95.50	93.70	96.40
Bayley MDI	94.80	96.30	101.00	100.50

MDI = mental developmental index; PDI = psychomotor developmental index.

B. EPA and DHA in Human Baby Formulas

DHA is clearly required by babies, including full-term infants (Gibson et al., 1996). Analyses of the frontal cortex of dead infants have shown that babies fed formula lacking DHA have a lower-than-normal DHA content (Byard et al., 1995). The brain of a child takes up 48% of the 10 mg of DHA incorporated each day. The brains of breast-fed babies (mother's milk provides about 60 mg/day) contain about 1 g DHA, while the brains of bottle-fed babies contain only 0.6 g DHA (Cunnane et al., 2000). Fetal accretion of omega-3 fatty acids was estimated at 67 mg/day during the third trimester (Clandinin et al., 1980a,b). In practice, formulas for premature babies should contain both ALA and DHA (Rodriguez et al., 2003), although there is yet to be a clear demonstration of the absolute need of DHA for cognition (Simmer and Patole, 2004). The negative effect of a lack of omega-3 fatty acids on the development of the nervous system (and vision) initially led to the addition of omega-3 fatty acids alone (both EPA and DHA, no omega-6 fatty acids), generally as fish oil. This improved visual acuity, but it does not favor the overall development of the infant, in terms of body weight, height, and head circumference. Finally, almost all experiments have provided evidence of causal links between altered brain concentrations of DHA during the perinatal period and subsequent cognitive or behavioral performance (McCann and Ames, 2005).

C. Importance of the Balance between Omega-6 and Omega-3 Fatty Acids

Consequently, baby formula must contain both DHA and ARA to maintain the omega-3/omega-6 fatty acid ratio. Although the biochemical and physicochemical results are quite conclusive, the behavioral results are somewhat less clear. Most studies on the cognitive/behavioral development of infants fed formula containing long-chain (omega-6 and omega-3) fatty acids have used the BSID, which is considered to be the best standard for assessing the overall ability of infants from birth to 42 months of age. They provide standardized indices of both psychomotor development (PDI) and mental development (MDI). The Fagan Test of Infant Intelligence (FTII) has also been used. An analysis of eight trials carried out in 2001 (Simmer, 2001) was inconclusive, but a second analysis, 3 years later, of 14 published studies comparing baby formulas with and without long-chain polyunsaturated fatty acids was positive. The 14 studies included 7 on the effects on cognitive development; the results take into account the fact that brain DHA is derived from both ALA (with a 10% conversion rate) and preformed dietary DHA (Uauy et al., 2003).

One study (Agostoni et al., 1995) showed a benefit at 4 months, as assessed by the DQ (Brunet–Lezine test), but there was no longer any difference when these children were examined later, at age 2–4 years (Agostoni et al., 1997) (Table 39.2). Another study found that adding ALA and DHA to the formula improved cognitive performance at 4 months and that the improvement persisted (Willatts et al., 1998; Willats, 2002). Thus, an effect at 4 months does not predict an effect at 24 months. However, there is still a close correlation between the long-chain fatty acids in erythrocytes and neurological development (Agostoni et al., 1997). A review of the literature showed a benefit for preterm infants somewhat more convincingly than for term infants (Heird and Lapillone, 2005).

The feeding habits of families undoubtedly vary considerably, so that the DHA status of an infant will be more influenced by the dietary pattern than by the nature of the baby formula/breast milk consumed during its initial months of life. This is probably why no difference was found in infants aged 39 months (Auestad et al., 2003), or any association between the status at birth and performance at age 7 years (Bakker et al., 2003). Another study found a statistically insignificant improvement in children fed formula containing DHA and ARA (Wezel-Meijler et al., 2002). In a more detailed study, a restricted number of children were monitored from before birth, showed that very long-chain polyunsaturated fatty acids are closely associated with an increased IQ at age 6.5 years (Gustafsson et al., 2004). The children of women who take cod liver oil during pregnancy and

TABLE 39.2
DHA in Milk, and Phospholipids in the Blood Plasma and Erythrocytes and the Neurodevelopment Quotient

	Formula 1	Formula 2	Mother's Milk
DHA in milk (g/100 g fat)	0.3	0	01–0.6
DHA in plasma phospholipids (%)	2.7	0.9	2.8
DHA in erythrocyte phospholipids (%)	4.1	1.8	4.1
Neurodevelopment quotient	105	96	102

Formula 1 = milk enriched in long-chain fatty acids; Formula 2 = standard cow's milk. The ALA content of the 3 milks was equivalent to 0.7 g/100 g fat.

lactation have improved mental performance measured at 4 years old (Helland et al., 2003). Other authors (Birch et al., 2002) suggest that babies should be given supplemented formula for at least 6 weeks to ensure maturation of the cerebral cortex and optimal visual performance in later years. A quantitative analysis of the influence of the prenatal intake of omega-3 fatty acids on cognitive development estimated that increasing maternal DHA intake by 100 mg/day increased child's IQ by 0.13 points (Cohen et al., 2005).

These studies used multiple tests, and it is quite possible that only some of them are influenced by dietary omega-3 fatty acids, as has been shown in animal studies (Frances et al., 1996b). They do demonstrate the advantage of breast-feeding over feeding formula containing DHA or ARA.

Several studies have shown the importance of breast-feeding and some have justified it by the amount of polyunsaturated fatty acids, particularly omega-3 fatty acids, in mother's milk. It improves the neurological development of newborns, especially if continued for over 6 weeks, as evaluated by motor activity (Bouwstra et al., 2003), and this effect can be measured in infants up to 1 year old. Some believe that this is due to the presence of omega-3 fatty acids, especially DHA (Agostoni et al., 2001). Others have found that babies thus fed have an IQ 8.3 points higher at 18 months (Lucas et al., 1992). One study using the Bailey test showed that breast-feeding had a positive effect, measured at 1 year old, on baby boys, but not on girls (Paine et al., 1999). The effect on neurological development is measurable in children up to the age of 7 or 8 (Horwood et al., 2001) or even 9 years (Lanting et al., 1994). But others have found that the effect cannot be measured at 13 months or 5 years (Angelsen et al., 2001). These widely differing results may be due to the different tests used.

In fact, small differences in brain concentrations of DHA, such as might occur between infants fed unsupplemented or supplemented formulas, may result in small, subtle effects that are currently difficult to detect, but could be significant. This is sustained by animal studies linking a decrease in the brain concentration of DHA to altered performance in cognitive and behavioral tests. Thus, the published literature shows that long-chain polyunsaturated fatty acids are important for the growth and development (cognitive) of human infants (Fleith and Clandinin, 2005).

III. ADULT HUMANS, EPIDEMIOLOGICAL AND EXPERIMENTAL EVIDENCE

A. Mental Health, Cognition, and Mood

It has been reported that omega-3 fatty acids improve cognitive development and learning under certain conditions. Dietary omega-3 fatty acids may improve intentional and physiological functions

involving complex cortical processing. Studies on the relationship between cognition alterations and mood and fatty acids (particularly omega-3 fatty acid) are scarce, but there has been a lot of speculation. These fatty acids are essential for normal general health and well-being, mainly because of their biochemical properties. An Australian study concluded that regular normal meals (including omega-3 fatty acid), including a good breakfast, improved mood and cognitive performance (Lombard, 2000). A New Zealand study found that the personal perception of good mental and physical health varied with the consumption of fish, thus of omega-3 fatty acids, so that they were considered to stabilize mood (Silvers and Scott, 2002). However, an English study found that the consumption of fish did not improve the mood of people who were not depressed (Ness et al., 2003). The food consumption and nutrient intake of subjects with depressed mood was studied, using anxiety and insomnia as indices of compromised mental well-being. Those subjects reporting anxiety or depressed mood had higher intakes of omega-3 fatty acids and omega-6 fatty acids (Hakkarainen et al., 2004b). It is thus too early to say that omega-3 fatty acids modulate cognitive processes by altering mood.

B. Stress

As fish oil is known to influence behavior cognition, at least indirectly, its influence on aggressive behavior was assessed. Anxiety is an incapacitating syndrome. Subjects were given capsules of vegetable oils to determine the optimum dietary ratio between omega-3 and omega-6 fatty acids needed to counteract stress. The ratio was found to be 4 for LA and ALA. This protected against changes in the hippocampus in response to excess cortisol and corticosteroids, avoiding impaired learning (Yehuda et al., 2000). Aggression was found to vary inversely with the consumption of fish; daily doses of 1.5–1.8 g DHA (found in fish oil) helped to reduce stress and decreased the aggressive tendencies of young adults, perhaps by modulating stress. Fish oils reduced the aggressiveness of subjects aged 50–60 years, when given for 2 months, by 30%, but doses of 150 mg per day were insufficient (Hamazaki et al., 2002). An adequate DHA intake could prevent aggression from increasing at times of mental stress; this may indicate how fish oils prevent diseases such as coronary heart disease.

If increasing the intake of omega-3 fatty acids is favorable, what happens if the intake of linoleic (omega-6) acid is reduced? There is evidence for a correlation between the consumption of seed oils, the major dietary source of LA, and a greater incidence of homicide in western countries with similar socioeconomic and background seafood intakes. Thus, a diet poor in LA may prevent behavioral disorders that are now the concern of correctional institutions, social services, and mental health providers (Hibbeln et al., 2004).

C. Hyperactive and Dyslexic Children, Dyslexia in Adult

The cluster of age-inappropriate behavioral abnormalities including inattention, impulsiveness, and hyperactivity are the hyperkinetic disorders. Fatty acids seem to be important for attention deficit associated with hyperactivity (Richardson and Puri, 2000). A pilot study carried out on 50 children showed that supplementing their diet with essential fatty acids (daily doses of 480 mg DHA, 80 mg EPA, 40 mg ARA, 96 mg γ-linolenic acid, and 24 mg tocopherol acetate) improved their symptoms (Stevens et al., 2003). However, another study showed that dietary supplements improved the blood parameters of hyperactive children suffering from attention deficit, but not their clinical symptoms (Voigt et al., 2001). Polyunsaturated fatty acids, including omega-3 fatty acid, could be implicated not only in disorders of cerebral development, attention deficit, hyperactivity, but also in dyslexia and even in autism (Richardson and Ross, 2000). The severity of dyslexic signs was found to vary with the lack of polyunsaturated fatty acids in boys, but not in girls (Richardson et al., 2000). Dyslexia in adults is accompanied by indications of a lack of polyunsaturated fatty acids (Taylor et al., 2000).

D. Depression

The major mood disorders can be roughly divided into unipolar major depression and bipolar disorder. Bipolar disorder, also known as manic-depressive illness, causes shifts in a person's mood and ability to function. It is a complex and chronic condition associated with considerable morbidity and mortality, including a high suicide rate. The increased prevalence of depression over the past half century seems to parallel fundamental changes in dietary habits, with a reduced intake of foods containing omega-3 fatty acids (Colin et al., 2003). The frequency of depression in British Columbia increased as the traditional dietary habit of fish eating was lost, and then fell as these dietary elements were reintroduced (Bates, 1988). There is a relationship between the drop in omega-3 fatty acid consumption (in fish) and the risk of depression, particularly as the incidence of the disorder varies from 1 to 50 per 1000 population, depending on the country, in parallel with fish consumption (Hibbeln and Salem, 1995; Tanskanen et al., 2001). This was not confirmed by another study (Hakkarainen et al., 2004b). Yet another study showed that, in Crete, there is an inverse relationship between the DHA concentration in adipose tissue and the risk of depression (Hibbeln, 2002). An overview of 41 published studies covering 23 countries shows that a fish-poor diet leads to a low-DHA concentration in mothers' milk (which is undesirable for newborns) and an increased risk that the mothers will suffer from postnatal depression (Hibbeln, 2002). However, there was no such relationship between dietary EPA and ARA.

There is still, however, little hard evidence showing a relationship between changes in dietary fatty acids and the risk of depression with aging, although plasma composition of fatty acids and depression are associated during aging (Tiemeier et al., 2003). Regular fish consumers in a community of elderly French people aged 65 years and above, had fewer depressive symptoms and scored higher on the Mini Mental Status Examination. The regular fish consumers (at least weekly) were better educated (OR 1.19–1.65) and had better incomes (1.37–1.89) than the controls (Barberger-Gateau et al., 2005).

Two clinical studies have used doses of 2 g per day of EPA ethyl ester to successfully treat cases of depression that responded only partially to classical psychiatric treatment (Peet and Horrobin, 2002; Puri et al., 2000). One patient was given EPA together with conventional treatment; this not only improved the clinical signs (suicidal tendencies, social phobias), but also resulted in morphological changes (reduced volume of the lateral ventricles) (Puri et al., 2001). DHA is also a successful treatment for minor depression (Mischoulon and Fava, 2000). A patient suffering from postnatal depression was successfully treated with omega-3 fatty acids (Chiu et al., 2003), while another study using fish oil (2.69 g per day, EPA/DHA = 1.4) starting at the 34–36 week of pregnancy and continuing until 12 weeks after birth obtained negative results (Marengell et al., 2004). Yet another study found that a dietary supplement of 200 mg DHA per day for 4 months after childbirth prevented the drop in plasma DHA but did not alter the patients' self-evaluated state of depression (Lombard, 2000). This could be because they measured mood changes rather than real depression and/or because the doses of DHA were too low. Treatment with 9.6 g omega-3 fatty acid per day for 8 weeks gave positive results with cases of major depression (Su et al., 2003), but DHA alone (2 g per day for 6 weeks) did not seem to be effective (Marangel et al., 2003). In fact, EPA seems to increase the action of antidepressant drugs (Murck et al., 2004).

A study of bipolar disorder patients (manic depressives) in 14 countries showed a correlation between the prevalence of the disorder and low fish consumption, with the threshold of vulnerability being 65 g per day (Noaghiul and Hibbeln, 2003); treatment with omega-3 fatty acids could be useful under certain specific conditions (Stoll et al., 1999).

Major depression is associated with lower omega-3 fatty acid levels in patients with recent acute coronary syndromes, thus dietary, genetic and hormonal factors may all play a role in both depression and coronary heart disease (Frasure-Smith et al., 2004).

Depressive symptoms are among the most prevalent psychiatric symptoms and are strongly associated with the development of depressive disorders; individuals with depressive symptoms are

at four times greater risk of developing major depression within 1 year. Depression is a major source of functional disability. This has been consistently demonstrated in epidemiological, primary care, and out-patient studies, at least in Western Europe and North America.

E. Drug Addiction

Drug addiction alters cognition. Omega-3 fatty acids, and perhaps omega-6 fatty acids, may also be involved in drug addiction. Ex-cocaine addicts more rapidly return to addiction if they lack polyunsaturated fatty acids (Buydens-Branchey et al., 2003a,b). It is possible that a diet-related change in the membranes of certain cerebral neurons makes some people more unstable, so that they may be more predisposed to drug addiction in response to other impulses. Whatever the cause, drug addicts often have very poor diets, but how this can aggravate their condition, interfere with curing their addiction or make re-addiction more likely remains a major question. Animal experiments have shown that a lack of ALA alters the response to morphine (Frances et al., 1996a).

F. Autism

Autism remains one of the very few conditions classified as a syndrome, defined only in terms of observable symptoms. This is largely due to the lack of accepted biochemical diagnostic markers. Sufferers from autism often have a range of physiological problems, and alterations in their fatty acid metabolism, particularly those related to eicosanoid production. An autistic boy aged 11 years was successfully treated with fish oil (540 mg EPA per day) for 4 weeks (Johnson and Hollander, 2003). The plasma phospholipids of autistic children contain 23% less DHA than do those of normal children, while the total omega-3 fatty acid concentration is 20% lower and their omega-6 fatty acids are unchanged (Vancassel et al., 2001). Another study found that the phospholipids in erythrocytes were 70% below normal (Bell et al., 2000).

G. Dementias

Alzheimer's disease is a neurological disorder that is characterized by progressive memory loss, intellectual decline, and eventually global cognitive impairment. Major symptoms include short-term and long-term memory loss, impaired speech and language, visual-spatial changes, impaired abstract reasoning, and poor judgment. Several epidemiological studies have shown that omega-3 fatty acids play a role in the prevention of dementia, as expanding knowledge in the area of lipid biochemistry suggests that Alzheimer's disease is associated with brain lipid defects. For example, the Rotterdam study found that the risk of dementia with vascular features is positively correlated with the consumption of saturated fatty acids, but negatively correlated with the consumption of omega-3 fatty acid-rich fish (Kalminjn et al., 1997a); these results are discussed in (Engelhart et al., 2002). A diet rich in unsaturated fatty acids and unhydrogenated fat was found to protect against Alzheimer's disease, in contrast to a diet rich in saturated fatty acids and *trans* fatty acids (Morris et al., 2003b). Some epidemiological studies have shown that the consumption of finfish also seems to protect against dementia, including Alzheimer's disease. In France, the consumption of meat, because of its saturated fatty acid content, is only poorly correlated with an increased risk of dementia, while the consumption of fish has a protective effect. Those subjects who ate fish at least once a week were 34% less likely to develop any form of dementia, and 31% less likely to suffer from Alzheimer's disease. The effect was still present when socioeconomic factors were taken into account, as these factors are linked to both the reduced risk of Alzheimer's disease and the fish consumption (Barberger-Gateau et al., 2002). A study carried out in the United States found that Alzheimer's disease was 60% less common in people that consumed about 60 mg DHA per day (at least one fish meal a week) than in people that ate very little fish (Morris et al., 2003a). The overall findings in Japan are the same (Otsuka et al., 2002).

A low plasma concentration of omega-3 fatty acids (including DHA) is an indication of risk of cognitive deficiencies and other types of dementia, besides Alzheimer's disease (Conquer et al., 2000).

Cardiovascular risk often clusters into a metabolic syndrome that may increase the risk of dementia. Epidemiological studies have implicated cerebrovascular disease and its antecedent as risk factors for Alzheimer's disease. Vascular dementias and Alzheimer's disease have nutritional factors in common: an excess of omega-6 fatty acids and a lack of omega-3 fatty acids; this leads to changes in the microvasculature, chronic inflammation, platelet aggregation, and endothelial dysfunction (Otsuka et al., 2002). This provides at least a partial explanation of why the cognitive disorders in very elderly people are positively correlated with the consumption of LA, and negatively correlated with the consumption of fish (Engelhart et al., 2002). The cardiovascular risk increases the risk of dementia, particularly vascular dementia (Kalmijn et al., 2000). Inflammatory processes may well be implicated in all these disorders (Simopoulos, 2002). It also seems clear that insufficient fish consumption is a significant risk factor, there has not yet been any published report on the use of omega-3 fatty acids in the preventive treatment of dementia of any type. One-fourth mixture of ALA and LA, given as a capsule, was shown to improve the quality of life for those suffering from Alzheimer's disease, as measured by tests of spatial orientation, cooperation, mood, appetite, short-term and long-term memory, sleep, and hallucinations (Yehuda et al., 1996). There have been no studies to date on the implication of omega-3 fatty acids in cognitive alterations due to alcoholism and in alcoholic dementia, although studies on experimental animals have shown that dietary ALA modulates the effects of alcohol on such things as the nerve terminals (Zerouga et al., 1991).

H. Schizophrenia

Antipsychotic drugs are the most effective treatment of schizophrenia, particularly the most disturbing symptoms such as agitation and psychosis. Treatment with new antipsychotics seems to have improved the negative symptoms and cognitive deficits that are considered difficult to treat. However, their side effects significantly reduce the patient's quality of life, so that it is important to develop adjunctive treatment strategies. Adjuncts of essential fatty acids, and their metabolites, such as eicosanoids, have been considered to improve the outcome of this disease. For instance, schizophrenics whose diet includes plenty of fish have less severe clinical signs (Peet et al., 1996).

Patients who ate 10 g of fish per day for 6 weeks seemed to have improved symptoms (Laugharne et al., 1996), as did patients given a combination of 120 mg EPA, 150 mg DHA, 500 mg vitamin C, and 400 IU vitamin E twice a day for 4 months, but the improvement was relatively modest (Arvindakshan et al., 2003). A single patient given EPA alone showed improved symptoms; the turnover of brain phospholipids (as measured by ^{31}P NMR) returned to normal and brain atrophy had receded after treatment for 6 months (Puri et al., 2000). This clearly needs to be confirmed. Some patients who had been treated and stabilized were then given EPA for 3 months (Peet et al., 2001). EPA has also been used to supplement a 6-month course of antipsychotic drugs, but it left residual symptoms (Emsley et al., 2002). One author reported that treatment with 3 g EPA per day produced no results (Fenton et al., 2001), perhaps because the dose was too low or because the patients were nonresponders (Horrobin, 2003). There have been several proposals as to how omega-3 fatty acids are involved in schizophrenia (Peet, 2003), including the modulation of neurotransmission, particularly dopaminergic transmission, but there is as yet no hard evidence (Peet et al., 2001).

Fatty acids differentially affect serotonin receptors and the binding of its transporters in the rat brain; this may be important for understanding neuropsychiatric diseases such as schizophrenia, where there seems to be an association between altered fatty acids levels and the serotoninergic system (Du Bois et al., 2006).

The erythrocyte membranes of schizophrenic patients contain subnormal concentrations of DHA and EPA, and a link has been found between the change in fatty acid profile and the severity of the clinical disease (Assies et al., 2001). Another study did not find these results (Hibbeln et al., 2003). However, there could well be subgroups of patients for whom the omega-3 fatty acids are

particularly important, which would explain why clinicians find divergent results in which the DHA content is either elevated, depressed, or normal, depending on the publication. In fact, there is a relationship between membrane phospholipids composition, alterations in neurotransmitter systems and schizophrenia (Du Bois et al., 2005), and hence cognitive alterations.

I. Cognition and Aging

Dietary factors might modify the cognitive decline that results from aging. Several studies have shown that cognitive deterioration in the elderly is associated with deficiencies of macronutrients and micronutrients. Fatty acids are the prime candidates, as they are quantitatively and qualitatively extremely important in the brain. The biochemical and physiological roles of unsaturated fatty acids (especially omega-3 fatty acids) in the brain at various ages and during aging have been reviewed (Bourre, 2004b). The changes that occur with advancing age are complex, in both animals and humans. Omega-3 fatty acids may be involved either directly or indirectly, depending on the part of the body, the structure, cells, and organelles, or lipids concerned. A recent French study showed that age-related cognitive deficit is linked to a reduction in the omega-3/omega-6 fatty acid ratio in erythrocytes (Heude et al., 2003); an excess of nutritional LA was also coupled to a decline in cognitive performance, while the reverse is true for fish oils (Kalmijn et al., 1997a,b). Studies on an aging population in southern Italy found that an elevated unsaturated fatty acid intake (monosaturated, unsaturated, and polyunsaturated), high intakes of antioxidant compounds, and a diet very low in saturated fatty acids could act synergistically to improve cognitive performance (Solfrizzi et al., 2005). Fish consumption may be associated with a slower cognitive decline with age: the rate was 10% slower among persons who consumed one fish meal per week, and 13% slower in persons who consumed two or more fish meals per week (Morris et al., 2005). Phosphotidyl-choline improves the memory, learning, concentration, vocabulary recall, and mood of elderly people suffering from cognitive loss. Phosphatidyl-choline, together with vitamin B_{12}, improves learning in aging mice (Hung et al., 2001). There appears to be no question but that an adequate intake of omega-3 fatty acids could ensure the turnover of membranes, so helping to protect against brain aging. However, a dietary supplement of high concentrations of omega-3 fatty acids produces behavioral changes that vary with the age of the individual, improving learning in young animals, but reducing learning and motor activity in older ones (Carrie et al., 2000). This should be borne in mind when considering dietary supplements.

There are well-established benefits of omega-3 fatty acids (from fish or fish oils) for vascular health, and theses advantages may explain better cognitive performances in those with high omega-3 fatty acids concentrations in their erythrocytes. (The evidence obtained from self-reported consumption of fish or fish-oil supplements is generally a less informative indicator than are measurements of erythrocyte omega-3 fatty acid contents.) Some vascular risk factors and cardiovascular diseases have been linked to cognitive decline (and dementia). Hence, fatty acid intake, mainly omega-3 fatty acids, might affect the development of cognitive impairment by influencing the development of thrombosis and atherosclerosis. Cerebrovascular disease is associated with a cognitive decline and progression of dementia, and this association could be weakened by a high intake of omega-3 fatty acids (from finfish or fish oils) to slow or prevent the development of age-related cerebrovascular disease. The vascular risk factors that predict stroke are associated with a wide range of cognitive alterations that occur around the age of 60 years; moreover, a lower childhood IQ is associated with an increased incidence of cardiovascular diseases.

These observations could be expanded to other stages of life. For instance, the consumption of oily fish and marine omega-3 fatty acids is associated with a reduced risk of impaired cognitive function, while a diet rich in cholesterol and saturated fat has been linked to an increased risk in a middle-aged population (Kalmijn et al., 2004). The spatial memory of rats fed sub-normal amounts of omega-3 fatty acids in the Morris maze is compromised. These animals seem to have fewer endothelial mitochondria, and a lower ratio of micro-vessels to degenerative pericytes (de Wilde et al., 2002).

Aging is associated with an increased production of free radicals and a decrease in antioxidant defences, both of which lead to increased oxidative stress that is implicated in altered cognition and the development of dementia. On the contrary, a diet rich in antioxidants such as vitamins E, A, and C, β-carotenoids, and flavonoids could protect against such changes. But only α-tocopherol is effective, at least in animals (Clement et al., 1995). It has been speculated that the loss of DHA in Alzheimer's disease may reflect its propensity for free radical-mediated lipid peroxidation. Thus, either a decreased intake or increased oxidative stress (or both) could contribute to brain DHA depletion and hence to altered cognitive function.

Food supplements (and erythrocyte content) are associated with better cognitive aging. If associations with omega-3 fatty acid are causal, optimizing the omega-3 and omega-6 fatty acid intakes could help preserve cognitive function in old age (Whalley et al., 2004). Greater fish oil intake is associated with better cognitive function in late adulthood. Supplementation is associated with improved attention and physiological functions, particularly those functions involving complex cortical processing, even in healthy subjects (Fontani et al., 2005).

IV. DISCUSSION

Omega-3 fatty acids have two broad actions, one long-term and the other short-term. Their long-term actions are on membrane composition and function. This is supported by studies on brain development and probably the role of dietary omega-3 fatty acids in the prevention of dementia, including Alzheimer's disease. Their short-term actions could involve phospholipid metabolism, and hence the modulation of signal transduction. The evidence for this includes the effect of EPA on depression, schizophrenia, and autism. But the two types of action can occur simultaneously, as in inflammation during Alzheimer's disease. It is too soon to state that omega-3 fatty acids prevent depression by treating inflammation, even though there are good indications that inflammation occurs during depression. Although there is clear evidence that omega-3 fatty acids do prevent and reduce these symptoms, to some extent, these relationships are not necessarily causal. Epidemiological studies showing that dietary fish, or fish oil capsules alleviate some psychiatric diseases, have flaws inherent in this type of epidemiological survey (e.g., association does not imply causation).

The timetable of cerebral development means that any short-term perturbation can result in long-term changes in the biochemistry, physiology, and function of the brain, and the possibilities of recovery are relatively restricted, because of the genetically programmed brain development, although a dietary lack of omega-3 fatty acids results in their replacement by other fatty acids. Dietary omega-3 fatty acids contribute to the construction and maintenance of the brain (Bourre, 2004a,b,c).

Dietary omega-3 fatty acids, especially DHA, have probably had a major influence of the evolution of the human brain. It is found in a few special vegetables, oily fish, all seafood (fish and shellfish), and certain eggs (Broadhurst et al., 2002). The lack of dietary ALA can readily be overcome by using rapeseed oil (canola oil) and walnut oil ("noix de Grenoble" oil) (soybean oil has too much omega-6 fatty acids) and a special variety of eggs (omega-3 eggs, Columbus® or Benefic®)—all other eggs, including organic ones, are unsuitable. Walnuts, mixtures of oils containing at least 50% rapeseed oil, or 10% linseed oil, and other plant-based foods rich in ALA are also useful (Bourre, 2005b). Thus, it is not difficult to find food rich in omega-3 fatty acids (Bourre, 2003, 2005b).

An adequate intake of the precursor ALA enables the body to regulate interconversion, as dietary DHA results in a regulatory systems being short-circuited, requiring precise definitions of nutritional requirements for all physiological and pathological situations, which is not presently possible. Dietary intake of DHA varies enormously and depends on where people live. Children are at particular risk of such deficiencies. Thus, those with low-dietary intakes need to be identified and counseled. Wild oily fish are generally very rich in DHA and EPA, as are farmed fish, provided they are fed correctly. The human nutritional value of meat and eggs, in terms of lipid (amounts of

omega-3 fatty acids), may vary considerably depending on the fats fed to the animals/hens (Bourre, 2003, 2005b).

Although a good dietary intake of omega-3 fatty acids is fundamental, it is not enough. The presence of omega-6 fatty acids must also be taken into account, to ensure that the omega-6/omega-3 ratio is not above 5. And this ratio is far too high in the diet of most people in the Western world. It should only be reduced by increasing the intake of omega-3 fatty acids, and most certainly not by decreasing the intake of omega-6 fatty acids, as our intake of omega-6 fatty acids is only slightly above the recommended value.

V. SUMMARY AND CONCLUSIONS

The effects of fatty acids, essentially omega-3 fatty acids, on cognition and behavior have been examined mainly during perinatal brain development and, to a lesser extent, during aging and in terms of some psychiatric diseases. Fatty acids control the structure and function of biological membranes, including membranes in the nervous system. The high omega-3 polyunsaturated fatty acid content of the brain clearly indicates that these lipids are involved in brain biochemistry, physiology, and functioning, and thus in cognitive performances during development and in some cognitive changes due to neuropsychiatric diseases and aging. Animal studies have provided convincing and consistent evidence linking a decrease in brain concentrations of DHA to altered performances in cognitive and behavioral tests. Some studies on perinatal cerebral development and omega-3 fatty acids have focused on ALA, while others have examined long-chain derivatives such as DHA and EPA. Other studies have examined the influence of ALA plus DHA, sometimes with the omega-6 fatty acid, ARA.

Studies on ALA first showed the effect of a dietary component on the structure and function of the brain. These include (1) cultures of dissociated brain cells, analyses of the fatty acids and lipids in whole organ, regions, cell types in the brain, and classes of phospholipids; (2) physicochemical studies on brain membrane fluidity, and biochemical and enzymological studies on enzymes such as ATPase; (3) physiological studies on dopaminergic, serotoninergic, and cholinergic neurotransmission; (4) toxicology of heavy metals and trans fatty acids; (5) studies on vision, hearing, and taste; and (6) electrophysiological studies (ERG, EEG) and cognitive and behavioral studies, memory, and habituation being specifically affected. For instance, dietary omega-3 deficiency influences specific neurotransmitters systems, particularly the dopamine systems of the frontal cortex, which is related to cognition.

The accumulation of considerable conclusive experimental evidence led to the inclusion of ALA in baby formulas. This decision was due to many studies on newborns, including those on cognition. The nature of the polyunsaturated fatty acids (particularly the omega-3 fatty acids) in baby formulas for both full-term and premature infants influences the infant's visual, neurological, cerebral, intellectual capacities and cognition. Infants fed vegetable oil-based formulas (poor in ALA) may have poorer visual functions, lower cognitive scores, and acquiring learning tasks are slower in comparison with those breast fed or those fed formulas supplemented with DHA. Despite a lack of exhaustive experiments, DHA and EPA were also added to baby formula, which may have a limited or even negative effect because of competition with omega-6 fatty acids. A combination of DHA, EPA, and ARA was later shown to improve membrane composition and cognition.

Dietary omega-3 fatty acids may also help prevent psychiatric disorders such as depression and dementia, particularly Alzheimer's disease. They probably directly influence major depression, bipolar disorder (manic-depressive illness), and schizophrenia. Omega-3 fatty acids may be important in diseases such as dyslexia and autism. Dietary omega-3 fatty acids deficiency can alter membrane turnover, and thus accelerate cerebral aging and cognitive decline. The lack of omega-3 fatty acids in today's occidental diet suggests that consumer must be persuaded to select foods that are rich in omega-3 fatty acids, such as rapeseed and walnut oils and oily fish.

40 Fatty Acids and Aging

José L. Quiles and M. Carmen Ramírez-Tortosa

CONTENTS

I. CONCEPT AND PRINCIPLES OF AGING

Aging is defined as the progressive loss of function accompanied by decreased fertility and increased mortality with the advance of age (Kirkwood and Austad, 2000). In addition, it is said to be a common phenomenon to all multicelled organisms and has been described as an endogenous and a progressive decline in the effectiveness of physiological processes after the reproductive phase of life (Camougrand and Rigoulet, 2001; Barja, 2002; Sohal et al., 2002). The aforementioned decline has been attributed either to a genetic program present in all the individuals of a species or else to the stochastic accumulation of errors in the somatic cells, which would give rise to the progressive loss of cell functions (Camougrand and Rigoulet, 2001). The study of aging confronts, among others issues, the problem of separating the process itself from diseases related to aging.

The determinants of longevity have captured the attention of researchers of a great variety of disciplines, including sociology, biology, psychology, and medicine (De Benedictis et al., 2001). Many studies made on the human species have concluded that humans have steadily increased their average life expectancy, owing to improved living conditions and advances in medicine, particularly the control of infectious diseases.

As a living being ages, the probability of death augments, reaching a certain characteristic age for each species at which all the individuals have died. In the case of the human, this maximum lifespan has been established at 110–120 years. The life expectancy requires a multifactorial treatment, given that it is affected by genetic as well as environmental factors, in addition to the stochastic component resulting from the interaction between individual changes for survival and unpredictable events that occur over the course of a lifetime (De Benedictis et al., 2001). At present, there are many

countries in which only a few individuals are capable of reaching this maximum lifespan, owing to infectious disease or inadequate nutrition. In industrialized countries the problem is different. Since 1840, the life expectancy has grown at a rate of approximately 3 months per year, and at the moment there are no signs that this tendency is going to change. The good news is that health has improved; however, the cost of health has also grown, and previously unknown diseases have appeared in the past 100 years, such as Alzheimer's, age-associated macular degeneration (currently the main cause of blindness), diverse cardiovascular diseases, cancers, and so forth. Therefore, it can be said that the average lifespan has lengthened in developed countries with respect to undeveloped ones, although the maximum duration of lifespan appears to be the same (Halliwell and Gutteridge, 1999; Partridge and Gems, 2002).

In relation to mean and maximum lifespan, Sanz et al. (2006) suggests that the endogenous character of aging is useful to distinguish between maximum and mean lifespan, two concepts too frequently mixed. In that sense, the maximum lifespan is determined mainly by genes, meanwhile mean lifespan is governed primarily by the environment and to a lesser extent by the genotype.

Until not long ago, scientists asked: if aging is harmful for individuals, why does it occur to everyone? The answer could be that aging is the collateral effect of something else. That is, the genes that delay aging could do so by repressing the cause that generates damage associated with aging. A source of this type of damage appears to be reproduction. Fertility is frequently reduced both evolutionary when aging decreases as well as by the presence of punctual mutations that extend the lifespan. Food appears to be another source of damage, since many of the genes that are involved in the reduction of aging also participate in the response to the change in nutrient levels. Furthermore, it is known that the reduction in the ingestion of food diminishes aging in a variety of organisms from yeasts to mammals (Masoro, 2000; Partridge and Gems, 2002).

II. SOME AGING THEORIES

A large number of theories have been proposed in order to explain how and why we age, although many lack the scientific bases to be seriously considered (Medvedev, 1990). Overall, any theory must explain, according to Sanz et al. (2006) some characteristics of aging: it is progressive, endogenous, irreversible, and deleterious for the individual. Other authors also stress that any theory should be able to fulfill the following conditions (Sohal et al., 2002):

- It should be able to explain how an organism loses the capacity of maintaining its homeostasis in the latter part of its life.
- It should clarify the bases for the wide variations in the duration of life of cohorts, genetic stocks, and species.
- It should be able to identify the factor or factors responsible for extending the lifespan by simple mutations or through experimental regimes such as caloric restriction in rodents and environmental temperature changes in poikilotherms.
- It should be able to demonstrate that the degree of aging can be manipulated by variations in the factors suspected of causing senescence.

The existing theories on aging can be grouped into two large blocks: stochastic theories and genetic-evolutionary theories. In general, it can be said that there is no single, unified theory that by itself can explain the phenomenon of aging in all its dimensions. This is because the mechanisms of aging can vary considerably in different organisms, tissues, and cells.

A. Stochastic Theories

Stochastic theories propose that aging is caused by random damage in different biological molecules. The damage accumulates little by little with age until reaching a level where the damage triggers the physiological decline known as aging.

Pearl (1928) proposed the *rate-of-living theory*, based on the observation that species with high metabolic rates had shorter lives, stating that life expectancy is inversely proportional to the metabolic rate of the species. Although initially the link between metabolism and longevity was unknown, Harman (1956, 2006) presented the biochemical explanation for this interrelationship, putting forward the *theory of free radicals*, this becoming one of the most widely accepted theories on aging. This theory suggests that normal aging is the result of the random damage to tissues by free radicals. With time, Harman began to focus his theory toward the mitochondrion as the primary source of the production of free radicals and the target of damage that these elements cause. Later, Miquel et al. (1980) proposed the *mitochondrial theory* (progressive damage to mitochondrial DNA (mtDNA) by reactive oxygen species, ROS). Given that at present many ROS are not known to be free radicals, the main theory today concerns oxidative stress (Yu and Yang, 1996).

There is another group of stochastic theories that bear similarities to the theory of oxidative stress and that in a certain way could be explained by it (Halliwell and Gutteridge, 1999). This group includes the *crossing-over theory* (the random crossing-over of proteins and DNA alter cell functioning); the *theory of the catastrophic error* (accumulation of random damage in protein synthesis), the *theory of glycosylation* (the formation of glycosylate proteins give rise to a serious disruption of cell functions); the *theory of longevity determinants* (aging is caused by the products of metabolism and the degree of aging is determined by the capacity to protect oneself against such products); the *membrane hypothesis* (damage to the cell membrane diminishes the capacity to eliminate waste products, a decreased protein synthesis, and a loss of water from the cytoplasm, thereby diminishing enzyme activity); and *entropy theory* (mechanisms such as the restriction of caloric intake, reducing the degree of entropy production, releasing energy more slowly, and delaying molecular deterioration).

B. Evolutive and Genetic Theories

This group of theories considers the aging process to be part of a phenomenon of continuous development and maturation, genetically controlled and programmed. Although these concepts are very attractive, such strict control with respect to developmental phenomena proves contradictory with regard to such a diverse degree of expression in aging effects.

According to the *immunological theory* (Walford, 1969), aging is brought about by the decline in the capacity of the immune system to produce antibodies. That is, as the immune response diminishes, the capacity of the system to discriminate between its constituents and foreign elements also declines, with an increase in autoimmune reactions. This theory has the drawback that it is applicable to the immune system and does not rule out the possibility that these changes might be secondary to other earlier ones, such as hormonal types.

The *neuroendocrine theory* (Medvedev, 1990; Weinert and Timiras, 2003) is based on the fact that no part of the body can act in isolation from the nervous and endocrine systems and, therefore, if one of these is disturbed, the other systems are affected in some way. However, as with the immunological theory, this theory lacks universality, as not all living beings have a neuroendocrine system but nevertheless undergo aging.

The *genetic-evolutionary theory* (Finch and Ruvkun, 2001) proposes that aging is the continuation of the developmental and differentiation process, unraveling a sequence of events encoded in the genome. This theory postulates that aging would be the late consequence of the expression of genes selected by evolution for increasing reproductive success. The power that favors the selection of beneficial genes is manifested more in the young, as these are the ones in charge of reproduction and genetic transmission, so that what occurs to these genes at later ages is not taken into account. Thus, a gene that favors reproduction but is harmful in the long term is not selected for elimination.

Within this group of theories, the *hypothesis of disposable soma* was proposed by Kirwood (2000). According to this theory, the utilization of energy over a lifetime should be used preferentially for reproduction, at the expense of repair mechanisms, which lose capacity soon after surpassing the reproductive age. This theory suggests that among the main candidates determining the life

expectancy of a species from the genetic standpoint are genes that regulate the repair and maintenance of somatic cells. The study of gene expression in aging rodents reveals the presence of genes that alter their expression with age, or their expression is altered with the intervention of the type of caloric restriction that affects the aging rate. It is not surprising that most of these genes are involved in the pathways of cell response to oxidative damage. According to the hypothesis of disposable soma, natural selection favors those genes that act in the early stages of life, thereby permitting reproduction of the species, against those genes that are in charge of preserving nongerminal cells or available soma. Therefore, the somatic lines (as opposed to the germinal cells) of all animals that decline and degenerate with age, provoking the phenotypic changes that we recognize as aging.

Some scientists believe that the keys to aging should be sought in the process of cell division, an idea that has led to the *telomeres theory*. According to this hypothesis, formulated by Olovnikov (1973), the shortening of the telomeres in each of the cycles of cell division is the factor responsible for the limitation in the proliferation of the cell cultures, the so-called Hayflick limit (1998).

III. THE ROLE OF MITOCHONDRIA IN AGING

Progressive loss of mitochondrial functionality is one of the common events associated with aging. For this reason, these organelles are considered the biological clock of aging (Salvioli et al., 2001). In fact, mitochondria have been proposed as the link between the age-dependent accumulation of oxidative damage produced by ROS and the physiological alterations associated with aging (Van Remmen and Richardson, 2001). In this sense, several experimental studies suggest that mitochondria is one of the main targets of the aging process. According to Salvioli et al. (2001) this evidence includes (1) accumulation of deletions and certain mutations of the mtDNA in addition to the decreased mtDNA copy number in some tissues; (2) age-dependent decline in the activity of some enzymes in the mitochondrial electron-transport chain (mtETC); (3) greater production of free radicals, presumably as a consequence of the above-described alterations; and (4) changes in the morphology of mitochondria and collapse of the mitochondrial membrane potential (ψ_{mt}).

Variations in the functionality of mitochondria may determine adequate or inadequate aging, according to studies of specific population groups around the world. For example, an inherited variation in an mtDNA germ line (halogroup J) has been associated with a more adequate aging process and to an extended lifespan in the Italian population (De Benedictis et al., 2000). On other hand, in Japan, three mutations associated with an mtDNA germ line have been found with a high frequency in centenarians in this part of the world (Tanaka et al., 1998).

Another compelling question is the role of mitochondria as a key element in cell-signal transduction. Thus, mitochondria may also be considered an element of control for the nuclear gene expression. In this sense, a number of adaptation or regulation proteins have been found at the mitochondrial level or are translocated to the mitochondria to cope with this role, as with Nur77/TR3, p53, PKCδ, JNK/SAPK, some caspases and several members of the bcl2 family, such as Bid, Bax, or Bim (Finkel and Holbrook, 2000).

Regarding mitochondria in the aging process, the control of apoptosis is vital. This control is frequently lost in aged cells, which in addition are more prone to suffer from oxidative stress. ROS decrease ψ_{mt}, allowing the opening of the transition pore and the subsequent escape to the outside of calcium and other substrates. This sequence of reactions leads to apoptosis in lymphocytes as well as liver and the brain cells of aged mice (Watson et al., 2000).

IV. MITOCHONDRIA AS THE CELLULAR SOURCE OF REACTIVE OXYGEN SPECIES

In recent years, it has been ascertained that although ROS are produced through a large number of pathways of the aerobic metabolism, the main source of these species is the mitochondria (Lenaz, 1998; Halliwell and Gutteridge, 1999; Cadenas and Davies, 2000; Sastre et al., 2000; Salvioli et al., 2001;

Van Remmen and Richardson, 2001). The inner mitochondrial membrane is markedly different from the rest of biological membranes since its protein content goes beyond 80% (most of biological membranes do not exceed of 50%) (Quiles, 1995). Because of its importance and significance in the context of oxidative stress, the protein complexes within the mtETC deserve to be mentioned. In aerobic organisms, the mtETC produces the energy needed for life support. Basically, food is oxidized through the loss of electrons that are accepted by such electronic carriers as nicotinamide adenine dinucleotide (NAD^+) and flavins (flavin mononucleotide, FMN, and flavin adenine dinucleotide, FAD). The reduced nicotinamide adenine dinucleotide (NADH) and the reduced flavins ($FMNH_2$ and $FADH_2$) are oxidized again by oxygen, producing great amounts of ATP. Oxidation occurs with small jumps in which energy is gradually released (Lenaz, 1998). The mtETC is composed mainly of five lipoprotein complexes (Quiles, 1995; Lenaz, 1998; Cadenas and Davies, 2000): (1) Complex I, NADH dehydrogenase complex; (2) Complex II, succinate dehydrogenase; (3) Complex III, bc_1 complex; (4) Complex IV, cytochrome *c* oxidase (CCO); and (5) Complex V, ATPase. The mtETC fraction that metabolizes oxygen is Complex IV. This enzyme uses four molecules of reduced cytochrome *c* to remove one electron from each one and to pass them to an oxygen molecule. This tetraelectronic reduction of oxygen is not tenable in a single step but rather must be done electron by electron. Because of this gradual reduction, the protein complex must be sure that partially oxidized oxygen, highly toxic, will not leak into the medium before being transformed into water.

Superoxide anion ($O_2^{\bullet -}$) and hydrogen peroxide (H_2O_2) are, respectively, the product of the monovalent and bivalent reduction of oxygen. Both species are usually produced during aerobic metabolism, mainly at the mitochondrial level (Cadenas and Davies, 2000). It has been estimated that a 1%–5% of the oxygen consumed by the mitochondria is not fully reduced to water. In turn, this small oxygen percentage is transformed to $O_2^{\bullet -}$, which spontaneously or as the result of the action of superoxide dismutase enzymes is transformed to H_2O_2. Although CCO is the enzyme involved in the oxygen reduction, it hardly generates free radicals. In contrast, the two main sites of free-radical production at the mtETC are complex I and complex II (Cadenas et al., 1977; Ksenzenko et al., 1983; Shimomura et al., 1985; Cross and Jones, 1991). What happens is that during the pass from one complex to the other, some electrons escape and directly join the surrounding oxygen, resulting in the generation of $O_2^{\bullet -}$. Moreover, at the external mitochondrial membrane there is an additional source of ROS. This source comes from the deamination process of biogenic amines by monoamine oxidases, which through a bi-electronic reduction produce H_2O_2 from O_2 (Hauptmann et al., 1996). The physiological level of ROS production at the mtETC depends on the metabolic state of mitochondria. Thus, the state of mitochondrial rest (state 4), characterized by a low respiration level and no ADP availability, is associated with a high rate of ROS production, probably as a consequence of the high degree of reduction of the chain components. The active mitochondrial state (state 3), characterized by high oxygen expenditure and elevated ADP availability, shows relatively low-ROS production. In the state of anoxia (state 5), distinguished by a limitation in the oxygen delivery and absence of respiration, no ROS production is observed (Cadenas and Davies, 2000). From the standpoint of aging, there seems to be a consensus on the major importance of complex I as the main site for ROS production (Sanz et al., 2006).

Biological membranes are overall very sensitive to oxidative stress because of the presence of a double carbon–carbon bond in the lipid tails of its phospholipids (PL) (Montine et al., 2002). Oxidative damage to membrane lipids may be directly generated through initiation by ROS as hydroxyl radicals or the superoxide anion, or indirectly by some products of the same lipid peroxidation such as some highly reactive aldehydes that maximize the phenomenon (Esterbauer et al., 1991). Irrespective of the way, oxidative damage of membrane lipids leads to its alteration and to changes in membrane fluidity, and as a consequence of all these changes to alterations in membrane function (Halliwell and Gutteridge, 1999). Moreover, there is a particular mitochondrial lipid called cardiolipin. This is a highly unsaturated lipid and consequently highly prone to oxidation. Cardiolipin oxidation is extremely important to mitochondria since it is involved in the function of mtETC proteins such as CCO or the adenine nucleotide transporter (ANT) (Paradies et al., 1998).

Since lipids and proteins are physically very close, oxidative damage to mitochondrial proteins, as result of direct oxidative stress or as a consequence of lipid peroxidation, may lead to cross-linking, degradation, and loss of function of such proteins. Several membrane proteins, such as ATPase, ANT, CCO, and so on, are easily inactivated by oxidative stress. Moreover, protein oxidation leads to the opening of the permeability transition pore, a key step in the process of apoptosis. In summary, mtETC protein alteration has as a direct consequence, the loss of mitochondrial functionality and indirectly a rise in the ROS production (Lippe et al., 1991; Forsmark-Andree et al., 1997).

Mitochondria have their own genome, which differs in structure and organization from the nuclear genome. It is composed of a variable number of copies of identical circular double-strand DNA (up to ten copies). It is located in the mitochondrial matrix, near specific areas of the inner mitochondrial membrane (i.e., close to the main source of ROS). It has a small size (16.5 kb) and codifies for 13 mitochondrial proteins: 7 subunits from complex I, 1 protein from complex III, 3 proteins from complex IV, 2 from complex V (ATPase), 22 trRNA and 2 rRNA (Lenaz, 1998; Cadenas and Davies, 2000; Van Remmen and Richardson, 2001). As opposed to nuclear DNA, mtDNA is not protected by histones and it has been traditionally considered of a high susceptibility to be oxidatively attacked (Richter et al., 1988). For a long time, it was considered that mitochondria did not have a system to repair damaged DNA. Recently, the existence of such a system was reported, although it is not yet well known (Bohr and Anson, 1999).

Many reports suggest that oxidative damage to mtDNA is more important from the perspective of aging than that involving lipids or proteins. This fact is due to the ability of mtDNA to be spread because of the division capacity of mitochondria and cells, which allows amplification of the physiological consequences of the damage inflicted. Furthermore, oxidative damage to mtDNA might be even more important than the damage to the nuclear DNA as the entire mitochondrial genome codifies for genes that are truly expressed, while the nuclear genome contains a huge amount of nontranscribed sequences (Van Remmen and Richardson, 2001). Oxidative stress may affect mtDNA in several ways, among which the most typical are the oxidative alteration to bases, the rise in the number of deletions and the occurrence of certain mutations. At the moment, the most popular approach to studying oxidative alterations to bases is through the analysis of 8-hydroxy-2-deoxyguanosine by HPLC attached to electrochemical detection. Using this procedure, several labs have reported higher levels of this biomarker at the mitochondrial level with respect to the values found in the nucleus during aging (Chung et al., 1992; Agarwal and Sohal, 1994). Concerning DNA deletions, rise has been reported in the frequency of these events with aging among a wide variety of postmitotic tissues from several species, including humans, monkeys, rodents, and nematodes (Yoneda et al., 1995). Moreover, the rise in the percentage of deletions has been directly correlated with oxidative damage. Among the most studied deletions, one has been called the "common deletion" because of its frequency, which increases twofold to threefold with aging in some tissues such as the brain (Cortopassi et al., 1992). Nonetheless, since the percentage at which the level of deletions increases does not exceed 2%–3%, the physiological significance that this phenomenon could have for aging is speculative (Van Remmen and Richardson, 2001). Mutations of mtDNA are the basis for a high number of human pathologies. This has opened a new field in mitochondrial research. This type of DNA is transmitted maternally and, moreover, there are many copies of the molecule in single cell (polyplasmy) so that there is the chance that a mutation undergoes different degrees of heteroplasmy. All these questions imply that a lesion is manifested only when around 80% of all the mtDNA in the cell become mutated (Lenaz, 1998; Michikawa et al., 1999).

V. MEMBRANE UNSATURATION AND LONGEVITY

One of the most important findings concerning fatty acids and aging comes from the collaborative work between Dr. Pamplona, at Lleida, and Dr. Barja, at Madrid, both in Spain. These scientists revealed over the past decade something that appears to be crucial to understand—that is, to explain and to update the mitochondrial free radical theory of aging. Briefly, it has been proven from

comparative studies that long-lived mammals and birds have low rates of mitochondrial ROS production and low levels of oxidative damage in their mtDNA (Pamplona et al., 2002). Now it is also possible to affirm that long-lived mammals and birds possess a low degree of unsaturation in their cell membranes (Sanz et al., 2006). In other words, animals with higher lifespan have membranes containing fatty acids less susceptible to lipid peroxidation. This leads to lower levels of DNA damage from lipid peroxidation and of lipoxidation-derived protein modification in such species (Pamplona et al., 1998, 1999, 2000a,b, 2002, 2004; Herrero et al., 2001; Sanz et al., 2006).

As stated above, oxidative damage to membrane lipid is extremely important in aging. Polyunsaturated fatty acids (PUFA) from membrane PLs are highly sensitive to oxidation. Thus, in this sense, membranes very rich in PUFA should be more prone to oxidation than those having a lower level of highly unsaturated fatty acids (UFA). A study on the fatty acid profile of liver mitochondrial membranes from eight animal species ranging in maximum lifespan from 3.5 to 46 years revealed that the degree of fatty acid unsaturation is inversely correlated with maximum lifespan (Pamplona et al., 1998). Authors stressed that this was not due to a low content of UFA in long-lived mammals, but mainly to redistribution between components of the polyunsaturated n-3 fatty acid series. What happened was that docosahexaenoic acid (22:6n-3) was predominant in short-lived animals, meanwhile in long-lived species the dominant n-3 fatty acid was linolenic acid (18:3n-3). This difference may explain why fatty acids from long-lived animals had the lowest peroxidizability index (the total number of double bonds present in UFA in the membrane). Something similar has also been found by these authors in the fatty acid profile of heart mitochondria in eight different species (mouse, rat, guinea pig, rabbit, sheep, pig, cow, and horse), in which the highly unsaturated 22:6n-3 predominated in the short-lived species meanwhile 18:2n-6 was the dominant in long-lived ones (Pamplona et al., 1999). These fatty acid redistributions among species may be attributable to differences in the elongase and desaturase systems, mainly at the levels of the biosynthetic pathways of 20:4n-6 (arachidonic acid) and 22:6n-3 from their dietary precursors, 18:2n-6 (linoleic acid) and 18:3n-3. As is well known, a fine control in the elongation and desaturation pathways is crucial for maintaining the membrane function through proper fluidity, signaling, and other means (Sanz et al., 2006).

What is the physiological meaning of the lower degree of unsaturation in long-lived animals? Couture and Hulbert (1995) have stated that the low double bond index (DBI) found in large body size mammals is related to the need to decrease their metabolic rates. This is assumed to be because a low DBI leads to a lower permeability to ions, ion pumping being one of the main determinants of metabolic rate. Body size has also been negatively correlated with permeability to Na^+ and K^+ in liver hepatocytes (Porter and Brand, 1995) and to H^+ in the inner mitochondrial membranes (Porter and Brand, 1993). However, although this explanation could be plausible for mammals of different sizes, Pamplona et al. (2002) state that it cannot explain the low DBI of birds since they have a similar or even higher metabolic rate than that of mammals of similar size. These authors hypothesize that instead a relation exists between DBI and metabolic rate, a true correlation between DBI, lipid peroxidation, and lipoxidative damage.

Differences in peroxidizability between species should lead to differences in oxidation at the level of lipids, DNA, or protein. In fact, this has been confirmed. For example, studies have been made of the fatty acid differences between a short-lived species such as the rat (maximum lifespan potential (MLSP) = 4 years) vs. a long-lived species such as the pigeon (MLSP = 35 years) in relation to lipid peroxidation and lipoxidation-derived protein modification in heart mitochondria (Pamplona et al., 1999). Results were as expected, in the sense that the lower double bond content present in different lipids of the pigeon (with substitution of the highly unsaturated 22:6n-3 or 20:4n-6 for less unsaturated 18:1n-9 or 18:2n-6) were associated with a lower concentration of lipid peroxidation products *in vivo*, and a lower level of malondialdehyde–lysine protein adducts in heart mitochondria of pigeons than in rats. Following these results, authors suggested that the constitutive lower level of unsaturation in long-lived animals helps to protect their tissues and mitochondria against lipid peroxidation and oxidative protein modification and can be a factor contributing to their slow rate

of aging. Comparable results have been also described for liver mitochondria of mouse, rat, guinea pig, dog, pig, cow, and horse (maximum lifespan potential ranging from 3.5 to 46 years) in relation to lipid peroxidation, as well as the presence and steady-state levels of malondialdehyde–lysine and N^{ε}–carboxymethyllysine adducts.

In summary, the above mentioned studies provide a correlation between the maximum longevity of animals and the degree of unsaturation of membrane fatty acids. That correlation joins the previously stated one between the rate of mitochondrial oxygen radical generation and the maximum longevity of animals. In long-lived homeothermic vertebrates, both free-radical production and the membrane fatty acid unsaturation are lower, offering an explanation for some of the main causes of the low aging rate peculiar to these animals. No studies have been carried out on these aspects in relation to dietary fat and, as it will be stated below, this is another notable aspect of fatty acids and aging.

VI. DIETARY FAT, MITOCHONDRIAL OXIDATIVE STRESS, AND AGING

The previous section discusses the relationship between the membrane fatty acid profile and longevity, in particular between the DBI and MLSP in different homeothermic species. Authors of these studies argue that diet has a moderate effect, if any, in establishing a particular fatty acid profile in a given biological membrane leading to the final MLSP. However, although the low impact of dietary fat on issues related to interspecies longevity, a different viewpoint may be taken in relation to human nutrition and health-related issues concerning dietary fat intake. In this sense, the importance of a particular dietary fat profile is well known in relation to avoiding cardiovascular disease, certain types of cancer, and alterations at the immunological level (Quiles et al., 2006b). In addition, in terms of aging, the dietary fatty acid profile has been demonstrated to be important to the mitochondrial oxidative stress associated with the aging process (Quiles et al., 2002b, 2004b, 2006a; Ochoa et al., 2003).

Nutrition has been related to aging for some time, a link that identified mainly at the level of caloric restriction and supplementation with antioxidants. The role of caloric restriction, that is, a limitation in food intake, was first described in 1935 by McCay et al. (1989). Since then, caloric restriction has been demonstrated to enhance mean lifespan in a wide range of species, and decreasing the development of age-related disease in rodents (Finkel and Holbrook, 2000; Masoro, 2000). These effects are suggested to be mediated by a reduction in the level of oxidative stress. This is supported by the fact that calorically restricted mice undergo less oxidative stress than their counterparts fed ad libitum (Finkel and Holbrook, 2000; Masoro, 2000). In addition, caloric restriction prevents many of the changes found at the level of gene expression during aging (e.g., increase in the expression of heat-shock proteins). Caloric restriction might be a powerful therapeutic tool to fight against aging since, a priori, it shows effectiveness against oxidative stress and aging (Roth et al., 1999). Nevertheless, the possible use of caloric restriction as an antiaging therapy in humans would involve practical and ethical difficulties that make it almost impossible to consider feasible or desirable (Finkel and Holbrook, 2000).

As described in previous sections, oxidative stress plays a very important role in the global process of aging. Thus, nutritional supplementation with molecules or substances endowed with antioxidant capacity would be useful as a possible antiaging therapy. Miquel and Economos (1979) performed some of the first studies in this field. These authors studied the capacity of thiazolidine carboxylate to enhance vitality and mean lifespan in mice. Later, Furukawa et al. (1987) showed the role of glutathione in the protection against the decline in immune function associated with aging. Many other antioxidants (including vitamin E, vitamin C, coenzyme Q, herbal extracts rich in polyphenols and flavonoids, and others) have been tested in relation to aging, showing more or less positive results (Halliwell and Gutteridge, 1999; Huertas et al., 1999; Watson et al., 2000). Although results found with these antioxidants have been successful in relation to the attenuation

of the age-related oxidative stress, they have had low or no success in extending lifespan. The reasons are not clear, but perhaps require a deeper understanding of the pharmacological properties of the molecules studied, particularly in relation to absorption, tissue distribution, metabolism, and dosage. Furthermore, it should be remembered that ROS play a role in cell signaling, and therefore the antioxidant dosage must be carefully adjusted in order to avoid changes in the redox state that could alter the cell function. These problems are being addressed through the use of a new generation of synthetic antioxidant substances, mimetic of the superoxide dismutase and catalase enzymes. These substances are being assayed with some success, for example, in relation to the extension of longevity in mice and *Caenorhabditis elegans* (Melov et al., 1998; Rong et al., 1999).

For the past 15 years, our group has been investigating changes in dietary fat with regard to oxidative stress. Dietary fat type influences several biochemical parameters at the mitochondrial membrane level (Mataix et al., 1998; Quiles et al., 1999a). The importance of fatty acids resides in the fact that the mitochondrial membrane (as with other biological membranes) adapts its lipid composition to some extent in response to dietary fat (Huertas et al., 1991a; Quiles et al., 1999c; Ochoa-Herrera et al., 2001). Thus, humans and animals fed on olive-oil-based diets have membranes richer in oleic acid than those fed on sunflower-oil-based diets, in which case the membranes are richer in linoleic acid. In addition, adaptations of the electron-transport system in response to dietary fat type have been widely reported (Huertas et al., 1991b; Quiles et al., 2001; Battino et al., 2002a). Moreover, oxidative stress is related to biological membrane composition. In that sense, a polyunsaturated fat source (e.g., sunflower oil) will make membranes more prone to oxidation than will a saturated (e.g., animal fat) or a monounsaturated (e.g., olive oil) source. This has been widely demonstrated under a wide range of physiological and pathological situations using both animal models and humans (Quiles et al., 1999b, 2002b; Ramírez-Tortosa et al., 1999; Battino et al., 2002b; Ochoa et al., 2002).

According to the above mentioned premises, the dietary-fat type affects mitochondrial structure and function as well as susceptibility to oxidative stress. In this way, if we build "customized" biological membranes according to a particular dietary fat type, it would be possible to alter in a positive way the manner in which different organs undergo the aging process. This working hypothesis represents a new approach to the study of aging from a nutritional perspective and it could have far-reaching implications for the study of the aging phenomenon.

We have conducted studies comparing virgin olive oil and sunflower oil as the single life long dietary fat source in rats (Table 40.1). All of the studies started at weaning and ended at 24 months of age of the animals, with samples being collected at different age periods (from 6 to 24 months). The results may be grouped into those related to general aspects of oxidative stress status in blood

TABLE 40.1
Fatty Acid Composition of Edible Oils Used in Most of Our Experiments

Fatty Acid Composition	Virgin Olive Oil (g/100 g)	Sunflower Oil (g/100 g)
C16:0	8.9	12.6
C16:1n-7	1.1	0.2
C18:0	1.9	1.9
C18:1n-9	78.7	24.1
C18:2n-6	8.4	60.1
C18:3n-3	0.9	1
Total saturated	10.9	14.6
Total unsaturated	89.1	85.4
Total monounsaturated	79.8	24.3
Total polyunsaturated	9.3	61.1

(Quiles et al., 2004b), those concerning the effects on liver mtDNA deletions and ultrastructural abnormalities (Quiles et al., 2006a) and those concerning differences between mitotic and nonmitotic tissues in relation to different aspects of mitochondrial function (Quiles et al., 2002b; Ochoa et al., 2003).

A. Studies on Fatty Acids, Oxidative Stress, and Aging in Blood

Concerning studies on blood and plasma aspects of oxidative stress during aging (Quiles et al., 2004b), the first question to answer is whether the dietary manipulation determines the plasma fatty acid profile. We followed the quantitative determination (mg/dL) of fatty acid profile in plasma-cholesterol esters (CE), triglycerides (TG), and PL. Although some studies suggest that fatty acids become more saturated with aging, this being associated with a decrease in the degree of polyunsaturation (Ulmann et al., 1991; Imre et al., 2000). Most authors (e.g., Engler et al., 1998) reported lower levels of saturated fatty acids (SFA) with aging as well as increased levels of selected PUFA. In the present study, concerning total SFA, animals fed only on olive oil led to cholesterol esters, TG, and PL more saturated with age. No changes in SFA were found with age in animals fed on sunflower oil. These results paralleled net increases in all classes of PUFA for cholesterol esters, TG, and PL for both dietary groups with aging (except for TG in the olive-oil group). These results suggest that net changes in fatty acids during aging depend to some extent on the specific dietary fat, although the general feature of increased polyunsaturation is maintained.

Consequences of the intake of PUFAn-6 or monounsaturated fatty acids (MUFA) on health are well established, apart from those related to the effects on blood lipids. Among these, consequences are those related to oxidative stress. In this sense, it has been reported that plasma and subcellular-membrane lipid profiles of animals fed on diets with PUFAn-6 fatty acids are associated with higher levels of oxidative stress at different levels than when animals are fed on virgin olive oil. Examples of such a situation include the stress produced by xenobiotics such as doxorubicin (Huertas et al., 1991a), the performance of physical exercise (Mataix et al., 1998) or the intake of thermally oxidized fats (Battino et al., 2002b; Quiles et al., 2002a). Even under the situation of aging, it has been demonstrated that lipid peroxidation is lower in animals fed on olive oil (Ochoa et al., 2003). Moreover, in an attempt to test whether antioxidant supplementation of PUFA-rich diets would help preserve the beneficial aspects of PUFAn-6 in health, avoiding their higher susceptibility to oxidation and other deleterious aspects during aging, rats were fed lifelong on a PUFAn-6 plus coenzyme Q_{10} diet. This treatment resulted in lower levels of DNA oxidative damage and to an improvement in the mean and maximal lifespan of animals compared with rats fed on a PUFAn-6-alone diet (Quiles et al., 2004a).

Opposing results concerning free radical damage and aging have been reported in recent years (Halliwell and Gutteridge, 1999). However, overall, it appears that free radical damage (and particularly the levels of DNA damage) increased during aging (Halliwell and Gutteridge, 1999; Chevanne et al., 2003). In our study, when studying DNA damage in peripheral blood lymphocytes (in terms of DNA double strand breaks), we found the lowest levels in young animals fed on virgin olive oil, which were approximately 50% lower than the damage found in the sunflower-oil group. Aging raised the levels of DNA oxidative damage in both dietary fat groups, with the highest values found in the sunflower-oil group. This finding agrees with the above mentioned assumption of higher DNA damage with aging, and is additionally consistent with the free radical theory of aging of Harman (2003).

B. Studies on Mitochondrial DNA Deletions, Oxidative Stress, and Ultrastructural Alterations in Liver

The liver is the central metabolic organ of the body; therefore, dietary changes can have a major impact on aging liver and on general health (Anantharaju et al., 2002). Moreover, the liver is critical in the

protection from oxidative damage and plays a major role in the breakdown of potentially harmful lipophilic toxins (Thomas et al., 2002). Although the aging liver appears to preserve its function relatively well (Anantharaju et al., 2002), several changes have been associated with this organ during the process of aging. We therefore investigated possible effects on the frequency of liver mtDNA deletions, oxidative stress, and mitochondrial abnormalities in liver mitochondria during aging by following the previously described model of feeding rats lifelong with two different dietary-fat sources (virgin olive or sunflower oils).

The study of the fatty acid profile of mitochondrial PL revealed the following. In relation to SFA, no differences were found for this fraction between both dietary treatments. A net increase was found in the amount of these types of fatty acids, individually as well as for total fatty acids, with aging (except for C24:0 in olive-oil group). MUFA were higher in animals fed on olive oil both at 6 and at 24 months. Aging increased these fatty acids in the virgin-olive-oil group. In animals fed sunflower oil, only the total amount of MUFA were affected by aging, showing a net increase. PUFAn-6 were higher in animals fed on sunflower oil for both time periods. Aging led to a net increase in all studied PUFAn-6 in both dietary groups. For PUFAn-3, virgin-olive-oil groups had a higher content in these fatty acids, both individually and as a total. Aging increased PUFAn-3 in both dietary groups. As a consequence of results on n6 PUFA and PUFAn-3, the total PUFA index showed no differences between dietary groups, but aging resulted in an enhancement. Something similar was found for the total fatty acid content. Finally, concerning the ratio between PUFAn-3 and PUFAn-6, animals fed on sunflower oil led to an index sevenfold higher than animals fed on virgin olive oil; aging did not alter this index. In summary, the different lipid profile of the diets were properly reflected in liver mitochondrial PL of young and old animals, suggesting, as for plasma, a proper adaptation of the rats to dietary fats.

There is substantial evidence from human and animal studies linking mtDNA deletions and aging. Deletion frequency is affected by age, tissue of origin, species, and the presence of some age-related diseases (such as Alzheimer's) and these aspects also vary widely depending on the laboratory (Kang et al., 1998). We have found increased frequency of the so-called common deletion at the mtDNA levels in aged animals (Quiles et al., 2006a), with those fed on sunflower oil being twice as frequent as those fed on virgin olive oil. This finding demonstrates that the age-related rise in mtDNA deletions can be modulated by the dietary-fat profile. A similar effect was previously demonstrated for caloric restriction (Kang et al., 1998). In addition, mtDNA deletions corresponded to increased levels of oxidative stress with aging in both dietary groups, although this increase was greater in animals fed on sunflower oil. We investigated whether changes in the frequency of mtDNA deletions and oxidative stress status could affect mitochondrial ultrastructure under our experimental conditions. We found that sunflower oil led to deterioration in mitochondrial structure, as suggested by the lower percentage of cristae per μm of mitochondrial contour found in old animals fed on sunflower oil compared to the young animals fed on the same oil (Quiles et al., 2006a). In addition, animals fed on virgin olive oil had a higher number of mitochondrial cristae in both age periods. Mitochondrial circularity (the increase of which represents control loss) was higher in old animals fed on sunflower oil compared to those fed on virgin olive oil (Quiles et al., 2006a,b). These results demonstrate that the age-related increase in liver mtDNA-deletion frequency is differentially modulated by the intake of different dietary fats, with virgin olive oil leading to a lower frequency of deletions than the n-6 polyunsaturated sunflower oil. On other hand, mtDNA-deletion frequency could be correlated with mitochondrial oxidative-stress status and ultrastructural alterations.

C. Differences between Mitotic and Nonmitotic Tissues

The third group of studies concerns differences between mitotic (liver) and nonmitotic (skeletal and cardiac muscles) tissues in relation to aging from the standpoint of mitochondrial oxidative stress and function. Regarding the fatty acid profiles, we found (Ochoa et al., 2003) that the proportion

of SFA in liver did not change with age in either group, although there was a higher proportion of these fatty acids in the sunflower group at 12, 18, and 24 months. Only dietary fat affected liver SFA. In heart, the sunflower group increased SFA with age. Differences between diets were found at 12 and 18 months, with animals fed on sunflower oil showing the highest levels. In skeletal muscle, differences between groups were detected only at 6 months, with the olive group registering the highest SFA proportion. The effect on age differed in the rats fed virgin olive oil having lower SFA levels at 12, 18, and 24 months. Age also affected skeletal muscle SFA. Animals fed on olive oil had higher MUFA levels in all tissues, except for 6 months in skeletal muscle. Aging affected the proportion of MUFA differentially, depending on the tissue. In liver, age did not affect olive group, while in the sunflower group the rats 18 and 24 months old showed significantly lower values than in rats 12 months old. In heart, MUFA decreased in both dietary groups at 18 and 24 months with respect to 6 months. In skeletal muscle, age led to increased MUFA in both groups. The lipid source significantly affected the three tissues studied, while age was significant only for heart and muscle. The proportion of PUFA, for all the tissues studied, proved higher in the sunflower group (except for heart at 18 months). No age effect was detected in liver. In heart, the olive group increased in PUFA at 18 and 24 months with respect to 6 and 12 months. The sunflower group registered a significant decrease at 12 months with respect to 6 and 24 months. In skeletal muscle, both groups showed a similar response, with the highest value at 18 months.

Oxidative stress in these animals was studied through the analysis of mitochondrial hydroperoxides (Ochoa et al., 2003). In liver, differences between diets were found only at 12 months, with the sunflower group reaching the highest levels. Both groups showed a significant decrease at 24 months compared with 6 and 18 months. Nonmitotic tissues (i.e., heart and skeletal muscle) increased hydroperoxide levels with age. Animals fed on sunflower oil reached higher values for all time periods except for 6 months. A two-way ANOVA revealed an effect of age in the three tissues studied. The lipid source had a direct effect only on heart and muscle hydroperoxides.

Mitochondrial function in these animals was investigated through the study of some elements of the mtETC (Quiles et al., 2002b), namely, cytochrome b, coenzyme Q (CoQ), and the amount and activity of the complex IV (the CCO system). In liver, CoQ levels for animals fed olive oil compared with sunflower oil were higher for 6 months of age and lower for 24 months. Age affected only the sunflower-oil group, with an increase in animals of 24 months of age. In heart, for both age periods, olive oil led to lower levels of CoQ than sunflower oil. A time-course increase was found for olive oil fed animals. In skeletal muscle, the olive-oil group registered lower levels of CoQ than did the sunflower-oil group at both ages. In terms of age, this molecule increased at 24 months for both dietary groups. Concerning cytochrome b in liver, the olive-oil group showed higher values for 6 months and lower levels for 24 months, compared with the sunflower-oil group. Age affected only the sunflower-oil group, with a sharp increase at 24 months. For heart, no differences were found between dietary treatments for 6 months of age, and higher levels were found in sunflower oil at 24 months. For skeletal muscle, both groups were similar at 6 months and the olive-oil group differed from the sunflower group at 24 months (with lower values). Aging boosted cytochrome b values in both groups at 24 months. Regarding the cytochrome a + a3 concentration for liver, dietary treatment had an effect only at 24 months, with higher levels found in rats fed sunflower oil. Age affected only the sunflower-oil group, with higher values at 24 months. In heart, no differences between diets were found for both age periods. Age affected both dietary groups, which decreased cytochrome a + a3 levels at 24 months. In skeletal muscle, no differences were found between dietary treatments. The age effect was reflected as higher values at 24 months for both groups. In terms of CCO activity in liver, differences were found between the diets at 24 months (higher activity for sunflower oil). No age effect was found for olive-oil-fed animals, but CCO activity increased at 24 months in sunflower-oil group. In heart, no differences between diets were found. Aging led to a decrease in both groups. For skeletal muscle, diet had an effect only at 6 months, with higher activity for the sunflower-oil group. Aging led to a reduction in CCO activity in the sunflower-oil group. Complex IV turnover for liver registered no differences with regard to diet or age. In heart,

a higher turnover was found at both age periods for sunflower-oil rats. Aging led to a sharp decrease in turnover for both dietary groups. In skeletal muscle, diet resulted in differences only at 24 months, with higher levels for the sunflower-oil group. Age decreased the turnover in both dietary groups, showing lower values for 24 months.

Aging, considered as an endogenous and progressive phenomenon (Barja, 2002), leads throughout the lifespan to different disturbances in mitochondria and their components, such as mtDNA (Sohal and Dubey, 1994; Lee et al., 1997; Michikawa et al., 1999). These disturbances (which have a high oxidative component) have a negative impact on mitochondrial structure and function. Depending on the capacity of the affected tissue to repair the damage or to replace the altered cell, tissue function is affected to a greater or lesser extent (Quiles et al., 2002b). In this way, tissues with the ability to regenerate their cells, such as liver, appear to be able to buffer the damage, at least in part, as suggested by the lack of alterations of mitochondrial function in terms of CCO activity (Quiles et al., 2002b). However, a loss in function is found in postmitotic tissues such as skeletal muscle, heart, or brain. These tissues lack the opportunity to replace damaged cells and are likely to have a less effective repair system (differences between liver and heart regarding repair mechanisms for mtDNA damage have previously been reported [Souza-Pinto et al., 1999]). This loss in function is reflected in the substantial decrease in CCO activity, which leads to the uncoupling of the mtETC, with the further bioenergetic inefficacy and increased ROS production (Quiles et al., 2002b; Ochoa et al., 2003). Mitochondria from postmitotic tissues buffer the unfavorable situation by increasing in some elements of the mtETC, such as cytochrome b or PUFA. The increase in polyunsaturation could enhance membrane fluidity and CCO activity by the presence of a more polyunsaturated cardiolipin, as has been suggested previously (Huertas et al., 1991b; Quiles et al., 2001). However, both actions raise ROS production. The role of dietary fatty acids in this mechanism could reside in the building of an environment more or less prone to the generation and propagation of ROS, especially when as the result of events such as aging, failures in the mtETC start to appear. Moreover, dietary fat could modulate the phenomenon through variations in the antioxidant system and overall upregulate or attenuate the process. Thus, as postmitotic tissues are the most affected by aging, the influence of diet should be particularly important in these tissues.

Summarizing the results from our group concerning dietary fat, mitochondrial oxidative stress and aging, one of the most important findings is that it is possible to modulate mitochondrial membranes through dietary fatty acid changes and that these changes are maintained lifelong if the diet is not changed. As a consequence of such manipulation, changes in mitochondrial oxidative stress, mtDNA deletions, mitochondrial ultrastructural alterations, and mitochondrial electron-transport function take place. In this sense, dietary fats rich in MUFA are more positive than fats rich in PUFA, in agreement with findings related to membrane unsaturation and evolution. Thus, from an evolutionary perspective or from a nutritional perspective, the way to extend the human lifespan is the same: to ameliorate reactive-oxygen production by reducing the unsaturation of the mitochondrial membranes. However, at least in the short term, we cannot manipulate evolution, but we can modulate our diet and this is a very attractive opportunity to improve our health.

VII. DIETARY FATTY ACIDS AND COGNITIVE FUNCTION IN AGING

Cognitive impairment is a major component of dementing syndromes in humans and influences the individual's ability to function independently (Solfrizzi et al., 2006). Cognitive decline in old age is typically attributed to a certain amount of brain atrophy, but there is growing evidence that the process is influenced by a complex interplay of health-related biological and nonbiological factors (Winocur and Greenwood, 2005). Previous work has linked cognitive decline to cardiovascular disease and generalized atherosclerosis (Breteler et al., 1994), diabetes mellitus (Naor et al., 1997), hypertension, and high and low blood pressure (Launer et al., 1995; Guo et al., 1997). Dietary effect on cognitive decline has been only partially studied and among dietary components, fat has focused

the attention of scientists (Winocur and Greenwood, 2005; Solfrizzi et al., 2006). In this sense, the effects of high-fat diets on cognitive function in rats have been studied mainly by the group of Dr. Winocur, while Dr. Solfrizzi and his colleagues have focused on the role of UFA on age-related cognitive decline (ARCD) in the Italian population.

In a series of studies, rats, administered diets high in saturated or polyunsaturated fat, were impaired on various tests of learning and memory (Greenwood and Winocur, 1990; Winocur and Greenwood, 1993; Gold, 1995). Tasks found to be sensitive to the negative effects of high-fat diets included Olton's radial arm maze, a nonspatial test of conditional associative learning, the Hebb–Williams complex maze series, and a variable-interval, delayed alternation (VIDA) test that highlighted deficits in rule-learning and specific memory function. The range of cognitive processes sampled in these diverse tests suggests that the dietary effects on brain function were not confined to specific brain regions and could be best described as nonspecific in nature. The impairments observed in rats fed high-fat diets were linked, to some extent, to the type of dietary fat. Thus, while impaired performance was associated generally with a high level of fat intake (20% by weight in high-fat diets compared to 5% in standard laboratory chow), rats fed dietary fats high in SFA, such as beef tallow or lard, typically were more impaired than rats fed dietary fats high in PUFA, such as soybean oil. Indeed, when fats and oils were blended in order to distinguish between the roles of SFA, PUFA, and MUFA, the impairment on the VIDA task was positively associated with the dietary level of SFA, and independent of the PUFA or MUFA levels (Greenwood and Winocur, 1990). The mechanism whereby SFA impairs cognitive performance has not been identified, but data suggest that broad changes to bulk-membrane fatty acid composition are probably not a primary factor (Greenwood and Winocur, 1990).

In the identification of the pathways that mediate the fat-induced effects on cognitive function, one possibility relates to the well-established fact that high-fat diets contribute to increased insulin resistance and decreased glucose uptake in the brain (Winocur and Greenwood, 2005). Impaired glucose regulation is an important factor in the cognitive decline associated with type-2 diabetes and normal aging (Gold, 1995). Since glucose treatment can temporarily improve memory function in aged rats and humans (Messier et al., 1999), presumably by facilitating glucose metabolism in specific brain regions (e.g., hippocampus), Greenwood and Winocur set out to determine whether effects would be similar in rats with cognitive impairment resulting from high-fat ingestion (Greenwood and Winocur, 2001). Once again, groups of rats fed diets high in saturated fat, unsaturated fat, or lab chow for 3 months were administered the VIDA test and, once again, the high-fat groups were impaired on all aspects of the task. Following baseline testing, rats were maintained on their respective diets and, for the following days, alternately received intraperitoneal injections of glucose (100 mg/kg) or an equal volume of saline. Glucose treatment significantly improved performance in both high-fat groups (but not in the chow group), with the effect being most pronounced at the longer inter-trial intervals where performance was sensitive to hippocampal impairment. The finding that glucose significantly improved memory function under hippocampal control was instructive and suggested that the memory component of dietary fat-related cognitive impairment is linked to insulin resistance and/or glucose intolerance. With this in mind, the authors administered the VIDA test to genetically obese Zucker fa/fa rats that present insulin resistance, along with a range of endocrinological characteristics that appear to model type-2 diabetes (Gold, 1995). The obese Zucker rats did not differ from their lean counterparts in terms of learning the basic alternation rule or in performing at short inter-trial intervals. However, the obese rats were significantly and selectively impaired at the long intervals where hippocampus-controlled memory function was reduced. These results, together with those of the previous studies from this group, provide convergent evidence that the hippocampus is particularly sensitive to the effects of insulin resistance, and that impaired glucose regulation, resulting in reduced glucose uptake in the hippocampus may account for the long-term memory loss in rats fed high-fat diets. If confirmed by subsequent research, this would constitute a promising beginning in describing the neurobiological mechanisms underlying the full range of cognitive impairment that can result from chronic high-fat ingestion.

The role of the diet in cognitive decline has not been extensively investigated in humans, with few data available on the role of macronutrient intake in the pathogenesis of dementia and ARCD (Solfrizzi et al., 2003). Since several dietary factors affect the risk of cardiovascular disease, and cardiovascular disease has been linked to cognitive decline (Breteler et al., 1994), it can be assumed that they also influence the risk of dementia. Some recent studies have suggested that dietary fatty acids may play a role in cognitive decline associated with aging or dementia. Only a few epidemiological and clinical studies have addressed the link between the intake of UFA and cognitive function, most being cross-sectional. In a recent cross-sectional French study, the association among macronutrient intake, functional variables, and cognitive functions was studied in 441 free-living elderly subjects aged 65 or over. A positive relationship was found in women between lipid intake and the Mini Mental State Examination (MMSE) score, which evaluates overall cognitive functions. A positive relationship was also found between PUFA intake and mobility in men, and between functional variables and alcohol intake in the whole sample.

The cross-sectional association between dietary macronutrients and cognitive impairment was also examined in 278 nondemented elderly subjects aged 65–84 years from the Italian Longitudinal Study on Aging (ILSA) (Solfrizzi et al., 1999). Dietary intake was assessed with a 77-item food-frequency questionnaire. Authors included MUFA, PUFA, and SFA in the analysis and found a positive Spearman correlation coefficient between MUFA intake and the MMSE (0.12; $p < .05$) and the Digit Cancellation Test (DCT) (0.16; $p < .01$), assessing visual selective attention. Also, the correlation coefficient between PUFA intake and the DCT was positive (0.12; $p < .05$). After adjustment for educational level, the odds ratios (ORs) of cognitive decline (MMSE score <24) decreased exponentially with the increase in MUFA energy intakes. Despite the lower education (%3 years), MUFA energy intake over 2400 kJ/day was associated with a reduction in OR of cognitive impairment (OR 0.6, 95% confidence interval [CI] 0.1–4.5). Age as a confounder of the interaction term "education by MUFA" was associated with a further increase in OR of cognitive impairment (OR 0.7, 95% CI 0.1–4.5). Furthermore, selective attention performances evaluated by DCT were independently associated with MUFA intake (OR 0.99, 95% CI 0.98–0.99) (Solfrizzi et al., 1999).

Conquer et al. (2000) measured the plasma fatty acid composition of various PL in blood samples from 84 subjects with different degrees of cognitive impairment, including Alzheimer's disease and other types of dementia. Without considering confounding factors, this study showed a statistically significant lower level of nKs3 PUFA in the plasma of subjects with cognitive impairment. Finally, in the cohort of the Etude du Viellissement Arteriel (EVA) Study, moderate cognitive decline (a O2-point of MMSE decrease) and erythrocyte membrane fatty acid composition were evaluated in 264 elderly subjects aged 63–74 years, during a 4-year follow-up. In this study, a lower content of PUFAn-3 (OR 0.59, 95% CI 0.38–0.93) was significantly associated with a higher risk of cognitive decline. In this study, after adjusting for age, gender, educational level and initial MMSE score, stearic acid [OR 1.91, 95% CI 1.16–3.15 for a 1 standard deviation (SD) difference] and total n-6 PUFA (OR 1.59, 95% CI 1.04–2.44 for a 1 SD difference) were consistently associated with an increased risk of cognitive decline. Moreover, a lower content of PUFAn-3 (OR 0.59, 95% CI 0.38–0.93 for a 1 SD difference) was significantly associated with cognitive decline, but after adjustment this association remained significant only for docosahexaenoic acid, and not for eicosapentaenoic acid (Hende et al., 2003).

Only a few epidemiological studies are available on the association between fatty acids and cognitive functioning (Kalmijn et al., 1997; Capurso et al., 2003; Morris et al., 2004), indicating a crucial need for prospective studies that could confirm initial observations. On the basis of the previous significant suggestions, Solfrizzi et al. (1999) tested the hypothesis that high-MUFA and PUFA intakes may protect against the development of cognitive impairment over time in a median follow-up of 8.5 years of the ILSA. The major finding of this study was that the MMSE performance over the course of an 8.5 years follow-up due to high PUFA ($R \geq 220$ kJ/day) and MUFA (>2000 kJ/day) intakes were significantly better than those due to low PUFA (<220 kJ/day) and MUFA (≤2000 kJ/day) intake, in all subjects and completers (Capurso et al., 2003).

Findings from the Chicago Health and Aging Project (CHAP) showed that in a large population-based sample of 2560 persons, aged 65 years and older, a high intake of saturated and *trans*-unsaturated fat was associated with a greater cognitive decline over a 6-year follow-up. Intake of MUFA was inversely associated with cognitive change among persons with good cognitive function at baseline and among those with stable long-term consumption of margarine, a major food source. Slower decline in cognitive function was associated with higher intake of PUFA, but the association appeared to be due largely to its high content of vitamin E, which shares vegetable oil as a primary food source and that is inversely related to cognitive decline. Finally, cognitive change was not associated with intakes of total fat, animal fat, vegetable fat, or cholesterol (Morris et al., 2004).

Therefore, several studies have suggested that increased SFA could negatively affect cognitive functions. Furthermore, a clear reduction of risk of cognitive impairment in cross-sectional studies and a cognitive decline in longitudinal studies have been found in population-based samples with high intakes of PUFA and MUFA. The mechanisms by which high-UFA intake could be protective against cognitive decline and dementia in healthy older people are, at present, unknown. However, Several hypotheses could explain the association between fatty acids and cognitive functioning, including mechanisms through the copresence of antioxidant compounds in food groups rich in fatty acids, via atherosclerosis and thrombosis, inflammation, accumulation of b-amyloid, or via an effect in maintaining the structural integrity of neuronal membranes, determining the fluidity of synaptosomal membranes that thereby regulate neuronal transmission.

VIII. SUMMARY AND CONCLUSION

Aging represents a great concern in developed countries because of the high number of people included in this group and because of the number of pathologies related with this phenomenon. According to the free-radical theory of aging and its further mitochondrial extension, aging is the result of the oxidative insult to the organism throughout life. Some of the damages are not entirely repaired and are accumulated, leading to organism malfunction. Such oxidative-stress-related events are particularly important in the mitochondria and especially at the mtDNA level. Oxidative stress is related to the fatty acid composition of membranes and a correlation has been established between the maximum longevity of animals and the degree of unsaturation of membrane fatty acids. This correlation joins to the previously established one between the rate of mitochondrial oxygen-radical generation and the maximum longevity of animals. In long-lived homeothermic vertebrates, both free-radical production and the membrane fatty acid unsaturation were lower, offering an explanation for some of the main causes of the low aging rate peculiar to these animals. In relation to results found on dietary fat, mitochondrial oxidative stress and aging, one of the most important finding is that it is possible to modulate mitochondrial membranes through dietary fatty acid changes and that these changes are maintained lifelong. These manipulations trigger changes in mitochondrial oxidative, dietary fat rich in MUFA being more positive from that viewpoint than those rich in PUFA, which agrees with events related to membrane unsaturation and evolution. From an evolutionary perspective or from a nutritional perspective, the way to extend human life is the same: by ameliorating reactive-oxygen production through reducing the unsaturation of the mitochondrial membranes. Finally, several studies have suggested that an increase in SFA could have negative effects on cognitive functions. Furthermore, a clear reduction of risk of cognitive impairment in cross-sectional studies and cognitive decline in longitudinal studies has been found in population-based samples with high intakes of PUFA and MUFA. The mechanisms by which high intake of UFA could protect against cognitive decline and dementia in healthy older people are, at present, unknown. In conclusion, we cannot, at least in the short term, manipulate evolution, but we can modulate our diet and this is a very attractive opportunity to improve our health.

41 Dietary Fat, Immunity, and Inflammatory Disease

Gilbert A. Boissonneault

CONTENTS

I. INTRODUCTION

Although the effects of dietary deficiency on risk of infection have long been known and studied, only in the relatively recent past the influences of dietary fat have been systematically investigated. Thus, the first review of the literature surfaced as recently as 1978 (Meade and Mertin, 1978) and others quickly followed (Vitale and Broitman, 1981; Beisel, 1982; Gurr, 1983; Johnston, 1985, 1988; Erickson, 1986; Perez and Alexander, 1988; Hwang, 1989; Kinsella et al., 1990). The field expanded to include examinations of the immune-modulating effects of specific fatty acids, fat level, cholesterol, plasma lipoproteins, and oxidized fats. Moreover, the role of fat and fat metabolism in the genesis, regulation, and management of various disease states is receiving increased notice. This chapter will review the literature addressing this rapidly expanding field of research.

The immune system imparts protection against threatening agents or situations, both internal and external to the organism. These threats include invading microbes such as bacteria, fungi, viruses, rickettsia, and mycoplasma; abnormalities of host tissue such as cancer; and tissue trauma. Under certain conditions, the immune system can itself cause disease by unwittingly responding against host tissues as in cases of autoimmunity or contribute to the etiology of other diseases, such as atherosclerosis and psoriasis. For in-depth coverage of immunity, autoimmunity, and host response I refer the reader to one of the many fine immunology textbooks available today.

II. DIETARY FAT AND IMMUNITY

A. Dietary Fat Level and Degree of Saturation

Numerous studies have demonstrated that diets high in fat suppress immune function. Diets rich in polyunsaturated fatty acids (PUFA), particularly of the n-6 family, have proven to be especially suppressive, at least in experimental animal studies. Dietary fats were shown to influence the fatty acid composition of membrane phospholipids in numerous studies, principally by increasing the amounts of the provided fatty acids (Marshall and Johnston, 1983; Prescott et al., 1985; Tiwari et al., 1986, 1987; Terano et al., 1987; Bankey et al., 1989; Chandrasekar et al., 1996). In addition, however, consumption of certain fatty acids affects not only their membrane concentrations directly but may also have significant effects on other, physiologically relevant fatty acids. For example, Calder (1998a,b) described how increasing amounts of the n-3 fatty acids in immune cell membrane phospholipids via dietary availability reduced the proportion of arachidonic acid (an n-6 fatty acid) while simultaneously increasing the proportion of n-3 fatty acids. These direct and indirect alterations in membrane phospholipids composition are believed to be in large part responsible for changes in immune function, either through influences on membrane-bound enzyme activity, availability of fatty acid precursors of immune-modulating eicosanoids (Stulnig, 2003; Fritsche, 2006), or other influences on intracellular signaling such as phosphatidylinositol pathways (Prosko and McColl, 2005), membrane lipid raft composition (Laethem and Leo, 2002), and nuclear receptor activation (Nencioni et al., 2003).

