When determining which anxiolytic and analgesic medications to initiate, the PICU provider should consider the underlying problem and the goals of treatment. It is important to distinguish between anxiety and pain, because pharmacologic therapy may be directed at either or both of these symptoms (Table 14–17). Additional considerations in sedative selection are the route of administration and the anticipated duration of treatment. Routes of administration may be limited by the patient's intravenous access or ability to tolerate oral medications. Children who will require more frequent dosing or tighter control of sedation level may benefit from a continuous infusion rather than intermittent dosing. Patients undergoing a bedside procedure, on the other hand, may only require a small number of discrete doses. Potential adverse effects are another important consideration in sedative and analgesic selection. For example, a medication known to cause hypotension may not be an optimal choice in a hemodynamically unstable child. Because of the known potential for adverse effects, all children should be appropriately monitored, with resuscitation equipment readily available.

Table 14–17. Commonly used intravenous medications for pain and anxiety control.

Drug	Suggested Starting Dose	Advantages	Disadvantages	Usual Duration of Effect
Morphine	0.1 mg/kg; continuous infusion, 0.05–0.1 mg/kg/h	Excellent pain relief, reversible	Respiratory depression, hypotension, nausea, suppression of GI motility, histamine release	2–4 h
Hydromorphone	0.015 mg/kg; continuous infusion, 1.5–3 mcg/kg/h	Good pain relief, reversible	Respiratory depression, histamine release, nausea, suppression of GI motility	2–4 h
Fentanyl	1–2 mcg/kg; continuous infusion, 0.5–2 mcg/kg/h	Excellent pain relief, reversible, short half-life	Respiratory depression, chest wall rigidity, severe nausea and vomiting	30 min
Midazolam	0.1 mg/kg; continuous infusion 0.05–0.2 mg/kg/h	Short half-life, only benzodiazepine given as continuous infusion	Respiratory depression	20–40 min
Lorazepam	0.1 mg/kg	Longer half-life, sedation and seizure control	Nausea and vomiting, respiratory depression, phlebitis	2–4 h
Diazepam	0.1 mg/kg	Sedation and seizure control	Respiratory depression, jaundice, phlebitis	1–3 h

▶ Sedation

Sedative (anxiolytic) medications may be indicated when the goals of treatment are to reduce anxiety, facilitate treatment or diagnostic procedures, manage acute confusional states, and diminish physiologic responses to stress, such as tachycardia, hypertension, or increased ICP. Although many classes of drugs cause sedation, the most commonly used classes in the PICU are the benzodiazepines and the opioids. These should be carefully titrated to effect to avoid over-sedation and resultant respiratory depression and/or hemodynamic instability.

▶ Benzodiazepines

The benzodiazepine class works through the neuroinhibitory transmitter γ-aminobutyric acid (GABA) system, resulting in anxiolysis, sedation, hypnosis, skeletal muscle relaxation and anticonvulsant effects. Benzodiazepines provide little to no analgesia and thus need to be combined with other medications when pain control is required.

Most benzodiazepines are metabolized in the liver, with their metabolites subsequently excreted in the urine; thus, patients in liver failure are likely to have long elimination times. Benzodiazepines can cause respiratory depression if given rapidly in high doses, an important consideration for the nonintubated patient. They can also cause cardiovascular compromise in the critically ill patient, making careful titration of doses essential.

In some children, benzodiazepines can cause a paradoxical effect, producing greater agitation than sedation. In those

cases, selection of an alternative agent may be more appropriate than escalation in dose. When overdose is a concern, flumazenil may be used to reverse benzodiazepine effects. Flumazenil must be used with care, however, as its effects generally wear off faster than those of most benzodiazepines. Additionally, in tolerant patients rapid reversal may result in benzodiazepine withdrawal symptoms, including seizures.

The three commonly used benzodiazepines in the PICU include midazolam, lorazepam, and diazepam. Each has differing half-lives, resulting in varying durations of effect, and multiple possible routes of administration. **Midazolam** has the shortest half-life and produces excellent retrograde amnesia lasting for 20–40 minutes after a single IV dose. Therefore, it can be used for short-term procedural sedation and anxiolysis with single or intermittent doses (IV, oral, intranasal) or for prolonged sedation as a continuous IV infusion. **Lorazepam** (PO, IV, or intramuscular) has a longer half-life than midazolam (or diazepam) and can achieve sedation for as long as 6–8 hours. It has less effect on the cardiovascular and respiratory systems than other benzodiazepines and is commonly used for short-term sedation or initial treatment of seizures. Continuous infusions of lorazepam should be avoided because its preservative, polyethylene glycol, can accumulate in patients with renal insufficiency and produce a metabolic acidosis. **Diazepam** has a longer half-life than midazolam and can be administered via IV, oral or rectal routes. It is used most commonly to treat muscle spasticity and seizures. A disadvantage of diazepam in the PICU is the long-half life of its intermediary metabolite, nordazepam, which may

accumulate and prolong sedation, making diazepam less ideal for short-term sedation.

Other Sedative Medications

Opioids are strong analgesics that also have sedative effects. They are commonly used as adjuncts in combination with other sedatives such as benzodiazepines. Specific medications are described further in the analgesic medication section below.

Ketamine (IV or IM) is a phencyclidine derivative that produces a trance-like state of immobility and amnesia known as dissociative anesthesia. Ketamine does not cause significant respiratory depression at non-anesthetic doses, an advantage for the nonintubated patient. Although it does have negative inotropic effects, this is countered by stimulation of the sympathetic nervous system resulting in an increase in heart rate, blood pressure, and cardiac output for most patients. This effect may make ketamine a good choice for hemodynamically unstable patients. Additionally, ketamine has bronchodilatory properties and, thus, may be an agent of choice for children with status asthmaticus. Finally, it has strong analgesic effects and therefore may be used as a single agent for sedation for painful procedures. The main side effects seen with ketamine are increased salivary and tracheobronchial secretions and unpleasant dreams or hallucinations. Atropine may be administered ahead of time to reduce secretions, and concurrent administration of benzodiazepines may reduce the hallucinatory effects. Although most frequently used for short-term sedation, low-dose continuous infusions may be used in selected patients.

Dexmedetomidine is an α_2-adrenoreceptor agonist that produces sedation with minimal respiratory depression and maintains the ability to rouse the patient easily if necessary. Dexmedetomidine does have some analgesic properties as well. These advantages have resulted in increasing use in critically ill children for procedural sedation as well as sedation to facilitate mechanical ventilation. The most frequent side effects observed are dose-related bradycardia and hypotension. Dexmedetomidine is primarily used as a short or long-term continuous infusion.

Propofol is an anesthetic IV induction agent with strong sedative effects. Its main advantages are a rapid recovery time and no cumulative effects resulting from its rapid hepatic metabolism. Because propofol has no analgesic properties, an analgesic agent should be concurrently administered for painful procedures. Propofol can cause significant vasodilation, resulting in dose-related hypotension, in addition to dose-dependent respiratory depression. Due to concerns for propofol infusion syndrome, a sudden-onset, profound, and often fatal acidosis associated with prolonged infusions, propofol is now used mostly for procedural or short-term sedation rather than prolonged sedation.

Barbiturates (phenobarbital and thiopental) can cause direct myocardial and respiratory depression and are, in general, poor choices for sedation of seriously ill patients. Phenobarbital has a very long half-life (up to 4 days), and recovery from thiopental, although it is a short-acting barbiturate, can be prolonged because remobilization from tissue stores occurs.

Analgesia

Opioid and nonopioid analgesics are the mainstay of treatment for acute and chronic pain in the PICU. Although several other medications used for sedation also have analgesic properties, they are uncommonly used for primary treatment of pain.

A. Opioid Analgesics

All drugs within the opioid class provide analgesia and have the potential for sedation that is dose-dependent. A range of plasma concentrations produce analgesia without sedation; the dose required to produce adequate analgesia varies significantly between patients. Therefore, the best approach to dosing with opioids is to start with a low-end dose but then titrate to effect, monitoring for side effects. The most common side effects of these agents are nausea, pruritis, slowed intestinal motility, miosis, cough suppression, and urinary retention. Opioids can also cause respiratory depression, particularly in infants. Morphine can cause histamine release leading to pruritus and even hypotension; fentanyl generally has few hemodynamic effects in a volume-replete patient. Opioids are metabolized in the liver, with metabolites excreted in the urine. Thus, patients with hepatic or renal impairment may have prolonged responses to their administration.

The choice and mode of delivery of agents within this class depends upon the physiologic state of the child and the etiology of pain. If the patient is awake and developmentally capable, a patient-controlled analgesia (PCA) approach with an infusion pump may be appropriate. Each of these medications may also be administered intermittently, in which case half-life and tolerability of side effects may be the primary considerations. For many patients in the pediatric ICU, a continuous infusion may be the best option. Several IV medications are commonly used as a continuous infusion or by PCA, including fentanyl, morphine and hydromorphone. For children who have more chronic, less severe pain and who can tolerate oral medications, there are many different options, including codeine, hydrocodone, hydromorphone, morphine, and oxycodone.

Naloxone may be used as an opioid reversal agent for narcotic overdoses. Because of its relatively short half-life compared to many opioids, symptoms may recur and repeat dosing may be necessary. Furthermore, caution should be used in patients with chronic opioid exposure to avoid precipitating severe withdrawal symptoms.

B. Nonopioid Analgesics

Nonopioid analgesics used in the treatment of mild to moderate pain include acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs). Because the effects of these agents can be additive with opiates, a combination of opiate and nonopiate medications can be a very effective approach to pain management in the ICU.

Acetaminophen is the most commonly used analgesic in pediatrics in the United States and is the drug of choice for mild to moderate pain because of its low toxicity and lack of effect on bleeding time. With chronic use and higher doses, acetaminophen may cause liver and renal toxicity.

Nonsteroidal anti-inflammatory drugs (NSAID) are reasonable alternatives for the treatment of pain, particularly those conditions associated with inflammation. All NSAIDs carry the risk of gastritis, renal compromise, and bleeding due to inhibition of platelet function. These side effects may limit use in patients with thrombocytopenia, bleeding, and kidney disease. *Ketorolac* is the only IV NSAID currently available. It can be very effective for children who cannot take oral medication or require a faster onset of action. Because of the concerns for more serious renal toxicity with longer-term use, ketorolac is primarily used for shorter-term pain control. *Ibuprofen* and *naproxen* are two oral NSAID options for patients who can tolerate oral medications. Ibuprofen has a shorter half-life and therefore requires more frequent dosing.

▶ Titration of Sedative and Analgesic Dosing, Delirium, and Withdrawal Syndromes

Recently, there has been an increasing appreciation of the disadvantages of sedative agents, including short- and long-term cognitive deficits, an increased risk of delirium, and withdrawal syndromes. Daily interruption of all continuous sedation with titrated reintroduction as necessary has been shown in adult ICU patients to dramatically reduce the duration of mechanical ventilation and length of stay in the ICU. Similar data are not yet available for pediatric patients but the untoward effects of sedation in critically ill children remain a concern and, in general, doses of these agents should be titrated downward daily to the minimum required doses.

Standardized scales have been developed to assist in the titration of sedatives and analgesics in children. In the awake and verbal patient, a pain scale can be used to determine the level of pain and need for treatment. In a nonverbal patient, this assessment can be more difficult, and the medical team may need to depend upon changes in physiologic parameters such as heart rate and blood pressure to indicate pain and the effect of treatment. When using these measures, however, the provider should also exclude or address physiologic causes of agitation, such as hypoxemia, hypercapnia, or cerebral hypoperfusion caused by low cardiac output.

Several scoring systems are available to assess the level of sedation and help guide sedation management decisions. These include the Ramsay scale, the COMFORT score, and the State Behavioral Scale (SBS). The SBS is the most recently developed and has been validated for infants and children who are mechanically ventilated. Utilizing such a measurement tool allows for better communication among team members with regard to the goals of treatment and the effectiveness of any changes in sedation plan.

As with adult patients, critically ill children are at risk for developing *delirium* while in the intensive care unit. Delirium may present with a wide variety of symptoms, commonly grouped as hypoactive or hyperactive. Hyperactive delirium is associated with restlessness, agitation, emotional lability and even combativeness. Hypoactive delirium, on the other hand, may be more difficult to recognize. With hypoactive delirium, patients may be quiet, withdrawn, and apathetic with decreased responsiveness. Parents may notice their child's personality is quite different from baseline. A newly developed PICU delirium scale (Pediatric Confusion Assessment Method for the ICU, or, pCAM-ICU) may help to better assess for delirium in the PICU population.

In critically ill children, as in adults, the risk of developing delirium appears to increase with severity of illness, administration of sedative medications such as benzodiazepines, and greater sleep disturbances. Preventing delirium completely may be difficult, but suggested strategies include avoiding over-sedation, changing environmental cues between day and night, and ensuring presence of parents and objects familiar to the child. Once delirium is present, returning to as normal a schedule and environment as possible can be very helpful. This includes promoting normal circadian rhythms, for example, greater activity during the day and quiet, dark rooms at night. Maintaining close involvement of family members may also bring reassurance and consistency for the child. Finally, in more extreme situations, treatment with medications can be considered. Antipsychotics may be used intermittently but with caution given their potential side effects. Benzodiazepines may calm the patient but also may induce a paradoxical reaction. Dexmedetomidine has also been proposed as an effective medication for treatment of delirium but this use has not been well studied in the pediatric population.

Withdrawal syndromes are another important aspect of the use of sedative and analgesic agents in the ICU. Long-term administration and high doses of continuous infusions of opioids or benzodiazepines can lead to tolerance and physical dependence. Acute reductions or cessation of these medications can result in withdrawal symptoms such as agitation, tachypnea, tachycardia, sweating, and diarrhea. The risk of withdrawal varies among individuals, but the longer patients receive opiates or benzodiazepines, the more likely they are to have withdrawal symptoms. Gradual tapering of the medication dosage over a period of 7–10 days often effectively prevents withdrawal symptoms. This gradual reduction

may be facilitated by transitioning to intermittent dosing of longer half-life agents, such as methadone or lorazepam. While weaning opiates or benzodiazepines, providers should assess daily for symptoms of withdrawal. This assessment can be facilitated by symptom scores such as the Withdrawal Assessment Tool-1 (WAT-1). A higher WAT-1 score suggests greater withdrawal symptoms and may indicate a need to slow the weaning plan. Conversely, if the WAT-1 score is consistently low, the patient is likely to tolerate the current pace or, possibly, an accelerated course of dose reduction.

END-OF-LIFE CARE AND DEATH IN THE PICU

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ End-of-life discussions in the PICU should include the patient, if possible, and family members as well as the medical team.

▶ PICU providers may assist in defining the limits of care provided, facilitating withdrawal of life support, and providing compassionate palliative care.

▶ The palliative care and ethics teams, if available, may facilitate end-of-life discussions in the PICU.

▶ Withdrawal of life-sustaining therapies should include a plan to treat any pain and discomfort in the patient.

▶ Brain death determination requires a systematic and age-appropriate evaluation consistent with institutional policies.

▶ Tissue and organ donation must be considered with every death.

▶ Grief/bereavement support for the family as well as medical team members should be provided following every death in the PICU.

▶ Death in the PICU

In-hospital pediatric deaths occur infrequently. A large proportion of pediatric deaths occur in the PICU, however, and the PICU provider may be called upon to help define the limits to care provided, assist in the withdrawal of life-sustaining medical therapies (LSMT), and provide compassionate palliative care. End-of-life discussions may have occurred prior to PICU admission for some children with congenital or chronic diseases. For other children, their PICU stay may be the first time a child or family discusses end-of-life decisions. Regardless of the individual patient's situation, the medical team has a responsibility to facilitate discussions regarding the goals of care in an honest and sensitive manner.

Deaths without any limitations on patient care comprise a small minority (10%–12%) of pediatric ICU deaths. In these circumstances, most recent studies have found greater family satisfaction with the care provided if family members are allowed to witness ongoing resuscitative efforts. The remainder of pediatric deaths is divided between brain death declarations (23%) and decisions to limit or withdraw medical care (65%).

▶ Brain Death

Severe neurologic injury can result in the irreversible loss of all brain functioning, or brain death. The concept of brain death arose when advances in ICU technologies allowed heart and lung function to be supported even in the absence of any brain activity. Brain death is diagnosed by a clinical examination (Table 14–18) and is based on published guidelines. The general approach in the diagnosis of brain death is similar in most medical centers, but there can be subtle institutional variations. Therefore, it is imperative for PICU providers performing the brain death examination to be familiar with their own institutional policies on brain death declaration. A patient declared brain dead is legally dead and further medical support is no longer indicated, though the timing of discontinuation of medical support should be discussed and agreed upon with the patient's family.

Brain death is determined through a complete clinical assessment of the patient. First and foremost, the provider must be confident that the patient's condition is irreversible and must exclude any potentially reversible conditions that may produce signs similar to brain death. These may include hypotension, hypothermia, or the presence of excessive doses of sedating medications. The brain death examination is a formal clinical examination directed at demonstrating the absence of cortical function (flaccid coma without evidence of response to stimuli) and brainstem function (cranial nerve testing). In order to meet the definition of brain death, guidelines require that qualified physicians document two separate clinical examinations consistent with brain death (ie, no evidence of brain function) separated by a

Table 14–18. Brain death examination.