The literature generally shows that diets containing high levels of PUFA reduce responsiveness of most aspects of immunity. T cell function in many of its facets is diminished. For example, consumption of high-PUFA diets reduced the response of mouse lymphocytes to T cell mitogens relative to low fat control diets (Erickson et al., 1980, 1983; Morrow et al., 1985; Kraus et al., 1987) to a greater extent than high levels of dietary saturated fatty acids (SFA) (Erickson et al., 1980; Olson et al., 1987). Other investigators were, however, unable to demonstrate a depression in T cell mitogenesis by high dietary fat levels in rats (Alexander and Smythe, 1988; De Deckere et al., 1988) or by high PUFA vs. high SFA in rabbits (De Deckere et al., 1988), mice, or rats (Alexander and Smythe, 1988). The proliferative response of spleen T cells to cell surface antigens of allogeneic lymphocytes (mixed lymphocyte response [MLR]) was depressed as the dietary corn oil level increased from 0.5% to 8% and 20%, with the observed reduction being statistically significant only at 20% dietary fat (Erickson et al., 1983). In this study, MLR was affected by dietary fat level but not by saturation.

Kelley et al. (1992) reported that lowering the total dietary fat content from 41.1% to 31.1% or 26.1% resulted in an increase in several indices of immunity such as T cell mitogen response and serum complement components. They did not see an effect of changing total PUFA content from 3.2% to 9.1% of calories within the noted ranges of total dietary fat. In a more recent report, Santos et al. (2003) reported that ten hyperlipidemic human volunteers were fed three 6-week diet plans containing 35%, 26%, and 15% fat. Following completion of these three maintenance diets all subjects were subjected for 12 weeks to the 15% fat diet at calorie levels to induce weight loss. At the end of each diet phase the following parameters were measured: delayed-type hypersensitivity (DTH); T lymphocyte proliferation to phytohemagglutinin (PHA); and interleukin-1 (IL-1), interleukin-2 (IL-2), and prostaglandin E2 production. DTH was significantly increased following the weight loss phase compared to the 35% maintenance diet, however, other parameters were not influenced by any of the dietary manipulations.

Bedoui et al. (2005) reported that tumor necrosis factor-α (TNF-α) production by blood monocytes and alveolar macrophages, as well as circulating TNF-α levels, was not different in rats made obese by up to 10 weeks of high-fat feeding. They went on to suggest that while obesity caused by severely elevated or reduced leptin levels present in leptin-deficient or leptin-receptor-deficient animals was related to altered immune function, leptin level variation in diet-induced obesity was unlikely to significantly alter immune function. Other studies have shown that leptin binding to

its receptors on T and B lymphocytes enhances signal transducer and activator of transcription-3 (STAT3) activation and suppresses Fas-mediated apoptosis (Papathanassoglou et al., 2006). Thus, within the range of fat recommended and typically consumed in the United States it is unlikely that dietary fat intake significantly affects T cell-mediated immune competence, although some studies suggest the possibility that significant reductions in total fat intake may be beneficial, presumably through influences independent of circulating leptin levels.

Other T cell functions that are influenced by dietary fat saturation include DTH (Thomas and Erickson, 1985; Kelley et al., 1997), cytotoxicity (Erickson, 1984), and generation of graft-vs.-host disease (Thomas and Erickson, 1985). However, there remains some inconsistency in the literature regarding the effects of high-fat and high-PUFA diets on these immune functions. For example, DeWille et al. (1981) reported no difference in the DTH response in mice fed 13% of energy (en%) corn oil vs. 50 en% corn oil.

B cell responses to mitogens or antigens appear to be influenced to a lesser extent by dietary fat level or degree of saturation. For example, varying the level of dietary corn oil from 13 en% to 70 en% did not influence the primary or secondary plaque forming cell (PFC) response to sheep red blood cells (sRBC) in mice after 35 or 70 days feeding (DeWille et al., 1979). The later report of Crevel et al. (1992) supports this finding. In contrast, Friedman and Sklan (1995) reported that antibody production developed more rapidly, reached a higher level, and was more persistent in chicks fed lower levels of linoleic acid.

Feeding mice 20% fat diets, compared to controls fed 5% fat, resulted in decreased lymphocyte binding to high endothelial venules in Peyer's patches and lymph nodes (Twisk et al., 1992). This effect was of the same magnitude with either sunflower oil (high PUFA) or lard (lower PUFA). The authors suggest that dietary fatty acid level and composition may affect expression of adhesion molecules responsible for lymphocyte homing.

Feeding rats a high-PUFA diet resulted in enrichment of neutrophil membranes with linoleic acid (the major PUFA in the oil source), whereas the levels of other elongation and desaturation products were not altered (Ringertz et al., 1987). The activity of these neutrophils was altered as evidenced by an increase in chemiluminescence to *N*-formyl-methionyl-leucyl-phenylalanine (fMLP) and leukotriene (LT) B4, and depressed aggregation (to LTB4 and calcium ionophore A23187) and chemotaxis to LTB4.

Tappia and Grimble (1996) reported that macrophages isolated from rats fed diets containing butter, coconut oil, corn oil, fish oil, or olive oil as fat source (also containing 10% of the total fat as corn oil to prevent essential fatty acid [EFA] deficiency) for 8 weeks resulted in differential enrichment of membrane phosphatidylethanolamine fatty acids with linoleic acid. Both linoleic acid intake and content of membrane phosphatidylethanolamine fatty acids were correlated with TNF-stimulated production of IL-1. IL-6 production showed a similar though less significant trend. These relationships were only in part explained by eicosanoid effects.

Gallai et al. (1995) reported that supplementing multiple sclerosis patients with 6 g of fish oil per day for 6 months reduced endotoxin-stimulated production of the cytokines IL-1 and TNF, and the eicosanoids PGE2 and LTB4 by blood mononuclear cells. They also reported reduction in PHA-induced production of IL-2 and γ-interferon, and the levels of serum soluble IL-2 receptors. These authors suggest that the reduced production of these proinflammatory cytokines may be beneficial in individuals with multiple sclerosis.

The consumption of diets rich in fat, particularly n-6 PUFA, increases many aspects of autoimmunity in mouse models (Fernandes, 1994). Examples of these effects include higher antidouble stranded DNA (Lin et al., 1996) and anticardiolipin (Lin et al., 1997) antibody levels, reduced lifespan, and worsened proteinuria in high-fat fed NZB/W F1 mice. High-fat fed mice also exhibited a higher percentage of cyclodextrin-5+ (CD5+) B cells (and greater mean fluorescent intensity of major histocompatibility antigens on the their surfaces), greater helper T cell (type 2) function, and elevated production of IL-6, TNF, and PGE2 from endotoxin-stimulated peritoneal macrophages (Lin et al., 1996). In contrast, diets rich in n-3 fatty acids appear to offer protection

(Simopoulos, 1991; Venkatraman et al., 1994; Chandrasekar et al., 1996); however, Tateno and Kobayashi (1994) did report fish oil supplementation to increase bovine serum albumin induced immune complex nephritis in NZB/W F1 mice. There are numerous mechanisms whereby n-3 fatty acids may reduce expression of autoimmune syndromes, detailed in a following section of this chapter.

B. Essential Fatty Acid Deficiency

Deficiency of dietary EFAs, that is, linoleic acid and its longer and/or more unsaturated derivatives, is known to alter immune function. Huang (1989) reviewed this field. As stressed by Huang, one of the major effects of EFA deficiency is to modulate the production of immunomodulatory eicosanoids including prostaglandins (PG), thromboxanes (TX), LT, hydroxy-fatty acids (HETE and HEPE), hydroperoxy-fatty acids, and lipoxins. It is also probable that alterations in membrane phospholipid fatty acid composition influence various membrane functions such as receptor recognition of ligands and subsequent signal transduction across the membrane.

The T cell response to mitogens was reported to be stimulated by consumption of EFA-deficient hydrogenated coconut oil as the sole fat source (Erickson et al., 1980, 1983; Marshall and Johnston, 1985; Kelley et al., 1988). However, the proliferative response of T cells to B16 melanoma cells was depressed in mice fed a fat-free EFA-deficient diet (Erickson et al., 1983). Several investigators reported that EFA deficiency reduced the DTH response (DeWille et al., 1981; Thomas and Erickson, 1985; Piegari et al., 2001) and DeWille et al. (1981) showed that refeeding EFA-deficient mice an EFA-adequate diet resulted in complete recovery of the DTH response within 7 days. Similar to the DTH response, EFA deficiency depressed Tc-mediated cytotoxicity against P51 melanoma target cells (Erickson, 1984). EFA deficiency was reported to have no effect on the graft-vs.-host response (Thomas and Erickson, 1985), although EFA deficiency was shown to prevent rejection of renal allografts in another study (Schreiner et al., 1988). Feeding of fat-free diets to mice resulted in depressed generation of concanavalin A (con A)-induced Ts and Keyhole Limpet hemocyanin-induced Th activity (Wee et al., 1988).

EFA deficiency has been reported to enhance (Boissonneault and Johnston, 1983; Boissonneault and Johnston, 1984) or depress (DeWille et al., 1979; Erickson et al., 1986) generation of antibody producing PFC, apparently dependent on whether the deficiency was induced using an EFA-free hydrogenated fat or a fat-free diet, respectively. Boissonneault and Johnston (1983, 1984) reported a direct correlation between inhibition of *in vivo* PG synthesis and elevation of the PFC response in Lewis rats, thereby linking alteration of eicosanoid production with changes in B cell function.

Macrophage killing of P51 melanoma cells was depressed by feeding a fat-free diet (Erickson et al., 1983; Erickson, 1984). Receptor-mediated pinocytosis was reported to be depressed in macrophages from EFA-deficient mice whereas phagocytosis was unaffected (Lefkowith et al., 1987). EFA deficiency was shown to reduce macrophage PGE2 (Adams et al., 1997) and nitric oxide (Boutard et al., 1994) formation. Neutrophils isolated from EFA-deficient rats exhibited decreased adherence to plastic in response to the calcium ionophore A23187 but not to LTB4 or fMLP (Lindstrom and Palmblad, 1988). Likewise, chemotaxis to fMLP was depressed whereas chemotaxis to LTB4 was unchanged.

Erickson and Schumacher (1989) reported that EFA deficiency was without effect on the activity or number of NK cells in mice fed fat-free diets.

C. Specific Fatty Acids

The roles of the eicosanoids in immune regulation have been widely studied and new eicosanoids, as well as new roles for these eicosanoids, continue to be discovered. Of dietary fatty acids, those of the omega 3 and omega 6 (or n-3 and n-6) families are most capable of influencing eicosanoid production. n-6 Fatty acids are precursors to the 1 and 2 series PG and the 3 and 4 series LT. n-3 Fatty acids are precursors to the 3 series PG and the 5 series LT. In addition, n-3 fatty acids inhibit

desaturation of linoleic acid (18:2n6) to its longer, more unsaturated derivatives, and also compete for transformation to eicosanoids. Hence, the ratio of dietary n-3 and n-6 fatty acids, as well as their absolute amounts, can have profound effects on immune function. Besides the prostaglandins and LTs, other eicosanoids have profound effects on immune modulation, including the hydroxyl- and hydroperoxy-fatty acids, lipoxins, and endocannabonoids. For background on the roles of the eicosanoids on immune function we refer the reader to several reviews (Peplow, 1996; Peters-Golden et al., 2004; Cabral, 2005; Parkinson, 2006).

Virtually all the studies of high dietary PUFA levels have been conducted using linoleic acid as the major PUFA. Generally, however, n-6 fatty acids were shown to depress T cell function while having little effect on B cell and NK cell function. Neutrophil responses to various stimuli were reported to change.

The effects of dietary n-3 fatty acids on immune function are currently under great scrutiny and have been reviewed elsewhere (Calder, 2003; Wu, 2004; Arterburn et al., 2006; Fritsche, 2006). Therapy with n-3 fatty acids may prove useful in the modulation of a number of disease states including heart disease and cancer, and in inflammatory diseases such as arthritis and psoriasis (Fernandes et al., 1998; Ergas et al., 2002; Harbige, 2003). As mentioned earlier, one of the primary mechanisms of action of n-3 fatty acids appears to be as a modulator of n-6 fatty acid-derived eicosanoid production and as precursor to other eicosanoid series.

Consumption of n-3 fatty acids, either as α-linolenic acid (18:3n3—primarily found in certain plant oils such as linseed oil) or eicosapentaenoic (EPA), docosapentaenoic (DPA), and docosa hexaenoic (DHA) acids (20:5n3, 22:5n3, and 22:6n3, respectively—primarily found in marine animal oils), resulted in incorporation of these fatty acids into membrane lipids of all tissues studied, including cells of the immune system (Marshall and Johnston, 1983; Lee et al., 1985a; Conroy et al., 1986; Chapkin et al., 1988; Bankey et al., 1989; Chandrasekar et al., 1996). These changes in membrane composition depressed production of PGE2 (Marshall and Johnston, 1985; Fritsche et al., 1993), 5-HETE (Lee et al., 1985a), and LTB4 (Lee et al., 1985a; Payan et al., 1986; Fritsche et al., 1993) by peripheral blood mononuclear cells whereas the production of the n-3 derived LTB5 was increased (Payan et al., 1986). Similar alterations of eicosanoid production were reported in spleen leukocytes (Lokesh et al., 1986a; Meydani et al., 1988; Chang et al., 1989a), peritoneal macrophages (Magrum and Johnston, 1985; Lokesh et al., 1986b, 1988, 1990; Lokesh and Kinsella, 1987; Cleland et al., 1990), Kupffer cells (Bankey et al., 1989), and neutrophils (Prescott et al., 1985; Lee et al., 1985a; Payan et al., 1986; Terano et al., 1987).

Marshall and Johnston (1985) reported that stimulation of T cells by the mitogens con A and PHA was unchanged in linseed oil-fed rats. Payan et al. (1986) reported that a dietary supplement of EPA to human volunteers increased the PHA response of T cells without modifying the numbers of Th or Ts. Similarly, Endres et al. (1989) reported that T cell proliferation in response to PHA was increased in n-3 fatty acid-supplemented humans. Supplementing human diets with arachidonic acid (n-6) did not influence the mitogen response to PHA, con A, or pokeweed mitogen (Kelley et al., 1997). Meydani et al. (1985) reported that spleen leukocyte mitogenesis was elevated in mice fed n-3 fatty acids. Likewise, the con A response of spleen leukocytes from 9-month-old, but not 5-month-old, autoimmunity-prone NZB/NZW mice was elevated. The response was, however, depressed in splenocytes from 4-month-old BALB/c mice (Alexander and Smythe, 1988). Meydani et al. (1991) reported that women supplemented with 2.4 g of n-3 rich oil for 3 months experienced a reduction in stimulated production of IL-1, TNF, IL-6, and IL-2, with older women experiencing a more dramatic reduction than younger women. Older women also have lower mitogenic responses to PHA than younger women prior to n-3 oil supplementation, and it was further reduced following n-3 supplementation. The authors questioned the desirability of further depressing immune activity in older women by regular use of n-3 fat supplements.

Other aspects of T cell function have been noted to be altered in animals fed diets enriched in n-3 fatty acids. Yoshino and Ellis (1987) reported that the DTH response to intradermal bovine serum albumin was reduced in n-3 fed rats. Although T cell subsets were not altered in two studies

of humans supplemented with n-3 fatty acids (Payan et al., 1986), Taylor et al. (1988) reported a transient reduction in the number of circulating Ts in n-3 fed rats. Wee et al. (1988) reported that supplementing EFA-deficient mice with n-3 fatty acids for 20 days did not alter con A-induced Ts. However, Th activity induced by Keyhole Limpet hemocyanin was enhanced. PGE1, PGE2, and LTB4 are known to depress T cell function (Rola-Pleszczynski et al., 1982; Payan and Goetzl, 1983; Payan et al., 1984; Linn et al., 1989) whereas LTB5 is less effective (Goetzl et al., 1986). Thus, alterations in T cell function may be a direct effect of modulation of eicosanoid synthesis.

The B cell proliferative response to the mitogen endotoxin was not altered in mice by dietary n-3 fatty acids (Alexander and Smythe, 1988; Wee et al., 1988). However, *in vitro* culture of B cells in the presence of EPA markedly depressed IgG/IgM production in response to PWM (Virella et al., 1989). Capping of B cell surface-bound immunoglobulin, a step preliminary to B cell response to antigen, was not changed (Alexander and Smythe, 1988). In their studies of n-3 supplemented EFA-deficient mice, Wee et al. (1988) reported restoration of antibody production against sRBC. The *in vitro* anti-sRBC response was also improved by n-3 supplementation; however, no change was noted in n-3 supplemented B cell antibody production in response to bacterial endotoxin. Prickett et al. (1982) likewise reported an increase in serum IgE and IgG levels in rats fed n-3 rich diets. In contrast, Virella et al. (1989) reported a time-dependent reduction in total serum IgG and IgM in humans fed supplemental n-3 fatty acids whereas IgA levels were not affected. Likewise, Watanabe et al. (1994) reported that linolenic acid suppressed antigen-induced IgE production and subsequent anaphylactic shock in mice. Finally, Huang et al. (1992) reported that n-3 feeding significantly reduced Ia antigen expression on peritoneal macrophages and splenic B cells. Others also report fish oil supplementation to reduce Ia antigen expression on peritoneal macrophages of mice and rats (Mosquera et al., 1990).

Graft rejection was reported to be suppressed by feeding n-3 rich lipids (Grimm et al., 1996). IL-6 production by blood mononuclear cells was also depressed by this treatment. A study investigating the effect of supplementing human renal transplant patients with 8 g of n-3 rich fat per day over 1 year showed a significant improvement in glomerular function (Maachi et al., 1995). Thus, n-3 fatty acid supplements have been proposed as nontoxic immunomodulatory agents for autoimmune, transplant, and other patients (Donadio, 1991; Calder, 1996).

As the prime producers of immune regulatory eicosanoids, the effect of n-3 fatty acids on monocytes/macrophages is of relevance to our discussion. Indeed, n-3 fatty acid supplementation influenced macrophage eicosanoid production, as previously mentioned (Magrum and Johnston, 1985; Lokesh et al., 1986b, 1988, 1990; Lokesh and Kinsella, 1987; Bankey et al., 1989; Cleland et al., 1990). Perez et al. (1989) reported that provision of rats with an n-3 oil supplement significantly reduced the T cell-dependent one-way MLR response. However, addition of control macrophages to the MLR cultures resulted in a 20-fold increase in the MLR response of spleen lymphocytes from n-3 supplemented rats whereas the MLR response from control rats was unchanged. In this experiment, oleic acid (18:1n9—a fatty acid of the n-9 family found in high concentrations in olive oil) had a similar effect to n-3 fatty acids, that is, it depressed the MLR, and the MLR response was elevated fivefold when cultures were enriched with control macrophages.

Phagocytosis and killing of ingested cells is a central function of monocyte/macrophages, and these combined functions may be altered by dietary n-3 fatty acids. Chemotaxis of human blood monocytes to fMLP or to C5a was not altered (Payan et al., 1986; Schmidt and Dyerberg, 1989) or was decreased (Schmidt and Dyerberg, 1989) by supplementation of human volunteers with EPA. Chemiluminescence in response to phagocytic signals, an index of oxygen radical production, was decreased (Magrum and Johnston, 1985) or not altered (Schmidt and Dyerberg, 1989) in monocytes or macrophages isolated from rats or humans, respectively. Magrum and Johnston (1986) reported that phagocytosis of yeast or carbon particles was not altered in peritoneal macrophages from n-3 supplemented rats, however, arginase activity was depressed. More recently, Boutard et al. (1994) reported a slight depression of arginase activity of macrophages from rats fed EFA-deficient or n-3 supplemented diets. Fish oil supplementation was also shown to reduce nitric oxide synthesis by

rat macrophages (Boutard et al., 1994). In contrast, Chapkin et al. (1992) reported that peritoneal macrophages from fish oil-supplemented mice phagocytosed zymosan at a greater rate than cells from n-6 fatty acid-supplemented animals. Macrophage killing in n-3 supplemented animals may be depressed, as this treatment resulted in depressed killing of *Mycobacterium tuberculosis* in guinea pigs (Mayatepek et al., 1994).

Macrophages obtained from n-3 containing fat-fed rats significantly increased clotting time of blood (van Dam-Mieras et al., 1986); this macrophage procoagulant activity may require macrophage plasma membrane involvement. Macrophage production of platelet-activating factor (PAF) was reported to be unchanged (Payan et al., 1986) or decreased (Sperling et al., 1987a,b) by supplementation of humans with n-3 fatty acids, whereas changes in intracellular calcium and inositol phosphate concentrations characteristic of the signal transduction response to PAF exposure was reduced (Bankey et al., 1989).

Lokesh et al. (1990) reported that IL-1 and TNF production by peritoneal macrophages was enhanced by feeding dietary n-3 fatty acids. Supporting this finding was the report of Hardardóttir et al. (1992a,b), who reported increased TNF production in resident, but not elicited, peritoneal macrophages from n-3 supplemented mice. Likewise, Ertel et al. (1993) reported that n-3 fatty acid supplementation increased IL-1 production by mouse peritoneal macrophages and suppressed PGE2-mediated immunosuppression following hemorrhagic shock. In contrast, Endres et al. (1989) reported that supplementation of human volunteers with large amounts of n-3 fatty acids diminished levels of IL-1 and TNF produced by peripheral blood monocytes. Guinea pigs fed an n-3 rich diet for 6 weeks exhibited a blunted fever response to injected recombinant IL-1 (Pomposelli et al., 1989).

Unlike the case with monocytes, neutrophil chemotaxis to fMLP (Payan et al., 1986; Terano et al., 1987; Ferrante et al., 1994), C5a (Payan et al., 1986), and LTB4 (Lee et al., 1985a; Payan et al., 1986; Terano et al., 1987; Sperling et al., 1993) was depressed by n-3 fatty acid supplementation. Culture of human neutrophils with EPA resulted in depressed release of lysozyme and elastase from cytosolic granules in response to immune complexes (Virella et al., 1989). Moreover, 6 weeks of n-3 fatty acid supplementation to a human volunteer markedly reduced neutrophil ingestion of latex beads and antibody-coated sRBC and decreased lysozyme release in response to fMLP and antibody-coated sRBC. In a similar vein, chemiluminescence and superoxide production was depressed in phagocytosing neutrophils isolated from human volunteers consuming n-3 fatty acid supplements (Fisher et al., 1986).

Prescott et al. (1985) reported that human neutrophil aggregation or adherence to nylon wool fibers was not affected by dietary treatment with n-3 fats, although Lee et al. (1985a) found that neutrophil adherence to bovine endothelial cell monolayers pretreated with LTB4 was inhibited by a similar dietary treatment. Thus, characteristics of the substrate may be important in determining the effects of dietary lipids on neutrophil adherence.

LTB4 is known to augment NK cell activity while LTB5 is less potent (Chang et al., 1989a). PGE2, on the other hand, is inhibitory to NK activity (Brunda et al., 1980; Goto et al., 1983). Thus, it is difficult to predict the effect of n-3 fatty acids on NK cells. In fact, several studies have demonstrated that NK cell activity is depressed by supplementation with n-3 fatty acids. NK activity was depressed in splenocytes from rats supplemented with EPA for 4 weeks (Chang et al., 1989a,b). Likewise, consumption of diets containing n-3 containing PUFA for 6 weeks depressed NK activity of 3-month-old mice but not of 24-month-old mice (Meydani et al., 1988). A single intraperitoneal injection of EPA (Yamashita et al., 1988) or *in vitro* incubation of splenocytes with EPA (Yamashita et al., 1986) resulted in an inhibition of NK cell activity.

Although the majority of research on specific fatty acids as influences of immune responsiveness have focused on the n-6 and n-3 fatty acid families, a recent paper by Stentz and Kitabchi (2006) reported that human T lymphocytes responded to the SFA palmitic acid differentially than other PUFA. In particular, human T cells responded to palmatic acid, but not to oleic, linoleic, linolenic, or arachidonic acids, demonstrated enhanced time and concentration-dependent expression of CD69, insulin receptors, insulin-like growth factor 1 receptors, GLUT 1 and 4 receptors, insulin receptor

substrate 1, generation of reactive oxygen species and the lipid peroxidation product MDA, and cytokine secretion (IL-1, IL-2, IL-6, IL-8, IL-10, and TNF-α). At this time these data have not been confirmed by other laboratories.

D. Cholesterol and Plasma Lipoproteins

Cholesterol is an important component of plasma lipoproteins and plays a critical role in cellular membrane function. A large number of studies have examined the immune-modulating effects of dietary cholesterol, oxidized cholesterol derivatives, *in vivo* exposure to cholesterol or membrane cholesterol depletion, and normal and pathologic lipoproteins. These studies were previously reviewed (Boissonneault, 2000). This section will address two current areas of study that illustrate cholesterol's contributions to regulating immune function: acute phase regulation of cholesterol availability to immune cells and membrane lipid rafts.

The acute phase response (APR) is a concerted response of the body to acute and chronic inflammatory stimuli that result in profound changes in bone marrow production of leukocytes, regulation of specific protein production by liver, macrophages and other immune cells, cytokine production, changes in tissue metabolism, and other changes. The specific proteins whose levels increase or decrease are known collectively as positive or negative acute phase proteins (APP), respectively. The primary positive APP in humans are C-reactive protein (CRP) and serum amyloid-A (SAA) (Gabay and Kushner, 1999; Pepys and Hirschfield, 2003; Manley et al., 2006). These and other APP enhance immune reactivity, divert metabolic substrates for support of essential bodily functions, including support of immune activity, and reduce availability of substrate from invading microorganisms.

The "APR" is a term used to describe the plethora of changes resulting from trauma or other events leading to a systemic inflammatory response. One "acute phase protein" produced in this response is SAA, a liver apoproprotein that displaces apolipoprotein A1 from the surface of HDL (Husebekk et al., 1987). Kisilevsky and Subrahmanyan (1992) reported that SAA binding to HDL reduced HDL's binding affinity for normal hepatocytes by twofold. It also increased binding of SAA-HDL to macrophages by threefold to fourfold. Thus, this change in binding of HDL was suggested to result in a shift of HDL to the role of reverse cholesterol transport from inflammatory sites. In a later report, Kisilevsky and coworkers reported that SAA also changed cholesterol metabolism in macrophages such as cholesteryl ester hydrolase activity (Lindhorst et al., 1997). The role of acute phase SAA and reverse cholesterol transport during the APR has been reviewed (Kisilevsky et al., 1996).

The major lipoprotein associated with HDL, apolipoprotein A1, is a negative APP (Burger and Dayer, 2002). The positive APP SAA circulates in the blood bound to high-density lipoprotein (HDL), forming what is known as "acute phase HDL" or SAA-HDL. This form of HDL binds with very high affinity to macrophages, displacing apolipoprotein A1 from the surface of HDL (Husebekk et al., 1987). Kisilevsky and Subrahmanyan (1992) reported that SAA binding to HDL reduced HDL's binding affinity for normal hepatocytes by twofold. It also increased binding of SAA-HDL to macrophages by threefold to fourfold (Husebekk et al., 1987), and consequently enhanced phagocytosis of these modified HDL particles (Kisilevsky and Subrahmanyan, 1992; Banka et al., 1995; Artl et al., 2000).

Thus, whereas noninflammatory HDL participates principally in the process known as "reverse cholesterol transport" (Lewis, 2006), SAA-HDL alters macrophage pathways of cholesterol metabolism. SAA was shown to inhibit macrophage acyl-CoA cholesterol acyl transferase (ACAT) and enhance the activity of neutral cholesterol ester hydrolase (nCEH) (Tam et al., 2002, 2005; Kisilevsky and Tam, 2003), making cholesterol available for export via the ABCA1 transporter system. In addition to phospholipids delivered to macrophages via SAA-HDL, additional phospholipids are actively transported to macrophages via CRP during the APR (Manley et al., 2006). Thus, SAA-HDL may contribute to redistribution of cholesterol and other lipids to support the markedly augmented requirement for these lipids to support cell proliferation during the ongoing immune

response, rather than storing the ingested cholesterol and other lipids in inert cytosolic lipid droplets. The roles of SAA-HDL in the APR, however, remain only partially understood. A recent editorial elegantly discusses some of the remaining questions and controversies in this rapidly developing field of research (Van Lenten et al., 2006).

The concept of discreet membrane lipid domains termed "lipid rafts" was first described by Simons and Ikonen in 1997. This field has expanded rapidly over the ensuing years, with over 777 related published articles indexed as of late 2006 (www.pubmed.gov, accessed September 17, 2006). Lipid rafts are densely packed lipid domains enriched with cholesterol, sphingomyelin, and glycosphingolipids (Simons and Ehehalt, 2002), which play an integral role to transmembrane signaling by virtue of their ability to restrict the movement of transmembrane signaling proteins and enhance the rate of association between complimentary proteins of signaling cascades. The cholesterol concentration influences the fluidity and liquid crystal structure of lipid rafts, potentially affecting their function (Ikonen and Parton, 2000). In order for cells of the immune system to respond to stimuli they, similar to most other cells, must transmit external signals through their lipid membranes, and lipid rafts are now known to be vitally important to this function.

A number of recent review articles describe the current state of knowledge surrounding lipid rafts in the regulation of lymphocyte activation (Pizzo and Viola, 2003, 2004; Becher and McIlhinney, 2005; Meiri, 2005). Rather than reiterate what is described in these and other excellent reviews, I will here present a description of how membrane cholesterol enrichment and depletion affect lipid raft function.

Becher et al. (2001) reported that saponin depletion of cholesterol from lipid rafts isolated from rat cerebellar membranes resulted in the disassociation of the membrane proteins Thy-1 and the GABAB receptor, as well as ganglioside GM1 into the supernatant fluid. Treatment of cerebellar membrane fragments with the cholesterol solubilizer methyl-β-CD likewise resulted in dissociation of Thy-1 and GABAB receptor into the supernatant fluid, confirming their first finding.

Methyl-β-CD depletion of cholesterol from lipid rafts isolated from 3T3-F442A cells reduced growth hormone (GH) receptor activation of extracellular signal-regulated kinase (ERK) by 45% ; ERK activation upon GH receptor stimulation could be reversed in these preparations by re-enrichment with cholesterol (Yang et al., 2004). In this study, GH receptor stimulation of signal transducer and activator of transcription (STAT5) tyrosine phosphorylation was unaffected by methyl-β-CD depletion of lipid raft cholesterol. The authors interpreted these divergent results as suggesting that these two signaling pathways may reside in different subregions of the plasma membrane, which are therefore differentially affected by cholesterol content.

Takebayashi et al. (2004) reported that methyl-β-CD treatment of wild-type PC12 cells reduced epidermal growth factor (EGF) receptor concentration associated with lipid rafts. In addition, methyl-β-CD depletion of cell cholesterol prior to EGF exposure resulted in an enhancement of EGF-induced phosphorylation of the EGF receptor, and functionally this translated as an increased rate of neurite sprouting. The authors reported that the increase in methyl-β-CD-induced PC12 neurite spouting was attenuated by simultaneous exposure to cholesterol. These data suggest that while some signaling proteins are activated by translocating into cholesterol-enriched lipid raft domains, the activity of others, such as the EGF receptor, may be suppressed in such an environment.

Nguyen et al. (2004) enriched Jurcat T cells with cholesterol to about four times normal cholesterol concentrations. This treatment was shown not to influence transferrin uptake, and it also did not interfere with or significantly alter the clustering of ganglioside GM1 on CEM-R5 cells. Antibody-mediated cross-linking of CD3 on the surface of cholesterol-enriched Jurkat T cells was likewise not altered compared to un-enriched cells, and it only weakly inhibited the ability to phosphorylate proteins upon αCD3 mAb stimulation. On the other hand, cholesterol enrichment significantly reduced intracellular calcium accumulation in response to αCD3 mAb stimulation. Similarly, cholesterol loading almost completely inhibited SDF-1α-induced intracellular calcium mobilization in Molt-4 T cells and Sup-T1 cells. Finally, preloading naive human T cells with cholesterol inhibited cell enlargement in preparation for cell division as well as IL-2 production when the T cells

were stimulated by cross-linking of surface CD3 and CD28 molecules with monoclonal antibodies. These results support the vital role that membrane lipid raft cholesterol concentration plays in supporting appropriate T lymphocyte function.

This brief review of selected reports illustrates the potentially far-reaching impacts of cholesterol enrichment or depletion from membrane domains such as lipid rafts on immune cell function. Immune modulation by statin drugs may also be mediated in part via modulation of lipid raft composition.

E. Parenteral Lipids

Parenteral use of fats in the United States began in 1977 with the FDA approval of Intralipid®, a linoleic acid-rich lipid emulsion made with soybean oil, phospholipids, and glycerol (Wretlind, 1981). Other lipids such as fish oil emulsions (Mascioli et al., 1988), MCT (Shils, 1988), and structured lipids (Babayan, 1987) have also been used for nutritional therapy of parenterally fed patients.

Providing lipids via total parenteral nutrition (TPN) poses the greatest potential for influencing the immune system because the route of their administration bypasses normal physiological mechanisms for lipid processing, for example, digestion and circulation in the form of lipoproteins made in the intestinal mucosa (chylomicrons) and liver (very-low-density lipoprotein [VLDL]). Similar to other intravenously injected lipid emulsions, there is the potential for stimulating massive uptake of the lipid particles by macrophages and other components of the reticuloendothelial cell system (Friedman et al., 1978; Lanser and Saba, 1981; Fraser et al., 1984), effectively diminishing the phagocytic and bactericidal capacity of macrophages and neutrophils (Di Luzio and Wooles, 1964; Berken and Benacerraf, 1968). This could profoundly increase risk for developing infection (Fischer et al., 1980; Fraser et al., 1984; Hamawy et al., 1985).

Early studies, mostly conducted *in vitro*, suggested that parenteral fat emulsions could result in impairment of critical phagocyte functions such as neutrophil and monocyte chemotaxis (Nordenström et al., 1979; Fraser et al., 1984), neutrophil cytotoxicity toward virus-infected cells (Loo et al., 1982), and neutrophil bactericidal activity (Fischer et al., 1980; Lanser and Saba, 1981). Later reports of work conducted *in vivo*, however, generally failed to support these findings. For example, there are now numerous reports that neutrophil chemotaxis (Palmblad et al., 1982; Ota et al., 1985; Escudier et al., 1986; Usmani et al., 1986), bactericidal activity (Palmblad et al., 1982; Ota et al., 1985), and chemiluminescence (Palmblad et al., 1982; Usmani et al., 1986) were not influenced in patients infused with traditional long-chain fatty acid-containing triglyceride (LCT), linoleic acid-rich parenteral fat emulsions such as Intralipid®. Likewise, no negative alteration of phagocytic activity of rat Kupffer cells (Romano Carratelli et al., 1986) or human peripheral blood leukocytes (PBL) (Szeinberg et al., 1986; Padeh et al., 1987), PBL bactericidal activity (Padeh et al., 1987), PBL generation and/or secretion of H_2O_2 (Padeh et al., 1987), superoxide (Strunk et al., 1985; Szeinberg et al., 1986), lysozyme, or PGE2 (Szeinberg et al., 1986) was reported to result from *in vivo* or *in vitro* exposure to parenteral lipids. Allen and Murray (1986) reported that long-term administration of Intralipid® to mice did not result in reticuloendothelial blockade, unlike phosphatidylcholine/cholesterol liposomes.

There have been reports of lung granulomas forming in pigs (Aksnes et al., 1994) and rats (Nordstrand et al., 1987) maintained on long-term soybean-based TPN lipids. This finding might be related to the activation of macrophages reported to occur in human (Gogos et al., 1992) and rat (Dahl et al., 1992) macrophages following administration of TPN lipids. Aksnes et al. (1995) reported that maintaining pigs on TPN with soybean-based lipids for 7 weeks resulted in a spontaneous twofold increase in nitroblue tetrazolium reduction in PBL and a 1.6-fold increase of this function in alveolar macrophages. Nitroblue tetrazolium reduction is indicative of phagocyte activation with production of oxygen radicals. In addition, the spontaneous rate of lymphocyte proliferation was increased threefold in TPN animals. Membranes from PBL, isolated from TPN animals, contain higher levels of linoleic acid and somewhat lower levels of arachidonic acid.

The effect of LCT fat emulsions on synthesis of complement components C2 and C4 by macrophages have been studied. Guinea pig peritoneal macrophages and human PBL incubated with Intralipid® produced less C2 and C4 than control cells (Strunk et al., 1978, 1983). On the other hand, Strunk et al. (1985) reported normal serum levels of C2 and C4 in infants receiving Intralipid® infusions, and Ota et al. (1985) found no change in serum C3 and C4 levels after Intralipid® administration. Etzioni et al. (1987) reported that generation of the anaphylatoxin C5a was depressed in serum from preterm infants infused with Intralipid®, although there was a large amount of variation in the results. No significant alterations in the opsonizing capacity of the sera were noted, suggesting that Intralipid® administration had no effect on complement activation.

Similar to the data just reviewed, most studies of nonphagocyte-mediated immunity indicate no influence or augmentation by parenteral LCT emulsions. Several laboratories have reported an elevation or no change in the number of blood T cells (Helms et al., 1983; Ota et al., 1985; Monson et al., 1986), Th, Ts (Ota et al., 1985; Monson et al., 1986), B cells, NK cells, and monocytes (Ota et al., 1985). Similarly, mitogenesis to PHA (Helms et al., 1983; Fraser et al., 1984; Ota et al., 1985) or PWM (Helms et al., 1983), and basal and stimulated IL-2 production (Monson et al., 1986) were reported to be unchanged or enhanced by parenteral lipids, although others reported that antigen-driven lymphoproliferation was inhibited by *in vitro* culture with Intralipid® or with hypertriglyceridemic plasma from humans or monkeys infused with Intralipid® (Ladisch et al., 1982). De Chalain et al. (1994) reported a greater mitogenic response to con A from rats, previously treated with surgery and hemorrhagic shock, provided intravenous Intralipid®, compared with control and enteral Intralipid® groups. In contrast, in this study bacterial translocation to mesenteric lymph nodes was greatest in rats provided intravenous Intralipid®.

Antibody-dependent cell-mediated cytotoxicity (Monson et al., 1986) and NK cytotoxicity (Almond et al., 1985; Kurzer et al., 1990) were also unaffected or augmented with host treatment with parenteral lipids. Thus, it is unlikely that phagocyte function is markedly affected by administration of parenteral LCT emulsions, particularly when fat provides less than 50% of non-nitrogen calories, especially during acute illness (Dahlstrom et al., 1988).

In 1999, Furukawa and coworkers reported on the effects of fat free, Intralipid®-containing TPN (20% of calories), or Intralipid®-containing and EPA-containing TPN (1.8 g/day) on immune and stress responses of humans undergoing esophagectomy with thoracotomy. Patients provided with Intralipid®-containing TPN following surgery had significantly elevated serum IL-6 compared with the fat-free TPN group. Provision of the EPA supplement to subjects provided with Intralipid® resulted in a reduction of IL-6 to levels at or below fat-free TPN subjects. Proliferative responses of subject T lymphocytes to mitogens con A and PHA were similar between fat-free and Intralipid® groups; however, provision of the EPA supplement to Intralipid®-fed subjects resulted in significantly elevated proliferation on postoperative day (POD) 21. In a second study, Furukawa et al. (2002) examined the effects of fat-free or Intralipid®-containing (20% of calories) TPN on immune response of humans undergoing moderate (gastric or colorectal surgery) or severe (esophagectomy) surgical stress. Although immune response was not affected by TPN energy source in subjects undergoing moderate surgical stress, parenteral lipid-fed subjects undergoing severe surgical stress showed similar results to their 1999 study, including elevated IL-6 levels that persisted through POD 10. Likewise, C-reactive protein levels were elevated at POD day 3 and 10, and serum glucagon was elevated at POD 1, indicative of a more robust APR. Whereas the proliferative response of T lymphocytes to con A and PHA were not different in severely stressed subjects before surgery, these responses were significantly depressed in subjects provided parenteral lipids on POD 7. Thus in these studies, provision of soybean-based TPN lipids resulted in augmentation of the stress response and diminished immunity, whereas supplementation with EPA rectified these effects.

Other parenterally administered lipids were studied regarding their impact on immune competence. Alexander et al. (1986) reported that administration of n-3 fatty acid-containing fish oil to burned Guinea pigs resulted in less weight and skeletal muscle mass loss, and lower resting metabolic rate than did other n-6 fatty acid-enriched parenteral lipids. Moreover, the DTH response and

opsonic index were both elevated, along with spleen weight, with the fish oil supplement. Mascioli et al. (1988) reported improved survival to an intraperitoneal injection of endotoxin in Guinea pigs provided with a fish oil emulsion vs. a safflower oil emulsion. As stated above, parenterally administered EPA eliminated the immune suppression related to parenteral Intralipid® administration in humans (Furukawa et al., 1999, 2002).

Similar to n-3 fatty acid-containing emulsions, those containing MCT have been investigated. Inclusion of MCT into parenteral fat emulsions was reported to have no effect on neutrophil function or morphology (Monico et al., 1988). On the other hand, Garnacho-Montero et al. (2002) described a study in which rats were assigned to one of five dietary treatments (chow, starvation, long-chain triglyceride TPN, long- and medium-chain triglyceride TPN, and oleic acid-rich olive oil TPN), followed 2 days later by intravenous inoculation with *E. coli*. Two days following infection, rats were killed and the extent of infection of liver and lungs was determined. Bacterial growth in the long- and the long-/medium-chain triglyceride TPN groups was significantly greater than in the chow-fed group, and the olive oil and starvation groups were intermediate. Other studies of the effects of parenteral MCT and structured lipids (Babayan, 1987) are warranted, given the paucity of data available concerning their influence on immune function.

Olive oil emulsions have now entered the clinical arena. A study by Moussa et al. (2000) investigated the effects of providing rats with an oleic acid-rich olive oil-based TPN lipid emulsion (ClinOleic®) or a linoleic acid-rich TPN lipid emulsion (Ivelip®) for 6 days, after which they measured expression level of CD25, the IL-2 receptor α-chain. Lymphocytes from rats provided with the oleic acid-enriched emulsion demonstrated greater CD25 expression compared with those provided with the linoleic acid-rich emulsion, and expression was correlated with oleic acid content of lymphocyte membrane phospholipids.

Granato et al. (2000) studied the effects of the same oleic acid-rich TPN emulsion, ClinOleic®, compared with linoleic acid-rich TMP emulsions Ivelip® or Intralipid®, on *in vitro* PHA-induced human lymphocyte activation (measured by thymidine incorporation, expression of CD25, and IL-2 release) and LPS-induced monocyte/macrophage activation (measured as HLA-DR expression and TNF-α release). Compared with control cells, PHA stimulation of lymphocytes incubated with Ivelip® or Intralipid® resulted in depressed thymidine incorporation compared with control or ClinOleic® incubated cells. Similarly, CD25 expression was nonsignificantly depressed and IL-2 release significantly reduced in Intralipid®-incubated but not ClinOleic®-incubated lymphocytes, as compared with control. TNF-α and IL-1β release were similarly reduced by both lipid emulsions.

Reimund et al. (2004) studied the effect of three lipid emulsions on human peripheral blood mononuclear cell TNF-α and IL-1β release in response to PHA and LPS stimulation. They used Intralipid® (long-chain triglycerides), Medialipid® (50:50 long- and medium-chain triglycerides), and ClinOleic® (olive oil based). Compared to control, each of the lipid emulsions reduced basal TNF-α and IL-1β production, although the effects of ClinOleic® were lesser in magnitude. Unlike the results reported by Granato et al. (2000), Reimund et al. (2004) found no impact of lipid emulsion incubation on PHA- or LPS-induced *in vitro* cytokine production.

In a more recent study by Buenestado et al. (2006), the effects of Intralipid® and ClinOleic® on human neutrophil function were evaluated. Neutrophils were incubated *in vitro* with various concentrations of lipid emulsions and stimulated with *N*-formyl–Met–Leu–Phe (FMLP). ClinOleic® had no effect on FMLP-induced rise in intracellular calcium, oxidative burst, chemotaxis, or elastase release, whereas Intralipid® incubation decreased intracellular calcium and chemotaxis while increasing oxidative burst compared with control. LTB4 production was augmented by both lipid emulsions whereas basal and FMLP-induced CD11b expression and serum-opsonized zymosan-induced phagocytosis were unchanged. LPS-induced TNF-α, IL-1β, and IL-8 mRNA and protein expression were unaffected by ClinOleic® whereas incubation with Intralipid® and a 50:50 long- and medium-chain triglyceride emulsion, Lipofundin®, decreased IL-1β mRNA and protein. Overall, the authors concluded that ClinOleic® had a reduced impact on neutrophil function compared with Intralipid® or Lipofundin®.

III. DIETARY LIPIDS AND INFLAMMATORY DISEASE

A. Psoriasis

Psoriasis is one of the most common skin ailments, affecting approximately 2% of the population (Champion, 1986; Baadsgaard et al., 1990). Grossly it is characterized by the eruption of raised, discrete, and confluent papules or a reddish color, and covered with flaking scales of shed skin. Rapid proliferation of keratinocytes results in the thickened, scaly plaques. The formation of macropapules is the result of fibroblast activation, vascular expansion, and infiltration of the area with neutrophils, macrophages, and T cells (Baadsgaard et al., 1990). The immune response responsible for the symptoms of this disease is similar to the DTH response; however, the stimulus for the response is currently unknown. It may be related to microbial antigens or to the anti-self-response of autoreactive T cell clones (Baadsgaard et al., 1990). Cytokines produced by T cells are known to be important effectors of disease symptoms (Quesada and Gutterman, 1986; Ristow, 1987; Baadsgaard et al., 1990; Gottlieb, 1990), including interferon, IL-1, and IL-6. The immunopathology of psoriasis has been reviewed (Christophers, 1996; Wolters, 2005).

The LTs are also known to be intimately involved in the disease process. The epidermis and scale chamber fluid of psoriatic lesions contain several lipoxygenase products including LTB4, LTC4, LTD4, 12-HETE, and 15-HETE. Epidermal and endothelial cells, keratinocytes, and macrophages, among other cells, are capable of synthesizing these eicosanoids. These eicosanoids are chemotactic, cause leukocyte aggregation and degranulation, and promote leukocyte adhesion to the endothelium; they also enhance vascular permeability, cause epidermal hyperproliferation, and vasodilation. Thus, modulation of eicosanoid production, and especially production of lipoxygenase products, may be of therapeutic importance.

Ziboh et al. (1986) reported that an 8-week treatment of psoriatic patients with fish oil (11–14 g of EPA/day) resulted in mild to moderate improvement in their psoriatic lesions. Fatty acids from the fish oil (i.e., EPA and DHA) were incorporated into neutrophils and the epidermis, and the improvement in clinical response was found to be related to incorporation of EPA and DHA into the epidermal tissues. Bittiner et al. (1988) also found that consumption of fish oil tablets for 8 weeks (1.8 g of EPA/day) resulted in a reduction of itching, erythema, and scaling, and a trend toward a decrease in the percentage of total surface area involved.

Both reports (Ziboh et al., 1986; Bittiner et al., 1988) suggested that the mode of action of the fish oil treatments was related to its inhibitory effects on the production of arachidonic acid-derived eicosanoids. Terano et al. (1989) conducted a study similar to those of Ziboh et al. (1986) and Bittiner et al. (1988) in order to gain insight into this question. In their study, patients consumed 3.6 g of EPA ethyl-ester/day for 3–6 months. By the third month both scaling and erythema had significantly improved and continued to improve throughout the remainder of the study. Neutrophil production of LTB4 was depressed from 1 month after the start of the study, whereas LTB5 and 5-HETE production increased significantly over the same time period.

In contrast to these reports, several other investigators failed to find significant improvement of psoriasis symptoms with n-3 fatty acid supplementation. Bjorneboe et al. (1988) supplemented patients with psoriasis with 10 g of fish oil daily containing approximately 1.8 g EPA acid. Control subjects received an olive oil placebo. They failed to find significant improvement in clinical symptoms after 8 weeks of treatment, though they reported an expected increase of n-3 fatty acid and decrease of n-6 fatty acid content in serum phospholipids following treatment. Using a similar experimental design, Gupta et al. (1990) supplemented psoriatic patients with fish or olive oil capsules in addition to traditional topical treatment with betamethasone diproprionate for 3 weeks. When the topical betamethasone was discontinued, symptoms worsened and no significant benefit of fish oil was noted. Finally, in a large human study with 145 patients with moderate to severe psoriasis, Soyland et al. (1993) provided 5 g of highly purified EPA/DHA esters or an equivalent mass of corn oil to treatment and control groups, respectively. Similar to the study of Gupta et al. (1990), although there was significant enrichment of plasma phospholipids with n-3 fatty acids in the treatment group

there was no significant clinical improvement associated with n-3 fatty acid supplementation. A recent literature review of the effects of intravenous n-3 fatty acids as a treatment for guttate psoriasis suggested that there was no firm evidence for its effectiveness (Chalmers et al., 2004).

Therefore, at this time it appears that n-3 fatty acid consumption is likely to have minimal if any benefits in ameliorating symptoms of psoriasis.

B. Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory disease of the joints, which appears to be autoimmune in nature, with the participation of cell-mediated and humoral arms of the immune system (Fogh, 1990). It is characterized by inflammation of the synovium and infiltration of the joint by neutrophils, macrophages, and T cells. The presence of IgG "rheumatoid factors" that bind to other IgG molecules, forming complement-activating immune complexes in the joint, is also characteristic. Activation of neutrophils and macrophages by T cell-derived cytokines, immune complexes, and activated complement factors ultimately results in increased vascular permeability, damage to the cells and connective tissues of the joint, and proliferation of synovial cells and chondrocytes. The final result of this inflammatory process is erosion of the cartilage and other components of the joint, eventually making movement exceedingly painful and paving the way for fusion of the joint.

As in all inflammatory responses, eicosanoids are an important component of RA (Fogh, 1990), and obstructing the synthesis of these eicosanoids can slow the progression of the disease. Synovial fluid from patients with RA contains LTB4 and 5-HETE (Klickstein et al., 1980; Fogh, 1990), and these lipoxygenase products serve as a potent source of chemotactic factors, as discussed previously. Interestingly, membranes from peritoneal macrophages isolated from rats with adjuvant-induced arthritis had significantly higher levels of linoleic acid (18:2n6) and lower levels of the elongation and desaturation product 22:5n6, whereas levels of arachidonic acid (20:4n6) were not different (Hawkes et al., 1991). Peritoneal macrophage membrane levels of n-3 fatty acids were not consistently affected by adjuvant-induced arthritis. Therefore, as in the case of psoriasis, the clinical course of arthritis may be influenced by dietary treatment with n-3 fatty acids, and indeed, several laboratories have investigated this area.

Prickett et al. (1984) reported that feeding a diet containing fish oil increased the incidence but not the severity of collagen-induced arthritis in rats. Yet, they found that the serum IgG titer against type II collagen as determined by enzymed-linked immunosorbent assay (ELISA) was depressed in the fish oil group whereas the serum hemagglutinating antibody titer and DTH response against type II collagen was not different from the control group. Moreover, synovial explants from the fish oil-fed rats produced significantly less PGE2 than those from control rats, without a change in PGE3 production. The authors suggested that the increase in incidence of arthritis in the fish oil-fed group was related to alterations in tissue fatty acid composition, although the actual mechanism remained unclear.

Contrary to the findings of Prickett et al. (1984), Leslie et al. (1985) found an increase in the time to onset of collagen-induced arthritis in mice, as well as reduced incidence and severity of the disease. Similar to the report of Prickett and coworkers, macrophages from fish oil-supplemented mice produced less PGE2 and PGI2 than macrophages from control mice. The difference between the results reported by Leslie et al. (1985) and Prickett et al. (1984) is unclear; however, all studies conducted with humans have corroborated the results of Leslie and coworkers.

Kremer et al. (1985) reported that RA patients who were supplemented with 1.8 g of EPA/day experienced fewer clinical symptoms after 12 weeks. However, the absolute effectiveness of the treatment was somewhat unclear, and the patients who received EPA supplements declined more rapidly than control patients did after a 1–2-month washout period. The authors concluded that this further deterioration also supported their interpretation that the EPA treatment was beneficial. In later studies (Kremer et al., 1987, 1990), these authors demonstrated significant improvement in mean time to onset of fatigue and number of tender joints in patients consuming fish oil supplements.

Other parameters improved with fish oil supplementation, although not significantly. Sperling et al. (1987b) and Magaro et al. (1988) also reported alleviation of symptoms of RA in patients supplemented with n-3 fatty acids.

In addition to alleviation of arthritis symptoms, neutrophil production of LTB4 was reduced (Kremer et al., 1987, 1990; Sperling et al., 1987b), and LTB5 (Kremer et al., 1987, 1990; Sperling et al., 1987b) and 5-HEPE (Sperling et al., 1987b) were produced only by neutrophils from fish oil-supplemented patients. Production of PAF by macrophages was depressed by fish oil treatment (Sperling et al., 1987a,b). Also, chemiluminescence decreased and chemotaxis to LTB4 increased (Sperling et al., 1987b) in neutrophils from fish oil-supplemented arthritic patients. Lastly, fish oil supplementation reduced macrophage IL-1 production (Kremer et al., 1990). Of interest in this regard, Hom et al. (1988) found that administration of IL-1 accelerated the development of collagen-induced arthritis in mice.

In a more recent study by Remans et al. (2004), 55 RA patients were supplemented with a cocktail of 1.4 g EPA, 0.211 g DHA, and 0.5 g γ-linolenic (n-6) acid plus a wide assortment of vitamins and minerals, or placebo each day for up to 4 months. At both 2 and 4 months in the study, the investigators noted no significant differences between control and experimental treatments, including the measurements of C-reactive protein, sedimentation rate, medication use, or indices of clinical RA status.

Overall, the evidence is modestly supportive for a beneficial role of n-3 fatty acids in RA treatment (Fortin et al., 1995; MacLean et al., 2004). Additional studies may clarify the reason for the variable results noted by investigators.

C. Asthma

Asthma is characterized by recurrent, reversible obstruction of pulmonary airflow resulting from pathologic bronchoconstriction. Approximately 5% of the Western population suffers from this disorder (Fleming and Crombie, 1987), which results from smooth muscle contraction, enhanced intraluminal secretion, and bronchiolar edema (Kaliner et al., 1987). A large number of stimuli for the asthmatic response exist including exercise, stress, and ingestion of certain compounds such as aspirin. The eicosanoids, including the prostaglandins, thromboxanes, hydroxy-fatty acids, and LTs are intimately involved in this multifaceted inflammatory response. Antagonists of the synthesis or actions of certain of these eicosanoids, particularly the LTs, are among the most effective treatment modalities. In contrast, PGE2 and PGI2 have bronchodilatory effects (reviewed in Thien and Walters, 1995).

Lee et al. (1985b) and Picado et al. (1988) suggested that by inhibiting cyclooxygenase activity, n-3 fatty acids might divert arachidonic acid toward synthesis of 5-lipoxygenase products, which augment the smooth muscle contraction and bronchoconstriction of asthma. A study by Broughton et al. (1997) found that somewhat greater than 40% of subjects with asthma responded to n-3 fatty acid supplementation with a reduction in methacholine-induced impairment of respiratory function. In this study, a significant increase in urinary 5-series LTs was found in responsive subjects, particularly at 1:2 ratio of dietary n-3 to n-6 fatty acids. On the other hand, an equally large fraction of subjects had no change in respiratory function as a result of n-3 fatty acid supplementation, and in some cases n-3 supplementation was related to a further loss of function. Interestingly, a smaller effect on increased excretion of urinary 5-series LTs was noted in nonresponders than in responders, particularly at the higher n-3 supplementation dose. Therefore, differences in responsiveness to n-3 fat supplementation or to the underlying pathophysiology of the disease may influence the response a person with asthma may experience to this dietary manipulation.

Emelyanov et al. (2002) provided 46 patients with atopic asthma two capsules of lipid extract from the New Zealand green-lipped mussel (each experimental capsule contained 50 mg n-3 fatty acids and 100 mg olive oil) or with placebo capsules (containing 150 mg olive oil) for a period of 8 weeks. At the end of the experiment, subjects receiving the experimental capsules reported

significant decreases in daytime wheezing and use of β2-agonists. Although measured forced expiratory volume in 1 s (FEV1) and evening peak expiratory flow (PEF) were not significantly altered, the researchers noted significant improvement in morning PEF and exhaled H_2O_2 in expired breath condensate (a marker of airway inflammation). The significance of the treatment effect from 100 mg n-3 fatty acids per day suggests that perhaps other active ingredients are present in New Zealand green-lipped mussel lipid extract in addition to their n-3 content.

Okamoto et al. (2000a,b) supplemented 14 patients with asthma with 10–20 g/day of Perilla seed oil (rich in α-linolenic acid, an n-3 fatty acid) or corn oil for a period of 1 month. The investigators reported that PEF, forced vital capacity (FVC), and FEV1 were significantly improved by the Perilla seed oil treatment compared with the corn oil placebo. In addition, they noted that generation of LTC4 by leukocytes from the treatment group was significantly reduced compared with the placebo group.

Hodge et al. (1998) conducted a study with 39 children, aged 8–12, with asthma. Over an experimental period of 6 months they consumed supplements containing fish oil, canola oil, and margarine (the n-3 fatty acid group, 1.2 g n-3 fatty acids per day) or safflower and sunflower oil (the n-6 group). At the conclusion of this 6-month trial, there was no significant difference between groups in clinical indices of asthma severity or plasma TNF-α concentration.

Broughton et al. (1997) utilized a crossover design (1 month on each treatment) to investigate the benefits of n-3 fatty acid supplementation on reducing methacholine-induced respiratory distress in an adult asthmatic population. For 1 month subjects consumed diets containing n-3 to n-6 fatty acid ratios of 0.1:1 (low n-3), followed by diets containing a 0.5:1 (high n-3) ratio. At the end of the low n-3 period, patients experienced increased methacholine-induced respiratory distress whereas at the end of the high n-3 period more than 40% of patients required an increased methacholine dose in order to respond with bronchospasm. Unexpectedly, some patients responded to the high n-3 period with a further loss of respiratory function. The authors suggested that the noted changes were related to changes in de novo production of 4-series vs. 5-series LTs.

Nagakura et al. (2000) supplemented the diets of 29 children with bronchial asthma with fish oil for 10 months in a randomized controlled experimental design. Fish oil supplement capsules contained 84 mg EPA and 36 mg DHA. Control capsules contained 300 mg olive oil. The daily dosages of EPA and DHA were assigned on a body weight basis (17.0 ± 26.8 and 7.3 ± 11.5 mg/kg body weight). The fish oil treatment group showed significant improvements in asthma symptom scores and reduced bronchoconstriction to acetylcholine from 6 to 10 months of treatment. Control subjects did not experience these benefits.

A recent review of the literature by Wong (2005), as well as the studies reviewed above, suggests that n-3 fatty acid supplementation provides benefits in symptom reduction for patients with asthma. On the other hand, a Cochrane review of the literature published in 2002 did not find sufficient support for the benefits of n-3 intake in children with asthma (Thien et al., 2002). Larger, double-blind, placebo-controlled studies may be necessary to clarify these issues.

D. Inflammatory Bowel Disease

Inflammatory bowel disease is a general term used to describe diseases such as ulcerative colitis and Crohn's disease (Kirschner, 1989; Fretland et al., 1990). Inflammation may be restricted to the mucosa of the colon, as in ulcerative colitis, or may involve the submucosa of any segment of the intestinal tract, as in Crohn's disease. Although the etiology of these diseases is unclear, the result of the loss of the mucosa and submucosa is malabsorption. The immunopathology of chronic inflammatory bowel disease has been described (Braegger, 1994; Nielsen and Rask-Madsen, 1996; MacLean et al., 2005). It is interesting to note that the risk for development of arthritis and other inflammatory diseases is increased in individuals with inflammatory bowel disease.

As in other inflammatory diseases, the eicosanoids have been implicated in the etiology of the disease (Fretland et al., 1990; Wallace, 2001). LTB4 was detected in the colonic mucosa of patients

with inflammatory bowel disease at levels greatly exceeding than those in normal individuals (Sharon and Stenson, 1984; Lobos et al., 1987). Moreover, PAF was found in the mucosa of patients with active ulcerative colitis (Eliakim et al., 1988) whereas it was not found in normal mucosa. Finally, Raab et al. (1995) reported markedly elevated levels of PGE2 in perfusates of affected colon specimens from patients with ulcerative colitis. These levels of PGE2 correlated well with levels of tissue eosinophil cationic protein, myeloperoxidase, and TNF.

Given the role of LTB4 and PAF in stimulating neutrophil chemotaxis into inflammatory sites and the inhibitory effect of n-3 fatty acids on the production of these compounds, it is not unexpected that some benefit might be had with this treatment. Evidence has accumulated for n-3 fatty acids ameliorating symptoms of ulcerative colitis (Lorenz et al., 1989; McCall et al., 1989) but not Crohn's disease (Lorenz et al., 1989). Hawthorne et al. (1992) studied the effects of marine n-3 oil supplementation on the course of ulcerative colitis. This blinded controlled study randomized 87 patients to treatments providing 4.5 g EPA or an equivalent volume of olive oil (placebo control) daily for 1 year. Standard drug therapy was continued throughout the trial. The EPA treatment increased rectal mucosa EPA content and also altered LT synthesis patterns by neutrophils, stimulating LTB5 and depressing LTB4 secretion in response to calcium ionophore. Clinical benefits of n-3 supplementation were limited: a significant reduction in corticosteroid requirement after 1 month and 2 months treatment, and a nonsignificant trend toward early remission. There was no significant difference in the rate of relapse between groups. The authors concluded that EPA supplementation provided modest benefit during active disease but was ineffective in maintenance therapy.

Stenson et al. (1992) studied the effects of dietary n-3 fatty acid supplementation with 18 patients with active ulcerative colitis in a double-blinded cross-over study design. Treatment capsules provided 3.24 g EPA and 2.16 g DHA daily whereas control subjects received vegetable oil containing placebo capsules through each 4-month arm of the study (a 1-month washout period occurred between arms of the study). The authors demonstrated a reduction in the dose of prednisone required for symptom management during the n-3 phase compared with placebo. Similar to Hawthorne et al. (1992), this study demonstrated a reduction in LTB4 concentration in rectal dialysates. Finally, histology index and weight gain were significantly improved on the n-3 treatment vs. control. Thus, this study showed significant though modest improvements associated with n-3 fatty acid administration. A related study by Aslan and Triadafilopoulos (1992) resulted in similar results though an improvement in histology index was not significant.

In 1996, Loeschke et al. carried out a 2-year double-blind, placebo-controlled trial of relapse prevention by 5.1 g n-3 fatty acids daily in 64 patients with ulcerative colitis. At the time of entry the patients were in remission and were not using steroid medications. Relapse-free survival was improved by n-3 fatty acid supplementation during months 2 and 3; however, cumulative relapse rate at 2 years was similar for those taking placebo vs. n-3 treated. These authors reported no consistent difference in clinical, macroscopic, and histologic disease activity between treatment groups. Hence, they concluded that while n-3 fatty acids may retard relapse of ulcerative colitis they are unable to prevent such relapse.

Lorenz-Meyer et al. (1996) published the results of a 1-year trial of n-3 fatty acid supplementation with 204 patients suffering from relapsing Crohn's disease. The study investigated the effects of daily 5 g n-3 oil supplementation or a reduced carbohydrate diet on further relapse. In this study, neither the n-3 treatment nor the modified carbohydrate diet showed significant improvement in relapse rate compared to the placebo group.

Inui et al. (1996) also reported that intravenous administration of an n-3 fatty acid-enriched emulsion nonsignificantly reduced indices of tissue inflammation and LTB4 in an acute rat model of inflammatory bowel disease. It is clear, however, that more research must be conducted in order for the therapeutic potential of n-3 fatty acids in inflammatory bowel diseases to be conclusively evaluated.

Belluzzi (2002) reviewed the literature concerning IBD and n-3 fatty acid supplementation, and concluded that there was an overall benefit for n-3 fatty acids as an adjunct treatment for IBD.

In contrast, a recent systematic review of the literature concerning n-3 fatty acid effects on various clinical scores, rates of remission or relapse, or requirements for drug treatment of Crohn's disease or ulcerative colitis found insufficient evidence to draw conclusions as to its effectiveness (MacLean et al., 2005). Other larger and well-controlled studies are called for to better understand the benefits, if any, to be afforded by n-3 fatty acid supplementation for remission control and symptom treatment in patients with IBD.

IV. CONCLUSIONS

Throughout this review I have attempted to present information that portrays the most current knowledge and understanding of each of the areas covered. It is clear that dietary lipids have the capability to modify immune function. The three major mechanisms include alterations in eicosanoid synthesis, changes in lipoprotein levels, and modifications in membrane composition, which affect transmembrane signal transduction. Much work remains to be conducted, especially with regard to the effects of dietary fats on signal transduction across biological membranes.

The potential for modification of inflammatory disease by dietary lipids, particularly n-3 fatty acids, provides exciting possibilities for diet therapy of these diseases. Caution should be exercised in the use of these fatty acids, however, as we are seldom fully aware of the implications of upsetting the natural balance of regulatory factors and processes. In addition, the ease with which n-3 fatty acids are oxidized raises another possible detrimental effect of these lipids—consumption of immuosuppressive, oxidized lipids.

42 Fatty Acids and Liver Disease

Amin A. Nanji and Bassam A. Nassar

CONTENTS

I. INTRODUCTION

The purpose of this chapter is to bring together information on the role of fatty acids in liver disease. Much of the information presented has been gathered by analysis of fatty acids in liver, liver microsomes, mitochondria, and hepatocytes. It should not, therefore, be assumed to be universal to other cells in the liver such as Kupffer's cells, endothelial cells, or hepatic stellate cells. Quite apart from the effects of fatty acids on liver disease or the effect of disease on fatty acid composition, the fatty acids are of importance as precursors of the prostaglandins, leukotrienes, and hydroxy fatty acid metabolites. Although a wide variety of liver disorders affects fatty acid metabolism, the majority of studies have been devoted to alcohol-induced liver injury. Thus, the major focus of this chapter is on alcoholic liver disease (ALD), which includes the role of fatty acids in the pathogenesis of liver injury as well as their role in the treatment of this disorder.

II. FATTY ACIDS IN THE PATHOGENESIS OF ALCOHOLIC LIVER DISEASE

Dietary fatty acids and alcohol both play an important role in the pathogenesis of ALD. There is considerable evidence to suggest that the amount of fat is an important determining factor in producing the lesions seen in ALD (French, 1993). Studies in rats fed a lipid diet containing alcohol showed that a steatogenic role for dietary fat and that fatty acids in the diet represented a major source of the lipids in the liver of animals fed ethanol (French, 1993). Studies with respect to the intragastric feeding rat model for ALD confirmed the role for dietary fat in ALD (French et al., 1986). When rats were fed a diet in which fat constituted 5% of the calories, only steatosis and focal necrosis

were induced in the centrilobular region of the liver. When the amount of fat was increased to 25% of total calories, over half of the rats developed centrilobular fibrosis similar to that seen in baboons and humans (French et al., 1986).

The role of dietary fat and fatty acids is further supported by epidemiological correlations that indicate that susceptibility to alcohol is related to different types of dietary fat (Nanji and French, 1986). In the first study, the deviation from expected mortality was correlated with the intake of saturated and unsaturated fatty acids and cholesterol (Nanji and French, 1986). The findings showed that saturated fat intake correlated inversely with deviation from expected mortality from cirrhosis suggesting that saturated fatty acids were protective. In a second study, cirrhosis mortality rates were correlated with pork and beef consumption (Nanji and French, 1985). A significant correlation was seen between pork consumption and cirrhosis mortality among countries with low carrier rates for hepatitis. There was no correlation with beef consumption.

To follow up on these epidemiological correlations, further studies were carried out using the intragastric feeding rat model for ALD. Rats that were fed ethanol and tallow (beef fat) developed none of the pathological features of ALD, rats fed ethanol and lard developed minimal to moderate ALD, and rats fed ethanol and corn oil showed the most severe pathological changes (Nanji et al., 1989). In each of the dietary groups, the percentage of calories derived from fat in the diet was similar (25%). Since the severity of histopathological changes was correlated with the content of linoleic acid (LA) in the diet, it was hypothesized that this component of the diet accounted for the differences in the pathology in the tallow-, lard-, and corn oil-fed groups. To confirm the role of LA in the diet, rats were fed ethanol together with tallow to which LA was added (Nanji and French, 1989). The animals supplemented with LA showed all of the pathological features of ALD, thus confirming the importance of this polyunsaturated fatty acid (PUFA) in the pathogenesis of experimental ALD.

The importance of PUFAs is further demonstrated by experiments in which fish oil was used as the source of fat. Feeding fish oil and ethanol produced more severe necrosis and inflammation than corn oil and ethanol (Morimoto et al., 1994; Nanji et al., 1994a).

Although several mechanisms have emerged to explain the development of alcohol-induced liver injury, which include upregulation of lipid peroxidation, increased levels of endotoxin, and induction of nuclear factor κB and its regulation of cytokines and inflammatory mediators that saturated fatty acids downregulate these events, additional mechanisms have also been proposed recently. Chronic ethanol administration is associated with inhibition of AMP-activated protein kinase (AMPK) and peroxisome proliferator-activated receptor-α (PPAR-α), two signaling molecules regulating pathways of hepatic fatty acid oxidation. Both molecules are major mediators of the metabolic effects of adiponectin. You and Crabb (2004) examined the effect of saturated fatty acids on chronic ethanol mice. They showed that chronic ethanol feeding with increased adiponectin levels led to the activation of signaling pathways controlled through AMPK, PPAR, and PPAR-γ coactivator. These alterations were associated with increased rates of hepatic fatty acid oxidation and prevention of steatosis. Importantly, AMPK is the downstream component of a kinase cascade that acts as a sensor of cellular energy change. ZAMPK is activated by rising AMP levels coupled to falling ATP levels, a feature of alcoholic liver injury.

III. FATTY ACIDS AND NONALCOHOLIC FATTY LIVER DISEASE

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of abnormal liver function tests in the general population. NAFLD is the term used to describe a spectrum of conditions characterized mainly by the histological findings of fat in the liver in individuals who consume little or no alcohol. The major feature of NAFLD, both histologically and metabolically, is the accumulation of triacylglycerol (TAG) in the liver.

The plasma nonesterified fatty acids (NEFA) pool contributes the majority of fatty acids that flow to the liver in the fasted state and provides a large proportion of the fatty acids in the very-low-density lipoprotein (VLDL) particles secreted by the liver.

The plasma NEFA pool accounts for approximately 60% of TAG in NAFLD patients thus reflecting the importance of the NEFA pool in NAFLD. Insulin resistance, an important feature of NAFLD, leads to a failure of insulin to fully suppress the activity of the hormone and the release of fatty acids for the TAG pool in adipose tissue is increased leading to an increase in NEFA pool (Step 1). Using nonreactive isotopes, metabolic pathways that lead to the accumulation of fat within the liver in NAFLD have recently been investigated. Important findings suggest that the rate of de novo lipogenesis (DNL) is elevated in NAFLD patients in the fasted state.

Liver cell apoptosis is a prominent feature of nonalcoholic steatohepatitis (NASH) and correlates with disease severity. Lipid-induced apoptosis is related to the degree of saturation of fatty acids. In a cellular model of steatosis and apoptosis, activation of apoptotic pathways was greater in cells treated with saturated than with monounsaturated fatty acids. Cell death was caspase dependent and associated with mitochondrial membrane depolarization.

It has long been known that alcohol abuse is associated with impaired immune function. Fatty acid ethyl esters (FAEEs) inhibit the production of interleukin 2 and influx of intracellular calcium into mononuclear cells. *In vivo* inhibition of the oxidative metabolism of ethanol using 4-methylpyrazole results in increased circulating concentrations of FAEE.

IV. FATTY ACIDS IN HEPATIC FATTY ACID COMPOSITION AND LIVER DISEASE

The fatty acid composition has been studied in a variety of liver disorders, but the most extensive studies have been carried out in ALD. The most consistent finding with respect to changes in the composition of fatty acids in the liver is a decrease in arachidonic acid (AA) (20:4n-6) (Reitz, 1978). Reduced levels of 20:4n-6 are seen in whole liver homogenates as well as mitochondrial and microsomal fractions (French et al., 1970; Alling et al., 1979; Cunningham et al., 1982; Cairns and Peters, 1983). In some studies, the decrease in 20:4n-6 was accompanied by an increase in LA (18:2n-6), although this is not a consistent finding (Reitz, 1978).

Ethanol-induced alterations in fatty acid composition can occur quite early after ethanol exposure. The total pospholipid fractions from liver mitochondria show increased levels of the monoene fatty acids and a decrease in 20:4n-6 after 2 h of exposure to ethanol vapor (Rouach et al., 1984). The magnitude of these changes were greater in the phosphotidylcholine component than in the phosphatidylethanolamine component. In humans, alcohol ingestion also leads to changes in the fatty acid composition that are similar to those seen in experimental animals. Patients with histological liver injury have higher levels of oleic acid (18:1n-9), total monoenoic fatty acids, and lower levels of total PUFAs (de la Muza et al., 1996). The 18:1/18:0 ratio was higher and 20:4/18:2 ratio lower in patients with liver injury compared to those patients ingesting alcohol but with no pathological liver injury.

The effects of different levels and types of dietary fat intake on the fatty acid composition of the liver in alcohol-fed animals have also been studied.

In one study, the effects of dietary fat and ethanol fatty acid composition were compared at two levels of fat intake (high fat, 34.2%; and low fat, 4.6%) in male and female rats (Thompson and Reitz, 1978). In male rats fed the high-fat diet, 16:0, 18:1n-9, and 18:2 were increased in liver mitochondria, whereas 20:4n-6, 22:4n-6, and 22:6n-3 were decreased. In the low-fat group, only the 18:2n-6 was increased and the 20:4n-6 decreased. In female rats, the level of dietary fat did not alter the ethanol effects; ethanol only affected the two saturated fatty acids (16:0 and 18:0) but not the polyunsaturated.

Varying the source of dietary fat in the diet also alters the microsomal fatty acid composition induced by ethanol, and these changes can also be related to the development of liver injury

(Nanji et al., 1994b). In rats fed medium-chain triglycerides and ethanol (no liver injury), the changes in fatty acids in liver microsomes were different from those seen with corn oil and ethanol (liver injury present). In particular, the concentration of AA (20:4n-6) increased and the level of oleic acid (18:1n-9) was decreased in the medium-chain triglyceride–ethanol group. These changes were opposite to what was seen in the corn oil–ethanol-fed animals. In rats fed fish oil and ethanol, it is noteworthy that higher levels of 22:5n-3 and 22:6n-3 were detected in the livers than in the fish oil diet itself (Nanji et al., 1994b). The most probable explanation for this observation is that the increased synthesis and preferential incorporation of 22:5n-3 and 22:6n-3 into liver phospholipids and triglycerides in rats fed fish oil is a compensatory response to the decrease in n-6 fatty acid synthesis in the fish oil-fed group.

Similar changes in fatty acids are also seen in other forms of liver injury due to alcohol-induced liver disease. In rats with chronic iron overload, a significant decrease in PUFAs and a parallel increase in saturated fatty acids (in mitochondrial and plasma membrane phospholipids) was seen after 9 weeks of iron treatment (Pietrangelo et al., 1990). There was no significant difference in the cholesterol/phospholipid molar ratio or in the lipid/protein ratio. Assessment of various membranes in liver using electron spin resonance spectroscopy did not show any change in the molecular order of the membranes suggesting that modification of the fatty acid profile in cellular membranes in *in vivo* chronic iron toxicity does not bring about modification in other physicochemical parameters relevant to cell membrane integrity. Modifications in fatty acid composition of liver plasma membranes in iron overload are also seen after *in vitro* induction of lipid peroxidation by addition of a ADP–Fe^{3+} complex to liver plasma membrane preparations (Pietrangelo et al., 1990).

Cholestasis also produces significant changes in microsomal fatty acid composition. After 2 days of bile duct ligation in rats, microsomal phospholipid fatty acids that were decreased included LA and AA (Bengochia et al., 1992). Phosphatidylcholine showed an increase in oleic and palmitic acids and a decrease in AAs. All fatty acids studied were decreased in the phosphatidylserine portion and were increased in the phosphatidylinositol fraction. Eight days after cholestasis, a global decrease in all fatty acids except oleic acid was seen in the phosphatidylcholine portion; an increase compared to the 2-day values was seen in all fatty acids in the phosphatidylserine fraction. The exact significance of these changes is unclear, and one hypothesis is that intrahepatic availability of fatty acids is distributed owing to bile flow impairment. Furthermore, steps in the synthesis of phophatidylcholine such as lysophosphatidylcholine acylation could be affected.

V. ROLE OF CYTOCHROME P-4502E1

Cytochrome P-450-dependent microsomal monoxygenase enzymes are involved in the oxidative metabolism of a wide variety of xerobiotics (Guengerich, 1995). One isoform of hepatic cytochrome P-450, cytochrome P-4502E1 (CYP2E1), is ethanol inducible and is a major component of the microsomal ethanol-oxidizing system (Lieber, 1988; Morimoto et al., 1993; Kessova and Cederbaum, 2003). The regulation of CYP2E1 by different types of dietary fatty acids has been demonstrated (Caro and Cederbaum, 2004). Corn oil, in comparison to a fat-free diet, increases the constitutive level of CYP2E1 protein and enzyme activity compared to animals fed lard or olive oil (Yoo et al., 1991). Dietary fatty acids also regulate the induction of CYP2E1 by ethanol. Levels of CYP2E1 are higher in the liver of rats fed ethanol with PUFAs compared to rats fed ethanol with saturated fatty acids (Takahashi et al., 1992; Morimoto et al., 1994; Nanji et al., 1994c). In addition to the results obtained in the *in vivo* studies, findings of *in vitro* studies also support a role for unsaturated fatty acids in ethanol-induced toxicity (Caro and Cederbaum, 2004). For example, addition of the substrate AA to a CYP2E1 expression line leads to increased levels of reactive oxygen species (ROS) and cellular cytotoxicity. The combination of iron and unsaturated fatty acids also decreases cell viability when compared to control CYP2E1-expressing cells. French and coworkers have evaluated the role of ethanol-induced CYP2E1 induction in the pathogenesis of changes in hepatic fatty acid composition induced by ethanol (Morimoto et al., 1995). Using inhibitors of

CYP2E1 (diallylsulfide and phenethyl isothiocyanate) in the intragastric feeding model for ALD, these investigators confirmed the observation that ethanol caused an increase in the 18:1/18:0 ratio and a decrease in the 20:4/18:2 ratio compared to pair-fed controls. The inhibitors of CYP2E1 partially prevented the above changes in hepatic fatty acid composition. These results indicate that induction of CYP2E1 could contribute to the decrease in 20:4n-6 after ethanol administration. Possible mechanisms include metabolism of 20:4 by the cytochrome P-450 system and enhanced lipid peroxidation (see below).

VI. EICOSANOIDS AND CYTOCHROME P-450 METABOLITES

To follow up on observation that AA is decreased in the liver after alcohol administration, experiments were conducted to evaluate whether eicosanoid production could, at least in part, account for this decrease in AA. Liver nonparenchymal cells were isolated from rats fed ethanol and different dietary fats. The findings of these studies showed that increased levels of thromboxane B_2 and leukotriene B_4 and decreased levels of prostaglandin E_2 (PGE_2) were seen in rats fed corn oil and ethanol (Nanji et al., 1993, 1994d). Production of the prostacyclin metabolite 6-ketoprostaglandin $F_{1\alpha}$ was also decreased in rats that develop liver injury (Nanji et al., 1994e). The enzyme responsible for the conversion of AA to prostanoids is cyclooxygenase (COX) or prostaglandin H synthase (DeWitt, 1996). It is now evident that two forms of COX exist in many cells: a constitutive enzyme designated COX1 and an inducible isoform known as COX2 (Otto and Smith, 1995; Pairet and Engelhardt, 1995). The expression of the two isoforms is regulated differently. Under physiological conditions, prostaglandin synthesis depends on the availability of AA and the enzymatic activity of COX1. COX2 is induced by a variety of stimuli that are upregulated in inflammatory liver disease (Hla et al., 1993). These stimuli include interleukin-1, tumor necrosis factor α, lipopolysaccharide, and oxidative stress (Hla et al., 1993; Hempel et al., 1994). Increased expression of COX2 in Kupffer's cells is associated with necroinflammatory changes in experimental ALD (Nanji et al., 1997a). COX2 upregulation is also associated with increased synthesis of vasoactive and proinflammatory eicosanoids such as the thromboxanes. The importance of thromboxanes in alcoholic liver injury is further suggested by studies, which show that necrosis and inflammation are attenuated by treatment with inhibitors of thromboxane synthesis and thromboxane receptors (Nanji et al., 1997b). Another possible explanation for the decrease in 20:4n-6 in microsomes after ethanol administration is the metabolism of 20:4n-6 by P-450 isoforms (Makita et al., 1996). These metabolites include the ω and ω-1 hydroxylation products of AA and the epoxide metabolites [epoxyeicosatrienoic (EET) acid] such as 14,15 EET; 11,12 EET; and 8,9 EET. The formation of such metabolites is increased in experimental ALD (French et al., 1997), and the interest in these metabolites is in their potential biological activities such as regulation of blood flow and enzyme activity such as Na, K ATPase (Capdevila et al., 1992).

VII. ROLE OF LIPID PEROXIDATION IN DECREASING HEPATIC ARACHIDONIC AND IN INDUCING LIVER INJURY

A significant body of evidence supports increased production of lipid peroxides in various forms of liver injury (Cederbaum, 1989; Lieber, 1997). The importance of lipid peroxidation and its relationship to fatty acids was suggested by the discovery of isoprostanes (IPs) as markers of peroxidation (Morrow et al., 1992a). IPs are prostaglandin-like compounds that are produced independent of the COX enzyme by free radical-catalyzed peroxidation of AA (Roberts and Morrow, 1996; Morrow and Roberts, 1997). Abstraction of *bis*-allylic hydrogens of AA by free radicals leads to the formation of arachidonyl radicals; subsequent attack by oxygen, endocyclization, and reduction leads to the formation of PGF_2-like compounds.

Measurements of IPs have provided new evidence for a role of oxidative stress in liver injury. In support of this notion, rats were administered carbon tetrachloride and the time course of the increases in levels of F_2-IPs in the liver and plasma were followed. Increased levels of esterified F_2-IPs increased rapidly, whereas the appearance of free IPs was delayed supporting the notion that IPs are initially formed *in situ* on phospholipids and subsequently released in free form (Morrow et al., 1992b). Increased levels of IPs have been demonstrated in the setting of liver ischemia (Mathews et al., 1994). IP levels also correlate with the severity of liver injury in experimental ALD in rats (Nanji et al., 1994f), and urinary F_2-IP excretion increases in a dose-dependent fashion following alcohol ingestion in humans (Lieber, 1997). Dietary iron overload is also associated with increased levels of F_2-IP esterified to lipids in the livers of rats (Dabbagh et al., 1994). Similarly, rats given halothane show increased levels of F_2-IPs esterified to hepatic lipids (Awad et al., 1996). Biliary measurements of IPs have been proposed as a measure of hepatic lipid peroxidation (Awad and Morrow, 1995).

VIII. FATTY ACID ETHYL ESTERS AND LIVER INJURY

FAEEs are esterification products of fatty acids and ethanol (Laposata et al., 1995). They are generated through the enzymatic action of FAEE synthase and, unlike acetaldehyde, represent a metabolic product of ethanol not generated by the oxidation of ethanol. Approximately 30% of the FAEEs in serum are bound to serum lipoproteins and the remaining 70% are bound to albumin (Bird et al., 1997). The LDLs contain most of the FAEEs among the different lipoproteins, and increasing FAEE concentrations result in increasing FAEE binding to lipoprotein relative to albumin. An autopsy study of individuals who were acutely intoxicated at the time of death showed that FAEEs and FAEE synthase, the enzyme responsible for their synthesis, were found predominantly in organs damaged by ethanol abuse (Laposata and Lange, 1986).

Once inside the cell, the mechanism(s) by which FAEEs or their metabolites, such as free fatty acids, produce their toxic effects is unknown. FAEEs have been shown to induce mitochondrial dysfunction by uncoupling of oxidative phosphorylation (Lange and Sobel, 1983), altering the fluidity of cell membranes (Hamamoto et al., 1990); increasing lysosomal fragility (Haber et al., 1993); and decreasing protein synthesis (Szczepiorkowski et al., 1995). Our preliminary studies show that unsaturated FAEEs are associated with alcohol-induced liver injury, whereas saturated FAEEs are not (Nanji et al., 1996a).

IX. PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS, FATTY ACIDS, AND LIVER DISEASE

A mechanism common to many diseases associated with fatty acid overload is impairment of mitochondrial fatty acid oxidation (Fromenty and Pessayre, 1995). The term *fatty acid overload* implies a role for long-chain fatty acids in producing the hepatic sequelae associated with these conditions. PPARs are proposed to function as sensors of fatty acid overload (Lemberger et al., 1996). In the liver, the predominant form of PPAR is PPAR-α. PPARs are members of the nuclear receptor family and long-chain fatty acids are important ligands of PPAR-α. Although a key mechanism to fatty acid overload is an increase in peroxisomal and microsomal oxidation of fatty acids (Kaikaus et al., 1993), the metabolism of fatty acids through these pathways may cause toxicity. Peroxisomal β oxidation generates hydrogen peroxide; although peroxisomes contain catalase, decreased catalase activity in certain disorders such as alcoholism may predispose to liver injury.

Sterol regulatory element-binding proteins (SREBPs) are key regulators of cholesterol and fatty acid synthesis. SREBP-1c and SREBP-2 predominate in the liver. The role of SREBPs is suggested by a number of studies which show that overexpressing SREBP-1a or SREBP-1c leads to the accumulation of increased amounts of cholesterol esters and triglycerides in liver. The role of SREBPs

in alcoholic fatty liver has indicated that in addition to increased activation of SREBP-1 ethanol induces the expression of several lipogenic enzymes (You and Crabb, 2004).

X. FATTY ACIDS IN THE TREATMENT OF ALCOHOLIC LIVER DISEASE

Although saturated fatty acids have been shown to be protective against alcohol-induced liver injury, little attention has been paid to the potential role of dietary fat as a treatment for established ALD. Lipid diets high in protein and calories or parenteral nutrition therapy have been used to treat ALD to reverse the protein–calorie malnutrition that often accompanies it (Nanji and Zakim, 2003). The rat intragastric feeding model allows for the evaluation of dietary fat as treatment in established ALD. Data from experimental studies show that a diet low in PUFAs administered to rats with established liver injury leads to near normalization of pathological changes such as fatty liver, necrosis, inflammation, and fibrosis (Nanji et al., 1995, 1996b). Histological improvement was associated with decreased levels of endotoxin, lipid peroxidation, and CYP2E1 activity, and reduced expression of COX2 and tumor necrosis factor-α (Nanji et al., 1997c). It is difficult to determine the relative contributions of each of these factors in ALD, but the results of the different studies show that dietary fat can be used as a pharmacological tool to downregulate the phenomena related to necrosis, inflammation, and fibrosis.

XI. THE ROLE OF FATTY ACIDS IN HEPATOCELLULAR CARCINOMA AND HEPATOCARCINOGENESIS

The role of PUFAs in the promotion and progression of cancers of various tissues has been the subject of many studies and is the subject of some debate (Diggle, 2002; Larsson et al., 2004). There are a number of studies that have reported the beneficial effects of fish and fish oil in cancer prevention, and it is generally considered that the cancer related effects of fatty acids are dependent on their structure. Fatty acids of the n-6 type, such as LA (C18:2n-6) for instance, have a strong promoting effect in some tumors (Sauer et al., 2000), while in contrast, n-3 PUFAs, such as α-linolenic acid (ALA; C18:3n-3) and its metabolites, eicosapentanoic acid (EPA; C20:5n-3), and docosahexanoic acid (DHA; C22:6n-3), may inhibit tumorogenesis (Reddy et al., 1991). ALA only differs from LA by a single double bond at the n-3 position, but this seemingly small structural difference is felt to lead to a remarkable functional contrasting impact between the two molecules.

A. n-6 Fatty Acids and Hepatocellular Carcinoma

Various mechanisms that promote hepatocarcinogenesis and involve fatty acids have been proposed and investigated. n-6 Fatty acids are seen to play a similar stimulatory role in liver cancer as they do in other malignancies. LA for instance, induces cell growth and DNA synthesis in the HTC-R_3T_3 rat hepatoma cell line, and may exert this effect by binding to a specific cellular protein, the liver fatty acid binding protein (L-FABP), an intracellular fatty acid carrier (Keler et al., 1992). *N*-2-fluorenylacetamide (FAA), which induces hepatocarcinoma formation in rats, interacts specifically with L-FABP, to induce its carcinogenic effect. L-FABP is thought to be involved in the biosynthesis of phospholipids by regulating lysophosphatedic transport to the endoplasmic reticulum to be converted to phosphatedic acid, a mitogen proposed to exert this effect through the *ras* protein. In hepatoma cells transfected with L-FABP and treated with FAA, exposure to LA leads to increased DNA synthesis and cellular growth, an effect not seen when those cells were exposed to other n-6 fatty acids, such as γ-linolenic (GLA), dihomo-γ-linolenic (DGLA), AA, or palmitoleic acids. This effect of LA is linked to its oxygenated metabolites, since indomethacin, a COX inhibitor, and α-tocopherol and nordihydroguaiaretic acid (NDGA), both antioxidant inhibitors of lipoxygenase, significantly

decrease the effect of LA on hepatoma cell growth. In rats transplanted with the hepatoma cell line 7288CTC and fed a diet containing LA, tumor growth is directly dependent on plasma concentrations of LA, and to a lesser extent on AA, where LA is converted by the hepatoma lipoxygenase enzyme into the mitogen 13-hydroxy-9,11-octadecadienoic acid (13-HODE) (Sauer et al., 1997). Sauer et al. (1999) also further show that 13-HODE, resulting from converted dietary LA, leads to increased DNA synthesis during *in vivo* perfusion. Inhibition of lipoxygenase activity by NDGA does not inhibit LA uptake by the tumor, but suppresses 13-HODE formation and subsequently tumor growth. In rats sustained on an LA-deficient diet, there was decreased tumor growth.

The effects of other PUFAs on hepatic tumors may differ from that seen with LA. For example, AA induces apoptosis rather than promoting growth. Dymkowska et al. (2006) reported that AA increase the rate of ROS formation in rat hepatoma AS-30D cells. Cell death is accompanied by the release of cytochrome *c* from the mitochondria, activation of caspase-3, and association with the BAX apoptotic protein. Although oleic acid did not induce ROS, it precipitated apoptosis, albeit to a lesser extent than AA.

Conjugated fatty acids, similar to conjugated LA (CLA), have recently been shown to interfere with LA metabolism and its effect in tumor tissue. CLA in mice causes smaller prostatic tumors than LA and a drastic reduction in lung metastases (Cesano et al., 1998). In mammary tissue, Banni et al. (1999) show that CLA interferes with LA metabolism resulting in decreased LA metabolites, including GLA, DGLA, and AA. The CLA dose–response effect on AA suppression corresponds closely with the dose–response CLA effect on cancer protection in the mammary tissue. This effect on tumor suppression, however, is not consistently seen in liver cancer. Yamasaki et al. (2002) show that in rats transplanted with hepatoma dRLh-84 and fed various concentrations of CLA, tumor growth is enhanced in comparison to non-CLA diet group. CLA decreases PGE_2 synthesis and COX2 levels without affecting AA levels. Sauer et al. (2004), in contrast, report that CLA isomers inhibit hepatoma 7288CTC tumor growth via a G-protein-coupled free fatty acid receptor by reducing intratumor cAMP, blocking LA uptake, and decreasing intratumor 13-HODE formation.

B. n-3 Fatty Acids and Hepatocellular Carcinoma

Data on the effect of n-3 fatty acids in hepatocellular carcinoma are mainly on animal studies and have provided evidence of an inhibitory effect on tumor growth. Calviello et al. (1998) show that Morris hepatocarcinoma 3924A grown in rats receiving EPA and DHA exhibit a 50% reduction in weight and volume of tumor in comparison to tumors in rats receiving oleic acid. Interestingly, DHA produced a greater degree of apoptosis than EPA. Sauer et al. (2000) have shown that ALA, EPA, and DHA inhibit the uptake of LA into hepatoma 7288CTC cells. The n-3 fatty acids also inhibit the uptake of saturated, monounsaturated, and other n-6 fatty acids. In addition, ALA and EPA inhibit the *in vivo* conversion of LA into the mitogen 13-HODE, leading to decreased tumor growth. The decrease in fatty acid uptake by ALA and EPA is thought to be due to their binding of an n-3 fatty acid receptor that inhibits a G_i-protein-coupled signal transduction pathway leading to decreased cAMP and LA uptake and its conversion to 13-HODE.

The enzyme fatty acid synthase (FAS) is overexpressed in tumors, and suppression of its activity reduces de novo fatty acid synthesis and is cytotoxic to tumors. Moon et al. (2002) show that n-3 PUFAs can negatively regulate FAS and its transcription factor, the SREBP-1. In addition, n-3 PUFAs induce necrosis and apoptosis of tumors cells and reduce tumor growth and metastatic spread (Diggle, 2002). Vecchini et al. (2004, 2005) show that ALA suppresses Morris hepatoma 3824A FAS, acetyl-CoA carboxylase mRNA, and SREBP-1, and induces apoptosis. Wu (2006) has recently reviewed the interaction between various fatty acid related genes in liver cancer. These include the role of COX2, PGE_2 and its G-protein-coupled E-prostanoid receptors, and their interaction with the epidermal growth factor (EFG) receptor and cross talk with c-Met oncogene. The interplay of COX2 with other cellular messengers such as inducible nitric oxide synthase and vascular EGF and potent gene transcription factors such as the PPARs x and y, which can also be modulated by fatty acids, remains to be further elucidated.

43 Essential Fatty Acids and Visual Dysfunction

Algis J. Vingrys and Anne E. Weymouth

CONTENTS

I. INTRODUCTION

The association between low omega-3 polyunsaturated fatty acid (PUFA) intake and visual dysfunction has been well documented (Vingrys et al., 2001; SanGiovanni and Chew, 2005; Singh, 2005). This chapter reviews recent research that provides insights into the mechanisms through which these essential fatty acids can act to modulate neural function. A brief overview of the importance of dietary omega-3 fatty acids in sustaining ocular health precedes a discussion of the functional contribution that omega-3 PUFA have as structural components of membranes. The specialized metabolism of these lipids by the retina as well as its accessibility by way of electroretinography render this tissue a useful model in which to consider the functional consequences of omega-3 deficiency. These functional losses are discussed with respect to the roles that omega-3 polyunsaturates are known to have in modulating membrane biophysical characteristics and membrane-bound protein function. Laboratory trials indicate that omega-3 metabolites should impact on membrane-bound protein activity in a predictable fashion, although *in vivo* animal or human studies fail to consistently demonstrate these effects. This review details possible explanations for the lack of concordance between the *in vivo* and *in vitro* outcomes.

II. OMEGA-3 FATTY ACIDS AND OCULAR HEALTH

Many aspects of ocular physiology and vision are affected by omega-3 lipids. Although much attention is paid to the role of these essential fatty acids in sustaining healthy neural function, there is increasing evidence for their benefits in other ocular conditions. This is not surprising given the myriad effects that omega-3 metabolites have in systemic physiology, as detailed in other chapters of this book.

A. Dry Eye

The transparent anterior surface of the eye, the cornea, is composed of connective tissue. Its structure contributes the curvature that underlies the refractive power of the eye in combination with the tear film which provides the optical surface for refraction. Image quality, therefore, is strongly dependent on the composition of the overlying tear film produced by glands within the conjunctiva and eyelids. Insufficient dietary intake of omega-3 fatty acids has been implicated in dry eye syndromes (Miljanovic et al., 2005). The reason for this association remains elusive although there are several possible explanations.

Increased plasma levels of omega-3 fatty acids may directly impact on the lipid profile of the tear film, thereby improving its stability and function. Alternatively, omega-3 fats may optimize meibomian gland health by modulating its secretions as well as suppressing the production of proinflammatory cytokines. It is also possible that omega-3 intake promotes the activity of transmembrane ionic pumps located in the conjunctival epithelium, improving tear quality or quantity (Shi and Candia, 1995). The relationship between membrane omega-3 PUFA composition and transmembrane protein activity will be discussed later. Finally, a greater omega-3 intake should improve the conjunctival and corneal epithelial surfaces, as it does elsewhere in the skin (Ziboh et al., 2000; Sinclair et al., 2002), making them more able to withstand periods of dryness and promoting comfort in cases of inadequate secretion.

B. Retinal Disease

Retinitis pigmentosa is an inherited degeneration of retinal photoreceptors, which has been associated with decreased plasma levels of omega-3 PUFA (Hoffman and Birch, 1995; Hoffman et al., 2001). Despite this altered plasma profile, there is no known causal link between the lower omega-3 PUFA and the retinal degeneration. Moreover, investigations of the functional benefits that dietary supplementation can have in this disease remain inconclusive (Wheaton et al., 2003; Berson et al., 2004a,b; Hoffman et al., 2004).

Apart from systemic complications, diabetes induces vascular anomalies (Stitt and Curtis, 2005; Kalantzis et al., 2006) and neural dysfunction (Phipps et al., 2004) within the retina, by way of diabetic retinopathy. DHA has been shown to decrease the inflammatory processes in diabetic retinopathy (Chen et al., 2005b) and there is ongoing research into the possibility that omega-3 PUFA may inhibit the retinal neovascularization of diabetes. Although fish oil supplementation has been shown to improve the dislipidemia associated with diabetes (Mori et al., 1990), vascular and neural effects have not been evaluated in clinical trials. Recent research from our laboratory has shown that diabetic animals given fish oil supplementation not only returned normal lipid profiles but also had no other signs of diabetic retinopathy (Yee et al., 2006).

The most common cause of vision loss in the elderly is age-related maculopathy (AMD) (Figure 43.1b). Recent findings into the pathophysiology of AMD have shown that the inflammatory cascade is upregulated in this disease (Johnson et al., 2001; Donoso et al., 2006; Gold et al., 2006). Thickening and lipid deposits within Bruch's membrane, a layer that overlies the choroidal

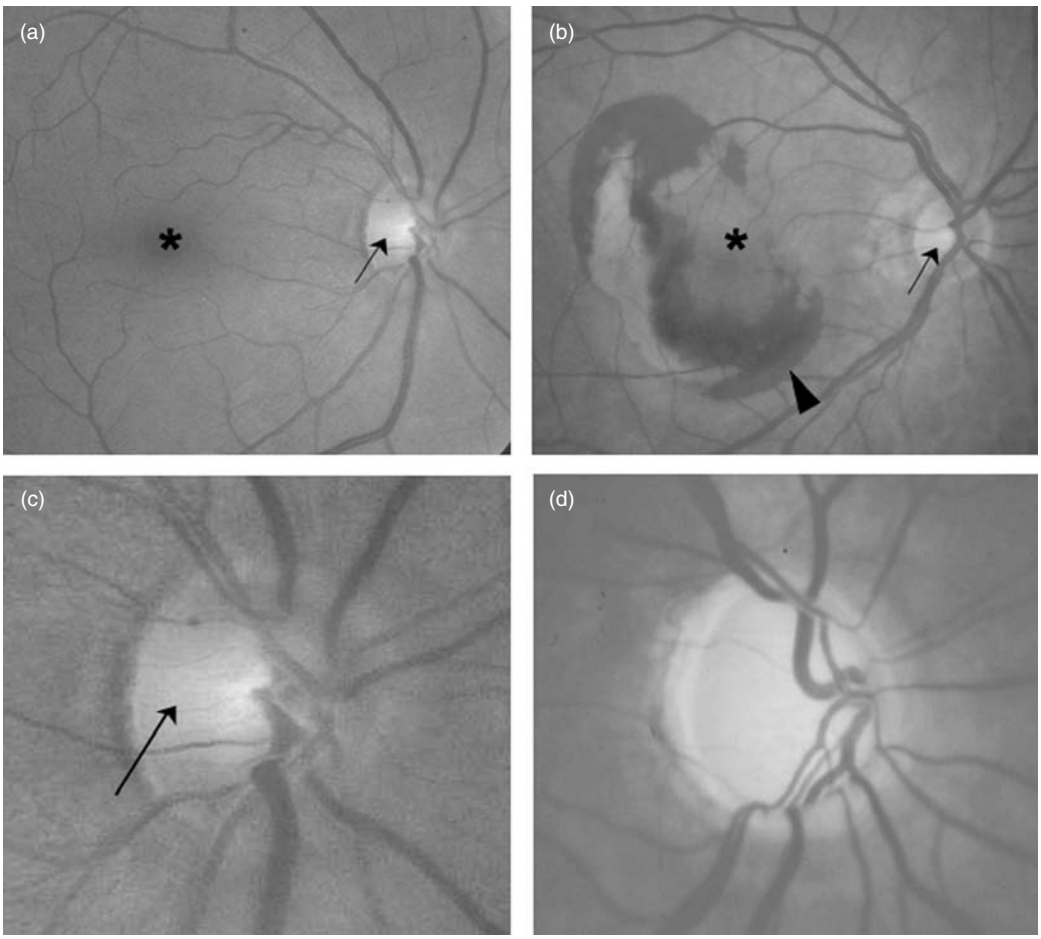

FIGURE 43.1 Retinal fundus images of a normal eye and two age-related diseases related to insufficient dietary omega-3 intake. (a) Healthy fundus showing optic nerve head (arrow) and macula (asterisk). (b) Age-related macular degeneration is evidenced by the macular scar (white area around asterisk) and subretinal hemorrhage (blood surrounding scar as indicated by the arrow head). (c) Enlargement of healthy optic nerve head shown in (a). Arrow indicates healthy neural tissue comprising the neuroretinal rim surrounding a central excavation or "cup." (d) Glaucomatous optic nerve head showing marked cup enlargement, pallor and absence of neural tissue within the optic nerve head.

blood supply to the retinal pigmented epithelium (RPE) (Figure 43.3), compromises photoreceptor integrity causing receptor atrophy and ultimately leads to subretinal neovascularization (Curcio et al., 1996; Mullins et al., 2000; Anderson et al., 2002; Rudolf et al., 2005; Sivaprasad et al., 2005; Tian et al., 2005). Other work indicates that anomalous cholesterol trafficking is associated with the onset or progression of AMD (Malek et al., 2005; Baird et al., 2006). Dietary intake of omega-3 fatty acids reduces the risk of macular degeneration (Smith et al., 2000; Seddon et al., 2001; Elner, 2002) and supplementation has been shown to ameliorate the clinical fundus signs (Feher et al., 2005) although the mechanisms underlying these benefits are unknown.

C. Glaucoma

Glaucoma refers to the syndrome of optic nerve loss with associated visual field deficits (Figure 43.1d). A major risk factor for this disease is elevated intraocular pressure (IOP) (Gordon et al., 2002). Intraocular pressure has been shown to be related to the level of dietary intake of omega-3 PUFA with pressure reduction arising from enhanced aqueous outflow (Nguyen et al., 2005). This improved outflow facility may arise from elevated omega-3 eicosanoid levels within the aqueous humour (Kulkarni and Srinivasan, 1989; Rosch et al., 2005). However, neuroprotective effects of omega-3 metabolites (Miyauchi et al., 2001; Bazan, 2005, 2006) may also impact on the glaucomatous neuropathy. Not surprisingly, the risk of development or progression of glaucoma has been shown to be inversely related to plasma levels of omega-3 fatty acids (Cellini et al., 1998; Ren et al., 2006). The role that omega-3 fatty acid supplements have in IOP modulation and glaucoma modification are not well defined and are in need of well designed clinical trials.

The relationship between the timing and quantity of dietary omega-3 PUFA intake and ocular disease prophylaxis remains to be investigated. As discussed later, there is specific and efficient accretion of omega-3 polyunsaturates, particularly docosahexaenoic acid (DHA) during fetal growth, and adequate levels are required to ensure normal development of the visual system. Less studied is the requisite for ongoing intake of omega-3 PUFA throughout life and the specific effects that insufficient intake can have on ocular aging and pathology.

There is a wealth of literature describing the importance of omega-3 fatty acids in optimizing visual development and ocular health. However, the optimal dietary intake and the mechanisms through which these lipids act are complex and many are yet to be determined. The remainder of this chapter will focus on the structural role of the long-chain omega-3 PUFA, DHA, within the nervous system. As discussed below, the visual pathway provides an accessible route for investigating the means through which omega-3 PUFA can optimize neural function. The fact that omega-3 fatty acids can modulate intraocular fluid flow and neural function bears witness to the complex physiological processes within the eye that are affected by lipid intake. Furthermore, the specialized metabolism of these lipids within the retina creates a unique context for understanding how omega-3 fatty acids maintain healthy neural function. This knowledge can then be projected to the central nervous system and other organs. By relating test-tube results to practical outcomes, the following sections consider the means through which membrane lipid composition can modify retinal function.

III. OMEGA-3 FATTY ACIDS IN THE NERVOUS SYSTEM

The nervous system accumulates and tenaciously retains omega-3 fatty acids more than any other tissue (O'Brien and Sampson, 1965; Sinclair, 1975; Bourre et al., 1992; Makrides et al., 1994; Abedin et al., 1999; Moriguchi et al., 2001; Haag, 2003). Neural retention of PUFA (Bazan et al., 1994) is exemplified by the time course required to create a change in membrane profiles following dietary manipulation (Galli et al., 1971; Neuringer et al., 1986; Watanabe et al., 1987; Connor and Neuringer, 1988; Bourre et al., 1989; Lin et al., 1991; Connor et al., 1992; Weisinger et al., 1995, 1996a, 1998; Moriguchi et al., 2001). Moreover, whereas hepatic fatty acid profiles fluctuate rapidly

subject to dietary intake, the relative omega-3 and omega-6 content of neural membranes remains constant over a wide range of dietary intakes (Abedin et al., 1999). Why the body should go to such lengths for fatty acid profile preservation is not clear given that the sole difference between the two long-chain metabolites, DHA, and its omega-6 counterpart, docosapentaenoic acid (DPA), is the absence of a double bond at carbon 19 in the omega-6 species (Salem et al., 2001). As discussed later, this apparently trivial structural difference can lead to substantial functional alteration.

Omega-3 PUFA in neural membranes comprises little eicosapentaenoic acid (EPA) as this substrate is rapidly recruited to eicosanoid synthesis or elongated into DHA (Hagve et al., 1988). DHA may be obtained directly from the diet or synthesized from one of its omega-3 precursors (Sprecher et al., 1995). Pawlosky et al. (1996) assert that, in addition to dietary sources and placental transfer, there must be local biosynthesis of DHA within nervous tissue for the production of such high local concentrations of DHA. There is increasing evidence of this occurring within the retina (Alvarez et al., 1994; Chen et al., 1999) and brain (Delton-Vandenbroucke et al., 1997; Moore, 2001; Williard et al., 2001a,b).

A. Preferential Accretion and Retention of Omega-3 Fatty Acids by the Retina

Given the significant function of membranes in the photoreceptor outer segments (Section VII), it is not surprising that the retinal membrane lipids are unique in their constituents and metabolism. The retina features unique mechanisms for DHA uptake, conservation and recycling in an effort to maintain adequate levels, even during prolonged dietary deficiency (Rodriguez de Turco et al., 1990; Stinson et al., 1991b; Anderson et al., 1992; Bazan et al., 1992).

Of the PUFAs in mammalian retinae, between 38% and 92% are DHA (Fliesler and Anderson, 1983; Salem et al., 1986; Martinez et al., 1988; Salem, 1989; Hrboticky et al., 1991; Wiegand et al., 1991; Gulcan et al., 1993; Makrides et al., 1994). Thirty percent of rod outer segment fatty acids incorporate DHA and 54% of retinal phosphatidylethanolamine (PE) acyl chains contain DHA (Benolken et al., 1973; Fliesler and Anderson, 1983; Bazan et al., 1990; Wiegand et al., 1991). The rod outer segment disc membrane contains 42%–45% each of phosphatidylcholine (PC) and PE and 10%–12% phosphatidylserine (PS) (Salem et al., 2001). Optimal photochemical function of rhodopsin has been reported to depend on both the surrounding phospholipid head group and the fatty acyl chain content (Wiedmann et al., 1988). Rhodopsin activation can also be modulated by rhodopsin concentration with elevated concentrations inhibiting activation (Niu and Mitchell, 2005).

Retinal DHA is concentrated through the formation of di-DHA species or by coupling with other unsaturated fats (Bell and Tocher, 1989; Stinson et al., 1991a; Polozova and Litman, 2000). DHA is commonly positioned at the *sn*-2 carbon although, uniquely within the retina, it may also occupy the *sn*-1 position (Lin et al., 1994). The DHA content of PE and PS is highest in the retina but is also found in high concentrations in synaptic vesicles and synaptic plasma membranes (Cotman et al., 1969; Anderson, 1970; Anderson and Sperling, 1971; Breckenridge et al., 1972; Sun and Sun, 1972; Breckenridge et al., 1973). Of the aminophospholipids, PS and PE have the highest concentrations of DHA (Yabuuchi and O'Brien, 1968).

Photoreceptors synthesize a small amount of DHA (Wetzel et al., 1991; Wang and Anderson, 1993a) and further production occurs in the pigmented epithelium (Wang and Anderson, 1993a) and vascular endothelium (Delton-Vandenbroucke et al., 1997). Most retinal DHA is transported from hepatic stores across the RPE and is incorporated into ellipsoids to form new photoreceptor outer segment disks (Bazan et al., 1992; Wang and Anderson, 1992, 1993b; Gordon and Bazan, 1993).

Despite the specialized processing of DHA within the retina, there is well-founded evidence for retinal omega-3 fatty acid depletion (Leat et al., 1986; Neuringer et al., 1986; Connor and Neuringer, 1988; Chen and Anderson, 1993; Weisinger et al., 1998; Abedin et al., 1999; Moriguchi et al., 2001) and subsequent functional losses following lengthy dietary deprivation of α-linolenic acid (LNA) or DHA (Benolken et al., 1973; Wheeler et al., 1975; Neuringer et al., 1986; Connor and Neuringer, 1988; Birch et al., 1992; Weisinger et al., 1996a; Armitage et al., 1999; Jeffrey et al., 2002a).

IV. METHODS OF ACHIEVING OMEGA-3 DEFICIENCY

Investigating the neural dysfunction that arises from omega-3 deficiency is dependent on the level of deficiency that can be attained. In animal models, this is achieved by the extent, nature and timing of dietary intervention. In humans, studies of omega-3 deficiency are limited to perinatal nutritional modifications or epidemiological assays of dietary habits, with the latter providing less precision than the former. However, achieving substantial omega-3 depletion within the nervous system, and particularly the retina, by dietary modification can be hindered by the tenacious retention and recycling mechanisms of this tissue, described in the previous section.

An important issue in diet modification trials is the timing of the intervention, given species-dependent variations in retinal growth and DHA accretion. Whereas there is substantial postnatal growth and differentiation of the retinal neurons of rodents (Bonting et al., 1961; Fulton et al., 1995), cellular differentiation and functional development in precocial species (guinea pigs, primates and humans) is completed *in utero* (Huang et al., 1990; Hendrickson, 1993; Greiner et al., 1996, 1997; Bui and Vingrys, 1999; Su et al., 1999; Vingrys and Bui, 2001). In precocial mammals, 35% of DHA accretion occurs in the last phase of gestation (Locke et al., 1998). Not surprisingly, maximum dietary modifications in humans are realized in premature, low birth weight infants (Uauy et al., 1990; Birch et al., 1992; Hoffman et al., 1993; Faldella et al., 1996; Leaf et al., 1996; Neuringer, 2000; Uauy and Hoffman, 2000; Innis, 2003). This implies that early manipulations of omega-3 intake either before or during pregnancy will have greatest effect on the fatty acid profiles of subsequent generations, an issue that will be developed in the following section.

However, human trials are limited by the modest capacity to which DHA profiles can be modulated by diet to induce changes within neonatal tissues. For example, the average breast milk DHA content of Western women (0.45% w/w) is about half that of non-Western women (0.88%) (Jensen, 1999), resulting in a small absolute dietary deficiency compared to that which can be realized in animals (~40:1) (Figure 43.2). Despite this relatively small modification, studies in human infants report benefits to visual and cognitive function by supplementing milk formulae with long-chain omega-3 PUFA (Uauy et al., 1990; Werkman and Carlson, 1996; Birch et al., 1998; Makrides et al., 2000).

As detailed in earlier editions of this book, human infants nourished with milk supplemented with DHA and EPA had larger electroretinogram (ERG) amplitudes than did infants fed the short-chain omega-3 precursor, ALA (Uauy et al., 1990, 1992; Birch et al., 1992; Hoffman et al., 1993, 2003). These findings contrast with a study in monkeys that revealed no differences in ERG amplitudes

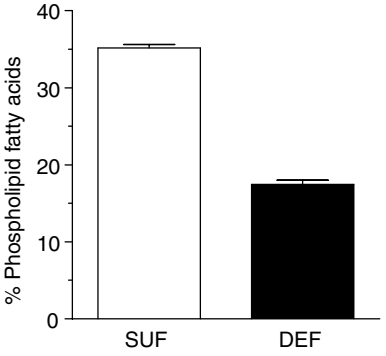

FIGURE 43.2 Retinal phospholipid DHA content of 20-week-old rats raised on an omega-3 deficient diet from conception. Mean (± SEM, n = 12/group) retinal DHA content expressed as a percentage of total retinal phospholipid fatty acids. Omega-3 sufficient rats (Suf, unfilled bar) were raised on a diet comprising 7% lipid by way of a mixture of safflower, flaxseed and tuna oils (5%:1.5%:0.5% ω-6/ω-3 = 5.5:1). Omega-3 deficient rats (Def, filled bar) were raised on a diet where the 7% lipid was provided by safflower oil alone (ω-6/ω-3 = 235:1).

following either ALA or DHA and arachidonic acid (AA) supplementation (Jeffrey et al., 2002b). Given the previous discussion of the importance that a mother's diet has on neonatal development, it is possible that the disparity between the human and monkey studies reflects differences in maternal omega-3 status. The mothers in the human trials were all of Western origin, presumably with relatively modest intakes of omega-3 lipids (Simopoulos, 2001), whereas the monkey chow may have contained higher levels of omega-3 fats. It is possible that the different maternal omega-3 status may have influenced neural development. Alternatively, the monkey study (n = 10/diet) (Jeffrey et al., 2002b) may have been of insufficient power to detect the modest ERG anomalies reported in human trials (n = 30/diet) (Hoffman et al., 2003).

Understanding the mechanisms involved in omega-3 modulation of neural physiology is facilitated by using animal models, where greater levels of dietary deprivation are possible. Larger magnitudes of tissue depletion increase the likelihood of functional deficits. Moreover, the changes to lipid profiles of specific neural tissues in animals can be directly assayed and correlated to the level of dysfunction, and the extent of deficiency can be amplified in animals by dietary manipulation across generations. For example, retinal DHA content can be reduced by 88% in guinea pigs after three generations (Leat et al., 1986; Weisinger et al., 1996b). In rats, the same period of intervention elicits a retinal DHA deficit of up to 62% (Leat et al., 1986; Weisinger et al., 2002), although most of the depletion appears to occur in the first generation (Leat et al., 1986). These substantial dietary manipulations can be considered extreme in terms of omega-3 intake; however, they are necessary for investigating the mechanisms through which omega-3 PUFA act in neural tissues. The consequences of small omega-3 insufficiencies over a period of many years, as is typical in humans, are unknown.

Single generation deficits are amplified by initiating maternal dietary intervention either during or preceding pregnancy. Weisinger et al. (1998) quantified the effect that maternal omega-3 status has in depleting guinea pig offspring. Prefeeding pregnant monkeys with omega-3 deficient diets achieved a retinal DHA deficit in their offspring of 80% by 20 weeks of age (Neuringer et al., 1986, 1991). Our laboratory has adopted this prefeeding protocol with rats and finds a 52% decrement in the retinal DHA of 20-week-old offspring (Figure 43.2). Artificial feeding in newborn rats (Moriguchi et al., 2004) gives rise to a greater DHA deficit, similar to that reported in monkeys, at the expense of more complex technical demands. This indicates that appropriate dietary intervention elicits extensive retinal DHA deficiency in rat pups, although natural, maternal prefeeding has a lesser capacity for depletion than artificial feeding.

V. FUNCTIONAL ASSESSMENT OF VISION

Assessment of the visual pathway is dependent on the species involved and the region of the visual pathway under study. Subjective measures that test visual thresholds using preferential looking can be adopted in humans and monkeys (Neuringer et al., 1984; Uauy et al., 1992; Birch et al., 1998). An objective correlate is the visual evoked potential (VEP), which is a measure of the local electroencephalogram of the visual cortex in response to a specific stimulus modality (e.g., contrast) and is particularly suited to the examination of nonverbal infants (Faldella et al., 1996; Birch et al., 1998; Makrides et al., 2000; Hoffman et al., 2003; Gillingham et al., 2005).

Objective measures can also be applied to animal models of omega-3 deficiency. The ERG is a sensitive method for evaluating the massed retinal response to light stimulation. Although focal or multifocal techniques are useful in localizing lesions across a diseased retina, the full-field flash ERG is appropriate for assessing the general deficits induced by systemic omega-3 deficiency in nonfoveate mammals such as rats. The ERG has been commonly used to assess retinal dysfunction following deprivation of omega-3 PUFA in animal models. The following sections provide an overview of retinal structure and how this relates to components of the ERG response. This is followed by specific consideration of the effects that omega-3 deprivation can have on these processes.

VI. RETINAL STRUCTURE

The retina is a multilaminar cellular structure composed of specialized neurons (Figure 43.3). The photoreceptors transduce visual stimuli into electrical signals which are transmitted to the brain via the optic nerve. The functional efficacy of this tissue is a reflection of the specific organization of its different neuronal classes. Several classes of retinal neurons have been identified (Kolb, 1991) and the mammalian retina may be divided into ten layers according to histological cellular arrangements (Kolb, 1991; Hendrickson, 1993).

The outermost retinal layer lies adjacent to the choroidal blood supply and consists of a single row of cells, forming the RPE (Figure 43.3). The RPE stratum, and its intercellular junctional occlusions, form the blood-retinal barrier and an element of electrical resistance called the "R membrane" (Brindley, 1970). This component of resistance has the capacity to alter the magnitude of electrophysiological recordings of retinal activity (Tomita et al., 1960). The outer segments of photoreceptors lie between the apical processes of RPE cells (McLaughlin and Boykins, 1981). The RPE has common embryological origins with other pigmented cells of the uvea (Hendrickson, 1993). They are cuboidal cells that support retinal metabolism (Boulton and Dayhaw-Barker, 2001), sustain photoreceptor outer segment turnover and renewal (Young, 1967; Gordon and Bazan, 1990) and mediate visual pigment regeneration (Bok, 1993; McBee et al., 2001).

Photoreceptors are elongated cells responsible for light capture and the transduction of light energy into a graded electrical potential that is passed onto other cells (Baylor and Fettiplace, 1976; Yau, 1994). Photoreceptors have an outer segment near the RPE connected to an inner segment via a ciliary stalk (Besharse et al., 1985). Two classes of photoreceptors are found in mammalian

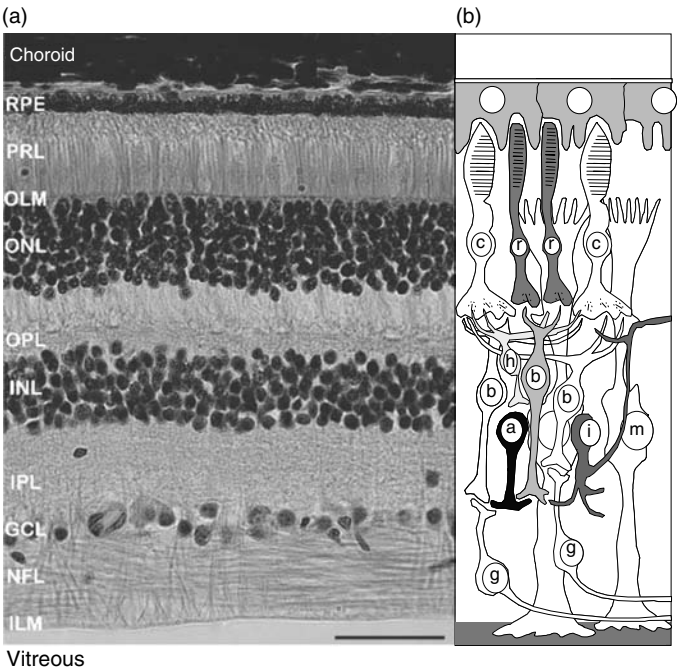

FIGURE 43.3 Cross-sectional retinal structure. (a) Vertical section of primate retina stained with hematoxylin and eosin showing cell bodies and synaptic stratification of the retina. Scale bar: 50 μm. (Photo courtesy of Dr. T. Puthussery.) (b) Schematic of the retinal structure shown to the left identifying the key layers as: RPE: retinal pigmented epithelium; PRL: photoreceptor layer; OLM: outer limiting membrane; ONL: outer nuclear layer; OPL: outer plexiform layer; INL: inner nuclear layer; IPL: inner plexiform layer; GCL: ganglion cell layer; NFL: nerve fiber layer; ILM: inner limiting membrane. The cells within these layers are: r: rod; c: cone; b: bipolar cell; h: horizontal cell; a: amacrine cell; i: interplexiform cell; g: ganglion cell; m: Müller cell.

retinae, rods (Figure 43.4) and cones (Szel et al., 2000), which differ in morphology and photopigment structure (Baylor et al., 1984b; Applebury and Hargrave, 1986). Cones are morphologically distinguished from rods in that the cone inner segment is of greater diameter than the outer segment and the outer segment can have a conical shape (Laties and Enoch, 1971; Borwein, 1983). The inner segments of both contain the nucleus and organelles needed for metabolism (Hoang et al., 2002; Lluch et al., 2003; Perkins et al., 2003). The outer limiting membrane of the retina is created by Müller cell processes which envelop the photoreceptors.

The structure of the photoreceptoral outer segment is significant in its role of capturing light (Figure 43.4). The outer segment membranes of both rods and cones invaginate and pairs of adjacent invaginations form a stack of double-membrane disks (Daemen, 1973). These membranes contain the highest concentrations of DHA in the body (Anderson, 1970; Anderson and Maude, 1970). In rods, these disks are contained within—but separated from—the outer plasma membrane, whereas those of cones remain continuous with the outer plasma membrane (Daemen, 1973). There is continuous regeneration of the photoreceptor outer segment disks as aged membranes are shed to be phagocytosed by the RPE (Young, 1967; Gordon and Bazan, 1993). It is within these disk membranes that the light-absorbing proteins, photopigments, are incorporated (Applebury and Hargrave, 1986; Szel et al., 2000).

Differences in retinal function between species can be, in part, attributed to variations in retinal structure. In contrast to the rat retina which has few cone photoreceptors (0.85%–1.5%, La Vail, 1976; Carter-Dawson and LaVail, 1979; Szel and Rohlich, 1992), 5% of the retinal photoreceptors in primates are cones (Wikler et al., 1990). The differences in cell structure, spatial organization (Laties and Enoch, 1971; Wikler et al., 1990) and neural wiring (Sassoe-Pognetto et al., 1994; Brandstatter et al., 1995) between these two classes of receptors provide cones with better temporal, color and spatial resolution (acuity) whereas rods possess greater contrast gain at low light levels (Rieke and Baylor, 1998). Particular to human and primate retinae (Szel et al., 2000), the close packing of cones at the fovea affords high visual acuity in this region (Wikler et al., 1990). The rodent retina is, therefore, useful for analyzing rod function, as it comprises a receptoral landscape typical of that found in the human peripheral retina.

Several specialized neurons are involved in signal transmission and modification within the retina (Brindley, 1970; Baylor and Fettiplace, 1976; Tomita, 1986; Ghosh et al., 2001). These include bipolar cells, horizontal cells, amacrine cells and interplexiform cells in the outer nuclear layer and mainly ganglion cells in the ganglion cell layer (Figure 43.3). The through pathway carries receptoral responses to the inner retina via two subtypes (ON- and OFF-) of bipolar cells which transmit graded potentials to ganglion cells (Euler and Wassle, 1995; Morgans, 2000; Berntson et al., 2003; Ichinose et al., 2005). Lateral processing via horizontal cells can modify the signal at the receptor-bipolar cell synapse in the outer plexiform layer whereas amacrine and interplexiform cells may alter the signal transmitted to the ganglion cell in the inner synaptic layer (Wu, 1991; Brandstatter et al., 1995; Hartveit, 1999; Trexler et al., 2005). In response to the input from the other retinal neurons, ganglion cells produce action potentials (Diamond and Copenhagen, 1995) that are transmitted to the brain along the optic nerve (Enroth-Cugell and Robson, 1984; Lipton and Tauck, 1987; Fitzgibbon and Taylor, 1996). Recently, a unique ganglion cell containing a photosensitive pigment, melanospin, has been described (Provencio et al., 2000; Berson et al., 2002; Dacey et al., 2005; Peirson and Foster, 2006). These cells appear to be involved in regulating the pupillary light response as well as circadian rhythms (He et al., 2003; Hannibal et al., 2005; Hattar et al., 2006). Müller cells are large glia whose somata extend throughout the thickness of the retina (Reichenbach, 1989). They provide metabolic support to retinal neurons and are involved in buffering extracellular ion concentrations (Oakley et al., 1992; Reichelt et al., 1993; Newman, 1999; Kofuji et al., 2002; Connors and Kofuji, 2006).

Axons leave the ganglion cell to extend across the retina and form the nerve fiber layer (Fitzgibbon and Taylor, 1996). Expanded Müller cell processes occupy the inner retinal face to form the inner limiting membrane that contains the nerve fiber layer (Shaw and Weber, 1983; Lundkvist et al., 2004). This separates the sensory retina from the vitreous body. Retinal nerve fibers bundle together at the optic disc to exit the globe as the optic nerve and terminate in midbrain centers.

VII. RETINAL SIGNAL PROCESSING

This section outlines the processes involved in visual signal transduction and visual pigment regeneration. These topics have been well covered in the following reviews (Stryer, 1986; Pugh and Lamb, 2000; McBee et al., 2001; Lamb and Pugh, 2004).

A. The Dark Current

The ability of the photoreceptors to respond to light arises from the maintenance of ionic gradients across the inner to outer segments (Schnapf and McBurney, 1980; Woodruff et al., 1982). These gradients are modulated by the state of membrane-bound cation channels (Figure 43.5).

Sodium/potassium-ATPases actively transport potassium ions into and sodium ions out of the inner segments (Berman et al., 1977; Baylor et al., 1984a; Stirling and Sarthy, 1985; Schneider and Kraig, 1990). This creates a longitudinal concentration gradient for sodium. Sodium ions extruded from the inner segment pass down their concentration gradient to enter outer segment pores that are held in an open state in the dark by cyclic-GMP (cGMP, Hagins and Yoshikami, 1975; Pinto and Brown, 1984; Gray and Attwell, 1985; Zimmerman et al., 1985; Matthews, 1986, 1987). The sodium ions that enter the outer segment are shunted to the inner segment via the connecting cilium, completing the circuit known as the "dark current" (Figure 43.5) (Hagins et al., 1975). A sodium/calcium:potassium ion exchanger maintains intracellular calcium and potassium ion concentrations in the outer segment (Bauer and Schauf, 2002). Innexr segment potassium concentrations are sustained by voltage-sensitive potassium channels (Barnes, 1994; Wollmuth, 1994).

This ionic flow is reliant on the Na^+/K^+-ATPase maintaining a concentration gradient for sodium ions across the receptoral inner and outer segments. The change in dark current brought about following light absorption (Schnapf and McBurney, 1980; Woodruff et al., 1982) results from hydrolysis of cGMP, reducing binding to the nonspecific cation channels located in the outer segments (Gray

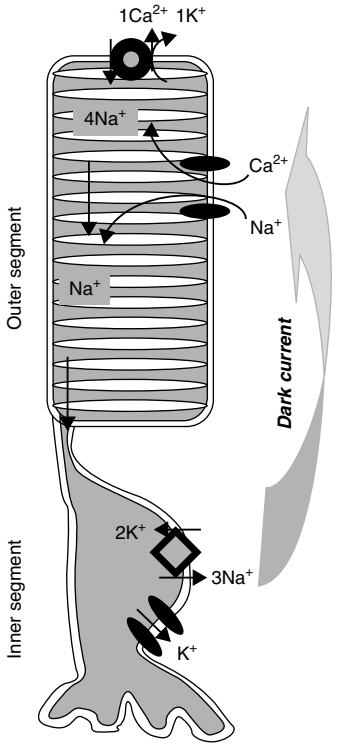

FIGURE 43.5 The inner segment Na^+/K^+-ATPase maintains the dark current. (Adapted from Saari, J.C., 1992. The biochemistry of sensory transduction in vertebrate photoreceptors. *Adler's Physiology of the Eye*. 9th ed., W.M. Jr. Hart, ed., St. Louis: Mosby-Year Book, Inc., p. 486.)

and Attwell, 1985; Matthews, 1987). This closes the channels (Figure 43.7), preventing sodium and calcium influx into the outer segment (Miller and Korenbrot, 1993). However, calcium extrusion via the 4 Na^+/Ca^{2+}:K^+ ion exchanger continues, resulting in decreased cytosolic Ca^{2+} concentration (Yau, 1994), a process important for adaptation mechanisms, as detailed later.

In the dark, the circulating "dark current" is maximal and maintains the photoreceptor membrane in a depolarized state (Moriondo et al., 2001) with continuous release of glutamate from the synaptic terminal of the photoreceptor. The light-induced closure of cation channels in the outer segment inhibits cation influx causing hyperpolarization (Baylor et al., 1984a,b). This is passively transmitted from the outer segment to the inner synaptic terminal causing a graded decrease in glutamate release (Kaneko and Shimazaki, 1976), proportional to the intensity of the light stimulus (Penn and Hagins, 1972; Baylor et al., 1979, 1984b; Gomez and Nasi, 1994).

B. Photon Absorption

Photoreceptor photopigments are responsible for light capture and are incorporated into the disk membranes (Dratz et al., 1979; Fotiadis et al., 2003; Liang et al., 2003). There are two components to each photopigment molecule: an opsin to which is attached a chromophore. The opsin is a seven-α-helix transmembrane protein (Applebury and Hargrave, 1986), a good template for studying G-protein-coupled receptors (Hargrave and McDowell, 1992; Lamb and Pugh, 1992). The chromophore is a vitamin A aldehyde (11-*cis*-retinal) and is directly responsible for light absorption. The spectral distribution of light absorption of each photoreceptor is determined by the structure of the opsin (Baylor et al., 1984b; Applebury and Hargrave, 1986) and its dielectric interactions

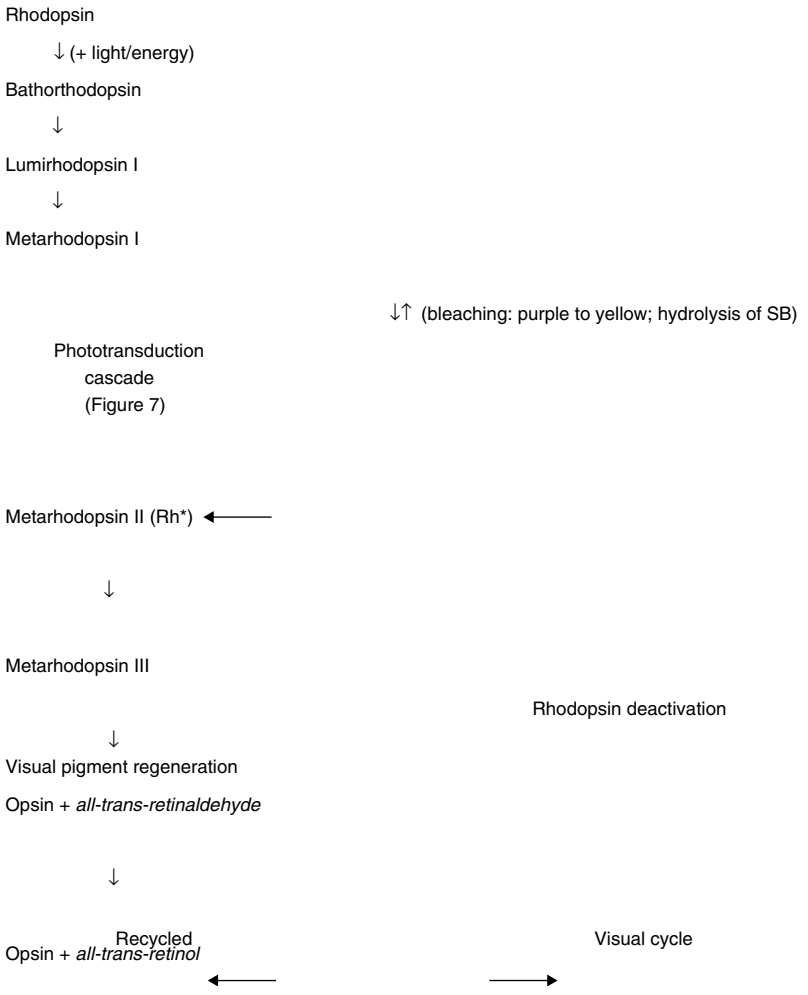

FIGURE 43.6 Steps involved in rhodopsin activation and processing. Rhodopsin is activated to metarhodopsin II by absorption of a photon of light (hv). The active form of rhodopsin (Rh* or metarhodopsin II) is formed on hydrolysis of the Schiff base (SB) linkage between the visual pigment (chromophore) and the opsin. The deactivation processes and rhodopsin regeneration are detailed in later sections.

with the chromophore (Kochendoerfer et al., 1999). The photopigment found in rods is known as rhodopsin (Fotiadis et al., 2003; Liang et al., 2003).

Chromophore activity is affected by the location of the photopigment molecule within the membrane (Piscitelli et al., 2006). A significant proportion of the rhodopsin molecule lies within the hydrophobic portion of the membrane bilayer, thus exposing it to interactions with other membrane phospholipids (Albert and Yeagle, 1983). The helical structure of rhodopsin also creates three cytoplasmic loops and three intradiscal loops (Liu and Northup, 1998; Bailey et al., 2003), with the cytoplasmic loops being important to the process of phototransduction (Figure 43.7). The chromophore is buried in the centre of the membrane bilayer, surrounded by the opsin helices (Hsu et al., 1993).

Absorption of a photon by the chromophore effects an alteration in its secondary structure called bleaching (Figure 43.6). This process involves the conversion of 11-*cis*-retinal to all-*trans*-retinol (Wald, 1968). A number of structural intermediaries are formed before hydrolysis of the Schiff base linkage (Longstaff et al., 1986) between the chromophore and the opsin (Straume et al., 1990).

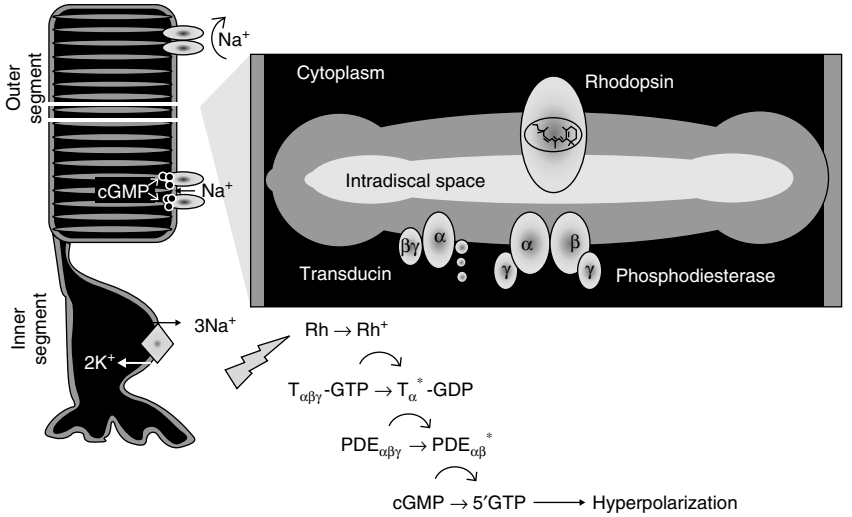

FIGURE 43.7 Phototransduction cascade. Schematic showing the orientation of the membrane-bound proteins that mediate phototransduction and the cascade of protein activations leading to hyperpolarization of the photoreceptor. Proteins diffuse within the outer segment disk membrane bilayer leading to sequential activation. Hydrolysis of cGMP results in a reduction in the cytoplasmic concentration of cGMP, releasing this molecule from the pore-binding site and leading to closure of the outer segment cation channels. Asterisks indicate active forms Rh: rhodopsin; GTP: guanosine triphosphate; GDP: guanosine diphosphate; PDE: phosphodiesterase; cGMP: cylic guanosine monophosphate. See text for details.

The formation of these intermediaries is temperature dependent (Lewis et al., 1981). One of the key products, metarhodopsin II, catalyzes the initial reaction of the transduction cascade (Figure 43.7, Kibelbek et al., 1991), and is often described as the active form of rhodopsin (Rh*).

C. Phototransduction Cascade

Phototransduction is achieved through (Pugh and Lamb, 2000) a cascade of sequential protein activations following light capture by rhodopsin (Figure 43.7). Cyclic GMP maintains the nonspecific cation channels in the rod outer segment open in the dark (Figure 43.5) (Matthews, 1987). Activated rhodopsin (Matthews et al., 1963) initiates a cascade of sequential interactions with the peripheral membrane proteins, transducin and cGMP phosphodiesterase (PDE) (Deterre et al., 1986; Stryer, 1986; Wensel and Stryer, 1986; Watanabe and Murakami, 1992). Transducin is a G-protein composed of three subunits: $T_{\alpha}GDP_{\beta\gamma}$ (Tanabe et al., 1985; Fong et al., 1986; Umbarger et al., 1992; Matsuda et al., 1994; Liu and Northup, 1998). Rod PDE is a tetrameric protein with an alpha, beta and two gamma subunits (Artemyev et al., 1996; Kameni Tcheudji et al., 2001; Kajimura et al., 2002; Cote, 2004; Guo et al., 2005). The gamma subunits in both these molecules are inhibitory and their cleavage activates the respective proteins (Kisselev et al., 1994; Granovsky and Artemyev, 2001; Kajimura et al., 2002).

Active PDE (Figure 43.7) catalyzes the hydrolysis of many cGMP molecules (Takizawa et al., 1998) allowing closure of sodium channels. The subsequent reduction in positive ionic influx results in hyperpolarization of the photoreceptor (Matthews, 1986; Koch and Stryer, 1988; Dumke et al., 1994). As detailed later, the multiple binding and activation of transducin and PDE and the subsequent multiple cGMP hydrolyses lead to amplification ($\times 10^5$) in the response. The lateral diffusion dependence of the activation of each of these proteins (Dumke et al., 1994; Koutalos et al., 1995; Calvert et al., 2001; Niu and Mitchell, 2005) introduces a delay to the various steps involved in phototransduction (Lamb and Pugh, 1992b).

The photoreceptor G-protein cascade, triggered by photopigment light capture, is considered a good model for the G-protein cascades throughout the rest of the body (Lamb and Pugh, 1992a).

D. Rhodopsin Deactivation and Regeneration of the Dark Current

The activated proteins formed during the phototransduction cascade continue in their role of activation until deactivated. The closure of the outer segment cation channels prevents calcium influx without altering the calcium efflux by the Na^+/Ca^{2+}:K^+ exchanger (Figure 43.5). This decrease in the cytosolic calcium concentration (Albani et al., 1980) allows calcium to dissociate from recoverin (Figure 43.8), decreasing the concentration of the inactive, membrane-bound form (Calvert et al., 1995; Sanada et al., 1996; Valentine et al., 2003). Recoverin promotes activation of rhodopsin kinase (Kuhn and Wilden, 1987; Palczewski et al., 1991; Hurley and Chen, 2001; Komolov et al., 2005) which then phosphorylates metarhodopsin II (Ohguro et al., 1996; Hurley et al., 1998; Mendez et al., 2000); the first step of rhodopsin deactivation. Subsequent "capping" of the phosphorylated metarhodopsin II complex by arrestin (Figure 43.8) inhibits further activity (Kuhn and Wilden, 1987; Hofmann et al., 1992; Pugh et al., 1999). Given the inactivation of metarhodopsin II, regeneration of the dark current requires the concurrent deactivation of transducin and PDE. The guanosine triphosphate (GTP) subunit of the activated T-GTP-PDE complex is hydrolyzed to form inactive T-GDP-PDE (Miller et al., 1989). The beta and gamma subunits of transducin reassociate with transducin and the inactive T-GDP complex dissociates from the inactive PDE. Cytoplasmic concentrations of cGMP are replenished by the enzymatic activity of transmembrane guanylate cyclases (Yang and Garbers, 1997).

E. Visual Pigment Regeneration

Deactivation of metarhodopsin II requires the chromophore to separate from the opsin and enter the visual cycle (McBee et al., 2001; Lamb and Pugh, 2004). Chromophore recycling involves a series of isomerization reactions that take place in the RPE (Figure 43.9). All-*trans*-retinal is transferred across rod and cone outer segment membranes and into the cytosol. A specific, transmembrane ATP-binding cassette transporter (ABCR) mediates this process for the membrane-bound fraction of all-*trans*-retinal (Sun et al., 1999; Weng et al., 1999; Schmitz and Kaminski, 2002; Beharry

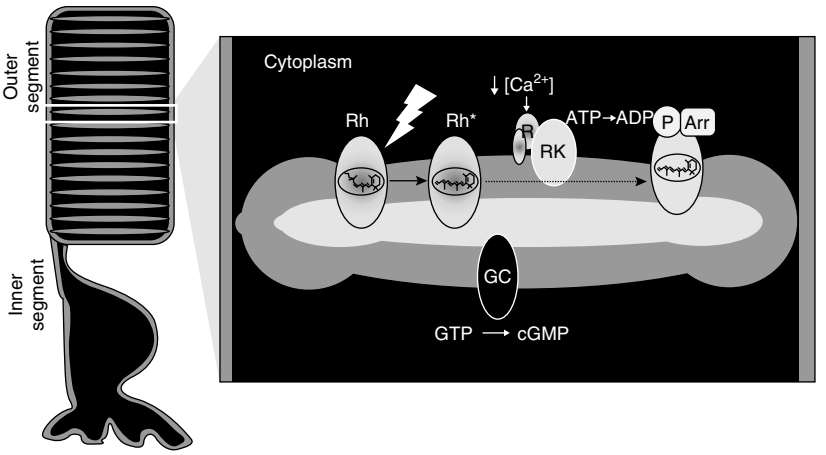

FIGURE 43.8 Schematic of rhodopsin activation by light (arrow) and subsequent deactivation (dotted arrow). Sequential recruitment of proteins involved in the deactivation of rhodopsin in the outer segment disks. Rh: rhodopsin; Rh* activated form of rhodopsin; R: recoverin; RK: rhodopsin kinase; P: phosphate; Arr: arrestin; GC: guanylate cyclase; GTP: guanosine triphosphate; cGMP: cyclic guanosine monophosphate. See text for details.

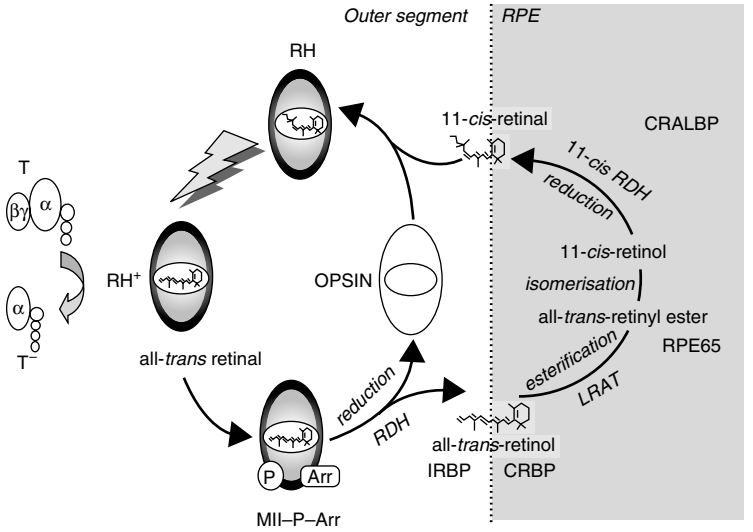

FIGURE 43.9 The visual cycle: pigment regeneration. Schematic of visual pigment regeneration in the RPE. Events leading to the transduction cascade are shown in Figure 43.6 and the formation of the MII–P–Arr complex are shown in Figure 43.8. Arr: arrestin; CRALBP: cellular retinaldehyde-binding protein; CRBP: cellular retinol-binding protein; IRBP: interphotoreceptor retinoid-binding protein; LRAT: lecithin retinol acyl transferase; MII: metarhodopsin II; P: phosphate; RDH: retinol dehydrogenase; Rh: rhodopsin; RPE: retinal pigmented epithelium; T: transducin. (Adapted from Leibrock, C.S., et al., 1998. *Eye.* 12 (Pt 3b), 511–520.)

et al., 2004). All-*trans*-retinol dehydrogenase (RDH) catalyzes the reduction of all-*trans*-retinal to all-*trans*-retinol in the cytosol (Zimmerman et al., 1975; Chen et al., 2005a). All-*trans*-retinol is then transported to the RPE, esterified by lecithin retinol acyl transferase (LRAT, Canada et al., 1990; Ruiz et al., 1999) and converted to 11-*cis*-retinol by an isomerohydrolase (Bernstein and Rando, 1986; Bridges and Alvarez, 1987; Rando, 1991; Moiseyev et al., 2003). 11-*cis*-retinol is reduced by 11-*cis*-RDH and returned to the photoreceptor outer segment where it binds opsin to form a new rhodopsin molecule (Zimmerman et al., 1975).

Retinoid-binding proteins modulate the rates of retinoid transport between the photoreceptors and the RPE and are DHA-dependent (Bazan et al., 1985). All-*trans*-retinol is transported to and from the RPE by interphotoreceptor retinoid-binding protein (IRBP, Noy and Xu, 1990; Noy and Blaner, 1991; Pepperberg et al., 1993; Chen and Noy, 1994) whereas cellular retinaldehyde-binding protein (CRALBP) mediates transport within the RPE (Stecher et al., 1999; McBee et al., 2000). A membrane-dependent protein, RPE 65 (Tsilou et al., 1997), has also been implicated in presenting the retinoid to the isomerase (Mata et al., 2004). Fluorescence assays indicate that IRBP affinity for DHA is twice that of AA and three times that of LNA (Chen et al., 1993). DHA also appears to alter the IRBP affinity for other retinoids in the visual cycle (Chen et al., 1996). Chen et al. proposed that this effect arises from the concentration gradient of DHA between the photoreceptor outer segments and the RPE, and increases the efficacy of the transport of retinoids across the interphotoreceptor matrix.

Although it has been asserted that the rate-limiting component of visual pigment regeneration is the reduction of all-*trans*-retinal to all-*trans*-retinol in mice (Saari et al., 1998; Chen et al., 2005a), more recent data from human studies suggests that the delivery of 11-*cis*-retinal to the opsin limits the regeneration of rhodopsin (Schadel et al., 2003; Lamb and Pugh, 2004).

VIII. ASSAYING RETINAL BIOCHEMICAL RESPONSES

The ERG has been used as an objective measure of retinal dysfunction in omega-3 deficiency (Birch et al., 1992; Hood and Birch, 1994; Weisinger et al., 1996b; Jeffrey et al., 2002a; Malcolm et al., 2003;

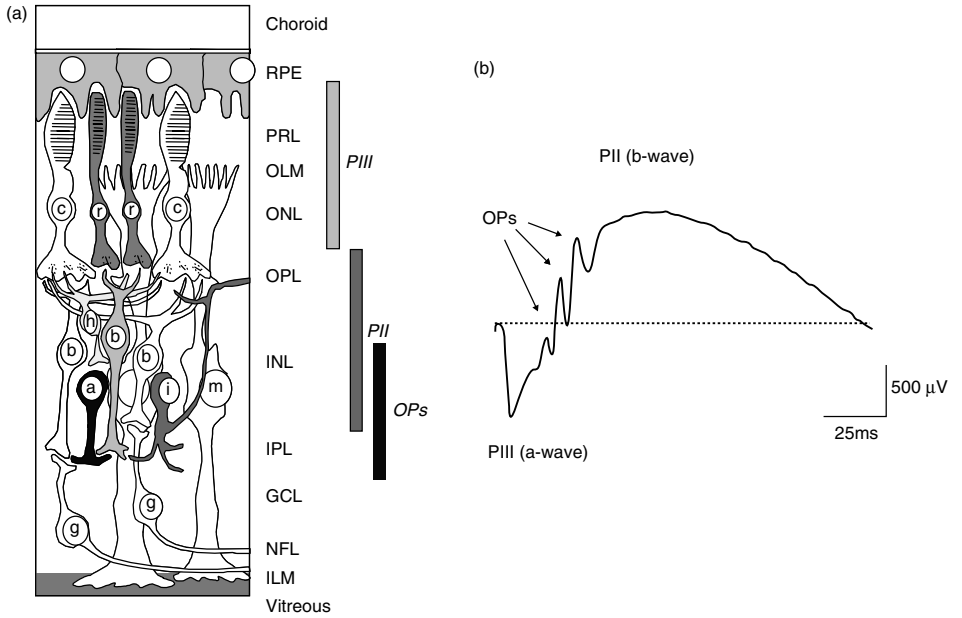

FIGURE 43.10 Neuronal derivations of ERG waveform components. (a) Schematic of retinal structure with the components defined in Figure 43.3. (b) Representative rat dark-adapted ERG waveform collected with a bright flash. Vertical bars identify layers of the retina that are thought to contribute to different waveforms of the ERG. See text for details.

Anderson et al., 2005). It quantifies the electrical activity of retinal neurons by recording changes to ionic gradients within the retina following light activation (Granit, 1933, 1968; Hood and Birch, 1990; Weisinger et al., 1996c). Unlike other objective (e.g., VEP) (Faldella et al., 1996; Birch et al., 1998; Makrides et al., 2000; Jeffrey et al., 2002b; Hoffman et al., 2003; Gillingham et al., 2005) and subjective (e.g., visual acuity) (Neuringer et al., 1984; Uauy et al., 1992; Auestad et al., 1997; Anderson et al., 2005) methods that have been used to assess the visual pathway following omega-3 deprivation, the ERG has the capacity to resolve retinal function independently of higher neural processing. This section details the extent to which component analysis of the ERG waveform affords localization of neuronal function within the retina. As for most studies, this review includes the early components (<500 ms) of the ERG, given that the later components are difficult to measure and reflect glial- or RPE-derived ionic fluxes.

Figure 43.10b shows a representative ERG from a dark-adapted rat. The major components have been labeled according to their order of appearance.

A. The a-Wave

Hyperpolarization of the photoreceptors consequent to the light-induced change in dark current (Figure 43.5) is detected as the corneal-negative a-wave of the ERG (Murakami and Kaneko, 1966; Penn and Hagins, 1969). It has a latency of 3–4 ms and reaches its maximum amplitude at an implicit time of 6–15 ms depending on stimulus intensity. The a-wave is only recordable at relatively bright light intensities when enough photoreceptors have been activated to produce an adequate signal. Due to relative rod-cone cell populations (Szel and Rohlich, 1992) as well as lower phototransduction amplification in cones (Tachibanaki et al., 2001), most of its magnitude is derived from the activity of rod photoreceptors (Fulton et al., 1995; Nixon et al., 2001). The leading edge of the a-wave, called the PIII, was so-named because it is the last (third) potential of the ERG to be suppressed under ether anesthesia (Granit, 1933). Later it became known as the fast PIII to differentiate

it from the slower, negative-going glial response, which is known as the slow PIII. The magnitude and gain of the fast PIII are dependent on stimulus intensity and the efficacy of the phototransduction cascade (Hood and Birch, 1990). This ultimately depends on the closure of cGMP-gated channels in the outer segment following phototransduction (Figure 43.5). The Hill equation describes the relationship between cGMP (cG) concentration and the fraction of open channels (Yau and Baylor, 1989), as shown in Equation 43.1.

$$F(t) = \left[\frac{\mathrm{cG}(t)}{\mathrm{cG}_{\mathrm{dark}}}\right]^{n} \tag{43.1}$$

Thus the circulating current at any time is normalized to the maximal dark current such that $F(t)$ is equivalent to the proportion of open cGMP-gated channels (n, the Hill coefficient, usually = 3). Lamb and Pugh (1992b) showed that this circulating dark current is a linear function of the rate of cGMP hydrolysis, which is the rate-limiting step in the phototransduction cascade. This can be used to specify the rising phase of the a-wave, $R(t)$, as a delayed Gaussian function of time (Equation 43.2).

$$R(t) = 1 - \exp\left[-\frac{1}{2}\Phi \mathrm{A}\left(t - t_{\mathrm{EFF}}\right)^{2}\right] \tag{43.2}$$

This equation models the rising phase of the a-wave as a function of the number of rhodopsin photoisomerizations, Φ, an amplification constant, A, and an effective time delay, t_{EFF} (Section VII C). The sources of amplification and some of the delay arise from the protein–protein interactions (Figure 43.7) during the cascade. The major sources of delay are associated with recording latencies, including the electrical time constant of the photoreceptor, the finite flash duration and electrical delays in the recording equipment (Lamb and Pugh, 1992b; Breton et al., 1994; Cideciyan and Jacobson, 1996).

The equivalent model of Hood and Birch (1990, Equation 43.3) expresses rod PIII amplitude as a function of intensity, i, rather than photoisomerizations, Φ, providing a more user-friendly formulary.

$$\mathrm{PIII}\ (i,t) \approx [1 - \exp\{-i \cdot S \cdot (t - t_{\mathrm{d}})^{2}\}] \cdot R_{\mathrm{m}_{\mathrm{PIII}}} \tag{43.3}$$

The summed rod photocurrent, PIII (μV), at any given time, t (seconds), is expressed as a fraction of the saturated response, $\mathrm{Rm}_{\mathrm{PIII}}$ (μV), stimulus luminous energy, i (log scot cd·s·m^{-2}), and a delay, t_{d} (seconds), scaled by sensitivity, S. Equations 43.2 and 43.3 are equivalent formulations that can be used to describe the rod a-wave.

At rod-saturating stimulus intensities, inaccuracies occur in describing the leading edge of the a-wave (Equation 43.2) due to the photoreceptor's capacitance having a greater influence on the recorded response (Cideciyan and Jacobson, 1996; Smith and Lamb, 1997). However, the application of the capacitive-corrected functions to dietary studies is limited by uncertainties in approximating their time constants across species and experimental manipulations.

Although the saturating exponential (Equation 43.2) has also been shown to describe the single cell recordings of cone photocurrents (Schnapf et al., 1990; Pugh and Lamb, 1993), Hood and Birch (1993) have proposed that cone phototransduction is better modeled by a Michelis–Menten function. They demonstrate that the waveform can be described by a modification of the Michelis–Menten that takes into account the longer capacitive time constant of the cone outer segment membrane (Hood and Birch, 1995) compared with the rod (Penn and Hagins, 1972). This finding is supported by others who have also incorporated terms for cone membrane capacitance in their models (Bush and Sieving, 1994; Cideciyan and Jacobson, 1996), although determining cone capacitance introduces a component of uncertainty, similar to that noted previously for the rod. Moreover, unlike the model

for rod phototransduction (Lamb and Pugh, 1992b), the Michelis-Menten has not been related to the processes of cone phototransduction, rendering its application less compelling for this purpose.

The relationship defined by Equation 43.3 has limited application. Increasing flash intensity increases a-wave amplitude where the maximum rate of rise (dR/dt_{MAX}) is a square-root function of intensity (Φ, e = 2.718, Equation 43.4, Lamb and Pugh, 1992b).

$$\frac{dR}{dt_{MAX}}(\Phi) = \sqrt{\frac{A\Phi}{e}} \tag{43.4}$$

This ceiling in a-wave saturation is caused by decreasing concentrations of cGMP being available for hydrolysis (Lamb and Pugh, 1992b). Decreased amplification might also produce a finite output of the phototransduction cascade at very high intensities. On the other hand, low stimulus intensities promote other processes that force the relation described in Equation 43.3 to deviate from the physiological response (Jamison et al., 2001). This involves intrusion from inner retinal neurons summating with photoreceptoral responses at the leading edge of the a-wave (Frishman and Steinberg, 1989).

It has been reported that postreceptoral intrusion of the photoreceptoral response is eliminated through the use of intensities eliciting a maximal PIII response within an implicit time of 14 ms (Jamison et al., 2001). Intraretinal recordings in the cat retina indicate that for intensities which saturate the amplitude of the a-wave, the implicit time for maximal photoreceptor activity is 8 ms, with partial recovery occurring before any postreceptoral intrusion (Kang Derwent and Linsenmeier, 2001). Consequently, some investigators quantify a-waves at a criterion time to avoid the effects of intrusion by these factors. Here the time is chosen such that it occurs before any postreceptoral intrusion and before the maximal response (~8 ms) is achieved.

B. The b-Wave

This corneal-positive component can be detected in response to low stimulus intensities due to amplification of the photoreceptoral response (see previous section). As its implicit time (60–120 ms) is later than that of the a-wave, it has been called the b-wave (Figure 43.10). Its neural generator is called the PII and reflects bipolar cell depolarization (Popova, 2003; Bramblett et al., 2004; Hanitzsch et al., 2004). Interaction between the fast PIII (a-wave), slow PIII and the PII forms the corneal-positive b-wave of the ERG (Robson and Frishman, 1995; Hood and Birch, 1996).

Traditionally, the b-wave was thought to arise from potassium fluxes across Müller cells (Hanitzsch, 1981; Yanagida, 1982; Dick and Miller, 1985; Frishman et al., 1988; Wen and Oakley, 1990; Katz et al., 1992), however a recent study found elimination of Müller cell potassium channels had no effect on the recorded b-wave (Kofuji et al., 2000) indicating that this signal arose directly from bipolar cells. Müller cells were shown to be involved in generating the slow PIII. Hyperpolarization of photoreceptors leads to a slow reduction of potassium ions in the extracellular space due to the continued activity of the Na^+/K^+-ATPase (Wurziger et al., 2001; Dhingra et al., 2002). This reduction in potassium is known as the "distal decrease" and it creates Müller cell currents that produce a corneal-negative slow PIII of the ERG.

C. Oscillatory Potentials

Under mesopic and photopic conditions, rapid oscillations (Figure 43.10) may be recorded on the ascending limb of the b-wave (Wachtmeister and Dowling, 1978; Dong et al., 2004). It has been proposed that oscillatory potentials (OPs) arise from inhibitory feedback currents generated in the inner retinal layers by amacrine, interplexiform, and ganglion cells (Wachtmeister and Dowling, 1978; Heynen et al., 1985). They have been isolated by band-pass filtering the conditioned waveform, where the a- and b-wave rising slope are removed using direct subtraction (Bui et al., 2002) or windowing in the time domain (Derr et al., 2002).

IX. RETINAL DYSFUNCTION IN OMEGA-3 DEFICIENCY

Defining the nature of retinal dysfunction following omega-3 deficiency is imperative for determining the mechanisms through which these lipids modulate neural function. The following sections outline evidence for omega-3 deficiency leading to functional deficits of specific retinal neurons.

A. Rhodopsin Activation

Studies in isolated membranes provide evidence for rhodopsin activation being dependent on the surrounding membrane composition (Mitchell et al., 1992; Litman and Mitchell, 1996; Niu and Mitchell, 2005). Brown (1994) reported that metarhodopsin II formation was facilitated by smaller phospholipid head groups and bulky membrane acyl chains. More recently, the rate and extent of metarhodopsin II formation has been directly related to membrane DHA content (Litman et al., 2001; Mitchell et al., 2003; Niu et al., 2004).

The earliest subcomponent of an ERG waveform in response to a bright stimulus is the early receptor potential (ERP) (not shown in Figure 43.10b). It was first reported by Brown and Murakami (1964) and requires a bright stimulus of short (<1 ms) duration and high sampling rates for detection (Cone, 1964; Sieving et al., 1978). It has been proposed that, on photon capture, the conformational changes involved in the thermal conversions of lumirhodopsin to metarhodopsin I, and metarhodopsin I to metarhodopsin II (Figure 43.6) result in charge displacement about the photopigment in the photoreceptor outer segment disks that gives rise to the corneal-positive (R_1) and corneal-negative (R_2) waveforms of the ERP (Brindley and Gardner-Medwin, 1966; Wald, 1968; Brown and Coles, 1979).

Although there has been little physiological investigation of the potential effects of omega-3 deficiency on the ERP, it is likely that the conformational change leading to charge displacement will be affected by altered membrane acyl chain packing. Vingrys et al. (2001) have reported a diet effect on the ERP on a limited sample of rats. One of the difficulties with interpreting the findings of the data given by Vingrys et al. (2001) is that they were undersampled and fail to properly define the ERP. This is a challenge for ERP recordings, as is the intrusion of the photovoltaic artefact; nevertheless, this limited dataset suggests that this waveform can be severely affected by omega-3 deficiency.

B. The Phototransduction Cascade

Benolken et al. (1973) were the first to report that omega-3 fatty acids could alter the ERG. Since then, other groups have evaluated the effect with divergent outcomes as to the nature of the functional changes. Although much of this work has involved relatively short term (<1 year), substantial dietary manipulation, it is taken as proof of the importance of omega-3 deficiency in humans. Other mechanisms that may be relevant to the chronic, low level of deprivation typical of human nutrition will be described later.

Evidence that omega-3 deficiency leads to a-wave changes differs across studies and possibly reflects the low experimental power of the small samples used in most of these works, an issue to be detailed later. For example, although a 58% decrement in retinal DHA induced reductions in Rm_{PIII} in guinea pigs (Weisinger et al., 1996a,b, 1999) no changes in Rm_{PIII} have been noted in adult monkeys following either deprivation (–10% red blood cell DHA, Jeffrey et al., 2002a) or supplementation (3 times higher plasma DHA, Jeffrey et al., 2002b) of omega-3 PUFA. Alternatively, this discrepancy might reflect the (adult) age of dietary intervention in these aforementioned studies. Intervention commenced at weaning that induced a 50% reduction in retinal DHA did lead to diminished rod and cone a-wave amplitudes in 3–4 month-old monkeys (Neuringer et al., 1991). Nevertheless, these functional anomalies were noted to resolve by 2 years of age.

The age of initiation of dietary intervention is obviously important in eliciting changes, with the largest and most consistent effects being reported in those studies that commenced dietary modification at weaning or during pregnancy. Weisinger et al. (1999) report a dose–response relationship

between retinal DHA content and PIII sensitivity in 16-week-old guinea pigs when the dietary modification commenced at weaning. In this study, sensitivity increased as a saturating function of retinal DHA. This contrasted with the finding for Rm_{PIII}, where a relative reduction in retinal DHA of –26% elicited maximal Rm_{PIII} reduction (–27%) and further DHA depletion did not cause any additional functional loss. It is also interesting to note that, whereas Rm_{PIII} was reduced at 6 weeks of age, sensitivity was normal at this time. The fact that the pattern and age of the loss due to retinal DHA depletion was different for PIII sensitivity and amplitude implies the presence of more than one mechanism underlying the functional anomalies measured by these two parameters. As detailed earlier, this is not surprising given that the Rm_{PIII} reflects the total dark current circulating about the rod outer segments and it can be affected by anatomical factors as well as the function of ionic pumps, such as the Na^+/K^+-ATPase (Figure 43.5), whereas the sensitivity parameter is independent of these factors and reflects the efficacy of the transduction cascade (Figure 43.7).

Rod sensitivity was reduced in rats that had been deprived of omega-3 over three generations (–55% retinal DHA, Weisinger et al., 2002), although this has not been replicated in monkeys with dietary intervention implemented from birth (–71% plasma DHA, Jeffrey et al., 2002b) or from maternal prefeeding (–97% plasma DHA, Jeffrey et al., 2002a).

There is no *in vivo* evidence for the *in vitro* prediction that omega-3 PUFA deficiency increases a-wave latency. In many cases, previous analyses were not appropriate for detecting such change as the investigators adopted the standard approach of fixing the delay parameter of phototransduction (t_d, Equation 43.3) to normal values (Weisinger et al., 1996a, 1999; Christensen et al., 1998). Nevertheless, studies in monkeys specifically considered the possibility of changes to the delay in omega-3 deficiency, with none being found (Jeffrey et al., 2002a). Instead, the membrane capacitance for rods was found to be decreased in PUFA- (DHA and AA) supplemented monkeys (Jeffrey et al., 2002b). Given that a change in capacitance would affect signal timing, this finding is difficult to interpret in the presence of normal implicit times for the later ERG components. However, a-wave implicit times were delayed in cats (Pawlosky et al., 1997) and monkeys (Jeffrey et al., 2002a) that had been deprived of omega-3 through maternal prefeeding.

Weisinger et al. (1999) report reduced activity within the cone pathway in omega-3 deprived guinea pigs although they did not specifically consider the phototransduction cascade of the cone photoreceptors. Conversely, Jeffrey et al. (2002b) report no effect on cone phototransduction in omega-3 supplemented monkeys. These findings lead to several possible interpretations. Given that the cone a-wave is small, a negative finding might reflect the reduced power of small sample studies, an issue to be developed later. Alternatively, the disparate results between studies might arise from a species-specific effect. A third possibility is that photoreceptor function is indeed normal, and that the effect that Weisinger et al. (1999) observed reflects postreceptoral anomalies.

Many of the discrepancies between the outcomes of studies restricting dietary omega-3 PUFA intake may reflect insufficient experimental power for detecting functional anomalies *in vivo*. Studies cited earlier included up to 10 monkeys, 5 cats, 12 guinea pigs and 6 rats per diet group. Later, it will be shown that these numbers are too small to provide an experimental power that will reliably detect the levels of change predicted from *in vitro* studies.

X. OMEGA-3 DEFICIENCY REDUCES BIPOLAR CELL ACTIVITY

A reduction in PII amplitude has been reported in omega-3 deficient guinea pigs (Weisinger et al., 1999) although diet does not appear to affect b-wave amplitude in monkeys (Jeffrey et al., 2002a,b; Anderson et al., 2005) or rats (Leat et al., 1986; Weisinger et al., 2002). Interestingly, Acar et al. (2002) report that dietary intake of *trans* omega-3 decreases b-wave amplitude in rats. Studies in rhesus monkeys revealed delayed b-wave implicit times in animals fed LNA compared with those on diets supplemented with DHA (Neuringer and Connor, 1986; Neuringer et al., 1991; Jeffrey et al., 2002b). Similar findings have been reported in rats (Weisinger et al., 2002) and humans (Birch et al., 1992; Leaf et al., 1996) but not in guinea pigs (Weisinger et al., 1999). Given the serial nature of the

ERG generators, a loss of a-wave amplitude should produce a reduced b-wave, whereas decreased a-wave sensitivity should result in delayed b-wave timing (Hood and Birch, 1992).

Cone bipolar cell activity has not been thoroughly assessed in omega-3 deficiency. Reduced cone trough-to-peak amplitudes have been reported in guinea pigs (Weisinger et al., 1999). Human infant studies suggest that omega-3 deficiency leads to delays in cone b-wave implicit time (Birch et al., 1992) in the presence of normal amplitudes (Uauy et al., 1990), consistent with effects sequential to a-wave sensitivity losses (Hood and Birch, 1992). Herein lies one of the shortcomings of much of this early work in that many investigators have not considered to what extent postreceptoral changes directly reflect downstream a-wave deficits, given the serial processing of the ERG signal. This is particularly germane for b-wave implicit times as Hood and Birch (1992) have demonstrated that abnormal a-wave sensitivity can delay b-waves. The literature has interpreted b-wave changes following dietary manipulation as either being serial to photoreceptoral losses in humans (Birch et al., 1992) and monkeys (Jeffrey et al., 2002b) or as being additive for the b-wave and OP amplitudes of guinea pigs (Weisinger et al., 1999). Delayed OPs were found in human infants fed a formula of comparatively lower omega-3 content from 10 days of age than in infants fed breast milk (Birch et al., 1992). Smaller OPs were also reported in omega-3 deficient guinea pigs (Weisinger et al., 1999) although a detailed evaluation of the nature of diet-mediated deficits to OPs has never been conducted.

Apart from these limited studies, there has been little other consideration of the effect that omega-3 PUFA has in modulating the activity of inner retinal neurons. This lack of information is rather surprising, as it could be argued that the inner retinal response would more closely mirror that of the cortex or of other neurons, in contrast to the specialized response of the photoreceptor.

XI. ADAPTATION AND SLOWED ROD RECOVERY

Given the role that DHA can have in modulating deactivation of the photoresponse (Section VII E), it is, perhaps, not surprising that Neuringer et al. (1986, 1991) and Jeffrey et al. (2002a) have reported that rod recovery from a saturated flash takes longer in omega-3 deficient monkeys. Monkeys raised on an omega-3 deficient diet reveal delays in both rod recovery (Jeffrey et al., 2002a) and dark adaptation (Neuringer et al., 1986). Analysis of the kinetics of rod recovery ($n = 7$) found abnormal rates of recovery in the presence of normal delays to onset (Jeffrey et al., 2002a). Similar findings have been reported in rats (Weymouth et al., 2005).

The delays in recovery are consistent with the decreased number of RPE phagosomes noted in omega-3 deficient rodents (Watanabe et al., 1987; Bush et al., 1991). Retinoid transport (Chen and Anderson, 1993; Chen et al., 1996) and isomerization (Rando, 1991) are also delayed with reduced DHA concentration. In particular, chromophore isomerization in the RPE is dependent on membrane lipid constituents (Canada et al., 1990). These factors have implications for chromophore recycling and would be expected to delay the dark adaptation of omega-3 deficient animals, a contention supported by the finding of slower regeneration of rhodopsin in DHA deficiency (Bush et al., 1991, 1994).

XII. PROPOSED MECHANISMS UNDERLYING FUNCTIONAL LOSSES

The nature of retinal dysfunction following omega-3 deficiency presented in the previous section reveals discrepancies between and within species, sometimes yielding divergent outcomes from the same laboratory. These *in vivo* findings have hindered the ability to identify potential mechanisms that underlie omega-3-mediated changes in neural physiology. In addition, the variety of outcomes does not concur with the systematic, directed predictions of *in vitro* methods, as detailed elsewhere in this book. The following sections summarize the proposed mechanism/s underlying retinal protein dysfunction determined from *in vitro* studies, and discuss possible reasons why *in vivo* findings do not fully support these predictions.

A. Membrane Biophysical Properties Modulate Retinal Protein Function

Biophysical properties of membranes are modulated by omega-3 content. Membrane lipid constituents are known to affect retinal protein activity (Litman and Mitchell, 1996; Litman et al., 2001; Mitchell et al., 2001; Niu et al., 2001). Studies in isolated membrane preparations propose that the changes to protein function in omega-3 deficiency directly reflect altered membrane biophysical properties (Wiedmann et al., 1988; Brown, 1994; Mitchell et al., 2001; Wu et al., 2001; Turner et al., 2003, 2005b; Niu et al., 2004).

The extent of formation of metarhodopsin II is modulated by the degree of unsaturation of retinal phospholipid (PC) fatty acids such that DHA-rich bilayers support the highest levels of MII formation (Litman and Mitchell, 1996; Litman et al., 2001). Furthermore, DHA-rich membranes reduce the inhibitory effect of cholesterol on rhodopsin activation (Litman and Mitchell, 1996). The degree of PC unsaturation is related in a similar way to the kinetics of formation of the activated rhodopsin–transducin complex (Mitchell et al., 2001; Niu et al., 2001). PDE activity reflects the combined result of both the extent of production of MII and the rate and extent of its subsequent formation of a complex with transducin. PDE activity is greater in DHA-rich bilayers than in more saturated membranes (Litman et al., 2001; Mitchell et al., 2003).

The unique ability of the retinal lipids to form dipolyenes is thought to result in the increased rate of rhodopsin activation (formation of metarhodopsin II) compared with a monoene structure (Mitchell et al., 1992; Brown, 1994; Litman and Mitchell, 1996). This may be a direct consequence of higher membrane concentrations of dipolyenes resulting in more rapid protein diffusion within a more fluid membrane (Mitchell et al., 1992, 2001; Brown, 1994; Litman and Mitchell, 1996; Booth et al., 1997; Litman et al., 2001; Niu et al., 2001). Alternatively, membrane incorporation of dipolyenes may alter the lipid microdomain surrounding rhodopsin, affecting the activity of this protein within its local environment (Albert and Yeagle, 1983; Wiedmann et al., 1988; Polozova and Litman, 2000; Simons and Toomre, 2000). Studies in reconstituted membranes reveal that rhodopsin is surrounded by di22:6-PC whereas the lipid composition surrounding cholesterol is rich in di16:0-PC (Polozova and Litman, 2000). This specificity in local lipid distribution may lead to increased efficacy in protein activation and interaction.

It is possible that DHA affects the protein–lipid interactions associated with receptor-mediated intercellular communication. DHA is highly enriched in aminophospholipids, especially PS, in neuronal membranes (Salem et al., 1980; Stinson et al., 1991a; Farquharson et al., 1995; Suh et al., 1996). PS content may affect cellular function through its influence on the activity of many signaling proteins, including the protein kinases (Mosior and Newton, 1998), modulation of gene transcription proteins and modification of hormone receptor activity within the cell nucleus (Lin et al., 1999; Kim et al., 2000, 2001). Although there is no direct evidence, it may also affect the G-protein cascade of phototransduction. The following section considers the membrane-dependent aspects of DHA modification.

Niu et al. (2001) propose that the lag and decreased amplitude and sensitivity of the leading edge of the a-wave in DHA deficiency is a consequence of the slower kinetics and reduced amplification associated with transducin activation during phototransduction. They also assert that other functional losses related to DHA deficiency may have a common underlying mechanism: decreased efficacy in G-protein signaling. Such a prospect is inconsistent with the observation made by Weisinger et al. (1999) for a different time course in the onset of rod sensitivity and Rm_{PIII} losses, suggesting multiple etiologies.

At a gross, anatomical level, the rate of rod outer segment disk synthesis (Wiegand et al., 1991), the number and morphology of photoreceptors (Benolken et al., 1973; Bush et al., 1991; Wiegand et al., 1991) and the width of the outer nuclear layer (Wiegand et al., 1991) remain unaltered in omega-3 deficient rats. Given these observations, it is unclear why the *in vivo* studies fail to support the findings of isolated membranes. It has been shown that the negative finding of Leat et al. (1986)

arose from the inadequate experimental power of that study (Weisinger et al., 1996a; Sinclair et al., 1997). The following section will consider in detail the importance of experimental power in designing *in vivo* studies.

B. Relating *In vitro* Predictions To *In vivo* Findings: Experimental Power

The advantage of *in vitro* studies compared with equivalent *in vivo* experiments is that noise tends to be lower and easier to control. Whereas *in vivo* studies incorporate variation between animals as well as within animal noise, intersample variation *in vitro* tends to be relatively lower and accounted for more readily. The following discussion defines the expected *effect size* from *in vitro* observations in order to determine appropriate sample sizes given the noise associated with signal acquisition *in vivo*.

The study by Niu et al. (2004) in isolated rod outer segment membranes, proposes that the changes in activation of proteins involved in phototransduction are a direct consequence of membrane biophysical properties being altered by DHA concentrations. In that study, weaning female rats were maintained on omega-3 sufficient or deficient diets then mated at 11 weeks of age. Second generation pups were sacrificed at 3 weeks of age to assess phototransduction protein activity and phospholipid acyl chain content in isolated rod outer segment membranes. There was no effect of diet on the ratio of rhodopsin to membrane phospholipids, and equivalent membrane protein concentration was ensured by removing all transducin and PDE and returning known aliquots of bovine counterparts to the isolated membranes of both diet groups. An average relative reduction of 78% in the retinal phospholipid DHA of omega-3 deprived rats was achieved. Niu et al. (2004) report that this induced a 23% reduction in the concentration of activated transducin relative to the omega-3 sufficient group. They also report timing delays by way of a 38% decrease in the rate of formation of activated transducin, a 16% delay in coupling of activated rhodopsin with transducin, and a 38% increase in the time constant of formation of activated transducin.

The magnitudes of the diet effect reported by Niu et al. (2004) *in vitro* predict a 23% reduction in Rm_{PIII}, a 16%–38% decrease in sensitivity and a 38% delay in t_d due to omega-3 deficiency. Given these expected changes, Table 43.1 lists the sample sizes required for an experimental power of 80% for different levels of experimental noise and separations between group means. The range of coefficients of variation (% variability) shown in Table 43.1 that encompass those typical of ERG recordings are shown in bold typeface.

The variability of ERG parameters is dependent on the test method, the parameter in question and the number of repeated observations. Average (± SEM, $n = 10$) interanimal variability for individual measures of trough-to-peak amplitude is 14% ± 6% and taking 10 signal repeats per animal reduces this coefficient of variation to 4% ± 1%. The smaller magnitudes of the rod a-wave response

TABLE 43.1
Sample Sizes for Two-Tailed *t*-Test with 80% Power

	Difference Between Means (%)				
% Variability	**18**	**23**	28	38	48
15	12	8	6	<5	<5
20	**20**	14	9	6	<5
25	30	**19**	13	8	6
30	45	28	19	11	8
40	>50	50	33	19	12
50	>50	>50	50	28	18

at 6 ms criterion time (A_6) demonstrate 19% ± 6% variability for $n = 10$ and taking 10 repeats per animal reduces this to 5% ± 1%. Table 43.1 shows that a sample size of 20 rats is sufficient to detect either an 18% difference between means given 20% variability in the data, or a 23% change in means (as predicted by Niu et al., 2004) with a more conservative estimate of 25% variability in the data. It is evident that large sample sizes and many signal repeats are both required to reduce variability in order to detect the magnitudes of diet effect predicted by *in vitro* membrane observations; neither of which has been achieved by past *in vivo* studies.

This analysis indicates that previous *in vivo* studies have had insufficient experimental power to expose the functional anomalies predicted from *in vitro* experiments (Table 43.1). Not surprisingly, *in vivo* studies of retinal function in omega-3 deprived animals do not fully concur with the findings of Niu et al. (2004). Whereas Weisinger et al. reported reductions in phototransduction amplitude in guinea pigs ($n = 12$ per diet, 1996a,b) and sensitivity in rats ($n = 6$ per diet, 2002), Jeffrey et al. (2002b) found a decrease in the membrane capacitance time constant for phototransduction in rods but no change in rod amplitude, sensitivity or cone phototransduction in long-chain PUFA-(DHA and AA) supplemented monkeys ($n = 10$ per diet, Jeffrey et al., 2002b). Elsewhere, these authors report no difference in any rod phototransduction parameters between omega-3 sufficient and deficient monkeys ($n = 7$ per diet, Jeffrey et al., 2002a).

Some discrepancies between *in vivo* and *in vitro* studies of omega-3 deficiency may reflect factors other than insufficient experimental power, especially considering the chronic nature of dietary insufficiency in humans. As discussed in the following sections, these possibilities might also explain why some species or ages are more susceptible to deprivation compared with others. In combination with altered membrane biophysical properties, they may prove sufficient to account for the age-related (Weisinger et al., 1999) and development-dependent (Armitage et al., 1999, 2005) anomalies in retinal function observed *in vivo*.

C. Does Omega-3 Modulate Retinal Protein Content?

Studies that have considered the relationship between total retinal rhodopsin and DHA content are inconclusive. When compared with rats fed LNA as the sole omega-3 fatty acid, rats fed omega-3 deficient diets were found to have higher levels of rhodopsin (Bush et al., 1991, 1994). However, the more recent work of Niu et al. (2004) failed to detect any diet-mediated difference in rhodopsin content in the presence of a 78% reduction in DHA.

Niu and Mitchell (2005) report that rhodopsin is most active in membranes with lower concentrations of rhodopsin, reinforcing the importance of protein motility within the membrane. Reduced local membrane DHA content has also been associated with decreased sensitivity for rhodopsin for light capture (Wiedmann et al., 1988; Brown, 1994; Litman and Mitchell, 1996).

The effect that omega-3 PUFA have on the concentration of retinal proteins requires further investigation and should provide insight into understanding the etiology of functional anomalies in omega-3 deficiency.

D. Does Omega-3 Modulate Protein Expression?

The variable nature of retinal dysfunction reported in *in vivo* studies may reflect multiple lesions underlying the attenuation of retinal protein function following omega-3 deficiency. The complex etiology of functional losses following omega-3 deprivation is also demonstrated in repletion studies where dysfunction is sustained despite normalization of retinal DHA profiles (Armitage et al., 1999; Anderson et al., 2005). It is possible that the increased rhodopsin concentration reported in omega-3 deficient rats (Bush et al., 1991, 1994) may reflect upregulation of protein expression. DHA has been implicated in modulating the extent of expression of genes regulating hepatic (Clarke and Jump, 1994; Price et al., 2000; Arachchige et al., 2006) and retinal fatty acid metabolism (Puskas et al., 2004). Rojas et al. (2003) reported a tendency for general retinal gene expression to be upregulated by omega-3 polyunsaturates and downregulated by omega-6 PUFA. The prospect that DHA

modulates the extent or nature of subunit expression of phototransduction proteins requires evaluation in order to define the nature of the deficit.

E. Does Omega-3 Modulate Ion Channel Proteins?

In response to a stimulus, membrane ion channels undergo conformational modifications within the membrane bilayer in order to increase or decrease their affinity for their substrate ion, hereby transporting the charged molecule across the hydrophobic barrier. This conformational change may be susceptible to the nature of the lipid species within the membrane bilayer. Alternatively, the membrane lipid constituents may alter the affinity of the ion pore for its substrate ion.

DHA has been shown to affect the potassium (Poling et al., 1995, 1996), sodium (Xiao et al., 1995; Kang and Leaf, 1996; Vreugdenhil et al., 1996; Young et al., 2000) and calcium (Kang and Leaf, 1996; Vreugdenhil et al., 1996) ion channels in neural membranes. Ehringer et al. (1990) demonstrated that DHA is more effective than LNA in enhancing membrane permeability. DHA and EPA reduce electrical excitability in single cell recordings of hippocampal neurons (Xiao and Li, 1999).

Ionic gradients across the rod outer segment membrane are mediated by the states of voltage- and cGMP-gated ion channels (Figure 43.5). Any change in structure or activity of these channels alters the dark current. The subsequent effects on phototransduction would manifest as a change in outer segment ion gradients as measured using electroretinography.

It has been well-documented that the activity of the Na^+/K^+-ATPase pump is dependent on the composition and biophysical properties of its surrounding membrane (Else et al., 1996, 2003; Else and Wu, 1999; Wu et al., 2001; Turner et al., 2003, 2005a–c). Given the ubiquity of these transporters throughout the body, this discussion has widespread implications. Dietary deficiency of long-chain omega-3 PUFA leads to decreased Na^+/K^+-ATPase activity in hepatic (Sennoune et al., 1999) and neural membranes (Bourre et al., 1989; Gerbi et al., 1993, 1994, 1997, 1998, 1999; Bowen and Clandinin, 2002). Gerbi et al. (1997, 1998, 1999) assert that the extent of Na^+/K^+-ATPase activity may reflect omega-3-mediated changes subsequent to preferential expression of the alpha subunits. These findings have implications for the photoreceptoral Na^+/K^+-ATPase in terms of its capacity to maintain the dark current. Despite the multiplicity of studies in other tissues, it is unknown whether or not retinal Na^+/K^+-ATPase activity is modulated by dietary omega-3 intake.