- Patient must have normal blood pressure, core temperature > 35°C, normal electrolytes and glucose, and not be receiving sedating medications or muscle relaxants.
- 24 hour waiting period suggested following CPR or severe brain injury before first brain death exam.
- Flaccid coma with no evidence of cortical function.
- Absence of brain stem reflexes:
  - Apnea ("apnea test": no respirations seen with $Paco_2 > 60$ mm Hg and a change in $Paco_2 > 20$ mm Hg).
  - Fixed dilated pupils with no response to light.
  - Absence of corneal reflexes.
  - Absence of eye movements including spontaneous, oculocephalic (doll's eye), or oculovestibular (cold caloric). Do not perform oculocephalic maneuver if there is potential for cervical spine injury.
  - Absence of gag and cough reflex.
- Examination consistent throughout observation period as documented by two separate clinical examinations by two different attending physicians.
- Recommended observation periods between brain death examinations:
  - Term newborn to 30 days old—24 h
  - 31 days to 18 years—12 h
- Ancillary testing (cerebral angiography, radionuclide scanning, electroencephalography, or transcranial Doppler ultrasonography) recommended if unable to perform cranial nerve examination or apnea testing due to patient instability or injuries.

period of observation. If a patient cannot tolerate some portion of the clinical examination (typically apnea testing) or is very young (especially < 1 year of age), an ancillary test such as electroencephalography or cerebral perfusion scan may provide supporting evidence of brain death. Once a child has been declared brain dead, their time of death is noted as occurring at the completion of the second examination even if they are still receiving cardiopulmonary support.

▶ Limitation or Withdrawal of Medical Care

Most patients who die in the pediatric ICU will do so following a decision to limit or withdraw medical support rather than via a brain death declaration. The discussions leading to these decisions should include the patient (to the extent possible given their medical condition and developmental age), family members, and members of the medical team. The primary goals of these discussions should be (1) to communicate information regarding the patient's medical status and anticipated prognosis, and (2) to clarify the goals of ongoing medical care both in regard to the patient's current status and in the event of an acute decompensation. If the opinion of the medical team is that the patient's condition is likely irreversible, the options for care include (1) continuing current

support with escalation as deemed medically reasonable by the healthcare team; (2) continuing current support but not adding any new therapies; (3) withdrawal of life sustaining therapies such as mechanical ventilation and hemodynamic support. The first two options may include a decision to withhold cardiopulmonary resuscitation in the event of a respiratory or cardiac arrest (Do Not Attempt Resuscitation or DNAR). The third option presumes a DNAR but this must be explicitly written in the medical record and communicated to team members.

Discussions with patients and families regarding the decision to limit resuscitation or to withdraw LSMT should respect the following basic principles:

- Discussions should be conducted by experienced personnel with the ability to communicate in a clear and compassionate manner and should occur at an appropriate time and place.

- Cultural needs should be considered prior to major discussions and may include the need for a translator or spiritual guidance.

- Deliberations should begin with a clear statement that the goal is to make decisions in the best interest of the patient, and that the healthcare team can support the patient and family in making reasonable decisions based on that goal.

- Potential options regarding limitations of care or withdrawal of care should be clearly elucidated for the decision-makers.

- Withdrawal of LSMT can be considered when the pain and suffering inflicted by prolonging and supporting life outweighs the potential benefit for the individual. If there is no reasonable chance of recovery, the patient has the right to a natural death in a dignified and pain-free manner.

The healthcare team should emphasize that decisions are not irrevocable; if at any time the family or healthcare providers wish to reconsider the decision, full medical therapy can be reinstituted until the situation is clarified.

Prior to the withdrawal of LSMT, the patient's family and care team should be prepared for the physiologic process of dying that the child will undergo. Key facets of the process to discuss include the possibility of agonal respirations, which can be disturbing to witness for family members and care providers, as well as the unpredictable length of time that the process may require. Additionally, the fact that patient will ultimately have a cardiopulmonary arrest and a member of the medical team will declare the time of death should be discussed. The family should also be reassured that the patient will be given appropriate doses of medications to treat signs and symptoms of pain or discomfort and that neither they nor the patient will be abandoned by the medical team during this process.

▶ Palliative Care & Bioethics Consultation

Palliative care teams and ethics consultation services are essential resources to help the healthcare team and families address difficult end-of-life decision-making. For families of children with congenital or chronic diseases, the palliative care team may have established relationships with the patient and family during prior medical episodes. For patients with new conditions or whose prognosis has changed, the palliative care team may be newly introduced in the PICU. In either case, the palliative care team can bring invaluable support and resources for families during end-of-life discussions. If conflict arises, surrounding decisions about limiting medical care, an ethics consultation in the ICU setting can aid the process by helping to identify, analyze, and resolve ethical problems. Ethics consultation can independently clarify views and allow the healthcare team, patient, and family to make decisions that respect patient autonomy and promote maximum benefit and minimal harm to the patient.

A more comprehensive discussion of palliative care can be found elsewhere in this book. Briefly, palliative care medicine has developed as a specialized field of practice to address the needs of dying children or children with a shortened lifespan. Many centers have developed palliative care teams that include medical personnel, social workers, and spiritual leaders to help families navigate the difficult process of dying and end-of-life decision-making, including withdrawal of support. Once the decision is made to limit or withdraw LSMT, a palliative care plan should be agreed on by all decision-makers, clarified to other healthcare providers and instituted with the primary goal of optimizing the patient's and family's experience prior to and following death. The plan, at minimum, should address: (1) adequate pain control and sedation, (2) provision of warmth and cleanliness, and (3) ongoing patient and family support and dignity.

▶ Tissue & Organ Donation

Organ transplantation is standard therapy for many pediatric conditions and many children die while awaiting a transplant due to short supply of organs. The gift of organ donation can be a positive outcome for a family from the otherwise tragic loss of their child's life. The 1986 U.S. Federal Required Request Law mandates that all donor-eligible families be approached about potential organ donation. The decision to donate must be made free of coercion, with informed consent, and without financial incentive. The state organ-procurement agencies provide support and education to care providers and families to make informed decisions.

To be a solid organ donor, the patient must be declared dead and have no conditions contraindicating donation. The most frequent type of solid organ donor in the PICU is a brain dead donor. However, the need for new donor organs has led to the emergence of protocols for procuring solid organs from non-heart-beating donors. Although this practice has been described by many terms including Donation after Cardiac Death, the most recent nomenclature is Donation after Circulatory Determination of Death (DCDD). In these cases, the patient does not meet brain death criteria but has an irreversible disease process, and the family or patient has decided to withdraw life-sustaining therapy and consented to attempted organ donation. In the DCDD process, LSMT is withdrawn and comfort measures are provided as per usual care. The withdrawal of care may take place in the PICU or the operating room without any surgical staff present, depending upon institutional policy. Once the declaring physician has determined cessation of cardiac function, the patient is observed for an additional short time period for auto-resuscitation (the re-initiation of cardiac activity without medical intervention). After this waiting period, the patient is declared dead and the organs are harvested for donation. If the patient does not die within a predetermined time limit after discontinuation of LSMT, comfort measures continue but solid organ donation is abandoned due to unacceptably long ischemic times.

Tissue (heart valves, corneas, skin, and bone) can be donated following a "traditional" cardiac death (no pulse or respirations), brain death, or DCDD.

▶ Bereavement and Grief Support

After any pediatric death, bereavement and grief support for families and healthcare providers are essential components of comprehensive end-of-life care. Families may need information about care of the body after the death, funeral arrangements, and autopsy decisions as well as about educational, spiritual, and other supportive resources available. Members of the medical team may feel their own grief and sense of loss with the death of a patient. These emotions, if not appropriately addressed, can negatively affect their personal and professional lives. Therefore, similar supportive services should be available to healthcare workers caring for dying children.

▼ QUALITY IMPROVEMENT INITIATIVES IN THE PICU

There has been intense interest in quality improvement initiatives in adult and pediatric ICUs in recent years given

the frequency and high cost of ICU-related complications. National collaboratives have identified six areas of focus for pediatric ICU quality and safety improvement efforts: risk adjustment (severity-adjusted mortality rates and length of stay measures), central venous catheter infection, mechanical ventilation, unplanned readmissions to the PICU, pain assessment, and medication safety. The two most widely applied quality initiatives are efforts to reduce central venous catheter-related infections and to reduce the incidence of ventilator-associated pneumonia. Efforts to reduce catheter-related infections have largely focused on implementation of procedure checklists to ensure strict adherence to sterile procedure during catheter insertion, including hand hygiene, barrier precautions and site preparation, as well as sterile practice when accessing the catheter during care. Efforts to reduce

ventilator-associated pneumonias include defined order sets ("order bundles") for mechanically ventilated patients specifying patient positioning, oral care, feeding, and endotracheal tube suctioning practices in an effort to reduce contamination of the airway and endotracheal tube with bacterial pathogens from the patient's GI tract or caregivers. More recent efforts have begun to focus on early identification and treatment of sepsis using defined diagnostic triggers and order sets. Most of the data supporting these interventions have been derived from adult ICU populations, and, to date, few large scale studies have been published documenting efficacy of these measures in the pediatric ICU population. Data that are available suggest that these initiatives are beneficial, although additional studies will likely be needed to refine and optimize these approaches in the pediatric ICU setting.

▼ GENERAL PRINCIPLES

DIAGNOSIS OF SKIN DISORDERS

Examination of the skin requires that the entire surface of the body be palpated and inspected in good light. The onset and duration of each symptom should be recorded, together with a description of the primary lesion and any secondary changes, using the terminology in Table 15–1. In practice, characteristics of skin lesions are described in an order opposite to that shown in the table. Begin with distribution, then configuration, color, secondary changes, and primary changes. For example, guttate psoriasis could be described as "generalized, discrete, red, or scaly papules."

TREATMENT OF SKIN DISORDERS

Topical Therapy

Treatment should be simple and aimed at preserving normal skin physiology. Topical therapy is often preferred because medication can be delivered in optimal concentrations to the desired site.

Water is an important therapeutic agent, and optimally hydrated skin is soft and smooth. This occurs at approximately 60% environmental humidity. Because water evaporates readily from the cutaneous surface, skin hydration (stratum corneum of the epidermis) is dependent on the water concentration in the air, and sweating contributes little. However, if sweat is prevented from evaporating (eg, in the axilla, groin), local humidity and hydration of the skin are increased. As humidity falls below 15%–20%, the stratum corneum shrinks and cracks; the epidermal barrier is lost and allows irritants to enter the skin and induce an inflammatory response. Decrease of transepidermal water loss will correct this condition. Therefore, dry and scaly skin is treated by using barriers to prevent evaporation (Table 15–2). Oils and ointments prevent evaporation for 8–12 hours, so they must be applied once or twice a day. In areas already occluded (axilla, diaper area), creams or lotions are preferred, but more frequent application may be necessary.

Overhydration (maceration) can also occur. As environmental humidity increases to 90%–100%, the number of water molecules absorbed by the stratum corneum increases and the tight lipid junctions between the cells of the stratum corneum are gradually replaced by weak hydrogen bonds; the cells eventually become widely separated, and the epidermal barrier falls apart. This occurs in immersion foot, diaper areas, axillae, and the like. It is desirable to enhance evaporation of water in these areas by air drying.

Wet Dressings

By placing the skin in an environment where the humidity is 100% and allowing the moisture to evaporate to 60%, pruritus is relieved. Evaporation of water stimulates cold-dependent nerve fibers in the skin, and this may prevent the transmission of the itching sensation via pain fibers to the central nervous system. It also is vasoconstrictive, thereby helping to reduce the erythema and also decreasing the inflammatory cellular response.

The simplest form of wet dressing consists of one set of wet underwear (eg, long johns) worn under dry pajamas. Cotton socks are also useful for hand or foot treatment. The underwear should be soaked in warm (not hot) water and wrung out until no more water can be expressed. Dressings can be worn overnight for a few days up to 1 week. When the condition improves, wet dressings are discontinued.

Topical Glucocorticoids

Twice-daily application of topical corticosteroids is the mainstay of treatment for all forms of dermatitis (Table 15–3).

Table 15–1. Examination of the skin.

Clinical Appearance	Description and Examples
Primary lesions (first to appear)	
Macule	Any flat circumscribed color change in the skin < 1 cm. Examples: white (vitiligo), brown (junctional nevus), purple (petechia).
Patch	Any flat circumscribed color change in the skin > 1 cm. Examples: white (nevus depigmentosa), brown (café au lait macule), purple (purpura).
Papule	A solid, elevated area < 1 cm in diameter whose top may be pointed, rounded, or flat. Examples: acne, warts, small lesions of psoriasis.
Plaque	A solid, circumscribed area > 1 cm in diameter, usually flat-topped. Example: psoriasis.
Vesicle	A circumscribed, elevated lesion < 1 cm in diameter and containing clear serous fluid. Example: blisters of herpes simplex.
Bulla	A circumscribed, elevated lesion > 1 cm in diameter and containing clear serous fluid. Example: bullous impetigo.
Pustule	A vesicle containing a purulent exudate. Examples: acne, folliculitis.
Nodule	A deep-seated mass with indistinct borders that elevates the overlying epidermis. Examples: tumors, granuloma annulare. If it moves with the skin on palpation, it is intradermal; if the skin moves over the nodule, it is subcutaneous.
Wheal	A circumscribed, flat-topped, firm elevation of skin resulting from tense edema of the papillary dermis. Example: urticaria.
Secondary changes	
Scales	Dry, thin plates of keratinized epidermal cells (stratum corneum). Examples: psoriasis, ichthyosis.
Lichenification	Induration of skin with exaggerated skin lines and a shiny surface resulting from chronic rubbing of the skin. Example: chronic atopic dermatitis.
Erosion and oozing	A moist, circumscribed, slightly depressed area representing a blister base with the roof of the blister removed. Examples: burns, impetigo. Most oral blisters present as erosions.
Crusts	Dried exudate of plasma on the surface of the skin following disruption of the stratum corneum. Examples: impetigo, contact dermatitis.
Fissures	A linear split in the skin extending through the epidermis into the dermis. Example: angular cheilitis.
Scars	A flat, raised, or depressed area of fibrotic replacement of dermis or subcutaneous tissue. Examples: acne scar, burn scar.
Atrophy	Depression of the skin surface caused by thinning of one or more layers of skin. Example: lichen sclerosus.
Color	
	The lesion should be described as white, red, yellow, brown, tan, or blue. Particular attention should be given to the blanching of red lesions. Failure to blanch suggests bleeding into the dermis (petechiae).
Configuration of lesions	
Annular (circular)	Annular nodules represent granuloma annulare; annular scaly papules are more apt to be caused by dermatophyte infections.
Linear (straight lines)	Linear papules represent lichen striatus; linear vesicles, incontinentia pigmenti; linear papules with burrows, scabies.
Grouped	Grouped vesicles occur in herpes simplex or zoster.
Discrete	Discrete lesions are independent of each other.
Distribution	
	Note whether the eruption is generalized, acral (hands, feet, buttocks, face), or localized to a specific skin region.

Table 15–2. Bases used for topical preparations.

Base	Combined with	Uses
Foam		Cosmetically elegant; increasing number of products available
Liquids		Wet dressings: relieve pruritus, vasoconstrict
	Powder	Shake lotions, drying pastes: relieve pruritus, vasoconstrict
	Grease and emulsifier; oil in water	Cream: penetrates quickly (10–15 min) and thus allows evaporation
	Excess grease and emulsifier; water in oil	Emollient cream: penetrates more slowly and thus retains moisture on skin
Grease		Ointments: occlusive (hold material on skin for prolonged time) and prevent evaporation of water
Gel		Transparent, colorless, semisolid emulsion: nongreasy, more drying and irritating than cream
Powder		Enhances evaporation

Table 15–3. Topical glucocorticoids.

Glucocorticoid	Concentrations
Low potency[a] = 1–9	
Hydrocortisone	0.5%, 1%, 2.5%
Desonide	0.05%
Moderate potency = 10–99	
Mometasone furoate	0.1%
Hydrocortisone valerate	0.2%
Fluocinolone acetonide	0.025%
Triamcinolone acetonide	0.01%
Amcinonide	0.1%
High potency = 100–499	
Desoximetasone	0.25%
Fluocinonide	0.05%
Halcinonide	0.1%
Super potency = 500–7500	
Betamethasone dipropionate	0.05%
Clobetasol propionate	0.05%

[a]1% hydrocortisone is defined as having a potency of 1.

Topical steroids can also be used under wet dressings. After wet dressings are discontinued, topical steroids should be applied only to areas of active disease. They should never be applied to normal skin to prevent recurrence. Only low-potency steroids (see Table 15–3) are applied to the face or intertriginous areas.

Bewley A; Dermatology Working Group: Expert consensus: time for a change in the way we advise our patient to use topical corticosteroids. Br J Dermatol 2008;158:917 [PMID: 18294314].
Devillers AC, Oranje AP: Efficacy and safety of "wet wrap" dressings as an intervention treatment in children with severe and/or refractory atopic dermatitis: a critical review of the literature. Br J Dermatol 2006;154:579 [PMID: 16536797].
Nolan K, Marmur E: Moisturizers: reality and the skin benefits. Dermatol Ther 2012 May–Jun;25(3):229–233.

Characteristics of bases for topical preparations:

1. Thermolabile, low-residue foam vehicles are cosmetically acceptable and use a novel permeability pathway for delivery.

2. Most greases are triglycerides (eg, Aquaphor, petrolatum, Eucerin).

3. Oils are fluid fats (eg, Alpha Keri, olive oil, mineral oil).

4. True fats (eg, lard, animal fats) contain free fatty acids that cause irritation.

5. Ointments (eg, Aquaphor, petrolatum) should not be used in intertriginous areas such as the axillae, between the toes, and in the perineum, because they increase maceration. Lotions or creams are preferred in these areas.

6. Oils and ointments hold medication on the skin for long periods and are therefore ideal for barriers, prophylaxis, and for dried areas of skin. Medication penetrates the skin more slowly from ointments.

7. Creams carry medication into skin and are preferable for intertriginous dermatitis.

8. Foams, solutions, gels, or lotions should be used for scalp treatments.

▼ DISORDERS OF THE SKIN IN NEWBORNS

TRANSIENT DISEASES IN NEWBORNS

1. Milia

Milia are tiny epidermal cysts filled with keratinous material. These 1- to 2-mm white papules occur predominantly on the face in 40% of newborns. Their intraoral counterparts are called Epstein pearls and occur in up to 60%–85% of neonates. These cystic structures spontaneously rupture and exfoliate their contents.