A role for the interaction of native DHA not associated with the membrane has also been reported. The activity of voltage-gated sodium and calcium ion channels in rat cardiomyocytes and hippocampal neurons is suppressed by DHA in its free fatty acid form (Leaf, 1995; Vreugdenhil et al., 1996). If this were to extend to the retina, it would suggest the potential for a complex functional outcome in terms of ERG waveforms.

XIII. SUMMARY

A balance of dietary intake of essential fatty acids is vital in maintaining healthy neural function. Omega-3 PUFA have been linked with many ocular disorders including dry eye, age-related macular degeneration, glaucoma and diabetic retinopathy. In many of these cases, it is possible that the dysfunction reflects complex changes in eicosanoid metabolism. However, omega-3 PUFA can also modulate the biophysical properties of membranes and are particularly concentrated in and retained by retinal membranes. Past work has identified anomalies within the phototransduction cascade and visual pigment processing as a consequence of dietary deprivation of omega-3 fatty acids. Studies assessing protein activity in isolated membranes have led to the assertion that lipid-mediated changes in the biophysical properties of the membrane give rise to the attenuation of protein function. It has been proposed that insufficient levels of omega-3 PUFA lead to greater membrane rigidity, hindering the function of membrane-bound proteins. If changes to membrane acyl chain packing were the sole reason for the protein dysfunction, a generalized susceptibility of all membrane-bound proteins to their lipid environment should ensue. This predicted effect is not consistent with the variety of aspects

of aberrant phototransduction that has been reported *in vivo* in humans and animals. This might reflect insufficient experimental power, or factors other than changes to membrane biophysical properties, that are responsible for the functional deficits. Future studies that address these possibilities will further our understanding of the multifaceted modulation of retinal function by omega-3 PUFA.

44 Fatty Acids and Cardiovascular Disease

Geza Bruckner

CONTENTS

I. INTRODUCTION

Cardiovascular disease (CVD) remains one of the most significant diet-related health problems in the United States and is also the leading cause of death in the United States. Heart disease and stroke, the principal components of CVD, are the first and third leading causes of death in the United States, accounting for nearly 40% of all deaths. Nearly 930,000 Americans die of CVDs each year, which amounts to one death every 33 s. About 70 million Americans (almost one-fourth of the population) have some form of CVD, which is responsible for more than 6 million hospitalizations each year (American Heart Association, 2005). Much of the burden of heart disease and stroke could be eliminated by reducing major risk factors associated with the disease: high blood pressure, high blood cholesterol, tobacco use, diabetes, physical inactivity, and poor nutrition. About 90% of middle-aged Americans will develop high blood pressure in their lifetime, and nearly 70% of those who have it now do not have it under control (American Heart Association, 2003). In 2002, more than 106 million people were told that they had total blood cholesterol levels that were above normal or high (≥200 mg/dL or higher) (American Heart Association, 2005).

Estimated cost for health care related to CVD increased from $128 billion in 1994 to $151 billion in 1996 (Stone, 1996). However, the cost has increased exponentially and in 2006 is estimated to be $403 billion, according to the American Heart Association and the National Heart, Lung, and

Blood Institute (NHLBI). This amount includes both direct and indirect costs. Direct costs include the cost of physicians and other professionals, hospital and nursing home services, the cost of medications, home health care, and other medical durables. Indirect costs include lost productivity that results from illness and death. During the past decade a great deal of progress has been made toward defining the role of dietary fats and hypercholesterolemia in the pathogenesis of atherosclerosis and other vascular disease. Our enhanced knowledge along with more public nutrition education may be related to the observed steady decline in morbidity and mortality from CVD during recent decades (Steyn et al., 1997) (see Figures 44.1 and 44.2). Since 1964, coronary heart disease mortality has declined steadily, by more than 32% overall (Higgins and Lefant, 1989; Ginter, 1997). However, not all populations have experienced declines, for example, there has been a significant increase in CVD in American Indians (Ellis and Campos-Outcalt, 1994).

CVD is multifaceted, and the course of its pathology is influenced by physiology, genetics, environment, and psychosocial stresses. However, the multifaceted nature of CVD has recently been questioned and it has been suggested that the true cause may be solely due to various lipid peroxidation reactions (Spiteller, 2005).

Major identified risk factors for CVD include cigarette smoking, elevated blood pressure, elevated plasma cholesterol, obesity, diabetes, and elevated plasma triglycerides. The single risk factor that has received the most attention is cholesterol; however, the mechanisms involved and the interactions between serum cholesterol and other factors such as sources of dietary protein, amounts and types of dietary fatty acids, and antioxidants are not clearly understood (Gaziano and Manson, 1996). During recent years, we have made great progress toward understanding the interrelationship between these variables; however, to define the exact mechanisms will require further investigative efforts. For example, it is known that different fatty acid isomers, n6 vs. n3, 20-carbon fatty acids, can elicit completely different vascular responses as evidenced by the Greenland Eskimo studies and subsequent reports by Bang and Dyerberg and others (Dyerberg and Bang, 1978; Bang and Dyerberg, 1981; Hornstra, 1989a).

Work by Grundy (1986), Daumerie (1992), and Woollet (1994) and epidemiological studies (Aravanis and Ionnidis, 1984; Caggiula and Mustad, 1997) also suggest that specific saturated and monounsaturated fatty acids (MUFAs), which contain *cis* or *trans* isomers (Aro, 1997), can have different serum cholesterol-lowering effects. Although it is well documented that serum cholesterol levels in a given population are closely correlated with increased risk for atherogenesis, there still remains skepticism regarding the relationship between dietary cholesterol intake and serum cholesterol concentrations (James et al., 1989; Hayes, 1995; McNamara, 1995). Analysis of the results of 30 years of studies related to cholesterol feeding indicate that for the majority of individuals modest changes in dietary cholesterol have little if any effect on plasma cholesterol levels (McNamara, 1995). Other factors such as the type and amount of fat consumed play a more regulatory role in influencing serum cholesterol (McNamara, 1987; Kris-Etherton and Yu, 1997; Mozaffarian et al., 2006).

Although there is general agreement that reducing the intake of cholesterol, saturated fat, and *trans* fatty acids would be beneficial, there still remains controversy as to what constitutes more beneficial dietary fats. For example, it has been demonstrated in both epidemiological and controlled studies that the incidence of CVD can be quite varied given the same serum cholesterol concentrations (Keys et al., 1980). Furthermore, a study by Wenxun et al. (1990) indicates that geographical differences in CVD mortality within China are caused by factors other than dietary or plasma cholesterol. A number of studies have shown that n3 fatty acids when consumed with equal, or even greater, amounts of dietary cholesterol, compared to an n6 diet, resulted in decreased platelet aggregability and a lower incidence of atherogenesis (Hornstra, 1989a). Other findings have generated even greater controversy because of clear contradictions to long-standing American Heart Association dietary recommendations. Notably the indication that lipid oxidation products may play an important role in the pathogenesis of CVD has raised many questions regarding the exact role of dietary lipids in the disease process (Spiteller, 2005). Animal, human, and epidemiological studies make it clear that the linkage between diet and serum cholesterol is still poorly understood. Questions still remain on issues such as (1) why is there a greater risk for CVD among men than among women?; (2) why is there an enhanced CVD risk in women after menopause?; (3) why is there lower CVD mortality in some countries, for example, France, Greenland, Greece, compared to the United States despite substantial cholesterol and fat intakes?; and (4) why do male U.S. railroad workers compared to a Mediterranean male population have twice the number of deaths given the same serum cholesterol levels? (Keys et al., 1980). What are the underlying causes that result in these intriguing exceptions to the long-held dogma that elevated serum lipids is the most significant statistically associated risk factor for CVD? Could lipid peroxidation and oxidative stress be the common link? The majority of CVD deaths in the total population occur in people with low serum lipids, and not all individuals with high serum lipids develop CVD. Although knowing the relationship between low-density lipoprotein (LDL) and high-density lipoprotein (HDL) ratios has

increased our understanding of risk factors, it is clear that these lipoproteins do not fully explain how atherogenesis truly develops. Could lipid peroxidation and oxidative stress be the common link?

The purpose of this chapter is to give an overview of how dietary fatty acids may influence the development of CVD through multifaceted and "lipid peroxidation" mechanisms.

II. DIET-RELATED CVD RISK FACTORS

Risk is a continuous gradient that is used in epidemiology to identify high-risk populations. Although epidemiological studies cannot demonstrate cause-and-effect relationships, they provide targeted research areas for investigators to better understand possible pathogenic mechanisms associated with a disease process (Caggiula and Mustad, 1997; Khor, 2004).

Hyperlipidemia has been identified as a major risk factor for atherosclerosis and is associated with elevated plasma levels of cholesterol, cholesteryl esters, and triglycerides. These lipid components are transported into the circulatory system in association with proteins, phospholipids, and carbohydrates in various micelle forms-chylomicrons (CM), very low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), LDL, HDL, lipoprotein (a), and various micelle remnants. Although the mechanisms are not completely understood, individuals with premature CVD generally exhibit some of the following: (1) increased LDL levels; (2) increased cholesterol and triglycerides, primarily in VLDL; and (3) increased triglycerides with normal cholesterol primarily as VLDL. A positive correlation with serum LDL and atherosclerotic events has been found, and this appears to be inversely related to serum HDL levels (Kris-Etherton et al., 1988; Kris-Etherton and Yu, 1997).

Other diet-related factors that may increase CVD risk are (1) total calories consumed; (2) amount of carbohydrate consumed (low-carb vs. High-carb diets); (3) amount of alcohol imbibed; (4) type of fat in the diet; (5) oxidative status of the diet and the individual; (6) levels of dietary trace minerals and vitamins, phytochemicals, type and the amount of these in the diet; and (7) type of dietary protein consumed. Diets high in simple carbohydrates are generally hypertriglyceridemic in humans and hypertriglyceridemia is considered to be an independent risk factor for CVD (Albrink et al., 1961; Austin, 2000). However, it is primarily in middle-aged women that elevated plasma triglycerides have been shown to be an important risk factor (Castelli, 1986). Therefore, it is questionable what role, if any, high-dietary carbohydrates play with respect to lipid metabolism in the overall onset of CVD. Interpopulation studies, in fact, indicate that diets high in complex CHOs are associated with a lower risk for CVD (Kagan et al., 1974; Connor et al., 1978; Shintani and Hughes, 1994; Seal, 2006). It is possible that some forms of hyperlipidemia, per se, are not detrimental when the amount of antioxidant components in the diet are high; the studies reported by Kushi et al. (1985), Aravanis and Ioannidis (1984), and Formica and Regelson (1995) suggest that fruit, vegetables, and grains might be protective; these foods contain ascorbic acid, β-carotene, isoflavones, bioflavonoids, and vitamin E, which might decrease lipid oxidation products and thereby reduce CVD risk.

Excessive calories, whether from carbohydrates, fats, or proteins, will result in obesity. Data from the Framingham Heart Study showed that increased relative body weight is an independent risk factor for CVD in addition to its association with low concentrations of HDL, decreased glucose tolerance, elevated plasma triglycerides and cholesterol, and hypertension (Hubert et al., 1983). The body type of the obese has also been associated with CVD risk; increased waist-to-hip circumference ratios, androgenic obesity, represent greater risk than lower body obesity (Bjontorp, 1988). The abdominal pattern of adiposity, and specifically visceral adiposity, appears to carry the highest risk. Abdominal adiposity has been identified as promoting insulin resistance, hypertension, and dyslipidemia (Garrison et al., 1996). Many studies have re-emphasized the notion put forward by Vague (1947) that obesity "android or male-type obesity" is not a homogeneous condition and that the regional distribution of adipose tissue is closely correlated to disturbances in glucose and lipid metabolism (Ohlson et al., 1985; Donahue, 1987; Bouchard et al., 1993). Some early studies used skinfold and waist-to-hip ratios to define visceral adiposity and therefore did not truly distinguish

between subcutaneous vs. visceral intra abdominal fat. Computed tomography (CT) clearly distinguishes fat from other tissues and allows the measurement of visceral and subcutaneous abdominal fat. Visceral fat area has been shown to closely correlate with glucose intolerance in the presence of hyperinsulinemia (Despres et al., 1989; Park et al., 1991; Pouliot et al., 1992) and other metabolic syndrome risk factors, for example, hypertriglyceridemia (Despres, 1991; Bjorntorp, 1997) and hypertension (Blair et al., 1984). Genetic susceptibility may modulate the risk associated with a given excess of visceral adipose tissue (Vague, 1947). There is general agreement that visceral fat is closely correlated with dyslipidemia and hyperinsulinemia, but controversy exists regarding the importance of subcutaneaous vs. visceral adipose stores on insulin sensitivity (Abate et al., 1995; Goodpaster et al., 1997). It was suggested that individuals with greater visceral fat mass, lose more visceral fat regardless of the intervention applied (Smith and Zachwieja, 1999). An increased amount of deep abdominal visceral fat has also been generally accepted as an important cardiovascular risk factor, and disturbances in hemostasis and fibrinolysis have been suggested to play a role (Mertens and Van Gaal, 2005). The mechanism(s) suggested for increased visceral fat loss appear to be related to a higher lipolytic rate for visceral fat in the steady state and this greater turnover and delivery to the liver have been implicated in various pathways to disease.

Endogenous cholesterol synthesis is apparently increased by 20 mg/day for every excess kilogram of body weight (McNamara, 1987). It is estimated that one-third of the population is sensitive to dietary cholesterol whereas two-thirds are resistant to plasma cholesterol changes. An average change in cholesterol intake of 100 mg/dL will potentially bring about a 2.5 mg/dL change in plasma cholesterol. However, a 1% decrease in energy intake from SFAs decreases plasma cholesterol by 3 mg/dL (McNamara, 1995).

Dietary fatty acids, as mentioned previously, have disparate results with respect to the risk for CVD. It is generally agreed that high-fat intakes (excess calories) are associated with increased risk, but it is not clear whether the risk is associated directly with the amount of fat consumed or with the resultant adiposity of the individual or the location of the adiposity, visceral vs. subcutaneous. Most studies indicate that increasing the ratio of polyunsaturated fatty acids to saturated fat (PUFA/SFA or P/S) decreases plasma cholesterol and in some studies plasma triglycerides (McNamara, 1987; Kris-Etherton and Yu, 1997). However, it is very evident that not all PUFAs and SFAs elicit the same cholesterolemic and/or triglyceridemic response.

Most unsaturated fatty acids in nature are found in the *cis* double bond configuration, but during hydrogenation of vegetable oils, inversions of the double bonds result in *trans* fatty acid isomers. These *trans* fatty acids also have double bonds in other than the normal n6, n7, n9, or n3 position from the methyl end of the fatty acid molecule. Many of the *trans* fatty acid isomers behave as saturated fats in most metabolic processes and therefore cannot be used in calculating P/S ratios based simply on the number of unsaturated double bonds. As mentioned, *trans* fatty acids appear to be as, or more, hypercholesterolemic than palmitic or myristic fatty acids and Mazaffarin et al. have recently covered this topic in an excellent review (Kris-Etherton and Yu, 1997; Mozaffarian et al., 2006).

Total dietary protein is considered to be of minor importance in the etiology of CVD, although epidemiological studies have shown that consumption of animal protein is positively correlated and vegetable protein negatively correlated with CVD mortality rates (Connor et al., 1978). Although a number of animal studies have shown that animal-derived protein is more atherogenic than vegetable protein, it is difficult to factor out these effects in human studies. It is also important to remember that animal protein and fat (particularly saturated fat) increases concomitantly in the diet (Kris-Etherton et al., 1988). Although soy protein has been found to have a modest hypocholesterolemic effect, the mechanisms by which it elicits these effects are unclear (Potter, 1995; Hecker, 2001).

In a number of epidemiological studies, moderate alcohol consumption has been associated with a reduced incidence of CVD (Yano et al., 1972; Klatsky et al., 1974; Garziano and Manson, 1996; Kannel and Ellison, 1996; Goldfinger, 2003). It appears that moderate alcohol consumption (7–14 oz weeks) increases the HDL cholesterol concentration and decreases LDL oxidation and

thus may offer protection against CVD. Most wines (red wines in particular) contain reserveratrol and piceid that function as antioxidants; these compounds functioning as antioxidants may protect against membrane damage by preventing lipid and lipoprotein oxidation (Kannel and Ellison, 1996; Sato et al., 1997; Singh, 2006). It is evident that the development of atherosclerosis and the dietary factors that constitute increased risk are far more complex than previously assumed.

III. ESSENTIAL AND NONESSENTIAL FATTY ACID METABOLISM

The requirements for essential fatty acids were first described by Burr and Burr (1930); however, almost 40 years elapsed before the connection between essential fatty acids and physiologically bioactive lipids (prostanoids and eicosanoids) was recognized (Bergstrom et al., 1964).

Polyunsaturated fatty acids are defined as fatty acids containing two or more unsaturated double bonds. Two broad categories of PUFAs exist that are of concern with respect to cardiovascular homeostasis, "essential" and "nonessential" fatty acids. Essential PUFAs (E-PUFAs) are considered to include linoleic and α-linolenic acids (all-*cis*-18:2n6 and 18:3n3, respectively). These essential fatty acids must be provided in the diet because they cannot be synthesized from simple carbon precursors in mammalian organisms. However, nonessential PUFAs (NE-PUFAs) can be synthesized from simple acetate units. If E-PUFAs are provided in the diet, the synthesis of nonessential highly unsaturated fatty acids, that is, 20:3n9 and 20:4n7 is minimal and only trace amounts can be detected in cellular storage lipids and membrane phospholipids. The n9 and n7 fatty acids cannot substitute for the membrane or biochemical functions that are associated with the n3 and n6 fatty acids (Vergroesen, 1988). The composition of PUFAs in membranes can be modified by diet and by alteration of cellular desaturation and acylation reactions (see Figure 44.3). Most cellular membranes appear to reflect the dietary fatty acid constituents, and as PUFAs are increased in the membrane there is an increase in membrane fluidity and membrane associated functions can be altered. As reported by Lands et al. (1990), there exists a quantitative relationship among PUFAs for specific esterification sites, primarily the *sn*-2 position of phospholipids. Although dietary fat can influence

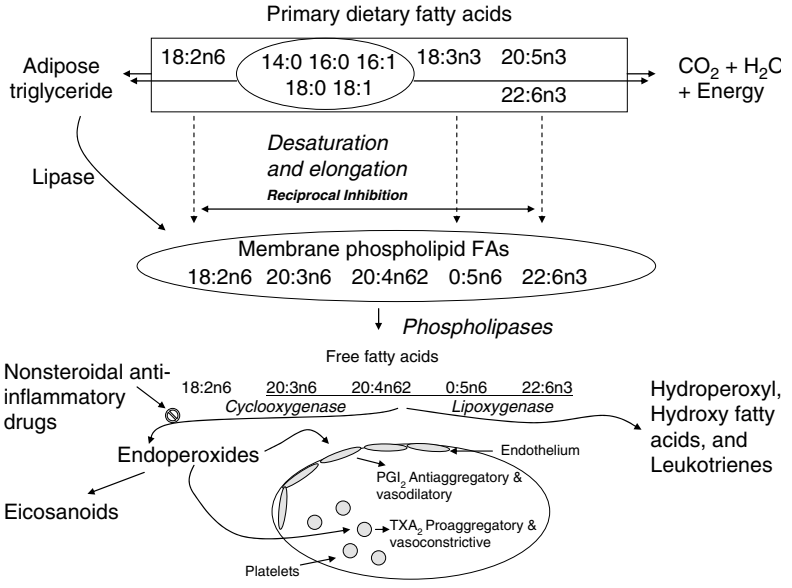

FIGURE 44.3 Effect of various dietary fatty acids on membrane fatty acid composition and eicosanoid production.

the levels of membrane fatty acids, there is an overall similarity in organ fatty acid composition between animal species. As the regulation of these membrane lipids appears to be tightly controlled, cellular function is closely associated with membrane composition.

Both the dietary essential and nonessential fatty acids can be desaturated and elongated to yield more unsaturated, longer chain fatty acid derivatives. For the nonessential saturated fatty acids (16:0 and 18:0), the first double bond that is introduced by Δ9 desaturase establishes the n7 and n9 fatty acid families (16:ln7 and 18:ln9, respectively). The next desaturation step (Δ6 desaturase) can apparently introduce a double bond in n7, n9, n6, or n3 fatty acids; Δ6 desaturase is the rate limiting enzyme and is regulated by feedback inhibitors (Brenner, 1981). In this key regulatory role, Δ6 desaturase can influence the PUFA composition of the membrane and the subsequent bioactive lipid end products formed (see Figure 44.2). By feeding long-chain PUFAs, that is, 20:4n6, 20:5n3, 22:6n3, the conversion of 18:2n6, 18:3n3, 18:ln9, and 16:ln7 to more unsaturated fatty acids can be inhibited. It has repeatedly been demonstrated that high-dietary levels of 20:5n3 and/or 22:6n3 will decrease the phospholipid and neutral lipid arachidonic acid (AA) concentrations; this occurs through inhibition of the Δ6 desaturase as well as competition for the phospholipid acylation sites. However, it is not the ratio of 18 carbon n3 to n6 fatty acids but rather the amount of each that appears to alter the end products produced (Goyens et al., 2006), suggesting that these fatty acids may be associated with specific Δ6 desaturase enzymes.

When animals are fed fat-free or completely saturated fat diets, their tissue lipids have decreased amounts of n3 and n6 PUFAs, and they accumulate the elongated, desaturated products of the n7 and n9 series, 20:3n9 and 20:4n7. As one includes n3 and n6 fatty acids in the diets of these essential fatty acid-deficient animals, the endogenous NE-PUFAs, are rapidly replaced by E-PUFAs at the *sn*-2 position of phospholipids and in storage lipids. The E-PUFAs, once released from the membrane, can serve as substrates for subsequent eicosanoid formation; eicosanoids are a group of compounds derived from PUFAs by the initial action of cyclooxygenase, p450, and/or lipoxygenase enzymes. With the discovery that AA could be converted by cyclooxygenase, p450, and/or lipoxygenase to bioactive lipid end products, many of the unexplained phenomena regarding the physiological effects of E-PUFAs became better understood.

Many of the eicosanoids produced via cyclooxygenase act in a "yin-yang" relationship and thereby modulate short-term localized responses to help maintain cardiovascular homeostasis. The pathways involved are detailed in the chapter by Dr. Hwang in this volume. As with the Δ6 desaturase, there is competition between the fatty acids for acylation into the membrane phospholipids as well as for the cyclooxygenase and lipoxygenase enzymes.

The fatty acids derived from marine animal fats differ from most oils and fats of terrestrial origin in that the marine oils generally contain longer carbon chains and higher degrees of unsaturation; the cold water marine oils are particularly rich in n3 fatty acids. Because the long-chain n3 fatty acids effectively compete for the desaturation and acylation enzyme sites with other fatty acid families, the changes in tissue fatty acid composition are greater than what the actual percent of the diet might predict. Moderate intakes of long-chain n3 fatty acids can markedly increase the concentration of these fatty acids in plasma, platelets, red blood cells, lung, kidney, liver, heart, adipose tissue, brain, macrophages, retina, nerve, and blood vessels; for a detailed review, see Herold and Kinsella (1986), Hornstra (1989a,b), and Vanden Heuvel (2004).

Since the n3 fatty acids replace primarily the n6 fatty acids from membrane lipids, the membrane content of AA is decreased (Hwang and Carroll, 1980; Bruckner et al., 1984; Harris, 1997a,b; Harris et al., 2003). The decreased availability of AA for eicosanoid formation and competition with the n3 fatty acid for the cyclooxygenase and lipoxygenase enzyme sites generally results in a decrease in the production of 2-series prostanoids, for example, thromboxane A_2 (TXA_2), PGE_2. TXA_2 is a potent stimulus for platelet aggregation and arteriole vasoconstriction. The release of this eicosanoid from the platelet membrane is primarily stimulated by thrombin, epinephrine, AA, and collagen. The vascular endothelium, via cyclooxygenase, produces prostacyclin (PGI_2) from AA, which is a potent antiaggregatory agent and vasodilator of blood vessels. Therefore, the "yin-yang"

relationship of these two eicosanoids appears to play a major role in normal vascular homeostasis as well as in vascular pathologies.

IV. EFFECTS OF SFAs, MUFAs, AND PUFAs ON THROMBOSIS–PLATELET–ENDOTHELIUM INTERACTIONS

Many of the experimentally induced forms of atherosclerosis are dependent on endothelial injury and subsequent platelet–macrophage–endothelium interactions. Ross (1985) proposed the "response to injury hypothesis" as the primary cause for the development of atherosclerosis. The endothelial injury may be subtle or intermediate or ultimately result in cell death. It has been demonstrated that platelet and macrophage interactions with the endothelium are required for lesion formation. These lesions may manifest themselves as endothelial cell separation from connective tissue, endothelial cell death, and/or increased endothelial cell permeability; any of these may result in endothelial retraction and endothelial cell desquamation. Many of these damaging events involve ROS. The exposure of the sub-endothelial connective tissue will propagate further platelet adherence and aggregation and possibly mural thrombus formation. Injury to the endothelial cells can result from exposure to endotoxins, vasoactive amines, viral infection, lipid peroxides, hypercholesterolemia, mechanical injury (hypertension), carbon monoxide, and/or hyperlipidemia. Once the endothelium or platelets are modified and platelet–endothelium interactions are initiated, a potentially pathogenic cascade may be triggered.

Platelets contain vasoactive amines, ADP, platelet-derived growth factor (PDGF), diacylglycerol (DAG), and platelet-activating factor (PAF) and are capable of synthesizing TXA_2, which is a proaggregatory and vasoconstrictive eicosanoid. Once the platelet is stimulated by an agonist, for example, collagen, the release of these bioactive substances can be triggered. PDGF is a principal mitogen responsible for the proliferation of smooth muscle cells, and it has been demonstrated that increased growth of intimal smooth muscle cells is a key factor in atherogenesis. In addition, the release of AA from the platelet membrane yields TXA_2, which potentiates the aggregatory response. During injury, such as disruption of the vessel wall, these positive feedback stimulatory responses lead to thrombus formation, vasoconstricition, and clot formation and thus prevent loss of vascular fluids. However, if these pathways are repeatedly stimulated, with migration of monocytes and macrophages to the site of injury, lipid accumulation and smooth muscle cell proliferation will lead to the formation of vascular plaque (see Figure 44.5). Under ideal conditions the "yin-yang" relationship between platelets and endothelial cells is maintained via production by the platelets of TXA_2 and PDGF and endothelial cell synthesis of PGI_2 and endothelium-derived relaxing factor (EDRF); EDRF has been identified as nitric oxide (NO), one of the most potent vasodilating substances known. Physiological regulation of platelet adhesion is mediated by both NO and superoxide, with the former inhibiting and the latter promoting platelet adhesion. The interactions between platelets and the vascular endothelium appear to have important implications in the initiation and/or progression of tissue injury associated with different experimental models of human disease (Tailor et al., 2005). Both PGI_2 and NO inhibit platelet aggregation and arteriole vasoconstriction. In addition, PGI_2 may stimulate the enzymes that metabolize cholesteryl esters that are known to accumulate in atherosclerotic plaque (Moncada, 1987). It appears that dietary lipids can modify the platelet–endothelial interactions via their cholesterol content (mostly oxidized cholesterol) and/or the type and amount of fatty acids consumed.

A. SFA/*Trans* Fatty Acid Effects

The Seven Countries Study (Keys et al., 1980) gave rise to the idea that dietary saturated fats contribute to high plasma cholesterol concentrations and atherogenesis, but skepticism remains about the degree of such an effect (Mann, 1977; Gurr, 1992). Renaud et al. (1981, 1986) and others (Mustard and

Murphy, 1962) have studied in a variety of ways the effects of diets high in saturated fats on both coagulation and platelet function. Merskey and Marcus (1963), in their comprehensive review, concluded that there was no evidence that the type of saturated dietary fat had any influence on coagulation and this opinion has been echoed regularly since then (Hoak, 1997). Factor VII activation by saturated fatty acids was reported and it was suggested that stearic acid may be responsible for this activation. However, the concentration used *in vitro* is not likely to be attained *in vivo*. As stated in the excellent recent review by Knapp (1997), others have reported that stearic acid interacted more favorably with the coagulation system (factor VII activity) than did palmitic, myristic, or lauric acids, whereas others found no effect of dietary saturated fat on platelet function or thromboxane generation or on the excretion of thromboxane and 6-keto-prostaglandin $F_{1\alpha}$. Although there is still ongoing debate, it appears that similar prothrombotic changes in platelet function and homeostatic variables are elicited by postprandial test meals of saturated or n6 unsaturated fatty acids or of the latter and saturated medium-chain triacylglycerols (Knapp, 1997). Also it has been noted, that stearic and *trans*-FA diets had similar effects on platelet activation and endothelial PGI_2 production (Turpeinen et al., 1998) and that stearic acid is not more thrombogenic than oleic or linoleic fatty acids (Thijssen et al., 2005). Furthermore, Sanders et al. (2003) demonstrated that *trans* fatty acids (*t*18:1) do not have any specific effects on known haemostatic risk markers for CVD in healthy young men in the short-term. *Trans* fatty acids may influence other risk factors for CVD. Consumption of *trans* fat reduced the activity of serum paraoxonase (de Roos et al., 2002) and impaired the postprandial activity of tissue plasminogen activator (Muller et al., 2001). The development of better techniques for assessing the many interactive components of coagulation and hemostasis *in vivo* will help to resolve these issues.

B. MUFA Effects

Oleic acid (18:1n9) is usually considered to be the neutral reference point for studying the potential antiaggregatory effects of polyunsaturated fats and proaggregatory effects of saturated fats (Knapp, 1997). However, it is not clear whether oleic acid is truly devoid of biological effects in humans. Olive oil and other oleic acid enriched oils certainly impact on cholesterol and lipoprotein homeostasis as discussed in the following section. A recent report indicated increased plasmin activity following 18:1n9 and 18:2n6 addition *in vitro* whereas saturated fatty acids were ineffective. As recently reported, factor VIIc was found to be lower on a MUFA diet vs. a saturated fat diet, but fibrinogen and insulin concentrations and plasminogen activator inhibitor-1 activity did not differ between diets (Allman-Farinelli et al., 2005). Certainly, the paucity of studies in this area contributes to our lack of fully understanding the effects of MUFAs on platelet–endothelial cell interactions and their involvement in the process of coagulation and atherogenesis.

C. PUFA Effects

Sinclair (1956) postulated that a deficiency of AA might lead to atherosclerosis; stated from a slightly different viewpoint, it appears that a diet high in saturated fat and consequently low in essential fatty acids contributes to CVD. Several epidemiological and experimental studies suggest that low tissue levels of linoleic acid might be an independent risk factor for CVD (Oliver et al., 1990). However, increased tissue levels of AA have also been postulated to increase risk for CVD. The mechanisms by which dietary linoleic acid compared to *trans* and more saturated fat diets might influence intravascular thrombosis are by (1) decreasing plasma cholesterol and LDL; (2) lowering blood pressure; (3) altering blood viscosity; (4) decreasing membrane fluidity; (5) altering signal transduction pathways; and (6) decreasing membrane cholesterol. Although a dietary linoleic acid deficiency would be expected to lower both TXA_2 and PGI_2 concentrations, owing to the synthesis of less 20:4n6, there may be differences between platelet and endothelial effects. For example, it has been shown that increased incorporation of cholesterol into platelet membranes will enhance TXA_2 production; endothelial membrane eicosanoid production under these conditions has not been studied.

It has been noted that Greenland Eskimos and Japanese fishermen have platelets that are less reactive *in vitro* than those of Caucasian Danes and Japanese farmers, respectively (Bang and Dyerberg, 1981). In addition, as summarized by Hornstra (1989a,b) and more recently by Knapp (1997) in a number of studies, there was a significant decrease in the number of circulating platelets after dietary fish oil (rich in 20:5n3 and 22:6n3) supplementation. Although the results are equivocal, it appears that diets high in fish oils or n3 fatty acids result in decreased synthesis of the 2-series eicosanoids by platelets, for example, TXA_2 measured as its TXB_2 metabolite (see Figures 44.3 and 44.5). After consumption of n3 fatty acids, not only the platelet TXA_2 synthesis but also the endothelial synthesis of PGI_2 is decreased. Therefore, it appears that fish oil fatty acids reduce the concentration of both the pro- and antiaggregatory eicosanoids. However, the n3 fatty acids have been shown not only to decrease the synthesis of 2-series eicosanoids but also to serve as substrates for the 3-series eicosanoids (see Chapter 28).

Eicosapentaenoic acid (EPA) (20:5n3) can be converted by platelets to TXA_3 and by endothelial cells to PGI_3. TXA_3 is a weak aggregatory and vasoconstrictive eicosanoid. However, the PGI_3 produced is equipotent to PGI_2 in its antiaggregatory and vasodilatory properties. Therefore, it is hypothesized that fish oils may decrease the overall potency of the proaggregatory and vasoconstrictive eicosanoids (TXA_2 and TXA_3) and maintains or increases the levels of the antiaggregatory and vasodilatory compounds (PGI_2 and PGI_3). Several laboratories have demonstrated significant *in vivo* synthesis of PGI_3 in humans after fish oil feeding, measured as the 2,3-dinor-Δ17-6 keto-PGFlα urinary metabolite (Hornstra, 1989a). As reviewed by Knapp (1997), at least 23 papers dealing with n3 fatty acid supplementation have demonstrated decreased TXA_2 production by platelets *in vitro*. The noninvasive assessment of endogenous thromboxane synthesis via measurement of its urinary metabolites provides a clinically useful index of *in vivo* biosynthesis. There have been few studies on this important point. Two groups found that in either patients with atherosclerosis who were supplemented with 10 g/day of 20:5n3 (Knapp et al., 1986) or apparently healthy individuals (Von Schacky and Weber, 1985) who excrete large amounts of dinorthromboxane B_2, there is a reduction toward the normal range. Relatively small amounts of dinorthromboxane B_3, formed from the biologically less-active thromboxane A_3, were noted and total thromboxane production was reduced. In healthy subjects with normal dinorthromboxane production, fish oil only changed the ratio of B_3/B_2 metabolites but did not decrease total production. The complexity of the effects of 20:5n3 on *in vitro* and *in vivo* processes in humans is apparent; certainly more direct *in vivo* measurements are needed to determine the effects of n3 fatty acids on not only thromboxane modulation but also on prostacylin biosynthetic rates as they relate to hemostasis.

In a series of elegant experiments utilizing an abdominal aortic loop model to measure obstruction time (OT, *in vivo* clotting time) of rats fed different dietary fats, it was clearly demonstrated that OT had a highly significant negative relationship with total saturated fatty acids and a positive relationship with PUFAs (Hornstra, 1989a; Hoak, 1997). The PUFAs had different effects on OT depending on the fatty acid families involved. Marine oils that contain high concentrations of n3 PUFAs and low amounts of saturated fatty acids proved to increase the OT, examples are cod liver and sperm whale oils. Other marine oils that are rich in n3 fatty acids also contain significant amounts of saturated fatty acids; whale and Peruvian fish oil were not effective in prolonging OT. PUFAs in whale oil are found at the 1- and 3-positions of the TGs, unlike those of fish oils, which contain PUFAs primarily in the 2-position (Bottino et al., 1967). These differences may occur because of differences in digestion and absorption of the monglycerides formed; more *sn*-2 monoglycerides are formed and therefore absorption may be higher than for the *sn*-1 or *sn*-3 monoglycerides. It should also be noted that not all saturated fatty acids elicit thrombogenic responses. Palm oil, which contains significant amounts of palmtic acid (16:0), does not appear to be as thrombogenic or as hypercholesterolemic as the shorter chain saturated fatty acids, 12:0 and 14:0 (Hornstra, 1989a; Hayes et al., 1990; Kris-Etherton and Yu, 1997).

Eicosanoid ratio changes, after fish oil ingestion, may not be the only explanation for the increased bleeding time and decreased platelet responsiveness *in vivo* and *in vitro*. Certainly, the thrombocytopenia noted in individuals after fish oil consumption may contribute to the observed

increases in bleeding and clotting time. Other mechanisms related to hemostasis may be due to membrane alterations as n3 fatty acids are incorporated into phospholipids. The increased n3 fatty acids in the membrane phospholipids have been reported to alter membrane fluidity, blood viscosity, receptor-agonist affinity, platelet–platelet and/or platelet–endothelial interactions, clotting factors and fibrinolysis (Knapp, 1997; Breslow, 2006).

Much has been publicized regarding COX-2 inhibitors and increased risk of cardiovascular events. Selective COX-2 inhibitors increase the risk of myocardial infarction and stroke that is attributed to their ability to inhibit PGI_2, resolvins, lipoxins, and endothelial nitric oxide (eNO) without affecting platelet COX-1 derived TXA_2. In contrast, aspirin blocks both COX-1 and COX-2 enzymes that results in increase in the intracellular concentrations of dihomo-gamma-linolenic acid (DGLA), AA, EPA, and docosahexaenoic acid (DHA), and reduced formation of eicosanoids. DGLA, AA, and EPA form precursors to PGE_1, PGI_2, and PGI_3, respectively, which are potent vasodilators and platelet antiaggregators. EPA has been shown to have antiarrhythmic action, and EPA, DHA, DGLA, and PGE_1 have anti-inflammatory actions as well. EPA, DHA, and AA augment eNO formation that has antiatherosclerotic action. Hence, combining EFAs with COX-2 inhibitors may prevent thrombotic cardiovascular events (DAS UN, 2005) and diminish the untoward effects of COX-2 inhibitors.

V. FATTY ACIDS AND LIPOPROTEIN METABOLISM

A. Lipoprotein Homeostasis

Lipoproteins are the key transport vehicles for cholesterol, cholesteryl esters, and triglycerides. Lipoproteins are in a constant state of flux as lipids are absorbed, packaged, and transported throughout the body. In the intestine, absorbed lipids are packaged into CM containing apoproteins B48, A-1, and A-V. These CM are transported via the thoracic lymph duct into the systemic circulation, where they acquire apo E and apo C from the circulating HDL. As the chylomicron comes into contact with the capillary endothelium, the enzyme lipoprotein lipase (LPL) hydrolyzes the triglycerides (TG) from the chylomicron. Thus the TG core of the chylomicron is decreased until only a cholesterol-enriched CM remnant remains. These CM remnants are catabolized by the liver (see Figure 44.4).

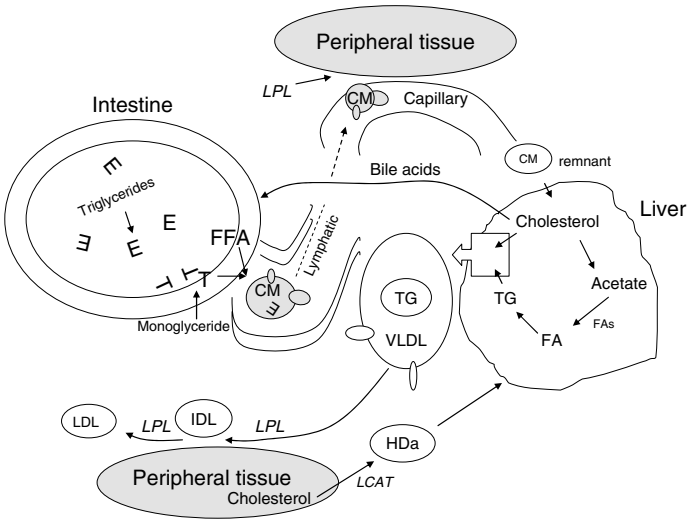

FIGURE 44.4 Lipoprotein homeostasis. LPL = lipoprotein lipase; CM = chylomicron; HDL = high-density lipoprotein; VLDL = very low-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LCAT = lecithin cholesterol acyl transferase.

If there is an excess in caloric intake from carbohydrates, fats, and/or proteins, there is an increase in acetate units available for fat or cholesterol biosynthesis. In the liver, the synthesized fatty acids and cholesterol are processed into VLDL containing apoproteins B-100, C, and E and secreted into the circulation. Once again lipoprotein lipase removes the triglycerides from these VLDL particles. As the TG content is decreased and the relative cholesterol portion increased, the micelle particle is designated as IDL and ultimately as LDL. Constant exchange occurs between the various lipoprotein fractions and HDLs as they are transported to and from the liver.

The LDL is a cholesterol-rich particle (LDL-C) and can be removed from the circulation by the liver, endothelial cells, and/or the macrophage scavenger pathway.

In all species studied to date, the liver is the primary site for the clearance of LDL-C from the plasma; 70%–85% of LDL-C removal from the plasma takes place in liver (Dietschy, 1997; Turley, 2004). Thus, while most cholesterol synthesis takes place in extrahepatic tissues, most plasma LDL-C is returned directly to liver.

Two separate transport processes have been described with regard to uptake of LDL particles from plasma, (1) receptor-dependent uptake that manifests saturation kinetics and almost certainly is mediated by the LDL receptor and (2) LDL receptor independent transport that manifests linear uptake kinetics with respect to the plasma LDL-C concentration. Of the total clearance of LDL-C from plasma, under normal dietary conditions, the receptor-dependent process accounts for approximately 60%–90% of LDL-C degradation. If hypercholesterolemic conditions prevail then more transport occurs via the receptor independent pathway; however, the mechanism(s) is unknown. As elegantly explained by Dietschy (1997) and Turley (2004), the control of cholesterol homeostasis can be influenced not only by the up-down regulation of LDL receptors and HMG CoA-reductase, but also by the rate of cholesteryl ester formation within the cell. Excess sterol is esterified by the enzyme sterol *O*-acyltransferase, the activity of which appears to be driven by the availability of the two substrates for the esterification reaction, cholesterol and the acyl-CoA derivative of *cis* 18:1n9 (Goodman, et al., 1964; Suckling and Strange, 1983; Dietschy, 1997). Thus, when free cholesterol in the liver is increased, there is presumably expansion of the pool of cholesteryl esters. According to the model detailed by Dietschy (1997), regulation of hepatic receptor activity by specific fatty acids is in part via an effect of these fatty acids on the sterol *O*-acyltransferase reaction. When the liver becomes enriched with a fatty acid that is not an ideal substrate for the sterol *O*-acyltransferase reaction, such as 16:0, the esterification reaction is partially inhibited, and the size of the free cholesterol pool is increased. As a consequence of this expansion of the free cholesterol pool, receptor messenger RNA concentration is reduced and LDL receptor activity in the liver is down regulated. However, if the preferred substrate, *cis* 18:1n9, for sterol *O*-acyltransferase is provided then cholesterol is apparently shifted into the cholesteryl ester pool and LDL receptor activity is upregulated. According to this model, the regulatory effects of both dietary cholesterol and fatty acids operate by altering the size of the free sterol regulatory pool. Therefore, this model better explains the regulatory effect of different dietary fatty acids when cholesterol is also present in the diet.

As mentioned previously, elevated levels of circulating LDL are positively correlated with increased risk for CVD, and HDL levels are negatively correlated with CVD risk (Kris-Etherton et al., 1988; Kris-Etherton and Yu, 1997; Kratz, 2005). However, it has recently been questioned whether it is the LDL or its oxidized, modified lipid, and/or protein constituents that are the primary CVD-risk-related factors. Lipid oxidation products include cholesterol oxides, fatty acid hydroperoxides, malonaldehyde, and other secondary breakdown products of lipid oxidation, such as cyclooxygenase and lipoxygenase lipid intermediates. In addition, the apoprotein moiety may also be modified (oxidized, glycosylated) and thus be taken up by the scavenger pathway in macrophages. The role of oxidized lipoproteins in atherogenesis has been reviewed by Berliner and Heinecke (1996) and Frostegard (2002) and it is evident that liporotein oxidation is promoted by several diffferent systems *in vitro*, including free and protein-bound metals, thiols, reactive oxygen species, lipoxygenase, and cyclooxygenase-derived active lipid intermediates, peroxynitrite and myloperoxidase. Although these have been shown to contribute to lipoprotein oxidation *in vitro*, the *in vivo* effects are not

clearly understood. Therefore, it is apparent that the type of dietary lipids ingested, the degree of lipid oxidation, the susceptibility of the lipid to peroxidation, and the subsequent composition of the membrane may alter the risk of CVD.

B. n6 PUFAs and Lipoprotein

Generally, it has been observed that dietary n6 PUFAs decrease plasma total cholesterol (Kris-Etherton, 1997), as predicted by the equations of Hegstead et al. (1965, 1993) and Keys et al. (1965). These equations predict that the plasma cholesterol-elevating effects of dietary SFAs are approximately twice the cholesterol-lowering effect of the n6 fatty acids. Dietary recommendations have therefore included decreasing the SFAs, increasing the n6 PUFAs, and reducing dietary cholesterol. The n6 PUFAs may lower plasma cholesterol by (1) increasing fecal bile acid secretion; (2) decreasing hepatic VLDL synthesis; and/or (3) altering VLDL, IDL, and LDL lipoprotein composition, and thereby influencing the metabolism of these circulating particles. Although most studies have shown that total plasma cholesterol is lowered by increasing the dietary content of n6 PUFAs, HDL cholesterol also appears to be lowered by n6 PUFAs; high-HDL cholesterol is associated with decreased CVD risk (Goldberg and Schonfeld, 1985). However, there is still ongoing debate as to whether high-LDL cholesterol or low HDL cholesterol is the best predictor of CVD risk. It appears that vegetarians who have a lower incidence for CVD have decreased plasma levels of both HDL and LDL cholesterols, suggesting that LDL cholesterol might be a more reliable index or that other vegetable constituents may provide a protective effect. It seems that dietary n6 PUFAs reduce plasma LDL cholesterol without altering VLDL cholesterol.

C. MUFAs and Lipoproteins

Monounsaturated fatty acids, such as 18:l n9, have been shown to lower plasma total cholesterol and LDL cholesterol when substituted for SFA in the diet. It is not clear whether the MUFAs are directly responsible for the decrease in plasma cholesterol or whether it is due to decreased SFA intake. However, it has recently been noted that MUFAs were as hypocholesterolemic as n6 fatty acids relative to SFAs when administered as liquid formulas. These cholesterol changes were primarily due to decreased LDL cholesterol because the HDL cholesterol remained unchanged (Grundy, 1986). Other more recent studies have noted that *cis* n9 fatty acids actually increase HDL while lowering LDL (Dietschy, 1997; Kris-Etherton, 1997; Sanders, 2003). Changes in HDL/LDL ratios by n9 fatty acids may, in part, explain the lower incidence of CVD noted in the Greek Island Studies, since the consumption of olive oil (rich in n9 fatty acids) in the Mediterranean diets is high (Keys et al., 1980).

D. Saturated Fatty Acids

Well-controlled dietary studies carried out in the 1950s and 1960s found that relative to an isoenergetic amount of carbohydrate, a mixture of saturated fatty acids increased serum total cholesterol concentrations (Hegsted et al., 1965; Keys et al., 1965). However, these earlier studies did not examine the effects of fatty acids on specific lipoproteins. Based on the recent meta-analysis, it can be stated that replacement of carbohydrates with saturated fatty acids not only increased serum total cholesterol concentration but also LDL and HDL. The total HDL cholesterol ratio however was not affected (Mensink et al., 2003).

E. *Trans* FAs and Lipoproteins

Naturally occurring MUFAs and PUFAs contain primarily fatty acids in the *cis* configuration; however, most processed foods also contain *trans* fatty acid isomers. These *trans* isomers are formed when animal fats or vegetable and marine oils are hydrogenated to alter their plasticity

and melting points. It was estimated in 1984 that 6%–8% of the total fat consumption is derived from these *trans* isomers (Emken, 1984); however, this amount has decreased to 2%–3% in 2006 (Mozaffarian et al., 2006). Elaidic acid (the *trans* isomer of *cis* 18:1n9) is most abundant in the diet. Although it was generally accepted that the *trans* isomers of MUFAs and PUFAs, as present in normal Western diets, do not precipitate in any known pathophysiologies, it has recently been shown that elaidic acid alters serum lipoproteins in a manner similar to 14:0 and 12:0 SFAs (Aro et al., 1997; Kris-Etherton, 1997). Mensink and Katan (1990) concluded that *trans* fatty acids are at least as unfavorable as the cholesterol-raising SFAs, because they not only raise LDL cholesterol but also decrease HDL cholesterol levels. However, the *trans* fatty acids appear to be less hypercholesterolemic than 14:0 (the most hypercholesterolemic) and 12:0 SFAs. Aro et al. (1997) compared the effects of a high *trans* diet to a high stearic acid diet and found that similar lipoprotein changes occurred with the two diets; however, Lp (a), a strong independent risk factor for CVD (Gries et al., 1990), was increased significantly more by the *trans* diet than by the stearic acid enriched diet. The Food and Drug Administration (FDA) ruled that, effective January 1, 2006, the nutrition labels for all conventional foods and supplements must indicate the content of *trans* fatty acids (Food and Drug Administration, 2005) and is the first substantive change to food labeling since 1990. The Department of Agriculture made a limited intake of *trans* fatty acids, a key recommendation of the new food-pyramid guidelines (Department of Health and Human Services, 2005) subsequent to the recommendations of the Dietary Guidelines Advisory Committee that the consumption of *trans* fatty acids be kept below 1% of total energy intake (Dietary Guidelines Advisory Committee, 2005). Each of these actions was prompted by evidence that consumption of *trans* fatty acids increases the risk of coronary heart disease (CHD). It seems evident that *trans* fatty acids contribute to risk associated with CVD.

F. n3 FAs and Lipoproteins

The discovery of the unique characteristics of n3 fatty acids, their role in lipoprotein regulation and possible role in preventing CHD, has sparked a flurry of research activity over the past two decades. Fish oils (rich in long-chain n3 fatty acids; 20:5n3 and 22:6n3) have been found to effectively lower VLDL levels in normal and hyperlipidemic subjects (Nestel, 1990; Harris, 1997a,b). The average reduction in VLDL is greater in hypertriglyceridemic subjects than in normal individuals. Decreased serum TGs (VLDL) are not due to changes in lipoprotein lipase or hepatic triglyceride lipase activities, which indicates that the n3 fatty acid effects are most likely due to altered synthesis rates. As shown by Nestel et al. (1984), the net synthesis of liver triglyceride as VLDL is greatly reduced. The reduced output of liver VLDL is dose-dependent and appears to be due to (1) increased mitochondrial and peroxisomal oxidation of fatty acids; (2) decreased fatty acid synthesis; (3) increased phospholipid vs. TG synthesis; and (4) decreased activity of the esterifying enzymes. It is speculated that lipogenesis is reduced owing to feedback inhibition of the acetyl CoA carboxylase, the rate-limiting enzyme. Apoprotein B100, which is an integral part of VLDL synthesis, is also suppressed by the n3 fatty acids.

Harris (1989, 1997a,b) summarized the lipoprotein changes that result from n3 fatty acid dietary supplementation. Linolenic acid (18:3n3), unlike the longer chain PUFAs found in fish oils, does not reduce VLDL in most studies but does exhibit hypocholesterolemic effects similar to the n6 fatty acids. Total cholesterol and LDL cholesterol are not changed markedly in normolipidemic individuals following fish oil supplementation. However, in hyperlipidemics the n3 fatty acids tend to elevate LDL-C (5%–10%) and HDL-C (1%–3%); serum triglyceride concentrations are decreased by 25%–30%. Only in cases where very high levels of n3 fatty acids (20+ g/day) were consumed have total cholesterol and LDL cholesterol serum levels decreased. In addition, it has been shown that up to 6 g, n3 fatty acids did not alter plasma Lp(a) levels; Lp(a) is positively correlated with CVD (Gries et al., 1990). As mentioned, n-3 PUFAs reduce plasma triacylglycerols and improve the lipoprotein profile by decreasing the fraction of atherogenic small, dense LDL. These effects are

likely mediated through the activity of transcription factors related to expression of genes involved in lipid synthesis and oxidation. It has been hypothesized that other pleiotropic effects of n-3 PUFAs may contribute to decreasing the burden of the metabolic syndrome, such as modulating inflammation, platelet activation, endothelial function, and blood pressure. Although studies comparing the effect of both major n-3 PUFAs are limited, DHA appears at least as effective as EPA in correcting several risk factors (Carpentier et al., 2006). It should be cautioned that although the overall effects of n3 fatty acids on serum lipoproteins appear to be beneficial, particularly with respect to VLDL, their susceptibility to oxidation may induce peroxidative damage to LDL, and thus increase the atherogenicity of this lipoprotein fraction (Hau et al., 1996; Tsai and Lu, 1997).

VI. CARDIOVASCULAR DISEASE AND LIPIDS

Hypertension is a primary risk factor for CVD and it has been noted that many populations with low mean blood pressure eat a diet low in total fat and saturated fatty acids. Specifically, linoleic acid levels in adipose tissue, a reflection of dietary intake, were inversely correlated to blood pressure in populations in Germany, Scotland, and eastern Finland; however, these correlations were not observed in other studies. These discordant findings may be caused by lack of multivariate analysis, which might include variables such as other fatty acids, alcohol intake, salt intake, and cigarette smoking (Sacks, 1989). The low blood pressure, observed in societies with a low intake of fat, may be due to other nutrients in vegetable products, such as the bioflavanoids.

In more controlled animal studies, the dietary intake of n3 PUFAs attenuate the development of hypertension in salt-induced, one-clip, DOCA-salt-induced (Bond et al., 1989), and subtotal nephrectomized rat models. Conversely, hypertension in the rat is accelerated by diets deficient in PUFAs.

The n3 fatty acids have been reported to exhibit hypotensive properties in humans; however, these effects are inconsistent. As the n3 fatty acids can alter the biosynthesis of eicosanoids, which in turn regulate physiological functions involved with blood pressure regulation, it is speculated that vascular reactivity, salt and water balance, renin release, and blood rheology may be altered by ingestion of these fatty acids. As summarized by Knapp (1989), pharmacological doses of n3 fatty acids appear to slightly lower blood pressure in humans, but this effect is most likely not mediated via altered production of eicosanoids.

Several mechanisms have been proposed to explain how EPA plus DHA might beneficially influence CVD (Breslow, 2006). These include preventing arrhythmias (Connor, 2000; Leaf et al., 2003), lowering plasma triacylglycerols (Harris, 1997b; Sacks and Katan, 2002), decreasing blood pressure (Geleijnse et al., 2002), decreasing platelet aggregation (Knapp, 1997; Hornstra, 2001), improving vascular reactivity (Goodfellow et al., 2000), and decreasing inflammation (Calder, 2001).

Other risk factors for the development of atherosclerosis include increased plasma concentrations of clotting factors, such as fibrinogen and platelet aggregation. In addition to the Greenland Eskimo studies, a number of investigators have reported that 3–5 g of n3 fatty acids results in prolonged bleeding time (Goodnight, 1986) and in some studies decreased platelet aggregation. However, n3 fatty acids do not appear to affect the plasma concentration of fibrinogen. In addition, an increased plasma plasminogen activator inhibitor (PPAI) has been associated with CVD; the effects of n3 fatty acids on PPAI are varied, and no correlations can be drawn (Hornstra, 1989a; Knapp, 1997).

Peripheral vascular disease is associated with vasoconstriction and venous and arteriole occlusions. Although the number of studies related to peripheral vascular disease is limited, there have been marked clinical improvements demonstrated in patients with chronic arterial occlusion following the administration of EPA-ethyl esters (Sakuri et al., 1987). Changes in peripheral capillary blood cell velocities were noted by Bruckner et al. (1987) in normal subjects after n3 fatty acid supplementation. Furthermore, the increased flow is apparently dependent on the oxidative status of the individual. Ware et al. (1992) found that n3 fatty acids given as supplements to elderly subjects compromised the peripheral blood flow, and increased flow was observed only with the concomitant

supplementation of vitamin E. It is possible that vascular tone is influenced not only by changes in eicosanoid ratios of TXA_2 and TXA_3 to PGI_2 and PGI_3 but also by increased synthesis of NO and decreased PAF. Changes in microviscosity might be another factor that contributes to increased blood flow. It has been reported that red blood cell deformability is increased and whole blood viscosity decreased after fish oil supplementation (Hornstra, 1989a; Knapp, 1997).

As stated by Schwalfenberg (2006) in an excellent recent review article, "omega-3 fatty acids are cardioprotective mainly due to beneficial effects on arrhythmias, atherosclerosis, inflammation, and thrombosis. There is also evidence that they improve endothelial function, lower blood pressure, and significantly lower triglycerides. *Physicians need to integrate dietary recommendations for consumption of omega-3 fatty acids into their usual cardiovascular care*."

VII. A UNIFYING HYPOTHESIS FOR VASCULAR EVENTS LEADING TO ATHEROGENESIS

CHD can be viewed as a three-phase process. During the first phase, initiation, an initial endothelial injury is produced, which may be due to lipid oxidation products, smoking (carbon monoxide), hypertension (shear stress), endotoxins, toxic oxygen metabolites, ROS, and/or viral infections. The second phase, progression, entails plaque formation due to cholesteryl ester deposition, oxidized LDL cholesterol macrophage uptake, proliferation of smooth muscle cells, and continued platelet activation. Phase three involves thrombosis, vascular spasm, and/or vascular occlusion leading to tissue damage, and ultimately tissue death (termination).

Ross (1985) postulated that atherosclerosis is a response to injury, which we can now expand to include injury via various ROS; however, the mechanisms by which specific initial injurious agents elicit endothelial damage are still not well understood. Lipid oxidation products can induce endothelial cell injury and may be one of the initial cytotoxic agents starting the atherosclerotic process. Assuming that lipid oxides are involved in the initiation process, the effects of dietary fatty acid isomers on atherogenesis can be related to their impact on the "oxidative status" of the organism.

The pathological process initiated by lipid oxides includes arterial endothelial injury, activation of platelets, monocyte recruitment, monocyte adherence, conversion of moncytes to macrophage scavenger cells, macrophage uptake of lipid peroxides, and transformation to foam cells; these events lead to the evolution of fatty streaks, intimal thickening, and ultimately to vessel occlusion. If one combines the Ross injury hypothesis, the lipid hypothesis, and the lipid peroxidation hypothesis, many of the discrepancies involving lipids and atherogenesis can be explained. To understand how dietary lipids are involved in initiation, propagation, and termination of vascular events, the long-standing dogma that cholesterol and saturated fatty acids are, in and of themselves, detrimental needs to be reconsidered (see Figure 44.5). As previously stated, not all SFAs are hypercholesterolemic and the role of MUFAs with respect to sterol *O*-acyltransferase specificity appears to play a significant role in cholesterol homeostasis. Cholesterol and most fatty acids in pure bound form do not appear to precipitate injurious vascular events; however, more work is needed to clarify this area since linoleic acid may be more injurious to endothelial cells than other unsaturated or saturated fatty acids (Hennig et al., 1993, 2006).

Evolution has provided for tight control mechanisms to regulate the amounts of free fatty acids and cholesterol as well as the specific types and amounts of these lipids found in membranes. Furthermore, due to the now apparent toxicity of oxidized lipids, nature has provided an elaborate antioxidant defense mechanism. These lipid protective compounds enter into the food chain as dietary vitamins E, C, β-carotene, bioactive flavonoids, alpha-lipoic acid (Packer et al., 1995), butylated hydroxytoluene (BHT), and other synthetic antioxidants added during processing; these compounds can protect foods (lipids) from autoxidation. Fruits and vegetables are rich sources of phenolic and other antioxidants and their consumption is correlated with decreased CVD. In addition, as pointed out by James et al. (1989), the decline in CVD in the United States, while paralleling the increased consumption of more PUFAs, is also paralleled by the increased consumption of antioxidants found or added to these vegetable oils and fats.

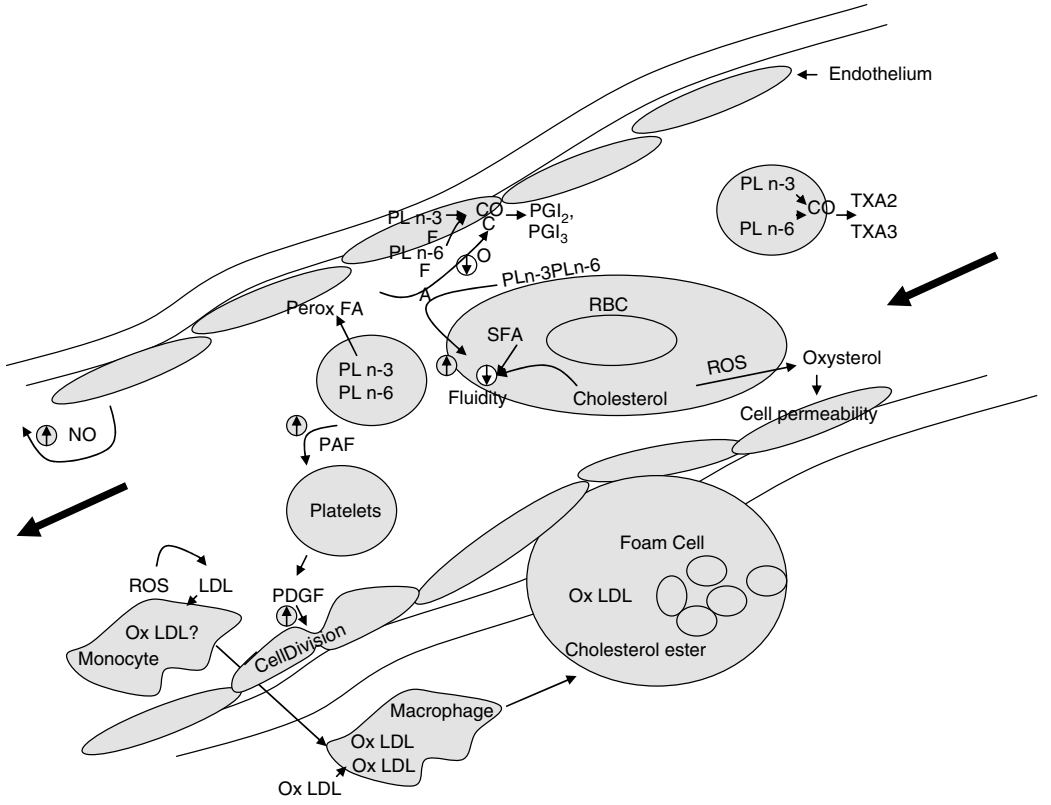

FIGURE 44.5 Pathways influenced by n-6 and n-3 fatty acids that may alter blood flow and atherogenesis. Possible antiatherogenic effects of n-3 fatty acids. 1: Decrease membrane 20:4n-6 (acylation and Δ6 desaturase inhibition). 2: Increase membrane 20:5n-3 (alter membrane fluidity). 3: Increase membrane 20:5n-3 (alter agonist-receptor sensitivity). 4: Increase synthesis of 3-series eicosanoids, TXA3 and PGI3, which favors vasodilatory-antiaggregatory environment. 5: Compete for cycloxygenase and lipoxygenase enzyme sites with n-6 fatty acids; thereby, (a) decrease 2-series and increase 3-series eicosanoids and (b) decrease production of unstable endoperoxide and hydroperoxide intermediates. 6: Decrease VLDL synthesis. 7: Increase HDL synthesis. 8: Increase blood flow (vasodilation-fluidity). 9: Increase EDRF, decrease PAF and PDGF. (↑) Vasoconstrictive-proaggregatory; (↓) vasodilatory-antiaggregatory; TXA_2, thromboxane A_2; TXA_3, thromboxane A_3; EPI, epinephrine; PGI_2, prostacycline I_2; PGI_3, Prostacycline I_3; Chol, Cholesterol; CO, cyclooxygenase; LO, lipoxygenase; PL, phospholipids; SFA, saturated fatty acid; FL, fluidity; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; and EDRF, endothelium-derived relaxing factor (nitric acid).

The findings that oleic and stearic acids also decrease serum cholesterol levels challenges many long-standing assertions. By focusing on lipids and their effects on systemic and cellular peroxidation reactions, many discrepancies related to the "lipid hypothesis" can be explained. It has been shown that cholestane-3β,5α,6β-triol and 25-hydroxycholesterol produce endothelial damage both *in vivo* and *in vitro* (Peng et al., 1985; Hennig and Boissonneault, 1987; Liu et al., 2004). Linoleic hydroperoxides have also been shown to have potent endothelial cytotoxic effects *in vitro* (Yagi, 1988). Numerous studies have been published that clearly indicate that the lipid and protein peroxidation products and not the pure compounds possess the atherogenic properties (Addis, 1990; Hennig et al., 1993; Liu et al., 2004).

These lipids oxidation products exhibit very different physiological responses compared to the pure compounds. For example, (1) cholesterol oxides and not pure cholesterol are scavenged by macrophages; (2) linoleic hydroperoxides inhibit PGI_2 synthesis whereas the pure fatty acid does not; (3) cholesterol oxides and not pure cholesterol increase endothelial cell permeability; and

(4) LDL containing oxidized vs. pure cholesterol is more chemotactic toward recruitment of monocytes (Berliner and Heinecke, 1996).

What are the sources of these oxidized lipid products? In the human diet, cholesterol oxides and fatty acid hydroperoxides are most likely formed during deep frying, dehydration, and powdering processes. During deep frying of french fries using animal fat, both cholesterol oxides and fatty acid hydroperoxides, aldehyde epoxides, and/or hydroxy acids can be formed; using vegetable oils, only the cholesterol products would be eliminated. To date, we do not know the biopotencies of these compounds relative to each other and therefore cannot accurately predict their biological effects.

Once pure lipids are absorbed, there are a multitude of enzymatic cellular reactions that may form lipid oxidation end products, for example, cyclooxygenase, lipoxygenase, P-450, and other heme-containing enzymes. These enzymes, which introduce O_2 into lipid molecules, are protected by an elaborate network of antioxidant molecules and enzymes capable of inactivating free radical and peroxidation reactions; examples are vitamins E, C, β-carotene, superoxide dismutase, catalase, and glutathione peroxidase. If the balance is upset between these prooxidant and antioxidant reactions, deleterious lipid oxidation products may be formed. During injury, such as a skin incision, the release of lipid oxides may protect against pathogenic organisms via their cytotoxicity; however, if the injury and release of these lipid oxides is due to lack of antioxidant defense mechanisms or due to sustained endothelial injury, atherogenesis may be precipitated.

These concepts indicate that the n3 fatty acids may be most protective with respect to atherogenesis only if the antioxidant dietary constituents and cellular defense mechanisms are intact. Many of the physiological effects of n3 fatty acids can be explained as they relate to membrane function, changes in eicosanoid biosynthesis, and their influence on other bioactive compounds, such as PAF, NO, PDGF, TNF, and interleukin-1. However, since these n3 fatty acids are not readily converted to the 3-series eicosanoids, they can also be viewed as monooxygenase competitive inhibitors. It is possible that the overall effect of n3 fatty acids binding to these monooxygenases results in a decrease in lipid peroxide intermediates; in addition, the eicosanoids that are produced appear to be beneficial.

Perhaps the primary effect of dietary fatty acids, as they relate to atherogenesis, is via their influence on membrane composition and the subsequent increase or decrease in monooxygenase activities; excess cholesterol in the platelet membrane has been shown to increase TXA_2 production. TXA_2 biosynthesis is accompanied by equimolar amounts of malonyldialdehyde, a lipid oxidation product.

Since the first publication of this chapter in 1991, there has been a flurry of research activity related to oxidative stress (injury), lipid oxidation, and atherogenesis. Our understanding of how atherogenesis may be initiated by oxidative stress and the contribution of specific fatty acids and antioxidants, to the regulation of lipid and lipoprotein metabolism via these mechanisms has given us greater insight toward helping to ameliorate CVD. There is also a concomitant flurry of research activity looking at the interactions of nutraceuticals (e.g., plant bioflavanoids) and lipid peroxidation reactions that hold great promise in ameliorating CVD.

45 Dietary Fatty Acids and Cancer

Howard Perry Glauert

CONTENTS

I. INTRODUCTION

The amount and type of fat consumed in the diet may be important in the development of human cancer. Several organizations have advocated decreasing the fat content of the diet as a means of preventing the development of cancer. For example, the American Institute for Cancer Research states to "limit consumption of fatty foods, particularly those of animal origin" (World Cancer Research Fund/American Institute for Cancer Research, 1997). On the other hand, the American Cancer Society no longer specifically recommends lowering fat intake, and instead advises individuals to "eat a variety of healthy foods, with an emphasis on plant sources" (American Cancer Society, 2006).

In this review, the role of dietary fat on the development of human and experimental cancer will be discussed. Because of the large number of studies published, reviews will be cited where possible. Cancer clearly is a disease of alterations both in genetic structure and in genetic expression, both of which can be affected by dietary fat.

II. EPIDEMIOLOGICAL STUDIES

Numerous epidemiological studies have examined the effect of dietary fat on human cancer. Several correlational studies have noted an increase in the rates of colon, breast, and other cancers in areas

where dietary fat consumption is high (Fraser, 1996). Additionally, studies with immigrant populations have identified dietary fat intake as a causative factor in the development of these cancers (Fraser, 1996).

For colon cancer, epidemiological studies have not reached a clear consensus about the influence of dietary fat. Case–control studies overall have not found a positive association with dietary fat, although many have observed a positive association with meat intake (Kushi and Giovannucci, 2002). Prospective epidemiological studies have conflicting results: some studies show a positive association, others see no effect, and others see an actual protective effect of high-fat intakes (Table 45.1). In several of these studies, the consumption of red meat was found to be significantly correlated with colon cancer risk, but independently of fat intake. The Women's Health Initiative intervention study was recently published (Beresford et al., 2006). In this study 19,500 women lowered their fat intake by about 10% compared to 29,000 women who did not alter their diet, for a follow-up period that averaged 8 years. The intervention group had a relative risk of 1.08, which was not statistically significant, indicating that a diet lower in fat did not inhibit the development of colon cancer in this study.

Numerous epidemiological studies have attempted to identify factors which influence breast cancer risk in humans. Established breast cancer risk factors include age of first pregnancy, body build, age at menarche or menopause, and the amount of radiation received by the chest (Kelsey and Berkowitz, 1988). The effect of dietary fat has been studied in correlational, case–control, and prospective epidemiological studies. Studies examining international correlations between dietary fat intake and breast cancer risk, and migrant studies have reported a positive association between dietary fat intake and breast cancer risk (Kelsey and Berkowitz, 1988). Case–control studies generally have also supported a connection between total fat intake and breast cancer risk (Kushi and Giovannucci, 2002). A combined analysis of 12 case–control studies found a significant positive association between breast cancer risk and saturated fat intake (Howe et al., 1990). Most prospective studies, however, did not find any link between dietary fat intake and the development of breast cancer (Table 45.2). Furthermore, a combined analysis of seven of these prospective studies did not find any evidence of a link between dietary fat intake and breast cancer risk, even for women consuming less than 20% of their calories as dietary fat (Hunter and Willett, 1996). The Women's Health Initiative intervention study (described in the preceding paragraph) examined the effect of low-fat diets on the development of breast cancer (Prentice et al., 2006). Although dietary fat did not significantly affect the development of breast cancer, there was a relative risk of 0.91 in the low-fat intervention group.

For the pancreas, international comparisons do not show as strong a trend as with colon or breast cancer (Howe and Burch, 1996). Case–control studies which have examined total or saturated fat intakes do not show a clear trend; studies examining the consumption of meat or cholesterol tend to show a positive correlation, however (Howe and Burch, 1996). In prospective studies, Nothlings et al. (2005) and Michaud et al. (2003, 2005) found that dietary fat did not influence the development of pancreatic cancer. However, Stolzenberg-Solomon et al. (2002) found that dietary fat enhanced the development of pancreatic cancer. Five prospective studies have examined the relationship of meat consumption with pancreatic cancer; four of the five reported a positive correlation (Hirayama, 1989; Michaud et al., 2003; Mills et al., 1988; Nothlings et al., 2005; Zheng et al., 1993).

A number of case–control and prospective studies have examined the role of dietary fat in prostate cancer. Several case–control studies observed a positive correlation between the intake of total and saturated fat and the development of prostate cancer, although others, particularly the more recent studies, did not see an effect (Kushi and Giovannucci, 2002; Wu et al., 2006). Four prospective studies have been performed, with two of these observing a positive association between dietary fat and prostate cancer incidence or mortality and two observing no effect (Kushi and Giovannucci, 2002; Wu et al., 2006).

Fewer studies have been conducted for other major forms of human cancer. For endometrial cancer, several but not all case–control studies have noted an association with dietary fat (Hill and

TABLE 45.1
Dietary Fat and Colorectal Cancer: Prospective Studies

Investigators	Subjects	Years of Follow-Up	Effect of Dietary Fat
Hirayama (1981)	265,118 subjects in Japan	13	Significant negative effect for meat
Stemmermann et al. (1984)	7,074 Hawaiian—Japanese men	15	Significant negative effect
Garland et al. (1985)	1,954 men in Chicago	19	No significant effect
Phillips and Snowdon (1985)	25,493 Seventh Day Adventists in California	21	No significant effect
Willett et al. (1990)	88,751 female nurses in United States	6	Significant positive effect for total, animal, monounsaturated, and saturated fat, and for red meat
Giovannucci et al. (1992)	7,284 male health professionals	2	Significant positive effect for total, animal, monounsaturated, and saturated fat, and for red meat
Thun et al. (1992)	764,343 men and women	6	No significant effect of fat or red meat
Goldbohm et al. (1994)	58,279 men and 62,573 women in Netherlands	3.3	No significant effect
Giovannucci et al. (1994)	47,949 male health professionals	6	No significant effect of fat, but significant positive correlation with red meat
Bostick et al. (1994)	35,215 women in Iowa	4	No significant effect
Gaard et al. (1996)	50,535 men and women in Norway	11	No significant effect of fat, but significant positive correlation with sausage intake
Chyou et al. (1996)	7,945 Japanese–American men in Hawaii	27–30	Significant negative correlation with total and monounsaturated fat for colon but not rectal cancer
Kato et al. (1997)	14,727 women in New York and Florida	7	No significant effect of fat or meat
Singh and Fraser (1998)	32,051 Seventh Day Adventist men and women in California	6	Significantly increased risk with red, white or total meat intake
Pietinen et al. (1999)	27,111 male smokers in Finland	8	No significant effect of fat or meat
Jarvinen et al. (2001)	9,959 Finnish men and women	27–32	High-cholesterol intake was associated with increased risk, but not consumption of total, saturated, monounsaturated or polyunsaturated fat
Terry et al. (2001a,b)	61,463 women in Sweden	9.6	No significant effect of intake of fat or a “Western” diet
Flood et al. (2003)	45,496 women in United States	8.5	No significant effect of fat or meat consumption
Chao et al. (2005)	148,610 men and women in United States	9, 19	Significant increase with red and processed meat consumption; poultry and fish consumption protective

TABLE 45.2
Dietary Fat and Breast Cancer: Prospective Studies

Investigator	Subjects	Years of Follow-Up	Effect of Dietary Fat
Jones et al. (1987)	5,485 women in United States	10	No significant effect
Willett et al. (1987)	89,538 nurses in United States	4	No significant effect
Mills et al. (1989)	20,341 Seventh Day Adventist women in California	6	No significant effect
Knekt et al. (1990)	3,988 women in Finland	20	No significant effect
Howe et al. (1991)	56,837 Canadian women	5	Slightly elevated risk
Graham et al. (1992)	18,586 women in New York State	7	No significant effect
Kushi et al. (1992)	34,388 women in Iowa	4	No significant effect
Willett et al. (1992)	89,494 nurses in United States	8	No significant effect
van den Brandt et al. (1993)	62,573 women in Netherlands	3.3	No significant effect
Toniolo et al. (1994)	14,291 women in New York City	6	No significant effect; but significant positive correlation with red meat
Gaard et al. (1995)	31,209 women in Norway	7–13	No significant effect for fat or saturated fat; but significant positive correlation with meat and monounsaturated fat
Holmes et al. (1999)	88,795 nurses in Unite States	14	No significant effect of total fat or specific fatty acids
Velie et al. (2000)	40,022 women in 29 centers throughout United States	5.3	No overall association; but among women with no history of benign breast disease, positive association between total and unsaturated fat intake and breast cancer risk
Thiebaut et al. (2001)	65,879 women in Europe	3.4	Small positive association between fat intake and breast cancer risk
Terry et al. (2001c)	61,463 women in Sweden	9.6	No association between “Western” dietary pattern and breast cancer risk
Byrne et al. (2002)	44,697 nurses in United States	14	No effect of fat in women with no history of benign breast disease

Austin, 1996; McCann et al., 2000; Salazar-Martinez et al., 2005). Case–control studies examining dietary fat and bladder cancer showed an association in some but not all studies; a prospective study did not observe a correlation between dietary fat intake and the development of bladder cancer (La Vecchia and Negri, 1996; Radosavljevic et al., 2005). Dietary fat has been found to be a risk factor for ovarian cancer in some epidemiological studies but not in others (Bertone et al., 2002; Kushi et al., 1999; Pan et al., 2004; Risch et al., 1994; Zhang et al., 2002). Lung cancer risk was not found to be significantly affected by dietary fat in two prospective studies, but several case–control studies have observed an association (Alavanja et al., 2001; Mohr et al., 1999; Ziegler et al., 1996), although several investigators indicated that their results may have been affected by confounding from smoking. For testicular cancer, case–control studies have observed an association between high-fat diets and increased incidence (Bonner et al., 2002; Sigurdson et al., 1999). Using case–control and cohort study designs, Granger et al. (2006) found that increased dietary fat consumption protected against the development of skin cancer. Davies et al. (2002), however, found that dietary fat did not influence basal cell carcinoma development. The development of esophageal cancer was found to be increased by dietary fat in a case–control study (Wolfgarten et al., 2001).

III. EXPERIMENTAL CARCINOGENESIS STUDIES

A. Nutritional Considerations

In most experiments examining the effect of dietary fat, fat is substituted for carbohydrate isocalorically in order to ensure that fat is the only experimental variable. In some studies, however, fat was added to a nutritionally complete diet, such as a ground unrefined diet. Since animals consume approximately the same number of calories, animals on such a high-fat diet would consume less of all other nutrients in the diet. Therefore, any changes seen in the high-fat group could not strictly be attributed to a higher consumption of fat. In other studies, fat was substituted for a carbohydrate (such as corn starch or dextrose) on a gram-for-gram basis. Since fat contains 9 kcal/g and carbohydrate contains only 4 kcal/g (National Research Council, 1989), such a protocol would also result in lower consumption of other nutrients in the diet.

Another issue in studies examining dietary fat and carcinogenesis is whether the enhancing effect of dietary fat, when it is seen, is due to dietary fat per se (e.g., by an effect on gene expression) or rather to a more efficient utilization of calories. Even when the ratio of calories to nutrients remains the same when the dietary fat content of the diet is raised, animals on high-fat diets frequently gain more weight than animals on a low-fat diet. When fat is substituted for carbohydrate isocalorically, the substitution is done on the basis of metabolizable energy rather than net energy. Donato and Hegsted (1985), however, have demonstrated that fat is used more efficiently than carbohydrate, so that equating their metabolizable energy values may be inaccurate.

B. Skin Carcinogenesis

Mouse skin is one of the oldest and most widely used systems for studying chemical carcinogenesis, including multistage carcinogenesis. Two-stage carcinogenesis (initiation–promotion) was first observed in mouse skin and involves initiation by a subcarcinogenic dose of radiation or of a chemical such as a polycyclic aromatic hydrocarbon (PAH) followed by the long-term administration of croton oil or its active ingredient 12-*O*-tetradecanoylphorbol-13-acetate (TPA) (Berenblum and Shubik, 1947). More recently, transgenic skin carcinogenesis models have been developed (Greenhalgh et al., 1996; Humble et al., 2005).

Most studies examining dietary fat have studied complete carcinogenesis by PAH or ultraviolet (UV) light. Early studies demonstrated that high-fat diets enhanced skin carcinogenesis induced by tar (Watson and Mellanby, 1930) or PAH (Baumann et al., 1939; Boutwell et al., 1949; Jacobi and Baumann, 1940; Lavik and Baumann, 1941, 1943; Tannenbaum, 1942, 1944). In studies where

skin tumors were induced by UV light, Mathews-Roth and Krinsky (1984) found that high-fat diets increased skin carcinogenesis, whereas Black et al. (1983) found that high-fat diets did not increase skin carcinogenesis, but that feeding a saturated fat inhibited tumorigenesis.

The effect of fatty acids on the initiation and promotion of skin carcinogenesis has also been studied. Certain fatty acids—oleic and lauric acids—were found to have promoting activity when applied daily to mouse skin after a single application of 7,12-dimethylbenz(a)anthracene (DMBA); stearic acid and palmitic acid did not have any effect (Holsti, 1959). When diets varying in their fat content were fed during the promotion stages of DMBA-initiated, TPA-promoted mouse skin carcinogenesis, high-fat diets were found to enhance the promotion of skin carcinogenesis in some studies (Birt et al., 1989b,c) but not in others (Lo et al., 1994; Locniskar et al., 1991b). High-fat diets also partially offset the tumor inhibitory effects of caloric restriction (Birt et al., 1996). Locniskar et al. (1990) found that substituting menhaden oil for corn oil or coconut oil did not affect skin tumor promotion by TPA. When benzoyl peroxide was used as the promoting agent, mice fed mainly coconut oil had the highest tumor incidence and mice fed corn oil had the lowest tumor incidence, with those fed mainly menhaden oil having an intermediate tumor incidence (Locniskar et al., 1991a). In a study using mezerein as the promoting agent, high-fat diets did not increase the skin carcinogenesis (Birt et al., 1994). High fat diets were found to not affect or slightly inhibit initiation (Birt et al., 1989c; Locniskar et al., 1991c), and substituting coconut oil for corn oil did not influence UV-induced skin carcinogenesis (Berton et al., 1996).

C. Hepatocarcinogenesis

Many early studies of dietary fat and cancer used the liver as the target organ. In these studies, aromatic amines and azo dyes were frequently used to induce hepatocellular carcinomas. In later studies, effects of dietary fat on initiation and promotion in the liver were examined. In initiation–promotion protocols, the administration of a single subcarcinogenic dose of a carcinogen (such as diethylnitrosamine (DEN) or DMBA) along with a proliferative stimulus (such as partial hepatectomy) followed by the long-term feeding of chemicals such as phenobarbital, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, or polyhalogenated biphenyls leads to a high incidence of hepatocellular adenomas and carcinomas (Glauert et al., 2001; Pitot and Dragan, 1994). Transgenic mouse models of liver carcinogenesis have also been developed (Calvisi and Thorgeirsson, 2005). In addition, foci of putative preneoplastic hepatocytes appear before the development of gross tumors. These foci, known as altered hepatic foci or enzyme-altered foci, contain cells which exhibit qualitatively altered enzyme activities or alterations in one or more cell functions (Pitot and Dragan, 1994). The enzymes most frequently studied include γ-glutamyl transpeptidase (GGT) and placental glutathione-*S*-transferase (PGST), which are normally not present in adult liver but which are often present in foci; and ATPase and glucose-6-phosphatase, which are normally present but which are frequently missing from foci (Hendrich et al., 1987; Pitot et al., 1985). Altered hepatic foci can also be identified on hematoxylin and eosin stained tissue (Bannasch et al., 1989; Harada et al., 1989). The appearance of foci has been correlated with the later development of malignant neoplasms (Emmelot and Scherer, 1980; Kunz et al., 1983).

The first studies examined the effect of dietary fat on the induction of hepatocellular carcinomas by complete hepatocarcinogens. In the liver, increasing the fat content of the diet enhances the development of 2-acetylaminofluorene- (AAF), *p*-dimethylaminoazobenzene- (DAB), and aflatoxin B_1 (AFB)-induced tumors and GGT-positive foci in rats (Baldwin and Parker, 1986; Hietanen et al., 1991; Kline et al., 1946; McCay et al., 1980; Sugai et al., 1962). Furthermore, hepatocarcinogenesis by DAB is enhanced by feeding a diet which contains a greater proportion of polyunsaturated fatty acids (Miller et al., 1944a,b). In these studies, however, the diets were administered at the same time as the carcinogen injections, so that the stage of carcinogenesis which was affected could not be determined.

More recent studies have examined whether this enhancement of hepatocarcinogenesis is caused by an effect on the initiation of carcinogenesis, the promotion of carcinogenesis, or both.

Misslbeck et al. (1984) found that increasing the corn oil content of the diet after the administration of ten doses of aflatoxin increased the number and size of GGT-positive foci, but Baldwin and Parker (1987), using a similar protocol, found no effect of dietary corn oil. Glauert and Pitot (1986) similarly found that increasing the safflower oil or palm oil content of the diet did not promote DEN-induced GGT-positive foci or greatly affect phenobarbital promotion of GGT-positive foci. The promotion of GGT-positive foci by dietary tryptophan also is not affected by dietary fat (Sidransky et al., 1986). Newberne et al. (1979) found that increasing dietary corn oil (but not beef fat) during and after the administration of AFB increased the incidence of hepatic tumors, but not when the diets were fed only after AFB administration. Baldwin and Parker (1987) also found that increasing the corn oil content of the diet before and during AFB administration increased the number and volume of GGT-positive foci. When rats are fed diets high in polyunsaturated fatty acids (but not in saturated fatty acids) before receiving the hepatocarcinogen DEN, they develop more GGT-positive and ATPase-negative foci than rats fed low-fat diets (Glauert et al., 1991). Finally, the feeding of diets high in corn oil but not lard enhanced the initiation of PGST-positive foci induced by azoxymethane (AOM) (Rahman et al., 2001). The results of these studies suggest that the enhancement of hepatocarcinogenesis by dietary fat is primarily due to an effect on initiation, and that polyunsaturated fats have a greater effect than do saturated fats.

D. Colon Carcinogenesis

Studies in experimental animals have produced differing results. A variety of chemicals have been used to induce colon tumors, usually in rats or mice. These include 1,2-dimethylhydrazine (DMH) and its metabolites AOM and methylazoxymethanol (MAM); 3,2'-dimethyl-4-aminobiphenyl (DMAB); methylnitrosourea (MNU); and *N*-methyl-*N*'-nitro-*N*-nitrosoguanidine (MNNG) (Druckrey, 1970; Nauss et al., 1984; Reddy and Ohmori, 1981; Rogers and Nauss, 1985). DMH and AOM have been used most frequently to study nutritional effects. Both can induce colon tumors by single (Decaens et al., 1989; Glauert and Weeks, 1989; Karkare et al., 1991; Schiller et al., 1980; Ward, 1975) or multiple (Bull et al., 1979; Glauert et al., 1981; Nauss et al., 1983; Reddy et al., 1974; Sakaguchi et al., 1986) injections. The Min mouse, which has a mutation in the mouse homolog of the adenomatous polyposis coli (APC) gene, develops colon tumors spontaneously and is used as a model of colon carcinogenesis (Thompson, 1997). In addition to tumors, putative preneoplastic lesions, aberrant crypt foci (ACF), are induced by colon carcinogens (Bird, 1987). ACF, which are identified by fixing the colon in formalin and then staining with methylene blue, are stained darker and are larger than normal crypts (Bird, 1987). Some but not all studies have shown that ACF correlate well with the later appearance of adenocarcinomas (Alrawi et al., 2006; Hardman et al., 1991; Pereira et al., 1994; Wargovich et al., 1996).

Animal studies examining the effect of dietary fat have used a variety of protocols, and the results obtained often have been dependent on the investigator's protocol. In these studies, rats or mice were subjected to multiple doses of a colon carcinogen, with the dietary fat content being varied (isocalorically) during, and frequently before or after, the carcinogen injections. Some of these studies found an enhancement when the dietary fat content of the diet was increased, but others saw no effect or even an inhibition of tumor development (Clinton et al., 1992; Glauert et al., 1981; Guillem et al., 1988; Hardman and Cameron, 1995; Rao et al., 2001; Rijnkels et al., 1997; Takeshita et al., 1997; Wargovich et al., 1990; Wijnands et al., 1999; Zhao et al., 1991). High-fat diets were found to influence the early stages of carcinogenesis more than the later stages (Bird et al., 1996). In several studies where fat was found to enhance colon carcinogenesis, fat was either added to a chow diet or was substituted for carbohydrate on a weight basis, so that the ratio of calories to essential nutrients was altered; therefore the effect could have been due to a lower consumption of essential nutrients rather than to an effect of fat (Glauert, 1993). In the Min model, high-fat diets were found to increase colon carcinogenesis in one study but not another (van Kranen et al., 1998; Wasan et al., 1997). Increasing the fat content of the diet has been found to increase the number

of ACF induced by colon carcinogens in several but not all studies (Baijal et al., 1998; Hambly et al., 1997; Ju et al., 2003; Koohestani et al., 1997; Kristiansen et al., 1995; Lafave et al., 1994; Liu et al., 2001; Morotomi et al., 1997; Parnaud et al., 1998; Rao et al., 2001; Wan et al., 2000). The type of fat (unsaturated vs. saturated) in the diet also produced conflicting results (Parnaud et al., 1998; Sakaguchi et al., 1984; Takeshita et al., 1997). ω-3 fatty acids can also influence colon carcinogenesis: feeding fish or flaxseed oil in place of corn oil, or eicosapentaenoic acid in place of linoleic acid, decreases the development of DMH- or AOM-induced colon tumors, but adding menhaden oil to a low-fat diet does not affect colon carcinogenesis (Bartoli et al., 2000; Dommels et al., 2003; Dwivedi et al., 2005; Latham et al., 1999; Minoura et al., 1988; Nelson et al., 1988; Rao et al., 2001; Reddy and Maruyama, 1986; Reddy and Sugie, 1988). Olive oil, high in ω-9 fatty acids, was also found to inhibit colon carcinogenesis when substituted for polyunsaturated fatty acids (Bartoli et al., 2000).

E. Pancreatic Carcinogenesis

Dietary fat has been studied extensively in animal models. A common model is induction of pancreatic tumors by azaserine; however, azaserine produces tumors in acinar cells (Grippo and Sandgren, 2005), whereas the primary site in humans is the ductal cell. Tumors can be produced in pancreatic ductal cells in hamsters, by the chemicals *N*-nitroso-*bis*-(2-oxypropyl)amine (BOP) and *N*-nitroso-*bis*-(2-hydroxypropyl)amine (BHP) (Grippo and Sandgren, 2005). A number of transgenic models have been developed (Grippo and Sandgren, 2005; Leach, 2004). A number of models used regulatory elements from the rat elastase gene, which targets acinar cells. These constructs produced acinar tumors or mixed acinar/ductal tumors (Grippo and Sandgren, 2005; Leach, 2004). Recently, a new model has been developed, which uses an oncogenic K-ras ($KRAS^{G12D}$) inserted into the endogenous K-ras locus (Hingorani et al., 2003). The gene has a Lox-STOP-Lox (LSL) construct inserted upstream. These mice are interbred with mice containing the Cre recombinase downstream from a pancreatic specific promoter, either PDX-1 or P48. The PDX-1-Cre;LSL-$KRAS^{G12D}$ mice develop pancreatic intraepithelial neoplasia (PanINs), which progress over time (Hingorani et al., 2003). In addition, when these mice are crossed to mice containing p53 mutations or Ink4a/Arf deficiency, the rapid development of pancreatic adenocarcinomas is observed (Aguirre et al., 2003; Hingorani et al., 2005).