2. Sebaceous Gland Hyperplasia

Prominent white to yellow papules at the opening of pilosebaceous follicles without surrounding erythema—especially over the nose—represent overgrowth of sebaceous glands in response to maternal androgens. They occur in more than half of newborns and spontaneously regress in the first few months of life.

3. Neonatal Acne

Inflammatory papules and pustules with occasional comedones predominantly on the face occur in as many as 20% of newborns. Although neonatal acne can be present at birth, it most often occurs between 2 and 4 weeks of age. Spontaneous resolution occurs over a period of 6 months to 1 year. A rare entity that is often confused with neonatal acne is **neonatal cephalic pustulosis.** This is a more monomorphic eruption with red papules and pustules on the head and neck that appears in the first month of life. There is associated neutrophilic inflammation and yeasts of the genus *Malassezia*. This eruption will resolve spontaneously, but responds to topical antiyeast preparations.

4. Harlequin Color Change

A cutaneous vascular phenomenon unique to neonates in the first week of life occurs when the infant (particularly one of low birth weight) is placed on one side. The dependent half develops an erythematous flush with a sharp demarcation at the midline, and the upper half of the body becomes pale. The color change usually subsides within a few seconds after the infant is placed supine but may persist for as long as 20 minutes.

5. Mottling

A lacelike pattern of bluish, reticular discoloration representing dilated cutaneous vessels appears over the extremities and often the trunk of neonates exposed to lowered room temperature. This feature is transient and usually disappears completely on rewarming.

6. Erythema Toxicum

Up to 50% of full-term infants develop erythema toxicum. At 24–48 hours of age, blotchy erythematous macules 2–3 cm in diameter appear, most prominently on the chest but also on the back, face, and extremities. These are occasionally present at birth. Onset after 4–5 days of life is rare. The lesions vary in number from a few up to as many as 100. Incidence is much higher in full-term versus premature infants. The macular erythema may fade within 24–48 hours or may progress to formation of urticarial wheals in the center of the macules or, in 10% of cases, pustules. Examination of a Wright-stained smear of the lesion reveals numerous eosinophils. No organisms are seen on Gram stain. These findings may be accompanied by peripheral blood eosinophilia of up to 20%. The lesions fade and disappear within 5–7 days. Transient neonatal pustular melanosis is a pustular eruption in newborns of African-American descent. The pustules rupture leaving a collarette of scale surrounding a macular hyperpigmentation. Unlike erythema toxicum, the pustules contain mostly neutrophils and often involve the palms and soles.

7. Sucking Blisters

Bullae, either intact or as erosions (representing the blister base) without inflammatory borders, may occur over the forearms, wrists, thumbs, or upper lip. These presumably result from vigorous sucking in utero. They resolve without complications.

8. Miliaria

Obstruction of the eccrine sweat ducts occurs often in neonates and produces one of two clinical scenarios. Superficial obstruction in the stratum corneum causes miliaria crystallina, characterized by tiny (1- to 2-mm), superficial grouped vesicles without erythema over intertriginous areas and adjacent skin (eg, neck, upper chest). More commonly, obstruction of the eccrine duct deeper in the epidermis results in erythematous grouped papules in the same areas and is called miliaria rubra. Rarely, these may progress to pustules. Heat and high humidity predispose the patient to eccrine duct pore closure. Removal to a cooler environment is the treatment of choice.

9. Subcutaneous Fat Necrosis

This entity presents in the first 7 days of life as reddish or purple, sharply circumscribed, firm nodules occurring over the cheeks, buttocks, arms, and thighs. Cold injury is thought to play an important role. These lesions resolve spontaneously over a period of weeks, although in some instances they may calcify. Affected infants should be screened for hypercalcemia.

Blume-Peytavi U et al: Skin care practices for newborns and infants: review of the clinical evidence for best practices. Pediatr Dermatol 2012 Jan–Feb;29(1):1–14 [PMID: 22011065].

PIGMENT CELL BIRTHMARKS, NEVI, & MELANOMA

Birthmarks may involve an overgrowth of one or more of any of the normal components of skin (eg, pigment cells, blood vessels, lymph vessels). A nevus is a hamartoma of highly differentiated cells that retain their normal function.

1. Mongolian Spot

A blue-black macule found over the lumbosacral area in 90% of infants of Native-American, African-American, and Asian descent is called a mongolian spot. These spots are occasionally noted over the shoulders and back and may extend over the buttocks. Histologically, they consist of spindle-shaped pigment cells located deep in the dermis. The lesions fade somewhat with time as a result of darkening of the overlying skin, but some traces may persist into adult life.

2. Café au Lait Macule

A café au lait macule is a light brown, oval macule (dark brown on brown or black skin) that may be found anywhere on the body. Café au lait spots over 1.5 cm in greatest diameter are found in 10% of white and 22% of black children. These lesions persist throughout life and may increase in number with age. The presence of six or more such lesions over 1.5 cm in greatest diameter is a major diagnostic criterion for neurofibromatosis type 1 (NF-1). Patients with McCune-Albright syndrome (see Chapter 34) have a large, unilateral café au lait macule.

3. Spitz Nevus

A Spitz nevus presents as a reddish-brown smooth solitary papule appearing on the face or extremities. Histologically, it consists of epithelioid and spindle shaped nevomelanocytes that may demonstrate nuclear pleomorphism. Although these lesions can look concerning histologically, they follow a benign clinical course in most cases.

MELANOCYTIC NEVI

1. Common Moles

Well-demarcated, brown to brown-black macules represent junctional nevi. They can appear in the first years of life and increase with age. Histologically, single and nested melanocytes are present at the junction of the epidermis and dermis. Approximately 20% may progress to compound nevi—papular lesions with melanocytes both in junctional and intradermal locations. Intradermal nevi are often lighter in color and can be fleshy and pedunculated. Melanocytes in these lesions are located purely within the dermis. Nevi look dark blue (blue nevi) when they contain more deeply situated spindle-shaped melanocytes in the dermis.

2. Melanoma

Melanoma in prepubertal children is very rare. Pigmented lesions with variegated colors (red, white, blue), notched borders, asymmetrical shape, and very irregular or ulcerated surfaces should prompt suspicion of melanoma. Ulceration and bleeding are advanced signs of melanoma. If melanoma is suspected, wide local excision and pathologic examination should be performed.

3. Congenital Melanocytic Nevi

One in 100 infants is born with a congenital nevus. Congenital nevi tend to be larger and darker brown than acquired nevi and may have many terminal hairs. If the pigmented plaque covers more than 5% of the body surface area, it is considered a giant or large congenital nevus; these large nevi occur in 1 in 20,000 infants. Other classification systems characterize lesions over 20 cm as large. Often the lesions are so large they cover the entire trunk (bathing trunk nevi). Histologically, they are compound nevi with melanocytes often tracking around hair follicles and other adnexal structures deep in the dermis. The risk of malignant melanoma in small congenital nevi is controversial in the literature, but most likely very low, and similar to that of acquired nevi. Transformation to malignant melanoma in giant congenital nevi has been estimated between 1% and 5%. Of note, these melanomas often develop early in life (before puberty) and in a dermal location. Two-thirds of melanomas in children with giant congenital nevi develop in areas other than the skin.

VASCULAR BIRTHMARKS

1. Capillary Malformations

▶ Clinical Findings

Capillary malformations are an excess of capillaries in localized areas of skin. The degree of excess is variable. The color of these lesions ranges from light red-pink to dark red.

Nevus simplex are the light red macules found over the nape of the neck, upper eyelids, and glabella of newborns. Fifty percent of infants have such lesions over their necks. Eyelid and glabellar lesions usually fade completely within the first year of life. Lesions that occupy the total central forehead area usually do not fade. Those on the neck persist into adult life.

Port-wine stains are dark red macules appearing anywhere on the body. A bilateral facial port-wine stain or one covering the entire half of the face may be a clue to Sturge-Weber syndrome, which is characterized by seizures, mental

retardation, glaucoma, and hemiplegia (see Chapter 25). Most infants with smaller, unilateral facial port-wine stains do not have Sturge-Weber syndrome. Similarly, a port-wine stain over an extremity may be associated with hypertrophy of the soft tissue and bone of that extremity (Klippel-Trénaunay syndrome).

▶ **Treatment**

The pulsed dye laser is the treatment of choice for infants and children with port-wine stains.

Richter GT, Friedman AB: Hemangiomas and vascular malformations: current theory and management. Int J Pediatr. 2012.

2. Hemangioma
▶ **Clinical Findings**

A red, rubbery vascular plaque or nodule with a characteristic growth pattern is a hemangioma. The lesion is often not present at birth but is represented by a permanent blanched area on the skin that is supplanted at age 2–4 weeks by red papules. Hemangiomas then undergo a rapid growth or "proliferative" phase, where growth of the lesion is out of proportion to growth of the child. At 9–12 months, growth stabilizes, and the lesion slowly involutes over the next several years. Histologically, hemangiomas are benign tumors of capillary endothelial cells. They may be superficial, deep, or mixed. The terms *strawberry* and *cavernous* are misleading and should not be used. The biologic behavior of a hemangioma is the same despite its location. Fifty percent reach maximal regression by age 5 years, 70% by age 7 years, and 90% by age 9 years, leaving redundant skin, hypopigmentation, and telangiectasia. Local complications include superficial ulceration and secondary pyoderma. Rare complications include obstruction of vital structures such as the orbit or airway.

▶ **Treatment**

Complications that require immediate treatment are (1) visual obstruction (with resulting amblyopia), (2) airway obstruction (hemangiomas of the head and neck ["beard hemangiomas"] may be associated with subglottic hemangiomas), and (3) cardiac decompensation (high-output failure). Historically, the preferred treatment for complicated hemangiomas has been prednisolone, 2–3 mg/kg orally daily for 6–12 weeks. Currently, oral propranolol (2 mg/kg/d divided BID) has replaced systemic steroids as the treatment of choice at most institutions. Reported side effects are sleep disturbance, hypoglycemia, and bradycardia. Recommendations on pretreatment cardiac evaluation vary between institutions. Interferon α_{2a} has also been used to treat serious hemangiomas. However, 10% of patients with hemangiomas treated with interferon α_{2a} have developed spastic diplegia, and its use is very limited. If the lesion is ulcerated or bleeding, pulsed dye laser treatment is indicated to initiate ulcer healing and immediately control pain. The Kasabach-Merritt syndrome, characterized by platelet trapping with consumption coagulopathy, does not occur with solitary cutaneous hemangiomas. It is seen only with internal hemangiomas or the rare vascular tumors such as kaposiform hemangioendotheliomas and tufted angiomas.

Bagazgoitia L et al: Propranolol for infantile hemangiomas. Pediatr Dermatol 2011 Mar–Apr;28(2):108–114.

3. Lymphatic Malformations

Lymphatic malformations may be superficial or deep. Superficial lymphatic malformations present as fluid-filled vesicles often described as resembling "frog spawn." Deep lymphatic malformations are rubbery, skin-colored nodules occurring most commonly in the head and neck. They often result in grotesque enlargement of soft tissues. Histologically, they can be either macrocystic or microcystic.

▶ **Treatment**

Therapy includes sclerotherapy with injection of picibanil, or doxycycline, radiotherapy, or surgical excision.

EPIDERMAL BIRTHMARKS

1. Epidermal Nevus
▶ **Clinical Findings**

The majority of these birthmarks present in the first year of life. They are hamartomas of the epidermis that are warty to papillomatous plaques, often in a linear array. They range in color from skin-colored to dirty yellow to brown. Histologically they show a thickened epidermis with hyperkeratosis. The condition of widespread epidermal nevi associated with other developmental anomalies (central nervous system, eye, and skeletal) is called the epidermal nevus syndrome.

▶ **Treatment**

Treatment once or twice daily with topical calcipotriene may flatten some lesions. The only definitive cure is surgical excision.

2. Nevus Sebaceus
▶ **Clinical Findings**

This is a hamartoma of sebaceous glands and underlying apocrine glands that is diagnosed by the appearance at birth of a yellowish, hairless plaque in the scalp or on the face. The lesions can be contiguous with an epidermal nevus on the face, and widespread lesions can constitute part of the epidermal nevus syndrome.

Histologically, nevus sebaceus represents an overabundance of sebaceous glands without hair follicles. At puberty, with androgenic stimulation, the sebaceous cells in the nevus divide, expand their cellular volume, and synthesize sebum, resulting in a warty mass.

▶ Treatment

Because it has been estimated that approximately 15% of these lesions will develop secondary epithelial tumors, including basal cell carcinomas (BCC), trichoblastomas, and other benign tumors, surgical excision at puberty is recommended by most experts. The majority of the tumors develop in adulthood, although BCCs have been reported in childhood and adolescence.

CONNECTIVE TISSUE BIRTHMARKS (JUVENILE ELASTOMA, COLLAGENOMA)

▶ Clinical Findings

Connective tissue nevi are smooth, skin-colored papules 1–10 mm in diameter that are grouped on the trunk. A solitary, larger (5–10 cm) nodule is called a shagreen patch and is histologically indistinguishable from other connective tissue nevi that show thickened, abundant collagen bundles with or without associated increases of elastic tissue. Although the shagreen patch is a cutaneous clue to tuberous sclerosis (see Chapter 25), the other connective tissue nevi occur as isolated events.

▶ Treatment

These nevi remain throughout life and need no treatment.

HEREDITARY SKIN DISORDERS

1. Ichthyosis

Ichthyosis is a term applied to several diseases characterized by the presence of excessive scales on the skin. These disorders represent a large and heterogeneous group of genetic and acquired defects of cornification of the skin. Classification of these diseases is clinically based, although the underlying genetic causes and pathophysiologic mechanisms responsible continue to be elucidated.

Disorders of keratinization are characterized as syndromic when the phenotype is expressed in the skin and other organs, or nonsyndromic when only the skin is affected. Ichthyoses may be inherited or acquired. Inherited disorders are identified by their underlying gene defect if known. Acquired ichthyosis may be associated with malignancy and medications, or a variety of autoimmune, inflammatory, nutritional, metabolic, infectious, and neurologic diseases. These disorders are diagnosed by clinical examination, with supportive findings on skin biopsy (including electron microscopy) and mutation analysis if available.

▶ Treatment

Treatment consists of controlling scaling with ammonium lactate (Lac-Hydrin or AmLactin) 12% or urea cream 10%–40% applied once or twice daily. Daily lubrication and a good dry skin care regimen are essential.

Oji V et al: Revised nomenclature and classification of inherited ichthyoses: results of the First Ichthyosis Consensus Conference in Sorèze 2009. J Am Acad Dermatol 2010 Oct;63(4):607–641.

2. Epidermolysis Bullosa

This is a group of heritable disorders characterized by skin fragility with blistering. Four major subtypes are recognized, based on the ultrastructural level of skin cleavage (Table 15–4).

For the severely affected, much of the surface area of the skin may have blisters and erosions, requiring daily wound care and dressings. These children are prone to frequent skin infections, anemia, growth problems, mouth erosions and esophageal strictures, and chronic pain issues. They are also at increased risk of squamous cell carcinoma, a common cause of death in affected patients.

▶ Treatment

Treatment consists of protection of the skin with topical emollients as well as nonstick dressings. The other medical needs and potential complications of the severe forms of epidermolysis bullosa require a multidisciplinary approach. For the less severe types, protecting areas of greatest trauma with padding and dressings as well as intermittent topical or oral antibiotics for superinfection are appropriate treatments. If hands and feet are involved, reducing skin friction with 5% glutaraldehyde every 3 days is helpful.

Fine JD et al: The classification of inherited epidermolysis bullosa (EB): report of the Third International Consensus Meeting on Diagnosis and Classification of EB. J Am Acad Dermatol 2008 Jun;58(6):931–950 [Epub 2008 Apr 18].

▼ COMMON SKIN DISEASES IN INFANTS, CHILDREN, & ADOLESCENTS

ACNE

Acne affects 85% of adolescents. The onset of adolescent acne is between ages 7 and 10 years in 40% of children. The early lesions are usually limited to the face and are primarily closed comedones.

▶ Pathogenesis

The primary event in acne formation is obstruction of the sebaceous follicle and subsequent formation of the microcomedo (not evident clinically). This is the precursor to all future

Table 15–4. Major epidermolysis bullosa subtypes.

Cleavage Level	Common Name	Targeted Protein(s)	Inheritance Pattern	Characteristic Clinical Features
Suprabasilar	Epidermolysis Bullosa Superficialis	Unknown	Autosomal dominant	Superficial erosions at birth; rare to no blistering
Suprabasilar	Plakophilin-deficient EB, Lethal acantholytic EB	Plakophilin, Desmoplakin	Autosomal recessive	Similar to above
Basilar	Epidermolysis bullosa simplex	Keratin 5 and 14	Autosomal dominant	Palm and sole blistering presents in early childhood with trauma
Basilar	EB simplex with muscular dystrophy	Plectin	Autosomal recessive	Blisters, muscular dystrophy
Basilar	EB with pyloric atresia	α-6 β-4 integrin	Autosomal recessive	Blisters, pyloric atresia
Junctional (within the basement membrane zone)	Junctional EB—Herlitz or non-Herlitz	Laminin 5, α-6 β-4 integrin, type XVII collagen	Autosomal recessive	Severe generalized blistering, oral involvement
Sub-basilar	Dystrophic EB or "dermolytic" EB	Type VII collagen	Autosomal dominant or recessive	Severe blisters and scarring

acne lesions. This phenomenon is androgen-dependent in adolescent acne. The four primary factors in the pathogenesis of acne are (1) plugging of the sebaceus follicle; (2) increased sebum production; (3) proliferation of *Propionibacterium acnes* in the obstructed follicle, and (4) inflammation. Many of these factors are influenced by androgens.