Dietary fat has been found to influence tumorigenesis in both rats and hamsters. In rats, feeding high-fat diets after, or during and after, the injection of azaserine enhances the development of pancreatic tumors and putative preneoplastic lesions (O'Connor et al., 1985a; Roebuck, 1986; Roebuck et al., 1981a,b, 1985, 1987; Woutersen and van Garderen-Hoetmer, 1988; Woutersen et al., 1989a,b). Pancreatic carcinogenesis induced by *N*-nitroso(2-hydroxypropyl)(2-oxopropyl)amine in rats is also enhanced by feeding high-fat diets (Longnecker et al., 1985). In several of these studies, the effect cannot be attributed unequivocally to dietary fat because fat was substituted for carbohydrate on a weight basis. In hamsters, BOP-induced pancreatic carcinogenesis is also increased by feeding high-fat diets (Birt and Pour, 1983; Birt et al., 1981, 1989a, 1990; Herrington et al., 1997; Woutersen and van Garderen-Hoetmer, 1988; Woutersen et al., 1989a,b). Roebuck and colleagues (Roebuck, 1986; Roebuck et al., 1981a, 1985) found that polyunsaturated fat, but not saturated fat, enhanced pancreatic carcinogenesis, and that a certain level of essential fatty acids are required for the enhancement of pancreatic carcinogenesis. Increased linoleic acid was also found to increase metastases to the liver in hamsters (Wenger et al., 1999). Appel et al. (1994), however, found that increasing the linoleic acid content of the diet did not increase pancreatic carcinogenesis in either rats or hamsters. Birt et al. (1990) found that feeding a saturated fat (beef tallow) enhanced pancreatic carcinogenesis in hamsters greater than a polyunsaturated fat (corn oil). Studies using fish oil have produced differing results, depending on the experimental protocol. Substituting fish oil for oils high in polyunsaturated fats decreases (O'Connor et al., 1985b, 1989) or does not affect (Appel and Woutersen, 1994) the development of azaserine-induced preneoplastic lesions in rats. Adding fish oil to a diet-containing adequate polyunsaturated fatty acids enhances azaserine-induced carcinogenesis in rats and BOP-induced carcinogenesis in hamsters (Appel and Woutersen, 1995, 1996, 2003).

Finally, it has been observed in 2-year carcinogenesis studies in which corn oil gavage has been used as the vehicle for the carcinogen that a higher incidence of pancreatic acinar cell adenomas is present in corn oil gavage-treated male Fischer-344 control rats than in untreated controls (Eustis and Boorman, 1985; Haseman et al., 1985). This association was not observed in female rats or in male or female $B6C3F_1$ mice.

F. Mammary Carcinogenesis

The effect of dietary fat on mammary carcinogenesis in experimental animals has been examined extensively: over 100 experiments have been conducted (Fay et al., 1997; Freedman et al., 1990; Welsch, 1995). The primary model used is a rat model (usually the Sprague-Dawley strain) in which mammary tumors are induced by DMBA or MNU. Genetically engineered models have also been developed, in which the Erbb2 or simian virus 40 (SV40) T/t-antigens are overexpressed in mammary epithelial cells (Green and Hudson, 2005). The use of these models is advantageous because tumor latency, tumor size, and tumor progression can easily be quantified by palpation of mammary tumors as they appear. Increasing the fat content of the diet clearly enhances the development of mammary tumors (Fay et al., 1997; Freedman et al., 1990; Welsch, 1995). In the rat model, a high-fat diet increases tumorigenesis both when it is fed during and after carcinogen administration, and when it is fed only after carcinogen injection. Feeding a diet high in fish oil instead of a diet high in polyunsaturated fat decreases the incidence of DMBA-induced tumors in rats (Fay et al., 1997; Freedman et al., 1990; Welsch, 1995). A meta-analysis of experimental animal studies found that n-6 fatty acids strongly enhanced carcinogenesis, saturated fatty acids were weaker at enhancing carcinogenesis, monounsaturated fatty acids had no effect, and n-3 fatty acids weakly (but nonsignificantly) inhibited carcinogenesis (Fay et al., 1997).

G. Other Sites

Dietary fat has also been studied for its effect on experimental carcinogenesis in other organs. In the lung, dietary fat enhanced benzo[a]pyrene- (BP) or BOP-induced carcinogenesis in hamsters (Beems and van Beek, 1984; Birt and Pour, 1983), whereas in mice a high-fat diet did not affect spontaneous carcinogenesis in one study but the feeding of egg extracts enhanced it in another (Szepsenwol, 1964; Tannenbaum, 1942). In the prostate, several studies have found that high-fat diets enhance the growth of transplantable prostate tumors, but that inconsistent effects are seen in chemically induced prostate carcinogenesis models (Leung et al., 2002; Mori et al., 2001; Rose, 1997; Zhou and Blackburn, 1997).

IV. MECHANISMS BY WHICH DIETARY FAT MAY INFLUENCE CARCINOGENESIS

A. Membrane Fluidity

An important function of dietary fatty acids is their presence in membrane lipids. Altering the fatty acid content of the diet alters the composition of membrane lipids, particularly in certain tissues; feeding diets high in n-6 or n-3 fatty acids increases the concentrations of these fatty acids in membrane lipids (Murphy, 1990). The activities of membrane-bound enzymes are increased in membranes that are more fluid, that is, that have a higher content of polyunsaturated fatty acids (Murphy, 1990). The alteration by dietary fatty acids of the catalytic abilities of membrane-bound enzymes, such as cytochrome P-450, may play an important role in carcinogenesis.

B. Toxicity

One possible mechanism by which dietary fat may enhance carcinogenesis is by the toxicity of fatty acids or of metabolites that increase after the feeding of high-fat diets. Such toxicity would bring

about a proliferative response in the tissue to replace lost cells. Cellular genes involved in cell proliferation, including cellular oncogenes, would likely be increased.

In the colon, toxicity may play a role in the enhancement of carcinogenesis by dietary fat. One hypothesis for the effect of dietary fat is that dietary fat increases the concentration of metabolites with carcinogenic or promoting activity in the fecal stream. Bile acids, particularly secondary bile acids, have promoting activity in the colon (Narisawa et al., 1974; Reddy et al., 1976, 1977b); their concentration in the feces has been found to be increased by dietary fat in some but not all studies (Gallaher and Franz, 1990; Glauert and Bennink, 1983; Reddy et al., 1974, 1977a, 1980). Bile acids function as detergents; therefore, high concentrations may be toxic to epithelial cells in the colon. Several studies have shown bile acids to induce apoptosis (Bernstein et al., 2005). This may result in a compensatory increase in cell proliferation; most studies have found that increasing the concentration of bile acids *in vivo* or *in vitro* increases colon epithelial cell proliferation (Bartram et al., 1997; Cheng and Raufman, 2005; Cohen et al., 1980; Deschner and Raicht, 1979; Deschner et al., 1981; Milovic et al., 2002; Ochsenkuhn et al., 1999, 2003; Peiffer et al., 1997; Skraastad and Reichelt, 1988; Wargovich et al., 1983). In addition, several studies found that bile acids induced DNA damage (Bernstein et al., 2005).

C. Eicosanoid Metabolism

Another mechanism by which dietary fat may influence carcinogenesis is by altering the synthesis of eicosanoids. Fatty acids that are consumed in the diet can be metabolized to a variety of other compounds, including longer and more unsaturated fatty acids, prostaglandins, leukotrienes, thromboxanes, hydroperoxyeicosatetraenoic acids, and hydroxyeicosatetraenoic acids (Rosenthal, 1987). Altering the type of fatty acid in the diet has been found to change the amounts and composition of the eicosanoids that are produced by the body (McEntee and Whelan, 2002; Whelan and McEntee, 2004). n-3 Fatty acids antagonize the metabolism of arachidonic acid to eicosanoids, which may be a mechanism in their inhibition of carcinogenesis (McEntee and Whelan, 2002; Whelan and McEntee, 2004). Specific eicosanoids bind to receptors and cause specific alterations in gene expression and cellular function (Hanasaki and Arita, 2002; Kobayashi and Narumiya, 2002; Toda et al., 2002; Tsuboi et al., 2002), some of which may be related to carcinogenesis. It has been found that inhibition of eicosanoid synthesis inhibits tumor promotion in several tissues (Fischer et al., 1987; Mao et al., 2005; Richter et al., 2001; Steele et al., 2000).

D. Caloric Effect

The issue of whether the enhancing effect of fat in carcinogenesis is due to higher consumption of calories or more efficient utilization of energy has been examined in several tissues. The earliest study was conducted by Boutwell et al. (1949) using the mouse skin carcinogenesis system; they attributed most of the enhancing effect of dietary fat to an increased consumption of calories. Birt et al. (1989c), however, found that the promotion of skin carcinogenesis was enhanced even though the high-fat diets were pair fed. The greater caloric density of fat has also been proposed to play a role in colon tumorigenesis. Caloric restriction inhibits chemically induced colon carcinogenesis, even if the percentage of dietary fat in the diet is greatly increased (Klurfeld et al., 1987; Reddy et al., 1987). In the pancreas, the enhancement by dietary fat appears to be an effect of dietary fat rather than of an increased consumption of calories, as pair feeding does not inhibit the enhancing effect of dietary fat in hamsters (Birt et al., 1989a). Several studies have suggested that the enhancement of mammary carcinogenesis by dietary fat may be caused, at least in part, by an alteration in the efficiency of energy utilization (Boissonneault et al., 1986; Thompson et al., 1985; Welsch et al., 1990). Using a combined statistical analysis of over 100 animal experiments, Fay et al. (1997) found that energy intake was not responsible for the enhancing effect of polyunsaturated fats on mammary carcinogenesis, although there was a slight (but not significant) effect. Finally, caloric restriction has been found to inhibit tumorigenesis in many tissues in experimental animals (Boissonneault, 1991).

E. Effect on Initiation

Dietary fat may also affect the initiation stage of carcinogenesis. Since initiation involves the mutation of DNA, its alteration (by dietary fat or other agents) would mainly affect the structure of genes rather than their expression. In rat liver, dietary fat appears to enhance carcinogenesis primarily by an effect on initiation. In other tissues, many protocols have varied the levels of dietary fat during the time of carcinogen injections; therefore dietary fat may be affecting some aspect of initiation in these studies. Higher levels of dietary fat may enhance initiation of carcinogenesis by several mechanisms, including alterations in absorption of the carcinogen from the gut, transport to the target organ, uptake by the target organ, metabolism by cytochrome P-450 or other drug-metabolizing enzymes to a form which can react with DNA, and DNA repair. Several of these processes occur in membranes, whose lipid composition can be altered by changing the amount or type of dietary fat (Baldwin and Parker, 1985; Neelands and Clandinin, 1983). Increasing the fat content of the diet increases cytochrome P-450 and related activities (Cassanol et al., 1987; Hammer and Wills, 1980; Rutten and Flake, 1987; Wade et al., 1978). Western analysis has indicated that higher amounts of enzyme protein are present after feeding diets high in polyunsaturated fat (Kim et al., 1990). Therefore dietary fat may be affecting both gene expression and the surrounding matrix necessary for optimum enzyme activity. The metabolism of several chemicals, including hexobarbital, aniline, ethylmorphine, BP, and dimethylnitrosamine, is also enhanced by feeding diets high in polyunsaturated fatty acids (Hammer and Wills, 1980; Lam and Wade, 1980, 1981; Wade et al., 1978, 1982).

F. Lipid Peroxidation

Another way in which dietary fat could affect carcinogenesis is through lipid peroxidation. Polyunsaturated fatty acids are susceptible to lipid peroxidation; therefore diets high in polyunsaturated fat could result in increased consumption of oxidized lipids present in the diet or increased lipid peroxidation in the body. Lipid peroxidation could affect carcinogenesis in a number of ways. Several products of lipid peroxidation are very toxic (Chow, 1999) and could influence the carcinogenic process through toxicity as described earlier. Lipid peroxidation products have the potential to exert genotoxicity and therefore could bring about tumor initiation. One of the products of lipid peroxidation is malondialdehyde, which forms DNA adducts and is mutagenic (Marnett, 2002). Another potential product is the hydroxyl radical, which can form DNA adducts such as 8-hydroxyguanosine (Poulsen, 2005). Finally, oxidation products could act on signal transduction pathways leading to altered cell proliferation or apoptosis (West and Marnett, 2006).

G. Induction of Specific Gene Expression

Altering the level of dietary fat changes the expression of many genes. Most of the genes studied, however, are related to carbohydrate or lipid metabolism and are not likely to play a role in carcinogenesis (Hillgartner et al., 1995). Dietary fat may alter signal transduction pathways that lead to altered cell proliferation or apoptosis. Fatty acids have been found to bind to several transcription factors, including the peroxisome proliferator-activated receptors (PPARs), PPARα, PPARβ, and PPARγ; the liver X receptors (LXRs), LXRα and LXRβ; and hepatocyte nuclear factor-4 (HNF-4) (Jump, 2004). PPARα activators induce hepatic tumors, but only in specific rodent species (O'Brien et al., 2005); PPARγ, however, has antineoplastic properties (Wang et al., 2006). Several studies have examined effects on protein kinase C (PKC), which consists of at least 12 subtypes (Jump, 2004). Increasing the fat content of the diet has been found to increase PKC activity in the colon, skin, and mammary gland (Birt, 1995; Hilakivi-Clarke and Clarke, 1998; Lafave et al., 1994; Pajari et al., 1997; Rao et al., 2000; Reddy et al., 1996).

Several papers have been published on the effect of dietary fat on the expression of oncogenes and tumor suppressor genes. In the colon, Guillem et al. (1988) found that dietary fat did not affect the expression of either c-*myc* or c-H-*ras* oncogenes in normal or tumor tissue, whereas Singh et al. (1997)

found that dietary corn oil increased AOM-induced expression of *ras*. In contrast, fish oil was found to inhibit *ras* expression. In the mammary gland, DeWille et al. (1993) found that high corn oil diets increased *ras* mRNA levels in mammary tumors from MMTV/v-Ha-*ras* transgenic mice. However, high-fat diets decreased the frequency of *ras* mutations in rat mammary gland tumors induced by the heterocyclic amine 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) (Roberts-Thomson and Snyderwine, 1997). Substituting n-3 fatty acid-rich oils for corn oil decreased the expression of the H-*ras* oncogene in the mammary gland in one study but had no effect in the other (Karmali et al., 1989; Ronai et al., 1991).

V. SUMMARY AND CONCLUSIONS

Clearly there is much variability in studies of dietary fat and cancer, both in epidemiological and experimental studies. In epidemiological studies, a relationship between dietary fat and breast cancer has been found in correlational and case–control studies, but prospective studies do not support a role for dietary fat. Prospective epidemiological studies examining the role of dietary fat in the development of colon, pancreatic, and prostate cancers have produced conflicting results. The Women's Health Initiative intervention studies did not show any significant effects for dietary fat in the development of either colon or breast cancer in women. In experimental studies, dietary fat generally enhances chemically induced skin, liver, pancreatic, and mammary carcinogenesis, whereas conflicting results have been seen in colon carcinogenesis. Dietary fat appears to act primarily during the promotional stage of carcinogenesis in all of these models except the liver, where the effect of dietary fat is primarily on initiation. Because of the variability seen in studies of dietary fat and cancer (particularly prospective epidemiological studies), it cannot be stated unequivocally at this time that human cancer can be prevented by decreasing the fat content of the diet.

The mechanisms by which high-fat diets enhance experimental carcinogenesis are unclear, but probably involve several mechanisms, some of which are organ specific. Nearly all of the mechanisms by which dietary fat may influence carcinogenesis involve alterations in genetic expression. The determination of genes which are turned on or off by dietary fat or its metabolic or oxidative products will likely provide answers as to the role of dietary fat in carcinogenesis.

46 Fatty Acids and Renal Disease

Stuart K. Ware

CONTENTS

I. INTRODUCTION

It has long been known that diet affects kidney function. However, whether lipids and their metabolic products affect the development of kidney disease is still under investigation. Various polyunsaturated fatty acids (PUFAs) serve as precursors for the production of eicosanoids (ECs), which are known to affect blood flow and blood pressure in the kidney, platelet aggregation, and inflammation. EC metabolism appears altered in a variety of renal pathophysiological states. Enhanced synthesis of certain ECs has been reported in various renal diseases and may delay further deterioration of kidney function, and the administration of such ECs often retards the development of or improves the disease. However, other ECs may contribute to renal disease as suggested by the improvement in renal function that occurs when inhibitors of these particular compounds are administered. Thus, the dietary PUFA intake may modulate some renal diseases, because the types of ECs produced are dependent on the quantity and composition of the dietary fatty acids. Indeed, a reduction in the progression of renal injury has been demonstrated in experimental animals given fatty acid precursors of ECs. Because certain ECs seem to promote renal injury, whereas others appear to protect the diseased kidney from further damage, the dietary significance of these observations are not yet clear. Other, noneicosanoid-mediated effects of fatty acids that may be beneficial or harmful to renal function include changes in blood rheological properties, membrane composition and function, and serum lipid concentrations.

II. BASIC RENAL FUNCTION

The kidneys are the guardians of the internal environment. That is, maintenance of the composition and volume of the extracellular fluid (and indirectly the composition of the intracellular fluid) is the primary function of the kidneys. Body balances of water and of many of the electrolytes of the extracellular fluid such as sodium, potassium, chloride, and inorganic acids are regulated primarily by the kidneys (i.e., the intake and/or metabolic production of such substances must equal their excretion and/or metabolic consumption). The kidneys are also important in excreting waste products such as urea, uric acid, and creatinine and in the elimination from the body of many foreign chemicals such as drugs, pesticides, food additives, and their metabolites. Other significant functions of the kidneys include the regulation of arterial blood pressure through their role in regulating sodium balance and blood volume, their participation in the renin–angiotensin system, and their production of various vasoactive substances such as ECs; the regulation of erythrocyte production by the bone marrow via the renal hormone erythropoietin; the hydroxylation of vitamin D to its active form; and gluconeogenesis during starvation.

Each kidney is composed of roughly 800,000 microscopic units called nephrons, which are considered to be the basic functional units of these organs (Figure 46.1). Since each nephron is capable of forming urine by itself, kidney function can be described by explaining the function of a single nephron. Each nephron is composed of a filtering component called the renal corpuscle (consisting of glomerular capillaries and Bowman's capsule), a renal tubule extending from it, and a peritubular capillary bed. The glomerular capillaries extend into the hollow Bowman's capsule, much like a fist pushed into an inflated balloon. The space inside the capsule (balloon) is Bowman's space, and it is into this cavity that fluid filters from the glomerular capillaries by crossing the capillary and capsular membranes. The vessel delivering blood to the glomerular capillaries is called the afferent arteriole (it descends from the renal artery), and blood leaving the glomerular capillaries enters into an efferent arteriole. Bowman's space is continuous with the first portion of the tubule, and the glomerular filtrate entering Bowman's space simply continues on into the tubule. The tubule itself, composed of a single layer of epithelial cells continuous with that of Bowman's capsule,

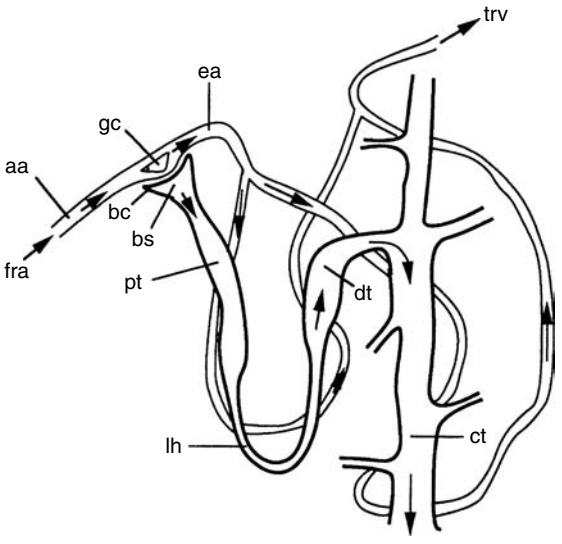

FIGURE 46.1 Nephron structure. aa, afferent arteriole; bc, Bowman's capsule; bs, Bowman's space; ct, collecting tubule; dt, distal tubule; ea, efferent arteriole; fra, blood from renal artery; gc, glomerular capillaries; lh, loop of Henle; pt, proximal tubule; trv, blood returning to renal vein. Arrows show direction of blood and filtrate flow. The blood vessels branching from ea are the peritubular capillaries.

is divided into segments corresponding to differences in morphology and function. The proximal tubule drains Bowman's capsule and extends into the deeper portion (medulla) of the kidney. The tubule then forms a hairpin loop (the loop of Henle) and returns toward the kidney surface (cortex) as the distal tubule. The distal tubule eventually joins the collecting tubule, which again runs deep into the kidney. The collecting tubule conveys fluid from several nephrons into the renal pelvis. The fluid is not altered in composition after it leaves the collecting tubule; thus, fluid in the renal pelvis is identical to urine, and urinary structures distal to this point are used simply to transport or temporarily store the urine.

The renal corpuscle acts as a high-pressure filter. Normally, about 20% of the blood plasma entering the glomerular capillaries is filtered into Bowman's space. The remainder moves on into the efferent arteriole. This arteriole soon divides into a set of capillaries, the peritubular capillaries, which are distributed to all portions of the renal tubule. This arrangement allows for the transport (not filtration) of water and solutes between the tubular lumen and the peritubular capillaries (Figure 46.2). The peritubular capillaries eventually drain into the renal vein, which returns blood to the general systemic circulation. Although not shown in Figure 46.1, the peritubular capillaries of a given nephron usually associate with the tubules of several nephrons, and each tubule is supplied with peritubular blood from several other nephrons.

There are three basic processes by which urine is formed: filtration, reabsorption, and secretion (Figure 46.2). Owing to the pressure of the blood in the glomerular capillaries, an essentially protein-free plasma is filtered into Bowman's space. Fluid that becomes glomerular filtrate must pass through several membranes making up the renal corpuscle (capillary endothelium, basement membranes, and Bowman's capsule epithelium). These membranes do not hinder the passage of small molecules (such as water, electrolytes, and nutrients) but large protein molecules cannot cross. As this filtrate passes through the renal tubule, its composition and volume are altered by the processes of reabsorption and secretion. Each substance in plasma is precisely regulated by a particular combination of filtration, reabsorption, and/or secretion, and these three basic processes are controlled by complex homeostatic mechanisms occurring both inside and outside the kidney. For most substances, the rate of reabsorption is the primary mechanism used to control their concentrations in the body fluids (notable exceptions are potassium and hydrogen ions that are controlled

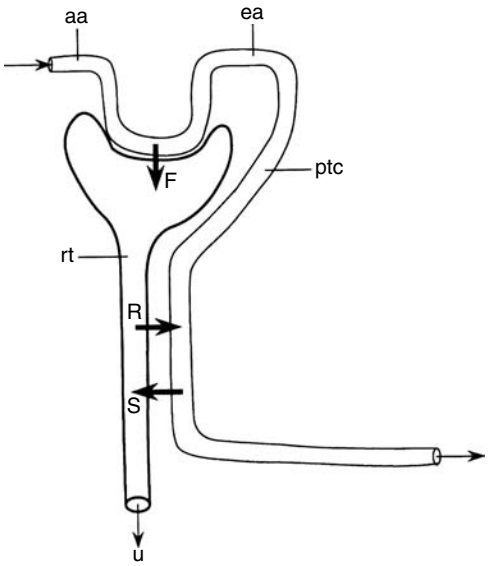

FIGURE 46.2 Basic nephron function. aa, afferent arteriole; ea, efferent arteriole; F, glomerular filtration; ptc, peritubular capillary; R, reabsorption; rt, renal tubule; S, secretion; u, urine flow (excretion).

primarily by secretion). That is, most substances in plasma are filtered into Bowman's space, and then as the filtrate flows through the renal tubule, unwanted substances fail to be reabsorbed and are thus excreted in urine, whereas needed substances are reabsorbed back into the blood. The kidneys filter large quantities of water and solutes from the plasma into the renal tubules each day (the glomerular filtration rate [GFR] is normally about 125 mL/min; that is, each minute about 125 mL of protein-free plasma is filtered into Bowman's space). Again, the rate at which such filtered substances are reabsorbed is the key to their regulation. Reabsorption of many solutes occurs by active transport. Water moves passively by osmosis once an osmotic gradient is established by active solute (primarily sodium chloride) reabsorption. Between 70% and 90% of the glomerular filtrate is reabsorbed from the proximal tubule, including nutritionally important solutes such as glucose, vitamins, and amino acids.

To summarize, the glomerular filtrate (plasma minus proteins) derived from the renal blood traverses the renal tubule and enters the pelvis of the kidney as urine. Along the way, substances are selectively reabsorbed (water, electrolytes, and nutrients) or secreted (potassium and hydrogen ions) by the tubular epithelium. Reabsorption plays a much greater role than does secretion in the formation of urine. About 99% of the water in the glomerular filtrate is eventually reabsorbed. Constituents of the filtrate not reabsorbed to the same extent as water will therefore be concentrated in the urine, and their concentrations in the extracellular fluids will decrease. In this way, the nephron separates substances that are to be conserved from those that are to be eliminated. For additional information on basic renal function, the reader should consult textbooks on renal physiology such as those of Rennke and Denker (2006) and Brenner et al. (1987a).

III. RENAL EICOSANOIDS AND LEUKOTRIENES

The ECs and leukotrienes (LTs) are groups of bioactive lipids synthesized from 20-carbon polyunsaturated essential fatty acids, and enzymes involved in their metabolism are present in the tissues of the kidneys, especially the renal medulla (Figure 46.3). The numbering of the compounds

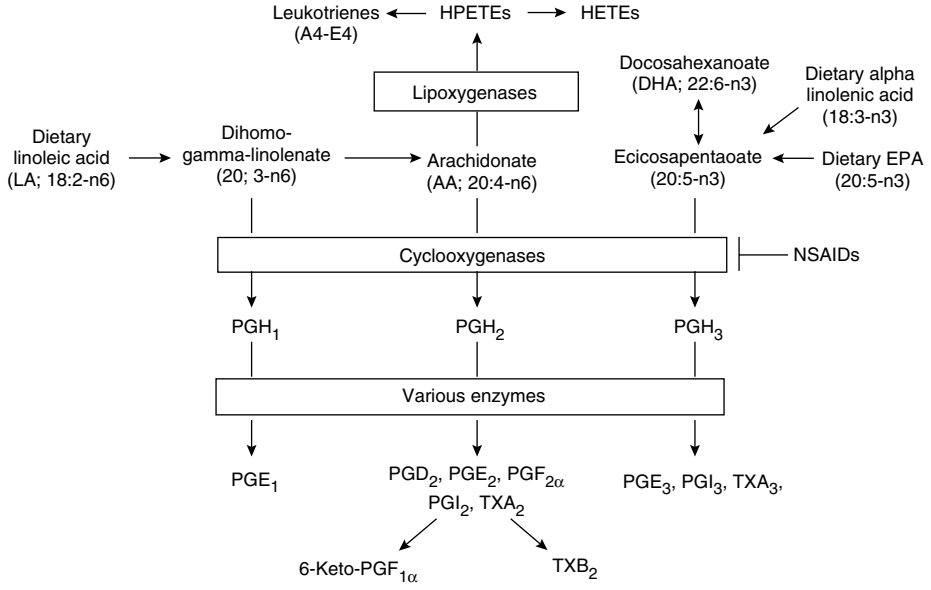

FIGURE 46.3 Renal production of eicosanoids and leukotrienes. EPA is also a source of leukotrienes of the five series.

denotes the number of double bonds (those derived from arachidonic acid (AA) have two, the eicosapentaenoic acid (EPA)-derived ECs have three, and the LTs have four). The ECs and LTs mostly function as autocrine and paracrine mediators. There are specific receptors for all ECs and LTs, allowing for pharmacological blockade of specific compounds. In general, ECs mediate local symptoms of inflammation, control of blood flow through vasoconstriction or vasodilation, blood coagulation, fever, and pain. The cyclooxygenase (COX) II isoform is responsible for inflammation and pain. The COX I isoform is responsible for platelet (coagulation) functions. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit the COX II isoform. LTs also play an important role in inflammation, and blocking their receptors may be useful in the management of some inflammatory diseases.

The most plentiful fatty acid precursor is arachidonic acid (AA; 20:4n-6), which is synthesized from the essential dietary fatty acid linoleic acid (LA; 18:2n-6). Thus, the membrane concentrations of AA are influenced by dietary levels of LA (the first step in EC synthesis is the release of the 20-carbon fatty acid from membrane phospholipids by phospholipase A_2 or from diacylglycerol by phospholipase C). LA is desaturated and elongated to form AA, and therefore both the intake and enzymatic regulation of this dietary lipid can alter the amount of AA available for EC biosynthesis. ECs are not stored, and the rate-limiting step in their biosynthesis appears to be the release of AA from membrane phospholipids into the intracellular environment in response to various stimuli that activate phospholipase A_2 and other acylhydrolases. Such stimuli include renal ischemia, mechanical trauma, stimulation of renal nerves, angiotensin II, and catecholamines. COX acts on AA to form the endoperoxide prostaglandin H_2 (PGH_2), which is then converted to the stable metabolites PGE_2 (a potent vasodilator), $PGF_{2\alpha}$ (which may be a weak vasoconstrictor), PGD_2 (a vasodilator), and the unstable metabolites thromboxane A_2 (TXA_2; a potent vasoconstrictor and stimulator of platelet aggregation) and PGI_2 (prostacyclin; a potent vasodilator and platelet inhibitor). The major ECs produced by the kidneys appear to be PGE_2 and PGI_2, with smaller amounts of $PGF_{2\alpha}$, TXA_2, and PGD_2, and the production of these ECs may be significantly increased in some renal disorders. Indeed, an upregulation of AA metabolism generally accompanies renal pathophysiological conditions (Lefkowith and Klahr, 1996). Different segments of the nephron, renal vasculature, and renal interstitium may synthesize different amounts and types of ECs (Figure 46.4). For example, in rats, PGI_2 is the primary product of the renal arteries and afferent arterioles, where it has a major influence on renal vascular tone, whereas PGE_2 is found in high concentration in the glomerulus correlated with its action on renin release (Terragno et al., 1978). The renal pattern of EC production can also be species specific. Human glomeruli produce mostly PGI_2 (Sraer et al., 1983), compared to rat glomeruli which synthesize primarily PGE_2. The ECs have diverse actions in the kidneys, including the modulation of renal blood flow (RBF) and its regional distribution (Herbaczynska-Cedro and Vane, 1973), GFR (Dworkin et al., 1983), water (Dunn, 1984), and solute (Kaojaren et al., 1983) flux across renal tubular membranes, and renin secretion (Larsson et al., 1974). However, under normal conditions, RBF and GFR are probably not EC dependent. The ECs are eventually metabolized in the kidney to compounds with minimal biological activity.

AA is converted by lipoxygenase enzymes into hydroperoxyeicosatetraenoic acids (HPETEs), which undergo dehydration to monohydroxy forms (HETEs). At least three such enzymes exist. The 12- and 15-lipoxygenases generate 12- and 15-HETE, whereas the 5-lipoxygenase pathway forms LTA_4 and 5-HETE. LTA_4 can then be converted to LTB_4 and LTC_4, and these products released from the cell. LTs D_4 and E_4 can then be produced from LTC_4 in plasma. It appears that the kidney can produce 5-lipoxygenase products, but whether glomerular cells can do so is uncertain (Pirotzky et al., 1984). Cells in the kidney also contain 12- and 15-lipoxygenase enzymes. LTs appear to have vasoconstrictive properties in the kidneys, probably by direct actions on vascular smooth muscle cells, at least in the rat (Rosenthal and Pace-Asciak, 1983). The renal vasculature in the dog may be insensitive to the LTs (Chapnick, 1984), and human studies are lacking. The LTs also play a role in immunological and inflammatory reactions by stimulating leukocyte chemotaxis and their degranulation (Goetzl et al., 1977; Ford-Hutchinson et al., 1980). Even if all of the known lipoxygenase

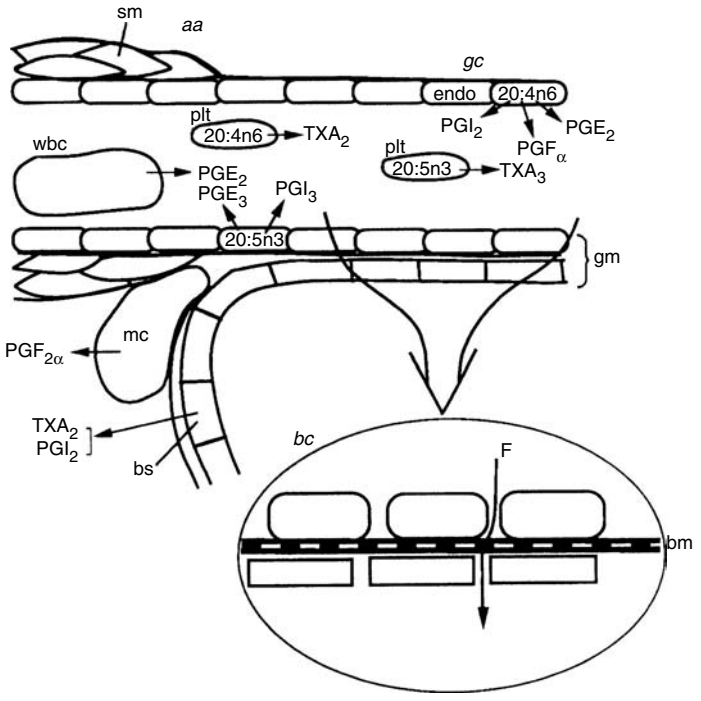

FIGURE 46.4 Sources of eicosanoids in the kidney. aa, afferent arteriole; bc, Bowman's capsule; bm, basement membrane; bs, Bowman's space; endo, endothelium; F, filtration; gc, glomerular capillary; gm, glomerular (renal corpuscle) membrane; mc, mesangial cell; plt, platelet; sm, smooth muscle; wbc, white blood cell.

enzymes are not present in renal cells, infiltrating neutrophils and other inflammatory cells may contain them. Thus, the lipoxygenase pathway may be especially important in inflammatory renal diseases. LT receptors are found in renal cells, and both LTC_4 and LTD_4 stimulate mesangial cell (glomerular) contraction, which may modulate glomerular hemodynamics and filtration. LTC_4 is known to decrease both the RBF and GFR and to alter the permeability of the glomerular membrane (Badr et al., 1984). The LTs may also modulate renal function through the activation of phospholipases and the subsequent production of COX metabolites (Cramer et al., 1983). The physiological actions of the lipoxygenase products on the kidney are not as well understood as those of the COX products. The term *eicosanoid*, as used in this chapter, refers primarily to the prostaglandins and thromboxanes (collectively called the prostanoids) rather than to the lipoxygenase metabolites (the LTs). A renal cytochrome P-450-dependent monooxygenase has been found that converts AA into various products (Schwartzman et al., 1986), but the renal significance of this pathway is largely unknown. Rats treated with fish oil showed increased hepatic concentrations of cytochrome P-450, but renal concentrations were not changed (Valdes et al., 1995).

When eicosapentaenoic acid (EPA; 20:5n-3) is the substrate for COX, the products are PGE_3 and PGI_3 (Knapp et al., 1986), which are vasodilators, and TXA_3. Unlike TXA_2, TXA_3 is not a potent vasoconstrictor and does not stimulate platelet aggregation (Needleman et al., 1979). Whereas n-6 PUFAs increase AA and the 2-series ECs, the n-3 PUFAs competitively inhibit the conversion of n-6 precursor fatty acids to AA; suppress production of the 2-series ECs, and the PGI_3 produced decreases platelet aggregability. Thus, enriching the diet with EPA at the expense of AA may be of benefit in diseases characterized by platelet activation and/or vascular smooth muscle contraction (Leaf and Weber, 1988). Very high does of EPA (about 10 g/day) are required to reduce the platelet production of TXA_2 by 85% in humans (Knapp et al., 1986), but little information is available regarding the dose-response relationship between fish oil and renal TXA_2 production in humans.

It is apparent that there is upregulation of AA metabolism with several renal diseases (Lianos et al., 1991; Yanagisawa et al., 1993) resulting in the production of he beneficial ECs PGE_2 and PGI_2 that suppress immune function and enhance renal hemodynamics, but also produced are TXA_2 and LTs that oppose these actions (Badr, 1992; Remuzzi et al., 1992). We now know that glomerular infiltration by platelets and neutrophils is obligatory for the upregulation of AA metabolism, probably by bringing in the necessary enzymes (such as COX and thromboxane synthetase), and also for the accompanying renal dysfunction leading to proteinuria (Couser, 1993; Wu et al., 1993). It is possible that the upregulation of AA results from activation of the inducable COX isozyme (COX 2) (Obanion et al., 1992) in leukocytes and resident mesangial cells by cytokines (Rzymkiewicz et al., 1994) or nitric oxide (Tetsuka et al., 1995) derived from leukocytes, macrophages, and mesangial cells. In this context, protection from inflammatory renal damage may occur by the use of inhibitors of COX 2 (Masferrer et al., 1994) or nitric oxide synthesis (Narita et al., 1995). Glomerular influx of monocytes and macrophages occurs at a later stage in renal disease and, by interaction with resident glomerular cells, causes glomerulosclerosis (GS) (Couser, 1993; Nikolic-Paterson et al., 1994). Since both n-3 fatty acid supplementation and essential fatty acid deprivation exert an anti-inflammatory effect by decreasing neutrophil chemotaxis (Lee et al., 1985), reducing LTB_4 synthesis (Lefkowith et al., 1990) and cytokine production (Endres et al., 1989), and decreasing nitric oxide production (Boutard et al., 1994) and the secretion of platelet-activating factor (PAF) (Sperling et al., 1987), such dietary changes may be of benefit in the treatment of inflammatory renal diseases such as glomerulonephritis (GN) and in preventing sclerosis.

The functions of ECs on the kidneys have been determined with the use of both COX inhibitors and exogenous ECs. NSAIDs are potent inhibitors of COX, and conventional doses of NSAIDs have been shown to reduce urinary ECs by 50%–80% (Gafni et al., 1978). The enzyme inhibition is probably greater in the renal cortex (where most of the glomeruli are located) than in the medulla (composed mostly of renal tubules) (Attallah, 1979). NSAIDs may, under certain circumstances, have adverse effects on renal function (Kimberly and Plotz, 1977; Ciabattoni et al., 1984). When NSAIDs are given to healthy individuals, no obvious changes occur in the RBF or GFR (Gullner et al., 1980); thus, under these conditions, renal functions do not seem to be EC dependent. However, individuals subjected to circulatory compromise (such as with heart failure, shock, or volume depletion) and those with preexisting renal dysfunction may react to NSAIDs with a reduction in kidney function that leads to acute renal failure (ARF) (Walshe and Venuto, 1979). This is thought to occur because the vasoconstrictive actions of catecholamines and angiotensin II (found in high concentrations with circulatory failure), or the already low RBF, are being counteracted by the intrarenal vasodilatory ECs (the most important may be PGI_2, since it is produced in renal vessels). The full ischemic action of the vasoconstrictors becomes evident when EC production is impaired by the NSAIDs. The more profound the circulatory compromise or renal failure the ECs are counteracting, the more deleterious will be the effects of COX inhibition. The harmful effects of NSAIDs on renal function are usually reversible once the drugs are discontinued, but not always (Kleinknecht et al., 1980). Thus, whenever blood pressure and cardiac output are threatened, the levels of circulating vasocontrictors increase and sympathetic activity is enhanced. To protect the function of the kidneys, renal vasodilator ECs are produced in response to such vasoconstrictive forces. Patients at high risk for developing complications with NSAIDs include those with low circulating blood volume, chronic renal failure (CRF), and the elderly (Henrich and Diamond, 1989). In some renal disorders, NSAIDs may improve renal functions; a reduction in proteinuria in patients with nephrosis has been noted (Arisz et al., 1976).

Drugs that inhibit the formation of the vasoconstrictor TXA_2 without causing a reduction in vasodilator ECs could be of advantage where the maintenance of renal function is dependent upon such vasodilators (Ciabattoni et al., 1984; Patrignani et al., 1984). Thromboxane receptor antagonists could also e therapeutically important, since they may selectively inhibit TXA_2 action without affecting the action of other ECs (Harris et al., 1984). It should be pointed out that by inhibiting certain metabolic pathways, enzyme-inhibiting drugs may shunt substrates to alternative pathways.

For example, inhibition of thromboxane synthetase may shunt endoperoxides toward an enhanced synthesis of the vasodilators PGE_2 and PGI_2, and indomethacin (an NSAID) could divert AA toward the vasoconstrictive and chemotaxic lipoxygenase pathway. Thus, an enzyme inhibitor may have actions that decrease the synthesis of undesired metabolites and increase the synthesis of beneficial ECs, or vice versa.

Some studies indicate that additional dilatory ECs are synthesized by the kidneys with renal failure or disease (Blum et al., 1981; Lianos et al., 1983; Schambelan et al., 1985), most likely as a compensatory reaction to the impaired renal function; however, exceptions have been noted (Ciabattoni et al., 1984). It appears that with certain renal diseases, vasodilatory ECs are important in sustaining the remaining functions of the kidney. The source of the additional vasodilatory ECs in some renal diseases may be inflammatory cells and fibroblasts (Nagle et al., 1976). In animal models of ARF, tubular necrosis due to impaired RBF may be prevented if vasodilator ECs are given before or at the time of the renal ischemia (Werb et al., 1978). However, deciphering the normal effects of renal ECs on renal function based on studies utilizing exogenous ECs may be difficult, because intravenous and intrarenal infusions may not distribute the ECs to the sites within the kidney where they are normally produced and have their actions.

Despite the evidence for enhanced EC production in experimental and clinical renal disease, the actual sources of the ECs remain equivocal, because both circulating and renal ECs appear in urine. Possible sources include infiltrating blood cells such as leukocytes (Goldstein et al., 1978) and platelets (Needleman et al., 1976) as well as the renal cells themselves (Ardaillou et al., 1983). Human studies have suggested that the major urinary metabolite of TXB_2 (2,3-dinor-TXB_2) is a sensitive marker of *in vivo* platelet activation, whereas urinary TXB_2 reflects the renal synthesis of the parent compound TXA_2 (FitzGerald et al., 1983; Catella et al., 1986). However, increased urinary TXB_2, together with 2,3-dinor-TXB_2, has been documented in patients with extrarenal platelet activation and normal renal function (Reilly et al., 1986). Under some circumstances, urinary EC excretion parallels the urine flow rate (Walker et al., 1981), and it is unclear if this actually represents an increased synthesis of ECs. Nevertheless, most investigators assume that urinary excretion rates of TXB_2 and 2,3-dinor-TXB_2 represent the synthesis rates of TXA_2 by renal and extrarenal sources, respectively. Urinary 6-keto-$PGF_{1\alpha}$ is thought to reflect intrarenal PGI_2 synthesis (Pugliese and Ciabattoni, 1983). Since infused PGE_2 and $PGF_{2\alpha}$ are not recovered as such in the urine, urinary PGE_2 and $PGF_{2\alpha}$ are usually considered of renal origin (Frolich et al., 1975).

To summarize the basic actions of the ECs (Table 46.1), renal vasoconstriction is caused by TXA_2, $PGF_{2\alpha}$, and possibly by the LTs, and these actions are countered by PGE_2 and PGI_2, which are potent vasodilators. Renal vasodilation is also elicited by PGE_1, PGD_2, PGE_3, and PGI_3. However, since PGI_2 and PGE_2 stimulate renin release and the subsequent production of the vasoconstrictor angiotensin II, under certain circumstances their indirect actions may result in vasoconstriction. Platelet aggregation is enhanced by TXA_2 and inhibited by PGI_2 and PGI_3. Additionally, from an inflammatory and immunological perspective, LTs are chemotactic, and PGE_2, PGI_2, and the 3-series prostaglandins may suppress neutrophil and T-cell function and reduce antibody production. The major renal ECs are PGE_2 and PGI_2, which are derived from dietary n-6 PUFAs. For additional information on renal ECs and LTs, see the reviews by Morrison (1986) and Ballermann et al. (1986).

IV. RENAL DISEASE

There are a large number of renal and extrarenal disorders that alter the function of the kidneys. As discussed earlier, the kidneys have many important functions, all of which are liable to suffer when the kidneys are affected by disease processes. This is especially true when the renal disease is chronic.

Many diseases that affect the kidneys cause a reduction in the GFR. However, compensatory mechanisms occur to help preserve homeostasis of the body fluids (Deen et al., 1974; Brenner, 1985). First, there is hypertrophy of the remaining functional nephrons, and their performance is

TABLE 46.1
Principal Actions of Renal Eicosanoids and Leukotrienes

Compound	Renal Actions
Leukotrienes	Vasoconstriction, proinflammatory
PGE_1	Vasodilation, suppresses immune functions
PGE_2	Vasodilation, suppresses immune functions, stimulates renin release
PGI_2	Vasodilation, inhibits platelets, suppresses immune functions, stimulates renin release
$PGF_{2\alpha}$	Vasoconstriction
PGD_2	Vasodilation
TXA_2	Inhibits platelets
	Vasoconstriction, stimulates platelets, proinflammatory
PGE_3	Vasodilation, suppresses immune functions
PGI_3	Vasodilation, suppresses immune functions, inhibits platelets
TXA_3	Not as vasoconstrictive nor pro-platelet as TXA_2

The 1 and 2-series ECs and the leukotrienes are derived from dietary n-6 PUFAs; the 3-series ECs originate from dietary n-3 PUFAs. The major renal ECs are PGE_2 and PGI_2.

enhanced such that the reduction in the total GFR is proportionately less than the reduction in the functional renal mass. That is, single-nephron GFR (SNGFR) increases, although the overall GFR may decrease. Second, as the plasma concentration of solutes increases, more of the solutes will be filtered into Bowman's space at a given GFR, because solute filtration is proportional to the plasma concentration of the solute. Thus, the content of solutes in the extracellular fluid will not increase indefinitely provided some glomerular filtration occurs. Third, reabsorption rates may decrease and secretion rates increase. Thus, more solutes are excreted by functional changes in these two mechanisms, and this serves further to reduce the accumulation of compounds as the kidneys fail.

A reduction in the GFR may occur because of various circulatory problems, such as hypotension, heart failure and circulating volume depletion resulting from edema or blood loss. It can also result from damage to nephrons caused by immune disorders, infections, nephrotoxins, renal vascular diseases, hypertension, and chronic urinary tract obstruction. When the overall GFR is reduced, circulating volume overload may occur, resulting in more hypertension and further nephron injury and loss. With nephron injury comes proteinuria (protein in the urine) and thus edema resulting from a reduction in blood oncotic pressure. Thus, despite a compensatory increase in the GFR in some nephrons, the above described positive-feedback cycle between nephron damage and a reduced GFR can ultimately lead to renal failure. The physiological disturbances and clinical symptoms which then occur are referred to as uremia. With chronic nephron loss, tubule damage, and reduced GFR, one would anticipate bone disease due to impaired vitamin D production, anemia caused by an inadequate erythropoietin secretion, an inability adequately to excrete water and various solutes, proteinuria, hematuria (blood in the urine), metabolic acidosis due to decreased acid excretion, edema, elevated blood urea and creatinine (azotemia), and other complications of CRF. Without dialysis or transplantation, death may ensue.

Acute renal failure (ARF) refers to a rapid decline of renal function in a patient whose renal function was previously normal. The GFR may drop precipitously within a few hours. Azotemia develops rapidly and is the clinical hallmark of ARF. ARF can occur with a variety of renal and extrarenal disorders, such as diminished perfusion of the kidneys (owing to heart failure blood loss, or shock) resulting in a reduced GFR and/or tubular necrosis, from inflammatory or immunological processes, from metabolic derangements, or from obstructions to urine flow. Toxic substances (such as lead, mercury, or some antibiotics) can alter renal function and may cause tubular necrosis. The most common cause of ARF is as a complication of catastrophic illness, and the pathological

process is usually assumed to be acute tubular necrosis. Treatment is directed toward correcting the primary problem so that the renal pathological process can heal itself. Dialysis may be appropriate in some cases. In ARF, it is often possible to reverse the deterioration in renal function if prompt treatment is initiated.

Chronic renal failure (CRF) is a syndrome in which there is a progressive and usually irreversible decrease in the GFR even when the disease that caused the renal damage has disappeared or abated. CRF (like ARF) occurs in association with a variety of primary renal diseases (such as inflammation and infection of the kidneys), systemic diseases (diabetes mellitus, hypertension, atherosclerosis, and lupus erythematosus), and nephrotoxins, with the most common histological manifestations of CRF being glomerular damage. Some investigators believe that immunological mechanisms account for the initial damage in many chronic renal diseases; however, the rate of progression may be influenced by a variety of nonimmunological factors. At the end of their clinical course, patients are said to have end-stage renal disease, and dialysis or transplantation may be necessary. More than 40,000 patients enter treatment for end-stage renal disease each year in the United States, most often due to diabetes and hypertension (Brazy, 1993).

By way of summary, all causes of acute and CRF can be classified into three basic groups. *Prerenal causes* of kidney failure include renal diseases resulting from a disordered perfusion (inadequate blood flow) of an otherwise normal kidney due to changes in the function of structures such as the heart or renal arteries, or drug effects on renal perfusion. Most cases of ACF are due to prerenal causes. *Renal causes* of failure include diseases of the small arteries feeding the glomeruli and/or the glomeruli themselves, disorders of other parts of the nephron and the interstitial tissue surrounding it, and intratubular obstructions. These disorders cause direct damage to the nephrons. *Postrenal causes* of kidney failure usually entail obstruction of the urinary system distal to the kidney. Obstructions of the urinary tract occur due to things such as tumors, prostatic hypertrophy, spasm, or drug effects, and these are among the most reversible causes of renal failure if caught early. ARF occurs abruptly and may be treated effectively if intervention is started early (some cases of ARF resolve spontaneously). CRF is insidious, slow to develop, and progressive and may be lethal without transplantation.

Some of the more common renal diseases, which may present as either acute or CRF, will be briefly discussed. Nephritis is an inflammation of the renal glomeruli. Azotemia, hematuria, and proteinuria are common, as is hypertension. There are many forms of nephritis recognized clinically, and several of these are dealt with later in this chapter with regard to their modulation by renal ECs and dietary fatty acids. Nephritis is thought to be immunologically mediated. Its causes are not well understood, but it often occurs following an infection or may develop as part of another disease (such as lupus erythematosus). Inflammation of the glomerulus increases the permeability of the glomerular membrane and causes proteinuria and hematuria. Progressive glomerular injury frequently results in GS (a thickening and hardening of the glomerular vasculature leading to obliteration of the glomerular capillary bed) and thus further disruption of kidney function, often leading to end-stage renal disease.

Nephrosis refers to renal disease where glomerular changes cause edema and massive proteinuria; hypertension is usually absent. Hyperlipidemia is common with nephrosis, but the pathogenesis of this disease is not completely understood (attenuation of mevolonate degradation by the kidneys is thought to be a contributory mechanism). The glomerular lesion in nephrosis is not inflammatory. Causes of nephrosis include infectious agents, poisons, and various metabolic disturbances.

Nephrotoxic renal disease occurs when a toxin or drug capable of destroying renal cells (especially tubules) is introduced into the body. Some nephrotoxins, such as those that cause nephrotoxic serum nephritis (NSN), damage the glomeruli, usually by causing an immune reaction there. Renal injury may also result from deposition of biologically active compounds such as immunoglobulins and lipoproteins or their lipid constituents in kidney tissues. Other factors that may initiate and sustain renal injury include renal blood coagulation and various factors released from renal cells and infiltrating leukocytes and platelets. For additional information on renal dysfunction, the reader

should consult textbooks on nephrology such as those of Brenner et al. (1987b), Johnson (2003), and Brenner (2004).

A. Obesity and Renal Disease

High body mass index (BMI) has been reported to be a strong risk factor for the development of end-stage renal disease in humans, independent of blood pressure and diabetes mellitus (Hsu et al., 2006). Obesity (as an increased abdominal waist circumference) is one of the defining criteria of the metabolic syndrome (along with hypertriglyceridemia, low serum LDL level, raised blood pressure, and an elevated fasting blood glucose level), and this syndrome has been shown to be a strong independent risk factor for chronic kidney disease (Chen et al., 2004; Reisin and Alpert, 2005). Kurella and coworkers (2005) showed that as the number of traits of the metabolic syndrome increased in nondiabetic adults, so did the odds of developing chronic kidney disease. The mechanisms linking metabolic syndrome to renal disease may include impaired pressure natriuresis, insulin resistance, excess excretory load, endothelial cell dysfunction, chronic inflammation, hyperfiltration, and a prothrombotic status (Zhang et al., 2005). Obesity in dogs caused by a high-fat diet is associated with glomerular hyperfiltration, thickening of the glomerular membrane, proliferation of mesangial cells, activation of the rennin–angiotensin system, and expansion of Bowman's capsule (Henegar et al., 2001) and obesity is associated with the eventual development of GS (Praga, 2002). Diet-induced obesity in mice has been shown to cause lipid accumulation in the kidneys, GS, and proteinuria, and the effects were mediated by a sterol regulatory element-binding protein (SREBP) pathway (high fat feeding stimulates this pathway) that activates genes involved in fatty acid and cholesterol synthesis (Horton et al., 2002; Jiang et al., 2005). It has also been reported that inhibition of cholesterol synthesis by HMG-CoA reductase inhibitors may protect against diabetic and nondiabetic renal disease (Bianchi et al., 2003; Guan, 2004). Studies have linked obesity with the presence of low-grade systemic inflammation (Ziccardi et al., 2002; Pedersen et al., 2003) and adipose tissue may contribute to this by secreting inflammatory cytokines such as interleukin-6 (Axelsson et al., 2004) and activation of inflammation-associated signaling pathways (Perreault and Marette, 2001; Hirosumi et al., 2002). The principal source of obesity-related cytokines may come from macrophages that infiltrate adipose tissue rather than adipocytes themselves (Weisberg et al., 2003), and many of these cytokines are postulated to play a role in renal pathophysiology (Wolf et al., 2002) supporting the suggestion that obesity and lipid-lowering therapies have the potential to improve renal diseases associated with the metabolic syndrome (Schelling and Sedor, 2004). Leptin is a hormone secreted by adipocytes that acts as a regulator of food intake and energy expenditure (it decreases food intake and increases energy expenditure). Blood leptin levels are increased with chronic kidney disease and correlate with C-reactive protein levels, implying that inflammation may be associated with the hyperleptinemia in patients with chronic kidney disease (Mak et al., 2006).

V. FATTY ACIDS, EICOSANOIDS, AND RENAL DISEASE

A. Nonimmunological Renal Disease

a. Subtotal Renal Ablation

The rat with subtotal renal ablation (SRA; partial infarction of one kidney and contralateral nephrectomy) has been used extensively to study the mechanisms underlying the progression of nonimmunological renal disease (Brenner, 1985). Such rats develop proteinuria, hypertension, GS, and chronic progressive renal failure in the viable portion of the remnant kidney (Chanutin and Ferris, 1932; Shimamura and Morrison, 1975); however, the pathogenesis of these abnormalities has not been completely elucidated. Compensatory hypertrophy of the residual renal mass occurs and is accompanied by a marked increase in plasma flow per nephron and in the SNGFR despite a decrease in the total GFR (Deen et al., 1974). It has been suggested that an increase in glomerular capillary pressure

secondary to increased transmission of the systemic blood pressure into the glomerular capillary bed (possibly mediated by vasodilator ECs) may be the adaptive response resulting in the increased SNGFR. However, the enhanced pressure and filtration may ultimately be responsible for the sclerosis and progression of the renal disease (Hostetter et al., 1981; Brenner et al., 1982; Klahr et al., 1988), but this hypothesis has been challenged (Purkerson et al., 1985; Jones et al., 1987; Yoshida et al., 1988). Observations by Berstrom et al. (1986) show that a reduction of blood pressure has a beneficial effect on intraglomerular hemodynamics and retards GS in humans with chronic renal disease regardless of its etiology. Dietary supplementation with either n-6 or n-3 fatty acids has been shown by some investigators to lower systemic blood pressure (Lacono et al., 1975; Norris et al., 1986) and thus may help to reduce such glomerular damage (if it occurs). However, not all workers have found a blood pressure-lowering effect with dietary PUFAs (Puska et al., 1985; Bruckner et al., 1987; Ware et al., 1990, 1992).

It has been shown that renal TXA_2 in rats with SRA is increased (Stahl et al., 1986). Long-term administration of an inhibitor of TXA_2 synthesis in rats with a remnant kidney decreased both proteinuria and urinary TXB_2 excretion, improved renal histology, and enhanced both the single-nephron plasma flow and the SNGFR (Purkerson et al., 1985). It thus appears that in animals with reduced renal mass, TXA_2 has deleterious physiological effects. Stahl et al. (1986) also reported that the glomerular production of PGE_2 is greater in rats with SRA compared to sham-operated controls, and that indomethacin significantly reduces the GFR in these animals. The reduced rate of filtration has been verified for rats (Nath et al., 1987), rabbits (Kirschenbaum and Serros, 1981), and dogs (Altscheler et al., 1978) with reduced renal mass and subjected to COX inhibition. Thus, enhancement of vasodilatory EC production may contribute to the augmented renal hemodynamic response to partial renal ablation. Ikeda et al. (1989) found that rats with SRA showed enhanced TXA_2 and PGI_2 production by the aorta. The former may be a pathological response to the hypertension induced by reduced renal mass, whereas the enhanced prostacyclin synthesis appears to be adaptive.

Similar renal functional changes (hyperfiltration, elevated RBF, glomerular hypertension) are observed in patients with diabetes mellitus during the early phase of diabetic nephropathy (Christiansen et al., 1981). The glomerular production of PGE_2 and $PGF_{2\alpha}$ is enhanced in diabetic rats, but the TXA_2 production is normal (Schambelan et al., 1985). Thus, increased synthesis of vasodilatory ECs may be a compensatory mechanism in diabetic nephropathy as it appears to be in animals with reduced renal mass. It is generally believed that n-3 fatty acids (e.g., EPA) are effective against many renal diseases, including diabetic nephropathy. This was most recently shown by Hagiwara et al. (2006) where they demonstrated that EPA improves the diabetic nephropathy of type 2 diabetic mice, and that this was accompanied by decreased serum triglycerides, improved glucose tolerance, reduced tubulointerstitial fibrosis, and down-regulation of monocyte chemoattractant protein-1. The imposition of a restricted calorie intake may be sufficient to prevent the proteinuria and histologic damage to the kidneys in a rat model of diabetic nephropathy, possibly by normalizing the oxidative and carbonyl stress imposed by a higher dietary intake (Nangaku et al., 2005). If this can be extended to humans, it suggests that the glomerular and tubulointerstitial damage characteristic of human diabetic nephropathy may be due in part to local oxidative stress associated with fuel metabolism.

Partial nephrectomy in rats suggests that LA plays a role in preventing the structural and functional deterioration that may occur as a consequence of the compensatory hypertrophy in the remaining nephrons (Barcelli et al., 1982). The LA-treated rats showed a decrease in proteinuria, no sclerosis of the enlarged glomeruli, less tubule and interstitial tissue damage, stabilization of renal function, and no evident deterioration of health. The renal production of PGE_2 was increased, and although TXA_2 production may also have been increased, PGE_2 production was quantitatively greater. The improved renal function was not due to changes in blood pressure or blood lipids, because no significant alterations of these parameters were noted. Others have observed that an LA-enriched diet is associated with an improvement or maintenance of renal function in rats with

SRA and may prevent some of the pathological changes leading to the development of GS (Barcelli et al., 1985; Heifets et al., 1985, 1987a; Izumi et al., 1986; Ingram et al., 1996). These effects of LA were often abolished by the administration of indomethacin (a COX inhibitor) suggesting that the improved renal function may be EC dependent. It has been shown that LA feeding significantly changes the lipid composition of kidney tissues and results in increased concentrations of renal LA and AA (Heifets et al., 1987a). Thus, altering LA in the diet enhances the membrane phospholipid content of n-6 fatty acids and may alter EC production. However, renal function is improved by feeding LA to SRA rats without apparent changes in urinary EC excretion (Heifets et al., 1987a). Another possible mechanism of action could be a reduction in blood pressure with LA feeding. It has been shown that LA-enriched diets attenuate the hypertension that usually occurs in rats with SRA (Heifets et al., 1985; Izumi et al., 1986), but this is not a consistent finding (Barcelli et al., 1982). Furthermore, membrane fluidity changes could occur with changes in membrane PUFA content (Beitz and Forster, 1980) and this might change membrane permeability characterists and/or alter hormone receptor activity in the target tissues.

It is known that dietary protein restriction is beneficial in CRF (Barsotti et al., 1983; Brazy, 1993). Ito et al. (1987) demonstrated that a low-protein high-linoleate diet had more benefit in partially nephrectomized rats than either diet alone, and it was postulated that the additive effects may have been mediated by an increased PGE_2 production from the dietary LA and its subsequent effect on renal hemodynamics. Since elevated blood lipids may contribute to the development of GS and renal injury (Kasiske et al., 1985; Keane and Guijarro, 1996), the LA-enriched diet might be of benefit because of its hypocholesterolemic effect. Muhlfeld and co-workers (2004) have shown that hyperlipidemia worsens the renal pathology and function (in part through increased renal expression of cytokines) of B6.ROP Os/+ mice, a model of reduced renal mass. Daily supplementation with n-3 PUFAs to patients with impaired renal function consuming a high-protein diet increased RBF and GFR (Schapp et al., 1987). Total renal resistance was reduced by 20%. Thus, n-3 fatty acids appear to improve renal function primarily by eliciting renal vasodilation.

A 13%–20% LA diet improved renal function in humans, as evidenced by an increased excretion of creatinine (Adam and Wolfram, 1984). Increasing the amount of fat in the diet usually results in a decreased carbohydrate intake and elevated plasma glucagon. Glucagon is known to increase RBF and creatinine excretion, and this might explain some of the dietary fat effects on renal function. Even an intake of 6%–8% LA increased creatinine excretion compared to a 0%–4% LA diet (Adam and Wolfram, 1984). Hirschberg et al. (1984) reported that a diet deficient in essential fatty acids was not detrimental to rats with SRA. However, glomerular lesions were found to be more severe in rats with SRA fed a low-LA diet (Heifets et al., 1987a).

As platelet aggregation in the glomerular capillaries and renal vasculature may play a role in the progression of renal disease in the SRA rat model, especially if there is endothelial damage by factors such as hypertension, it is significant that dietary LA may alter platelet aggregation. McGregor et al. (1980) demonstrated that 0%–6% dietary LA was correlated with a decreased susceptibility of platelets to aggregate (thrombin induced) and a prolongation of the clotting time of platelet-rich plasma. Similar results on platelet function have been reported when diets were enriched with n-3 PUFAs (Leaf and Weber, 1988). Increased fibrinolytic activity has been reported in rats fed increased levels of PUFAs (Rondeau et al., 1986), and this may also favorably alter the progression of renal disease by reducing intraglomerular thrombosis.

Barcelli et al. (1986) demonstrated that there was improvement in renal function in rats with SRA when they were fed diets rich in various PUFAs. Rats fed evening primrose oil (high in LA and gamma-linolenic acid [GLA]) showed enhanced production of PGI_2, and it has been shown by others that GLA increases PGE_1 and PGE_2 production (Kernoff et al., 1977) and improves renal function (Ingram et al., 1996). Rats fed safflower oil (high in LA) showed greater synthesis of PGE_2 and PGI_2. Rats fed salmon oil (n-3 rich) demonstrated an increase in PGE_3 production and a decrease in urinary excretion of TXB_2.These changes in ECs were associated with improved renal function. All three oil diets reduced serum triglycerides, and since a lowering of serum lipids has been associated

with improved renal function (Keane et al., 1988), this may help to explain their beneficial effect on the kidneys. There is, however, some question as to whether triglycerides are important in this regard (Hirschberg et al., 1984). In studies using animal models of SRA, diets supplemented with n-3 fatty acids improved renal function and ameliorated structural damage (Barcelli et al., 1985, 1986; Scharschmidt et al., 1987), but this is not a universal finding because some studies have found EPA to worsen the renal disease in rats with partial nephrectomy (Hirschberg et al., 1984; Scharschmidt et al., 1985). Logan and coworkers (1990) found fish oil to enhance the GFR and RBF in uninephrectomized rats, and the changes were associated with a decrease in the dienoic ECs and a rise in the 3 series. These authors caution that because hyperperfusion and hyperfiltration of nephrons is thought to lead to progressive renal disease in rats with SRA, dietary modifications that elicit increases in GFR and RBF may eventually lead to GS and renal failure. Since PUFAs are the precursors of ECs, it is presumed that by substitution of EPA for AA, the COX metabolites produced will decrease platelet aggregation and reduce renal vasoconstriction (Table 46.2). Various studies have demonstrated that rats fed n-3 PUFAs show a lower renal synthesis of dienoic ECs (Schoene et al., 1981; Croft et al., 1984; Ito et al., 1988). Prostaglandin E_3 was found in renal tissue after 22 weeks on n-3 fatty acid supplementation (Ferretti et al., 1981). Thus, the synthesis of diene ECs by the kidney decreases with increased n-3 consumption and PGE_3 production increases. However, Kasiske et al. (1989) found that fish oils decreased renal prostacyclin (PGI_2) production but not the production of TXA_2. It is not clear why these discrepancies occur, but they may be related to the oxidative status of the oil, dosage, duration of treatment, and other factors. Fish oils also improve glomerular function in diabetic rats (Sinha et al., 1990) that have renal impairments similar to those in rats with SRA. Thus, fatty acid supplements have direct effects on renal ECs and subsequent renal function, but the mechanisms are not clearly understood. It has been reported that n-3 fatty acid supplements reduce blood viscosity and increase red blood cell deformability in humans both with (Clark et al., 1989) and without (Terano et al., 1983; Woodcock et al., 1984) renal disease, but the reduced viscosity does not apply to plasma alone (Ware et al., 1992). Since uremic patients have been found to have impaired red cell deformability (Kikuchi et al., 1982), n-3 PUFAs, by improving deformability,

TABLE 46.2
Renal Diseases and Associated Fatty Acids/Eicosanoids

		Compounds	
Disease	**Characteristics**	**Harmful[a]**	**Beneficial[b]**
Nonimmunological			
Partial Nephrectomy (SRA)	Eventual renal failure in remaining viable tissue	TXA_2	PGE_2, PGI_2, PGE_3, LA, EPA
Hypertension	Kidneys regulate blood pressure by controlling blood volume	TXA_2	PGE_2, PGE_3, LA, EPA
Immunological			
Nephritis	Renal inflammation and injury; many forms recognized	TXA_2, LTs	PGE_1, PGE_2, PGI_2, PGE_3, PGI_3, EPA
Nephrosis	Noninflammatory renal injury	TXA_2	EPA
Nephrotoxicity	Nephrotoxin-induced renal injury	TXA_2	EPA

Saturated fatty acids appear harmful in most renal diseases. LA may be helpful in some immunological renal diseases, but without effect or harmful in others. Supplementing the diet with LA increases the 2-series ECs and reduces the 3-series ECs; EPA does the opposite.

[a] May be responsible for some of the disease etiology.
[b] Eicosanoids may be elevated as a compensatory response.

may improve these rheological disturbances. Several studies suggest a role for lipid abnormalities in glomerular injury, and a strong correlation between plasma lipids and progression of renal disease in humans has been shown (Moorhead et al., 1982; Keane and Guijarro, 1996). A greater intake of cholesterol in the diet accelerates the development of GS in animals (Keane et al., 1988; Klahr and Harris, 1989; Kasiske et al., 1990), and lowering serum lipids ameliorates the sclerosis in rats with SRA (Keane et al., 1988; Keane and Guijarro, 1996). Daily exercise decreases serum cholesterol and triglycerides in rats with SRA and improves renal function compared to that of sedentary rats with SRA (Heifets et al., 1987b). Moreover, some dietary saturated fatty acids may contribute to renal impairement by causing hypercholesterolemia, especially in individuals in whom some degree of renal dysfunction already exists. Indeed, an increased intake of saturated fats has been shown to worsen the renal disease in mice with glomerular inflammation (Kelley and Izui, 1983). In this context, dietary monounsaturated and polyunsaturated fatty acids have been shown to lower blood lipids and thus may improve renal function. Deposition of lipid in glomerular cells occurs in a variety of renal diseases (Grond et al., 1986a), and it has been postulated that lipids may be nephrotoxic (Moorhead et al., 1982). Hypertriglyceridemia has been implicated in renal dysfunction in uremic rats. However, Hirschberg et al. (1984) showed that triglyceride-rich diets were not harmful to rats made uremic by SRA or to mice with immune-mediated glomerular injury with regard to survival, renal histology, or development of azotemia. These results suggest that a higher intake of dietary lipids may not necessarily contribute to hypertriglyceridemia, and therefore the nephrotoxicity of dietary lipids is still not clearly understood. Diets rich in PUFAs could have various roles in the glomerular scarring caused by GS: They could alter the early compensatory hemodynamics by changing the renal EC levels; they could inhibit platelet aggregation and intraglomerular thrombosis; and they may contribute to membrane functional changes.

b. Hypertension

The kidneys play a primary role in both the development and prevention of hypertension. Certain forms of hypertension may result from excess renin-angiotensin activity, sympathetic nervous stimuli, or excess renal vasopressor ECs. A common view suggests that a deficiency in renal EC vasodilators is fundamental to essential hypertension (hypertension without apparent cause). Infusion of prostacyclin into patients with essential hypertension reduces blood pressure, but whether this means that PGI_2 is involved in the etiology of the disease is not known. It is possible that PGI_2 released into renal venous blood could escape inactivation in the lungs and thus modulate resistance in systemic vascular beds. Renal ECs are important regulators of sodium excretion and blood volume through their effects on renal vascular resistance, GFR, and renal sodium reabsorption. By modulating renin release, ECs regulate the levels of circulating vasoconstrictors (such as angiotensin II) and aldosterone (which acts on the kidneys to increase sodium reabsorption in the distal and collecting tubules). Increased renal vascular tone may be present in many cases of essential hypertension, possibly due to increased activity of the sympathetic nervous system. Studies indicate that essential hypertension is rare in persons with a normal renal circulation free of excessive vascular tone.

Spontaneously hypertensive (SH) rats have been used as a model of essential hypertension in humans. Although the exact pathogenesis of the genetic hypertension in these rats has not been determined, several renal abnormalities have been established. Included are an enhanced renal vascular resistance and sensitivity to vasopressor agents (Fink and Brody, 1979), increased renal production of vasodilatory PGE_2 and PGI_2 (Limas and Limas, 1977; Konieczkowski et al., 1983), and enhanced sodium reabsorption (Farman and Bonvalet, 1975). Martineau and colleagues (1984) found reduced renal PGE_2 synthesis in SH rats and suggested that it may be contributory to the hypertension. Watanabe et al. (1989) found renal phospholipids in SH rats to contain a relatively higher level of AA and relatively lower levels of EPA and dihomo-gamma-linolenic acid compared to normotensive controls. Thus, more substrate availability for the 2-series ECs might somehow contribute to the hypertension in these animals, possibly by augmenting the production of TXA_2.

Indomethacin administration to SH rats causes a rise in systolic blood pressure (Levy, 1977), suggesting that at least one AA metabolite is involved in attenuating the hypertension. Renal TXA_2 synthesis is enhanced in SH rats (Shibouta et al., 1981), and inhibition of thromboxane synthetase appears to delay the development of the hypertension (Uderman et al., 1982; Purkerson et al., 1986). Therefore, an increased synthesis of TXA_2 may play a role in the development of hypertension, possibly by causing an enhanced renal vascular resistance (Grone et al., 1986b; Stegmeier et al., 1987). Little is known regarding TXA_2 levels in human hypertension, but dietary saturated fats are known to be associated with salt retention and hypertension (Preuss, 1977). In contrast to results with SH rats, EC excretion rates in humans with essential hypertension are reduced (Tan et al., 1978; Grose et al., 1980). Despite this, COX inhibition is associated with a further rise in blood pressure (Donker et al., 1976) and an enhanced response to the vasoconstrictor angiotensin II (Negus et al., 1976). Thus, the use of NSAIDs in hypertensive patients may worsen the disease.

Depletion of dietary LA, which is the precursor of the dienoic ECs, results in both biochemical and physiological essential fatty acid deficiency (EFAD) symptoms. When rats are placed on such a diet, PGE_2 excretion in urine falls significantly (Cox et al., 1982). Since PGE_2 is a natriuretic compound, the animals fed a high-salt diet show enhanced sodium reabsorption and develop hypertension. The EFAD rats also demonstrate a defect in water excretion possibly due to the natural antagonism of PGE_2 for antidiuretic hormone, which is now somewhat lacking. These effects are reversible when the rats are fed LA and probably result from the action at the tubular level rather than by an alteration of RBF or GFR. An EFAD diet in rabbits and rats causes elevated blood pressure, increased sensitivity to the vasopressor angiotensin II (O'Brien and Pipkin, 1979), and increased renal sodium reabsorption (Rosenthal et al., 1974). Goldblatt's hypertension resembles clinical renal hypertension and can be produced in experimental animals by decreasing the kidney blood flow by placing a clip on the renal artery. Occasionally, the contralateral kidney is removed. The addition of LA to the diet of rats attenuates the development of two-kidney, one-clip Goldblatt's hypertension (Reddy et al., 1989) and reduces the rise in blood pressure following subtotal nephrectomy (Izumi et al., 1986; Heifets et al., 1987a). Codde et al. (1985) found no difference in blood pressure in rats with the one-kidney, one-clip model of hypertension fed either cod liver oil/linseed oil (n-3 rich) or sunflower oil (n-6 rich), and Watanabe et al. (1989) could not improve the hypertension in SH rats by feeding n-6 fatty acids. However, the antioxidant status of the diets was not clearly defined and may contribute to the observed results. A LA-enriched diet significantly delays the onset and magnitude of NaCl-induced hypertension in the Dahl S strain of rats, a strain that is highly susceptible to salt-induced hypertension. It appears that this effect may be due to a 2.5-fold rise in the renal PGE_2 production in these rats (Tobian, 1983). LA-supplemented diets in SH rats (Schoene et al., 1980), salt-loaded rats (MacDonald et al., 1981), and essential hypertensive patients (Comberg et al., 1978) reduce blood pressure. LA in the rat increases PGE_2 production (Schoene et al., 1980); thus, LA appears to reduce blood pressure by an increased synthesis of vasodilatory ECs and by increasing sodium and water excretion. Therefore, endogenously produced ECs may, in some cases, protect against the development of high blood pressure, but this is certainly not a universal finding (Izumi et al., 1986). Although PGE_2 and PGI_2 cause the release of renin from the kidney (Jackson et al., 1982a), LA is reported to inhibit the activity of renin *in vivo* (Reddy et al., 1987). Reddy et al. (1989) found that LA reduced blood pressure in two-kidney, one-clip hypertensive rats, whereas indomethacin administration did not affect this response; thus, the hypotensive action of LA is most likely due to inhibition of the activity of renin in peripheral tissues rather than an alteration in EC synthesis. Thromboxane A_2, a renal vasoconstrictor, may inhibit renin release (Hackenthal et al., 1990). The secretion of renin from the kidney eventually results in the production of angiotension II and to reduced renal excretion of sodium, which may lead to volume expansion. Thus, the effects of the renal ECs on blood pressure are complex. Furthermore, one must distinguish between alterations in EC levels causing the pathological changes and alterations in EC levels that are compensatory responses to changes in blood pressure, salt balance, or circulating hormones.

Eicosopentaenoic acid given to rats has been reported to have protective effects against epinephrine (adrenaline)-induced renal functional impairment (Sadjak et al., 1987), which may be due to

inhibition of the renal vasocontriction that epinephrine causes. This n-3 PUFA also antagonizes the vascular effects of angiotensin II, and the effects may be independent of trienoic EC production. The administration of n-3 fatty acids to humans and experimental animals, both with and without hypertension, has often resulted in a lowering of blood pressure (Sanders et al., 1981; Singer et al., 1983). Fish oil feeding (10% of calories) was shown to lower blood pressure in the borderline hypertensive rat receiving 1% NaCl (Mills et al., 1989) through mechanisms other than salt and water metabolism. This strain of rats is produced by backcrossing the SH rat with its normotensive parent strain, and such animals become hypertensive with high-salt intake. Bond et al. (1989) found dietary fish oil to attenuate the development of hypertension in the deoxycorticosterone acetate (DOCA)-alt hypertensive rat unrelated to alterations of net sodium balance. It also lowered total, LDL, and HDL cholesterol levels. However, Watanabe et al. (1989) could not decrease hypertension in SH rats by feeding n-3 fatty acids. Stroke-prone SH rats (a well-established animal model of malignant hypertension) fed a high-salt diet develop renal damage, and this renal impairment can be prevented or minimized with dietary fish oil but not with canola or safflower oils (Hobbs et al., 1996). It was suggested that the prevention of hypertensive renal damage may occur as a result of an enhanced incorporation of long-chain n-3 fatty acids in the kidney (such as EPA and docosahexanoic acid [DHA]); n-6 fatty acids exacerbated the development of renal failure in these salt-loaded rats. Fish oil feeding is also usually accompanied by a reduction in AA in such tissues (Otten et al., 1993), but this is not a consistent finding (Cao et al., 1995). Miyazaki and coworkers (2000) examined the effects of dietary oils and docosahexaenoic acid (DHA; 22:6-n3) on renal injury in the stroke-prone SH rat. Compared to soybean oil, both rapeseed and safflower oil-supplemented diets had adverse effects on renal function, whereas the DHA-supplemented diet inhibited the development of proteinuria and suppressed the hypertension in these rats.

LA-enriched diets appear to attenuate hypertension and lessen the renal disease caused by SRA in rats. The mechanism(s) could include an enhanced production of vasodilator ECs (PGE_2 and PGI_2), an inhibition of renin activity, a decrease in TXA_2 synthesis and platelet aggregation, less intraglomerular coagulation, and a decrease in plasma lipids. Thromboxane A_2 production is usually elevated in renal disease and its inhibition improves the pathological condition. Thus, in rats with SRA, excess renal TXA_2 production could be one of the primary mechanisms that eventually lead to end-stage renal disease. Prostaglandins E_2 and I_2 are usually elevated with these renal disorders, possibly as a compensatory mechanism. Fish oil (rich in n-3 fatty acids) also attenuates renal disease and hypertension, possibly by reducing TXA_2 synthesis and by increasing the production of PGE_3 and PGI_3. Changes in cell membrane fatty acid composition reflect the PUFA components of the diets, and these compositional changes could lead to changes in membrane function (ion channels, receptors, and membrane flexibility) that may favorably alter renal physiology. Studies on how PUFAs modify membrane functions and thus impact renal disease and hypertension deserve further study. GLA lowers blood pressure in SH rats, and Yu et al. (2006) showed that this pressure lowering effect involves increases in the vasodilatory epoxyeicosatrienoic acids (EETs) and decreases in the vasoconstrictive hydrosyeicosatetraenoic acid (20-HETE). The EETs and 20-HETE are cytochrome P450-derived ECs from AA, and a GLA-enriched diet apparently alters this P450-catalyzed AA metabolism.

c. Polycystic Kidney Disease

Polycystic kidney disease (PKD) is the most common life threatening genetic disease, affecting about 13 million people worldwide. PKD is a genetic disorder characterized by the progressive development of multiple cysts in both kidneys. The disease can also damage other organs. There are two major forms of PKD that are distinguished by their patterns of inheritance. Autosomal dominant PKD is generally a late onset disorder characterized by progressive renal cyst development bilaterally. Manifestations include renal function abnormalities, hypertension, and renal insufficiency. Autosomal dominant PKD affects about 1 in 500 people, and approximately 50% of patients with this disorder develop end-stage renal disease by 60 years of age, requiring some form of renal

replacement therapy (e.g., dialysis). Autosomal recessive PKD is much rarer than the autosomal dominant form (it is estimated to occur in 1 in 20,000–40,000 people) and is often lethal. The signs and symptoms of the condition are usually apparent at birth or in early infancy.

Several studies have investigated the effects of dietary lipids on the development of PKD. A flaxseed- or flax oil-supplemented diet (resulting in the replacement of LA with alpha-linolenic acid) modifies renal PUFA metabolism such that the ratio of omega-3 to omega-6 fatty acids increases (Ogborn et al., 1999, 2002), and this is associated with the production of less inflammatory ECs (Gibson et al., 1992). This diet reduces renal injury in a rat model of PKD (the Han:SPRD-cy rat) (Ogborn et al., 1999; Sankaran et al., 2004). One of the simplest ways to reduce AA and other omega-6 PUFAs is by feeding alpha-linolenic acid, and fish oil supplements appear beneficial in several renal conditions, such as IgA nephropathy and diabetic nephropathy (McCarty, 1998) and also in PKD (Ogborn et al., 2002; Lu et al., 2003). A high-fat diet increases the pathological injury in PKD (Jayapalan et al., 2000; Sankaran et al., 2004). Ogborn et al. (2003) demonstrated that conjugated linoleic acid (CLA) reduced the renal inflammation and fibrosis in the Han:SPRD-cy rat model of PKD by reducing the renal production of PGE_2, and it is known that diets high in n-3 fatty acids also reduce the production of PGE_2.

B. Immunological Renal Disease

Unlike the nonimmunological renal diseases, immunologically mediated renal diseases are not characterized by an increased SNGFR. In fact, most nephrons show a normal or reduced filtration rate. What mechanisms lead to progression of renal disease in these disorders is not clear. It is apparent that invasion of mononuclear cells and lymphocytes play a greater role in these diseases than in renal diseases where hemodynamic changes are more clearly involved.

a. Nephritis

Nephritis is an inflammation of the kidney, usually caused by infections or autoimmune processes. It usually affects the membrane of the renal corpuscle such that the membrane becomes highly permeable to the filtration process (e.g., proteins enter into the glomerular filtrate and are excreted). There are various subtypes of nephritis, including GN (inflammation of the glomeruli), interstitial nephritis and tubulo-interstitial nephritis (inflammation of the interstitial tissues between renal tubules), pyelonephritis (caused by a urinary tract infection that reaches the kidneys), and lupus nephritis (caused by systemic lupus erythematosus).

Kelley et al. (1986) demonstrated that renal TXA_2 synthesis is positively correlated to the severity of lupus nephritis in both MRL/lpr and NZB/NZW F_1 hybrid mice. However, neither renal PGE_2 nor PGI_2 was consistently increased as the disease became more severe. Thus, as the GN becomes more extreme, renal TXA_2 production is enhanced, and this vasoconstrictor may contribute to the renal disease. Prostaglandin E_1 (a vasodilatory COX product of dihomo-gamma-linolenic acid derived from LA) markedly increases survival in mice with lupus nephritis (Zurier et al., 1977a, 1978) and improves the histological appearance of the glomeruli (Zurier et al., 1977b). Kelley and coworkers showed beneficial renal effects with exogenous PGE_1 and PGE_2 in both MRL/lpr and NZB/NZW mice (Kelley et al., 1981). These ECs may suppress T- and B-cell function (Kelley et al., 1979; Rogers et al., 1980), reduce the activity of natural killer cells (lymphocytes distinct from B and T cells) (Brunda et al., 1980), and depress neutrophil function (Fantone et al., 1983). Thromboxane B_2 excretion is elevated in mice and humans with lupus nephritis, and the source is thought to be renal (Patrono et al., 1985; Kelley et al., 1986). Renal prostaglandin E_2 secretion is also increased in humans with lupus (Kimberly et al., 1978a), and renal synthesis of prostacyclin (PGI_2) appears to play a role in maintaining the RBF and GFR in patients with chronic GN (Ciabattoni et al., 1984). Ibuprofen, a nonselective COX inhibitor altering both renal and platelet EC production (Kimberly et al., 1978b), caused a deterioration of renal function in patients with GN (Ciabattoni et al., 1984), as did aspirin (Kimberly et al., 1978a), but sulindac, a compound that selectively inhibits renal

and platelet TXA_2 formation (Ciabattoni et al., 1980), did not impair renal function nor alter urinary PGE_2 or 6-keto-$PGF_{1\alpha}$ (renal PGI_2) excretion, but production of TXA_2 decreased significantly (Ciabattoni et al., 1984). Ibuprofen decreased urinary 6-keto-$PGF_{1\alpha}$, PGE_2, and TXB_2 in patients with GN, which may be related to the observed decrease in plasma creatinine clearance (Patrono et al., 1985). It appears that a predominance of renal vasodilator ECs in GN is beneficial to the maintenance of kidney function. Clark and coworkers (1993) reported that fish oil did not improve renal function or reduce disease activity in humans with lupus nephritis after 1 year of dietary supplementation. Studies have demonstrated some improvement in systemic lupus erythematosus with high doses of EPA (20 g/day) (Walton et al., 1991), or little or no improvement with smaller doses (Moore et al., 1987; Westberg and Tarkowski, 1990), but the effects of dietary n-3 PUFAs on human lupus nephritis remain equivocal (Lefkowith and Klahr, 1996).

A diet deficient in LA has been shown to have (1) a beneficial effect on the GN of the NZB/NZW mouse (Hurd et al., 1981) and (2) no effect on murine GN (Hirschberg et al., 1984). Thus, it is possible that at least one of the LA metabolites plays a role in the pathogenesis of this disease, and that when LA is removed from the diet, the production of such dienoic EC(s) is reduced.

EPA has been shown to have significant beneficial effects on kidney function in murine models of lupus nephritis (Prickett et al, 1983; Robinson et al., 1985), possibly by impairing TXA_2-mediated changes in platelet and renal function. A diet enriched in EPA prolonged survival and reduced proteinuria in NZB/NZW F_1 mice compared to mice receiving beef tallow (Prickett et al., 1981). The group fed beef tallow showed severe glomerular injury on autopsy. Thus, a diet high in EPA prevents or delays the development of GN in NZB/NZW F_1 mice. However, this may be due to inadequate n-6 fatty acids, because n-6-deficient diets have also been noted to diminish GN (Hurd et al., 1981). Additionally, dietary n-3 fatty acids appear to have beneficial effects on the MRL/lpr murine model of lupus; progression of renal injury was suppressed and survival prolonged (Kelley et al., 1985). It was noted that renal PGE_2 and TXB_2 production was reduced compared to safflower oil-treated animals and that trienoic EC production increased. Immunological changes were also observed, such as decreased lymphoid hyperplasia and reduced circulating immune complexes. The reduced PGE_2 with n-3 supplementation initially appears difficult to reconcile with the beneficial effects usually attributed to the pharmacological use of that EC (Kelley et al., 1981). However, TXA_2 is diminished by n-3 PUFAs, and TXA_2 appears to accelerate renal diseases by stimulating lymphocyte production, platelet aggregation, and renal vasoconstriction. It is possible that the increased synthesis of renal PGE_3 helped to offset the reduction in PGE_2; overall, the n-3 PUFAs may ameliorate the deleterious effects of renal TXA_2. Clark et al. (1989) found that n-3 fatty acids given to humans with lupus nephritis improved blood rheology, reduced collagen-induced platelet aggregation, and, at high doses (18 g/day), improved the serum lipids by reducing both triglycerides and cholesterol. Platelet EPA was increased, whereas platelet AA was decreased, and the production of PGI_3 was enhanced while that of PGI_2 remained unchanged. Thus, the n-3 PUFAs may reduce the progression of renal atherosclerotic disease and GS. Furthermore, these authors observed a reduction in the neutrophil release of LTB_4, and elevated levels of this LT have been implicated in the pathogenesis of lupus nephritis (Spurney et al., 1991). PAF has been implicated in the glomerular injury observed with lupus, most likely because of its inflammatory and vasoconstrictive properties (Baldi et al., 1990). How dietary fatty acids may alter PAF synthesis or secretion by platelets in renal disease is not known. Bhattacharya and coworkers (2003) showed that fish oil plus antioxidants may prevent kidney disease in NZB/W mice, and that both n-3 and n-6 dietary lipids are susceptible to lipid peroxidation.

Yang and Cook (2003) have shown that feeding conjugated linoleic acid (CLA; isomers of LA found in dairy products and meat) to autoimmune-prone NZB/W F_1 mice after the onset of proteinuria had a beneficial effect on cachexia (mice fed regular rodent chow lost 25% more weight than mice fed CLA) and the CLA-fed mice survived an average of 1.7× longer. Other workers have shown CLA feeding to have a number of health benefits, including reducing atherosclerosis in hamsters (Nicolosi et al., 1997), modulating immune responses (O'Shea et al., 2004), improving

type II diabetes mellitus (Belury et al., 2003), reducing body fat while enhancing lean body mass in mice (DeLany et al., 1999; West et al., 2000), and anticancer properties (Wang et al., 2006). Park and coworkers (2005) found that CLA-feeding may improve survival in male Fischer 344 rats after developing renal disease due to a high protein diet.

NSN is a disease of the glomerulus that occurs because of antibody binding to glomerular structures and the ensuing host immune response to the bound antibody. Its progression is extremely rapid following nephrotoxin injection, and proteinuria and renal failure quickly ensue (Sakai et al., 1984). Glomerular TXB_2 production is significantly elevated within 2 h of the initiation of the disease (Lianos et al., 1983), and inhibitors of TXA_2 synthesis result in attenuation in the acute RBF and GFR changes. Glomerular PGE_2 and, to a lesser extent, TXA_2 are elevated at 1 and 14 days after nephrotoxin administration (Stork and Dunn, 1985); these changes are accompanied by increases in RBF and GFR. However, the inhibition of TXA_2 synthesis appears to have only a short-term beneficial effect despite a continued high glomerular TXA_2 production, whereas COX inhibition results in a significant deterioration in renal function. Since both PGE_2 and TXA_2 are increased with NSN, the major hemodynamic effects are most likely mediated by PGE_2 rather than by TXA_2. Thus, early renal vasoconstriction by TXA_2 production probably reduces renal function in rats with NSN, whereas later stages are characterized by an improvement in RBF and GFR by enhanced renal PGE_2 production. At day 14, PGE_2 production by glomeruli was about twice that of TXB_2 (Stork and Dunn, 1985). Pretreatment with aspirin, however, has been reported to prevent the proteinuria of rats with NSN without changing either RBF or GFR (Kurokawa and Sakamoto, 1982), possibly by altering some part of the glomerular pathological process. Rats with NSN that were treated with PGE_1 showed less proteinuria and fewer glomerular effects, but the deposition of antibody into the glomerulus was not altered (Kunkel et al., 1982). Lianos and coworkers (1985) found that rats with NSN showed enhanced lipoxygenation of AA to 12-hydroxyeicosatetraenoic acid, which is chemotactic and proinflammatory. Therefore, lipoxygenase products of AA metabolism may mediate some aspects of the glomerular injury. A diet deficient in LA did not alter the course of the disease in rats with NSN; in fact, a greater deposition of fibrin in their glomeruli was noted (Dubois et al., 1982), implying that an LA-deficient diet in rats with this disease may be harmful.

Immune complex-mediated glomerulonephritis (ICGN) can be induced in animals by the intraperitoneal injection of human plasma, apoferritin, or bovine serum albumin. Glomerular PGE_2 and TXB_2 production may be elevated with ICGN (Rahman et al., 1985). Since indomethacin therapy results in 30%–40% reductions in RBF and GFR, the decreased EC production (e.g., PGE_2) suggests a compensatory role for EC vasodilators in renal function related to this disease. Saito et al. (1984) reported that TXA_2 synthesis inhibition in rabbits resulted in less severe ICGN. Thromboxane synthetase inhibition resulted in increased PGI_2 in rats treated with mercuric chloride and was associated with a decline in TXB_2 excretion, less proteinuria, and 25% greater survival (Papanikolaou, 1987) Herring oil (rich in EPA) increased the survival rate of these animals to 100% and prevented the deposition of antibody in the glomeruli. Rats treated with mercuric chloride without dietary intervention had a survival rate of 60%. When mercuric chloride-treated rats were given evening primrose oil (which contains LA and GLA), survival was increased to 100%, proteinuria decreased, TXB_2 synthesis was reduced, and PGE_2 production was enhanced. In mice with ICGN, exogenous PGE_1 has been reported to reduce the proteinuria and lessen the pathological changes in the glomeruli (Kelley and Winkelstein, 1980; McLeish et al., 1980). Similar findings were reported with administration of AA (McLeish et al., 1982b). When high levels of dietary LA were supplemented to apoferritin-injected mice, the LA diet resulted in reduced proteinuria and serum creatinine and attenuated the pathological characteristics of ICGN (Barcelli et al., 1984; Kher et al., 1985), but it was not determined if the effects of LA were due to enhanced dienoic EC production. The reduction of ICGN with PGE_2 and PGE_1 may be due to a reduction in the synthesis of antiapoferritin antibody (McLeish et al., 1982a). Thus, a direct effect of ECs on the immune system may be related to the beneficial effects of these ECs on immunemediated renal disease.