Drug-induced acne should be suspected in teenagers if all lesions are in the same stage at the same time and if involvement extends to the lower abdomen, lower back, arms, and legs. Drugs responsible for acne include corticotropin (ACTH), glucocorticoids, androgens, hydantoins, and isoniazid, each of which increases plasma testosterone.

▶ **Clinical Findings**

Open comedones are the predominant clinical lesion in early adolescent acne. The black color is caused by oxidized melanin within the stratum corneum cellular plug. Open comedones do not progress to inflammatory lesions. Closed comedones, or whiteheads, are caused by obstruction just beneath the follicular opening in the neck of the sebaceous follicle, which produces a cystic swelling of the follicular duct directly beneath the epidermis. Most authorities believe that closed comedones are precursors of inflammatory acne lesions (red papules, pustules, nodules, and cysts). In typical adolescent acne, several different types of lesions are present simultaneously. Severe, chronic, inflammatory lesions may rarely occur as interconnecting, draining sinus tracts. Adolescents with cystic acne require prompt medical attention, because ruptured cysts and sinus tracts result in severe scar formation.

▶ **Differential Diagnosis**

Consider rosacea, nevus comedonicus, flat warts, miliaria, molluscum contagiosum, and the angiofibromas of tuberous sclerosis.

▶ **Treatment**

Different treatment options are listed in Table 15–5. Recent data have indicated that combination therapy that targets multiple pathogenic factors increases the efficacy of treatment and rate of improvement.

A. Topical Keratolytic Agents

Topical keratolytic agents address the plugging of the follicular opening with keratinocytes and include retinoids, benzoyl peroxide, and azelaic acid. The first-line treatment for both comedonal and inflammatory acne is a topical retinoid (tretinoin [retinoic acid], adapalene, and tazarotene). These are the most effective keratolytic agents and have been shown to prevent the microcomedone. These topical agents may be used once daily, or the combination of a retinoid applied to acne-bearing areas of the skin in the evening and a benzoyl peroxide gel or azelaic acid applied in the morning may be used. This regimen will control 80%–85% of cases of adolescent acne.

B. Topical Antibiotics

Topical antibiotics are less effective than systemic antibiotics and at best are equivalent in potency to 250 mg of tetracycline orally once a day. One percent clindamycin phosphate

Table 15–5. Acne treatment.

Type of Lesion	Treatment

Comedonal acne	One of the following:
	    Tretinoin, 0.025, 0.05, or 0.1% cream; 0.01 or 0.025% gel; 0.4% or 0.1% microgel
	    Adapalene, 0.3% gel, 0.1% gel or solution; 0.05% cream

Papular inflammatory acne	One from first grouping, plus one of the following:
	    Benzoyl peroxide, 2.5, 4, 5, 8, or 10% gel or lotion; 4 or 8% wash
	    Azelaic acid, 15% or 20% cream
	    Clindamycin, 1% lotion, solution, or gel
	    Combination products include benzoyl peroxide-erythromycin (Benzamycin); benzoyl peroxide-clindamycin (Duac, BenzaClin, Acanya); tretinoin-clindamycin (Ziana, Veltin)

Pustular inflammatory acne	One from first grouping, plus one of the following oral antibiotics: Minocycline or doxycycline, 50–100 mg, bid
Nodulocystic acne	Isotretinoin, 1 mg/kg/d, goal dose 120–150 mg/kg total

solution is the most efficacious topical antibiotic. Most *P acnes* strains are now resistant to topical erythromycin solutions. Topical antibiotic therapy alone should never be used. Multiple studies have shown a combination of benzoyl peroxide or a retinoid and a topical antibiotic are more effective than the antibiotic alone. Benzoyl peroxide has been shown to help minimize the development of bacterial resistance at sites of application. The duration of application of topical antimicrobials should be limited unless benzoyl peroxide is used. Several combination products (benzoyl peroxide and clindamycin, tretinoin and clindamycin, adapalene and benzoyl peroxide) are available which may simplify the treatment regimen and increase patient compliance.

C. Systemic Antibiotics

Antibiotics that are concentrated in sebum, such as tetracycline, minocycline, and doxycycline, should be reserved for moderate to severe inflammatory acne. The usual dose of tetracycline is 0.5–1.0 g divided twice a day on an empty stomach; minocycline and doxycycline 50–100 mg taken once or twice daily can be taken with food. Monotherapy with oral antibiotics should never be used. Recent recommendations are that oral antibiotics should be used for a finite time period, and then discontinued as soon as there is improvement in the inflammatory lesions. The tetracycline antibiotics should not be given to children younger than 8 years of age due to the effect on dentition (staining of teeth).

Doxycycline may induce significant photosensitivity, and minocycline can cause bluish-gray dyspigmentation of the skin, vertigo, headaches, and drug-induced lupus. These antibiotics have anti-inflammatory effects in addition to decreasing *P acnes* in the follicle.

D. Oral Retinoids

An oral retinoid, 13-*cis*-retinoic acid (isotretinoin; Accutane), is the most effective treatment for severe cystic acne. The precise mechanism of its action is unknown, but apoptosis of sebocytes, decreased sebaceous gland size, decreased sebum production, decreased follicular obstruction, decreased skin bacteria, and general anti-inflammatory activities have been described. The initial dosage is 0.5–1 mg/kg/d. This therapy is reserved for severe nodulocystic acne, or acne recalcitrant to aggressive standard therapy. Side effects include dryness and scaling of the skin, dry lips, and, occasionally, dry eyes and dry nose. Fifteen percent of patients may experience some mild achiness with athletic activities. Up to 10% of patients experience mild, reversible hair loss. Elevated liver enzymes and blood lipids have rarely been described. Acute depression may occur. Isotretinoin is teratogenic in young women of childbearing age. Because of this and the other side effects, it is not recommended unless strict adherence to the Food and Drug Administration (FDA) guidelines is ensured. The FDA has implemented a strict registration program (iPLEDGE) that must be used to obtain isotretinoin.

E. Other Acne Treatments

Hormonal therapy (oral contraceptives) is often an effective option for girls who have perimenstrual flares of acne or have not responded adequately to conventional therapy. Adolescents with endocrine disorders such as polycystic ovary syndrome also see improvement of their acne with hormonal therapy. Oral contraceptives can be added to a conventional therapeutic regimen and should always be used in female patients who are prescribed oral isotretinoin unless absolute contraindications exist. There is growing data regarding the use of light, laser, and photodynamic therapy in acne. However, existing studies are of variable quality, and although there is evidence to suggest that these therapies offer benefit in acne, the evidence is not sufficient to recommend any device as monotherapy in acne.

F. Patient Education and Follow-Up Visits

The multifactorial pathogenesis of acne and its role in the treatment plan must be explained to adolescent patients. Good general skin care includes washing the face consistently and using only oil-free, noncomedogenic cosmetics, face creams, and hair sprays. Acne therapy takes 8–12 weeks to produce improvement, and this delay must be stressed to the patient. Realistic expectations should be encouraged

in the adolescent patient because no therapy will eradicate all future acne lesions. A written education sheet is useful. Follow-up visits should be made every 12–16 weeks. An objective method to chart improvement should be documented by the provider, because patients' assessment of improvement tends to be inaccurate.

BACTERIAL INFECTIONS OF THE SKIN

1. Impetigo

Erosions covered by honey-colored crusts are diagnostic of impetigo. Staphylococci and group A streptococci are important pathogens in this disease, which histologically consists of superficial invasion of bacteria into the upper epidermis, forming a subcorneal pustule.

▶ Treatment

Impetigo should be treated with an antimicrobial agent effective against *Staphylococcus aureus* (β-lactamase–resistant penicillins or cephalosporins, clindamycin, amoxicillin–clavulanate) for 7–10 days. Topical mupirocin and fusidic acid (three times daily) are also effective.

2. Bullous Impetigo

All impetigo is bullous, with the blister forming just beneath the stratum corneum, but in "bullous impetigo" there is, in addition to the usual erosion covered by a honey-colored crust, a border filled with clear fluid. Staphylococci may be isolated from these lesions, and systemic signs of circulating exfoliatin are absent. Bullous impetigo lesions can be found anywhere on the skin, but a common location is the diaper area.

▶ Treatment

Treatment with oral antistaphylococcal drugs for 7–10 days is effective. Application of cool compresses to debride crusts is a helpful symptomatic measure.

3. Ecthyma

Ecthyma is a firm, dry crust, surrounded by erythema that exudes purulent material. It represents invasion by group A β-hemolytic streptococci through the epidermis to the superficial dermis. This should not be confused with ecthyma gangrenosum. Lesions of ecthyma gangrenosum may be similar in appearance, but they are seen in a severely ill or immunocompromised patient and are due to systemic dissemination of bacteria, usually *Pseudomonas aeruginosa,* through the bloodstream.

▶ Treatment

Treatment is with systemic penicillin.

4. Cellulitis

Cellulitis is characterized by erythematous, hot, tender, ill-defined, edematous plaques accompanied by regional lymphadenopathy. Histologically, this disorder represents invasion of microorganisms into the lower dermis and sometimes beyond, with obstruction of local lymphatics. Group A β-hemolytic streptococci and coagulase-positive staphylococci are the most common causes; pneumococci and *Haemophilus influenzae* are rare causes. Staphylococcal infections are usually more localized and more likely to have a purulent center; streptococcal infections spread more rapidly, but these characteristics cannot be used to specify the infecting agent. An entry site of prior trauma or infection (eg, varicella) is often present. Septicemia is a potential complication.

▶ Treatment

Treatment is with an appropriate systemic antibiotic.

5. Folliculitis

A pustule at a follicular opening represents folliculitis. Deeper follicular infections are called furuncles (single follicle) and carbuncles (multiple follicles). Staphylococci and streptococci are the most frequent pathogens. Lesions are painless and tend to occur in crops, usually on the buttocks and extremities in children. Methicillin-resistant *Staphylococcus aureus* (MRSA) is now an increasing cause of folliculitis and skin abscesses. Cultures of persistent or recurrent folliculitis for MRSA are advisable.

▶ Treatment

Treatment consists of measures to remove follicular obstruction—either warm, wet compresses for 24 hours or keratolytics such as those used for acne. Topical or oral antistaphylococcal antibiotics may be required.

6. Abscess

An abscess occurs deep in the skin, at the bottom of a follicle or an apocrine gland, and is diagnosed as an erythematous, firm, acutely tender nodule with ill-defined borders. Staphylococci are the most common organisms.

Treatment

Treatment consists of incision and drainage and may require adjuvant systemic antibiotics. Recent studies have suggested that incision and drainage alone may be adequate for uncomplicated MRSA skin abscesses in otherwise healthy patients.

7. Scalded Skin Syndrome

This entity consists of the sudden onset of bright red, acutely painful skin, most obvious periorally, periorbitally, and in the flexural areas of the neck, the axillae, the popliteal and antecubital areas, and the groin. The slightest pressure on the skin results in severe pain and separation of the epidermis, leaving a glistening layer (the stratum granulosum of the epidermis) beneath. The disease is caused by a circulating toxin (exfoliatin) elaborated by phage group II staphylococci. Exfoliatin binds to desmoglein-1 resulting in a separation of cells in the granular layer. The causative staphylococci may be isolated not from the skin but rather from the nasopharynx, an abscess, sinus, blood culture, joint fluid, or other focus of infection.

Treatment

Treatment is with systemic antistaphylococcal drugs.

Zabielinski M et al: Trends and antibiotic susceptibility patterns of methicillin-resistant and methicillin-sensitive *Staphylococcus aureus* in an outpatient dermatology facility. JAMA Dermatol 2013 Apr;4(149):427–432 [PMID 23325388].

FUNGAL INFECTIONS OF THE SKIN

1. Dermatophyte Infections

Dermatophytes become attached to the superficial layer of the epidermis, nails, and hair, where they proliferate. Fungal infection should be suspected with any red and scaly lesion.

Classification & Clinical Findings

A. Tinea Capitis

Thickened, broken-off hairs with erythema and scaling of underlying scalp are the distinguishing features (Table 15–6). Hairs are broken off at the surface of the scalp, leaving a "black dot" appearance. Diffuse scaling of the scalp and pustules are also seen. A boggy, fluctuant mass on the scalp called a kerion, represents an exaggerated host response to the organism. *Microsporum canis* and *Trichophyton tonsurans* are the cause. Fungal culture should be performed in all cases of suspected tinea capitis.

B. Tinea Corporis

Tinea corporis presents either as annular marginated plaques with a thin scale and clear center or as an annular confluent dermatitis. The most common organisms are *Trichophyton*

Table 15–6. Clinical features of tinea capitis.

Most Common Organisms	Clinical Appearance	Microscopic Appearance in KOH
Trichophyton tonsurans (90%)	Hairs broken off 2–3 mm from follicle; "black dot"; diffuse pustule; seborrheic dermatitis-like; no fluorescence	Hyphae and spores within hair
Microsporum canis (10%)	Thickened broken-off hairs that fluoresce yellow-green with Wood lamp	Small spores outside of hair; hyphae within hair

mentagrophytes, Trichophyton rubrum, and *M canis*. The diagnosis is made by scraping thin scales from the border of the lesion, dissolving them in 20% potassium hydroxide (KOH), and examining for hyphae.

C. Tinea Cruris

Symmetrical, sharply marginated lesions in inguinal areas occur with tinea cruris. The most common organisms are *T rubrum, T mentagrophytes,* and *Epidermophyton floccosum.*

D. Tinea Pedis

The diagnosis of tinea pedis is becoming more common in the prepubertal child, although it is still most commonly seen in postpubertal males. Presentation is with red scaly soles, blisters on the instep of the foot, or fissuring between the toes. *T rubrum* and *T mentagrophytes* are the cause.

E. Tinea Unguium (Onychomycosis)

Loosening of the nail plate from the nail bed (onycholysis), giving a yellow discoloration, is the first sign of fungal invasion of the nails. Thickening of the distal nail plate then occurs, followed by scaling and a crumbly appearance of the entire nail plate surface. *T rubrum* is the most common cause. The diagnosis is confirmed by KOH examination and fungal culture. Usually only one or two nails are involved. If every nail is involved, psoriasis, lichen planus, or idiopathic trachyonychia is a more likely diagnosis than fungal infection.

Treatment

The treatment of dermatophytosis is quite simple: If hair is involved, systemic therapy is necessary. Griseofulvin and terbinafine are both effective. Terbinafine does not work for Microsporum canis. Topical antifungal agents do not enter hair or nails in sufficient concentration to clear the infection. The absorption of griseofulvin from the gastrointestinal

tract is enhanced by a fatty meal; thus, whole milk or ice cream taken with the medication increases absorption. The dosage of griseofulvin is 20 mg/kg/d (maximum 500 mg/dose). With hair infections, cultures should be done every 4 weeks, and treatment should be continued for 4 weeks following a negative culture result. The side effects are few, and the drug has been used successfully in the newborn period. Terbinafine dosing is (62.5 mg/d, < 20 kg–125 mg/d, 20–40 kg–250 mg/d, > 40 kg). For nails, daily administration of topical ciclopirox 8% (Penlac nail lacquer) can be considered, as can terbinafine for 6–12 weeks or pulsed-dose itraconazole (50 mg/twice a day < 20 kg–100 mg/twice a day, 20–40 kg–200 mg/twice a day, > 40 kg) given in three 1-week pulses separated by 3 weeks.

Tinea corporis, tinea pedis, and tinea cruris can be treated effectively with topical medication after careful inspection to make certain that the hair and nails are not involved. Treatment with any of the imidazoles, allylamines, benzylamines, or ciclopirox applied twice daily for 3–4 weeks is recommended.

Kelly BP: Superficial fungal infections. Pediatr Rev 2012;33: e22–e37 [PMID: 22474120].

2. Tinea Versicolor

Tinea versicolor is a superficial infection caused by *Malassezia globosa,* a yeastlike fungus. It characteristically causes polycyclic connected hypopigmented macules and very fine scales in areas of sun-induced pigmentation. In winter, the polycyclic macules appear reddish brown.

▶ Treatment

Treatment consists of application of selenium sulfide (Selsun), 2.5% suspension, zinc pyrithione shampoo, or topical antifungals. Selenium sulfide and zinc pyrithione shampoo should be applied to the whole body and left on overnight. Treatment can be repeated again in 1 week and then monthly thereafter. It tends to be somewhat irritating, and the patient should be warned about this difficulty. Topical antifungals are applied twice a day for 1–2 weeks. Fluconazole 400 mg single dose may also be used.

3. Candida albicans Infections (See also Chapter 43)
▶ Clinical Findings

Candida albicans causes diaper dermatitis; thick, white patches on the oral mucosa (thrush); fissures at the angles of the mouth (perleche); and periungual erythema and nail plate abnormalities (chronic paronychia). Candida dermatitis is characterized by sharply defined erythematous patches, sometimes with eroded areas. Pustules, vesicles, or papules may be present as satellite lesions. Similar infections may be found in other moist areas, such as the axillae and neck folds. This infection is more common in children who have recently received antibiotics.

▶ Treatment

A topical imidazole cream is the drug of first choice for *C albicans* infections. In diaper dermatitis, the cream form can be applied twice a day. In oral thrush, nystatin suspension should be applied directly to the mucosa with the parent's finger or a cotton-tipped applicator. In candidal paronychia, the antifungal agent is applied over the area, covered with occlusive plastic wrapping, and left on overnight after the application is made airtight. Refractory candidiasis will respond to a brief course of oral fluconazole.