Fish oil, rich in n-3 PUFAs, has been demonstrated to be beneficial in protecting against ICGN (Barcelli et al., 1984) and reduced the severity of GN in the mouse (Robinson et al., 1985) and rat (Thaiss and Stahl, 1987). The effects of the n-3 PUFAs may be related to changes in the dienoic and trienoic ECs by effectively reducing TXA_2 and substituting PGE_3 for PGE_2.

Mesangial nephropathy is a common form of GN in which antibody deposition occurs in the mesangial cells of the glomeruli. A significant number of patients with this disease will eventually progress to renal failure. Despite a preliminary report suggesting a beneficial effect of the n-3 fatty acids (Hamazaki et al., 1984), another study could not confirm these earlier findings (Bennett et al., 1989). However, Pestka et al. (2002) showed that fish oil impaired the development of immunopathology in mice with immunoglobulin A (IgA) nephropathy (IgAN). This is important given that human IgAN is the most common type of GN in the world even though the specific causes for overreactive IgA responses in IgAN are not known, although it is known that interleukin-6 deficient mice are resistant to IgA nephropathy (Pestka and Zhou, 2000). That n-3 fatty acids have these effects may not be surprising in that epidemiologic studies of fish oil consumption link it with very low incidences of autoimmune and inflammatory disorders.

There is good evidence that platelets are involved in GN. Platelet aggregation can be stimulated by immune complexes, and platelets may release factors that enhance the deposition of immune complexes in the cells of the glomerulus (Cochrane, 1971). Platelets may release substances that also enhance the inflammatory process (Baldi et al., 1990), attract white blood cells (Weksler and Coupal, 1973), and alter glomerular permeability leading to proteinuria (Camussi et al., 1984). Platelet-inhibitor drugs may be used in glomerular renal diseases where their use has delayed progression to end-stage renal disease. Of course, the beneficial effect of platelet inhibitors may also be due to both platelet and renal EC production changes (such as a reduction in TXA_2) and the consequent effects on renal hemodynamics. Dietary modification of platelet aggregation may be achieved by altering the intake of fatty acids. Both n-3 and n-6 PUFAs have been shown to reduce platelet aggregation to various agonists (McGregor et al., 1980; Leaf and Weber, 1988).

b. Nephrosis

Nephrosis refers to noninflammatory disease of the kidney. Some authors may use this term to include any damage or disease of the kidneys, including inflammatory changes (nephritis). Other authors may use the term nephropathy to indicate global renal diseases, reserving the terms nephrosis for noninflammatory kidney disorders and nephritis for inflammatory renal diseases. We will follow this latter terminology. Nephrosis may result from longstanding diabetes mellitus resulting in angiopathy of glomerular capillaries and nodular GS, or from hypertension that causes pathological changes in the small arteries and arterioles of the kidneys resulting in ischemic damage to various kidney structures.

Nephrosis (often characterized by increased glomerular permeability to proteins that may precede the development of renal failure and GS) can be induced in rats by the administration of adriamycin (Bertani et al., 1986), and this is a commonly used experimental model of human chronic kidney disease. These animals exhibit enhanced glomerular TXB_2 production concomitant with proteinuria (Remuzzi et al., 1985). The proteinuria associated with nephrosis is attenuated by TXA_2 synthetase inhibition, which also reduced urinary TXB_2 excretion to normal levels. Thus, TXA_2 may change permeability characteristics of the glomerular membrane. Thromboxane synthetase inhibitors used in humans with nephrosis also resulted in decreases in proteinuria and TXB_2 excretion. Indomethacin treatment in nephrotoxic humans reduced both proteinuria and GFR (Arisz et al., 1976). Thus, despite deterioration in the GFR, COX blockade improved the proteinuria attendant with this disease. The lessened proteinuria is probably not a result of the reduced GFR but rather due to an alteration in glomerular permeability (Tiggeler et al., 1979). It is known that adriamycin causes apoptosis of renal tubular cells, and Chen and co-workers (2006) have shown that prostacyclin (PGI_2) can protect the renal tubular cells from this programmed cell death.

Nephrosis appears to be associated with a thrombotic tendency due to platelet hyperactivity (Bang et al., 1973). Platelet-rich plasma from patients with nephrosis demonstrates enhanced aggregation to various agonists. The proteinuria with this disease causes hypoalbuminemia, and this is thought to contribute to an enhanced platelet production of the proaggregatory TXA_2 (Jackson et al., 1982b) and to defective platelet production of the antiaggregatory PGD_2. It has been shown that dietary fish oils protect against structural and functional deterioration in nephrotic rats, possibly by improving the plasma lipid profile (Ito et al., 1988).

c. Nephrotoxicity

The use of cyclosporine to prevent graft rejection is often associated with nephrotoxicity (Klintmalm et al., 1981), which can manifest as both acute and CRF. The mechanisms for the renal toxicity are not clear. Cyclosporine may increase urinary TXB_2 excretion (Kawaguchi et al., 1985), but renal PGE_2 and PGI_2 synthesis does not appear to change. The increased TXA_2 synthesis is thought to be at least partly responsible for the decline in GFR that accompanies the use of this drug. The mechanism may be due to the effect of TXA_2 on increasing glomerular vascular resistance and thus reducing RBF, or it may result from TXA_2 reducing the glomerular surface area by eliciting mesangial cell contraction (Schor et al., 1981; Scharschmidt et al., 1983).

When fish oil (rather than olive oil) is used as the vehicle to administer cyclosporine to rodents, some protection from renal tubular damage and reduced GFR has been reported. This is probably due to the effect of n-3 fatty acids to reduce the renal production of TXA_2. Fish oil also appears to be beneficial in experimental models of cyclosporine nephrotoxicity (Elzinga et al., 1987), and evening primrose oil (rich in LA and GLA) normalizes renal function in cyclosporine-treated rats, possibly by changing the renal phospholipid fatty acid profile (Mills et al., 1994). Liver transplant recipients receiving cyclosporine plus fish oil showed increased GFR and RBF and reduced renal vascular resistance compared to such patients receiving cyclosporine plus corn oil (Badalamenti et al., 1995), and there are various reports of improved renal function in renal allograft patients receiving n-3 fatty acids (Berthoux et al., 1992; Homan van der Heide et al., 1992). Holm and coworkers (2001) demonstrated that n-3 fatty acids can preserve renal function in hypertensive heart transplant patients taking cyclosporine to prevent rejection. The n-3 fatty acids prevented increases in blood pressures and vascular resistances, and also prevented a rise in plasma creatinine and a decrease in the GFR (in contrast to controls). However, Kooijmans-Coutinho and coworkers (1996) found no differences in renal function or rejection episodes between renal transplant patients receiving cyclosporine plus coconut oil (rich in short-chain saturated fatty acids) and those receiving cyclosporine plus fish oil, and there is other research indicating that fish oil supplementation does not alter renal function in kidney transplant patients, both with and without cyclosporine treatment, and in normal volunteers (Hansen et al., 1995). The nephrotoxic effects induced in rats by intramuscular injection of gentamicin was attenuated by fish oil supplementation, but not by sunflower oil (n-6 rich) (Abdel-Gayoum et al., 1995). In a review of the literature, Lefkowith and Klahr (1996) concluded that fish oil supplements may be of more consequence to patients with new transplants than to those with established allografts.

Whether ECs modulate renal events in ARF (as caused by nephrotoxins or ischemia) is unclear. Vasoconstriction usually occurs in the early phases of ARF, and a deficiency of vasodilator ECs has been proposed as the mechanism (Fine, 1970). However, since it has been found that PGE_2 and PGI_2 production and excretion are usually enhanced during the development of ARF (McGiff et al., 1970; Torres et al., 1979), this hypothesis is probably not valid. The enhanced EC production may be the result of phospholipase activation by tissue injury and ischemia attendant with ARF. Indomethacin administration causes further declines in the RBF and GFR in rabbits with ARF (Torres et al., 1975). It has been shown that PGE_1 has protective actions on the kidneys in ARF (Mauk et al., 1977). Furthermore, PGE_2 and PGI_2 infusions provide some degree of protection against renal failure induced experimentally (Casey et al., 1980). It is possible that vasodilatory ECs are produced in

the first few days of ARF to enhance kidney function. Acute tubular necrosis is associated with enhanced PGE_2 during the recovery phase of the disease, but cause and effect have not been clearly established (Funaki et al., 1982).

To summarize, it appears that immunological renal diseases are usually associated with increased rates of renal TXA_2 production. Inhibition of the action or synthesis of this EC often results in an amelioration of the disease. Thromboxane may alter glomerular filtration independent of changes in hemodynamics, possibly by altering glomerular permeability or surface area. The role of vasodilatory ECs is less clear, because they are increased in some immunological renal diseases but not others. However, the administration of exogenous vasodilatory ECs (usually PGE_2 and PGI_2) appears to be of benefit, possibly by having a negative modulatory effect on the proliferation and/or function of B and T cells, antibody production, and the action of neutrophils, in addition to their vasodilatory properties, which augment the RBF and GFR. LA-enriched diets may be helpful in some diseases, but they have either no effect in others or may possibly be harmful. In lupus nephritis, an LA-deficient diet was of benefit. Fish oils almost always proved beneficial in immunological renal diseases; however, it is not clear whether the attenuation of the disease process is due to increased n-3 fatty acids or to concomitant decreases in n-6 fatty acids. The postulated mechanisms of action include a reduction in plasma lipids (especially triglycerides), anti-inflammatory properties (Lee et al., 1985), reduced TXA_2 synthesis, and enhanced trienoic EC production. Both EPA and DHA are known to be anti-inflammatory n-3 fatty acids, and they may have synergistic properties with each other (Robinson et al., 1993).

C. Diet and Renal Patients

Nutritional management is a critical aspect of the treatment of CRF. An excellent review is presented by Grundy (1990).

Since hyperlipidemia is a common finding in patients with renal disease, dietary recommendations to improve the serum lipid profile may serve to prevent associated disorders. A number of investigators have demonstrated an increased incidence of myocardial infarction and coronary artery disease in patients with chronic renal disease, but some dispute any causal connection between lipid abnormalities seen in renal failure and the atherosclerotic lesions that frequently develop in such patients. However, the GS occurring in some renal disorders is thought to be partly due to elevated lipoproteins. In CRF, plasma triglycerides are elevated, HDL cholesterol is usually low, and LDL cholesterol is often elevated. A deficiency of lipoprotein and hepatic lipase has been well documented, and this causes a reduction in triglygeride-rich lipoprotein clearance from the blood. Both lipoprotein and apoprotein metabolism appears to be abnormal in renal patients.

Diets traditionally prescribed for patients with CRF substitute carbohydrate and fat for protein. Low-protein diets have been used to alleviate the symptoms of uremia in patients with renal dysfunction, and there is evidence that protein restriction may slow the renal pathogenesis (Klahr and Purkerson, 1988). However, the high-carbohydrate intake may exacerbate the hypertriglyceridemia. Since recent advances in our understanding of atherogenesis implicate lipids as a major contributing factor, the importance of treating the hyperlipidemia associated with renal disease is warranted. A low-carbohydrate diet with a high polyunsaturated/saturated fat ratio (P/S) can help to normalize triglyceride and cholesterol levels in CRF. Fats should provide about 40% of the total caloric requirement, and the P/S ratio should be high (Tsukamoto et al., 1982). Thus, a PUFA-rich diet comprising both n-3 and n-6 fatty acids and low in carbohydrates may reduce-triglycerides, increase high-density lipoprotein (HDL) cholesterol, and decrease the development of atherosclerosis in CRF patients. Fat intake may be increased further (at the expense of carbohydrates) if serum triglycerides remain high. Regular exercise may also be effective in lowering the triglycerides and improving the plasma lipid profile (Goldberg, 1984). In fact, exercise improves glucose tolerance, reduces anemia, and decreases the requirement for antihypertensive medications as well. Occasionally, lipid-lowering drugs may be required. In addition to their pathogenic role in atherosclerosis, lipids may themselves

contribute to glomerular and tubular injury. The possible nephrotoxic actions of lipids may be ameliorated with the correction of lipid abnormalities accompanying chronic renal disease.

VI. CONCLUSIONS

The beneficial effects of altering the dietary supply of n-3 and n-6 fatty acids in various renal pathologies may be due in part to changes in the mono-, di-, and trienoic ECs thus produced. Acting as local hormones, these ECs have profound effects on vascular musculature and platelet aggregability and may modulate the immunological and inflammatory events associated with some renal diseases. Thus, alterations in the balance of the various ECs may affect kidney function and thus change the clinical and pathological courses of some renal diseases. It has been demonstrated that renal ECs are important factors in the maintenance of kidney function in patients with preexisting renal or circulatory disease, because COX inhibition precipitates deleterious effects on these patients. The increased vasodilator EC production in many chronic renal diseases and in animal models of acute and CRF suggest a compensatory mechanism to the compromised renal function. Renal TXA_2 synthesis is usually found to be elevated in animals and humans with diminished renal function. Thus, pharmacological doses of PGE_1 or PGE_2 or thromboxane inhibition have been shown to have beneficial effects in a variety of renal diseases. Often both n-6 and n-3 dietary supplements will improve a given renal disorder. Since the effects of these two fatty acids on the formation and metabolism of AA are totally different, changes in EC synthesis may not be the only mechanism responsible for the improved renal function. Since changes in PUFA intake can change the phospholipid composition of cell membranes, changes in membrane function may also be involved. Membrane changes could alter fluidity and permeability, solute transport, enzyme activities, receptor functions, and immunological and inflammatory reactions, and these changes could be independent of alterations in EC production. Omega-3 PUFA-supplemented diets may alter the production of tumor necrosis factor and interleukin-1 in macrophages and thus attenuate the inflammatory response (Endres et al., 1989). PUFAs may also improve kidney function through their actions on serum lipids. Changes in blood fibrinolytic activity and blood viscosity may improve the rheological disturbances that could contribute to renal insufficiency. At the present time, we do not fully understand the patho-physiological role of ECs in renal disease, and additional research is essential. Further studies are warranted to define the cellular origin of the ECs, to determine the extent to which renal diseases can be ameliorated by modulating EC synthesis or action via the use of specific enzymatic inhibitors or receptor blockers, and to determine how changes in fatty acid membrane composition affect renal processes. The possible relationship between hyperlipidemia and the progression of renal disease has received much attention, but further work is needed to elucidate fully the relationship and the extent to which renal disease can be changed by altering the serum lipids. It may turn out that modifications in dietary fats could be a relatively easy and practical way to attenuate or prevent some renal diseases. Indeed, dietary PUFA modulation appears to be a useful strategy that is recently finding increased clinical application.

47 Fatty Acid Metabolism in Diabetes

Sam J. Bhathena

CONTENTS

I. INTRODUCTION

The two major abnormalities in both insulin-dependent diabetes mellitus (IDDM, type 1) and noninsulin-dependent diabetes mellitus (NIDDM, type 2) are hyperglycemia and dyslipidemia.

In normal as well as many pathological conditions, the metabolism of carbohydrates, especially glucose, is closely linked to the metabolism of lipids. Insulin is intimately involved in the control of carbohydrate and lipid metabolism. There is either an absolute (in IDDM) or relative (in NIDDM) deficiency of insulin in diabetes or peripheral resistance to insulin, particularly in obese NIDDM subjects. Thus, in untreated as well as poorly controlled diabetic subjects, hyperlipidemia is often associated with hyperglycemia. Close relationship has also been reported for fasting plasma glucose and fasting and meal-stimulated free fatty acid (FFA) levels (Coates et al., 1994). Newgard and McGarry (1995) recently advanced the concept that important signal for insulin secretion may reside at the linkage between glucose and lipid metabolism, namely the generation of malonyl coenzyme A (CoA) that promotes fatty acid esterification and inhibits oxidation. The treatment of hyperglycemia by both diet and exercise, oral agents (sulfonylureas, biguanides, thiazolidinediones), or insulin often also results in the partial reduction of hyperlipidemia.

A major proportion of fatty acids are present in the esterified form as a component of phospholipids, triglycerides, or cholesterol esters. In contrast, only a small fraction of total fatty acids in the body (plasma and tissues) is in the free form (nonesterified or FFAs). The metabolism of fatty acids is intimately linked to the metabolism of lipids and lipoproteins. The differences in the composition of lipids and lipoproteins between control and diabetic subjects are both quantitative and qualitative. In diabetes the most common abnormalities in lipid metabolism, and therefore of fatty acids, are elevated triglycerides (TGs) and very-low-density lipoproteins (VLDL), altered lipogenesis, and accelerated lipolysis (Randle, 1963; Tarrant et al., 1964; Fredrickson et al., 1967; Saudek and Eder, 1979; Brown et al., 1982; Dunn, 1988, 1990; Garg and Grundy, 1990; Fagot-campagna et al., 1997). An increase in small dense low-density lipoprotein (LDL), an integral part of insulin resistance syndrome, has been recognized as an independent risk factor for coronary heart disease (CHD) and may be a predictor of NIDDM (Austin et al., 1995, 1996). The increased VLDL levels are due to increased production as well as decreased clearance. As a consequence, there is an increase in FFA in the plasma of diabetic subjects. Increased levels of plasma TG, total and LDL-cholesterol, apolipoprotein B (apo B), apolipoprotein A-IV (apo A-IV), and phospholipids are also observed in poorly controlled IDDM subjects (Attia et al., 1997). The increased level of lipoproteins containing apoprotein B appears to be due to increased secretion rather than intracellular degradation due to increased FFA flux from liver (Ginsberg, 1996). In poorly controlled diabetic patients there is also an increased nonenzymatic glycosylation of LDL apoprotein B (Steinbrecher and Witztum, 1984; Taskinen, 1987), increased oxidation of LDL lipoproteins (Dimitriadis et al., 1996) and apo A-IV levels (Verges et al., 1994) and decreased high-density lipoprotein (HDL) and HDL_2-cholesterol (Verges et al., 1994). The low levels of HDL are due to a decreased production (Golay et al., 1987) and an increased catabolism due to the increased hepatic TG lipase activity (Kasim et al., 1987). Autoantibodies to LDL are also increased in NIDDM subjects with and without atherosclerosis and are accompanied by high levels of polyunsaturated fatty acids (PUFAs) in LDL (Griffin et al., 1997). Abnormalities in lipid metabolism have been reported in animal models of diabetes, namely, streptozotocin-treated rat, d*b*/d*b* mouse, and in newer models of NIDDM, the obese SHR/N-cp rat and obese WKY/N-cp rat (Hennig and Dupont, 1983; Cunnane et al., 1985; Michaelis et al., 1986; Bhathena et al., 1989a). The abnormalities of lipid metabolism also accompany various complications of diabetes, namely retinopathy, nephropathy, peripheral neuropathy, coronary arterial disease, microangiopathy, lipodystrophy, and ketoacidosis (Vannini et al., 1984; Appel et al., 1985; Winocour et al., 1987; Stacpoole et al., 1988; Vandongen et al., 1988). The vascular complications of diabetes may be in part due to increased lipoperoxidation of LDL in erythrocytes and other cell membranes (Rabini et al., 1994).

This chapter covers only the alterations in plasma and tissue fatty acid composition, the role of dietary fatty acids in different types of diabetes and its complications, the metabolism and hormonal regulation of fatty acids in diabetes, and how the control of diabetes by diet and exercise, oral hypoglycemic and hypolipidemic agents, and insulin affects fatty acid metabolism. Though earlier studies will be referred to, this chapter concentrates more on the studies carried out in the past 10 years. Only a few references are cited; several more could have been easily added.

II. FATTY ACID COMPOSITION OF TISSUE LIPIDS

Dietary fatty acids have been shown to influence the fatty acid composition of lipids in plasma and tissues in normal as well as in pathological conditions such as diabetes (Horrobin, 1989; Popp-Snijders and Blonk, 1995; Berry, 1997). The trend in past 40–50 years indicate increased consumption of saturated fats, *trans* fatty acids (TFA), vegetable oils rich in linoleic acid and decreased consumption of long-chain PUFA (arachidonic acid, AA; eicosapentaenoic acid, EPA; and docosahexaenoic acid, DHA) leading to increased incidence of NIDDM and related disorders (Simopoulos, 1994).

The fatty acid composition of cholesterol esters appear to be related to the risk of development diabetes. The risk is increased when cholesterol esters are rich in saturated fatty acid, palmitoleic acid, γ-linolenic acid (GLA), and dihomo-γ-linolenic acid (DHLA), and low in linoleic acid (Vessby et al., 1994). The prevalence of diabetes may also be correlated with the dietary ratio of ω6–ω3 fatty acids (Berry, 1997). Besides diet, genetic factors may also play a role in altering fatty acid composition of cholesterol esters (Vessby et al., 1994). Feeding very long-chain fatty acids (C24–C34) increases these fatty acids in phosphatidyl choline but not in other phospholipids of some organs such as rod of outer segments in normal as well as diabetic rats (Suh et al., 1994).

In untreated and poorly controlled diabetic subjects, desaturases involved in the metabolism of fatty acids are decreased (see below) and 18-carbon fatty acids with a low number of double bonds predominate both in plasma and in tissues. Thus, even though the composition of fatty acids in plasma reflects that in the diet, metabolites may be different. Mikhailidis et al. (1986) fed DHLA to controls and IDDM subjects. In controls there was an increase in DHLA as well as its metabolite AA in erythrocyte lipids, but in IDDM subjects there was no proportionate increase in AA in erythrocyte lipids, indicating a possible defect in Δ5 desaturase. Similarly, conversion of DHLA to prostaglandin E_1 (PGE_1) was also inhibited in IDDM subjects but not in controls (Mikhailidis et al., 1986). Decreased AA in plasma and 6-keto-$PGF_{1\alpha}$ in urine have been reported in IDDM (Pottathil et al., 1985). Bassi et al. (1996) reported decrease in plasma phospholipid ω6 fatty acids in IDDM subjects with mild ketosis, which was primarily due to decrease in AA. There was also an increase in 20:4 to 20:3 ratio indicating decreased Δ5 desaturase activity during mild ketosis. Fatty acids in platelets from control nondiabetic subjects showed a significant inverse correlation between linoleic acid and AA. No such relationship was observed in IDDM and NIDDM subjects, indicating that both Δ5 and Δ6 desaturases are impaired in the diabetic state (Jones et al., 1986). Diabetic children in good control showed a direct correlation between apo A-I and PUFAs and the ratio of PUFA/saturated fatty acids in TGs, while APO A-II correlated with the ratio of DHLA and AA (Ewald et al., 1982).

Some differences have been observed in the fatty acid compositions of plasma lipids between IDDM and NIDDM subjects (Seigneur et al., 1994). A decrease in EPA was observed in the livers of diabetic subjects (Singer et al., 1980) but, in another study, EPA in liver TGs was high (greater than 30%) in diabetic subjects without hyperlipoproteinemia (Singer et al., 1984). In another study, no significant differences were observed in plasma concentrations of AA, EPA, DHA or the saturated fatty acids (palmitic and stearic) between normal and poorly controlled diabetic Melanesian subjects (Rao and Erasmus, 1996). In red blood cells of IDDM (van Doormaal et al., 1984) as well as NIDDM (Prisco et al., 1989a) subjects, phospholipids have significantly higher saturated fatty acids and decreased PUFA. A similar fatty acid profile was observed in plasma of IDDM subjects (van Doormaal et al., 1984; Juhan-Vague et al., 1986), which was normalized when diabetes was improved by insulin infusion (van Doormaal et al., 1984). However, in another study insulin treatment had no significant effect on the fatty acid composition of erythrocyte membrane phospholipids (Persson et al., 1996). In NIDDM subjects with hyperlipidemia, there is an increase in saturated fatty acid and monounsaturated fatty acid (MUFA) in plasma lipids and a decrease in ω6 PUFA metabolites and C_{20}–C_{22} PUFA (Bohov et al., 1997). Diabetic subjects with macroangiopathy had significantly lower EPA and DHA acid but higher AA in platelet phospholipids than diabetic subjects without macroangiopathy and control subjects (Morita et al., 1983; Prisco et al., 1989b). Increased AA has also been observed in LDL and in erythrocyte membrane phospholipids of diabetic subjects

compared to controls (Rabini et al., 1994). Similarly, in patients with diabetic nephropathy, levels of DHLA, α-linolenic acid (ALA) and DHA are low in plasma phospholipids compared to control subjects (Das, 1995). Alteration in fatty acid composition is also observed in milk of diabetic mothers, especially lower levels of long-chain PUFA (Jackson et al., 1994), indicating altered metabolism in the mammary gland (Bitman et al., 1989).

Since hyperlipidemia and other abnormalities of lipid and lipoprotein metabolism associated with coronary artery disease are usually present in diabetic subjects, especially obese NIDDM, they are prudently recommended to consume diets low in total fat and saturated fatty acids and high in PUFA (Mann et al., 1976; American Heart Association, 1986; American Diabetes Association, 1987; Kissebah and Schectman, 1988; Margolis and Dobs, 1989; Clandinin et al., 1993). It is therefore not surprising to find higher levels of linoleic acid, GLA, and AA as well as EPA and DHA and lower levels of saturated fatty acids in plasma and tissues of well-controlled diabetic subjects (Ewald et al., 1982; O'Dea and Sinclair, 1985; Mann, 1986). Increased levels of EPA have been observed in plasma (Glauber et al., 1988; Landgraf-Leurs et al., 1990), red blood cells (Glauber et al., 1988), erythrocyte membranes (Kamada et al., 1986), platelets (Tilvis et al., 1987; Landgraf-Leurs et al., 1990), and pancreatic B cells (Lardinois, 1987) in diabetic subjects given a daily supplement of fish oils. Since fatty acids from the ω-3 family compete with those from the ω-6 family (Holman, 1986), feeding fish oil decreases linoleic acid and AA from tissue lipids, especially phospholipids (Dang et al., 1989; Landgraf-Leurs et al., 1990).

As stated earlier, atherosclerosis is a common abnormality of diabetes. Thickness of carotid intima-media is one of the predictor of atherosclerosis. In a population-based study, Ma et al. (1997) observed positive correlation between saturated fatty acid and MUFA composition of plasma phospholipids and cholesterol esters and carotid artery intima-media thickness. There was a negative correlation for PUFA and carotid artery intima-media thickness. This study further indicates the benefit of reducing dietary intake of saturated fatty acids to reduce the incidence of cardiovascular complications in diabetic subjects. The importance of MUFA in addition to ω3 fatty acids in reducing cardiovascular risk in Asian Indian diabetic subjects has been stressed (Peterson et al., 1994).

In animal models of diabetes, a somewhat different picture is observed. Most of the data on the fatty acid composition of various tissues in the diabetic state have come from animal studies. Significant changes in fatty acid composition of lipids, especially phospholipids, have been observed in many but not all tissues. In streptozotocin diabetic rats, the incorporation of palmitate, oleate, and linolenate into erythrocyte membrane phospholipids is reduced but arachidonate incorporation is not affected (Arduini et al., 1995). This is partially reversed by the treatment with propionyl-L-carnitine treatment (Arduini et al., 1995). In alloxan diabetic sheep (Henderson et al., 1982) and streptozotocin diabetic rat (Takahashi et al., 1987), there is a decrease in saturated fatty acids and an increase in PUFA in liver TGs, which are the major lipids. TG levels are also elevated in the hearts of diabetic animals (Denton and Randle, 1967; Murthy and Shipp, 1977; Paulson and Crass, 1982; Murthy et al., 1983), and the level of linoleic acid is increased (Gudbjarnason et al., 1987). Increased levels of TGs in the hearts of diabetic animals are due to both stimulation of esterification (synthesis) (Murthy and Shipp, 1977; Paulson and Crass, 1982) and an inhibition of lipolysis (Paulson and Crass, 1982; Murthy et al., 1983). In phospholipids, however, there is a significant decrease in PUFA in diabetic animals (Henderson et al., 1982; Takahashi et al., 1987), indicating a shift in PUFA from phospholipids to TGs. Similar decreases in AA and other PUFAs have been observed in whole liver (Holman et al., 1983) and in mitochondrial and microsomal lipids from diabetic rats (Labonia and Stoppani, 1988; Burke and Fenton, 1989; Dang et al., 1989). There was however, an increase in DHA in mitochondrial and microsomal membranes (Labonia and Stoppani, 1988; Burke and Fenton, 1989). Modulation of adipose tissue fatty acid by dietary fatty acids has been reviewed by Clandinin et al. (1993). Lipid changes in the heart in diabetes have been reviewed by Dhalla et al. (1992). Decreases in PUFA, especially AA, are also observed in adipocytes and from streptozotocin diabetic rat (Field et al., 1988, 1989, 1990; Clandinin et al., 1993) and in heart muscle of alloxan (Gudbjarnason et al., 1987) as well as streptozotocin (Holman et al., 1983) diabetic rat compared

to controls. The levels were normalized when the diabetic rats were fed diets with high PUFA/saturated fatty acid ratios (Field et al., 1988, 1990).

Dietary fatty acids produced no significant change in brush border membrane phospholipids (Keelan et al., 1987) or cholesterol esters in controls as well as the streptozotocin diabetic rats. Lack of alteration in lipid composition by dietary fatty acids in intestinal brush border membrane as opposed to a significant effect in liver and adipose tissue may be due to the fact that both the liver and adipose tissue are actively involved in lipid metabolism as opposed to the intestine. Also, unlike liver and adipose tissue, the intestine is not insulin sensitive (Shiau and Holtzapple, 1980) and therefore is less likely to show metabolic responses to dietary fatty acids. Abnormalities of PUFA metabolism were also observed in T cells (Singh et al., 1988), glomeruli (Kanzaki et al., 1987), testes (Wilder and Coniglio, 1984), and diaphragm and renal cortex (Chorvathova and Ondreicka, 1983) of streptozotocin diabetic rats. In the streptozotocin diabetic rat, dietary fatty acids did not alter AA content in plasma phospholipids, but in aortic phospholipids there was a significant decrease in AA, which was increased by feeding diets high in ω-6 fatty acids (Takahashi et al., 1988). In genetically diabetic d*b*/d*b* mice, decreases in AA in phospholipids in the pancreas and in TGs in the liver have been observed and were normalized by dietary essential fatty acids (EFAs) (Cunnane et al., 1985).

Thus, most tissues show a decreased level of AA in phospholipids in streptozotocin-treated animals, even when they are fed diets high in linoleic acid and GLA such as soybean oil and evening primrose oil, clearly indicating a defect in Δ5 and Δ6 desaturases. Streptozotocin produces hypoinsulinemia by destroying pancreatic B cells resembling IDDM in humans with absolute insulin deficiency, and insulin is required for normal functioning of desaturases.

III. METABOLIC EFFECTS OF DIETARY FATTY ACIDS IN DIABETES

A. Unsaturated Fatty Acids

There are at least four families of unsaturated fatty acids. However, fatty acids from only two families, ω-6 and ω-3, are considered essential. The two most common EFAs are linoleic acid (18:2ω6) and ALA (18:3ω3). They are required for normal growth and other biological processes and cannot be synthesized in humans owing to the lack of specific desaturases required to insert double bonds at the correct positions. Both acids, linoleic and ALA, as well as oleic acid are involved in cholesterol transport and oxidation. Most of the other biological effects of both of these fatty acids appear to be through their conversion to longer chain, more unsaturated fatty acids, such as GLA and AA from linoleic acid and EPA from ALA. GLA, in fact, is 170 times as active as linoleic acid in lowering cholesterol levels (Horrobin and Manku, 1983). High cholesterol-lowering activity has also been reported for AA (Kingsbury et al., 1961). These fatty acids are precursors for leukotrienes (LTs) and prostanoids that are biologically active. In addition, AA is a major component of cellular membrane structure, and the nature and unsaturation of the membranes determine the biological function (see below). The importance of EFA in human and animal nutrition has been reviewed by Sinclair (1984). It has been shown that dietary PUFA also regulate transcription of genes thereby influencing the metabolic directions of fuels (Clarke et al., 1997). Though precise mechanism of how PUFA regulate gene transcription is not known, it may be via modulation of transcription factor peroxisome proliferator-activated receptor (PPAR) action.

In diabetes, in general there is increased concentration of saturated fatty acid and MUFA and decreases in PUFA (see above). EFAs of both families have been shown to have several beneficial effects in normal and diabetic subjects. Complications of diabetes, namely, retinopathy, nephropathy, and peripheral neuropathy, may occur in chronic EFA deficiency (Sinclair, 1984). However, some deleterious effects of EFA have also been observed. Dietary fish oils contain proportionately higher concentrations of EPA and DHA. Their role in diabetes will be discussed separately.

B. ω-6 Fatty Acids

Most studies in human diabetic subjects used vegetable oils rich in linoleic acid. Few studies have used dietary AA and evening primrose oil that contain appreciable amounts of GLA as well as linoleic acid. In IDDM and NIDDM the beneficial effects include decreased cholesterol and TG levels especially with high doses of GLA (Chaintreuil et al., 1984); reversal of abnormalities in lipid metabolism caused by very low-fat diet (Piper et al., 1986); improved platelet function (Monnier et al., 1983), possibly by increased prostanoid and LT synthesis and secretion; enhanced erythropoiesis and decreased glycosylated hemoglobin levels (van Doormaal et al., 1988); and increased bleeding time (O'Dea and Sinclair, 1985), thereby reducing the risk of coronary artery disease. In addition, linoleic acid has been shown to have a protective effect in diabetic retinopathy (Houtsmuller et al., 1980; Howard-Williams et al., 1985), and GLA has beneficial effect in the prevention and treatment of diabetic polyneuropathy (Jamal and Carmichael, 1990; Keen et al., 1993). The beneficial effect of GLA on neurophysiological parameters in diabetic subjects has been reviewed by Horrobin (1997). Similarly, increased linoleic acid in LDL- and HDL-cholesterol in NIDDM subjects appear to protect against the oxidation of LDL (Dimitriadis et al., 1996). An epidemiological study in Australian aborigines also reported a beneficial effect of diets low in fat but high in PUFA in preventing the development of diabetes and cardiovascular diseases (Naughton et al., 1986). Diabetic subjects also showed a greater insulin response to PUFA compared to saturated fat.

Yam et al. (1996) reported increased incidence of NIDDM, cardiovascular diseases, hypertension, and obesity with hyperinsulinemia and insulin resistance as the underlying causes in Israeli population, which has the highest consumption of PUFA to saturated fatty acid ratio in the world. Thus, instead of being beneficial, high consumption of PUFA may have serious long-term effects. In animal studies, high PUFA intake has been shown to increase incidence of variety of tumors. Higher concentrations of long-chain PUFAs, especially C_{20}–C_{22} in muscle membrane phospholipids are shown to reduce insulin resistance, while linoleic acid appears to increase insulin resistance (Simopoulos, 1994).

Most of the studies in animals have been carried out in streptozotocin diabetic rats. Beneficial effects of PUFA have been observed after both short- and long-term feeding (Keelan et al., 1989). Diabetic rats fed PUFA had lower plasma and urinary glucose (Rajotte et al., 1988), lower glycosylated hemoglobin (Rajotte et al., 1988; Keelan et al., 1989), lower relative decline in glucose after intravenous glucose load, lower cholesterol and TG levels, and near-normal microsomal glucose-6-phosphatase activity (Keelan et al., 1989). However, in another study no improvement was seen during oral and intravenous glucose tolerance tests (Rajotte et al., 1988). In diabetes there is an increase in passive transport of both glucose and lipids. Saturated fatty acids further increase passive transport of lipids (Thomson et al., 1988). PUFAs decrease the enhanced glucose (Thomson et al., 1987a,b) and galactose (Thomson et al., 1987a) transport, possibly by increasing intestinal brush border membrane alkaline phosphatase activity (Thomson et al., 1987b), and also by enhancing lipid transport (Thomson et al., 1988). Others have not observed the beneficial effect of PUFAs on intestinal glucose uptake (Keelan et al., 1989).

As seen in human diabetic subjects, EFAS, especially GLA, improves nerve conductance in streptozotocin diabetic rats and improves symptoms of diabetic polyneuropathy (Julu, 1988; Tomlinson et al., 1989; Cameron and Cotter, 1994; Dines et al., 1995). Ascorbyl GLA appears to be more effective in improving neurovascular defect in diabetic rats than GLA, ascorbate or the combination of the two (Cameron and Cotter, 1996a). Similar synergistic effect was observed when GLA was given in combination with antioxidant (Cameron and Cotter, 1996b) or the aldose reductase inhibitors (Cameron et al., 1996; Cameron and Cotter, 1997). The beneficial effect of GLA may be in part due to increased prostacyclin production. A beneficial effect of AA on diabetes-related embryopathy has also been reported (Pinter et al., 1988). Reece et al. (1996) reported *in vivo* decreased incidence of neural tube defect in diabetic rats fed safflower oil. The effect was attributed to the conversion of linoleic acid to AA. In human skin fibroblast cultured in the presence of lipoprotein-deficient

serum, linoleic acid and AA increased carbohydrate oxidation as measured by increased pyruvate dehydrogenase activity (Loriette et al., 1987).

Dietary PUFA has been reported to increase glucose utilization (Awad, 1981; Field et al., 1990) along with increased insulin binding (Field et al., 1988) and improved insulin sensitivity (Field et al., 1990). Others, however, have reported increased insulin resistance in liver and muscle in diabetic rats fed linoleic acid and saturated fatty acids (Storlien et al., 1987). In obese as well as insulin-treated diabetic rats, PUFA from corn oil appears to suppress lipogenic enzyme gene expression stimulated by insulin (Iritani et al., 1995; Iritani and Fukuda, 1995). PUFAs compared to saturated fat, decreases insulin binding, autophosphorylation of the receptor and the kinase activity in liver, which are partially reversed by pioglitazone (Iritani and Fukuda, 1995). In streptozotocin diabetes, T-cell-dependent immune function is decreased. Although dietary linoleic acid did not improve the T-cell function, diets low in linoleic acid further decreased the immune function (Singh et al., 1988). In diabetic mice, dietary linoleic acid increases the incorporation of AA in phospholipids of the pancreas and liver (Cunnane et al., 1985).

Several studies in animal models of diabetes have reported detrimental effects of EFA and beneficial effects of feeding EFA-deficient diets. Thus, in diabetes prone BB rats, feeding an EFA-deficient diet, which lowers the concentrations of AA, decreased the incidence of spontaneous diabetes (Lefkowith et al., 1990). It is possible that AA or its eicosanoid metabolites may be responsible for the inflammatory injury in this model of autoimmune diabetes (Lefkowith et al., 1990), which resembles human IDDM. In this regard, it is interesting to note that injection of arachidonate in BB rats increased the concentrations of thromboxane B_2 (TXB_2) and trioxilin A_3 and decreased 6-keto-$PGF_{1\alpha}$ (Pace-Asciak et al., 1988). This increased ratio of TXB_2 to 6-keto-$PGF_{1\alpha}$ is in line with the prothrombotic nature of platelets associated with diabetes (Pace-Asciak et al., 1988). Similarly, in nonobese diabetic mice, EFA deficiency decreases the incidence of diabetes and has the protective effect on autoimmunity (Benhamou et al., 1995). There is an increase in splenocyte interleukin-4 production and a reduction in interferon-γ production, while in macrophages there is an increase in tumor necrosis factor-α (TNF-α) and interleukin-1 and a reduction of PGE_2 indicating altered eicosanoid metabolism (Benhamou et al., 1995). The beneficial effect of EFA deficiency was also observed in low-dose streptozotocin-treated diabetic mice, possibly by decreasing the lipid mediators of autoimmunity such as prostaglandin and LTs (Wright et al., 1988). The destruction of pancreatic B cells was also low in EFA-deficient mice (Wright et al., 1988; Fraser et al., 1997). EFA deficiency also prevents diabetes in low-dose streptozotocin mice treated with cyclosporin A (Wright et al., 1995), the later is known to increase the severity of diabetes in streptozotocin-treated mice. Also streptozotocin- and alloxan-treated diabetic rats were less EFA deficient than control rats when fed diets deficient in EFA (Riisom et al., 1981). The levels of AA in liver and heart phospholipids were higher in diabetic rats than in controls fed an EFA-deficient diet (Riisom et al., 1981). The reason for this is not clear. It could be that the concentration of AA in phospholipids is well preserved in diabetes or that a specific phospholipase (phospholipase A_2) may be less active. It is also possible that processes of desaturation and elongation of fatty acids are less affected in diabetes. The latter possibility is less attractive because desaturases have been shown to be decreased in diabetes.

C. ω-3 Fatty Acids and Fish Oils

In diabetic subjects, dietary supplementation of long-chain PUFAs present in fish oils has been studied more extensively than that of other fatty acids. The two predominant PUFAs in fish oils are EPA and DHA. In nondiabetic but hyperlipidemic subjects, fish oil feeding has been shown to have more beneficial effects, especially in reducing the risk of heart disease, and few deleterious effects, as reviewed by Mueller and Talbert (1988), Gibson (1988), Margolis and Dobs (1989), Harris (1989), Nestel (1990), Flaten et al. (1990), and Kinsella et al. (1990). In a prospective study with Physicians, moderate consumption of fish had no effect on lowering the risk of cardiovascular disease (Morris et al., 1995). In diabetic subjects, however, supplementation with fish oils has not produced beneficial

TABLE 47.1
General Effects of Dietary Fish Oils in Normal and Diabetic Subjects

Reduce risk of heart disease
Lower TGs and lipoproteins
Increase HDL-cholesterol (HDL_2 and HDL_3)
Reduce thrombogenicity of platelets in microcirculation
Reduce platelet aggregation
Decrease incidence of NIDDM
Increase insulin secretion and insulin sensitivity
Prevent insulin resistance caused by high fat and saturated fat diets
Improve fluidity of cell membranes in IDDM but not NIDDM subjects
Decrease blood pressure in hypertensive individuals
Decrease as well as increase plasma or blood viscosity
Increase total and LDL-cholesterol
Increase fasting and postprandial blood glucose
Increase hepatic glucose output
Impair insulin secretion (in diabetic patients)
Increase nonenzymatic glycosylation
Altered eicosanoid production
Increase bleeding time
Impair red cell deformity
Decrease vitamin E absorption
Increase caloric intake and hence weight gain
Cause stomach and intestinal irritation

effects to the extent seen in nondiabetic subjects. The role of dietary fish oils in diabetic subjects has been reviewed by Axelrod (1989), Sorisky and Robbins (1989), and Vessby (1989). Fish oil concentrate K-85, containing 92% of total fatty acids as ω3 fatty acids has been shown to lower serum TG and VLDL in nondiabetic hypertriglyceridemic subjects (Mackness et al., 1994). Its effect in diabetic subjects however, needs to be explored. ω3 Fatty acids also have antihypertensive effects (Knapp, 1996). The known metabolic and biological effects of fish oils in nondiabetic and diabetic subjects are summarized in Table 47.1.

In diabetic subjects, the most consistent beneficial effect of dietary fish oils is the lowering of plasma TG levels (Popp-Snijders et al., 1986, 1987; Schectman et al., 1988, 1989; Borkman et al., 1989; Mori et al., 1989; Rillaerts et al., 1989; Schmidt et al., 1989; Stacpoole et al., 1989; Bagdade et al., 1990; Landgraf-Leurs et al., 1990; Rivellese et al., 1996; Sirtori et al., 1997), though in one study no significant lowering of TG was observed in NIDDM (Kasim et al., 1988). Singer et al. (1984) observed a negative correlation between TG and EPA in the liver of diabetic subjects. In most studies (Haines et al., 1986; Schectman et al., 1988; Vandongen et al., 1988; Mori et al., 1989; Stacpoole et al., 1989) but not all (Borkman et al., 1989; Rillaerts et al., 1989), total cholesterol and LDL-cholesterol were increased. However, this deleterious effect was negated by increases in HDL-cholesterol (especially in HDL_2 and HDL_3 subfractions) (Vandongen et al., 1988; Mori et al., 1989; Rillaerts et al., 1989; Schectman et al., 1989; Schmidt et al., 1989; Bagdade et al., 1990). There was also a lowering of the cholesterol/phospholipid ratio (Kamada et al., 1986) and the cholesterol/HDL-cholesterol ratio (Rillaerts et al., 1989; Schmidt et al., 1989), which is a measure of atherogenic index. Decrease in plasma VLDL TG and FFA and increase in long-chain ω3 fatty acids in erythrocyte phospholipids have been observed after 6 months of feeding fish oil to NIDDM subjects (Rivellese et al., 1996) but had no significant effect on blood glucose control in these subjects. Fish oil increases lipoprotein lipase (LPL) activity in NIDDM (Kasim et al., 1988) but has no effect in IDDM (Bagdade et al., 1990). In a study comparing ω3 fatty acids from fish oil (EPA + DHA) with that from linseed oil (linolenic acid), fish oil decreased plasma TGs in NIDDM subjects but

linseed oil was without effect (Goh et al., 1997) indicating that preformed long-chain ω3 fatty acids are more effective in lowering lipid levels in diabetic subjects than linolenic acid. ω3 Fatty acids are also more readily incorporated in brain and other tissues as compared to those from vegetable oils. Recognizing the need for preformed long-chain PUFA for brain development and function, infant milk formulas are now being supplemented with fish oil (Clandinin et al., 1992; Carlson, 1994). This has led to improved brain and visual function in infants (Makrides et al., 1994; Uauy et al., 1994). The beneficial effects of fish oil on lipid metabolism in NIDDM subjects are potentiated by high-fiber intake (Sheehan et al., 1997).

Dietary fish oils have several deleterious effects on carbohydrate metabolism in diabetic subjects. There is an increase in fasting and postprandial glucose (Glauber et al., 1988; Kasim et al., 1988; Schectman et al., 1988; Borkman et al., 1989; Friday et al., 1989; Vessby, 1989), increased levels of glycosylated hemoglobin (Schectman et al., 1988), increased hepatic glucose output (Glauber et al., 1988), but unaltered glucose disposal (Glauber et al., 1988; Friday et al., 1989) and thus worsened glycemic control. However, in a multicenter study, ethyl ester of ω3 fatty acid did not worsen the glycemic control (Sirtori et al., 1997). In another study, fish oil improved glucose homeostasis in some but not all subjects (Zak et al., 1996). Short-term feeding of fish oil was shown to increase gluconeogenesis from glycerol but not the overall glucose production or the glycemic control (Puhakainen et al., 1995). Owing to the increase in gluconeogenesis from glycerol, long-term feeding of fish oil is anticipated to deteriorate glucose control. Insulin secretion is also impaired by fish oil feeding (Glauber et al., 1988; Lardinois et al., 1988), but plasma insulin levels are generally not altered (Borkman et al., 1989; Friday et al., 1989). In some diabetic subjects, fish oil feeding also increases the daily insulin requirement for metabolic control (Stacpoole et al., 1989). Dietary fish oil, however, prevents insulin resistance caused by a high-fat diet or by saturated fat (Storlien et al., 1987; Borkman et al., 1989) and improves insulin sensitivity (Popp-Snijders et al., 1987; Vessby, 1989). Beneficial effects of dietary ω-3 fatty acids have been observed in a diabetic subject with acanthosis nigricans and lipodystrophy (Sherertz, 1988); however, this needs to be confirmed. ω3 Fatty acids also increased fluidity of erythrocyte membranes in IDDM (Kamada et al., 1986; Tilvis et al., 1987), but no change was seen in NIDDM subjects (Popp-Snijders et al., 1987; Rabini et al., 1993). Dietary fish oil affects several hormones besides insulin. Thus, fish oil feeding decreased glucagon and somatomedin-C (Bhathena et al., 1991) and β-endorphin (Bhathena et al., 1993).

In diabetic subjects there is a decrease in thromboxane but normal prostacyclin production (Tilvis et al., 1987), and increased platelet aggregation (Landgraf-Leurs et al., 1990). ω-3 Fatty acids further lower thromboxane production *in vitro* in platelets stimulated with collagen or adenosine diphosphate (Haines et al., 1986; Tilvis et al., 1987; Landgraf-Leurs et al., 1990), but thromboxane production from exogenous AA is increased (Tilvis et al., 1987). Fish oil feeding either decreased platelet aggregation (Landgraf-Leurs et al., 1990) or prolonged the lag phase before aggregation (Haines et al., 1986). Harris et al. (1997) reported that antiatherogenic effect of fish oil may also be in part due to enhance arterial nitric oxide (NO) production, which has vasodilatory effects. Other beneficial effects of dietary ω-3 fatty acids in diabetic subjects include decreased blood viscosity (Rillaerts et al., 1989), lowering of blood pressure (Kasim et al., 1988), and increased neutrophil but not monocyte chemotaxis (Schmidt et al., 1989). The formation of eicosanoids and their effects in diabetes are discussed later in this chapter.

ω-3 Fatty acids in fish oils are highly unsaturated and are easily oxidized. Vitamin E decreases this peroxidation, and hence in some diabetic subjects, especially children, high intake of fish oil causes vitamin E deficiency, which may lead to neurological disturbance when severe malabsorption problems exist (Margolis and Dobs, 1989). The apparent differences in the observed fish oil effects in different studies are partly due to different doses of fish oil concentrate as well as the length of feeding.

Very few studies on the effects of dietary fish oils have been carried out with animal models of diabetes. In diabetes-prone BHE rats fed fish oil, thyroxine increased fatty acid synthesis in liver and adipose tissue (Pan and Berdanier, 1990). In low-dose streptozotocin-treated mice, fish oil decreased elevated blood glucose and improved immune function (Linn et al., 1989) but increased the development of retinopathy (Hammes et al., 1996). In streptozotocin-treated rats, ω-3 fatty acids had no

effect on glucose, TG, or cholesterol levels, but the development of cardiomyopathy was partially blocked, possibly by improving Ca^{2+} transport activity in cardiac sarcoplasmic reticulum (Black et al., 1989). However, in diet induced, insulin resistant mildly diabetic rats, fish oil did reduce plasma TG and cholesterol and corrected hyperinsulinemia (Luo et al., 1996). Infusion of perilla oil rich in ALA compared to soybean oil in streptozotocin-treated diabetic rats increased the proportion of EPA and decrease AA in serum and liver phospholipids accompanied by a decrease in TXA_2 production (Ikeda et al., 1995). These changes were independent of plasma insulin levels. In hepatic microsomes, ω-3 fatty acids decreased the incorporation of AA acid in phospholipids and also decreased Δ5 desaturase activity. There was a corresponding increase in DHA in hepatic microsomes (Dang et al., 1989), indicating a competition between ω-3 and ω-6 fatty acids. ω3 Fatty acids also increase cholesterol to phospholipid ratio in liver microsomal membranes of normal as well as experimental diabetic rats (Igal and de Gomez Dumm, 1997). In β-TC3 insulinoma cell line, EPA-potentiated glucose-stimulated insulin secretion without affecting glucose metabolism (Konard et al., 1996).

From human studies, it is thus clear that in diabetic subjects ω-3 fatty acids appear to have some beneficial effects on lipid metabolism and may decrease the severity of cardiac disorder and lower the incidence of coronary artery disease. However, ω-3 fatty acids have detrimental effects on carbohydrate metabolism and worsen glycemic control even though insulin sensitivity is improved. Also, the beneficial effects on lipid metabolism cannot be sustained by prolonged fish oil treatment and are reversed when fish oil feeding is stopped. Thus, on the basis of the present knowledge, it is not prudent to supplement high doses of ω-3 fatty acids for a prolonged time to diabetic subjects. The beneficial effect of lowering hypertriglyceridemia in diabetic subjects can be achieved by substituting starch for simple sugars in the diet. The consumption of fish is more beneficial than fish oil for diabetic individuals. The reasons for this are beyond the scope of this chapter.

D. Saturated Fatty Acids

Several studies have shown that saturated fat intake is a risk factor for hyperinsulinemia. Folsom et al. (1996) observed a positive correction between saturated fatty acid percentage in plasma phospholipids and insulin levels. Rasmussen et al. (1996) compared the effect of butter and olive oil in NIDDM subjects and showed that saturated fat increase insulin response more than MUFAs.

Saturated fatty acid (palmitate) also increases glucose-induced insulin release but not basal release, which is reversed by epinephrine. Palmitate appears to act via increasing calcium flux and the mobilization of intracellular calcium (Warnotte et al., 1994). Though saturated fatty acids stimulate glucose transport in isolated rat adipocytes acutely, prolonged treatment induces insulin resistance via postreceptor defect (Hunnicutt et al., 1994). The stimulation of glucose transport by saturated fatty acids in adipocytes is via stimulation of insulin receptor autophosphorylation (Hardy et al., 1991).

E. *Trans* Fatty Acids

The average estimated consumption of TFA in the United States is 6%–8% of total daily intake (Senti, 1988). Most of it comes from margarines and other hydrogenated oils used for frying (Enig et al., 1990), from milk (Parodi, 1976), and in small quantities from some green vegetables. In humans and animals, dietary TFAs are readily and reversibly incorporated into plasma and tissue lipids, especially TGs, and to a small extent in phospholipids (Moore et al., 1980; Vidgren et al., 1998). TFAs have also been found in human milk after feeding diets high in TFA (Aitchison et al., 1977). In phospholipids TFAs are normally incorporated in position 1, where saturated fatty acids are also preferentially incorporated. Mitochondrial enzymes can metabolize TFAs via 2-*trans*-enoyl CoA or 3-*trans*-enoyl CoA depending on the position of the double bond (Schettler, 1986).

The biological effects of TFAs are not fully understood. Compared to oleic acid, TFAs have been shown to elevate serum TG (Anderson et al., 1961; Mensink and Katan, 1990), total cholesterol (Vergroesen, 1972; French et al., 2002), and LDL-cholesterol (Laine et al., 1982; Mensink

and Katan, 1990), and to lower HDL-cholesterol (Mensink and Katan, 1990). Mattson et al. (1975), however, did not observe the elevation in cholesterol or TG. The TFAs also elevate apo B and lower apo A-I compared to oleic acid (Mensink and Katan, 1990). Thus, the effects of TFAs on lipid and lipoprotein metabolism are worse than those of saturated fatty acids (Mensink and Katan, 1990). The TFAs of the ω-9 family (18:1ω9) inhibit Δ6 desaturase involved in the conversion of linoleic acid to GLA in the liver and heart but have no effect on Δ5 desaturase in the ω-6 family. They also decrease Δ9 desaturase (Hill et al., 1982). In monkeys, Barnard et al. (1990) reported that, unlike *cis* isomers, TFAs had no effect on erythrocyte membrane fluidity but affected insulin receptors by decreasing the number and increasing the affinity, an effect similar to that observed with saturated fatty acids (Ginsberg et al., 1979; Gould et al., 1982; Berlin et al., 1989). In brain TFAs are less potent in inhibiting binding of opiates to their receptors and in decreasing membrane viscosity compared to corresponding *cis* fatty acids (Remmers et al., 1990). They also alter the concentration of dopaminergic neurotransmitters in brain (Acar et al., 2003).

It is important to note that these studies were carried out in normal humans and animals. No studies on the effects of TFA in diabetic subjects have been reported. Since in most studies, TFAs have been shown to be as atherogenic as saturated fatty acids (and certainly more than unsaturated fatty acids) and also to lower insulin receptor number, it is possible that, compared to unsaturated fatty acids, TFAs will have deleterious effects in diabetic subjects. It is therefore advisable for diabetic individuals to restrict their intake of fats containing TFAs. Studies on the effects of TFAs on lipid profile, glucose homeostasis, and insulin and other hormones in diabetic subjects are long overdue.

F. Free Fatty Acids

One of the complications of lipid metabolism in diabetes is the increased lipolysis, which results in the increased plasma concentration of FFAs. Thus, increases in plasma FFAs have been observed in both IDDM and NIDDM subjects with or without ketoacidosis (Liewendahl and Helenius, 1976; Yue et al., 1981; Linfoot et al., 2005). Intra abdominal fat appears to be the precursor for increased lipolysis (Kissebah, 1996). In control subjects as well as in NIDDM subjects elevated levels of FFA inhibits insulin-stimulated glucose uptake in skeletal muscle by suppressing glycolysis and increasing insulin-stimulated glycogen synthesis (Kim et al., 1996) and hence may play a significant role in the pathogenesis of insulin resistance in NIDDM (Reaven and Chen, 1988; Randle et al., 1994; Boden, 1996; Charles et al., 1997). In NIDDM subjects, cigarette smoking further aggravates insulin resistance by increasing plasma FFA and decreasing lipid peroxidation (Targher et al., 1997). Elevated levels of FFA are also observed in the myocytes of diabetic animals (Kenno and Severson, 1985). FFAs can be both oxidized and re-esterified within tissues without oxidation (Felber et al., 1987). Increased availability of FFA increases fat oxidation (Lillioja et al., 1985; Felber et al., 1987). Elks (1990) suggested that increased availability of FFA for oxidation by muscle and other tissues may lead to the impairment of carbohydrate oxidation, thereby leading to the glucose intolerance seen in obese diabetic subjects. However, rate of lipid oxidation by muscle is reduced in NIDDM subjects (Kelley and Simoneau, 1994). Glucose-fatty acid cycle appears to act via inhibition of PDH complex by acetyl CoA and NADH (Wieland, 1983). In diabetes PDH level falls significantly and glucose utilization by inhibiting fatty acid oxidation is much less in diabetic monocytes than that of normal cells (Abdel-aleem et al., 1995). Increased activity of carnitine palmitoyltransferase-I (CPT-I) and carnitine acetyl transferase and decreased activity of PDH complex is also observed in diabetic d*b*/d*b* mice leading to increased oxidation of fatty acid and decreased oxidation of glucose (Makar et al., 1995). Glucose-fatty acid cycle may also operate in patients with insulin resistance and hyperlipidemia (Kumar et al., 1994). FFAs appear to stimulate insulin release (Crespin et al., 1973) and inhibit glucagon release (Madison et al., 1968) from pancreatic islets. However, long-term exposure of islets to high levels of FFA results in beta cell dysfunction and diminishes glucose-induced insulin secretion (Zhou and Grill, 1994; Girard, 1995; Newgard and McGarry, 1995; Hirose et al., 1996).

In pubertal IDDM subjects insulin has no significant effect on plasma FFA (Caprio et al., 1994). Higher concentrations of FFA in blood are associated with morphological changes in the arteries of diabetic rats (Reinila, 1981), which may be due to their high-detergent activity (Shaw, 1985). Elevated FFA in plasma in diabetes and other disorders result in hypercorticoidism and initiates a positive feedback loop between adipocytes and hypothalamic-pituitary-adrenal axis (Widmaier et al., 1995). In the fasting state and in diabetes, high levels of FFA increase platelet aggregation (Gjesdal et al., 1976; Mikhailidis et al., 1981), possibly by inhibiting vascular adenosine diphosphate activity and thereby decreasing the concentration of adenosine, an inhibitor of aggregation and a vasodilator as compared to adenosine diphosphate, which stimulates platelet aggregation (Barradas et al., 1987). Another mechanism may involve inhibition of prostacyclin (PGI_2) synthesis and acceleration of its degradation. Significant decreases in PGI_2 have been observed in the aorta and bladder of streptozotocin diabetic rats (Colwell et al., 1983; Jeremy et al., 1986, 1987). Recently NO has been suggested to play a role in FFA-induced insulin secretion since, islets from prediabetic Zucker fatty diabetic rats, FFA-induced significant rise in NO and reduced insulin secretion (Shimabukuro et al., 1997b).

IV. METABOLISM OF FATTY ACIDS IN DIABETES

The metabolism of fatty acids includes synthesis, desaturation and elongation, oxidation, and formation of eicosanoids. Desaturation and elongation of EFA is necessary for the synthesis of AA, which is generally not obtained from the diet and is required for eicosanoid formation (see below). AA is also a vital component of phospholipids of cellular membranes. Alteration in AA would lead to abnormal membrane formation and result in altered unsaturation and fluidity of the membranes.

A. Desaturation

There are four specific microsomal desaturases that are involved in the desaturation of fatty acids (Sinclair, 1984; Holman, 1986; Axelrod, 1989). Δ9 desaturase is involved only in the ω-9 and ω-7 series and converts palmitic acid to palmitoleic acid and stearic acid to oleic acid. Δ6, Δ5, and Δ4 desaturases are involved in the desaturation of fatty acids of all four families. Though not clearly demonstrated, it is presumed that the same desaturase is involved in the insertion of double bonds in specific positions in fatty acids of different families, that is, that there is only one each of Δ9, Δ6, Δ5, and Δ4 desaturases. Thus, there is interaction and competition between fatty acids of different families for the desaturase. This interaction has been reviewed by Holman (1986). Usually fatty acids with greater unsaturation are preferentially desaturated. Thus, fatty acids of the ω-3 family would be preferentially desaturated compared to other families, and fatty acids of the ω-7 and ω-9 families will be desaturated more only when the availability of EFAs is diminished.

In human diabetic subjects and experimental diabetic animals, the activity of all four desaturases is decreased. Though desaturase activity is present in liver microsomes, the alteration in fatty acid composition in diabetes, especially low levels of AA, in several tissues such as platelets, kidney, heart, testes, and plasma indicate that desaturation possibly occurs in these tissues as well. It is important to note that Δ5 and Δ6 desaturases are not present in human skin (Chapkin et al., 1986). The decrease in all four desaturases explains higher levels of fatty acids with 16- and 18-carbon atoms and lower levels of fatty acids with 20- and 22-carbon atoms in diabetic subjects and experimental diabetic animals (see above) except those fed fish oil, which supplies preformed EPA and DHA.

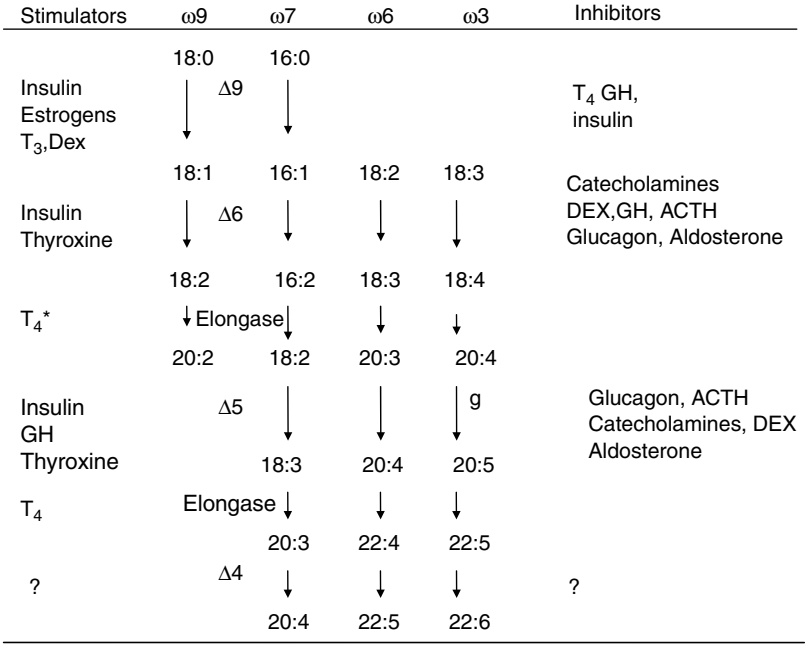
A decrease in Δ9 desaturase has been reported in diabetic rats (Friedmann et al., 1966; Gellhorn and Benjamin, 1966; Mercuri et al., 1974; Eck et al., 1979; Faas and Cater, 1980; Garg et al., 1986; Dang et al., 1988). Since it is not involved in the metabolism of EFA, Δ9 desaturase is of less importance. On the basis of direct *in vitro* studies in liver microsomes as well as on altered fatty acid composition, decreased Δ9 desaturase activity has been observed in liver, platelets, aorta, and plasma (Faas and Carter, 1980; Garg et al., 1986; Dang et al., 1988). Dietary carbohydrates

also modulate the desaturases in the normal as well as the diabetic state (Worcester et al., 1979). Different sugars have quantitatively different effects on Δ9 desaturase in liver and adipose tissue. In liver, dietary fructose stimulates Δ9 more than glucose in normal as well as diabetic rats (Mercuri et al., 1974; Worcester et al., 1979). Prasad and Joshi (1977) reported 20-fold stimulation of hepatic Δ9 desaturase by fructose in diabetic rats. In adipose tissue, fructose produced less stimulation of Δ9 desaturase than glucose (Worcester et al., 1979). Of all the four desaturases, Δ9 desaturase is most affected in diabetes (Gellhorn and Benjamin, 1964; Friedmann et al., 1966; Eck et al., 1979). Studies on the activity of Δ9 desaturase in human diabetic subjects are lacking. It is, however, possible that the decrease in Δ9 desaturase may also occur in diabetic humans especially in poorly controlled IDDM subjects, since insulin plays an important role in desaturation (see below).

A decrease in Δ6 desaturase has been suggested on the basis of fatty acid composition as well as direct measurement of the enzyme in diabetic humans (Tilvis and Miettinen, 1985; Jones et al., 1986; Tilvis et al., 1986; Keen et al., 1993). The enzyme is also decreased in experimental diabetic animals (Friedmann et al., 1966; Eck et al., 1979; Faas and Carter, 1980; Dang et al., 1988; Shin et al., 1995) and is increased after insulin treatment (Shin et al., 1995). It is a rate-limiting enzyme in the conversion of linoleic acid to AA (Marcel et al., 1968). Decreased Δ6 desaturase activity or its fatty acid metabolic products have been shown in several tissues including liver, kidney, aorta, platelets, testes, and plasma (Faas and Carter, 1980; Dang et al., 1988). Erythrocytes appear to be devoid of this enzyme (Shin et al., 1995). Riisom et al. (1981) reported increased Δ6 desaturase activity in liver microsomes of alloxan- and streptozotocin diabetic rats fed EFA-deficient diets compared to control rats fed the same diet. They also observed higher levels of AA in liver and heart phospholipids in diabetic rats than in control rats. It is important to note that in this model, EFA deficiency actually reduced the severity of diabetes and that diabetic rats were less EFA deficient than control rats. Therefore, increased Δ6 desaturase activity is not unexpected. The fatty acid composition in liver and heart, however, did not parallel the activity of desaturase in liver microsomes. It is possible that AA is better preserved in phospholipids or that lipolysis is decreased when diabetes is accompanied by EFA deficiency.

Decreases in Δ5 desaturases in several tissues have also been shown or suggested in diabetic humans (Stone et al., 1979; Tilvis and Miettinen, 1985; Jones et al., 1986; Tilvis et al., 1986; El Boustani et al., 1989; Bassi et al., 1996) and experimental animals (Holman et al., 1983; Wilder and Coniglio, 1984; Dang et al., 1988). Studies on the activity of Δ4 desaturase in humans and animals are lacking. Studies reporting changes in desaturases on the basis of fatty acid composition should be viewed with caution. Besides desaturases, fatty acid concentration in tissue and plasma can be changed because of utilization, oxidation, and membrane lipid degradation and synthesis.

The activity of desaturases, especially Δ6 and Δ5, is modulated by several factors. Two important factors are diet and hormones. Cholesterol feeding has been shown to decrease Δ5 and Δ6 desaturase activity in rats (Huang et al., 1985, 1990; Garg et al., 1986). However, dietary cholesterol stimulates Δ9 desaturase (Garg et al., 1986). This would tend to increase concentration of unsaturated 18-carbon fatty acids including oleic acid. No direct study of dietary cholesterol on desaturases has been carried out in humans, but increased levels of linoleic acid and decreased levels of AA observed in some hypercholesterolemic subjects may indicate a decrease in desaturase activity. Similarly, studies in diabetic animals with cholesterol feeding have not been done. Primrose oil, which is relatively high in GLA, may be beneficial in diabetic subjects because it bypasses the critical step in the formation of AA. TFAs have been reported to decrease desaturase activity (Brenner, 1981; Hill et al., 1982; Holman, 1986). High-fat diets also decrease the activity of Δ9, Δ6, and Δ5 desaturases (Garg et al., 1986). PUFAs increase Δ6 and Δ5 desaturases (Pugh and Kates, 1984; Garg et al., 1986). Both increases (Pugh and Kates, 1984) and decreases (Garg et al., 1986) have been observed in Δ9 desaturase by dietary PUFAs compared to saturated fats. Theoretically, fish oils, which are rich in EPA and DHA, are clearly beneficial for diabetic subjects because they need not be desaturated or elongated. However, high doses of fish oil compete with AA for the formation of eicosanoids. Eicosanoids formed from EPA have effects on platelet function diametrically opposite to those formed from AA (see below) and hence may not be of advantage for diabetic subjects.



* In microsomes but not in mitochondria

FIGURE 47.1 Hormonal control of fatty acid desaturation and elongation. The stimulatory and inhibitory effects of various hormones on different desaturases and elongase are shown. Note that the hormonal control of Δ4 desaturase is not yet defined. *Abbreviations:* T_3, triiodothyronine; T_4, thyroid hormone; Dex, dexamethasone; GH, growth hormone; ACTH, adrenocorticotropic hormone. *Nutritional Neurosc*. 9:1–10, 2006. With permission.

Like lipases, desaturases are also controlled by hormones. There is indirect, as well as, direct evidence that hormones control desaturation of fatty acids. Indirect evidence comes from the alteration of fatty acid composition in diabetic, thyroidectomized, hypophysectomized, and adrenalectomized animals where one or more hormone is lacking. Figure 47.1 summarizes the stimulatory and inhibitory effects of various hormones on desturation and elongation. Insulin plays an important role in fatty acid desaturation. Insulin treatment in humans (Tilvis et al., 1986; El Boustani et al., 1989) as well as experimental diabetic animals (Gellhorn and Benjamin, 1964; Prasad and Joshi, 1977; Eck et al., 1979; Faas and Carter, 1980) stimulates desaturases. Faas and Carter (1980) reported that insulin increased Δ6 desaturase levels, yet AA decreased in the liver, which they suggested could be due to increased utilization in excess of increased synthesis by desaturase. Glucagon and catecholamines, which antagonize the effect of insulin, decrease desaturase activity (de Gomez Dumm et al., 1975, 1976a,b; Brenner, 1981). Thus, decreased insulin and elevated glucagon in diabetic subjects would account for decreased desaturase activity in diabetes. Desaturase activity is also influenced by lipid-lowering agents. Using a ratio of 20:4 to 20:3 as an index of Δ5 desaturase activity, Matsui et al. (1997) showed that bezafibrate increases Δ5 desaturase activity and thereby improving insulin sensitivity.

Insulin has been shown to stimulate as well as inhibit Δ9 desaturase. Estrogens, triiodothyronine and synthetic glucocorticoid, dexamethasone, stimulate Δ9 desaturase (Marra and de Alainz, 1995; Stanton et al., 2001), while thyroid and growth hormones inhibit it (Gueraud and Paris, 1997). In obese women insulin stimulates Δ5 desaturase (Medeiros et al., 1995). Insulin and thyroxine also stimulate Δ5 and Δ6 desaturases while catecholamines, glucagon, aldosterone, adrenocorticotropic hormone (ACTH) and dexamethasone inhibit both desaturases. Thus, decreased insulin and increased glucagon in diabetic subjects would account for decreased desaturase activity in diabetic state. However, Liu et al. (2000) reported increased Δ6 desaturase activity in diabetes.

Testosterone, aldosterone, and corticosterone inhibit Δ6 desaturase in HTC cells (Marra et al., 1988). The hormonal control of Δ4 desaturase is not well defined. Δ4 Desaturase is also involved in the conversion of EPA to DHA in brain (Anderson et al., 1990). However, it is not clear whether any hormone or neuropeptide play a role in its modulation in brain. The TFAs of the ω9 family (18:1ω9) inhibit Δ6 desaturase involved in the conversion of linoleic acid to GLA in the liver and heart but have no effect on Δ5 desaturase in the ω6 family. Others have reported that TFAs also inhibit Δ5 desaturase and can also inhibit cyclooxygenase and lipooxygenase and thereby decrease eicosanoid production. They also decrease Δ9 desaturase (Hill et al., 1982). The effects of TFAs on desaturases in diabetes have not been elucidated.

B. Elongation

Elongation of fatty acids is carried out in the endoplasmic reticulum and in microsomes. Studies on the conversion of 18-carbon fatty acids to 20- and 22-carbon fatty acids have concentrated more on desaturases. Chain elongation is catalyzed by discrete enzymes using CoA derivatives as substrates (Sprecher, 1982). The elongases act much faster than desaturases (Sinclair, 1984). As observed for desaturation, there is also competition for elongation between the families of fatty acids. Thus, GLA is elongated to a greater extent than ALA. Unsaturated fatty acids of the ω-6 family increase elongation while saturated fatty acids decrease elongation of fatty acids of both families (Christiansen et al., 1968). No specific defect has been reported to occur in elongation of fatty acids in diabetes. Thyroxine has been shown to stimulate elongase in liver microsomes but not in mitochondria. The effects of other hormones on elongases have not been reported in normal or diabetic state.

C. Oxidation of Fatty Acids in Diabetes

Fatty acids are normally oxidized in liver mitochondria via β oxidation to acetyl CoA and then to CO_2 via the citric acid cycle. Short- and medium-chain fatty acids enter the mitochondria where they are esterified to CoA before oxidation. Long-chain fatty acids, however, are first esterified in the cytosol and then transported across mitochondrial membrane by CPT-I and CPT-II (McGarry et al., 1989) where they undergo β oxidation via fatty acyl-CoA dehydrogenase. The oxidation of short, medium-, and long-chain fatty acids is catalyzed by three isoenzymes. In general, unsaturated fatty acids are more readily oxidized than saturated fatty acids and hence saturated fatty acids are stored in tissue lipids more than unsaturated fatty acids. In human muscle, oxidation of long-chain fatty acids is controlled by glucose plus insulin via regulation of entry into mitochondria. However, mitochondrial uptake and oxidation of medium-chain fatty acids is not dependent on glucose and/or insulin (Sidossis et al., 1996). In diabetes, owing to the lack of insulin, oxidation of glucose is reduced and is compensated by increased oxidation of fatty acids. The ratio of fatty acid oxidation to esterification is higher in streptozotocin diabetic rats than in control animals and is not significantly affected by insulin treatment (Moir and Zammit, 1994). β oxidation of fatty acids in heart can be down regulated by intra mitochondrial acetyl CoA derived from carbohydrate oxidation (Lopaschuk and Gamble, 1994). The formation of ketone bodies occurs when production of acetyl CoA exceeds the capacity of the citric acid cycle to metabolize acetyl CoA to CO_2 and H_2O as seen in the case of IDDM subjects with severe insulin lack (see below). DHA, oleic acid, and its *trans* isomer inhibit β oxidation in mitochondria because of the accumulation of 2, 4-di- or 2, 4, 7-trienoyl CoA. In diabetes, these fatty acids have less inhibitory effect on β oxidation, since 2, 4-dienoyl CoA can be readily oxidized, as mitochondria from diabetic rats have increased 2, 4-dienoyl CoA reductase activity (Osmundsen and Bjornstad, 1985).

In the heart of diabetic rats oxidation of fatty acids is increased more than glucose oxidation during heavy work load (Christe and Rogers, 1995) and in the absence of palmitate, both, TG lipolysis and endogenous palmitate oxidation rates are higher in the heart of diabetic rats (Saddik and Lopaschuk, 1994). The increased palmitate oxidation in diabetic rats may be due to decreased activity of PDH and acetyl CoA flux through the Krebs cycle (Abdel-aleem et al., 1997). In untreated diabetic rats, hepatic mRNA levels of acetyl CoA carboxylase (ACC) and fatty acid synthase (FAS)

are reduced. Vanadate treatment restores mRNA and the activities of these enzymes in liver but not in adipose tissue. The action appears to be via improvement of thyroid function (Brichard et al., 1994). In pancreatic islets ACC is abundant but FAS is poorly expressed. Fatty acid oxidation in islets appears to be regulated by malonyl CoA (Brun et al., 1996).

In addition to β oxidation, fatty acids can also be oxidized via ω oxidation in microsomes, though to a much lesser extent. In diabetic subjects (Lippe et al., 1987) as well as in experimental diabetic animals (Bjorkhem, 1973; Wada and Usami, 1977; Kam et al., 1978; Hemmelgarn et al., 1979), the rate of ω oxidation of fatty acids is increased compared to controls and accounts for almost 15% of overall fatty acid oxidation. The increased ω oxidation of fatty acids in diabetes can be advantageous for both carbohydrate and lipid metabolism. Dicarboxylic acids formed via ω oxidation are further metabolized by β oxidation to form succinyl CoA (Hemmelgarn et al., 1979), which leads to decreased glucose formation (Kam et al., 1978; Hemmelgarn et al., 1979). Second, increased ω oxidation also decreases the incorporation of fatty acids into phospholipids (Wada et al., 1971) and hence lowers lipid synthesis. The administration of long-chain dicarboxylic acids to diabetic rats also decreases the concentration of ketone bodies in the blood (Wada et al., 1971). Shimabukuro et al. (1997a) reported increased FFA oxidation in cultured islets by leptin. However, in islets of obese, mildly diabetic Zucker rat leptin had no effect possibly due mutation of leptin receptor. The Zucker diabetic fatty rats also have increased fatty acid transport by adipocytes as measured by the uptake of oleate (Berk et al., 1997).

It is not clear whether insulin or other hormones have significant effects on β or ω oxidation of fatty acids. However, increased ω oxidation in diabetes indicates that the lack of insulin may be responsible. By reducing lipolysis and glycogenolysis, insulin enhances the relative contribution of carbohydrate oxidation and reduces fat oxidation in resting state as well during exercise in diabetic rats (Houwing et al., 1995). The hormonal control of fatty acid oxidation in diabetes needs to be addressed.

D. Binding Proteins and Fatty Acid Oxidation

Fatty acid-binding proteins (FABP) play an important role in the fatty acid oxidation. In streptozotocin diabetic rat, fatty acid oxidation in liver homogenate increases significantly but the FABP content decreases. FABP also decreases in the aorta of streptozotocin diabetic rats and is reversed by insulin treatment (Sakai et al., 1995). In heart, fatty acid oxidation is unaltered but FABP content is increased (Glatz et al., 1994). Thus, changes in fatty acid oxidation capacity do not appear to correlate with FABP content during the development of diabetes (Veerkamp et al., 1996). This indicates that though FABP in different tissues are structurally identical, there is differential regulation of FABP in different tissues in diabetes. In muscle of streptozotocin diabetic rats, heart-FABP (H-FABP) level and mRNA are increased but the transcription rate was unchanged indicating that the regulation of expression of H-FABP in muscle may not be at the level of transcription (Carey et al., 1994). In streptozotocin diabetic rat fatty acid binding characteristics of myocardial plasma membrane FABP are altered in that there is a decrease in the affinity for the binding of saturated fatty acids but not for unsaturated fatty acids as indicated by the decreased affinity of *trans*-parinaric acid (Heylinger et al., 1995).

In Pima Indians, intestinal FABP with threonine at codon 54 instead of alanine has been shown to result in higher insulin resistance and increased fat oxidation *in vivo* and threonine-containing protein had twofold greater affinity for long-chain fatty acids than the alanine-containing protein indicating increased absorption and/or processing of dietary fatty acid by the intestine and thus increased fat oxidation (Baier et al., 1995; Tataranni et al., 1996).

In adipocytes, FABP has been shown to be a glycoprotein IV or CD36. CD36 is also responsible for fatty acid building in erythrocytes and platelets. It is strongly expressed in cardiac and skeletal muscle and adipose tissue but not in liver, pancreas, and brain (Greenwalt et al., 1995). It is up regulated in diabetes and by high fat feeling (Greenwalt et al., 1995). Type of fatty acids appears to modulate RNA for CD36 protein. In capillary endothelial cells CD36 expression appears to be

correlated with parenchymal cell fatty acid utilization (Greenwalt et al., 1995). CD36 transfers bound fatty acid to the fatty acid acyl-CoA enzyme on the inside of the membrane (Sfeir et al., 1997). Two other proteins have also been shown to have the same function, namely membrane-bound aspartate aminotransferase ($FABP_{pm}$) with a molecular weight of 43 kDa (Berk et al., 1990) and fatty acid transport protein (FATP) with a molecular weight of 63 kDa (Schaffer and Lodish, 1994). It is not clear whether FABP present in enterocytes, heart, mammary cells, adipocytes, and blood cells are same or different proteins. It has been suggested that FABP2, or a tightly linked gene may be associated with insulin resistance (Mitchell et al., 1995).

E. Conversion of EFAs to Eicosanoids

Formation of eicosanoids is another important biological function of EFAs. Eicosanoids can be formed only from fatty acids with 20-carbon atoms and at least three double bonds. There are three different pathways involving different enzyme systems. Microsomal cyclooxygenase converts fatty acids to prostanoids (prostaglandins, prostacyclins, and thromboxanes); lipoxygenase gives rise to hydroperoxyeicosatetraenoic acids, which are quickly converted to LTs, and cytochrome p450 monooxygenase which leads to formation of epoxides and hydroxyeicosatetraenoic acids. The three important fatty acids involved in eicosanoid production are DHLA, AA, and EPA. As they have different numbers of double bonds, they each give rise to a different series of eicosanoids. Thus, prostanoids of 1-series and LTs of 3-series are formed from DHLA. AA produces prostanoids of 2-series and LTs of 4-series, while EPA is converted to prostanoids of 3-series and LTs of 5-series. The two families of fatty acids, ω-3 and ω-6, compete for the same enzymes, and hence, depending on the availability of fatty acids, products of different series are formed. Thus, EPA inhibits the production of prostaglandins (cyclooxygenase pathway) from AA (Culp et al., 1979; Corey et al., 1983). The products formed from AA and EPA are biologically more active and more important. These fatty acids are usually derived from phospholipids by the action of phospholipase A_2. Prostanoids are produced in most tissues, whereas LTs are generally formed in different blood cells, pancreatic islets, and glomerular cells. Kinsella et al. (1990) have reviewed the conversion of fatty acids to eicosanoids.

In platelets, AA forms TXA_2 whereas EPA forms TXA_3. In endothelial cells of blood vessels, the major product of AA is prostacyclin PGI_2 and that of EPA is PGI_3. TXA_2 has potent platelet-aggregating activity; TXA_3 either has weak activity or is inactive. Both PGI_2 and PGI_3 have strong antiaggregating activity and are vasodilators. They prevent platelet clumping and increase bleeding time. PGE_1 derived from DHLA also has antiaggregating activity. LTs, on the other hand, cause chemotaxis in neutrophils and eosinophils, and stimulate cyclic adenosine monophosphate (cAMP) production and the release of lysosomal enzymes from polymorphonuclear cells. LTC_4 and LTD_4 are humoral agents and promote smooth muscle contraction.

In diabetes, AA in membrane phospholipids is decreased (see above). This is caused by decreases in Δ5 and Δ6 desaturases and in lipase activity. As a result there is decreased formation of TXA_2 and PGI_2 in diabetic subjects (Nordoy, 1981; Goodnight et al., 1984; Mikhailidis et al., 1986; Tilvis et al., 1987; Prisco et al., 1989b). There is also an increase in PGH_2 (Shimizu et al., 1993) and $PGF_{2\alpha}$ (Harrison et al., 1978) in vascular tissues. In IDDM subjects, DHLA is also decreased, leading to decreased PGE_1 formation (Mikhailidis et al., 1986). There is also a decrease in PGI_2 synthesis in IDDM as measured by the urinary 6-keto-$PGF_{1\alpha}$. These changes explain the increased adhesiveness and aggregation of platelets observed in IDDM subjects (Bern, 1978; Waitzman, 1979; Colwell and Halushka, 1982; Ewald et al., 1983; Mikhailidis et al., 1986). The role of different prostaglandins in platelet function in diabetes has been reviewed by Colwell and Halushka (1982).

In streptozotocin diabetic rats, PGI_2 synthesis in the aorta is decreased (Jeremy et al., 1987). The decrease in PGI_2 formation increases with the duration rather than the severity of diabetes. However, in the bladder there is increased PGI_2 formation, possibly due to distention (Jeremy et al., 1986). Fujii et al. (1986) observed a slight increase in PGI_2 and a greater increase in TXA_2

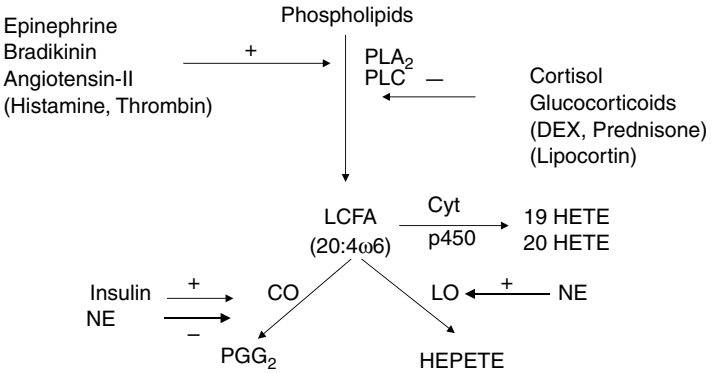


FIGURE 47.2 Role of hormones in eicosanoid formation. Most hormones affect eicosanoid formation by controlling lipolysis of phospholipids. Insulin and nor epinephrine act on the cyclooxygenase and lipooxygenase. The different PLA_2s involved are $cPLA_2$, cytosolic PLA_2 which is Ca^{2+} dependent; $IPLA_2$, cardiac PLA_2 which is Ca^{2+} independent; and $spPLA_2$, sarcoplasmic PLA_2. *Abbreviations:* PLA_2, phospholipase A_2; PLC, phospholipase C; Dex, dexamethasone; LCFA, long-chain fatty acids; cyt p450, cytochrome p450; CO, cyclooxygenase; LO, lipooxygenase; PGG_2, prostaglandin G_2; NE, norepinephrine; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid. *Nutritional Neurosc*. 9:1–10, 2006. With permission.

(as measured by its inactive metabolite TXB_2) and PGE_2 synthesis in the mesenteric vascular bed of streptozotocin-treated diabetic rats compared to control rats. Thus, there was a decrease in the PGI_2/TXA_2 ratio, indicating a tendency for increased platelet aggregation. In streptozotocin-treated diabetic rat, mRNA for cyclooxygenase is decreased in sciatic nerve and aorta but not in kidney and retina (Fang et al., 1997). Evening primrose oil increased mRNA for cyclooxygenase in nerve and retina indicating a tissue specific effect. Aldose reductase inhibitor, on the other hand, had no effect on cyclooxygenase expression (Fang et al., 1997).

Various hormones are involved in eicosanoid formation (Figure 47.2). The hormonal control occurs during the conversion of long-chain PUFA by phospholipases and also at the level of cyclooxygenase and lipooxygenase. Epinephrine, bradikinin, and angiotensin II stimulate phospholipase A_2 and phospholipase C (Vane, 1976; Van Den Bosch, 1980; Shukla, 1982) while cortisol and synthetic glucocorticoids, dexamethasone, and prednisone, inhibit the lipases (Blackwell et al., 1980). They appear to act via lipocortin. Histamine and thrombin also stimulate these lipases (Van Heugten et al., 1996). Insulin acts directly on cyclooxygenase and stimulates the conversion of AA to PGG_2, which is then converted to various prostanoids. TNF has also been reported to stimulate prostaglandin synthesis (Burch and Tiffany, 1989). The interactions between hormones and prostanoids have been reviewed by Myers et al. (1989).

Prostaglandins also play a role in insulin secretion. Sodium salicylate, which inhibits cyclooxygenase and thereby decreases prostaglandin synthesis, increases basal as well as glucose-stimulated insulin secretion in diabetic subjects indicating involvement of prostaglandin. Robertson and Chen (1977) infused PGE_2 in normal humans and inhibited acute insulin response to glucose. In addition, prostaglandins are also involved in abnormal collagen metabolism in diabetes (Yue et al., 1985). Bradykinin has been shown to stimulate phospholipids to release AA which is then metabolized via cyclooxygenase, lipooxygenase, and cytochrome p450 to yield vasoactive products (Quilley et al., 1994).

LTs formed by lipoxygenase are also biologically active. LT_5 formed from ω-3 fatty acids is more active in immune functions in humans (Kelley et al., 1991). Neutrophils and monocytes increase LT formation from EPA more than from AA (Lee et al., 1985). This explains the beneficial effects of fish oil on immune function in low-dose streptozotocin diabetic mice in which fish oil decreased the number of class II antigen-expressing cells in pancreatic islets (Linn et al., 1989).

F. Hormones, Eicosanoids, and Platelet Aggregation in Diabetes

Increased plasma glucose appears to be a factor in platelet aggregation in diabetes. In control animals, glucose infusion increases TXA_2 production and decreases the ratio of PGI_2/TXA_2. Insulin treatment reverses the ratio (Fujii et al., 1986). Glucose also decreases prostacyclin-stimulating activity in cultured aortic endothelial cells. This activity is increased by LDL and linoleic acid (possibly by conversion to AA), but insulin has no effect on the activity (Umeda et al., 1990). Thus, increased plasma glucose levels in diabetic subjects may be partly responsible for decreased PGI_2 levels and hence increased platelet aggregation. Alteration in platelet phosphoinositide has also been reported in streptozotocin diabetic rats (Jethmalani et al., 1994).

In diabetic subjects who consume large quantities of fish oil, the situation is different. There is an increase in TXA_3 and PGI_3 synthesis and decreased TXA_2 and PGI_2 owing to the decreased availability of AA and the competition of the ω-3 fatty acids from fish oil. Thus, because of the decreased TXA_2 and PGI_2 and the increased PGI_3 and inactive TXA_3, there is less platelet aggregation, which is beneficial for diabetic subjects with coronary artery disease and hypertension (Leaf and Weber, 1988; Knapp and Fitz-Gerald, 1989; Kasim, 1993; Nishikawa et al., 1997). Figures 47.3 and 47.4

summarize the role of hormones, hormone receptors, and prostanoids in platelet aggregation in normal and diabetic states.