VIRAL INFECTIONS OF THE SKIN (SEE ALSO CHAPTER 40)

1. Herpes Simplex Infection
▶ Clinical Findings

Painful, grouped vesicles or erosions on a red base suggest herpes simplex. Rapid immunofluorescent tests for herpes simplex virus (HSV) and varicella-zoster virus (VZV) are available. A Tzanck smear is done by scraping a vesicle base with a No. 15 blade, smearing on a glass slide, and staining the epithelial cells with Wright stain. The smear is positive if epidermal multinucleated giant cells are visualized. A positive Tzanck smear indicates herpesvirus infection (HSV or VZV). In infants and children, lesions resulting from herpes simplex type 1 are seen most commonly on the gingiva, lips, and face. Involvement of a digit (herpes whitlow) will occur if the child sucks the thumb or fingers. Herpes simplex type 2 lesions are seen on the genitalia and in the mouth in adolescents. Cutaneous dissemination of herpes simplex occurs in patients with atopic dermatitis (eczema herpeticum) and appears clinically as very tender, punched-out erosions among the eczematous skin changes.

▶ Treatment

The treatment of HSV infections is discussed in Chapter 46.

2. Varicella-Zoster Infection
▶ Clinical Findings

Grouped vesicles in a dermatome, usually on the trunk or face, suggest varicella-zoster reactivation. Zoster in children may not be painful and usually has a mild course. In patients with compromised host resistance, the appearance of an erythematous border around the vesicles is a good prognostic sign. Conversely, large bullae without a tendency to crusting and systemic illness imply a poor host response to the virus.

Varicella-zoster and herpes simplex lesions undergo the same series of changes: papule, vesicle, pustule, crust, slightly depressed scar. Lesions of primary varicella appear in crops, and many different stages of lesions are present at the same time (eg, papules), eccentrically placed vesicles on an erythematous base ("dew drop" on a rose petal), erosions, and crusts.

▶ Treatment

The treatment of VZV infections is discussed in Chapter 46.

3. Human Immunodeficiency Virus Infection (See also Chapter 41)
▶ Clinical Findings

The average time of onset of skin lesions after perinatally acquired HIV infection is 4 months; after transfusion-acquired infection, it is 11 months. Persistent oral candidiasis and recalcitrant candidal diaper rash are the most frequent cutaneous features of infantile HIV infection. Severe or recurrent herpetic gingivostomatitis, varicella zoster infection, and molluscum contagiosum infection occur. Recurrent staphylococcal pyodermas, tinea of the face, and onychomycosis are also observed. A generalized dermatitis with features of seborrhea (severe cradle cap) is extremely common. In general, persistent, recurrent, or extensive skin infections should make one suspicious of HIV infection.

▶ Treatment

The treatment of HIV infections is discussed in Chapter 46.

VIRUS-INDUCED TUMORS

1. Molluscum Contagiosum

Molluscum contagiosum is a poxvirus that induces the epidermis to proliferate, forming a pale papule. Molluscum contagiosum consists of umbilicated, flesh-colored papules in groups anywhere on the body. They are common in infants and preschool children, as well as sexually active adolescents.

▶ Treatment

Treatment for molluscum is either immunological (topical imiquimod, oral cimetidine, intralesional candida antigen injection) or cytodestructive (topical cantharidin, cryotherapy with liquid nitrogen, and curettage). Left untreated, the lesions resolve over months to years.

2. Warts

Warts are skin-colored papules with rough (verrucous) surfaces caused by infection with human papillomavirus (HPV). There are over 200 types of this DNA virus, which induces the epidermal cells to proliferate, thus resulting in the warty growth. Flat warts are smoother and smaller than common warts and are often seen on the face. Certain types of HPV are associated with certain types of warts (eg, flat warts) or location of warts (eg, genital warts).

▶ Treatment

Thirty percent of warts will clear in 6 months. As with molluscum, the treatment of warts is also immunological (topical imiquimod, oral cimetidine, intralesional candida antigen injection, and squaric acid contact therapy) or cytodestructive. Liquid nitrogen is painful, user dependent, and can lead to blistering and scarring. Topical salicylic acid may also be used. Large mosaic plantar warts are treated most effectively by applying 40% salicylic acid plaster cut with a scissors to fit the lesion. The adhesive side of the plaster is placed against the lesion and taped securely in place with duct or athletic tape. The plaster and tape should be placed on Monday and removed on Friday. Over the weekend, the patient should soak the skin in warm water for 30 minutes to soften it. Then the white, macerated tissue should be pared with a pumice stone, cuticle scissors, or a nail file. This procedure is repeated every week, and the patient is seen every 4 weeks. Most plantar warts resolve in 6–8 weeks when treated in this way. Vascular pulsed dye lasers are a useful adjunct therapy for the treatment of plantar warts.

For flat warts, a good response to 0.025% tretinoin gel or topical imiquimod (Aldara) cream, applied once daily for 3–4 weeks, has been reported.

Surgical excision, electrosurgery, and nonspecific burning laser surgery should be avoided; these modalities do not have higher cure rates and result in scarring. Cantharidin may cause small warts to become large warts and should not be used.

Venereal warts (condylomata acuminata) (see Chapter 44) may be treated with imiquimod, 25% podophyllum resin (podophyllin) in alcohol, or podofilox, a lower concentration of purified podophyllin, which is applied at home. Podophyllin should be painted on the lesions in the practitioner's office and then washed off after 4 hours. Re-treatment in 2–3 weeks may be necessary. Podofilox is applied by the patient once daily, Monday through Thursday, whereas imiquimod is used three times a week on alternating days. Lesions not on the vulvar mucous membrane but on the adjacent skin should be treated as a common wart and frozen.

No wart therapy is immediately and definitively successful. Realistic expectations should be set and appropriate follow-up treatments scheduled.

INSECT INFESTATIONS

1. Scabies
▶ Clinical Findings

Scabies is suggested by linear burrows about the wrists, ankles, finger webs, areolas, anterior axillary folds, genitalia,

or face (in infants). Often there are excoriations, honey-colored crusts, and pustules from secondary infection. Identification of the female mite or her eggs and feces is necessary to confirm the diagnosis. Apply mineral oil to a No. 15 blade and scrape an unscratched papule or burrow and examine microscopically to confirm the diagnosis. In a child who is often scratching, scrape under the fingernails. Examine the parents for unscratched burrows.

▶ Treatment

Permethrin 5% is the treatment of choice for scabies. It should be applied as a single overnight application and repeated in 7 days. Oral ivermectin 200 mcg/dose × 1 and repeated in 7 days may be used in resistant cases.

2. Pediculoses (Louse Infestations)
▶ Clinical Findings

The presence of excoriated papules and pustules and a history of severe itching at night suggest infestation with the human body louse. This louse may be discovered in the seams of underwear but not on the body. In the scalp hair, the gelatinous nits of the head louse adhere tightly to the hair shaft. The pubic louse may be found crawling among pubic hairs, or blue-black macules may be found dispersed through the pubic region (maculae cerulea). The pubic louse is often seen on the eyelashes of newborns.

▶ Treatment

Initial treatment of head lice is often instituted by parents with an over-the-counter pyrethrin or permethrin product. If head lice are not eradicated after two applications 7 days apart with these products, malathion 0.5% is highly effective but is toxic if ingested, and flammable. A second application 7–9 days after initial treatment may be necessary. Treatment of pubic lice is similar. Treatment of body lice is clean clothing and washing the infested clothing at high temperature.

3. Papular Urticaria
▶ Clinical Findings

Papular urticaria is characterized by grouped erythematous papules surrounded by an urticarial flare and distributed over the shoulders, upper arms, legs, and buttocks in infants. Although not a true infestation, these lesions represent delayed hypersensitivity reactions to stinging or biting insects. Fleas from dogs and cats are the usual offenders. Less commonly, mosquitoes, lice, scabies, and bird and grass mites are involved. The sensitivity is transient, lasting 4–6 months. Usually no other family members are affected. It is often difficult for the parents to understand why no one else is affected.

▶ Treatment

The logical therapy is to remove the offending insect, although in most cases it is very difficult to identify the exact cause. Topical corticosteroids and oral antihistamines will control symptoms.

DERMATITIS (ECZEMA)

The terms *dermatitis* and *eczema* are currently used interchangeably in dermatology, although the term *eczema* truly denotes an acute weeping dermatosis. All forms of dermatitis, regardless of cause, may present with acute edema, erythema, and oozing with crusting, mild erythema alone, or lichenification. Lichenification is diagnosed by thickening of the skin with a shiny surface and exaggerated, deepened skin markings. It is the response of the skin to chronic rubbing or scratching.

Although the lesions of the various dermatoses are histologically indistinguishable, clinicians have nonetheless divided the disease group called dermatitis into several categories based on known causes in some cases and differing natural histories in others.

1. Atopic Dermatitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Dry skin
▶ Presence of eczema
▶ Onset before 2 years of age

▶ Pathogenesis

Atopic dermatitis is a polygenic disease with positive and negative modifiers. Atopic dermatitis results from an interaction among susceptibility genes, the host environment, skin barrier defects, pharmacologic abnormalities, and immunologic response. The case for food and inhalant allergens as specific causes of atopic dermatitis is not strong. There is significant evidence that a primary defect in atopic dermatitis is an abnormality in the skin barrier formation due to defects in the filaggrin gene. Not all people with filaggrin abnormalities have atopic dermatitis and not all people with atopic dermatitis have filaggrin abnormalities.

▶ Clinical findings
A. Symptoms & Signs

Many (not all) patients go through three clinical phases. In the first, infantile eczema, the dermatitis begins on the

cheeks and scalp and frequently expresses itself as oval patches on the trunk, later involving the extensor surfaces of the extremities. The usual age at onset is 2–3 months, and this phase ends at age 18 months to 2 years. Only one-third of all infants with infantile eczema progress to phase 2 childhood or flexural eczema in which the predominant involvement is in the antecubital and popliteal fossae, the neck, the wrists, and sometimes the hands or feet. This phase lasts from age 2 years to adolescence. Only one-third of children with typical flexural eczema progress to adolescent eczema, which is usually manifested by the continuation of chronic flexural eczema along with hand and/or foot dermatitis. Atopic dermatitis is quite unusual after age 30 years.

▶ Differential Diagnosis

All other types of dermatitis must be considered.

A few patients with atopic dermatitis have immunodeficiency with recurrent pyodermas, unusual susceptibility to herpes simplex viruses, hyperimmunoglobulinemia E, defective neutrophil and monocyte chemotaxis, and impaired T-lymphocyte function (see Chapter 33).

▶ Complications

A faulty epidermal barrier predisposes the patient with atopic dermatitis to dry, itchy skin. Inability to hold water within the stratum corneum results in rapid evaporation of water, shrinking of the stratum corneum, and cracks in the epidermal barrier. Such skin forms an ineffective barrier to the entry of various irritants. Chronic atopic dermatitis is frequently infected secondarily with *S aureus* or *Streptococcus pyogenes.* Herpes simplex virus may also superinfect atopic dermatitis and severe widespread disease is known as Kaposi's varicelliform eruption or eczema herpeticum. Patients with atopic dermatitis have a deficiency of antimicrobial peptides in their skin, which may account for the susceptibility to recurrent skin infection.

▶ Treatment

A. Acute Stages

Application of wet dressings and medium-potency topical corticosteroids is the treatment of choice for acute, weeping atopic eczema. The use of wet dressings is outlined at the beginning of this chapter. Superinfection with *S aureus*, *Streptococcus pyogenes,* and herpes simplex virus may occur, and appropriate systemic therapy may be necessary. If the expected improvement is not seen, bacterial and HSV cultures should be obtained to identify the possibility of a superinfection.

B. Chronic Stages

Treatment is aimed at avoiding irritants and restoring water to the skin. No soaps or harsh shampoos should be used, and the patient should avoid woolen or any rough clothing. Bathing is minimized to every second or third day. Twice daily lubrication of the skin is very important.

Nonperfumed creams or lotions are suitable lubricants. Plain petrolatum is an acceptable lubricant, but some people find it too greasy and during hot weather it may also cause considerable sweat retention. Liberal use of Cetaphil lotion four or five times daily as a substitute for soap is also satisfactory as a means of lubrication. A bedroom humidifier is often helpful. Topical corticosteroids should be limited to medium strength (see Table 15–3). There is seldom a reason to use super- or high-potency corticosteroids in atopic dermatitis. In superinfected atopic dermatitis, systemic antibiotics for 10–14 days are necessary.

Tacrolimus and pimecrolimus ointments are topical immunosuppressive agents that are effective in atopic dermatitis. Because of concerns about the development of malignancies, tacrolimus and pimecrolimus should be reserved for children older than 2 years of age with atopic dermatitis unresponsive to medium-potency topical steroids. It has been argued that an increased risk of malignancy has not been seen in immunologically normal individuals using these products. Recommendations for usage likely will change with time. Treatment failures in chronic atopic dermatitis are most often the result of noncompliance. This is a frustrating disease for parent and child. Return to a normal lifestyle for the parent and child is the ultimate goal of therapy.

Batchelor JM, Grindlay DJ, Williams HC: What's new in atopic eczema? An analysis of systematic reviews published in 2008 and 2009. Clin Exp Dermatol 2010;35:823 [PMID: 20649899].

2. Nummular Eczema

Nummular eczema is characterized by numerous symmetrically distributed coin-shaped patches of dermatitis, principally on the extremities. These may be acute, oozing, and crusted or dry and scaling. The differential diagnosis should include tinea corporis, impetigo, and atopic dermatitis.

▶ Treatment

The same topical measures should be used as for atopic dermatitis, although more potent topical steroids may be necessary.

3. Primary Irritant Contact Dermatitis (Diaper Dermatitis)

Contact dermatitis is of two types: primary irritant and allergic eczematous. Primary irritant dermatitis develops within a few hours, reaches peak severity at 24 hours, and then disappears. Allergic eczematous contact dermatitis (described

in the next section) has a delayed onset of 18 hours, peaks at 48–72 hours, and often lasts as long as 2–3 weeks even if exposure to the offending antigen is discontinued.

Diaper dermatitis, the most common form of primary irritant contact dermatitis seen in pediatric practice, is caused by prolonged contact of the skin with urine and feces, which contain irritating chemicals such as urea and intestinal enzymes.

Clinical Findings

The diagnosis of diaper dermatitis is based on the picture of erythema and scaling of the skin in the perineal area and the history of prolonged skin contact with urine or feces. This is frequently seen in the "good baby" who sleeps many hours through the night without waking. In 80% of cases of diaper dermatitis lasting more than 3 days, the affected area is colonized with *C albicans* even before appearance of the classic signs of a beefy red, sharply marginated dermatitis with satellite lesions. Streptococcal perianal cellulitis and infantile psoriasis should be included in the differential diagnosis.

Treatment

Treatment consists of changing diapers frequently. The area should only be washed following a bowel movement. Washing should be done with a wash cloth and warm water only. Because rubber or plastic pants prevent evaporation of the contactant and enhance its penetration into the skin, they should be avoided as much as possible. Air drying is useful. Treatment of long-standing diaper dermatitis should include application of a barrier cream such as zinc oxide with each diaper change and an imidazole cream twice a day.

4. Allergic Eczematous Contact Dermatitis (Poison Ivy Dermatitis)

Clinical Findings

Plants such as poison ivy, poison sumac, and poison oak cause most cases of allergic contact dermatitis in children. Allergic contact dermatitis has all the features of delayed type (T-lymphocyte–mediated) hypersensitivity. Many substances may cause such a reaction; other than plants, nickel sulfate, potassium dichromate, and neomycin are the most common causes. Nickel is found to some degree in all metals. Nickel allergy is commonly seen on the ears secondary to the wearing of earrings, and near the umbilicus from pants snaps and belt buckles. The true incidence of allergic contact dermatitis in children is unknown. Children often present with acute dermatitis with blister formation, oozing, and crusting. Blisters are often linear and of acute onset.

Treatment

Treatment of contact dermatitis in localized areas is with potent topical corticosteroids. In severe generalized involvement, prednisone, 1–2 mg/kg/d orally for 10–14 days, can be used.

Bonitisis NG et al: Allergens responsible for allergic contact dermatitis among children: a systematic review and meta-analysis. Contact Dermatitis 2011;64:245 [PMID: 21480911].

5. Seborrheic Dermatitis

Clinical Findings

Seborrheic dermatitis is an erythematous scaly dermatitis accompanied by overproduction of sebum occurring in areas rich in sebaceous glands (ie, the face, scalp, and perineum). This common condition occurs predominantly in the newborn and at puberty, the ages at which hormonal stimulation of sebum production is maximal. Although it is tempting to speculate that overproduction of sebum causes the dermatitis, the exact relationship is unclear.

Seborrheic dermatitis on the scalp in infancy is clinically similar to atopic dermatitis, and the distinction may become clear only after other areas are involved. Psoriasis also occurs in seborrheic areas in older children and should be considered in the differential diagnosis.

Treatment

Seborrheic dermatitis responds well to low-potency topical corticosteroids.

6. Dandruff

Dandruff is physiologic scaling or mild seborrhea, in the form of greasy scalp scales. The cause is unknown. Treatment is with medicated dandruff shampoos.

7. Dry Skin Dermatitis (Asteatotic Eczema, Xerosis)

Children who live in arid climates are susceptible to dry skin, characterized by large cracked scales with erythematous borders. The stratum corneum is dependent on environmental humidity for its water, and below 30% environmental humidity the stratum corneum loses water, shrinks, and cracks. These cracks in the epidermal barrier allow irritating substances to enter the skin, predisposing the patient to dermatitis.

Treatment

Treatment consists of increasing the water content of the skin in the immediate external environment. House humidifiers

are very useful. Minimize bathing to every second or third day.

Frequent soaping of the skin impairs its water-holding capacity and serves as an irritating alkali, and all soaps should therefore be avoided. Frequent use of emollients (eg, Cetaphil, Eucerin, Lubriderm) should be a major part of therapy.