V. HORMONAL CONTROL OF FATTY ACID METABOLISM IN DIABETES

The hormonal control of fatty acid metabolism is summarized in Figure 47.5 and has been reviewed in normal and diabetic subjects (Liljenquist et al., 1974; Storlien et al., 1997; Saleh et al., 1999; Bhathena, 2006). The metabolic processes, lipogenesis and lipolysis, which control fatty acid concentration in plasma and tissues, are under hormonal control. The principal hormones involved in lipid metabolism are insulin, glucagon, catecholamines, cortisol, and growth hormone. Many other hormones also affect fatty acid metabolism as shown in Figure 47.5. The levels of these hormones are altered in diabetes, which explains altered lipid metabolism in diabetes. Insulin has multiple effects on lipid metabolism. Though insulin stimulates lipogenesis (Beynen et al., 1982; McTernan et al., 2002), its major effect is antilipolytic, especially the inhibition of hormone-stimulated lipolysis (Jungas and Ball, 1963; Mahler et al., 1964; Fain and Shepherd, 1979; Cavallo-Perin et al., 1992; Suda et al., 1993; Linfoot et al., 2005). Glucagon, catecholamines, cortisol, and growth hormone, which are counterregulatory hormones to insulin, have predominantly lipolytic activity (Ball and Jungas, 1963; Gerich et al., 1976; Rosen et al., 1981; Goodman and Grichting, 1983). However, glucagon (Wu et al., 1990a), growth hormone (Davidson, 1987), and catecholamines (Wahrenberg et al., 1989) also have antilipolytic activity. In humans, glucagon has only a marginal effect on LPL, but it has a much stronger effect in young animals. The lipolytic activity of catecholamine is mediated via β-adrenoreceptors and the antilipolytic effect is mediated through α-2-adrenoreceptors

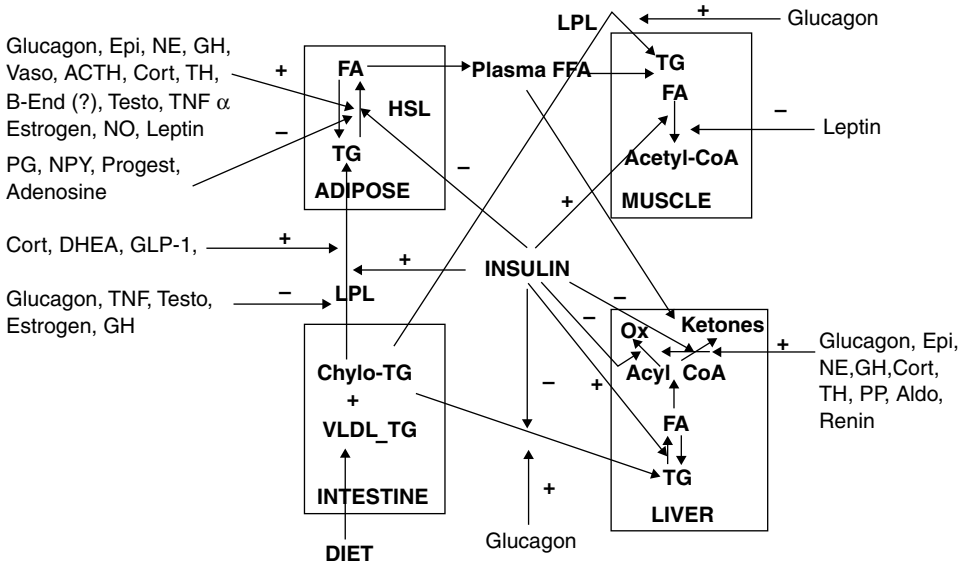

FIGURE 47.5 Hormonal control of fatty acid metabolism. Schematic diagram showing how different hormones control fatty acid metabolism in intestine, adipose tissue, muscle, and liver. "+" indicates stimulatory (positive) effect and "—" indicates inhibitory (negative) effect on different processes. *Abbreviations:* HSL, hormone-sensitive lipase; LPL, lipoprotein lipase; Epi, epinephrine; NE, norepinephrine; GH, growth hormone; Vaso, vasopressin; ACTH, adrenocorticotropic hormone; Cort, cortisol; TH, thyroid hormone; β-end, β-endorphin; Testo, testosterone; TNF-α, tumor necrosis factor-α; NO, nitric oxide; PG, prostaglandins; NPY, neuropeptide Y; Progest, progesterone; DHEA, dehydroepiandrosterone; GLP-1, glucagon-like peptide 1; PP, pancreatic polypeptide; Aldo, aldosterone. *Nutritional Neurosc*. 9:1–10, 2006. (Leibel and Hirsch, 1987; Pecquery et al., 1988). The effects of these hormones on lipolysis occur through hormone-sensitive lipase that is activated by cAMP. Glucagon, catecholamine, cortisol, and growth hormone all increase cAMP formation by activating adenylate cyclase and hence stimulate lipolysis.

Insulin stimulates phosphodiesterase, which catabolizes cAMP and decreases cAMP level, thereby inhibits lipolysis. LPL present in adipose tissue, muscle, and heart, is responsible for the lipolysis of TG-rich lipoproteins (Nicoll and Lewis, 1980) and for the production of HDL-cholesterol (Nikkila et al., 1978), while TG lipase present in liver increases the catabolism of HDL-cholesterol (Kuusi et al., 1980). The effect of type of dietary fatty acids on insulin action is reviewed by Storlien et al. (1997). High intake of saturated fat appears to produce hyperinsulinemia and increases risk of diabetes. PUFAs appear to have the opposite effect. The role of insulin in controlling fatty acid metabolism is reviewed by Dutta-Roy (1994).

In diabetes, the counterregulatory hormones are generally elevated while either insulin is decreased or there is peripheral resistance to insulin. In IDDM, plasma norepinephrine is decreased. Also, the antilipolytic effect of catecholamines is normal, but the lipolytic effect is increased 10-fold (Wahrenberg et al., 1989). Thus, these changes in hormones favor increased lipolysis, and hence elevated levels of FFAs are observed in IDDM as well as NIDDM. Unsaturated fatty acids as well as glucose play an important role in these processes. Thus, the increased concentration of unsaturated FFAs stimulates the lipogenic effect of insulin on adipocytes (McTernan et al., 2002). In muscle, however, FFAs are antagonistic to insulin (Randle et al., 1963). In humans, glucose potentiates the antilipolytic effect of insulin on isolated adipocytes (Arner et al., 1983). In poorly controlled diabetic subjects, however, the antilipolytic activity of insulin is decreased (Trevisan et al., 1986; Jensen et al., 1989) because of the reduced insulin sensitivity. In rats, glucose has no effect on insulin-stimulated antilipolysis (Thomas et al., 1979) but inhibits the antilipolytic effect of catecholamine-stimulated lipolysis (Desai et al., 1973). In diabetic subjects, TG lipase is inversely proportional to HDL-cholesterol, being higher in subjects with low HDL-cholesterol and lower in those with elevated HDL-cholesterol (Kasim et al., 1987). In streptozotocin diabetic rats, TG lipase activity is decreased (Jansen and Hulsmann, 1975; Elkeles and Hambley, 1977), but this is reversed by PUFA (Hulsmann et al., 1977). Unlike TG lipase, insulin stimulates LPL (Garfinkel et al., 1976; Sadur and Eckel, 1982). In NIDDM subjects, LPL activity is decreased in adipose tissue and skeletal muscle (Taskinen and Nikkila, 1979). Insulin also stimulates phospholipase C in adipose tissue (Farese et al., 1986). In livers of diabetic mice insulin increases transcription of FAS (a key enzyme in lipogenesis) gene (Paulauskis and Sul, 1989). In human adipocytes, LPL is suppressed by TNF in the presence of insulin and dexamethasone (Fried and Zechner, 1989) but not in the absence of insulin (Kern, 1988). TNF decreases LPL mRNA levels, rates of LPL synthesis, and the LPL activity. Thus, TNF may be important in the pathogenesis of hypertriglyceridemia (Feingold et al., 1989; Fried and Zechner, 1989). It is important to note that TNF is involved in the pathogenesis of diabetes, and its administration to diabetic animals increase blood glucose levels without changes in insulin concentration (Feingold et al., 1989). Farese (1990) has reviewed the role of insulin in phospholipid metabolism. In line with its lipogenic activity, insulin stimulates phospholipid synthesis in adipocytes (Farese et al., 1982; Pennington and Martin, 1985), hepatocytes (Cooper et al., 1990), and diaphragm and skeletal muscle (Ishizuka et al., 1990). Various actions of insulin on fatty acid metabolism in adipose, liver, and muscle are summarized in Table 47.2.

Insulin also plays a role in cholesterol synthesis by controlling hydroxymethylglutaryl CoA reductase, a key enzyme in cholesterol biosynthesis. Insulin stimulates the activity of the enzyme *in vitro* and hence cholesterol synthesis (Bhathena et al., 1974; Geelen et al., 1980). It is important to note that owing to lack of insulin, lipogenesis in insulin-sensitive tissues is decreased but lipogenesis is normal in the intestine, which is insulin insensitive. Lipogenesis in the intestine is dependent on substrate availability, and in diabetes, because there is an increase in substrate availability, fatty acid and TG synthesis are elevated (Popper et al., 1985; Feingold et al., 1990). Thus, de novo intestinal synthesis partly accounts for the increased TG in VLDL in diabetes. However, Jiao et al. (1989)

TABLE 47.2
Insulin and Fatty Acid Metabolism

Adipose	
↓	HSL (↓ rate of lipolysis, ↓ plasma FFA)
↑	FA and TG synthesis (re-esterification)
↑	Fatty acyl-CoA and fatty acyl transferase
↑	LP lipase (↑ uptake of TG from plasma)
Liver	
↑	FA and TG synthesis (de novo lipogenesis from glucose)
↑	VLDL formation (↑ FAS and ACC)
↑	Cholesterol synthesis
↓	Rate of FA oxidation and ketone formation (↓CAT-1)
Muscle	
↓	Rate of FA oxidation (↓ malonyl CoA)
↓	Ketogenesis

reported inhibition of cholesterol synthesis and esterification in cultured human intestinal cell line Caco-2.

In diabetes there is an increase in lipid peroxidation as measured by free and total malondialdehyde (MDA). Insulin treatment reduces free MDA but not total MDA (Peuchant et al., 1997) indicating a partial protection against elevated lipid peroxidation in diabetes. Although insulin therapy in NIDDM subjects with secondary failure to oral agents increases GLA in TG and cholesterol esters, it does not alter the platelet function in these subjects (Rodier et al., 1995).

Figure 47.6 summarizes the hormonal control of fatty acid synthesis in adipose tissue. Glucagon has multiple effects on lipid metabolism. It stimulates lipolysis by activating lipase (see above). The action is via stimulation of adenylate cyclase. It also stimulates LPL in muscle but not in adipose tissue (Geelen et al., 1980). In liver, glucagon stimulates fatty acid oxidation (McGarry and Foster, 1981) and suppresses fatty acid synthesis (Allred and Roehrig, 1972; Bricker and Levey, 1972; Goodridge, 1973; Watkins et al., 1977). Glucagon also inhibits cholesterol synthesis (Geelen et al., 1980). In diabetes, increased lipolysis is also observed in the heart (Kenno and Severson, 1985) and is stimulated by epinephrine to the same extent as in controls (Rosen et al., 1981), but not by isoproterenol (Kenno and Severson, 1985). Many of the effects of hormones on lipogenesis have been studied in rats or in isolated cells *in vitro*. It is important to note that in humans lipogenesis occurs

predominantly in the liver, whereas in rats both liver and adipose tissue are involved. Although the intestine is insensitive to insulin *in vivo*, in isolated intestinal cells insulin has an inhibitory effect on cholesterol synthesis.

A major consequence of increased FFA in diabetes in the face of decreased insulin is ketoacidosis. Increased glucagon and decreased insulin will stimulate lipolysis in adipose tissue, producing FFA in plasma that is transported to liver. Decreased availability of insulin reduces lipogenesis, and hence FFAs are converted to ketone bodies (acetoacetate and β-hydroxybutyrate). Glucagon plays a critical role in ketoacidosis. In normal subjects, infusion of glucagon stimulates insulin secretion, and no rise in ketones occurs. However, in diabetic subjects deficient in insulin (IDDM), glucagon infusion produces a rise in ketones (Liljenquist et al., 1974). The role of glucagon in ketogenesis in diabetes has been shown by many others (Gerich et al., 1975; Schade and Eaton, 1975; McGarry and Foster, 1979). Ketogenesis by increased glucagon and decreased insulin has been shown to occur also in experimental animals and isolated cells (Keller et al., 1977; Woodside, 1979). McGarry and Foster (1981) suggested the following mechanism for ketogenesis in diabetes. Glucagon acutely suppresses fatty acid synthesis by blocking the formation of malonyl CoA (a key metabolite in lipogenesis from glucose), which in turn causes depression of carnitine acyltransferase I and activates fatty acid oxidation, leading to accelerated production of ketone bodies. Schade and Eaton (1979) also reported that other hormones counterregulatory to insulin, such as catecholamine, also stimulate ketogenesis. However, an elevated ratio of glucagon to insulin is the primary factor for accelerated ketogenesis in diabetes (McGarry and Foster, 1977, 1981) as shown in Figure 47.7. In diabetic ketoacidosis, saturated unbranched fatty acids, succinic and adipic, are predominantly excreted in the urine and can be used as a marker of the ketoacidotic state (Liebich et al., 1980).

Elevated FFA in plasma in diabetes and other disorders results in hypercoticoidism and initiates a positive feedback loop between adipocytes and hypothalamic-pituitary-adrenal axis (Widmaier et al., 1995). Abnormality in thyroid function and altered thyroid hormone levels have been reported in diabetic subjects and that dysfunction of the hypothalamic-pituitary-thyroid axis may be involved (Suzuki et al., 1994). Fluctuations in estrogens and insulin-like growth factor-II (IGF-II) have been reported to contribute to the pathogenesis of NIDDM and that IGF-II and insulin may be inversely regulated in NIDDM (Holden, 1995). Recently leptin has been reported to increase fatty acid oxidation and decrease fatty acid incorporation into TGs in soleus muscle and thus oppose the lipogenic effect of insulin (Muoio et al., 1997). Leptin also increases fatty acid oxidation in cultured pancreatic islets (Shimabukuro et al., 1997a). In healthy subjects no correlation was observed between plasma leptin levels and plasma glucose, insulin, TG or FFA (Pratley et al., 1997). Similarly, in obese, mildly diabetic Zucker rat, leptin had no effect possibly due to mutation of the leptin receptor.

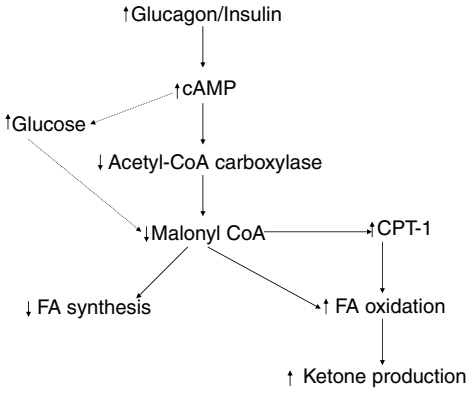

FIGURE 47.7 Hormonal control of fatty acid metabolism in liver in diabetes. Increased glucagon/insulin ratio in diabetic state leads to stimulation of cAMP in liver leading to increased fatty acid oxidation and increase ketone production. *Nutritional Neurosc*. 9:1–10, 2006. With permission.

VI. EFFECT OF TREATMENT OF DIABETES ON FATTY ACID METABOLISM

Hyperglycemia of diabetes is normally controlled by (1) diet and exercise, (2) oral agents, and (3) insulin. Diabetes in many cases is also associated with other complications such as hypertension, polyneuropathy, nephropathy, retinopathy, obesity, insulin resistance, and in most instances, hyperlipidemia, especially in NIDDM subjects. Until recently most drug therapy for diabetes was geared toward reducing hyperglycemia and correcting insulin responsiveness with less emphasis on correcting lipid abnormalities. Normalizing blood sugar levels by any means also partially lowers hyperlipidemia. However, more attention should be given to reduce lipid abnormalities in diabetes and the associated metabolic disorders. The reduction of elevated FFA levels and hyperlipidemia will help glucose-fatty acid cycle which is operative in many tissues by shifting the oxidation of FFA in favor of oxidation of glucose. The effects of insulin in the management of diabetes have been discussed throughout this chapter. The management of dyslipidemia of secondary complications of diabetes has been briefly reviewed by Garg and Grundy (1990). This section therefore deals primarily with the effect of diet, exercise, oral agents (hypoglycemic and hypolipidemic), and metal ions on fatty acid metabolism.

A. Diet and Exercise

The importance of dietary carbohydrate and lipid sources in the management of diabetes and their effects on fatty acid metabolism has been discussed throughout this chapter. Recently, several studies in humans and animals have shown beneficial effects of soybean and flaxseed meal in diabetes (Kaminskas et al., 1992; Nestel et al., 1997; Hermansen et al., 2001; Bhathena and Velasquez, 2002; Jayagopal et al., 2002; Torres et al., 2005). In addition to modulating hyperglycemia, soy protein reduces hyperlipidemia and hyperinsulinemia. In streptozotocin diabetic rats, soy protein compared to casein, lowered EPA and increased AA, which resulted in decreased ratio of aortic prostacyclin production to TXA_2 (Ikeda and Sugano, 1993). Soy protein along with its associated isoflavones and fiber reduces total cholesterol, LDL-cholesterol, VLDL-cholesterol, apolipoprotein B100, FFAs and TGs but has no significant effect on HDL-cholesterol, glucose or HbA1c (Hermansen et al., 2001). Zhan and Ho (2005) carried out meta-analysis of 23 human studies and found that soy protein with intact isoflavones was associated with significant decrease in serum total cholesterol, LDL-cholesterol, and TGs and significant increase in serum HDL-cholesterol. In another meta-analysis similar results were seen namely soy protein isolate with high isoflavones lowered serum LDL-cholesterol (Zhou et al., 2004). The hypocholesterolemic effect of isoflavones appears to be due in part to the modulation of steroid hormones involved in lipid metabolism (Ali et al., 2004). In contrast, recently, Sacks et al. (2006) analyzed data from 22 randomized trials and found no significant effect of soy protein with isoflavones compared to milk or other proteins on lipid parameters. Soy isoflavones also had no significant effect. It is possible that soy protein or isoflavones may not affect lipid parameters in normal subjects when lipid levels are in normal range, but may affect lipid levels when they are elevated as in diabetic subjects. Soy protein also reduces insulin/glucagon ratio which in turn down regulates the expression of hepatic sterol regulatory element-binding protein (SERBP-1) that results in decreased lipogenic enzymes leading to decreased LDL- and VLDL-cholesterol and TG (Torres et al., 2005). ω6 Fatty acids in soybean oil and ω3 fatty acids in flaxseed oil also activate SERBP-1 (Rodriguez-Cruz et al., 2005). They also activate alpha and gamma PPAR leading to increased lipid oxidation and hepatic steatosis.

The beneficial effects of flaxseed on lipid parameters in diabetes appear to be due to the presence of ω3 fatty acids. Flaxseed oil improves insulin sensitivity, decreases LDL oxidation and increases HDL-cholesterol (Nestel et al., 1997). In hypercholesterolemic rabbits, lignan present in flaxseed, secoisolariciresinol diglucoside, also lowers serum total- and LDL-cholesterol (Prasad, 1999). Secoisolariciresinol diglucoside also reduces the incidence of diabetes in both, type 1 and type 2

diabetic rats (Prasad, 2000, 2001; Prasad et al., 2000). The beneficial effects of isoflavones and lignans on tissue lipids may be due in part to their antioxidative actions since oxidative stress has been shown to be one of the causes of both type 1 and type 2 diabetes.

The beneficial effects of exercise on fatty acid metabolism, especially in NIDDM subjects, is primarily due to decreased body weight, increased insulin sensitivity, and lowered blood glucose level (National Institutes of Health, 1987). Improved insulin response to exercise is only acute and reverses after inactivity. Strenuous and prolonged exercise increases the rate of FFA metabolism in muscle and other tissues. There is a moderate fall in insulin, increased insulin sensitivity, increased insulin clearance and increases in glucagon, catecholamines, growth hormone, and cortisol (Keller et al., 1977; Schade and Eaton, 1979; Gray et al., 1980; Horton, 1988; Wasserman et al., 1989; Tuominen et al., 1997). As a consequence, there is an increase in lipolysis and increased ketone body production in the liver, which can be used for energy by muscle. In several prospective studies, exercise has been shown to reduce plasma TG and total and LDL-cholesterol and to increase HDL-cholesterol. The beneficial effects of light to moderate exercise on ischemic heart disease in diabetes are also suggested by epidemiological evidence (Leon, 1988). Exercise also improves altered immune function in obese diabetic rats (Plotkin and Paulson, 1996). The role of exercise training in NIDDM has been reviewed by Horton (1996) and Ivy (1997). Benefit of moderate exercise is also seen in IDDM subjects, where glucose uptake and oxidation is lower and fat oxidation is enhanced (Raguso et al., 1995). It is important to note that in poorly controlled IDDM subjects, strenuous exercise may not be beneficial because it can increase lipolysis, ketogenesis, and blood glucose levels due to insulin deficiency. Similarly, in well-controlled IDDM subjects, the dose of insulin should be reduced or extra carbohydrate should be given to prevent hypoglycemia.

In diabetic rats exercise causes increase in FFA more than in control rats. This mobilization appears to be due to reduced inhibition of lipolysis by the relative lack of insulin since insulin levels that are already low are unaltered (Houwing et al., 1997).

B. Oral Hypoglycemic Agents

The two classes of oral agents most frequently used in glycemic control are sulfonylureas and biguanides. A residual pancreatic insulin secretion is a prerequisite for the use of oral agents. The rationale for their use and the mechanisms of their actions have been extensively reviewed by Krall (1991), Lebovitz (2001, 2004), Ferner (1988), and others (Olefsky, 1985). The most widely used sulfonylureas are first-generation tolbutamide, second-generation glyburide (glibenclamide), and now third-generation glimepiride. The mechanisms of their action include increased glucose-stimulated insulin secretion and increased insulin responsiveness (decreased resistance) and action in target tissues due to increased insulin receptor number (Bhathena, 1987). They also decrease hepatic gluconeogenesis. In diabetic subjects, sulfonylureas also inhibit platelet aggregation *in vivo* (Sagel et al., 1975).

The commonly used biguanides are metformin and phenformin. Unlike sulfonylureas, they are not known to stimulate insulin secretion, but they do potentiate insulin action and increase insulin binding to hepatocytes and adipocytes and increases tyrosine kinase activity (Rossetti et al., 1990). More importantly, they inhibit glucose absorption and increase glucose utilization by the liver and muscle. They may also inhibit gluconeogenesis and hepatic glucose output in diabetic subjects thereby preventing hyperglycemia from occurring (Bailey, 1992). Phenformin causes increased lactic acidosis and is now used less frequently. Its use is banned in the United States but that of metformin has increased.

Both groups of compounds affect lipid metabolism. Stone and Brown (1966) reported that tolbutamide has antilipolytic activity. Thus, in IDDM subjects, injection of tolbutamide decreased plasma FFA concentration. *In vitro* studies in adipocytes from fasted nondiabetic rats, tolbutamide, but not phenformin, induced a significant decrease in FFA and glycerol release (Stone et al., 1966). This effect of tolbutamide may be related to decreased hyperglycemia, since sodium sulfadiazine,

another sulfonylurea that is nonhypoglycemic, had no effect on lipolysis. In NIDDM subjects, glibenclamide decreased plasma FFA and lactate concentrations (Jeng et al., 1989) but had no effect on apolipoproteins (Billingham et al., 1989). Insulin, however, reversed the apolipoprotein changes. In NIDDM subjects, metformin decreased serum total- and LDL-cholesterol. The effect persisted for a long time (Rains et al., 1989). Metformin also decreases fatty acid oxidation, reduces hepatic synthesis of VLDL TGs (Muntoni, 1974; Fedele et al., 1976) and reduces plasma FFA (Riccio et al., 1991; Perriello et al., 1994) and this may be in part responsible for its antidiabetic property (Gregorio et al., 1997). In short-term (21-day) treatment in IDDM subjects, metformin had no significant effect on plasma cholesterol, TG, glucose level, or glycosylated hemoglobin, but decreased maximum platelet aggregation stimulated by low-dose adenosine diphosphate (Gin et al., 1989). The site of action of metformin appears to at muscle, liver, and adipose tissue. It is important to note that insulin is more effective than oral agents in raising HDL-cholesterol levels in NIDDM subjects. In nondiabetic obese subjects, however, short-term (15-day) treatment with metformin decreased plasma TG and insulin concentrations. In muscle metformin has been shown to activate 5′-AMP-activated protein kinase which lowers lipid synthesis and increases oxidation of fatty acids. In type 2 diabetes atypical protein kinase C is defective and long-term metformin treatment in type 2 diabetic subjects improves basal as well as insulin-stimulated atypical protein kinase C in muscle (Luna et al., 2006). Metformin also lowered the elevated levels of plasminogen activator inhibition activity and increased the depressed euglobin fibrinolytic activity (Vague et al., 1987; Nagi and Yudkin, 1993). This indicates that biguanides may have a role in platelet function. The effects of oral hypoglycemic agents on platelet function in diabetic subjects needs to be explored further. The metabolic effects of metformin including its effect on fatty acid and lipid metabolism, have been reviewed by Wu et al. (1990b); Del Prato et al. (1995); Bailey and Turner (1996); Davidson and Peters (1997); and Raptis and Dimitriadis (2001).

C. Oral Agents to Treat Lipid Disorders

In the past two decades new classes of compounds has been introduced to treat lipid disorders of diabetes. The effects of some of them on fatty acid metabolism are briefly described. They are reviewed by Ilarde and Tuck (1994); Rachman and Turner (1995); Lefebvre and Scheen (1995); Dagogo-Jack and Santiago (1997); Raptis and Dimitriadis (2001); and Stumvoll (2003).

a. Insulin Sensitizers

Thiazolidinediones: The commonly used thiazolidinediones are rosiglitazone, pioglitazone, and troglitazone. They also affect fatty acid mobilization and oxidation. They lower blood glucose level without stimulating insulin secretion but increase insulin effectiveness (Chaiken et al., 1995) indicating that their action is peripheral. The effect appears to be due to lowering of plasma FFA levels (Miles et al., 1997). They also inhibit gluconeogenesis at the level of pyruvate carboxylase and glyceraldehyde 3-phosphate dehydrogenase reaction (Fulgencio et al., 1996) and stimulate glucose uptake by the muscle (Miles et al., 1997). Thiazolidinediones inhibit oxidation of long-chain fatty acid (18:1) but not the medium-chain fatty acid (octanoate). The inhibition of oxidation is via the inhibition of mitochondrial and microsomal long-chain acyl-CoA synthase activity but have no effect on mitochondrial CPT-I. In liver they increase insulin-stimulated conversion of glucose into fatty acids.

Thiazolidinediones are high-affinity ligands of PPAR-γ, a key factor for adipocyte differentiation. In preadipose cells they exert potent effect on the expression of genes encoding proteins involved in fatty acid metabolism such as FAS and phosphoenolpyruvate carboxykinase (Ibrahimi et al.,1994; Hallakou et al., 1997), LPL and hormone-sensitive lipase (Teruel et al., 2005). In adipose tissue thiazolidinediones act to conserve lipid by reducing lipid supply and subsequent utilization (Oakes et al., 1997). Troglitazone lowers serum FFA and TG concentrations by inhibiting TG synthesis and raises HDL-cholesterol level (Mimura et al., 1994; Kumar et al., 1996) but has no effect on

phospholipid synthesis. Plasma LDL-cholesterol increases with doses up to 600 mg/day but not at 800 mg/day of troglitazone. The possible side effect appears to be reduction in neutrophil counts at high doses of troglitazone (Kumar et al., 1996). In type 2 diabetic subjects rosiglitazone decreases postprandial FFA concentration (Boden et al., 2005; Van Wijk et al., 2005) and TG concentration (Tan et al., 2005) and increases oxidation of FFA in muscle (Wilmsen et al., 2003), total body fat, and oxidative phosphorylation (Boden et al., 2005). It also enhances downstream insulin receptor signaling in muscle (Miyazaki et al., 2003).

b. Fatty Acid Oxidation Inhibitors

Bromopalmitate and methylpalmoxirate (fatty acid derivatives) are fatty oxidation inhibitors. In 3T3-L1 adipocytes, 2-bromopalmitic acid, and 4-bromocrotonic acid inhibited basal as well as isoproterenol and dibutyryl cAMP-stimulated lipolysis (Fong et al., 1997). The effect of 4-bromocrotonic acid appears to be due to inhibition of hormone-sensitive lipase (Fong et al., 1997).

Dexfenfluramine, increase FFA turn over and oxidation rates in obese NIDDM subjects. It also reduces serum glucose but has no effect on insulin secretion (Greco et al., 1995).

c. Inhibitors of Lipolysis

Acipimox, a nicotinic acid analog, is an inhibitor of lipolysis. In lean and obese NIDDM subjects it decreases plasma FFA, glycerol and ketone levels and muscle lipid peroxidation, and increases insulin levels and insulin sensitivity (Vaag et al., 1991; Fulcher et al., 1992; Kumar et al., 1994; Piatti et al., 1996). In normal rats it decreases plasma FFA, inhibits lipolysis and hepatic gluconeogenesis and enhances the ability of insulin to suppress hepatic glucose production and peripheral glucose utilization (Al-Shurbaji et al., 1990; Lee et al., 1996). It may be used to treat lipid disorders in diabetes in combination with hypoglycemic agents.

Adenosine A1 agonist SDZ WAG944 is a potent inhibitor of adenosine deaminase-induced lipolysis. In diabetic rats it decreases plasma FFA and TG concentration. Antilipolytic agent *N*-{(1s, *trans*)-2 hydroxycyclopentyl} adenosine (GR 79236) reduces plasma FFA concentration and improves ketoacidosis in diabetic rats (Thompson et al., 1994). Inhibitor of hepatic fatty acid oxidation, B-aminobetaine is a carnitine analog and inhibits CPI-1 in hepatocytes but may induce fat deposition in the liver (Kashiwagi, 1995).

d. Lipid-Lowering Agents

Bezafibrate normalizes fatty acid changes in skeletal muscle TG of rats fed high fructose + lard (Matsui et al., 1997), which tend to produce insulin resistance. Whether bezafibrate has similar effect in diabetic animals or humans with insulin resistance and altered lipid and fatty acid composition needs to be evaluated. It also increases $\Delta 5$ desaturase activities.

Gemfibrozil decreases plasma FFA, TG, and phospholipids in elderly diabetic subjects. There is also a decrease in long-chain saturated fatty acids in phospholipids suggesting an impairment of chain elongation of fatty acid in liver microsomes (Brosche and Kipfmuller, 1996). However, in another study in NIDDM subjects it increased plasma FFA and LPL activity but it decreased insulin sensitivity (Ohrvall et al., 1995). It also decreased VLDL-cholesterol and TG.

Pravastatin, a HMG CoA-reductase inhibitor, is effective in patients with hypercholesterolemia secondary to diabetes and renal diseases (Haria and Mctavish, 1997). Hence it may be useful in combination therapy in diabetic patients who are at high risk of cardiovascular morbidity. Simvastatin, another HMG CoA-reductase inhibitor, also decreases LDL-cholesterol, and LDL/HDL ratio in NIDDM subjects with hyperlipoproteinemia (Ohrvall et al., 1995). Simvastatin has been shown to increase (Paolisso et al., 1991) as well as decrease (Ohrvall et al., 1995) insulin sensitivity. Its use in the treatment of NIDDM is not very effective, but may be used in conjunction with other treatments.

D. Metal Ions

The commonly used metal ions to treat diabetes and having an effect on fatty acid metabolism are chromium, vanadium, and molybdenum.

a. Chromium

The role of chromium in improving diabetes and its effect on lipid metabolism has been reviewed by Anderson (1995). In humans and diabetic animals chromium has been shown to have beneficial effects on glucose homeostasis and on lipid metabolism. Chromium appears to act via potentiating the effects of insulin by increasing insulin binding to cells (Anderson et al., 1987). Trivalent chromium in organic form appears to be a biologically active form. Chromium has been shown to decrease total cholesterol, LDL-cholesterol and TG, and increase HDL-cholesterol in subjects with IDDM as well as NIDDM (Canfield, 1979; Nath et al., 1979; Mossop, 1983; Evans, 1989; Anderson et al., 1997). In streptozotocin diabetic rats, glucose tolerance factor (GTF), a chromium-containing compound, reduces TG and FFA levels but has no effect on total cholesterol or HDL levels (Mirsky, 1993). In genetically diabetic mice, GTF decreased plasma TG and cholesterol levels (Tuman and Doisy, 1977).

b. Vanadium

In streptozotocin diabetic rats, vanadium compounds have beneficial effects on glucose and lipid metabolism. Vanadium lowers serum glucose level, decreases serum FFA and normalizes epinephrine-stimulated FFA release from adipose tissue (Brichard et al., 1994; Nakai et al., 1995; Sakurai et al., 1995). Vanadium appears to act via incorporation into adipose tissue (Nakai et al., 1995) and by improving low thyroid hormone status (Sakurai et al., 1995). Vanadium also partially increases mRNA and activities of key lipogenic enzymes, ACC and FAS in liver but not in adipose tissue (Brichard et al., 1994). Recently, new vanadium and zinc complexes have been synthesized (Yamaguchi et al., 2006). Vanadium compounds appear to have more insulin-mimetic activity than zinc compounds as measured by the effect on FFA release from rat adipocytes treated with epinephrine (Yamaguchi et al., 2006). Similarly, in streptozotocin diabetic rat macrocyclic binuclear oxovanadium complex lowered the elevated levels of lipids in plasma and tissue to near normal levels. It lowered the levels of LDL-cholesterol and increased the HDL-cholesterol levels and also normalized the altered fatty acid composition in liver and kidney (Ramachandran and Subramanian, 2005). The insulin-mimetic activity and the molecular mechanisms of various vanadium complexes had been reviewed by Scior et al. (2005). Wang et al. (2006) reported that in streptozotocin-treated mice, zinc supplement prevents diabetic cardiomyopathy via increased cardiac metallothionein.

c. Molybdenum

In streptozotocin diabetic rats, molybdenum decreased hyperglycemia and glucosuria and corrected the elevation of plasma FFA. Molybdenum also reversed low expression and activity of ACC and FAS in liver but not in adipose tissue (Ozcelikay et al., 1996). Thus, both vanadium and molybdenum, mimics certain insulin actions.

E. Other Agents

Probucol, an antioxidant, appears to decrease the oxidation of LDL in diabetic subjects. Addition of MUFA further decreases LDL oxidation, especially of dense LDL, which is more susceptible to oxidation (Reaven et al., 1996) and is more atherogenic.

Hydralazine, an antihypertensive drug, decreases serum TG and cholesterol in streptozotocin diabetic rats without affecting hyperglycemia. It also increases the binding of fatty acids by myocardial plasma membrane FABP (Heylinger et al., 1995).

Pyrazinoylguanidine reduces serum FFA, glucose and TG in hypertensive diabetic subjects and reduces glycosuria (Vesell et al., 1994). Thus, this drug appears to be beneficial for treatment of glucose as well as lipid abnormalities. Whether it is effective in treating diabetic subjects without hypertension remains to be studied.

β_3 *Adrenergic receptor* (β3AR) agonist treatment has been reported to normalize blood glucose, and decrease insulin and FFA levels in obese (ob/ob) mice (Arbeeny et al., 1995). Since similar defects are present in diabetes, β3AR agonists may also have therapeutic value in the treatment of NIDDM. Thus, a decrease in basal level of mRNA for the β3AR in brown adipose tissue in obese mice compared to lean controls has been observed.

Ascorbic acid supplementation alleviates hyperlipidemia in streptozotocin diabetic rats without affecting hyperglycemia or hypoinsulinemia (Dai and McNeill, 1995) suggesting that combination treatment of hypoglycemic and hypolipidemic agents may be beneficial.

Indobufen is an antiaggregatory agent and inhibits platelet aggregation by interfering with cyclooxygenase enzymes in platelets. In diabetic subjects it significantly lowers lipid peroxidation without affecting fatty acid composition of platelet phospholipids (Dmoszynska et al., 1995).

L-Propionylcarnitine (LPC) has beneficial effect in the heart of streptozotocin diabetic rats. It increases the rates of glucose and palmitate oxidation by heart (a favorable shift in glucose and fatty acid metabolism) and prevents the depression of cardiac mitochondrial respiration seen in diabetes (Broderick et al., 1996). LPC also has beneficial effect on neuropathy and retinopathy (Hotta et al., 1996).

Etomoxir, an inhibitor of CPT-I and fatty acid synthesis, has been reported to reduce high serum TG, FFA, and cholesterol in streptozotocin diabetic rats. It had no effect on low serum insulin or triiodothyronine (T_3) (Rupp et al., 1994). In NIDDM subjects it decreased blood glucose and improved lipid parameters, namely decreases in TG and cholesterol (Ratheiser et al., 1991).

Enprostil, a synthetic dehydoprostaglandin E_2, treatment for 1 week significantly reduced postprandial plasma FFA and TG and slightly decreased in cholesterol in NIDDM patients (Reaven et al., 1988). Thus, it may be useful in treating lipid disorders in type 2 diabetic subjects.

NO lowering agents such as nicotinamide and aminoguanidine may also be considered for diabetic treatment.

VII. CONCLUSIONS AND AREAS FOR FURTHER STUDY

In diabetes, fatty acid metabolism is altered qualitatively as well as quantitatively. Dyslipidemia appears to be due to altered lipogenesis as well as lipolysis, possibly due to hormonal imbalance. The desaturases that are responsible for synthesis of PUFAs are decreased in diabetes. This leads to more saturated fatty acid and less PUFA, especially AA in tissue phospholipids and other lipids. As a consequence, membrane fluidity is altered and eicosanoid production of 2-series is decreased. Dietary fish oils have several beneficial effects in normal and nondiabetic hyperlipidemic subjects, but in diabetic subjects the beneficial effects on lipid metabolism are offset by the deleterious effects on glucose homeostasis, and hence fish oils should be used with caution. Exercise has beneficial effects on carbohydrate and lipid metabolism in both NIDDM and IDDM, but in IDDM blood glucose levels and insulin dose requirements should be closely monitored during strenuous and/or prolonged exercise. Recently, soybean and flaxseed containing isoflavones and lignans have been found to have beneficial effects in lowering lipids in diabetic subjects.

Though we have gained significant knowledge on the fatty acid metabolism in diabetes, several areas need to be further explored.

1. The effect of ω-3 fatty acids, especially those from fish oils, on insulin has been studied in detail, but the effects on other hormones have not been investigated in detail in normal or diabetic subjects.
2. Lipid and carbohydrate metabolism are quantitatively different between males and females. In addition to pancreatic hormones, female sex hormones also play a role in lipid metabolism (Bhathena et al., 1989b). The differences in lipid metabolism between male and female diabetic subjects need to be studied in detail.
3. Recently, opiates and neuropeptides have been shown to be involved in the control of glucose and lipid metabolism. Limited data exist regarding the effect of dietary lipids on opiates and neuropeptides in diabetes.
4. The role of dietary fatty acids on insulin receptors in diabetes have been studied in detail, but the effects on the receptors of the counterregulatory hormones—glucagon, cortisol, growth hormone, catecholamines—need to be explored.
5. Diabetes, more often than not, is accompanied by increased risk and incidence of micro- and macroangiopathy, atherosclerosis, hypertension, nephropathy, peripheral polyneuropathy, and retinopathy. Though not discussed in this chapter, several abnormalities in the lipid metabolism have been well documented in these complications. However, the effects of dietary lipids on hormonal balance and metabolic fate of fatty acids—de novo synthesis, oxidation, desaturation, formation of eicosanoids—need to be further explored in these conditions.
6. Alteration in membrane fluidity has been clearly demonstrated in diabetic subjects. The effect of fatty acids on membrane fluidity in normal subjects has been studied in detail, and several of these studies have suggested the possible role of dietary fatty acids in the alteration in membrane fluidity in diabetic subjects. However, this needs to be demonstrated experimentally.
7. The TFAs appear to have more deleterious effects in humans than saturated fatty acids. No significant data exist on the metabolism of TFA in diabetes. Also the role of hormones on the metabolism of TFAs and the effects of TFAs on hormone levels in diabetes are not known.
8. The decrease in Δ9 and Δ4 desaturases and their regulation by dietary fatty acids and other factors remain unexplored.
9. The control of ω oxidation of fatty acids in diabetes also needs to be explored.
10. The role of oral hypoglycemic and lipid-lowering agents on platelet function and eicosanoid formation in diabetes is briefly reported here, but it needs further study.
11. Recently, amylin, interleukins and other cytokines, calcitonin gene-related peptide, and TNFs have been implicated in the pathogenesis of diabetes. Except for TNF's role in LPL modulation, not much is known about the role of these factors in lipid and fatty acid metabolism in diabetes. This is a new and exciting area of research.
12. Modified insulin (lispro insulin) where lysine and proline are exchanged at position B29 and B30, as well as acetylated insulin derivative (lys B29-tetradecanoyl des-[B30]) have been introduced to treat diabetes. Their effect on fatty acid and lipid metabolism needs to be evaluated.
13. Some of the advantages of breast feeding are attributed to the fatty acid composition of human milk (Lanting and Boersma, 1996). It is thus important to study long-term effect of fatty acids in breast milk compared to formula milk on the incidence of NIDDM and other chronic diseases in children.
14. Though progress has been made in the area of relationship between fatty acids and insulin resistance, the possible beneficial effects of lowering or preventing insulin resistance through increasing AA, EPA, and DHA and lowering linoleic acid and TFA on the incidence of NIDDM need to be further studied.
15. The studies on fatty acid metabolism in gestational diabetes are lacking and need to be carried out.

48 Fatty Acid Metabolism in Skeletal Muscle and Nerve, and in Neuromuscular Disorders

Charles J. Rebouche and Jeffrey K. Yao

CONTENTS

I. INTRODUCTION

Fatty acids, mostly as their activated coenzyme A esters, participate in many metabolic processes in human nerve and skeletal muscle (Figure 48.1). They are broken down, primarily in mitochondria and peroxisomes, to release electrons to be used to drive ATP synthesis, or to remove species (e.g., phytanic acid) with no biological function in humans. They are used for synthesis of complex lipids that are incorporated into membranes, or that are storage vehicles (triacylglycerols). Fatty acids

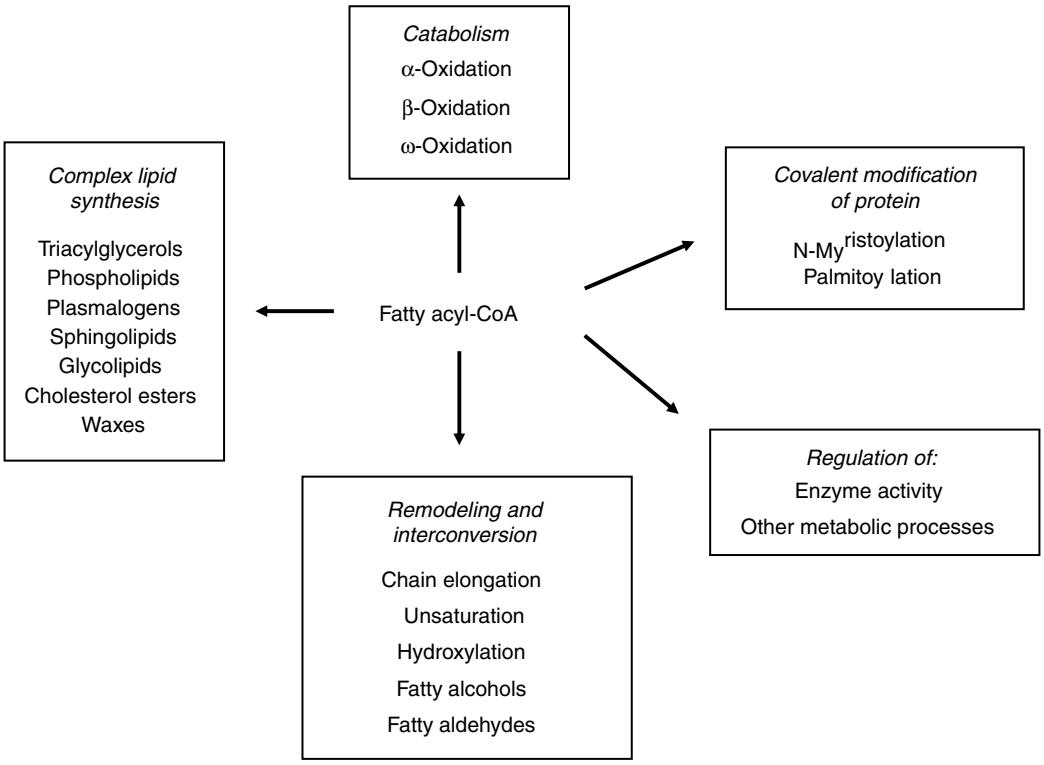

FIGURE 48.1 Metabolic roles of long-chain fatty acyl-CoA esters. (From Watkins, P.A. (1997). *Prog. Lipid Res. 36*:55–83. With modifications.)

contribute to covalent modification of proteins (N-myristoylation and palmitoylation), and participate in regulation of enzymatic activities and other metabolic processes.

Lipid abnormalities are often associated with neurologic and skeletal muscle dysfunction. Many disorders are due to single or multiple enzyme deficiencies, with resultant abnormal lipid storage in tissue, or abnormal lipid composition of membranes. For example, alterations of fatty acid metabolism are often associated with the process of demyelination in nervous tissues, because of their important role in the structure of membranes. In both nerves and skeletal muscle, enzyme deficiencies in pathways of fatty acid oxidation cause neuropathy, myopathy, muscle weakness, and abnormal lipid storage. Deficiency of dietary intake of fatty acids, as in protein-calorie malnutrition and anorexia nervosa, also may cause pathologic dysfunction of nerve and skeletal muscle. The purposes of this chapter are (1) to review fatty acid metabolism in nerve and skeletal muscle, and in other tissues where abnormal fatty acid metabolism impacts nerve and muscle function and (2) to review the current state of knowledge of some of the neuromuscular diseases caused by or are associated with abnormal fatty acid metabolism.

II. FATTY ACID METABOLISM IN MUSCLE AND NERVE

Skeletal muscle and nerve acquire free fatty acids from diet and from adipose tissue. Fatty acids derived from dietary triacylglycerols are reesterified and packaged into chylomicrons in enterocytes and released into the circulation. Fatty acid components of circulating chylomicrons are liberated by endothelial lipoprotein lipase. Fatty acids from triacylglycerols stored in adipose tissue are released by hormone-sensitive lipase. Nonesterified fatty acids bound to circulating albumin are the primary exogenous substrates for tissue fatty acid acquisition and subsequent storage, use in anabolic

processes, or oxidation. There is no general agreement as to whether exogenous fatty acids enter cells primarily by diffusion or by protein-mediated transport across the plasma membrane. Many long-chain fatty acids readily diffuse across model bilayer membranes (McArthur et al., 1999). However, the emerging view is that long-chain fatty acids cross plasma membranes via protein-mediated mechanisms, involving a number of fatty acid binding proteins, including fatty acid translocase (FAT/CD36), peripheral plasma membrane binding protein ($FABP_{pm}$), and possibly fatty acid transport protein 1 (FATP1) (Bonen et al., 2004; Koonen et al., 2005). Consistent with a role for diffusion, increased concentration of circulating fatty acids leads to increased accumulation of fatty acids in muscle. However, evidence for saturability of fatty acid uptake has been obtained in exercising human muscle, and correlations between abundance of FAT/CD36 and $FABP_{pm}$ in red oxidative skeletal muscle and white glycolytic muscle (both higher in red fibers) suggest an important role for protein-mediated uptake of fatty acids at the sarcolemmal membrane (Rasmussen and Wolfe, 1999). In the cytoplasm, long-chain fatty acids are transferred between intracellular membranes by binding to soluble fatty acid binding proteins ($FABP_c$). The predominant FABP isoform in muscle tissues, heart-type $FABP_c$ (H-$FABP_c$) is responsible for delivery of long-chain fatty acids from the sarcolemma through the cytoplasm to the outer mitochondrial membrane, the site of acyl-CoA synthetase (Koonen et al., 2005). This enzyme activates long-chain fatty acids to coenzyme A esters to make them available for triacylglycerol synthesis or mitochondrial β-oxidation.

A. Fatty Acid Metabolism in Peroxisomes

Peroxisomes utilize fatty acids in both catabolic and anabolic pathways. Peroxisomes catalyze α-oxidation and β-oxidation of activated fatty acids (as CoA-esters), and utilize fatty acids for synthesis of ether lipids. Although most β-oxidation of fatty acids occurs in mitochondria, peroxisomes are responsible for chain-shortening of very-long-chain fatty acids (C24 and C26), and long-chain dicarboxylic acids. Phytanic acid and 2-hydroxy fatty acids (as coenzyme A esters) undergo first α-oxidation and then β-oxidation in peroxisomes.

a. The Fatty Acid β-Oxidation Pathway in Peroxisomes

Peroxisomes contain at least 17 enzymes associated with the β-oxidation pathway. These include two acyl-CoA synthetases (Uchida et al., 1996), two acyl-CoA oxidases, two bifunctional proteins, two β-ketothiolases, α-methylacyl-CoA racemase, carnitine acetyl-transferase, carnitine octanoyl transferase, two enoyl-CoA isomerases, two enoyl-CoA reductases, and two acyl-CoA thioesterases (Wanders and Waterham, 2006). The peroxisomal membrane contains four half-ABC transporters, at least one of which is required for entry of activated fatty acids into peroxisomes.

Long-chain acyl-CoA synthetase (also known as palmitoyl-CoA ligase, and identical to mitochondrial and microsomal enzymes of the same name; Miyazawa et al., 1985) and very-long-chain acyl-CoA synthetase (also known as lignoceroyl-CoA ligase and cerotoyl-CoA synthetase) are associated with the peroxisomal membrane. The catalytic site of long-chain acyl-CoA synthetase is located on the cytoplasmic (external) side of peroxisomal membranes (Mannaerts et al., 1982; Lageweg et al., 1991). The catalytic site of very-long-chain acyl-CoA synthetase is located on the luminal (interior) side of peroxisomal membranes (Lazo et al., 1990; Steinberg et al., 1999). Thus, long-chain fatty acids are activated externally and are transported into peroxisomes as coenzyme A esters, but very-long-chain fatty acids enter peroxisomes as free acids. Short- and medium-chain acyl-CoA esters generated from chain-shortening of fatty acids are not transported out of peroxisomes as CoA esters, but rather, as esters of carnitine (Verhoeven et al., 1998a; Ramsay, 1999), or as acetate (Leighton et al., 1989). In mammals, peroxisomal acyl-CoA synthetases have mostly been studied with liver preparations. The presence, expression level, and existence of isozyme species in extrahepatic tissues have not been extensively characterized.

The enzymatic reaction sequence for β-oxidation in peroxisomes is similar but not identical to that in mitochondria. Two electrons are first extracted from activated fatty acids, by palmitoyl-CoA

oxidase (specific for very-long-chain fatty acids and straight chain mono- and dicarboxylic acids) and pristanoyl-CoA oxidase, which is active with activated branched-chain fatty acids (e.g., pristanoyl-CoA). Unlike the acyl-CoA dehydrogenases in mitochondria, peroxisomal acyl-CoA oxidases transfer electrons directly to molecular oxygen, producing hydrogen peroxide (Wanders et al., 2001). Peroxisomes contain two bifunctional proteins, each containing enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities, but with distinct substrate-specific activities (Wanders and Waterham, 2006). Human peroxisomes contain two thiolases, one reactive with unbranched 3-ketoacyl-CoA esters, and one specific for 2-methyl (2S configuration) branched-chain ketoacyl-CoA esters. Auxiliary enzymes are required for metabolism of (2R)-methyl branched-chain fatty acids (2-methylacyl-CoA racemase), unsaturated fatty acids (2,4-dienoyl-CoA reductase and Δ^3, Δ^2-enoyl-CoA isomerase) and unsaturated fatty acids with a double bond at an odd-numbered position ($\Delta^{3,5}$,$\Delta^{2,4}$-dienoyl-CoA isomerase, $\Delta^{2,4}$-dienoyl-CoA reductase, and Δ^3,Δ^2-enoyl-CoA isomerase) (Wanders and Waterham, 2006).

b. The Fatty Acid α-Oxidation Pathway

The peroxisomal α-oxidation pathway provides for initial degradation of dietary phytanic acid, and dietary and endogenous α-hydroxy fatty acids (Figure 48.2). Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) is derived from the phytol side chain of chlorophyll. Microorganisms in the rumen of domestic ruminant animals cleave the phytol side chain, and it is subsequently converted to phytanic acid (Verhoeven et al., 1998b). Phytanic acid is present in the human diet primarily in dairy products and ruminant fats, but is also found in lower concentrations at all levels of the food chain. Humans do not readily absorb chlorophyll from plant material; approximately 95% of ingested chlorophyll passes through the digestive system intact (van den Brink and Wanders, 2006). Chlorophyll may be degraded to a small extent by microorganisms in the large intestine of humans. Phytol released in this manner may be absorbed and metabolized to phytanic acid by a pathway present in microsomes and peroxisomes (van den Brink and Wanders, 2006). However, this pathway does not appear to be a significant source of phytanic acid in normal humans or in patients with Refsum disease (Wierzbicki, 2004).

Phytanic acid metabolism probably occurs mostly in the liver, but failure to degrade this fatty acid results in the serious neurological disorder, Refsum's disease (Refsum, 1981; Yao and Dyck, 1987). A major degradation product of phytanic acid, pristanic acid (2,6,10,14-tetra-methylpentadecanoic acid), is also present in the diet and is degraded by peroxisomal β-oxidation. α-Hydroxy derivatives of straight-chain C20 to C26 saturated or monounsaturated fatty acids are synthesized primarily in neural tissues for incorporation into sphingolipids, and are a major constituent of myelin (Alderson et al., 2004). Degradation of sphingolipids releases α-hydroxy fatty acids, which are degraded via the peroxisomal α-oxidation pathway.

Phytanic acid is activated to its coenzyme A ester by very-long-chain acyl-CoA synthetase. The activated fatty acid is then hydroxylated at the α carbon, by the catalytic action of phytanoyl-CoA hydroxylase, an α-ketoglutarate-requiring dioxygenase (Mihalik et al., 1995; McDonough et al., 2005). 2-Hydroxyphytanoyl-CoA is cleaved by 2-hydroxyphytanoyl-CoA lyase, producing pristanal and formyl-CoA (Foulon et al., 1999). This reaction requires the cofactor thiamine pyrophosphate. Long-chain fatty aldehydes are produced from long-chain α-hydroxy fatty acids by this same pathway (Foulon et al., 2005). Long-chain fatty aldehydes, including pristanal, are oxidized to the corresponding acids by aldehyde dehydrogenase (Jansen et al., 2001). These acids are subsequently activated to coenzyme A esters and are further metabolized by peroxisomal and mitochondrial β-oxidation.

c. Synthesis of Ether Lipids

Ether lipids differ from other phospholipids in that they contain an ether linkage at the *sn*-1 position instead of the more common ester linkage. Ether lipids, 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine,

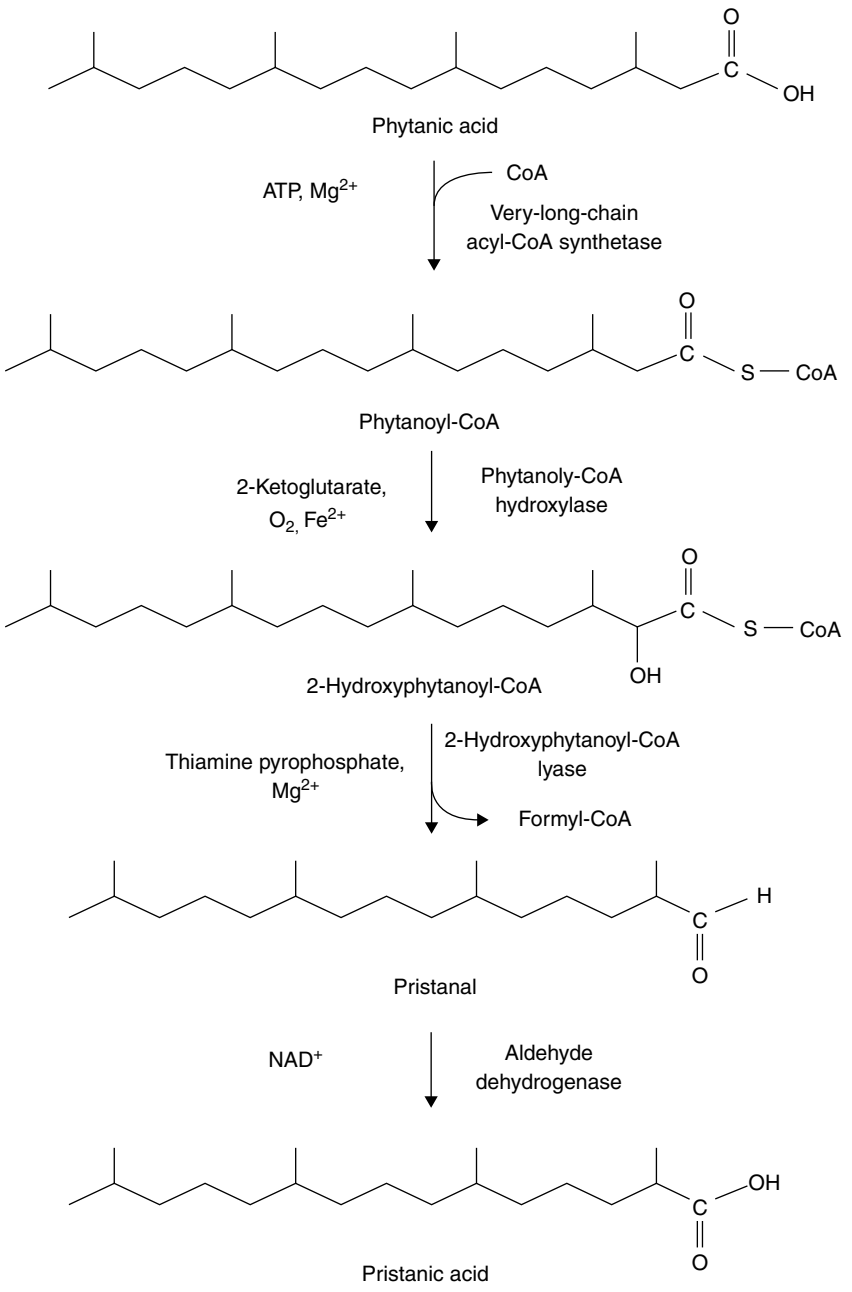

FIGURE 48.2 Pathway of α-oxidation of phytanic acid in peroxisomes.

1-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine, 1-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphocholine, and 1-alk-1′-enyl-2-acyl-*sn*-glycero-3-ethanolamine, are synthesized by a series of enzymatic reactions that occur sequentially in peroxisomes and endoplasmic reticulum. 1-Alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphocholine (plasmenylcholine) and 1-alk-1′-enyl-2-acyl-*sn*-glycero-3-ethanolamine (plasmenylethanolamine) are called plasmalogens. In humans, plasmalogens make up about 18% of total phospholipid mass (Wanders and Waterham, 2006). Plasmenylethanolamine is an abundant component of the myelin membrane. Because of their surface charge and geometry,

plasmalogens reduce membrane fluidity and influence the temperature of phase transition (Thai et al., 1997). Plasmenylethanolamine in brain contains a high percentage of polyunsaturated fatty acids (PUFA) in the *sn*-2 position, including arachidonic acid (AA) and docosahexaenoic acid (DHA); it has been suggested that this molecule serves as a storage depot for these species (Brites et al., 2004). Plasmalogens may also have a role in signal transduction, cholesterol transport and metabolism, and oxidative stress (Brites et al., 2004; Wanders and Waterham, 2006). The importance of plasmalogens is underscored by the fact that single enzyme deficiencies in their biosynthesis have severe clinical consequences.

Synthesis of plasmalogens is a multistep process utilizing enzymes located in peroxisomes and endoplasmic reticulum. The committed step in this pathway is the condensation of a long-chain fatty alcohol with acyl dihydroxyacetone phosphate to form alkyl dihydroxyacetone phosphate and releasing the acyl group as a fatty acid (Wanders and Waterham, 2006). This reaction is catalyzed by peroxisomal alkyl-dihydroxyacetone phosphate synthase (Singh et al., 1993). Reactions catalyzing formation of substrates for this reaction also are peroxisomal. Long-chain fatty alcohol is formed by reduction of fatty acyl-CoA on the external surface of peroxisomes, catalyzed by the peroxisomal membrane protein acyl-CoA reductase (Burdett et al., 1991). Two molecules of NADPH provide four electrons for this two-step reduction. Acyl dihydroxyacetone phosphate is formed by the condensation of an acyl-CoA ester with dihydroxyacetone phosphate, with release of coenzyme A. The reaction is catalyzed by acyl-CoA:dihydroxyacetone phosphate acyltransferase. The active form of this enzyme is part of a heterotrimeric complex with alkyl-dihydroxyacetone phosphate synthase (Biermann et al., 1999). Alkyl dihydroxyacetone phosphate is reduced to form 1-alkyl glycerol-3-phosphate. This reaction is catalyzed by acyl-/alkyl-dihydroxyacetone phosphate reductase, an enzyme located in the peroxisomal membrane with its catalytic site on the external surface (Datta et al., 1990). NADPH is the preferred source of electrons for the reduction reaction.

The remaining reactions in the pathway of plasmalogens synthesis occur in the endoplasmic reticulum. 1-Alkyl glycerol-3-phosphate is acylated at the 2 position of glycerol. The phosphate is hydrolyzed producing 1-alkyl-2-acylglycerol. This molecule is condensed with CDP-choline or CDP-ethanolamine to produce 1-alkyl-2-acylglycerophosphocholine or 1-alkyl-2-acylglyceroethanolamine, respectively. The desaturase catalyzing formation of plasmalogens is similar to the enzyme that introduces double bonds into long-chain acyl-CoA esters (Berg et al., 2002). Co-substrates for the reaction are O_2 and NADH.

The physiological significance of segregation of the early steps of ether lipid synthesis in peroxisomes appears to be the need to overcome the inhibition by extraperoxisomal NADPH, which inhibits formation of ether lipids from dihydroxyacetone phosphate by reducing acyl dihydroxyacetone phosphate as soon as it forms (Hajra, 1995).

B. β-Oxidation of Fatty Acids in Mitochondria

In muscle and nerve, most fatty acid catabolism occurs in mitochondria. Long-chain fatty acids in the cytosol are first activated by esterification to coenzyme A (Figure 48.3). This reaction occurs on or in the outer membrane of mitochondria, and is catalyzed by long-chain acyl-CoA synthetase (Watkins, 1997). Activated fatty acids are transesterified to carnitine by the action of carnitine palmitoyltransferase I (CPT I), located on the inner aspect of the mitochondrial outer membrane. The fatty acyl carnitine esters are transported in the mitochondrial inner membrane by carnitine-acylcarnitine translocase (CACT). The activated fatty acids are then transesterified to intramitochondrial coenzyme A by the action of carnitine palmitoyltransferase II (CPT II) located on the matrix side of the mitochondrial inner membrane.

Activated long-chain fatty acids undergo successive rounds of mitochondrial β-oxidation. The first step in this process involves the loss of two electrons, and is catalyzed by one of three acyl-CoA dehydrogenases. Very-long-chain fatty acyl-CoA dehydrogenase (VLCAD; Izai et al., 1992) and acyl-CoA dehydrogenase-9 (ACAD-9, so-named because it was the ninth member of this enzyme

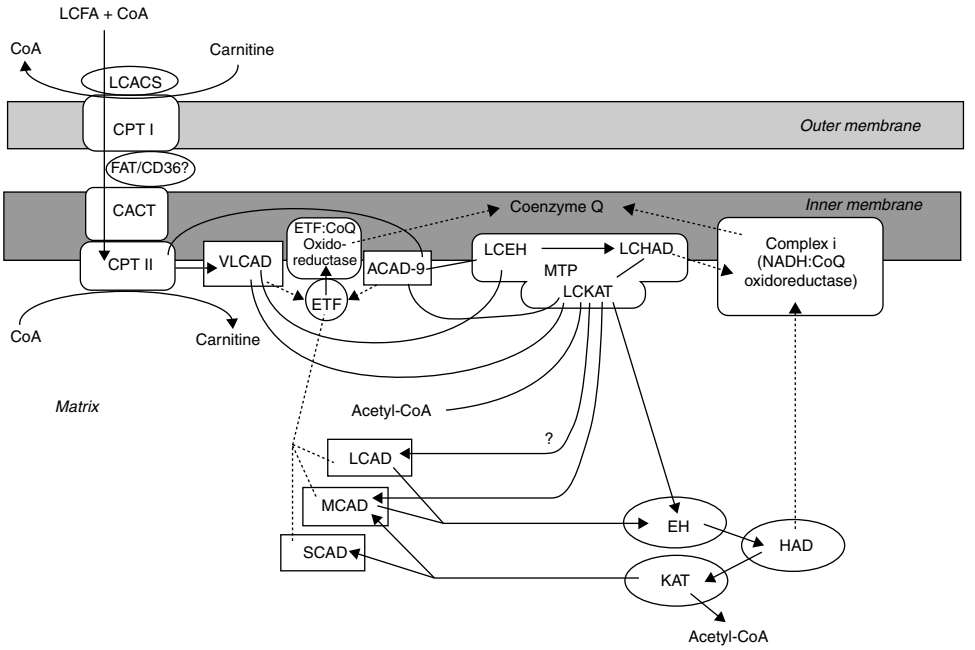

FIGURE 48.3 Schematic diagram of long-chain fatty acid β-oxidation in mitochondria. Solid lines indicate flow of carbon; dashed lines indicate flow of electrons. *Abbreviations:* LCFA, long-chain fatty acid; CoA, coenzyme A; LCACS, long-chain acyl-CoA synthetase; CPT, carnitine palmitoyltransferase; FAT, fatty acid transporter; CACT, carnitine-acylcarnitine translocase; VLCAD, very-long-chain acyl-CoA synthetase; ACAD-9, acyl-CoA synthetase-9; ETF, electron transfer flavoprotein; CoQ, coenzyme Q; MTP, mitochondrial trifunctional protein; LCEH, long-chain 2-enoyl-CoA hydratase; LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase; LCKAT, long-chain 3-ketoacyl-CoA thiolase; LCAD, long-chain acyl-CoA dehydrogenase; MCAD, medium-chain acyl-CoA dehydrogenase; SCAD, short-chain acyl-CoA dehydrogenase; EH, 2-enoyl-CoA hydratase; HAD, 3-hydroxyacyl-CoA dehydrogenase; KAT, 3-ketoacyl-CoA thiolase; and NADH, reduced nicotinamide adenine dinucleotide.

family to be identified; Zhang et al., 2002) are associated with the mitochondrial inner membrane. They catalyze electron transfer from activated long-chain saturated and unsaturated fatty acids, respectively, although there is some overlap in specificity (Ensenauer et al., 2005). VLCAD kinetics is most favorable with saturated, unbranched activated fatty acids 16–22 carbons in length (Izai et al., 1992). ACAD-9 has optimal activity toward C16:1-, C18:1-, C18:2-, and C22:6-CoA (Ensenauer et al., 2005).

Long-chain acyl-CoA dehydrogenase (LCAD) is located in the matrix of mitochondria. Before discovery of VLCAD and ACAD-9, LCAD was believed to be responsible for initiation of β-oxidation in mitochondria of all activated long-chain fatty acids. However, with the discovery of the two membrane-associated dehydrogenases, the role of LCAD has come into question. Its activity towards palmitoyl-CoA is tenfold lower than that for VLCAD (Izai et al., 1992). LCAD has been implicated in the initial cycles of β-oxidation of activated branched-chain fatty acids (Mao et al., 1995; Wanders et al., 1998) that are not substrates for VLCAD. Targeted disruption in mice of the gene coding for LCAD revealed profound abnormalities, including frequent gestational loss, severely reduced fasting tolerance with hepatic and cardiac lipidosis, hypoglycemia, elevated serum free fatty acids, and nonketotic hypoglycemia (Kurtz et al., 1998), indicative of an essential function for LCAD beyond its role in branched-chain fatty acid oxidation. The work of Eder et al. (1997) and Le et al. (2000) suggest that LCAD is important for oxidation of both saturated and unsaturated fatty acyl-CoA esters of 10–14 carbons chain length, which may be native or result from chain-shortening initiated by VLCAD, ACAD-9, or peroxisomal β-oxidation.

Fatty-acyl 2-enoyl-CoA esters generated by the action of acyl-CoA dehydrogenases are further metabolized by the mitochondrial trifunctional protein (MTP), located in or associated with the mitochondrial inner membrane (Uchida et al., 1992), or with the soluble enzymes enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase located in the mitochondrial matrix. Each of these three enzyme activities also resides on the MTP. Products of the long-chain acyl-CoA esters reactions with VLCAD or ACAD-9 may be channeled directly to MTP for efficient cycling without release of reaction products. Evidence from a number of experimental studies suggests that fatty acyl-CoA synthetase, CPT I, CACT, CPT II, VLCAD, and MTP are spacially organized in a "metabolon" to channel long-chain fatty acids from the cytosol to the mitochondrial matrix without release of intermediates (see Eaton, 2002, for a review of arguments both for and against supramolecular organization of these proteins).

Chain-shortened (≤ 14 carbon atoms) acyl-CoA esters undergo further β-oxidation cycles in the soluble matrix of mitochondria. Successive reaction cycles of acyl-CoA dehydrogenases [LCAD, medium-chain acyl-CoA dehydrogenase (MCAD), or short-chain acyl-CoA dehydrogenase (SCAD)], 2-enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase reduce acyl-CoA esters to acetyl-CoA, which then feeds into the tricarboxylic acid cycle, or the activated acetyl is exported as acetyl-carnitine via CACT. Accessory enzymes (*cis*-Δ^3-enoyl-CoA isomerase, 2,4-dienoyl-CoA reductase, $\Delta^{3,5}$,$\Delta^{2,4}$-dienoyl-CoA isomerase, and short-branched-chain acyl-CoA dehydrogenase) metabolize unsaturated and branched-chain acyl-CoA esters (Berg et al., 2002; Di Donato and Taroni, 2004).

Efficient β-oxidation of activated fatty acids requires pathways for electron transfer to the electron transport chain. The acyl-CoA dehydrogenases transfer electrons from their associated flavin adenine dinucleotide (FAD) to electron transfer flavoprotein (ETF). ETF gives up its electrons to ETF:coenzyme Q oxidoreductase, which in turn reduces coenzyme Q (CoQ). ETF is a soluble protein in the mitochondrial matrix, and ETF:CoQ oxidoreductase is a component of the mitochondrial inner membrane. CoQ is linked to electron transport chain complexes I, II, and III. 3-Hydroxyacyl-CoA dehydrogenases (in the matrix and associated with MTP) transfer electrons to electron transport chain complex I via redox cycling of nicotinamide adenine dinucleotide.

C. Regulation of Fatty Acid Metabolism in Skeletal Muscle

Fatty acids are a major source of fuel for ATP production in skeletal muscle. At rest, fatty acid-triglyceride substrate cycling between adipose tissue and liver provides a relatively stable source of circulating fatty acids and at the onset of exercise. Free fatty acids from this substrate cycle can be used as a buffer to supply additional energy to skeletal muscle (Rasmussen and Wolfe, 1999). However, neutral lipid stored in muscle provides a ready source of fatty acids for β-oxidation and is perhaps quantitatively more important than exogenous fatty acids, at least in the initial phase of muscle activity (Dyck and Bonen, 1998). Indeed, the processes of intracellular fatty acid esterification and β-oxidation are dynamic and occur simultaneously. Hormonal influences also impact fatty acid metabolism in muscle. For example, insulin increases free fatty acid entry into skeletal muscle, and increases triacylglycerol synthesis while decreasing the rate of β-oxidation (Dyck et al., 2001). Adiponectin and leptin both increase the rate of fatty acid oxidation and decrease muscle lipid content (Dyck et al., 2006).

Control of β-oxidation flux appears to be largely at the level of entry of acyl groups to mitochondria. Although skeletal muscle has a relatively limited capacity for de novo lipogenesis, it does synthesize malonyl-CoA, a potent inhibitor of CPT I. Malonyl-CoA concentration rises in response to insulin, which may at least in part account for the shift from oxidation to triacylglycerol synthesis in skeletal muscle in response to insulin. The malonyl-CoA response to insulin is mediated by glucose binding to acetyl-CoA carboxylase. Glucose is an allosteric activator of this enzyme. Conversely, malonyl-CoA concentration decreases in response to adiponectin. A proteolytic cleavage product of adiponectin, gACRP30, activates AMP-activated protein kinase (AMPK), a fuel-sensing enzyme present in most mammalian tissues. AMPK phosphorylates and inhibits acetyl-CoA

carboxylase and phosphorylates and activates malonyl-CoA decarboxylase, leading to a decrease in the concentration of malonyl-CoA (Tomas et al., 2002).

The putative plasma membrane fatty acid transporter FAT/CD36 also is associated with the mitochondrial outer membrane (Bezaire et al., 2006), and coprecipitates with CPT I in human skeletal muscle (Schenk and Horowitz, 2006). Inhibition of FAT/CD36 translocase activity with the specific inhibitor sulfo-N-succimidyloleate reduced palmitate oxidation by 95% and palmitoylcarnitine oxidation by 92% in purified human skeletal muscle mitochondria (Bezaire et al., 2006). Octanoate oxidation and CPT I activity were not inhibited under the same experimental conditions. In normal humans, whole-body fat oxidation rates and palmitate oxidation rates in isolated mitochondria progressively increased during aerobic exercise, and the latter was positively correlated with a 63% increase in mitochondrial FAT/CD36 protein content in mitochondria (Holloway et al., 2006). These observations are consistent with a vital role for FAT/CD36 in entry of long-chain fatty acids into mitochondria; FAT/CD36 may provide an additional layer of regulation (in addition to malonyl-CoA concentration) for entry of long-chain fatty acids into mitochondria.

In addition to CPT I, the enzymes of the β-oxidation cycle may participate in regulation of flux through the pathway, through substrate availability and product inhibition. In particular, the redox state of nicotinamide adenine dinucleotide (NAD^+/NADH) and ETF may significantly influence the activities of the dehydrogenases of the cycle. The relative concentrations of acetyl-CoA and coenzyme A may alter the activity of the 3-ketoacyl-CoA thiolases, but the ratio of these metabolites also will be regulated by export of acetyl groups from mitochondria as esters of carnitine. Sharing of control between CPT I and other enzymes allows for flexible regulation of metabolism and the ability to rapidly adapt β-oxidation flux to differing requirements in skeletal muscle and other tissues (Eaton, 2002).

III. NEUROMUSCULAR DISORDERS ASSOCIATED WITH FATTY ACID METABOLISM

A. Peroxisomal Disorders

Peroxisomal disorders are divided into two major categories (Table 48.1), disorders of peroxisome assembly and disorders resulting from a single enzyme or transporter deficiency (Moser et al., 1995;

TABLE 48.1
Genetically Determined Peroxisomal Disorders Associated with Fatty Acid Metabolism

Category	Disorder
Peroxisomal assembly deficiency	Zellweger syndrome
	Infantile Refsum disease
	Neonatal adrenoleukodystrophy
	Rhizomelic chondrodysplasia punctata type 1
Single enzyme/transporter deficiency	Adult Refsum disease (phytanoyl-CoA hydroxylase deficiency)
	X-linked adrenoleukodystrophy
	Acyl-CoA oxidase deficiency
	D-Bifunctional enzyme deficiency
	3-Ketoacyl-CoA thiolase deficiency
	α-Methyl-CoA racemase deficiency
	Alkyl dihydroxyacetone phosphate synthase deficiency (rhizomelic chondrodysplasia punctata type 2)
	Dihydroxyacetone phosphate acyltransferase deficiency (rhizomelic chondrodysplasia punctata type 3)

Source: From Moser, A.B., et al. (1995). *J. Pediatr. 127*:13–22.

Watkins et al., 1995). In disorders of peroxisome assembly, the organelle fails to form normally and multiple functions are lost.

a. Peroxisome Assembly Disorders

This group of diseases is characterized by total absence of peroxisomes (Zellweger syndrome) or loss of partial functions of peroxisomes due to inability to import required proteins (neonatal adrenoleukodystrophy, infantile Refsum disease, and rhizomelic chondrodysplasia punctata type 1). These diseases are characterized by cellular accumulation of metabolites that are normally metabolized by peroxisomes (very-long-chain fatty acids, phytanic acid, and pristanic acid), or the inability to synthesize plasmalogens (rhizomelic chondrodysplasia punctata type 1 [RCDP1]).

Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease are referred to as the "Zellweger spectrum," and whose phenotypes represent a continuum of disease severity: Zellweger syndrome is the most severe phenotype, neonatal adrenoleukodystrophy is intermediate in severity, and infantile Refsum disease is the mildest form of the disease spectrum (Weller et al., 2003). Neurological symptoms in the Zellweger spectrum include severe hypotonia, seizures, developmental delay, and development of sensorineural hearing loss. Biopsy and autopsy findings include demyelination and loss of nerve fibers in infantile Refsum disease and diffuse white matter degeneration in neonatal adrenoleukodystrophy (Thomas and Goebel, 2005). The degree of neurologic impairment ranges from individuals with complete absence of psychomotor development to patients with the ability to learn to walk and communicate (Weller, 2003). The most severely affected patients die within the first months after birth, while patients at the mild end of the spectrum survive into the fourth or fifth decade of life. The milder forms of the disease may be misdiagnosed and only become apparent after careful genetic analysis.

The clinical phenotype of RCDP1 includes severe skeletal abnormalities characterized by rhizomelia with severe shortening and disturbed ossification of the proximal limbs. Neurologic symptoms include hypotonia and moderate-to-severe psychomotor retardation. Survival generally is up to several years.

Proteins necessary for peroxisomal biogenesis, including matrix protein import, membrane biogenesis, organelle proliferation and inheritance, are called peroxins, and the genes coding for these proteins are referred to as *PEX* genes (Distel et al., 1996). The known characteristics and functions of these proteins have been reviewed in detail by Weller et al. (2003). Mutations in 12 of these genes are known to cause defects in peroxisome biogenesis (Wanders and Waterham, 2006). Mutations in 11 of these genes (*PEX*1, 2, 3, 5, 6, 10, 13, 14, 16, 19, and 26) have been implicated in the Zellweger spectrum of peroxisomal biogenesis disorders.

RCDP1 results from a mutation in the *PEX*7 gene. Peroxisomal matrix proteins are synthesized on free cytosolic ribosomes and imported into peroxisomes. These proteins contain in their amino acid sequence a peroxisomal targeting sequence (PTS), of which there are two types, PTS1 and PTS2. Most imported proteins contain the PTS1 sequence, but a small number contain the PTS2 sequence. *PEX*7 encodes a peroxin protein required for import of proteins with a PTS2 sequence. In humans, alkyl dihydroxyacetone phosphate synthase, phytanoyl-CoA hydroxylase, and peroxisomal 3-ketoacyl-CoA thiolase contain a PTS2 sequence (Ofman et al., 1998). Thus, in RCDP1, these proteins cannot be imported into peroxisomes. Activity of acyl-CoA:dihydroxyacetone phosphate acyltransferase also is low in RCDP1. RCDP1 patients are deficient in plasmalogens and have an increased plasma phytanic acid concentration (de Vet et al., 1998).

b. Disorders Associated with Single Enzyme Deficiencies in Peroxisomes

i. Adult Refsum Disease

Adult Refsum disease (heredopathia atactica polyneuritiformis) is a rare autosomal recessive disorder of fatty acid oxidation characterized clinically by retinitis pigmentosa, blindness, anosmia,

deafness, cerebellar ataxia, and peripheral polyneuropathy (Weinstein, 1999; Wierzbicki et al., 2002). Accumulation of phytanic acid in adult Refsum's disease was first recognized by Klenk and Kahlke (1963). The age of onset varies from late childhood to late adulthood. The metabolic error in many cases of adult Refsum disease lies in a failure of the conversion of phytanoyl-CoA to α-hydroxyphytanoyl-CoA, which leads to a widespread tissue storage of phytanic acid (Steinberg et al., 1967, Herndon et al., 1969; Mize et al., 1969; Yao and Dyck, 1987). Missense mutations and deletions in the *PHYH* gene on chromosome 10p13 are responsible for absence of phytanoyl-CoA hydroxylase activity (Jansen et al., 1997; Mihalik et al., 1997). Some cases of adult Refsum disease also result from mutations in the *PEX*7 gene (van den Brink et al., 2003). Adult Refsum disease may also be caused by mutations in the gene coding for sterol carrier protein-2 (SCP-2; Mukherji et al., 2002). SCP-2 is a peroxisomal accessory protein that facilitates phytanoyl-CoA hydroxylation by maintaining its solubility and by retarding its hydrolysis (Mukherji et al., 2002). Adult Refsum disease is distinguished from infantile Refsum disease in that the latter is a peroxisomal biogenesis disorder (also called a multiple peroxisomal function disorder) involving abnormalities in phytanic acid and very-long-chain fatty acid metabolism and plasmalogen synthesis (Bader et al., 2000).

Treatment with diets low in phytanic acid reduces plasma phytanic acid concentration and brings about significant improvement in peripheral nerve function; however, full restoration of function is seldom achieved (Steinberg, 1989). Plasma exchange is an option when dietary control is inadequate (Winters et al., 2000; Wills et al., 2001). Plasma exchange has been shown to be particularly useful for rapidly lowering plasma phytanic acid levels during acute attacks and may be useful as a maintenance therapy (Weinstein, 1999).

In addition to the α-oxidation pathway for degradation in peroxisomes, phytanic acid also can be degraded to a limited extent by ω-oxidation in microsomes, followed by cycles of β-oxidation in peroxisomes. Degradation of phytanic acid by this pathway has been observed in normal humans and in patients with adult Refsum disease, with excretion of 3-methyladipic acid (Wierzbicki et al., 2003). Pharmacological stimulation of microsomal ω-oxidation conceivably could provide an alternate treatment option for patients with Refsum disease.

Mitochondria appear to be a major target of pathology associated with accumulation of phytanic acid. In isolated rat brain mitochondria, phytanic acid dissipated membrane potential and released cytochrome c (Reiser et al., 2006). Astrocytes from rat brain exposed to phytanic acid die within a few hours (Schönfeld et al., 2006). Death is preceded by depolarization of mitochondria, and an increase in cytosolic Ca^{2+} concentration. In both isolated mitochondria and intact astrocytes phytanic acid increased generation of reactive oxygen species. Bunik et al. (2006) observed that phytanoyl-CoA is a potent inhibitor of purified mitochondrial pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Indeed, phytanoyl-CoA was seen to be ten times more potent an inhibitor than palmitoyl-CoA. These authors suggest that the neuropathology seen in Refsum disease may be at least in part due to inhibition of mitochondrial metabolism at the level of these enzymes. They further point out, however, that *in vivo* these enzymes are located in the mitochondrial matrix, and that a means to achieve a sufficiently high concentration of phytanoyl-CoA in this organelle has not been demonstrated.

ii. Deficiency of Enzymes of Very-Long-Chain Fatty Acid Oxidation

Complementation analysis has identified patients with three distinct genotypes associated with deficiency of acyl-CoA oxidase, D-bifunctional protein, or 3-ketoacyl-CoA thiolase in the pathway of very-long-chain fatty acyl-CoA oxidation (Watkins et al., 1995). The clinical manifestations of these disorders are similar to those of the peroxisome assembly disorders (Zellweger syndrome and neonatal adrenoleukodystrophy), but differ from those of X-linked adrenoleukodystrophy (Watkins et al., 1995).

iii. X-Linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy (X-ALD) is an inherited neurodegenerative disease with variable phenotypes. The most frequent phenotypes are childhood cerebral X-ALD with inflammatory cerebral

demyelination, and adult-onset adrenomyeloneuropathy, a slowly progressive form that affects mainly spinal cord and peripheral nerves of the limbs (Oezen et al., 2005). Adreno-cortical insufficiency is common to both forms. The childhood form is more severe. It affects primarily young males, is rapidly progressive, leading to death resulting from the central nervous system lesions (Powers et al., 2005).

Biochemically, the hallmark of X-ALD is increased presence of saturated, unbranched, and very-long-chain fatty acids (C26:0 and C24:0) in plasma and tissues, particularly in the cholesterol ester and ganglioside fractions of brain white matter and adrenal cortex. Powers et al. (2005) suggest that pathogenesis occurs in two stages: a primary defect in myelination (due to incorporation of very-long-chain fatty acids into myelin gangliosides and phospholipids and the proteolipid protein) that destabilizes myelin and leads to its spontaneous breakdown, and a secondary inflammatory demyelination process. X-ALD is caused by mutations in the *ABCD1* gene that encodes the peroxisomal membrane protein ALDP (Mosser et al., 1993). This protein belongs to a family of ATP-binding cassette membrane transport proteins, of which four are present in the peroxisomal membrane. X-ALD was initially thought to be due to a deficiency of very-long-chain acyl-CoA synthetase, because this enzyme activity is low or absent in ALD patients. However, recent evidence suggests that normally there is a physical interaction between very-long-chain acyl-CoA synthetase and ALDP in the peroxisomal membrane (Makkar et al., 2006). Loss of this interaction may cause dysfunction of very-long-chain acyl-CoA synthetase in X-ALD.

Dietary therapy has been considered in treatment of X-ALD. Kishimoto et al. (1980) have shown that hexacosanoic acid (C26:0) given orally appeared in brain cholesterol esters of an X-ALD patient, demonstrating that diet can contribute to the very-long-chain fatty acid load of X-ALD patients. Very-long-chain fatty acids are for the most part minor components of dietary lipids and usually are not reported separately in fatty acid analyses of foods. However, Brown et al. (1982) found microgram quantities of C26:0 in single serving amounts of a variety of common foods such as French fries, orange juice, bananas, low-fat chocolate milk, and yogurt. Peanut oil had the highest concentration at 10.42 μg/tsp. Although dietary therapy may be useful, a diet that sharply reduced the intake of saturated very-long-chain fatty acids did not alter plasma C26:0 concentrations (Brown et al., 1982).

Dietary supplement therapy with Lorenzo's Oil, a 4:1 mixture of glyceryl trioleate and glyceryl trierucate, has shown some benefit in neurologically asymptomatic patients (Moser et al., 2005). Erucic acid (C22:1) inhibits chain elongation of saturated fatty acids. Lorenzo's Oil was shown to normalize the concentrations of saturated very-long-chain fatty acids in plasma in most patients with X-ALD (Rizzo et al., 1989). In the study by Moser et al. (2005), asymptomatic patients treated with Lorenzo's Oil and a restricted fat diet showed a reduction of plasma C26:0, that correlated with reduced risk of developing brain structural abnormalities identified by magnetic resonance imaging. Earlier single-arm clinical trials, however, led to the consensus that Lorenzo's Oil did not alter the rate of progression significantly in patients who were already neurologically symptomatic when therapy was initiated (Moser et al., 2005). Lorenzo's Oil therapy may slow the progression of X-ALD patients with the milder adrenomyeloneuropathy form of the disease (Moser, 2006).

Very-long-chain fatty acids are substrates for hepatic microsomal ω-oxidation. ω-Oxidation is catalyzed by cytochrome P450 enzymes. Two P450 enzymes, CYP4F2 and CYP4F3B participate in ω-oxidation of very-long-chain fatty acids, and the hydroxylated acids are further metabolized to dicarboxylic acids by cytochrome P450-mediated reactions (Sanders et al., 2006). Thus, an alternative or adjunct treatment for X-ALD may involve pharmacological stimulation of the microsomal ω-oxidation pathway as a means to reduce the accumulation of very-long-chain fatty acids.

iv. α-Methylacyl-CoA Racemase Deficiency

Two patients with adult-onset sensory motor neuropathy and one child diagnosed with Nieman–Pick type C were examined for biochemical abnormalities and found to have elevated plasma pristanic acid (Ferdinandusse et al., 2000). Pristanoyl-CoA, whether derived from dietary pristanic acid or

phytanic acid, occurs in two stereochemical configurations, 2R and 2S. The 2R configuration must be converted, by α-methylacyl-CoA racemase (AMACR), to the 2S configuration before it can be further metabolized in peroxisomes. None of these patients had detectable α-methylacyl-CoA racemase activity in cultured fibroblasts. Sequence analysis of *AMACR* cDNA from the patients identified two different mutations that are likely to cause the disease.

v. Rhizomelic Chondrodysplasia Punctata Types 2 and 3

Rhizomelic chondrodysplasia punctata types 2 (RCDP2) and 3 (RCDP3) are caused by mutations in genes coding for acyl-CoA:dihydroxyacetonephosphate acyltransferase and alkyl-dihydroxyacetonephosphate synthase, respectively (Ofman et al., 1998; de Vet et al., 1998). Patients with these disorders were identified as not belonging to the same complementation group as those with RCDP1. However, patients with RCDP2 and RCDP3 display severe clinical abnormalities similar to those seen with RCDP1 (de Vet et al., 1998).

B. Genetic Disorders of Mitochondrial Fatty Acid Oxidation

Efficient mitochondrial fatty acid oxidation is dependent on proper functioning of three general pathways, the carnitine cycle (including carnitine entry into cells), the β-oxidation spiral (including electron transfer to the respiratory chain), and the respiratory chain. Mutations in nuclear genes coding for transport proteins and enzymes of the carnitine cycle and β-oxidation have been identified that cause metabolic diseases of skeletal muscle and/or nerve (Table 48.2). Abnormalities in the respiratory chain are due to defects in either the nuclear or the mitochondrial genomes.

a. Disorders of the Carnitine Cycle

This group of disorders includes primary systemic carnitine deficiency, CACT deficiency, and CPT II deficiency. Liver CPT I deficiency also belongs to this group of disorders, but has no muscle or nerve involvement and will not be considered here. No defects in the gene coding for the muscle form of CPT I have been identified at this time.

TABLE 48.2
Genetic Diseases Associated with Mitochondrial Fatty Acid Metabolism in Skeletal Muscle and Nerve

Type	Deficient Protein or Enzymatic Activity
Transporters	Carnitine transporter (OCTN2)
	Carnitine-acylcarnitine translocase (CACT)
Enzymes of the mitochondrial inner membrane	Carnitine palmitoyltransferase II (CPT II)
	Very-long-chain acyl-CoA dehydrogenase (VLCAD)
	Mitochondrial trifunctional protein (MTP)
	Electron transfer flavoprotein (ETF)/ETF:coenzyme Q (CoQ) oxidoreductase
Enzymes of the mitochondrial matrix	Medium-chain acyl-CoA dehydrogenase (MCAD)
	Short-chain acyl-CoA dehydrogenase (SCAD)
	Short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD)
	Medium-chain 3-ketoacyl-CoA thiolase (MCKAT)

Source: Modified from Vockley, J., and Whiteman, D.A.H. (2002). *Neuromuscul. Disord. 12*:235–246; Gregersen, N., et al. (2004). *Eur. J. Biochem. 271*:470–482.

i. Primary Systemic Carnitine Deficiency

A sufficiently high concentration of intracellular carnitine is necessary for efficient entry of activated long-chain fatty acids into mitochondria. Primary systemic carnitine deficiency is a rare disorder resulting from molecular defects in the gene coding for the high-affinity carnitine transporter OCTN2. OCTN2 is the primary mediator of carnitine transport into most tissues, including skeletal muscle and nerve. Typically, carnitine concentrations are much higher in tissues such as skeletal muscle and heart than in the circulation, owing to the highly efficient concentrating power of OCTN2. Carnitine is synthesized in mammals at a rate that is considered adequate (e.g., it is not considered an essential nutrient) for normal metabolic function. Carnitine is synthesized primarily in liver and kidney, but is not synthesized in skeletal muscle and heart. Carnitine balance is maintained by dietary intake and endogenous synthesis and active renal reabsorption of carnitine, such that modest loss by renal excretion equals synthesis plus dietary accrual. Renal reabsorption of carnitine is mediated at the apical membrane by OCTN2. Typically 90%–98% of filtered carnitine is reabsorbed by normal humans. In the absence of OCTN2 carnitine is not effectively reabsorbed, leading to depletion of circulating carnitine. In addition, tissues dependent on OCTN2 for carnitine transport, including skeletal muscle and heart, fail to concentrate carnitine from the circulation. The combination of low circulating carnitine concentration (typically 5%–20% of normal) and the inability to concentrate carnitine in tissues leads to a severe impairment of long-chain fatty acid oxidation, particularly in skeletal muscle and heart.