8. Keratosis Pilaris

Follicular papules containing a white inspissated scale characterize keratosis pilaris. Individual lesions are discrete and may be red. They are prominent on the extensor surfaces of the upper arms and thighs and on the buttocks and cheeks. In severe cases, the lesions may be generalized.

▶ Treatment

Treatment is with keratolytics such as urea cream or lactic acid, followed by skin hydration.

9. Pityriasis Alba

White, scaly macular areas with indistinct borders are seen over extensor surfaces of extremities and on the cheeks in children with pityriasis alba. Sun tanning exaggerates these lesions. Histologic examination reveals a mild dermatitis. These lesions may be confused with tinea versicolor.

▶ Treatment

Low-potency topical corticosteroids may help decrease any inflammatory component and may lead to faster return of normal pigmentation.

COMMON SKIN TUMORS

If the skin moves with the nodule on lateral palpation, the tumor is located within the dermis; if the skin moves over the nodule, it is subcutaneous. Seventy-five percent of lumps in childhood will be either epidermoid cysts (60%) or pilomatricomas (15%).

1. Epidermoid Cysts

▶ Clinical Findings

Epidermoid cysts are the most common type of cutaneous cyst. Other names for epidermoid cysts are epidermal cysts, epidermal inclusion cysts, and "sebaceous" cysts. This last term is a misnomer since they contain neither sebum nor sebaceous glands. Epidermoid cysts can occur anywhere, but are most common on the face and upper trunk. They usually arise from and are lined by the stratified squamous epithelium of the follicular infundibulum. Clinically, epidermoid cysts are dermal nodules with a central punctum,

representing the follicle associated with the cyst. They can reach several centimeters in diameter. **Dermoid cysts** are areas of sequestration of skin along embryonic fusion lines. They are present at birth and occur most commonly on the lateral eyebrow.

▶ Treatment

Epidermoid cysts can rupture, causing a foreign-body inflammatory reaction, or become infected. Infectious complications should be treated with antibiotics. Definitive treatment of epidermoid and dermoid cysts is surgical excision.

2. Pilomatricomas

These are benign tumors of the hair matrix. They are most commonly seen on the face and upper trunk. They are firm and may be irregular. Their color varies, flesh colored or blue. The firmness is secondary to calcification of the tumor.

▶ Treatment

Treatment is by surgical excision.

3. Granuloma Annulare

Violaceous circles or semicircles of nontender intradermal nodules found over the lower legs and ankles, the dorsum of the hands and wrists, and the trunk suggest granuloma annulare. Histologically, the disease appears as a central area of tissue death (necrobiosis) surrounded by macrophages and lymphocytes.

▶ Treatment

No treatment is necessary. Lesions resolve spontaneously within 1–2 years in most children.

4. Pyogenic Granuloma

These lesions appear over 1–2 weeks at times following skin trauma as a dark red papule with an ulcerated and crusted surface that may bleed easily with minor trauma. Histologically, this represents excessive new vessel formation with or without inflammation (granulation tissue). It should be regarded as an abnormal healing response.

▶ Treatment

Pulsed dye laser for very small lesions or curettage followed by electrocautery are the treatments of choice.

5. Keloids

Keloids are scars of delayed onset that continue to grow for up to several years and to progress beyond the initial wound margins.

The tendency to develop keloids is inherited. They are often found on the face, earlobes, neck, chest, and back.

► Treatment

Treatment includes intralesional injection with triamcinolone acetonide, 20–40 mg/mL, or excision and injection with corticosteroids. For larger keloids, excision followed by postoperative radiotherapy may be indicated.

PAPULOSQUAMOUS ERUPTIONS

Papulosquamous eruptions (Table 15–7) comprise papules or plaques with varying degrees of scale.

1. Pityriasis Rosea
► Pathogenesis & Clinical Findings

Pink to red, oval plaques with fine scales that tend to align with their long axis parallel to skin tension lines (eg, "Christmas tree pattern" on the back) are characteristic lesions of pityriasis rosea. The generalized eruption is usually preceded for up to 30 days by a solitary, larger, scaling plaque with central clearing and a scaly border (the herald patch). The herald patch is clinically similar to ringworm and can be confused. In whites, the lesions are primarily on the trunk; in blacks, lesions are primarily on the extremities and may be accentuated in the axillary and inguinal areas (inverse pityriasis rosea).

This disease is common in school-aged children and adolescents and is presumed to be viral in origin. The role of human herpesvirus 7 in the pathogenesis of pityriasis rosea is debated. The condition lasts 6–12 weeks and may be pruritic.

► Differential Diagnosis

The major differential diagnosis is secondary syphilis, and a VDRL (Venereal Disease Research Laboratories) test should be done if syphilis is suspected, especially in high-risk patients with palm or sole involvement. Fever and widespread

Table 15–7. Papulosquamous eruptions in children.

Psoriasis
Pityriasis rosea
Tinea corporis
Lichen planus
Pityriasis lichenoides (acute or chronic)
Dermatomyositis
Lupus erythematosus
Pityriasis rubra pilaris
Secondary syphilis

lymphadenopathy is often found in secondary syphilis. "Pityriasis rosea" lasting more than 12 weeks is likely to be pityriasis lichenoides.

► Treatment

Exposure to natural sunlight may help hasten the resolution of lesions. Oral antihistamines and topical steroids can be used for pruritus. Often, no treatment is necessary. Pityriasis rosea that lasts more than 12 weeks should be referred to a dermatologist for evaluation.

2. Psoriasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ► Erythematous papules and plaques with thick, white scales.
- ► Elbows, knees and scalp often affected.
- ► Nail pitting and distal onycholysis.

► Pathogenesis

The pathogenesis of psoriasis is complex and incompletely understood. It has immune-mediated inflammation, is a familial condition, and multiple psoriasis susceptibility genes have been identified. There is increased epidermal turnover; psoriatic epidermis has a turnover time of 3–4 days versus 28 days for normal skin. These rapidly proliferating epidermal cells produce excessive stratum corneum, giving rise to thick, opaque scales.

► Clinical Findings

Psoriasis is characterized by erythematous papules covered by thick white scales. Guttate (droplike) psoriasis is a common form in children that often follows by 2–3 weeks an episode of streptococcal pharyngitis. The sudden onset of small papules (3–8 mm), seen predominantly over the trunk and quickly covered with thick white scales, is characteristic of guttate psoriasis. Chronic psoriasis is marked by thick, large scaly plaques (5–10 cm) over the elbows, knees, scalp, and other sites of trauma. Pinpoint pits in the nail plate are seen, as well as yellow discoloration of the nail plate resulting from onycholysis. Psoriasis occurs frequently on the scalp, elbows, knees, periumbilical area, ears, sacral area, and genitalia.

► Differential Diagnosis

Papulosquamous eruptions that present problems of differential diagnosis are listed in Table 15–7.

Treatment

Topical corticosteroids are the initial treatment of choice. Penetration of topical steroids through the enlarged epidermal barrier in psoriasis requires that more potent preparations be used, for example, fluocinonide 0.05% (Lidex) or clobetasol 0.05% (Temovate) ointment twice daily.

The second line of therapy is topical vitamin D3 medications such as calcipotriene (Dovonex) or, calcitriol (Vectical), applied twice daily or the combination of a superpotent topical steroid twice daily on weekends and calcipotriene or calcitriol twice daily on weekdays.

Topical retinoids such as tazarotene (0.1%, 0.5% cream, gel) can be used in combination with topical corticosteroids to help restore normal epidermal differentiation and turnover time.

Anthralin therapy is also useful. Anthralin is applied to the skin for a short contact time (eg, 20 minutes once daily) and then washed off with a neutral soap (eg, Dove). This can be used in combination with topical corticosteroids.

Crude coal tar therapy is messy and stains bedclothes. The newer tar gels (Estar, PsoriGel) and one foam product (Scytera) cause less staining and are most efficacious. They are applied twice daily. These preparations are sold over the counter and are not usually covered by insurance plans.

Scalp care using a tar shampoo requires leaving the shampoo on for 5 minutes, washing it off, and then shampooing with commercial shampoo to remove scales. It may be necessary to shampoo daily until scaling is reduced.

More severe cases of psoriasis are best treated by a dermatologist. Narrow band UVB phototherapy and multiple systemic medications and new biologic agents (antibodies, fusion proteins, and recombinant cytokines) are effective in more widespread, severe cases.

De Jager ME et al: Efficacy and safety of treatments for childhood psoriasis: a systematic literature review. J Am Acad Dermatol 2010;62:1013 [PMID: 19900732].

HAIR LOSS (ALOPECIA)

Hair loss in children (Table 15–8) imposes great emotional stress on the patient and the parent. A 60% hair loss in a single area is necessary before hair loss can be detected clinically. Examination should begin with the scalp to determine whether inflammation, scale, or infiltrative changes are present. The hair should be gently pulled to see if it is easily removable. Hairs should be examined microscopically for breaking and structural defects and to see whether growing or resting hairs are being shed. Placing removed hairs in mounting fluid (Permount) on a glass microscope slide makes them easy to examine.

Three diseases account for most cases of hair loss in children: alopecia areata, tinea capitis (described earlier in this chapter), and hair pulling.

Table 15–8. Other causes of hair loss in children.

Hair loss with scalp changes
Atrophy:
Lichen planus
Lupus erythematosus
Birthmarks:
Epidermal nevus
Nevus sebaceous
Aplasia cutis congenita
Hair loss with hair shaft defects (hair fails to grow out enough to require haircuts)
Monilethrix—alternating bands of thin and thick areas
Pili annulati—alternating bands of light and dark pigmentation
Pili torti—hair twisted 180 degrees, brittle
Trichorrhexis invaginata (bamboo hair)—intussusception of one hair into another
Trichorrhexis nodosa—nodules with fragmented hair

1. Alopecia Areata
Clinical Findings

Complete hair loss in a localized area is called alopecia areata. This is the most common cause of hair loss in children. An immunologic pathogenic mechanism is suspected because dense infiltration of lymphocytes precedes hair loss. Fifty percent of children with alopecia areata completely regrow their hair within 12 months, although as many may have a relapse in the future.

A rare and unusual form of alopecia areata begins at the occiput and proceeds along the hair margins to the frontal scalp. This variety, called ophiasis, often eventuates in total scalp hair loss (alopecia totalis). The prognosis for regrowth in ophiasis is poor.

Treatment

Superpotent topical steroids, minoxidil (Rogaine), contact therapy, and anthralin are topical treatment options. Systemic corticosteroids given to suppress the inflammatory response will result in hair growth, but the hair may fall out again when the drug is discontinued. Systemic corticosteroids should never be used for a prolonged time period. In children with alopecia totalis, a wig is most helpful. Treatment induced hair growth does not alter risk of recurrence.

Alkhalifah A et al: Alopecia areata update: part I. Clinical picture, histopathology and pathogenesis. J Am Acad Dermatol 2010;62:177 [PMID: 21015945].

Alkhalifah A et al: Alopecia areata update: part II. Treatment. J Am Acad Dermatol 2010;62:191 [PMID: 21015946].

2. Hair Pulling
▶ Clinical Findings

Traumatic hair pulling causes the hair shafts to be broken off at different lengths, with an ill-defined area of hair loss, petechiae around follicular openings, and a wrinkled hair shaft on microscopic examination. This behavior may be merely habit, an acute reaction to severe stress, trichotillomania, or a sign of another psychiatric disorder. Eyelashes and eyebrows rather than scalp hair may be pulled out.

▶ Treatment

If the behavior has a long history, psychiatric evaluation may be helpful. Cutting or oiling the hair to make it slippery is an aid to behavior modification.

REACTIVE ERYTHEMAS

1. Erythema Multiforme
▶ Clinical Findings

Erythema multiforme begins with papules that later develop a dark center and then evolve into lesions with central bluish discoloration or blisters and the characteristic target lesions (iris lesions) that have three concentric circles of color change. Erythema multiforme has sometimes been diagnosed in patients with severe mucous membrane involvement, but Stevens-Johnson syndrome is the diagnosis when severe involvement of conjunctiva, oral cavity, and genital mucosa also occur.

Many causes are suspected, particularly concomitant herpes simplex virus; drugs, especially sulfonamides; and *Mycoplasma* infections. Recurrent erythema multiforme is usually associated with reactivation of herpes simplex virus. In erythema multiforme, spontaneous healing occurs in 10–14 days, but Stevens-Johnson syndrome may last 6–8 weeks.

▶ Treatment

Treatment is symptomatic in uncomplicated erythema multiforme. Removal of offending drugs is an obvious measure. Oral antihistamines such as cetirizine 5–10 mg every morning and hydroxyzine 1 mg/kg/d at bedtime are useful. Cool compresses and wet dressings will relieve pruritus. Steroids have not been demonstrated to be effective. Chronic acyclovir therapy has been successful in decreasing attacks in patients with herpes-associated recurrent erythema multiforme.

2. Drug Eruptions

Drugs may produce urticarial, morbilliform, scarlatiniform, pustular, bullous, or fixed skin eruptions. Urticaria may appear within minutes after drug administration, but most reactions begin 7–14 days after the drug is first administered.

Table 15–9. Common drug reactions.

Urticaria
Barbiturates
Opioids
Penicillins
Sulfonamides
Morbilliform eruption
Anticonvulsants
Cephalosporins
Penicillins
Sulfonamides
Fixed drug eruption, erythema multiforme, toxic epidermal necrolysis, Stevens-Johnson syndrome
Anticonvulsants
Nonsteroidal anti-inflammatory drugs
Sulfonamides
DRESS syndrome
Anticonvulsants
Photodermatitis
Psoralens
Sulfonamides
Tetracyclines
Thiazides

DRESS syndrome = drug eruptions with fever, eosinophilia, and systemic symptoms.

These eruptions may occur in patients who have received these drugs for long periods, and eruptions continue for days after the drug has been discontinued. Drug eruptions with fever, eosinophilia, and systemic symptoms (DRESS syndrome) is most commonly seen with anticonvulsants, but may be seen with other drugs. Drugs commonly implicated in skin reactions are listed in Table 15–9.

MISCELLANEOUS SKIN DISORDERS SEEN IN PEDIATRIC PRACTICE

1. Aphthous Stomatitis

Recurrent erosions on the gums, lips, tongue, palate, and buccal mucosa are often confused with herpes simplex. A smear of the base of such a lesion stained with Wright stain will aid in ruling out herpes simplex by the absence of epithelial multinucleate giant cells. A culture for herpes simplex is also useful in differential diagnostics. The cause remains unknown, but T-cell–mediated cytotoxicity to various viral antigens has been postulated.

▶ Treatment

There is no specific therapy for this condition. Rinsing the mouth with liquid antacids provides relief in most patients. Topical corticosteroids in a gel base may provide some relief. In severe cases that interfere with eating, prednisone, 1 mg/kg/d

orally for 3–5 days, will suffice to abort an episode. Colchicine, 0.2–0.5 mg/d, sometimes reduces the frequency of attacks.

2. Vitiligo

Vitiligo is characterized clinically by the development of areas of depigmentation. These are often symmetrical and occur mainly on extensor surfaces. The depigmentation results from a destruction of melanocytes. The basis for this destruction is unknown, but immunologically mediated damage is likely and vitiligo sometimes occurs in individuals with autoimmune endocrinopathies.

▶ **Treatment**

Treatment is with potent topical steroids or tacrolimus. Topical calcipotriene has also been used. Narrow-band ultraviolet B radiation (UVB 311 nm) may be used in severe cases. Response to treatment is slow often requiring many months to years.

Tamesis ME, Morellij JG: Vitiligo in childhood: a state of the art review. Pediatr Dermatol 2010;27:437 [PMID: 20553403].

Eye

Rebecca Sands Braverman, MD

16

Normal vision is a sense that develops during infancy and childhood. Pediatric ophthalmology emphasizes early diagnosis and treatment of pediatric eye diseases in order to obtain the best possible visual outcome. Eye disease in children is not always limited to the ocular system and may be a sign of systemic disease.

▼ COMMON NONSPECIFIC SIGNS & SYMPTOMS

Nonspecific signs and symptoms commonly occur as the chief complaint or as an element of the history of a child with eye disease. Five of these findings are described here, along with a sixth—leukocoria—which is less common, but often has serious implications. Do not hesitate to seek the help of a pediatric ophthalmologist when you believe the diagnosis and treatment of these signs and symptoms requires in-depth clinical experience.

RED EYE

Redness (injection) of the bulbar conjunctiva or deeper vessels is a common presenting complaint. It may be mild and localized or diffuse and bilateral. Causes include superficial or penetrating foreign bodies, trauma, infection, allergy, and conjunctivitis associated with systemic entities such as Stevens-Johnson syndrome, uveitis, or Kawasaki disease. Irritating noxious agents also cause injection. Subconjunctival hemorrhage may be traumatic, spontaneous, or may be associated with hematopoietic disease, vascular anomalies, or inflammatory processes. Uncommonly, an injected eye can be due to an intraocular or orbital tumor.

TEARING

Tearing in infants is usually due to nasolacrimal obstruction but may also be associated with congenital glaucoma, in which case photophobia and blepharospasm may also be present. Inflammation, allergic and viral diseases, or conjunctival and corneal irritation can also cause tearing.

DISCHARGE

Purulent discharge is usually associated with bacterial conjunctivitis. In infants and toddlers with nasolacrimal obstruction, a *mucopurulent discharge* may be present with low-grade, chronic dacryocystitis. *Watery discharge* occurs with viral infection, iritis, superficial foreign bodies, and nasolacrimal obstruction. *Mucoid discharge* may be a sign of allergic conjunctivitis or nasolacrimal obstruction. A mucoid discharge due to allergy typically contains eosinophils, whereas a purulent bacterial discharge contains polymorphonuclear leukocytes.

PAIN & FOREIGN BODY SENSATION

Pain in or around the eye may be due to foreign bodies, corneal abrasions, lacerations, acute infections of the globe or ocular adnexa, iritis, and angle-closure glaucoma. Large refractive errors or poor accommodative ability may manifest as headaches. Trichiasis (inturned lashes) and contact lens problems also cause ocular discomfort.

PHOTOPHOBIA

Acute aversion to light may occur with corneal abrasions, foreign bodies, and iritis. Squinting of one eye in bright light is a common sign of intermittent exotropia. Photophobia is present in infants with glaucoma, albinism, aniridia, and retinal dystrophies such as achromatopsia. Photophobia is common after ocular surgery and after dilation of the pupil with mydriatic and cycloplegic agents. Photophobia in individuals with no ocular pathology may be due to migraine headache, meningitis, and retrobulbar optic neuritis.

▲ **Figure 16–1.** Leukocoria of the left eye caused by retrolental membrane (persistent hyperplastic primary vitreous or persistent fetal vasculature).

LEUKOCORIA

Although not a common sign or complaint, leukocoria (a white pupil) is associated with serious diseases and requires prompt ophthalmologic consultation. Causes of leukocoria include retinoblastoma, retinopathy of prematurity (ROP), pupillary membrane, cataract, vitreous opacities, retinal detachment, *Toxocara* infection, and retinal dysplasia (Figure 16–1).

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Significant refractive errors (myopia, hyperopia, astigmatism, or anisometropia) may cause decreased visual acuity, amblyopia, and strabismus.
► Symptoms and signs of uncorrected refractive error include blurred vision, squinting, headaches, fatigue with visual tasks, and failure of visual acuity screening.

▼ REFRACTIVE ERRORS

▶ Pathogenesis

Refractive error refers to the optical state of the eye (Figure 16–2). The shape of the cornea and, to a lesser extent, the shape of the lens and length of the eye play a role in the refractive state of the eye. Children at particular risk for refractive errors requiring correction with glasses include those who were born prematurely; have Down syndrome; have parents with refractive errors; or have certain systemic conditions such as Stickler, Marfan, or Ehlers-Danlos syndrome.
▲ **Figure 16–2.** Different refractive states of the eye. **A:** Emmetropia. Image plane from parallel rays of light falls on retina. **B:** Myopia. Image plane focuses anterior to retina. **C:** Hyperopia. Image plane focuses posterior to retina. **D:** Astigmatism, myopic type. Images in horizontal and vertical planes focus anterior to retina. **E:** Astigmatism, hyperopic type. Images in horizontal and vertical planes focus posterior to retina. **F:** Astigmatism, mixed type. Images in horizontal and vertical planes focus on either side of retina.

▶ Diagnosis

There are three common refractive errors: myopia, hyperopia, and astigmatism. Inequality of the refractive state between the two eyes (anisometropia) can cause amblyopia. The refractive state is determined by an eye care professional via a procedure called refraction. The determination of the refractive state in a preverbal child often proves challenging. If there is concern that there may be a significant problem with a preverbal child's vision, they should be referred to an eye care professional specially trained for treating children.

▶ Treatment

Not all refractive errors require correction, but severe errors can cause amblyopia (reduced vision with or without an organic lesion). Refractive errors in children are most commonly treated with glasses. Less often, contact lenses are required, usually for very high or asymmetrical refractive errors, or for adolescents who do not want to wear glasses. Laser refractive surgery is not indicated for most children.

MYOPIA (NEARSIGHTEDNESS)

For the myopic or nearsighted individual, objects nearby are in focus; those at a distance are blurred. This is because the plane of focus is anterior to the retina. The onset is typically at about age 8 years and may progress throughout adolescence and young adulthood. A myopic person may squint to produce a pinhole effect, which improves distance vision. Divergent lenses provide clear distance vision. Many studies have attempted to slow or stop myopic progression. Atropine eye drops have shown some effect, but produce many side effects. A newer drug, pirenzepine, has shown promise in animal studies, but human studies have not shown a significant decrease in myopic progression.

HYPEROPIA (FARSIGHTEDNESS)

Saying that the hyperopic child is sighted for far (not near) vision is somewhat misleading, because the child can focus on near objects if the hyperopia is not excessive. Large amounts of uncorrected hyperopia can cause esotropia (inward deviation, or crossing, of the eyes) and amblyopia (see later sections Amblyopia and Strabismus). Most infants have a hyperopic refraction that begins to diminish during the toddler years and does not require correction.

ASTIGMATISM

When either the cornea or the crystalline lens is not perfectly spherical, an image will not be sharply focused in one plane. Schematically, there will be two planes of focus. Both of the planes can be either in front of or behind the retina, or one of the planes can be in front of the retina and the other behind it. This refractive state is described as *astigmatism*. Large amounts of astigmatism not corrected at an early age can cause decreased vision from amblyopia, but proper refractive correction can prevent this.

▼ OPHTHALMIC EXAMINATION

A history suggesting poor vision or misalignment of the eyes, visual acuity that falls outside the expected level for a specific age, eyelid malposition, abnormal pupil reactivity or shape, and presence of an asymmetric/abnormal red reflex requires referral to an ophthalmologist.

The American Academy of Pediatrics (AAP), American Association for Pediatric Ophthalmology and Strabismus (AAPOS), and the American Academy of Ophthalmology (AAO) policy statements for red reflex testing can be accessed at http://aappolicy.aappublications.org/.

Prompt detection and treatment of ocular conditions can prevent a lifetime of visual disability. The ophthalmic examination should be a part of every well-child assessment.

It is crucial to check newborn infants for vision or life-threatening conditions that present with an abnormal red reflex that may be caused by cataracts or intraocular tumors. Eyelid ptosis (droopy eyelid) that obstructs the visual axis can cause permanent visual acuity loss from deprivation amblyopia and/or induced astigmatism, and requires urgent consultation with an ophthalmologist.

From birth to 3 years of age, the ophthalmic examination should include taking a history for ocular problems, vision assessment, inspection of the eyelids and eyes, pupil examination, ocular motility assessment, and red reflex check.

The ophthalmic examination of children older than 3 years should include taking a history for ocular problems, inspection of the eyelids and eyes, pupil examination, ocular motility assessment, and red reflex check and visual acuity testing with Allen, Lea, HOTV, Tumbling E, or Snellen symbols. Direct ophthalmoscopy should be attempted. Testing of binocular status can be accomplished by various tests, including the Random Dot E stereoacuity test.

HISTORY

Evaluation begins with the chief complaint and history of the present illness. Elements of the ocular history include onset of the complaint, its duration, whether it is monocular or binocular, treatment received thus far, and associated systemic symptoms. If an infectious disease is suspected, ask about possible contact with others having similar findings. The history should include prior ocular disease, perinatal and developmental history, history of allergy, and history of familial ocular disorders.

VISUAL ACUITY

Visual acuity testing is the most important test of visual function and should be part of every general physical examination (http://one.aao.org/Flash/VisionScreening/PediatricVisionScreening.html). Acuity should be tested in each eye individually, using an adhesive eye patch to prevent peeking. Glasses that were previously prescribed should be worn during vision screening. In older children who can cooperate, use of a pinhole will improve vision in children not wearing the appropriate spectacle prescription.

Vision Screening

Vision screening in the pediatric age group is a challenge, especially in younger and developmentally delayed children. Accuracy of the screening test being administered to a particular population and expense in terms of time, equipment, and personnel are some factors that must be considered in choosing a screening test. Vision screening should be done at well child visits. Further information on vision screening can be found at the AAP website (http://www.aap.org). Risk factors that should be screened for because they interfere with normal visual development and are amblyogenic include media opacities (such as cataracts), strabismus

(misalignment of the visual axes of the eyes), and refractive errors that are different in the two eyes (anisometropia) or of large magnitude in both eyes.

In the sleeping newborn, the presence of a blepharospastic response to bright light is an adequate response. At age 6 weeks, eye-to-eye contact with slow, following movements is usually present. By age 3 months, the infant should demonstrate fixing and following ocular movements for objects at a distance of 2–3 ft. At age 6 months, interest in movement across the room is the norm. Vision can be recorded for the presence or absence of fixing and following behavior, and whether vision is steady (unsteady when nystagmus is present) and maintained.

In the verbal child, the use of familiar icons will allow for a quantitative test. Allen or Lea symbols with familiar pictures can be used to test children 2–3 years of age. When it is not possible to measure visual acuity or assess alignment in the preschool-aged child, random dot stereopsis testing (for depth perception) is effective in screening for manifest strabismus and amblyopia, but this test may miss some cases of anisometropic (unequal refractive error) amblyopia and small-angle strabismus, and is not designed to detect refractive errors.

Four-year-old children are often ready to play the tumbling E game (in which the child identifies the orientation of the letter E, which is turned in one of four directions) or the HOTV letters game (in which these four letters are shown individually at a distance and matched on a board that the child is holding). Literate children are tested with Snellen letters. Typical acuity levels in developmentally appropriate children are approximately 20/60 or better in children younger than 2–3 years, 20/40–20/30 in 3-year-old children, 20/30–20/25 in 4-year-old children, and 20/20 in literate children 5–6 years old. Referral criteria for children 3–5 years of age include visual acuity of less than 20/40 or 10/20 in either eye or a two-line difference between the eyes. Children 6 years or older should be referred if their visual acuity is less than 20/30 or 20/15 in either eye or a two-line difference is noted between the eyes.

The practitioner should be aware of two situations in which vision screening is complicated by nystagmus. Children who require a face turn or torticollis (in which the head is tilted to the right or left) to quiet the nystagmus will have poor visual acuity results when tested in the absence of the compensatory head posture. When latent nystagmus is present, acuity testing is particularly challenging (see later section Nystagmus). Nystagmus appears or worsens when an eye is occluded, degrading central vision. To minimize the nystagmus, the occluder should be held about 12 in in front of the eye not being tested. Testing both eyes simultaneously without occlusion often gives a better visual acuity measurement than when either eye is tested individually.

Traditional vision screening methods using eye charts in children aged 3–5 years require the child's cooperation as well as proficiency in testing by the examiner. Additional screening modalities including photoscreening and autorefractors have been used by various volunteer programs in schools, day care facilities, and physician offices. Photoscreening does not screen directly for amblyopia but for amblyogenic factors, which include strabismus, media opacities, eyelid ptosis, and refractive errors. Autorefractors can determine if there is a significant refractive error present in either eye or if there is a significant difference between the two eyes. Some autorefractors can also detect strabismus and eyelid ptosis. If the screening results suggest an amblyogenic factor, children are referred to an eye care professional for a complete eye examination. Problems exist with sensitivity and specificity of the instruments and poor follow-up for referrals to eye care professionals. The cost-effectiveness of various vision screening modalities remains an area of continued research.

EXTERNAL EXAMINATION

Inspection of the anterior segment of the globe and its adnexa requires adequate illumination and often magnification. A penlight provides good illumination and should be used in both straight-ahead and oblique illumination. A Wood lamp or a blue filter cap placed over a penlight is needed for evaluation after applying fluorescein. Immobilization of the child may be necessary. A drop of topical anesthetic may facilitate the examination.

In cases of suspected foreign body, pulling down on the lower lid provides excellent visualization of the inferior cul-de-sac (palpebral conjunctiva). Visualizing the upper cul-de-sac and superior bulbar conjunctiva is possible by having the patient look inferiorly while the upper lid is pulled away from the globe and the examiner peers into the upper recess. Illumination with a penlight is necessary. The upper lid should be everted to evaluate the superior tarsal conjunctiva (Figure 16–3).

When indicated for further evaluation of the cornea, a small amount of fluorescein solution should be instilled into the lower cul-de-sac. Blue light will stain defects yellow-green. Disease-specific staining patterns may be observed. For example, herpes simplex lesions of the corneal epithelium produce a dendrite or branchlike pattern. A foreign body
▲ **Figure 16–3.** Eversion of the upper lid. **A:** The patient looks downward. **B:** The fingers pull the lid down, and an index finger or cotton tip is placed on the upper tarsal border. **C:** The lid is pulled up over the finger. **D:** The lid is everted.

lodged beneath the upper lid shows one or more vertical lines of stain on the cornea due to the constant movement of the foreign body over the cornea. Contact lens overwear produces a central staining pattern. A fine, scattered punctate pattern may be a sign of viral keratitis or medication toxicity. Punctate erosions of the inferior third of the cornea can be seen with staphylococcal blepharitis or exposure keratitis secondary to incomplete lid closure.

PUPILS

The pupils should be evaluated for reaction to light, regularity of shape, and equality of size as well as for the presence of afferent pupillary defect. This defect, which occurs in optic nerve disease, is evaluated by the swinging flashlight test (see later section Diseases of the Optic Nerve). Irregular pupils are associated with iritis, trauma, pupillary membranes, and structural defects such as iris coloboma (see later section on Iris Coloboma).

Pupils vary in size due to lighting conditions and age. In general, infants have miotic (constricted) pupils. Children have larger pupils than either infants or adults, whereas the elderly have miotic pupils.

Anisocoria, a size difference between the two pupils, may be physiologic if the size difference is within 1 mm and is the same in light and dark. Anisocoria occurs with Horner syndrome, third nerve palsy, Adie tonic pupil, iritis, and trauma. Medication could also cause abnormal pupil size or reactivity. For example, contact with atropine-like substances (belladonna alkaloids) will cause pupillary dilation and limit pupillary reaction. Systemic antihistamines and scopolamine patches, among other medicines, can dilate the pupils and interfere with accommodation (focusing).

ALIGNMENT & MOTILITY EVALUATION

Alignment and motility should be tested because amblyopia is associated with strabismus. Besides alignment, ocular rotations should be evaluated in the six cardinal positions of gaze (Table 16–1; Figure 16–4). A small toy is an interesting target for testing ocular rotations in infants; a penlight works well in older children.

Alignment can be assessed in several ways. In order of increasing accuracy, these methods are observation, the corneal light reflex test, and cover testing. Observation is an educated guess about whether the eyes are properly aligned. Corneal light reflex evaluation (Hirschberg test)

Table 16–1. Function and innervation of each of the extraocular muscles.

Muscle	Function	Innervation
Medial rectus	Adductor	Oculomotor (third)
Lateral rectus	Abductor	Abducens (sixth)
Inferior rectus	Depressor, adductor, extorter	Oculomotor
Superior rectus	Elevator, adductor, intorter	Oculomotor
Inferior oblique	Elevator, abductor, extorter	Oculomotor
Superior oblique	Depressor, abductor, intorter	Trochlear (fourth)
MR = medial rectus   LR = lateral rectus
SR = superior rectus   IR = inferior rectus
SO = superior oblique   IO = inferior oblique

▲ **Figure 16–4.** Cardinal positions of gaze and muscles primarily tested in those fields of gaze. Arrow indicates position in which each muscle is tested.

▲ **Figure 16–5.** Temporal displacement of light reflection showing esotropia (inward deviation) of the right eye. Nasal displacement of the reflection would show exotropia (outward deviation) of the left eye.

is performed by shining a light beam at the patient's eyes, observing the reflections off each cornea, and estimating whether these "reflexes" appear to be positioned properly. If the reflection of light is noted temporally on the cornea, esotropia is suspected (Figure 16–5). Nasal reflection of the light suggests exotropia (outward deviation). Accuracy of these tests increases with increasing angles of misalignment.

Another way of evaluating alignment is with the cover test, in which the patient fixes on a target while one eye is covered. If an esotropia or an exotropia is present, the deviated eye will make a corrective movement to fixate on the target when the previously fixating eye is occluded. The other eye is tested similarly. When the occluder is removed from the eye just uncovered, a refixation movement of that eye indicates a phoria, or latent deviation, if alignment is reestablished (Figure 16–6). If the uncovered eye picks up fixation and strabismus is still present, that eye can be presumed to be dominant and the non-preferred eye possibly amblyopic.

If the eye remains deviated after the occluder is removed, a tropia is noted to be present. A deviated eye that is blind or has very poor vision will not fixate on a target. Consequently, spurious results to cover testing may occur, which can happen with disinterest on the part of the patient, small-angle strabismus, and inexperience in administering cover tests.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ The handheld ophthalmoscope is the tool necessary to check the red reflex of the eye.
▶ Simultaneous examination of both pupils at the same time is called the *Brückner test*.

Red Reflex Test

▶ Clinical Findings

The examiner should see a round, red light in both eyes. The red reflex of each eye can be compared simultaneously when the observer is approximately 4 ft away from the patient. The largest diameter of light is shown through the ophthalmoscope, and no correction (zero setting) is dialed in the ophthalmoscope unless it is to compensate for the examiner's uncorrected refractive error. A red reflex chart is available through the AAP policy statement on red reflex testing on pediatric patients at http://aappolicy.aappublications.org/.

Eyes straight (maintained in position by fusion).

Position of eye under cover in orthophoria (fusion-free position). The right eye under cover has not moved.

Position of eye under cover in esophoria (fusion-free position). Under cover, the right eye has deviated inward. Upon removal of cover, the right eye will immediately resume its straight-ahead position.

Position of eye under cover in exophoria (fusion-free position). Under cover, the right eye has deviated outward. Upon removal of the cover, the right eye will immediately resume its straight-ahead position.

▲ **Figure 16–6.** Cover testing. The patient is instructed to look at a target at eye level 20 ft away. Note that in the presence of constant strabismus (ie, a tropia rather than a phoria), the deviation will remain when the cover is removed. (Reprinted, with permission, from Riordan-Eva P, Whitcher J: *Vaughan & Asbury's General Ophthalmology,* 17th ed. McGraw-Hill; 2008.)

Differential Diagnosis

The red reflex test (Brückner test) is useful for identifying disorders such as media opacities (eg, cataracts), large refractive errors, tumors such as retinoblastoma, and strabismus.

Treatment

A difference in quality of the red reflexes between the two eyes constitutes a positive Brückner test and requires referral to an ophthalmologist.