Patients typically present early in life with hypoketotic hypoglycemia, hepatic encephalopathy, skeletal and cardiac myopathy (Longo et al., 2006), and more rarely with peripheral neuropathy (Makhseed et al., 2004). Treatment includes oral carnitine supplementation, low-fat diet, and avoidance of fasting.

ii. Carnitine-Acylcarnitine Translocase (CACT Deficiency)

CACT deficiency is a severe, life-threatening disease that manifests in early infancy with hypoketotic hypoglycemia, cardiomyopathy, liver failure, and muscle weakness (Iacobazzi et al., 2004a). Diagnostic features that distinguish CACT deficiency from other disorders of fatty acid oxidation include a normal ketone response after administration of medium-chain triglycerides (indicating that the disease is specific for long-chain fatty acids), relatively few fatty acid metabolites in urine during fasting (unlike in defects of the β-oxidation spiral), and an elevation of plasma long-chain acylcarnitine ester concentrations (consistent with a defect distal to CPT I) (Hsu et al., 2001). Relatively few of the reported cases have had a mild phenotype compatible with long-term survival; the majority of cases have had a severe phenotype with cardiomyopathy and death in early childhood. Treatment with carnitine supplementation and formula containing medium-chain triacylglycerols (with minimal long-chain triacylglycerols) has been effective in some cases (Iacobazzi et al., 2004b).

iii. Carnitine Palmitoyltransferase II (CPT II) Deficiency

CPT II deficiency occurs in three forms: neonatal, infantile, and adult. The neonatal and infantile forms are severe and mainly involve liver and heart but without skeletal muscle involvement. The adult form is primarily associated with skeletal muscle symptoms, including recurrent attacks of myalgias and muscle stiffness and weakness, and often associated with myoglobinuria (Bonnefont et al., 1999). Attacks last from several hours to several weeks. Rhabdomyolysis may be severe enough to precipitate renal failure or respiratory insufficiency. There is no liver or heart involvement in the adult form of CPT II deficiency. Symptoms usually appear after prolonged exercise, fasting, or other metabolic stress. Age of onset is usually 6–20 years. Remarkable clinical signs or markers of the disease (elevated serum creatine kinase and transaminase) only appear during episodic attacks. Effective prevention of attacks may be accomplished with a high-carbohydrate, low-fat diet with frequent and regularly-scheduled meals, and by avoiding metabolic stress associated with, for example, cold exposure or prolonged exercise (Di Donato and Taroni, 2004).

b. Disorders of the β-Oxidation Spiral and Electron Transfer to the Respiratory Chain

Generally, mitochondrial fatty acid oxidation disorders have several common clinical features, including metabolic decompensation during fasting, hypoketotic hypoglycemia, and acute or chronic dysfunction of one or more fatty acid-dependent tissues, and in particular, skeletal muscle, heart and liver (Kamijo et al., 1997). Disorders with skeletal muscle and/or nervous system involvement are summarized below.

i. Very-Long-Chain Acyl-CoA (VLCAD) Deficiency

Three phenotypes of VLCAD deficiency have been described: (1) a severe form presenting in infancy or early childhood with high incidence of cardiomyopathy, hypoglycemia, and mortality; (2) a milder childhood form characterized by hypoketotic hypoglycemia and low mortality; and (3) a milder adult form with isolated skeletal muscle involvement, rhabdomyolysis, and myoglobinuria usually triggered by exercise or fasting (Andresen et al., 1999; Bartlett and Pourfarzam, 2002; Gregersen et al., 2004). In the milder childhood and adult forms, some residual enzyme activity is present and in the adult form this activity is sufficient to maintain normal oxidation of fatty acids at rest, but cannot increase the rate of fat oxidation above basal levels during exercise (Ørngreen et al., 2004). Evidence of a clear correlation of genotype with disease phenotype has been demonstrated (Andresen et al., 1999). Management strategies for VLCAD deficiency are similar to those for CPT II deficiency, and include avoidance of fasting, dietary cornstarch and/or medium-chain triacylglycerol and carnitine supplementation (Nyhan and Ozand, 1998).

ii. Mitochondrial Trifunctional Protein (MTP) Deficiencies

The MTP is a hetero-octamer consisting of four α subunits and four β subunits. These subunits are coded by two contiguous, coordinately expressed genes (*HADHA* and *HADHB*) on chromosome 2p23 (Bartlett and Pourfarzam, 2002). Long-chain L-3-hydroxyacyl-CoA dehydrogenase (LCHAD) activity resides on the C-terminal end of the α subunits. A common mutation in the gene coding for the α subunit, resulting in substitution of glutamine for glutamic acid at position 474 of the protein, is responsible for deficiency of this enzymatic activity, with no effect on the other two MTP activities. In some patients, LCHAD deficiency was associated with impaired respiratory chain activity, thought to be due to inhibition particularly of respiratory chain complex I enzymes by fatty acid oxidation intermediates that accumulate due to the primary LCHAD deficiency (Tyni and Pihko, 1999). The *HADHB* gene encodes long-chain 3-ketoacyl-CoA thiolase (LCKAT). Two patients have been reported with isolated LCKAT deficiency (Das et al., 2006). Molecular analysis revealed compound heterozygosity for 185G→A (R62H) and 1292T→C (F431S) mutations in the *HADHB* gene in these patients. Loss or deficiency of all three enzyme activities are due to mutations in either the α or β subunits, resulting in MTP complex instability (Spiekerkoetter et al., 2004b). Clinically, the combined deficiency is similar to but more severe than the isolated LCHAD deficiency. Like CPT II deficiency and VLCAD deficiency, clinical presentation is heterogeneous. Patients identified in the neonatal period present with hypoglycemia, whereas the adolescent or adult variant of the disease is characterized predominantly by myopathy. Patients presenting during adolescence or adulthood generally have some residual enzyme activity. A small number of patients with adult-onset, relatively benign disease, present with recurrent exercise-induced rhabdomyolysis similar to that seen in adult form of CPT II deficiency (Schaefer et al., 1996). An additional feature of both isolated LCHAD deficiency and the combined deficiency is peripheral neuropathy (Schaefer et al., 1996; Tyni and Pihko, 1999; Di Donato and Taroni, 2004; Spiekerkoetter et al., 2004a).

Treatment of MTP deficiency includes avoidance of fasting and a high-carbohydrate diet with medium-chain triacylglycerols replacing all but essential long-chain triacylglycerols (Bartlett and Pourfarzam, 2002; Angdisen et al., 2005).

iii. Medium-Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency

MCAD deficiency was the first acyl-CoA dehydrogenase deficiency to be discovered (in 1983) and is the most common of the fatty acid oxidation disorders. The phenotypic expression of this disease includes intermittent hypoketotic hypoglycemia, myopathy, cardiomyopathy, sudden infant death syndrome, and hyperammonemia. (Nyhan and Ozand, 1998; Vockley and Whiteman, 2002). Muscle weakness and lipid accumulation in muscle, C6 to C10 dicarboxylic aciduria during recurrent hypoglycemic attacks, and mild carnitine deficiency have been observed. Attacks generally occur in response to fasting or infections associated with reduced food intake and increased energy requirements (Rinaldo et al., 2002). The disease is often recognized within the first two years of life, although some affected individuals may remain asymptomatic into adulthood. The most common genetic alteration responsible for MCAD deficiency is the 985A→G mutation of the MCAD gene (*ACADM*), which changes a highly conserved lysine at position 304 into a glutamate, impairing assembly of the tetrameric mature protein and decreasing its stability (Yokota et al., 1992). Eighty percent of patients are homozygous for this mutation, 18% are compound heterozygous with this mutation on one allele and a rare disease-associated sequence variation on the other allele, and only about 2% carry other sequence variations on both alleles (Gregersen et al., 2004). The outcome for these patients is very good once the correct diagnosis is made. Treatment regimens include foremost avoidance of fasting. Carnitine supplementation may be beneficial.

iv. Medium-Chain 3-Ketoacyl-CoA Thiolase (MCKAT) Deficiency

MCKAT catalyzes cleavage of medium- to short-chain 3-ketoacyl-CoA esters with release of acetyl-CoA in the mitochondrial matrix. To date only one case, a neonate who died shortly after presentation at 2 days of age, has been reported (Kamijo et al., 1997). Clinical features of this infant included vomiting, dehydration, metabolic acidosis, liver dysfunction, and terminal rhabdomyolysis with myoglobinuria. Laboratory analyses revealed ketotic lactic acidosis and C_6 to C_{12} dicarboxylic aciduria, and reduced MCKAT protein concentration in fibroblasts (to 60% of normal), as determined by immunoprecipitation.

v. Short-Chain Acyl-CoA Dehydrogenase (SCAD) Deficiency

SCAD catalyzes the first step in mitochondrial β-oxidation of activated fatty acids four to six carbons in length. Patients present with a wide range of clinical symptoms, including hypoglycemia, metabolic acidosis, vomiting, drowsiness, myopathy, hypotonia, and seizures (Pedersen et al., 2003; Seidel et al., 2003). Axonal neuropathy was reported in two unusual cases (Kurian et al., 2004). Some individuals bearing the genetic alterations associated with SCAD deficiency remain asymptomatic (Bok et al., 2003). Ethylmalonic aciduria is a common finding in this disease, but is nonspecific (Seidel et al., 2003).

Molecular genetic analysis has uncovered several rare pathogenic mutations that result in undetectable enzymatic activity in homozygous patients (Corydon et al., 2001; Seidel et al., 2003). In addition, two common susceptibility gene variations [625G→A (G185S) and 511C→T (R147W)] are associated with varying degrees of decreased enzyme activity when present as double heterozygotes (a pathogenic mutation in one allele and susceptibility gene variation in the other allele) or with one susceptibility gene variation in each allele (Corydon et al., 2001). Molecular biochemical analysis of mutant proteins has led to the conclusion that some variants of SCAD (R22W, G68C, W153R, and R359C) were susceptible to severe misfolding, whereas others (R147W, G185S, and Q341H) were only mild folding variants (Pedersen et al., 2003). These mutant proteins were susceptible to proteolytic degradation by mitochondrial proteases, and formed aggregates of nonnative conformers.

vi. Short-Chain L-3-Hydroxyacyl-CoA Dehydrogenase (SCHAD) Deficiency

SCHAD deficiency is a rare disorder with highly variable presentation. Of the few cases reported, diagnosis was made in infancy, early childhood, or adolescence. Those identified early in life presented with typical liver-associated abnormalities including fasting-induced vomiting, ketosis, and hypoglycemia (Bartlett and Pourfazam, 2002). Hyperinsulinism was noted in one infant (Clayton et al., 2001). One adolescent presented with recurrent myoglobinuria, hypoketotic hypoglycemic encephalopathy, and hypertrophic cardiomyopathy (Tein et al., 1991). In this case, skeletal muscle SCHAD activity was approximately 35% of normal, with normal activity in cultured fibroblasts. Mutation analysis in the infant with hyperinsulinism revealed a homozygous mutation (773C→T) resulting in a P258L enzyme with no catalytic activity (Clayton et al., 2001). Mutation analysis was not done or was inconclusive in the other reported cases (Rinaldo et al., 2002).

vii. Electron Transfer Flavoprotein (ETF)/ETF:Coenzyme Q (ETF:CoQ) Oxidoreductase Deficiencies

Molecular defects in either the α or β subunits of ETF or in ETF:CoQ oxidoreductase are responsible for the group of diseases commonly referred to as glutaric aciduria type 2 or multiple acyl-CoA dehydrogenase deficiency. At least, nine mitochondrial acyl-CoA dehydrogenases transfer electrons to the respiratory chain via ETF and ETF:CoQ oxidoreductase. Three different clinical phenotypes have been described (Schiff et al., 2006). Two present in the neonatal period and are most severe. Congenital abnormalities, dysmorphic features reminiscent of peroxisomal disorders, and acute metabolic decompensation are characteristics of the first type. Patients of the second type lack congenital anomalies and may survive beyond infancy. The third type, also referred to as ethylmalonic-adipic aciduria, includes patients with a milder form of the disease, in which residual enzyme activity is present. These patients have muscle weakness and may not be diagnosed until early adulthood. They are characterized by recurrent, potentially life-threatening episodes of vomiting, hypoglycemia, hepatomegaly, and myopathy (Rinaldo et al., 2002). A relationship between genotype and clinical phenotype has been demonstrated (Olsen et al., 2003). Treatment of these disorders includes restriction of dietary fat and protein, and supplementation with glycine and carnitine.

A variant of glutaric aciduria type 2 is a true multiple acyl-CoA dehydrogenase deficiency that is responsive to riboflavin supplementation. The vitamin riboflavin is a precursor for the electron acceptors/donors FAD and flavin mononucleotide (FMN). FAD is a tightly-bound cofactor for the mitochondrial acyl-CoA dehydrogenases, ETF, and ETF:CoQ oxidoreductase. This disorder, called riboflavin-responsive multiple acyl-CoA dehydrogenase deficiency, apparently is due to malabsorption of riboflavin, a defect in synthesis of FAD from riboflavin, or a defect in import of FAD into mitochondria. It is thought that deficient mitochondrial FAD causes an accelerated breakdown of flavin-dependent proteins. The two major phenotypes are the infantile form with nonketotic hypoglycemia, hypotonia, failure to thrive, and acute metabolic episodes similar to Reye syndrome, and a juvenile form that includes progressive proximal myopathy with lipid storage in muscle fibers (Di Donato and Taroni, 2004). This disease is not associated with defects in genes coding for the acyl-CoA dehydrogenases, ETF or ETF:CoQ oxidoreductase. The genetic and molecular etiology is unknown, but perhaps is due to poor absorption of riboflavin, impaired delivery to tissues, or a defect in the synthesis of FAD. Oral supplementation with riboflavin dramatically reverses the course of this disease and normalizes activities of the flavin-dependent mitochondrial enzymes (Russell et al., 2003).

C. Chanarin–Dorfman Disease

Chanarin-Dorfman disease, also known as multisystem triglyceride storage disease or neutral-lipid-storage disease with ichthyosis, is a rare genetic disease characterized by ichthyosis, neutral lipid storage (as triacylglycerol droplets) in many tissues and cells, including skeletal muscle, and

a variety of neurologic manifestations, including psychomotor delay in childhood, nystagmus, ataxia, neurosensory hearing loss, microcephaly, and myopathy (Di Donato and Taroni, 2004). The disease has been found mostly in Middle Eastern, Mediterranean populations.

Mutations specific for this disease have been localized to the gene *CGI-58* (comparative-gene-identification-58) (Lefèvre et al., 2001). The protein product of this gene, CGI-58, interacts with proteins on the surface of lipid droplets that are associated with esterification and hydrolysis of fatty acids in lipid droplets, including perilipin and ADRP (Yamaguchi et al., 2004). CGI-58 recently was shown to be required for activation of adipose triglyceride lipase (ATGL) (Lass et al., 2006), itself a recently identified enzyme important for mobilization of triglycerides in adipose tissue (Zimmermann et al., 2004). ATGL is highly expressed in adipose tissue, but only weakly expressed in skeletal muscle (Zimmermann et al., 2004). Thus, it remains speculative whether lack of CGI-58-mediated activation of ATGL in skeletal muscle is responsible specifically for lipid droplet accumulation in this tissue.

D. Barth Syndrome

Characteristics of Barth syndrome include mitochondrial myopathy, dilated cardiomyopathy, cyclic neutropenia, and short stature (DiMauro and Bonilla, 2004). The disease can be fatal in infants and children due to cardiac failure or sepsis (van Werkhoven et al., 2006). Barth syndrome is caused by abnormalities in cardiolipins, acidic phospholipids highly enriched in the mitochondrial inner membrane. Cardiolipins are essential for the proper assembly and function of the respiratory chain. Cardiolipins contain four fatty acids, two each in two phosphatidylglycerol moieties. Cardiolipin biosynthesis occurs via the cytidine diphosphate-diacylglycerol pathway. Newly formed cardiolipins undergo extensive remodeling by deacylation and reacylation to produce mature forms with three or four linoleic acid moieties (Schlame et al., 2000). Tetralinoleoyl-cardiolipin (Figure 48.4) is specifically enriched in skeletal muscle and heart (Schlame et al., 2002). Synthesis of cardiolipins in fibroblasts from patients with Barth syndrome was observed to be normal, but the cardiolipin content of these cells was reduced (Vreken et al., 2000). Moreover, incorporation of linoleic acid into cardiolipins was abnormally low. A subsequent study found tetralinoleoyl-cardiolipin was very

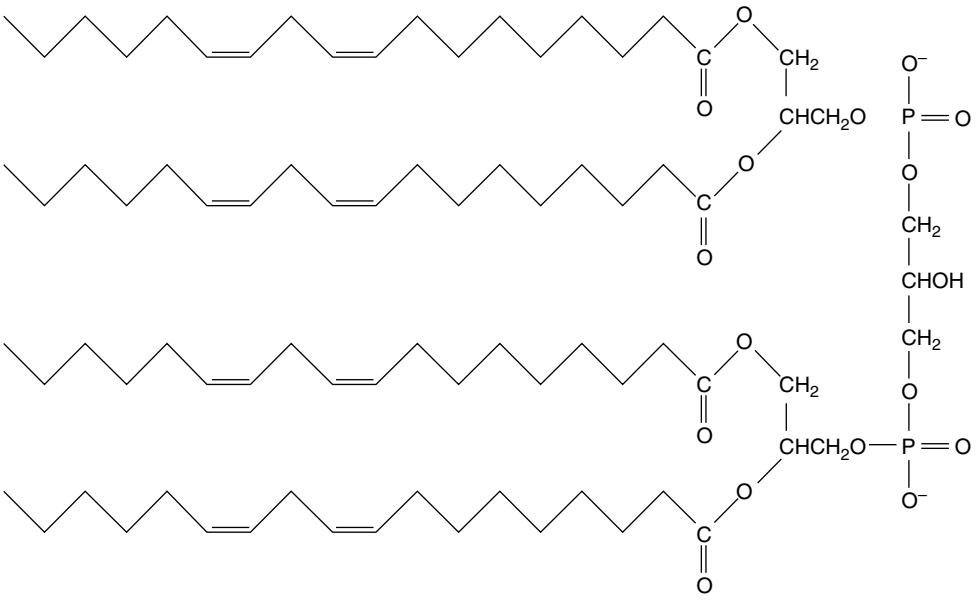

FIGURE 48.4 Structure of tetralinoleoyl-cardiolipin.

low or absent in skeletal muscle, heart, and platelets of children with Barth syndrome (Schlame et al., 2002).

The gene responsible for Barth syndrome (*TAZ*) encodes the protein tafazzin (Claypool et al., 2006). Tafazzin is thought to be involved in remodeling of cardiolipins, specifically adding linoleic acid to lysocardiolipins to produce mature and functional tetralinoleoyl-cardiolipin (Chicco and Sparagna, 2006). Lysocardiolipin has been found to be increased in cultured fibroblasts from Barth syndrome patients (van Werkhoven et al., 2006). Incubation of Barth syndrome fibroblasts with linoleic acid led to a time- and dose-dependent increase in cardiolipin concentration (Valianpour et al., 2003). Whether or not dietary treatment with linoleic acid will be useful in patients with Barth syndrome remains to be determined.

E. Diabetes and Obesity

a. Diabetic Neuropathy

One of the major complications of diabetes mellitus is peripheral neuropathy, which occurs to some degree in up to 60% of diabetic patients (Pirart, 1978; Thomas and Tomlinson, 1993). Main pathologic features of diabetic polyneuropathy include loss of myelinated and unmyelinated fibers; clusters of regenerating fibers; thickening of endoneurial blood vessels; and increased durability and rigidity of Schwann cell basal laminae (Llewelyn et al., 2005). Hyperglycemia is probably the most important initiator of the process that leads to neuropathy. Hyperglycemia causes secondary biochemical changes in the polyol pathway, nonenzymatic glycation of macromolecules, and oxidative stress. Tricyclic antidepressants are the most commonly prescribed symptomatic treatments for diabetic neuropathy, but these have little if any impact on the progression of the disease. Experimental treatments to address progression have included aldose reductase inhibitors (ARI) (to inhibit accumulation of polyols; Greene et al., 1999; Misawa et al., 2006), various botanicals and dietary supplements, including evening primrose oil, capsaicin, acetyl-L-carnitine and α-lipoic acid (Halat and Dennehy, 2003), and neurotrophic peptides (Tam et al., 2006).

Beneficial effects of dietary treatment with γ-linolenic acid (GLA) in both streptozotocin-induced diabetes and patients with distal diabetic polyneuropathy have rekindled interest in the role of essential fatty acids in the prevention and treatment of diabetic neuropathy. A defect in the pathway for synthesis of PUFA (Figure 48.5) in experimental diabetes was first recognized by Peifer and Holman in 1955. They found that diabetic animals required much higher amounts of linoleic acid to compensate their deficiency of essential fatty acids than those of normal controls. Later, an altered fatty acid profile showing increased linoleic acid and DHA as well as decreased AA was also found in central and peripheral nervous systems of diabetic animals (Holman et al., 1983; Lin et al., 1985). In human diabetes, Horrobin (1988, 1992) further demonstrated that levels of dihomo-γ-linolenic acid (DGLA) and AA were substantially reduced in patients with type 1 diabetes. These findings were confirmed in a large-scale study comprised of 319 normal controls, 224 type 1 and 364 type 2 diabetic patients (Horrobin, 1997a). As expected, the ratio of linoleic acid to DGLA + AA was elevated in plasma and RBC lipids of type 1 patients, but to a lesser degree in those of type 2 patients. Moreover, there was a marked reduction of PUFA (both n-6 and n-3 types) in RBC membranes of all patients.

Characteristic fatty acids of peripheral nerve myelin are mainly saturated and monounsaturated (Yao, 1984). A marked increase of PUFA, particularly AA, was found in endoneurial phosphatidylethanolamine of both developing and regenerating rat sciatic nerve (Yao, 1982). Furthermore, the cyclooxygenase derivatives of PUFAs have been shown to be required for normal nerve conduction (Horrobin et al., 1977). Inhibition of prostaglandin biosynthesis can slow nerve conduction and decrease action potential amplitudes. These observations suggest an important role of PUFA in peripheral nerve metabolism and function. There is ample evidence demonstrating that PUFA metabolism is altered in diabetes, possibly due to a deficiency of 6-desaturase (Figure 48.5) and partial loss of 5-desaturase (Eck et al., 1979; Poisson, 1985; Horrobin, 1988; Dang et al., 1989).

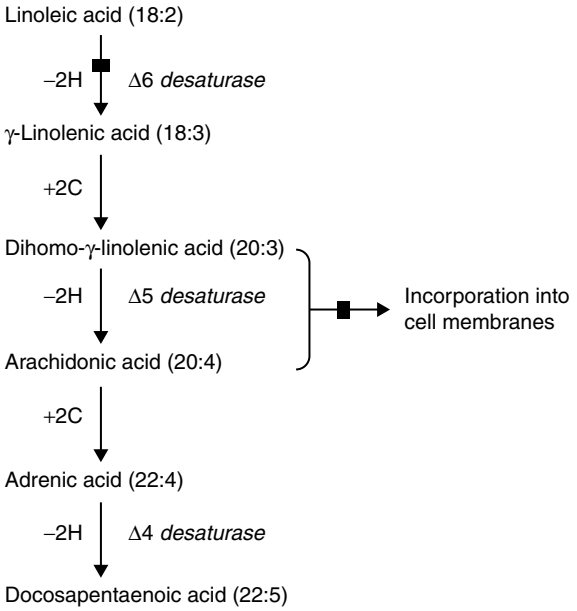

FIGURE 48.5 Proposed metabolic blocks in the elongation pathway of n-6 family of essential fatty acids in patients with diabetic neuropathy.

The accumulation of polyols in the lens is postulated to increase osmotic pressure and overhydration, leading to lens fiber disruption and to the formation of cataracts (van Heyningen, 1962; Chylack and Kinoshita, 1969). Interestingly, high-fat diets (rich in maize oil) can inhibit or delay the development of cataracts in streptozotocin-induced diabetic rats (Patterson, 1955; Patterson et al., 1965; Hutton et al., 1976). Sorbitol levels in the lenses of treated diabetic rats, however, were still substantially higher than those of normal rats, which raise doubt that sorbitol is the only cause of diabetic cataracts.

To correct the abnormal linoleic acid desaturation pathway, evening primrose oil enriched with GLA has been used to treat diabetic animals. GLA supplementation may prevent as well as normalize the impaired nerve functions (i.e., nerve blood flow, nerve conduction, and microcirculation) in streptozotocin-induced diabetic rats (Julu, 1989; Tomlinson et al., 1989; Cameron and Cotter, 1993; Stevens et al., 1993; Omawari et al., 1996). The efficacy of GLA treatment, however, depends on the source of natural oils. Evening primrose oil appears to be the choice of treatment as compared to blackcurrant, borage, and fungal oils (Dines et al., 1996). Alternatively, diabetic rats treated with AA-enriched oil also showed improvements of nerve conduction and perfusion deficits (Cotter and Cameron, 1997).

Jamal and Carmichael (1990) conducted a 6-month randomized, double-blind, parallel, placebo-controlled study with evening primrose oil in humans. When patients with distal diabetic polyneuropathy were treated with 8×500 mg twice daily (providing a daily dose of 360 mg of GLA), their clinical, neurophysiological, and thermal threshold parameters were significantly improved as compared to those treated with a placebo. A similar dietary treatment with GLA supplementation was subsequently conducted in two multicenter trials. The first trial involving 111 patients in seven centers demonstrated more favorable responses to GLA diet than that with a placebo (Keen et al., 1993). The second trial involving 293 patients in ten centers (Horrobin, 1997b) confirmed the findings of the first trial. To date, no serious adverse effects have been reported, suggesting a high degree of safety of GLA treatment. Collectively, these findings support a beneficial effect of GLA supplementation in the management of diabetic neuropathy (Horrobin, 1997a,b), but the body of evidence remains inconclusive (Halat and Dennehy, 2003).

There are multiple defects involving metabolic functions associated with diabetic neuropathy. As a result of increased flux in polyol pathway, ARIs have been applied effectively to restore nerve blood flow and conduction velocity in experimental diabetes (Cameron et al., 1994, 1996). Cameron and Cotter (1997) demonstrated that the combined ARI and evening primrose oil treatment produced a tenfold amplification of nerve conduction velocity and blood flow responses. In human trials, however, clinical improvements with ARIs have been less successful. Aldose reductase pathway inhibition in diabetic patients with moderate glycemic control resulted in small improvements in nerve conduction velocity but did not improve clinical symptoms (Greene et al., 1999; Misawa et al., 2006). Combined therapy in humans with evening primrose oil and ARIs, and/or longer-term therapy with high-dose, potent ARIs such as zenarestat may provide better outcomes.

b. Fatty Acids and Insulin Resistance in Skeletal Muscle

Insulin resistance in skeletal muscle is a major feature of obesity and type 2 diabetes mellitus. Accumulation of intracellular triacylglycerol and a low capacity to oxidize fatty acids are correlated with the presence of insulin resistance in skeletal muscle. Elevated intramuscular triacylglycerol stores may be only a marker of abnormal fatty acid metabolism. Accumulation of more reactive lipids derived from fatty acids, including long-chain acyl-CoA, diacylglycerol, and/or ceramides, may actually be responsible for impaired insulin signaling (Dyck et al., 2006).

Kelley (2005) has described an elegant model of metabolic flexibility of skeletal muscle with regard to utilization of glucose and fatty acids. During fasting, the lean, aerobically fit (metabolically flexible) individual displays a robust preference for fat oxidation in muscle with suppressed glucose oxidation, whereas in the obese, aerobically unfit (metabolically inflexible) individual, glucose oxidation is less suppressed and the preference for fat oxidation is blunted. During insulin-stimulated conditions, the metabolically flexible individual will suppress fat oxidation and utilize glucose for energy, whereas the metabolically inflexible individual is less able to stimulate glucose oxidation and thus does not substantially suppress fatty acid oxidation. Thus, the "metabolically flexible" individual has considerably more latitude to utilize glucose when it is abundant, and spare glucose when it is not. In type 2 diabetes and obesity, skeletal muscle manifests inflexibility in the transition between lipid and carbohydrate fuels (Kelley et al., 2002).

Insulin sensitivity and metabolic flexibility may result from neuroendocrine and environmental factors, or could be due to genetic, epigenetic or other mechanisms intrinsic to muscle cells. Ukropcova et al. (2005) have demonstrated that insulin sensitivity and metabolic inflexibility are at least in part programmed within muscle cells, and are retained when those cells are removed from their *in vivo* neuroendocrine environment. Skeletal muscle insulin resistance in type 2 diabetes and obesity is caused at least in part by accumulation of intracellular triacylglycerols and long-chain acyl-CoA esters. These accumulations result from an increased rate (approximately threefold) of intracellular fatty acid esterification, normal or reduced rate of fatty acid oxidation, and an increased rate (approximately fourfold) of fatty acid transport into muscle cells (Bonen et al., 2004). The increased rate of fatty acid transport is associated with an increase in sarcolemmal FAT/CD36 that resulted from increased translocation of sub-sarcolemmal protein to the membrane, and not increased expression of the FAT/CD36 gene. One alteration that may contribute to insulin resistance in skeletal muscle of obese individuals and patients with type 2 diabetes is a concurrent increase in translocation of FAT/CD36 and decrease of translocation of the glucose transporter GLUT4 to the sarcolemma.

FAT/CD36 also is present in the mitochondrial membranes and has a role in activated long-chain fatty acid translocation into mitochondria. Exercise training and diet intervention, but not diet intervention alone, increased the amount of FAT/CD36 that coprecipitated with CPT I from mitochondria of obese women, and this increase was strongly correlated with an increase in whole-body fatty acid oxidation (Schenk and Horowitz, 2006). Thus, it is conceivable that skeletal muscle insulin resistance is at least in part due to misdirection of FAT/CD36 to the sarcolemma and away from mitochondria, and that aerobic exercise could lead toward normalization of FAT/CD36 distribution,

with concomitant increase in fatty acid oxidation and decrease in triacylglycerol and acyl-CoA accumulation.

CACT activity may be a mitigating factor in insulin resistance in susceptible individuals. In obese, insulin-resistant humans, mitochondrial carnitine-carnitine and carnitine-acylcarnitine exchange rates were shown to be significantly lower than in mitochondria from normal subjects (Peluso et al., 2002). CACT mRNA levels were reduced by about 75% in affected subjects compared to controls, and the exchange rate was reduced by 50%–75%. Thus, CACT expression and activity, in addition to FAT/CD36 activity, may contribute to cytosolic accumulation of long-chain fatty acids, acyl-CoA esters, and triacylglycerols in insulin-resistant individuals. Insulin resistance in obese individuals and patients with type 2 diabetes may be at least partially overcome by administration of carnitine or acetyl-L-carnitine (Mingrone, 2004). Administration of either of these compounds increases nonoxidative glucose disposal in normal and affected humans. Carnitine and acetyl-L-carnitine may regulate trafficking of fatty acids to correctly meet energy demand, and/or may regulate synthesis of transporters, including CACT, and key enzymes involved in glycolytic and gluconeogenic pathways.

F. Nutritional Deficiencies

a. Protein-Energy Malnutrition

A reversible neuromuscular syndrome has been described in malnourished children (Dastur et al., 1979; Donley and Evans, 1989). Hypotonia, weakness, and absent stretch reflexes, and electromyographic abnormalities were observed. Histologic examination revealed decreased muscle fiber diameter, group atrophy suggestive of denervation, and variation in fiber size and rounding, suggestive of myopathic change (Dastur et al., 1979). Clear differences in this syndrome and specific vitamin deficiencies (e.g., thiamine and vitamin D deficiency) were found (Donley and Evans, 1989). Improvement in strength and reflexes was observed after adequate nutrition was restored.

b. Anorexia Nervosa

Anorexia nervosa is a psychological disorder characterized by an obsession for weight loss. Patients develop bradycardia, hypotension, hypothermia, a depressed metabolic rate, and effort intolerance (Essen et al., 1981). It is most common in adolescent and young adult females. During the early stages of anorexia nervosa, avoidance of carbohydrate and lipid leads to negative energy balance and depletion of body stores of lipids. Eventually, undernutrition becomes severe and leads to protein-energy malnutrition. Muscle mass in addition to fat stores becomes reduced. Patients with anorexia nervosa may develop a reversible metabolic myopathy with type 2 muscle fiber atrophy (McLoughlin et al., 1998). Individuals with severe weight loss (40%) develop proximal muscle weakness and a diminished lactate response to ischemic exercise (McLoughlin et al., 1998).

c. Myopathy, Wasting Syndrome, and Lipodystrophy Associated with HIV Infection

Wasting syndrome is a significant cause of morbidity and mortality in patients with type 1 human immunodeficiency virus (HIV) infection, and is considered an AIDS-defining illness (Miró et al., 1997). Clinical findings include extreme fatigue and marked amyotrophy involving proximal and distal segments of the limbs (Bélec et al., 1992). Malnourishment is an early feature of HIV infection. Wasting syndrome seems to be closely related to the reduced nutritional status. In addition to anorexia and malabsorption (Sharkey et al., 1992), intermediary metabolism is deranged. Oxidation of carbohydrates is suppressed and sensitivity to insulin increased, plasma triacylglycerols are increased, and the turnover of protein may be increased, the net result of which is a redirection of absorbed substrates into lipid rather than lean tissue (Macallan et al., 1995). Inflammatory myopathy

often accompanies the wasting syndrome. HIV-related muscle wasting is a cachectic process that affects type 2 muscle fibers, and is separate from HIV myositis and myopathy associated with AZT (zidovudine) therapy (Dalakas, 2004).

Lipodystrophy syndrome encompasses both fat accumulation and wasting. Changes include abdominal fat accumulation with fat wasting of the face, buttocks, and extremities. Both fat accumulation and loss may be present in the same individual, or occur independently. Thus, these possibly are distinct pathological processes, rather than components of a whole-body maldistribution syndrome (Day et al., 2004). Both appear linked to antiretroviral therapy and are seen in association with metabolic abnormalities in glucose and lipid metabolism.

IV. SUMMARY

Defects in metabolic pathways of fatty acid utilization or disposal can lead to many profound functional disturbances of nerve and muscle tissues. In addition to those diseases mentioned in the text, there are many other neurological disorders (e.g., hereditary motor and sensory neuropathies, Friedreich's ataxia, multiple sclerosis, epilepsy) showing fatty acid and phospholipid abnormalities. These changes are probably secondary to primary defects and the attendant secondary pathology, including oxidative stress, inflammation, and tissue degeneration/regeneration. On the other hand, proper dietary treatment with specific or restricted fatty acid(s) can be beneficial to some patients with a primary fatty acid disorder (e.g., Refsum's disease). Dietary therapy, however, mainly prevents or arrests the progress of the disease, and does not necessarily correct or replace the enzyme defect or fully restore the neurological and/or muscular functions.

49 Fatty Acids and Psychiatric Disorders

Sarah M. Conklin, Ravinder D. Reddy, Matthew F. Muldoon, and Jeffrey K. Yao

CONTENTS

I. INTRODUCTION

Research suggests that fundamental aspects of brain function depend on the adequate consumption and thus membrane levels of polyunsaturated fatty acids (PUFAs), particularly, eicosapentaenoic acid [EPA, 20:5(n-3)], docosahexaenoic acid [DHA, 22:6(n-3)] and also arachidonic acid [AA, 20:4(n-6)]. It has been shown that by increasing the incorporation of these fatty acids into membrane phospholipids several basic properties of the membrane are improved. PUFAs are integral

components of cell membrane lipids, primarily phospholipids such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylinositol comprising 80% of total membrane phospholipids. The central nervous system is highly enriched in PUFAs, primarily AA and DHA (Salem et al., 2001). In addition to helping maintain normal membrane structure and function, PUFAs also are critical in all aspects of normal brain development and neurotransmission (Das, 2003; Casper, 2004).

Since the dynamic state of the neuronal membranes is dependent on its composition, small changes in particular PUFAs that make up phospholipids, can lead to altered receptor binding, neuro-transmission, signal transduction, and prostaglandin synthesis (Clandinin et al., 1992; Hulbert et al., 2005). Given the fact that AA and EPA function as a second messengers, deficits in membrane PUFAs may underlie many biological, physiological, and clinical phenomenon observed in psychiatric disorders. In humans, relative membrane deficiency of dietary n-3 and n-6 PUFAs has been implicated in schizophrenia (Yao, 2003; Mahadik and Yao, 2006) and in major depressive disorder (Hibbeln and Salem, 1995; Freeman, 2000; Logan, 2003; Peet and Stokes, 2005). PUFA deficiencies have also been linked to aggressive behavior and disorders of impulse control (Hallahan and Garland, 2004) and impaired cognitive function. In this chapter, our goal is to review literature linking PUFA deficits to psychiatric disorders, with particular emphasis on schizophrenia and depression as clinical research is most developed for these diagnoses. However, as research extends the relevance of PUFAs to other areas in psychiatry, we will conclude by discussing how these fatty acids are implicated in other syndromes and symptoms with psychiatric relevance.

II. SCHIZOPHRENIA

Numerous theories have been proposed aiming to conceptualize the pathophysiology of schizophrenia, focusing on neuronal maldevelopment, impaired neurotransmission, viral infections, and autoimmune dysfunction, among others. A point of convergence for these proposed mechanisms occurs at the level of the neuronal membrane, which is the structural and functional site of neurotransmitter receptors, ion channels, signal transduction, and most drug effects. The membrane also is a point where there is a natural intersection between genetic and environmental factors (Horrobin et al., 1995). Two lines of evidence demonstrate the presence of membrane fatty acid defects in schizophrenia: (1) levels of phospholipid and fatty acids in red blood cell (RBC) membranes, platelets, and postmortem brain tissue; and (2) functional measures of cerebral phosphorus metabolism.

A. Membrane Lipid Defects

a. Erythrocytes and Platelets

i. Phospholipids

Stevens (1972) first reported that, compared to that of healthy controls, the RBC membranes of schizophrenic patients is characterized by a relative excess of PS and a relative deficiency of PC and PE. These results were later replicated by Henn and Henn (1982) as well as by Tolbert et al. (1983). On the other hand, Hitzemann and Garver (1982), and Hitzemann et al. (1984) found that the deficiency in RBC-PC that was compensated by an increase of sphingomyelin (SM) or ethanolamine plasmalogens, not PS. In contrast, Sengupta et al. (1981) showed that the percentages of both PC and PS were relatively increased in RBC and platelets from schizophrenic patients. Finally, Cordasco et al. (1982), and Lautin et al. (1982), failed to show any significant changes of PC, PE, and SM.

Results of the above studies are difficult to interpret due to differences in lipid methodology, in diagnostic criteria, and current or prior treatment. Since PUFA's are major constituents of membrane phospholipids, the discrepancies of RBC membrane phospholipid abnormalities obtained from patients with schizophrenia in different studies may be explained in part by the finding (Glen et al., 1994) of a bimodal distribution of RBC PUFAs in patients, in contrast to the unimodal distribution seen in normal controls. Since treatment can affect neurochemistry it is notable that

phospholipid abnormalities have been found in medication-free schizophrenic patients (Keshavan et al., 1993a), and decreases in all four key membrane phospholipids were found in fibroblasts from neuroleptic-naive patients with schizophrenia (Mahadik et al., 1994). These latter findings suggest that phospholipid and fatty acid abnormalities may be disease related. At the very least, they are present early in the course of illness, prior to initiation of treatment. Other factors likely contribute to these discrepancies, one being that fatty acids from schizophrenic patients appear to be hydrolyzed more rapidly during freezer storage at –20°C than those of nonpatient controls. Fox et al. (2003) reported that the decay rates of schizophrenic patients' RBC PUFAs were nearly twice that of nonpatient control participants when stored at –20°C. The authors proposed that elevated phospholipase A_2 (PLA_2) activity in the patients was likely responsible for the increased degradation. Consequently, additional *in vivo* measurements of fatty acids with magnetic resonance spectroscopy may be useful to avoid the problems associated with freezer storage (Glen and Glen, 2004).

ii. Fatty Acid Composition

Fatty acid abnormalities have been found in the plasma and RBC membranes of psychotic patients. Horrobin et al. (1989) reported a significant decrease of both LA [18:2(n-6)] and AA [20:4(n-6)], and an increase of total n-3 fatty acids in the plasma of three schizophrenic patient groups from England, Scotland and Ireland (Table 49.1). Similarly a decrease of 18:2(n-6), but not of 20:4(n-6) was found in plasma of schizophrenic patients from Japan (Kaiya et al., 1991). In RBC membranes, both 20:4(n-6) and 22:6(n-3) were also significantly reduced in schizophrenic patients (Vaddadi et al., 1989; Glen et al., 1994; Peet et al., 1995). In cultured skin fibroblasts, only 22:6(n-3) and the total n-3 PUFAs were found significantly lower in schizophrenic patients than in normal subjects and bipolar patients (Mahadik et al., 1996).

The above studies were mainly carried out in patients with schizophrenia on neuroleptic treatment. We (Yao et al., 1994b) have reported a significant decrease of PUFA's, particularly 18:2(n-6) and 20:4(n-6), in the RBC ghost membranes of schizophrenic patients on and off haloperidol (HD) treatment (Table 49.2). Such a decrease remained in those patients withdrawn from HD for >5 weeks. Similarly, decreased 18:2(n-6) in RBC membranes of schizophrenic patients was reported in a double-blind trial of EFA supplementation in patients with tardative dyskinesia (Vaddadi et al., 1989). Such a decrease was persistent in schizophrenic and schizoaffective patients followed for four and half years (Vaddadi, 1996). A decrease of RBC 18:2(n-6) was also present in the first degree relatives of patients with schizophrenia (Peet et al., 1996), as well as patients with first-episode neuroleptic-naive schizophrenia (Table 49.3) (Reddy et al., 2004), suggesting a familial tendency of membrane PUFA differences in schizophrenia. Similarly, Sobczak et al. (2004) reported that the first degree relatives of patients with bipolar spectrum disorders had lower total n-3 and increased total n-6 relative to a nonpatient control group.

To test whether the levels of PUFAs and the degree of fatty acid unsaturation in RBC ghost membranes of schizophrenic patients were related to their severity of psychopathology, we (Yao et al., 1994a) compared the levels of 18:2(n-6), 20:4(n-6), total PUFAs, and the fatty acid unsaturation index (FAUI) with various behavioral ratings. The usual complexity of natural mixtures makes it difficult to understand the overall unsaturation. To obtain the average number of double bonds per fatty acid molecule, the FAUI was thus calculated as $\Sigma N_i L_i / M_i$, where N_i is the number of double bonds in the fatty acid, "i" in L_i is the percentage by weight of the fatty acid in the given sample, and M_i is the molecular weight (Dole et al., 1959). It was shown that decreases in both RBC 18:2(n-6) and FAUI were significantly correlated to the increases in psychosis ratings (Figure 49.1), suggesting a close association between fatty acid abnormality and the severity of symptomatology.

Glen et al. (1994) reported that patients with prominent negative symptoms (e.g., poverty of thought and anhedonia) were associated with high levels of saturated fatty acids and low levels of PUFA's in RBC membranes, while patients with positive symptoms (hallucinations and delusions) showed the opposite association. Interestingly, schizophrenic patients RBC membrane unsaturated fatty acids with 20 and 22 carbons appeared to have a bimodal distribution. Such a bimodal distribution

[c] The total is greater than the sum of listed fatty acids in each case because some small amounts of PUFAs were omitted from the final tabulation.
[d] Results are expressed as mean ± SD mg/100 mg total lipid present.
[e] Values are from schizophrenic patients with tardive dyskinesia.

was later confirmed by Peet et al. (1996), although psychiatric rating scales were not determined to differentiate positive from negative symptoms patients in their study.

Hibbeln et al. (2003) failed to replicate such a bimodal distribution but pointed out that PUFA abnormalities, especially in schizophrenic patients, may be an artifact of smoking status. Following n-3 supplementation for 16 weeks, patients with schizophrenia who smoked had the lowest EPA. However, it remains unclear whether smoking causes reduction of RBC PUFA levels since there was not a normal control group. On the other hand, Yao et al. (2001) indicate that the altered antioxidant defenses, as well as PUFA levels were not associated with the degree of smoking in patients with schizophrenia.

b. Brain

^{31}P magnetic resonance spectroscopy (^{31}P MRS) permits noninvasive study of cell membrane phosphorus metabolism in humans. Phosphomonoesters (PMEs) are precursors, and phosphodiesters (PDEs)

the breakdown products of membrane phospholipids. PME and PDE concentration reflect membrane turnover and may differ between healthy and pathological states. In fact, phospholipids themselves constitute a large part of the broad resonance underlying the PDE and PME peaks. Pettegrew et al. (1991, 1993) demonstrated a significant reduction of PMEs and significantly increased levels of PDEs in the dorsolateral prefrontal cortex of neuroleptic-naïve first-episode schizophrenic patients

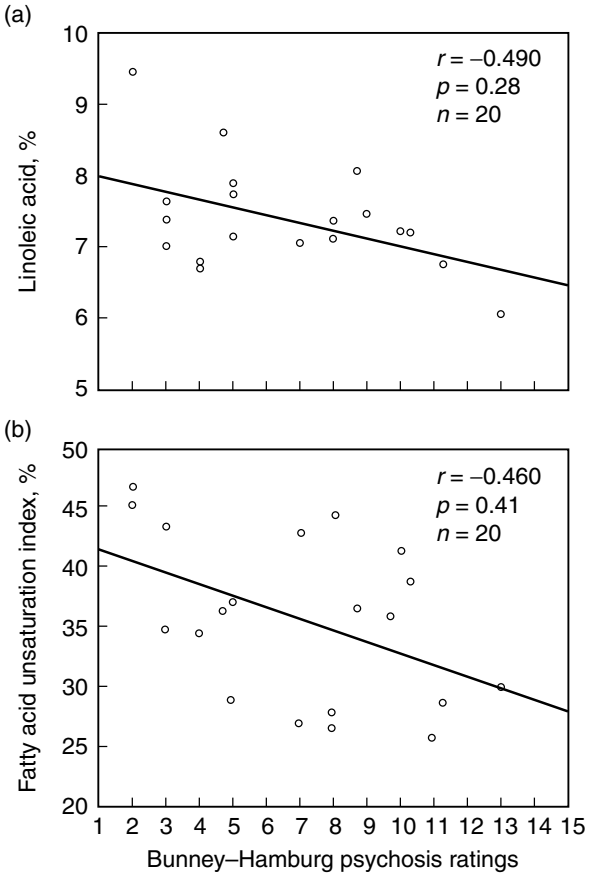

FIGURE 49.1 (a) Relationships of linoleic acid and (b) fatty acid unsaturation index of red blood cell membrane phospholipids to Bunney–Hamburg psychosis ratings (3-day mean) in drug-free schizophrenic patients. *Source:* Adapted from Yao, J.K., et al. (1994a). *Schizophr. Res*. 13:227–232.

as compared to control participants. In addition, an increased level of ATP and decreased inorganic orthophosphate were also found in the frontal cortex of schizophrenic patients. Pettegrew et al. (1993) suggested that changes in membrane phospholipids may be related to molecular changes that precede the onset of clinical symptoms and brain structural changes in schizophrenia, while changes in high energy phosphate metabolism may be state dependent. Other groups (Williamson et al., 1991; Fukazako et al., 1992, 1996; Deicken et al., 1993; Stanley et al., 1994) reported similar perturbations in membrane phospholipids in both acutely and chronically ill patients. Based on ^{31}P MRS findings, Keshavan et al. (1993b) suggested a possible familial basis for membrane phospholipid changes in schizophrenia. Post mortem studies have provided direct evidence of decreased fatty acid levels in the frontal cortex (Horrobin et al., 1991) as well as the caudate nuclei (Yao et al., 2000) of patients with schizophrenia relative to normal controls (Table 49.4). These studies demonstrated significant reductions of AA in phosphatidylethanolamine (PE; which contains the highest concentration of EFA among the phospholipids), which are consistent with findings in plasma (Horrobin et al., 1989; Kaiya et al., 1991) and RBC lipids (e.g., Glen et al., 1994; Yao et al., 1994b).

Furthermore, a significant correlation was found between RBC phospholipid PUFAs and ^{31}P MRS measures of phospholipid metabolites in the combined right and left frontal lobe, but not other brain regions including caudate, occipital, parietal, and temporal areas (Yao et al., 2002). Specifically, both the total PUFA and the individual 20:4(n-6) contents were significantly correlated with the freely-mobile phosphomonoester [PME(s-τ_c)] levels (Figure 49.2). The 18:2(n-6) PUFA

content correlated positively with freely-mobile PDE [PDE(s-τ_c)] levels (Figure 49.2). The above correlations were present in the combined right and left prefrontal region of the brain while other regions including the basal ganglia, occipital, inferior parietal, superior temporal, and centrum semiovale yielded no significant correlations. Our data thus support the association between the decreased RBC membrane phospholipid PUFA content and the decreased building blocks [PME (s-τ_c)] and breakdown products [PDE(s-τ_c)] of membrane phospholipids in the prefrontal region of patients with first-episode neuroleptic-naive schizophrenia.

Thus, there is ample evidence for the existence of phospholipid and fatty acid pathology, in both peripheral and central nervous system membranes, in early and chronic, and medicated and unmedicated, schizophrenia. As is known from membrane physiology, changes in the composition of membranes lead to a number of functional disturbances, and such pathological changes of relevance to schizophrenia are reviewed below.

B. Pathological Consequences of Impaired Membrane Dynamics

The membrane is a complex structure that provides scaffolding for many key functional systems, including transmembrane ion channels, neurotransmitter receptor binding, signal transduction, immune-inflammatory process, and in the case of mitochondrial membranes the electron-transport chain. Alterations due to changes in membrane composition can lead to pathological alterations in a number of these systems, some of which have been found in schizophrenia.

a. Decreased Membrane Fluidity

Biological membranes are highly dynamic structures composed predominantly of lipids and proteins. The dynamic state, or fluidity, of the cell membrane is dependent on its composition and, in the intact cell, is also influenced by motion imposed by the cytoskeleton. Small changes in membrane fluidity have been shown to have considerable effects on a wide variety of membrane functions. Specifically, alterations in membrane fluidity have been implicated in the regulation of the densities and binding affinities of neurohormone and neurotransmitter receptors, including dopamine (De la Pressa Owens and Innis, 1999; Zimmer et al., 2000), serotonin (Heron et al., 1980a,b; De la Pressa Owens and Innis, 1999), norepinephrine (Hirata and Axelrod, 1980), and opiates (Heron et al., 1980a,b). Therefore, the observed changes in membrane phospholipid composition associated with schizophrenia may result in altered neurotransmission by virtue of a perturbation of membrane fluidity. Hitzemann et al. (1986) demonstrated a significant increase in the steady-state anisotropy (r_s) of DPH-labeled RBC ghost membranes from patients with schizophreniform disorder that pointed out that five of eight schizophreniform patients had values higher than the highest control value. Later, Pettegrew et al. (1990) reported an increased molecular motion on the RBC membrane surface and in the phospholipid head group region in the unmedicated schizophrenic patients. No significant motional differences, however, were found in the membrane hydrocarbon core of the same unmedicated patients. We (Yao and van Kammen, 1994) have reported a significant increase in r_s values from schizophrenic patients withdrawn from HD. Furthermore, changes in r_s values of drug-free patients were significantly correlated with their increase in psychosis ratings as well as decreases in the FAUI (Figure 49.3). Therefore, decreased RBC membrane fluidity in schizophrenia is consistent with decreased PUFA's in RBC membranes (Vaddadi et al., 1986; Glen et al., 1994; Yao et al., 1994b).

b. Increased Free Radical Production

It is well known that elevations in free AA are associated with oxidative stress (Yao et al., 2001; Yao and van Kammen, 2004). Metabolism of AA by oxygenases yields superoxide and hydroxyl radical production (Chan and Fishman, 1980). Increased superoxide production is seen with application of

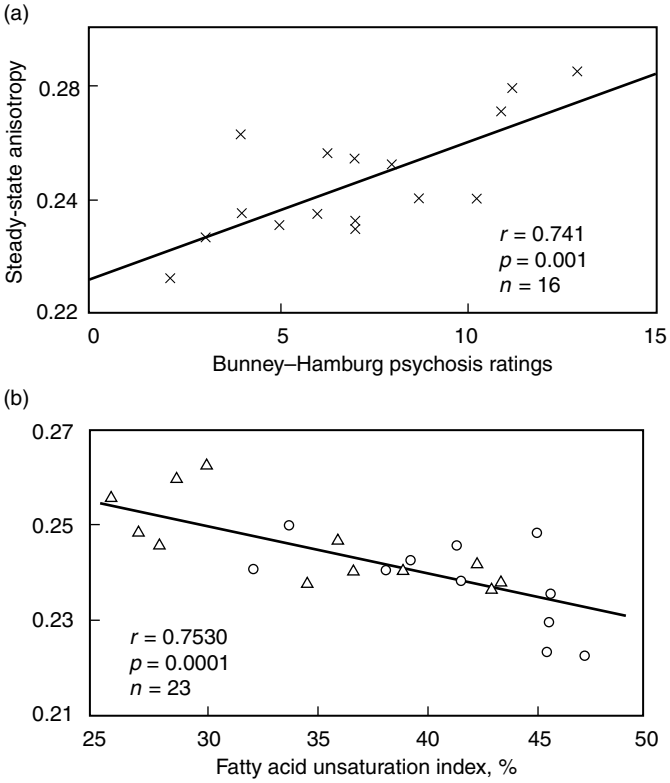

FIGURE 49.3 (a) Relationships of the steady-state anisotropy (r_s) of 1,6-diphenyl-1,3,5-hexatriene-labeled RBC ghost membranes to 3-day mean Bunney–Hamburg psychosis ratings from drug-free schizophrenic patients (x) and (b) between the fatty acid unsaturation index of RBC membrane phospholipids and steady-state anisotropy of normal subjects (O) and drug-free schizophrenic patients (Δ). *Source:* Adapted from Yao, J.K., and van Kammen, D.P. (1994). *Schizophr. Res*. 11:209–216; Yao, J.K., et al. (1994b). *Schizophr. Res.* 13:217–226.

exogenous AA, and indomethacin (blocks cyclooxygenase metabolism of AA) inhibits AA-induced free radical generation and subsequent lipid peroxidation (Hall et al., 1993). Lipid peroxidation, in turn, causes significant membrane damage (reviewed in Reddy and Yao, 1996; Yao and van Kammen, 2001; Mahadik and Yao, 2006), and may lead to further depletion of AA. There is independent evidence for the presence of oxidative stress in first-episode and chronic schizophrenia, which may be closely linked to phospholipid and fatty acid deficits seen in schizophrenia. For example, high levels of hydrogen peroxide and lipid peroxides lead to decreased synthesis of prostaglandins (Deby and Deby-Dupont, 1980), which also have been reported in schizophrenic patients (Rotrosen and Wolkin, 1987; van Kammen et al., 1989). There are a variety of adverse effects on neurotransmitter binding (dopamine, GABA, serotonin) that are induced by oxidative stress, likely mediated by alterations in membrane composition and function (Yao et al., 2001; Skosnik and Yao, 2003; Yao and van Kammen, 2004; Hulbert et al., 2005).

c. Decreased Dopamine Transporter Receptor (DATR)

Changes in membrane dynamics can affect the transmembrane processes that are mediated through the conformational changes of the membrane-bound proteins (Hitri et al., 1994). Maguire and Druse (1989) have demonstrated an inhibition of transmembrane process of DA uptake by increasing the ratio of cholesterol to phospholipid (C/PL) in the synaptic plasma membrane. Thus, the function

of the transporter is highly influenced by the lipid composition of membrane environment. Given a DAT model that mediates the transport of DA through a series of sequential conformational changes of the transporter protein (Hitri et al., 1994), it is likely that the conformational state of DAT is regulated by the synaptic membrane fluidity. Moreover, both n-6 and n-3 series of PUFAs may be involved in the presynaptic receptor control of dopamine release (Davidson et al., 1988). It is therefore possible that an elevated ratio of C/PL and/or a reduced degree of fatty acid unsaturation may be associated with a decrease in the density of DATR in the cortical areas of the schizophrenic brain with high metabolic activity. In laboratory animals, Zimmer et al. (2000) reported the effects of chronic PUFA deprived diet on DA transmission in the nucleus accumbens. Remarkably, chronic deprivation of n-3 dietary PUFA lead to a 60% reduction in DA transporter sites.

d. Serotonin Dysfunction

5-HT_2 receptors in the brain are thought to play a regulatory role in behavior (Leysen and Pauwels, 1990). However, conflicting findings had left unresolved the role of abnormal serotonin (5-hydroxytryptamine; 5-HT) function in schizophrenia. The development of serotonin-dopamine antagonists (atypical) antipsychotic drugs that potently block 5-HT_2 receptors has renewed interest. 5-HT stimulates the release of AA in hippocampal neurons through the activation of PLA_2 that is independent of inositol-phospholipid hydrolysis (Felder et al., 1990). Thus, 5-HT may potentially mediate some pathophysiological processes through receptor-stimulated AA or eicosanoids.

Previously, we demonstrated that drug-free schizophrenic patients exhibited reduced physiologic responsivity mediated through the platelet 5-HT_2 receptor complex, which can be modified by HD treatment (Yao et al., 1996b). Similarly, blunted platelet serotonergic responsivity was also demonstrated in first-episode treatment-naive patients with schizophrenia, but not with mood disorders (Reddy et al., in press). It has been observed that n-3 fatty acids such as DHA can influence the turnover rate of 5-HT in the brain (Hibbeln and Salem, 1995), and that cerebrospinal fluid 5-hydroxyindoleacetic acid (5-HIAA, metabolite of 5-HT) and plasma DHA levels are correlated in the healthy volunteers (Hibbeln et al., 1998). Thus, it is plausible that membrane PUFA deficits may lead to the blunted serotonergic platelet responsivity in patients with schizophrenia.

C. Biochemical Mechanisms Underlying Decreased Membrane PUFAs

There are several known mechanisms that can lead to altered membrane fatty acid composition that characterizes schizophrenia, and include: (1) low dietary intake or synthesis of essential PUFAs; (2) decreased fatty acid incorporation into phospholipids; (3) increased phospholipid degradation; and (4) increased lipid peroxidation. The most compelling evidence in schizophrenia exists for increased phospholipid degradation and decreased incorporation of AA, which are discussed below.

a. Low Intake or Synthesis of Arachidonic Acid

Unlike saturated/monounsaturated fatty acids, long-chain PUFAs cannot be synthesized de novo by humans. Therefore, we must obtain the long-chain PUFAs directly in the diet or consume their 18 carbon precursors linoleic acid (18:2n-6 or LA) and (18:3n-6 or ALA). Increased intake of n-6 fatty acids or reduced intake of both n-6 and n-3 can cause deficits in brain and behavioral development (Simopoulos, 1999). Substantial cultural differences exist in the quantity of EFA, particularly n-3 EFA consumption, primarily due to the local availability of these substances in the diet, in addition to effects of lifestyle and consumption of antioxidants (Peet et al., 1995; Mahadik et al., 2001). Christensen and Christensen (1988) found that geographic differences in the clinical outcome of patients with schizophrenia, studied by the WHO, were related to differences in the patients' dietary intake of oils from fish and vegetables, the primary sources of n-3 EFAs, ALA, and DHA. In addition, the increased incidence of schizophrenia seen in children born during the Dutch famine

(Hoek et al., 1999) may have resulted from reduced consumption of fresh fruits and vegetables (primary sources of antioxidants and precursor EFAs).

Other lifestyle characteristics of individuals with schizophrenia may affect brain PUFAs through prooxidant effects such as high intake of calories, fat, alcohol, and little exercise (Brown et al., 1999). Ecological studies of patients with schizophrenia have found that these patients consumed higher amounts of saturated fats and sugars compared to intakes for the U.S. population (Peet, 2003). High caloric intake has been reported to cause peroxidative brain damage and cognitive deficits in animals (Bruce-Keller et al., 1999).

b. Decreased Fatty Acid Incorporation

Demisch et al. (1987, 1992) have shown that incorporation of [^{14}C]AA into platelet phospholipids was significantly lower in untreated patients (>6 months) with a schizophreniform or schizoaffective disorder than in normal control subjects. The incorporation rates were only slightly but not significantly reduced in chronic schizophrenic patients. This suggests that the rate of AA incorporation was related to the type and time course of the disorder. We (Yao et al., 1996a) demonstrated that the total incorporation of [^{3}H]AA in drug-free patients was significantly lower than in the same individuals on HD treatment as well as that of normal controls. No significant difference was demonstrated between relapsed and nonrelapsed drug-free patients. Thus, it is unlikely that changes in AA incorporation are related to a specific syndrome or its intensity. More importantly, these two studies suggest that neuroleptic treatment ameliorate symptoms while normalizing AA incorporation into phospholipids, indicative of a connection between these two phenomena.

c. Increased Phospholipids Degradation

PLA_2 is enriched in neuronal membranes and is a key enzyme responsible for the breakdown of membrane phospholipids. Importantly, this enzyme regulates the production of prostaglandins, or hormones involved in inflammatory processes (du Bois et al., 2005). Increased cytoplasmic PLA_2 activity has been observed in serum of drug-free schizophrenic patients (Gattaz, 1992; Noponen et al., 1993; reviewed in Law et al., 2006). Such increases in serum PLA_2 activity, however, were also found in patients with other psychiatric disorders (Noponen et al., 1993), including bipolar disorder (Ross et al., 2006), questioning the specificity of this finding to schizophrenia. Albers et al. (1993) found no significant differences of serum PLA_2 activity between neuroleptic-naive schizophrenics and normal controls. These discrepancies may be due to the differences in assay procedure and the heterogeneous class of extracellular PLA_2 (Ross et al., 1997). Gattaz et al. (1995) showed that the intracellular membrane-bound PLA_2 activity was significantly higher in the platelets of schizophrenic patients than in normal and psychiatric controls, with no significant differences between normal and psychiatric controls. It is thus unlikely that increased platelet PLA_2 activity in schizophrenia results from nonspecific stressors. Furthermore, HD treatment reduced platelet PLA_2 activity to control levels. Other neuroleptics also inhibit PLA_2 activity (Aarsman et al., 1985; Taniguchi et al., 1988).

Further support of elevated PLA_2 activity in schizophrenia comes from the findings of increased lysophosphatidylcholine (LPC; the break-down product of PLA_2 reaction) found in platelets of schizophrenic patients (Pangterl et al., 1991; Steudle et al., 1994). The increased LPC was significantly correlated with duration of illness in neuroleptic-naive but not previously treated patients, suggesting an accelerated breakdown of membrane phospholipids after the onset of disease. Such a correlation is consistent with the findings that duration of illness prior to first-episode treatment in drug-naive patients was significantly associated with time to remission (Wyatt, 1986; Loebel et al., 1992).

d. Increased Lipid Peroxidation

PUFAs are highly susceptible to free radical insult and autoxidation to form peroxyradicals and lipid peroxide intermediates, the existence of which within cell membranes result in unstable membrane

TABLE 49.5
Association of RBC-PUFA Levels with Plasma Lipid Peroxides[a]

Biochemical Measures	Normal Controls	FEP	CSP-CT
RBC-20:4(n-6), %	14.52 ± 2.00	3.12 ± 2.55	6.68 ± 3.60
RBC-22:6(n-3), %	2.99 ± 0.79	0.25 ± 0.71	1.08 ± 0.90
Plasma TBARS, nmol/mL	5.67 ± 2.11	24.67 ± 4.87	16.23 ± 3.95

Abbreviations: RBC, red blood cells; PUFA, polyunsaturated fatty acid; TBARS, thiobarbituric acid-reactive substance; FEP, first-episode drug-naïve psychotic patients; CSP-CT, chronic schizophrenic patients with clozapine treatment.

[a] From Khan, M.M., et al. (2002). *Schizophr. Res.* 58:1–10. With permission.

structure, altered membrane fluidity and permeability, and impaired signal transduction. The brain has a higher concentration of long-chain PUFAs than any other organ and, is particularly vulnerable to free radical-mediated damage (reviewed in Yao et al., 2001; Skosnik and Yao, 2003). Thus, lipid peroxidation can lead to both increased free radical production and decreased membrane AA content. For example, Arvindakshan et al. (2003) reported that never medicated patients with schizophrenia had reduced RBC membrane AA levels and were negatively associated with greater levels of oxidative stress, reflected in plasma thiobarbuturic acid reactive substances (TBARS). This association was only apparent in never-medicated schizophrenic patients and not in a well-matched normal control group. Considering the observed negative association, the authors interpreted these findings as evidence that reduced membrane AA and DHA levels were the result of increased lipid peroxidation in the schizophrenic group. In other work, higher plasma TBARS were associated with greater severity of negative symptoms in schizophrenic patients (Mahadik et al., 1998). Similarly, lower erythrocyte membrane AA and DHA were associated with significantly higher levels of TBARS in first-episode drug-naive schizophrenic patients than matched normal controls (Table 49.5) (Khan et al., 2002). Interestingly, a third group of chronically medicated patients showed higher AA and DHA relative to the drug-naive group suggesting that the PUFA membrane deficits may potentially contribute to illness onset and that antipsychotic treatment may increase PUFA levels; although TBARS remained elevated relative to the control group. As suggested by the authors, future research should continue to explore the effect of simultaneous supplementation with antioxidants as a method to reduce lipid peroxidation.

D. Therapeutic Effects

a. Dietary Essential Fatty Acid Supplementation

A dose-ranging study with adjunctive ethyl-EPA (placebo, 1, 2, or 4 g/day for 12 weeks) in patients with persistent schizophrenic symptoms inadequately responsive to clozapine, atypicals (olanzapine, risperidone, or quetiapine), or one of the typical antipsychotic drugs has been reported (Peet and Horrobin, 2002). Placebo was 4 g/day of liquid paraffin that has been used up to 15–30 g/day as a laxative. It was concluded that 2 g/day of ethyl-EPA had the maximum therapeutic effect. However, patients on typical antipsychotics and new atypical drugs did not show improvement with the adjunctive ethyl-EPA over patients on placebo, which showed significant improvements from baseline. The clozapine group had very little placebo effect and therefore responses to 2 g dose of ethyl-EPA were substantially better than placebo. However, changes in RBC membrane EPA and DHA did not correlate with clinical response, whereas clinical improvement was proportional to changes in membrane AA. In any case, the therapeutic benefit of EPA in this small trial warrants further investigation.

Since increased oxidative stress-mediated PUFA peroxidative degradation as well as defective phospholipid-PUFA metabolism exists in schizophrenia, the use of a combination of PUFAs and antioxidants (e.g., vitamins E and C) for supplementation may be preferable (Mahadik et al., 2001). Antioxidants have been found to be very effective in protecting membrane PUFAs, in addition to preventing oxidative damage of vital cellular proteins, mitochondria, and DNA. Earlier studies have also used only vitamin E; supplementation with vitamin C, an effective intracellular antioxidant, has not yet been tried.

One study has reported the effects of 4 months supplementation of a combination of EPA:DHA (360 mg:240 mg) and vitamins E:C (800 IU:1 g) per day in two equal doses in 34 chronic schizophrenic patients on stable antipsychotic medications (Arvindakshan et al., 2003). Patients showed over 25% reductions in most of the psychopathological scores, and these effects were sustained up to 4 months after termination of supplementation. However, this study did not have a placebo group. RBC membrane EPA and DHA concentrations rose from baseline, to those of matched normal controls without any change in the plasma lipid peroxides. This indicated that such a low dose PUFA treatment may be adequate to correct the preexisting membrane PUFA deficits when combined with antioxidants. Pretreatment AA levels were similar to normal controls, fell during treatment, and returned to pretreatment levels by 4 months posttreatment. This suggests that supplementation of n-3 PUFAs (Peet and Horrobin, 2002), may reduce AA incorporation in membranes by competition. Finally, two small double-blind placebo-controlled pilot studies of EPA and DHA for improvement of schizophrenia related symptoms yielded promising results (both reported in Peet et al., 2003). In the first study, following 3 months of supplementation with EPA, a significant reduction of positive symptoms was observed. No reduction was seen with DHA or the placebo. In the second study, treatment with EPA ($n = 14$), compared to placebo, lead to significantly lower scores on a positive symptom measure.

Recently, we examined whether supplementation with the n-3 fatty acid eicosapentaenoic acid (EPA) modified 5-HT amplified ADP-induced platelet aggregation in patients with schizophrenia (Yao et al., 2004). Two grams of ethyl-EPA was administered daily for 6 months adjunctively to ongoing antipsychotic treatment in 12 patients with chronic schizophrenia, using an open-label design. RBC membrane fatty acids and platelet functions (platelet aggregation and dense granule secretion) were monitored at baseline, 1-, 3-, and 6-months. The EPA levels were elevated more than fivefold in RBC membranes of all patients after 3 months of supplementation, indicating a high degree of compliance. Consistent with previous reports (Kristensen et al., 1989), there was inhibition of ADP-induced platelet aggregation by EPA supplementation. Moreover, EPA markedly enhanced the 5-HT responsivity as measured by the magnitude of 5-HT amplification on ADP-induced platelet aggregation (Figure 49.4). Previously, we demonstrated a significant inverse correlation between 5-HT responsivity and psychosis severity in unmedicated patients with schizophrenia (Yao et al., 1996b). Taken together, the present data support the notion that EPA may be mediating its therapeutic effects in schizophrenia via modulation of the 5-HT_2 receptor complex.

More recently, Kemperman et al. (2006) assessed the nutritional status and effects of subsequent supplementation with n-3 fatty acids in schizophrenic patients. As a group, the schizophrenic patients had elevated RBC saturated and monosaturated fatty acids but low PUFA (RBC 20:3n-9 >0.46 mol %), as well as increased homocysteine levels probably due to poor B-vitamin status. Following a 100-day supplementation period in the patients low PUFA status with an EPA/DHA combination of 310 mg and 200 mg, respectively, the PUFA nutritional deficits were improved, although, changes in symptomatology were not assessed.

b. Atypical Antipsychotic Drugs

Apolipoprotein (ApoD) is a member of the lipocalin superfamily of transporter proteins that bind small hydrophobic molecules, including AA. The ability of apoD to bind AA implicates it in

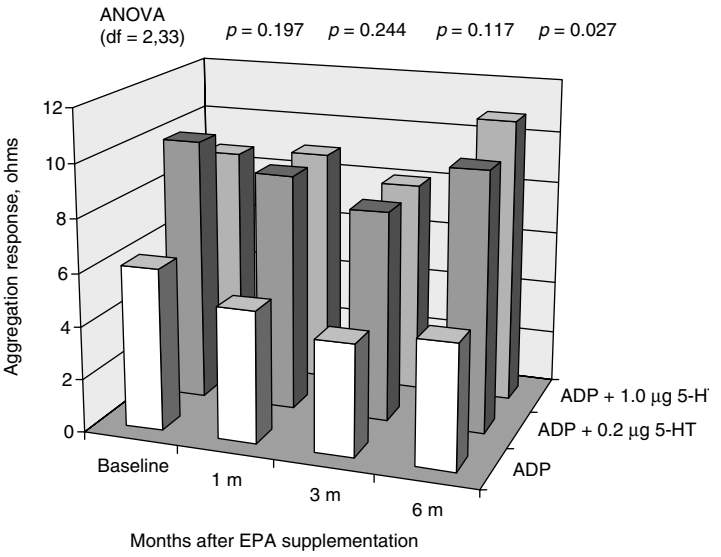

FIGURE 49.4 Increased platelet serotonin responsivity in clinically stable patients with chronic schizophrenia (n = 12) following ethyl-EPA supplementation. *Source:* Adapted from Yao, J.K., et al. (2004). *Prostaglandins Leukot. Essent. Fatty Acids* 71:171–176.

pathways associated with membrane phospholipid signal transduction and metabolism. An increased expression of apoD in the mouse brain after clozapine treatment suggested a role for apoD in the pharmacological action of clozapine (Thomas et al., 2003). Recently, we have demonstrated that plasma apoD levels were significantly correlated with RBC-AA and DHA in first-episode neuroleptic-naive patients with schizophrenia (Yao et al., 2005). Moreover, Thomas and Yao have further collaborated to study membrane phospholipids and fatty acids in brains from apoD knock-out (KO) mice and wild-type (WT) controls that were treated with clozapine, olanzapine, or saline. Preliminary data (Thomas and Yao, in press) indicate significant decreases in the levels of AA, its precursors, 18:2(n-6) and 20:3(n-6), and its elongated product, 22:4(n-6); in response to clozapine treatment in the brains of apoD KO mice, but not WT mice. Clozapine treatment also caused a reduction in other fatty acids and in the membrane phospholipids, phosphatidylinositol, and phosphatidyl-serine in both apoD KO and WT mice, and a reduction in PE in apoD KO mice only. Taken together with other *in vitro* studies, these results support the view that an increased expression of apoD such as the one induced by atypical antipsychotic drugs may facilitate incorporation of AA into membrane phospholipids by its selective binding to AA.

E. Summary

The above findings reported in the literature and those from our laboratory indicate in patients with schizophrenia exhibit differences in membrane PUFAs in a variety of peripheral cell types and brain tissues (see recent reviews by Skosnik and Yao, 2003; Law et al., 2006; Mahadik and Yao, 2006). These differences appear to be independent of neuroleptic treatment (based on findings from drug-free and neuroleptic-naive patients), and is associated with illness severity. The key mechanisms that may lead to reduced membrane PUFA are increased phospholipid hydrolysis and/or decreased incorporation. The accelerated breakdown of membrane phospholipids is supported by the ^{31}P MRS findings in brains of schizophrenic patients. Supplementation of PUFAs may improve clinical state, indicating that behavioral changes parallel membrane PUFA changes. A proposed model of relations between membrane AA and treatment outcome is illustrated in Figure 49.5.

III. MAJOR DEPRESSION

According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), depression is one of the major mood disorders and is characterized by loss of interest or pleasure, and disturbances of affect severe enough to alter cognition, judgment, and interpersonal relationships. As with schizophrenia the molecular basis of major depression remains unclear. Considerable data point to several neurobiological mechanisms in depression, including norepinephrine (NE) and serotonin (5-HT) dysregulation, corticotropin-releasing factor (CRF) stress response abnormalities, as well as differences in neurotrophic factors and cellular transduction factors (Ressler and Nemeroff, 2000; Trivedi, 2003; Duman and Monteggis, 2006). A deficiency of 5-HT activity in brain appears to increase vulnerability to depression (Maes and Meltzer, 1995). Decreased 5-HT uptake and 5-HT transporter binding in platelets (Kaplan and Mann, 1982; Nemeroff, 1998) and in brain (Malison et al., 1998) has been reported in patients with depressive disorders. Thus, changes in the NE and 5-HT systems

may mediate many of the signs and symptoms in depression. It is generally agreed that long-term antidepressant administration is associated with a decreased neurotransmission of NE system and increased 5-HT transmission (Owens, 1997; Delgado and Moreno, 2000). Selective serotonin reuptake inhibitors (SSRIs) are effective treatments for depression (Vaswani et al., 2003).

A. Reduced Membrane PUFAs

Since the early 1900s, there has been an increased incidence rate of major depression. One hypothesis is that this is secondary to a dramatic increase in the ratio of n-6/n-3 PUFAs in the Western diet (Smith, 1991). This association was in general agreement with recent data that such an imbalanced diet can led to high levels of n-6 PUFAs in tissues and low levels of n-3 PUFAs in plasma and membranes of Western population (Sinclair et al., 1994). Moreover, an increased incidence of cardiovascular and inflammatory disorders has also coincided with an increased ratio of n-6/n-3 PUFAs (Smith, 1991). Studies by Maes et al. (1996, 1997) have shown that an increased ratio of 20:4(n-6) to 20:5(n-3) is not only related to depression but also to a higher risk of cardiovascular disease. Among patients with recent acute coronary syndromes, major depression was associated with low levels of n-3 PUFAs (Frasure-Smith et al., 2004).

We recently investigated these potential associations in a convenience sample of 105 adult community volunteers, with untreated hypercholesterolemia (Conklin et al., unpublished data). Subjects completed the Beck Depression Inventory, the NEO-Five Factor Inventory and the Barratt Impulsiveness Scale, and their fasting serum fatty acid composition was determined. Controlling for gender, race and age, we found that a 1 SD increase in DHA reduced by approximately 50% the odds of mild or greater depressive symptomatology (Beck score ≥ 10, $p < .02$) (Figure 49.6). EPA and DHA also correlated negatively with both neuroticism and cognitive impulsiveness (p value range 0.04–0.002) (Table 49.6). These data suggest that n-3 fatty acid status contributes to the normative variability in affective regulation, personality, and impulse control.

As previously discussed, there are several mechanisms that may contribute to the depletion of membrane PUFA's. When RBC membranes from normal controls were exposed to hydrogen peroxide, the resulted changes in fatty acid composition closely resembled to those found in depressive patients (Peet et al., 1998). This finding suggests that differences in the n-3 PUFA pathway in

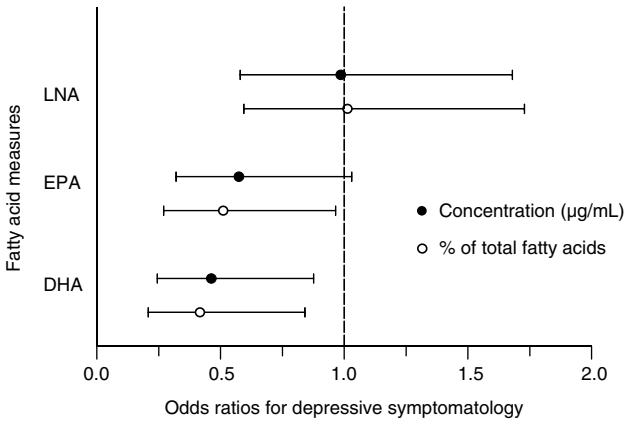

FIGURE 49.6 Odds ratios and 95% confidence intervals for depressive symptomatology (BDI-II ≥ 10) for a one SD increase in fatty acid measures. The figure illustrates a significant reduction in the odds for scoring ≥10 on the BDI-II with each SD increase in EPA expressed as a percentage of the total serum fatty acids (OR = 0.51, 95% CI = 0.27–0.97) and for a 1 SD increase in DHA expressed as a concentration (OR = 0.46, 95% CI = 0.24–0.88) or as a percentage of the total fatty acids (OR = 0.42, 95% CI = 0.21–0.84). *Source:* Adapted from Conklin, S.M., et al. *Psychiatry Res.*, in press.

patients with major depression may be due to oxidative membrane damage, possibly resulting from an increased oxidative stress load or decreased antioxidant defense mechanisms.

Another mechanism may be reduced dietary intake of the n-3 PUFAs. For example, global ecological studies have found that low dietary intake of n-3 and high n-6: n-3 ratios are associated with increased rates of depression (Figure 49.7), (Hibbeln, 1998, 2002; Tanskanen et al., 2001a), whereas populations with higher fish consumption have lower rates of depression (Hibbeln, 2002) and also suicide (Tanskanen et al., 2001b). Other observational studies conducted within single populations links low n-3 and/or high n-6 intake or blood levels with depressive symptomatology (Adams et al., 1996; Mamalakis et al., 2002; Timonen et al., 2004), major depressive disorder (Edwards et al., 1998; Peet et al., 1998; Maes et al., 1997; Frasure-Smith et al., 2004), and other forms of negative affect, including hostility (Iribarren et al., 2004) and social anxiety disorder (Green et al., 2006).

B. Pathological Consequence of Reduced Membrane n-3 PUFAs

As mentioned earlier, small changes in membrane fatty acid composition can alter the dynamic state of cellular membranes and, subsequently, a variety of membrane functions. It has been shown that depressive patients have a decreased serotonin uptake (Mellerup and Plenge, 1988; Ellis and Salmond, 1994). We (Yao and van Kammen, 1994) have previously demonstrated that decreases in the degree of fatty acid unsaturation was significantly correlated to the increases in "structure order" of RBC ghost membrane as measured by the steady-state fluorescence anisotropy. Thus, the observed decrease of RBC n-3 PUFAs may lead to decreased membrane fluidity, and consequently, reduced serotonergic transport. Such an effect of plasma membrane fluidity on serotonin transport

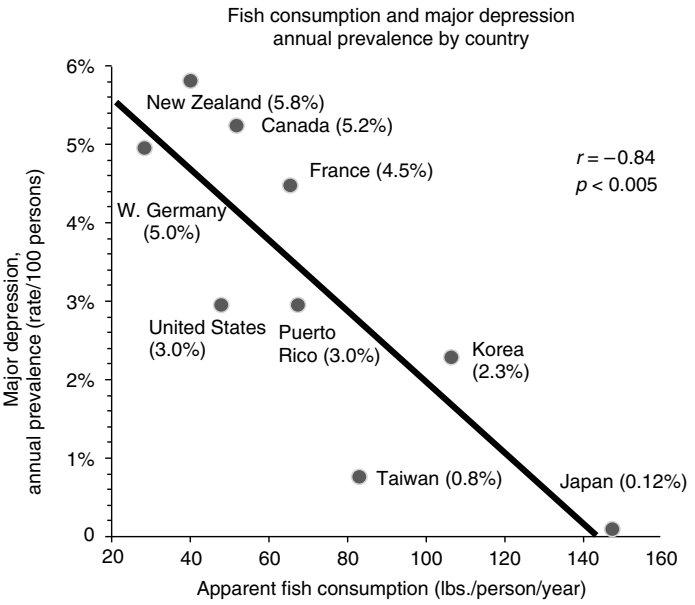

FIGURE 49.7 Relationship between national fish consumption and annual prevalence of major depression by country. *Source:* Adapted from Hibbeln, J.R. (1998). *Lancet* 351:1213.

has been previously demonstrated in endothelial cells (Block and Edwards, 1987). In addition, increased membrane fluidity has been associated with an improved serotonin binding in mouse brain membranes (Heron et al., 1980b). This is due to the biophysical effects of changes in membrane fluidity on receptor binding sites (Heron et al., 1980b). Basic neurotransmission appears to depend on the integrity of membrane structure and receptor function, which in turn provides a theoretical model relating the membrane PUFA deficits to the traditional monoaminergic hypotheses of major depression (Maes et al., 1996, 1997; Peet et al., 1998).

Decreased levels of serum brain-derived neurotrophic factor (BDNF) were demonstrated in clinically depressed patients (Shimizu et al., 2003; Aydemir et al., 2006). In addition to physical and psychological stress, diets with high saturated fat and sucrose can inhibit BDNF expression, an effect that is reversed by supplementation or consumption of n-3 fatty acids (Wu et al., 2004). By contrast, antidepressants can promote neurogenesis (Vaidya and Duman, 2001) and enhance BDNF expression (Russo-Neustadt, 2003). Depletion of cell membrane n-3 PUFAs, particularly DHA, has been postulated to play an etiologic role in major depression (Hibbeln and Salem, 1995). There is also an increasingly recognized role of proinflammatory cytokines in the pathophysiology of depression. Below, we discuss the evidence that supports the role of membrane PUFA and immune alterations, in depression.

C. PUFAs and Immune Function

A high n-6/n-3 PUFA ratio in the diet can also lead to an overproduction of inflammatory cytokines (Endres et al., 1993), since PUFAs are precursors of eicosanoids that play a pivotal role in the inflammatory process. Supplementation of fish oil (rich in the n-3 PUFAs) substantially reduces cytokine production while linoleic acid (the n-6 PUFA) increases proinflammatory cytokine secretion (Meydani et al., 1991; Endres et al., 1993; Caughey et al., 1996). These findings support an association between increased ratio of 20:4(n-6) to 20:5(n-3) and increased production of proinflammatory cytokine in major depression (Maes et al., 1996).

Both n-6 and n-3 PUFAs are involved in the regulation of inflammatory responses. The n-6 PUFAs, particularly AA, have proinflammatory features, since AA is the precursor of proinflammatory

eicosanoids, prostaglandin E_2 (PGE_2) and leukotriene B_4 (LTB_4) and increase production of interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), and IL-6 (Soyland et al., 1994; Tashiro et al., 1998). On the other hand, the n-3 PUFAs, EPA, and docosahexaenoic acid (DHA) suppress the production of AA-derived eicosanoids, thus having comparatively anti-inflammatory and immunosuppressive effects (Tashiro et al., 1998). Several groups have reported that n-3 PUFA-enriched diets (e.g., fish or fish oil) can lead to partial replacement of AA by EPA in cell membranes and significantly reduce the *ex vivo* production of proinflammatory cytokines (Calder, 1998; De Caterina et al., 2004; Mori and Beilin, 2004). Therefore, an imbalance of n-6/n-3 PUFAs may result in an increased production of proinflammatory cytokines. Smith (1991) proposed that abnormal fatty acid composition might be related to the inflammatory response system underlying pathophysiology of major depression. Maes et al. (1997, 1998) have further substantiated the role of n-3 PUFAs in predicting the response of proinflammatory cytokines to psychological stress.

D. Dietary Effects of PUFAs Supplementation

In some but not all preliminary clinical trials, supplementation with the long-chain n-3 PUFAs have significantly improved mood in patients with major depression and bipolar disorder (Stoll et al., 1999; Peet and Horrobin, 2002; Nemets et al., 2002; Emsley et al., 2003; Marangell et al., 2003; Ness et al., 2003; Su et al., 2003). The effect appears to be specific to EPA, and not other n-3 fatty acids, that is, DHA (Marangell et al., 2003). There also appears to be dose specific effects; as higher doses of EPA may not be effective (EPA 6 g/day) (Post et al., 2003). Of particular note is the onset of response with EPA. Peet and Horrobin (2002) found a significant reduction in severity of depressed mood as early as 2 weeks and maximally at 4 weeks. Emsley et al. (2003) found significant treatment response at 4 weeks. Thus, response to EPA occurs relatively rapidly. This may be important in managing patients who are not responding to conventional treatments and remain at risk for complications of depression, such as suicide. In the above placebo-controlled trials, there were no dropouts due to EPA-related side effects. An additional advantage is that EPA is not known to alter levels of psychotropic drugs used in treatment of depression.

IV. OTHER PSYCHIATRIC DISORDERS

The relevance of PUFAs in psychiatry is not limited to schizophrenia and depressive disorders. In fact, low serum levels and/or dietary intake of n-3 PUFA have been implicated in psychopathologies for which problems of impulse control figure prominently, including substance dependence (Buydens-Branchey et al., 2003), borderline personality disorder (Stoll et al., 1999; Zanarini and Frankenburg, 2003), suicide (Huan et al., 2004), and ADHD (Richardson and Puri, 2002; Richardson and Montgomery, 2005). Increasing evidence suggests that such disorders may involve essential fatty acid nutritional deficiencies or imbalance (Richardson and Ross, 2000; Hallahan and Garland, 2004). For example, compared to healthy controls, both children and adults with ADHD have lower levels of n-3 PUFAs in their plasma and RBC phospholipids (Taylor et al., 2000; Stevens et al., 1995; Young et al., 2004). The clinical trial evidence, albeit limited, suggests that supplementation with DHA alone is not effective (Voigt et al., 2001; Hirayama et al., 2004). However, combined EPA and DHA, benefits children with ADHD, dyslexias, or dyspraxias (Richardson and Puri, 2002; Stevens et al., 2003; Richardson and Montgomery, 2005). In addition to improving ADHD symptoms, supplementation with combined n-3 PUFAs reduces parent-rated cognitive problems (i.e., difficulties with attention, concentration, and working memory) (Richardson and Puri, 2002) and improves scores on standardized tests of reading and spelling (Richardson and Montgomery, 2005). Similarly, a number of small, controlled trails have reported that increasing n-3 PUFA consumption improves mood and reduces impulsive and aggressive behaviors (Hamazaki et al., 1999, 2002, 2005; Itomura et al., 2005). For example, EPA supplementation significantly reduced aggression in women with borderline personality disorder (Zanarini and Frankenburg, 2003) and, in incarcerated criminals, supplementation with essential fatty acids and vitamins reduced violent offences by 26% (Gesch et al., 2002).

Additionally, several pediatric behavioral, neurological, and language disorders such as dyslexia (Richardson et al., 2000, 2006), autism (Richardson, 2006), and Asperger's syndrome (Bell et al., 2004) also have been found to be associated with altered levels of phospholipid-PUFAs. Dyslexia is a developmental disorder that is marked by visual dysfunction and difficulties in learning to read and write. It has been noted that dyslexia is associated with increased schizotypal personality features and shares many of the neuropsychological features of schizophrenia including language, attentional, and working memory deficits (Richardson, 2000). Initial studies in a small group of schizophrenic patients have shown impaired electroretinogram (ERG) in patients with reduced levels of RBC-DHA (Peet et al., 2003). Likewise, receptive language difficulties have been observed repeatedly in both schizophrenic patients and in the siblings of individuals with schizophreniform-spectrum disorder (Condray et al., 2002). It is possible that since these disorders are associated with increased risk for adult psychotic disorders (Keshavan et al., 2003), these are related illnesses, even though qualitatively different, and represent a continuum of membrane/phospholipid spectrum disorders.

As discussed previously, PUFA-deficient diets fed to laboratory animals in early development significantly reduces frontal cortex monoaminergic concentrations of dopamine and serotonin as well as their degrading metabolites, 3,4-dihydroxy-phenylacetic acid (DOPAC), homovanillic acid (HVA), and 5-hydroxyindolacetic acid (5-HIAA), respectively (De la Pressa Owens and Innis, 1999). PUFA intake also affects brain development in humans. For example, babies fed formula deficient in long-chain PUFAs have lower brain DHA and poorer cognitive functioning when compared to breast-fed infants (Anderson et al., 1999). Lastly, PUFAs modulate the expression of numerous genes relevant to learning processes (Kitajka et al., 2004).

V. CONCLUSIONS

Evidence to date suggests that the membrane lipid environment has a significant impact on the behavior of neurotransmitter systems. Although, the notion that lipids play a key role in several psychiatric disorders, research has not been exhaustive. Recent investigations have shown that n-6 and/or n-3 membrane PUFAs are significantly lower in schizophrenic and depressive patients than in normal subjects. Such changes in membrane fatty acids not only have been associated with symptom severity but also provide a theoretical basis in predicting psychotropic effect of EFA supplementation. A collaborative 8-nation study of schizophrenia by World Health Organization (WHO) demonstrated a significant correlation between dietary fat intake and the outcome of schizophrenia (Christensen and Christensen, 1988). A good outcome was positively correlated with diets enriched in EFA (e.g., high intake of fish and vegetables). Thus, it is unequivocal that a balanced EFA diet is essential, particularly during the early stages of brain development. On the other hand, to determine whether membrane PUFA deficits are of primary etiological significance in these psychiatric disorders will require further investigation. Since a variety of apparently disparate biological findings have been reported (Lieberman and Koren, 1993; Yao, 2003), very likely there is etiologic heterogeneity that exists a final common pathogenic pathway that mediates the recognizable clinical syndromes. Nonetheless, there is sufficient evidence to support large-scale systematic clinical trials of adjunctive EFA supplementation to modify the course and severity of schizophrenia and depression as well as other clinical group previously characterized by in part n-3 deficiency.

FATTY ACIDS IN FOODS *and their* HEALTH IMPLICATIONS

THIRD EDITION

Since the publication of the bestselling second edition, mounting research into fatty acids reveals new and more defined links between the consumption of dietary fats and their biological health effects. Whether consuming omega-3 to prevent heart disease or avoiding *trans* fats to preserve heart health, it is more and more clear that not only the quantity but also the type of fatty acid play an important role in the etiology of the most common degenerative diseases. Keeping abreast of the mechanisms by which fatty acids exert their biological effects is crucial to unraveling the pathogenesis of a number of debilitating chronic disorders and can contribute to the development of effective preventive measures.

Retaining the highly detailed, authoritative quality of the previous editions**, Fatty Acids in Foods and their Health Implications, Third Edition** is thoroughly revised to incorporate the most recent research findings throughout the book.

New Chapters Include:

- Fatty Acids in Fermented Foods
- The Effects of Heating and Frying on Oils
- Consumption of Fatty Acids
- Significance of Dietary γ-Linolenate in Biological Systems: Alternation of Inflammation and Proliferative Process
- Biological Effects of Alpha-Linolenic Acid
- Biological Effects of Conjugated Linoleic Acid
- Fatty Acid and Cognition, Behavior and Brain Development, and Mood Disease