American Academy of Pediatrics; Section on Ophthalmology; American Association for Pediatric Ophthalmology and Strabismus; American Academy of Ophthalmology; American Association of Certified Orthoptists: Red reflex examination in neonates, infants, and children. Pediatrics 2008;122(6):1401–1404 [PMID: 19047263].

OPHTHALMOSCOPIC EXAMINATION

A handheld direct ophthalmoscope allows visualization of the ocular fundus. As the patient's pupil becomes more constricted, viewing the fundus becomes more difficult. Although pupillary dilation can precipitate an attack of closed-angle glaucoma in the predisposed adult, children are very rarely predisposed to angle closure. Exceptions include those with a dislocated lens, past surgery, or an eye previously compromised by a retrolental membrane, such as in ROP. Therefore, if an adequate view of the fundus is precluded by a miotic pupil, use of a dilating agent (eg, one drop in each eye of 2.5% phenylephrine or 0.5% or 1% tropicamide) should provide adequate mydriasis (dilation). In infants, one drop of a combination of 1% phenylephrine with 0.2% cyclopentolate (Cyclomydril) is safer. Structures to be observed during ophthalmoscopy include the optic disc, blood vessels, the macular reflex, and retina, as well as the clarity of the vitreous media. By increasing the amount of plus lens dialed into the instrument, the point of focus moves anteriorly from the retina to the lens and finally to the cornea.

▼ OCULAR TRAUMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► A careful history of the events that lead to the ocular injury is crucial in the diagnosis and treatment of ocular trauma.

► The examination of the traumatized eye may be difficult in the child due to poor cooperation and significant discomfort.

► If the extent of the eye injury is difficult to determine or if it is sight threatening, urgent referral to an ophthalmologist is necessary.

OCULAR FOREIGN BODIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► A foreign body of the eye/globe or adnexa may be difficult to visualize due to its small size or location.

► The clinician should always maintain a high index of suspicion for an occult or intraocular foreign body. If the history suggests this, an ophthalmologic referral should be considered.

Prevention

Protective goggles or prescription glasses can help prevent ocular injuries and should be encouraged while participating in activities at risk for eye injuries, such as grinding metal, hammering, or sawing wood.

Clinical Findings

Foreign bodies on the globe and palpebral conjunctiva usually cause discomfort and red eye. The history may suggest the origin of the foreign body, such as being around a metal grinder or being outside on a windy day when a sudden foreign body sensation was encountered associated with tearing, redness, and pain. Pain with blinking suggests that the foreign body may be trapped between the eyelid and the eye.

Magnification with a slit lamp may be needed for inspection. Foreign bodies that lodge on the upper palpebral conjunctiva are best viewed by everting the lid on itself and removing the foreign body with a cotton applicator. The conjunctival surface (palpebral conjunctiva) of the lower lid presents no problem with visualization. After simple removal of a foreign body that is thought not to be contaminated, no other treatment is needed if no corneal abrasion has occurred.

Differential Diagnosis

Corneal abrasion, corneal ulcer, globe rupture/laceration.

Complications

Pain, infection, and potential vision loss from scarring.

▶ Treatment

When foreign bodies are noted on the bulbar conjunctiva or cornea (Figure 16–7), removal is facilitated by using a topical anesthetic. If the foreign body is not too adherent, it can be dislodged with a stream of irrigating solution (Dacriose or saline) or with a cotton applicator after instillation of a topical anesthetic. Otherwise, a foreign body spud or needle is used to undermine the foreign body. This must be done with adequate magnification and illumination. An antibiotic ointment is then instilled. Ferrous corneal bodies often have an associated rust ring, which may be removed under slit-lamp visualization in cooperative children or under anesthesia if necessary.

A
B

▲ **Figure 16–7. A:** Corneal foreign body at the nasal edge of the cornea. **B:** Subconjunctival foreign body of graphite.

▶ Prognosis

Usually excellent if treatment is obtained shortly after injury.

CORNEAL ABRASION

🧩 ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A corneal abrasion results in loss of the most superficial layer of corneal cells and causes severe ocular pain, tearing, and blepharospasm.

▶ An inciting event is usually identifiable as the cause of a corneal abrasion.

▶ Pathogenesis

Children often suffer corneal abrasions accidentally while playing with siblings or pets as well as participating in sports. Contact lens users frequently develop abrasions due to poorly fitting lenses, overnight wear, and use of torn or damaged lenses.

▶ Prevention

Proper contact lens care and parental supervision can prevent activities that can lead to a corneal abrasion.

▶ Clinical Findings

Symptom of a corneal abrasion is sudden and severe eye pain, usually after an inciting event such as an accidental finger poke to the eye. Decreased vision secondary to pain and tearing are common complaints. Eyelid edema, tearing, injection of the conjunctiva, and poor cooperation with the ocular examination due to pain are common signs of a corneal abrasion. Fluorescein dye is instilled into the eye and a cobalt blue or Wood lamp is used to illuminate the affected eye. The area with the abrasion will stain bright yellow.

▶ Differential Diagnosis

Ocular or adnexal foreign bodies, corneal ulcer, corneal laceration.

▶ Complications

Possible vision loss from corneal infection and scarring.

▶ Treatment

Ophthalmic ointment, such as erythromycin ointment, lubricates the surface of the cornea and also helps prevent infections. Patching the affected eye when a large abrasion

is present may provide comfort, but it is not advised for corneal abrasions caused by contact lens wear or other potentially contaminated sources. Large corneal abrasions result in referred pain to the ipsilateral brow. If a brow ache is present, it may be treated by the use of a topical cycloplegic agent such as 1% cyclopentolate. Daily follow-up is required until healing is complete.

▶ Prognosis

Excellent if corneal infection and scarring do not occur.

INTRAOCULAR FOREIGN BODIES & PERFORATING OCULAR INJURIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Severe trauma may result in penetration of the eye by foreign bodies or retained foreign bodies, and is an ocular emergency.

▶ Pathogenesis

Intraocular foreign bodies and penetrating injuries are most often caused by being in close proximity to high-velocity projectiles such as windshield glass broken during a motor vehicle accident, metal ground without use of protective safety goggles, and improperly detonated fireworks.

▶ Prevention

Use protective eyewear when engaging in activities at risk for ocular injury.

▶ Clinical Findings

Sudden ocular pain occurs; vision loss, as well as multiple organ trauma, may be present.

Intraocular foreign bodies and corneal and scleral lacerations (ruptured globe) require emergency referral to an ophthalmologist. The diagnosis may be difficult if the obvious signs of corneal perforation (shallow anterior chamber with hyphema, traumatic cataract, and irregular pupil) are not present (Figure 16–8). Furthermore, nonradiopaque materials such as glass will not be seen on x-ray film.

Computed tomographic (CT) scan may be useful in evaluating ocular trauma, including bony injury and intraocular foreign bodies. Magnetic resonance imaging (MRI) must be avoided if a magnetic foreign body is suspected.

▶ Differential Diagnosis

Corneal abrasion, superficial foreign body of the eye or eyelids.
▲ **Figure 16–8.** Corneal laceration with irregular pupil and vitreous loss.

▶ Complications

Vision loss, intraocular infection, loss of the eye.

▶ Treatment

In cases of suspected intraocular foreign body or perforation of the globe, it may be best to keep the child at rest, gently shield the eye with a metal shield or cut-down paper cup, and keep the extent of examination to a minimum to prevent expulsion of intraocular contents. In this setting, the child should be given nothing by mouth in case eye examination under anesthesia or surgical repair is required.

▶ Prognosis

Prognosis depends on the extent of the trauma.

BLUNT ORBITAL TRAUMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Blunt orbital and soft tissue trauma may produce "black eye," which is ecchymosis (blue or purplish hemorrhagic areas) of the eyelids.

▶ Pathogenesis

Trauma to the orbit from a closed fist, collision with another player during team sports, and falls are common causes of blunt orbital injuries. Orbital compartment syndrome, which may result from severe orbital trauma, is caused by hemorrhaging within the orbit or severe orbital edema (or

both). This is an emergency which may lead to permanent vision loss if not treated urgently.

Prevention

Protective eyewear during athletic activities and adequate supervision of children at home and school.

Clinical Findings

Blunt trauma to the orbit may result in orbit fractures. The orbital floor is a common location for a fracture (called a *blowout fracture*). A specific fracture that occurs mainly in children after blunt orbit trauma is called the *white-eyed blowout fracture*. This results from a greenstick fracture of the orbit with entrapment of extraocular muscles. It is called "white-eyed" because the external orbital soft tissue injury may appear to be minimal, but the patient will have severe pain with eye movement, as well as nausea, vomiting, and restriction of eye movements.

A blowout fracture must be suspected in a patient with symptoms of double vision, pain with eye movements, and restriction of extraocular muscle movements after blunt orbital trauma. CT images of an orbital floor fracture often reveal herniation of orbital fat or the inferior rectus muscle into the maxillary sinus. Assessment of ocular motility, globe integrity, and intraocular pressure will determine the extent of the blunt orbital injury. Consultation with an ophthalmologist is necessary to determine the full spectrum of the injuries.

Orbital compartment syndrome is an emergency requiring immediate treatment. Patients present with severe edema or ecchymosis of the eyelids (which makes it very difficult to open the eyelids), proptosis, and possibly an acute traumatic optic neuropathy, resulting in decreased vision or an afferent pupillary defect. Neuroimaging may reveal a retrobulbar hemorrhage and proptosis.

Differential Diagnosis

Orbit fracture with or without muscle entrapment, globe rupture, orbital compartment syndrome, and traumatic or ischemic optic neuropathy.

Treatment

Orbital compartment syndrome requires emergent lateral eyelid canthotomy and cantholysis to decompress the orbit. Treatment should not be delayed in order to image the orbits. Prompt treatment can prevent permanent vision loss.

Patients with clinical signs of muscle entrapment require urgent surgical repair to avoid permanent ischemic injury to the involved extraocular muscle. Large fractures may need repair to prevent enophthalmos, a sunken appearance to the orbit. This can usually be performed on a nonemergent basis.

Cold compresses or ice packs for brief periods (eg, 10 minutes at a time) are recommended in older children in the first 24 hours after injury to reduce hemorrhage and swelling.

Prognosis

The prognosis depends on the severity of the blunt trauma, associated ocular injuries, and extent of the orbit fractures.

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Inspection of the eyelids reveals the extent and severity of the traumatic laceration.
> ▶ Lacerations of the nasal third of the eyelid and involving the eyelid margin are at risk for lacrimal system injury and subsequent chronic tearing.

LACERATIONS

Pathogenesis

Lacerations of the eyelids and lacrimal system often result from dog bites, car accidents, falls, and fights.

Prevention

Supervision of children at home and at school.

Clinical Findings

Eyelid lacerations may be partial or full thickness in depth depending on the extent of the injury. Foreign bodies, such as glass or gravel, may be present depending on the mechanism of the injury.

Differential Diagnosis

Lacerations involving the eyelid may or may not involve the nasolacrimal duct system or eyelid margin. Globe injury may be associated with eyelid lacerations as well.

Complications

Poor surgical repair of lacerations of the eyelid margin can result in eyelid malposition, which causes chronic ocular surface irritation and possible corneal scarring.

Treatment

Except for superficial lacerations away from the globe, repair in children is best performed in the operating room under general anesthesia. Special consideration must be given to lacerations involving the lid margin, significant tissue

▲ **Figure 16–9.** Laceration involving right lower lid and canaliculus.

loss, full-thickness lacerations, lacerations that may involve the levator muscle in the upper lid, and to those that may involve the canaliculus (Figure 16–9). These injuries are best repaired by an ophthalmologist and may require intubation of the nasolacrimal system with silicone tubes.

► Prognosis

Prognosis depends on severity of the injury, tissue loss, and adequacy of surgical repair.

BURNS

> **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
>
> ► Severe thermal or chemical burns can result in permanent vision loss, ectropion or entropion of the lid, and scarring of the conjunctiva and cul-de-sac.

► Pathogenesis

Chemical burns with strong acidic and alkaline agents can be blinding and constitute a true ocular emergency. Examples are burns caused by exploding batteries, spilled drain cleaner, and bleach. Eyelid burns can occur in toddlers from contact with a lighted cigarette. The cornea is often involved as well. Curling irons can cause similar burns. Burns of the conjunctiva and cornea may be thermal, radiant, or chemical. Radiant energy causes ultraviolet keratitis. Typical examples are welder's burn and burns associated with skiing without goggles in bright sunlight.

► Prevention

Protective eyewear when engaging in activities that pose a potential risk for exposure to hazardous chemicals, radiant energy, or when explosive conditions are possible.

► Clinical Findings

Superficial thermal burns cause pain, tearing, and injection. Corneal epithelial defects can be diagnosed using fluorescein dye, which will stain areas of the cornea bright yellow where the epithelium is absent. The fluorescein dye pattern will show a uniformly stippled appearance of the corneal epithelium in ultraviolet keratitis.

► Differential Diagnosis

Corneal abrasion, iritis.

► Complications

Significant corneal injury, especially if associated with an alkali burn, may lead to scarring and vision loss. Eyelid scarring can result in chronic exposure, dry eye, irritation, and entropion or ectropion.

► Treatment

Alkalis tend to penetrate deeper than acids into ocular tissue and often causes severe injury. Damage to the conjunctival vessels gives the eye a white or blanched appearance, resulting in ocular ischemia. Immediate treatment consists of copious irrigation and removal of precipitates as soon as possible after the injury. Initial stabilization of the injury is initiated by using topical antibiotics and patching the injured eye closed. A cycloplegic agent such as cyclopentolate 1% may be added if corneal involvement is present. This reduces the pain from ciliary spasm and iritis that may accompany the injury. The patient should be referred to an ophthalmologist after immediate first aid has been given.

► Prognosis

Prognosis depends on the severity of the injury.

HYPHEMA

> **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
>
> ► Slit-lamp examination or penlight examination may reveal a layer of blood within the anterior chamber. Other injuries to the globe and orbit are often present.
> ► A hyphema may be microscopic or may fill the entire anterior chamber (Figure 16–10).

▲ **Figure 16–10.** Hyphema filling approximately 20% of the anterior chamber.

Pathogenesis

Blunt trauma to the globe may cause a hyphema, or bleeding within the anterior chamber, from a ruptured vessel located near the root of the iris or in the anterior chamber angle (Figure 16–10).

Prevention

Protective eyewear and appropriate supervision at home and at school.

Clinical Findings

Blunt trauma severe enough to cause a hyphema may be associated with additional ocular injury, including iritis, lens subluxation, retinal edema or detachment, and glaucoma. In patients with sickle cell anemia or trait, even moderate elevations of intraocular pressure may quickly lead to optic atrophy and permanent vision loss. Therefore, all African Americans whose sickle cell status is unknown should be tested if hyphema is observed. These patients require extra vigilance in diagnosing and treating hyphema.

Differential Diagnosis

Nontraumatic causes of hyphema include juvenile xanthogranuloma and blood dyscrasias. Rarely, hyphema is noted in the newborn after a stressful birth.

Complications

Increased intraocular pressure, glaucoma, permanent corneal staining, and vision loss.

Treatment

A shield should be placed over the eye, the head elevated, and arrangements made for ophthalmologic referral.

Prognosis

The prognosis is worse if intraocular pressure is elevated, the patient has sickle cell disease, or if other associated ocular injuries are present.

ABUSIVE HEAD TRAUMA & NONACCIDENTAL TRAUMA

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Traumatic head trauma, commonly known as *shaken baby syndrome,* is a form of nonaccidental trauma characterized by a constellation of examination findings, including traumatic brain injury, retinal hemorrhages, and fractures of long bones or ribs.

▶ The history leading to the diagnosis of shaken baby syndrome is often vague and poorly correlated with the extent of injury.

Pathogenesis

The mechanism of injury has been ascribed to a rapid back and forth shaking of young children that results in brain and ocular injuries. It is now believed that injuries may also be the result of blunt impact. Additional injury may result from spinal cord injuries and hypoxia.

Clinical Findings

Victims often have multiple organ system involvement that includes, but is not limited to, traumatic brain injury, bone fractures, and retinal hemorrhages. The presentation can vary from irritability to emesis, change in mental status, or cardiopulmonary arrest.

Neuroimaging of the brain and a skeletal survey are used to diagnose shaken baby syndrome. Ophthalmic consultation and a dilated retinal examination are necessary to document retinal hemorrhages. Hemorrhages may be unilateral or bilateral and may be located in the posterior pole or periphery. Whereas retinal hemorrhages tend to resolve fairly quickly, those in the vitreous do not. If a blood clot lies over the macula, deprivation amblyopia may occur and may require intraocular surgery by a retinal specialist. Other ocular findings associated with nonaccidental trauma include lid ecchymosis, subconjunctival hemorrhage, hyphema, retinal

folds, retinoschisis (traumatic separation of the retinal layers), and optic nerve edema. Acute-onset esotropia can also occur.

Differential Diagnosis

The differential diagnosis of retinal hemorrhages includes those secondary to a fall, seizures, chest compressions during cardiopulmonary resuscitation, blood dyscrasias, and Terson syndrome, among others. A team effort between the primary treating physician, neurosurgery, orthopedics, ophthalmology, and social services is often needed to determine the true cause of a patient's injuries.

Complications

The severity of injuries dictates the long-term outcome. Severely diffuse retinal hemorrhages, associated traumatic optic neuropathy, and cortical injury adversely affect the potential for normal vision.

Treatment

Management of any systemic injuries is required. Observation by an ophthalmologist for resolution of retinal hemorrhages is the usual management. Vitreous hemorrhages or large preretinal hemorrhages that do not resolve within several weeks may need surgical treatment by a retinal specialist.

Prognosis

Prognosis depends on the severity of ocular and brain injuries.

Levin AV: Retinal hemorrhage in abusive head trauma. Pediatrics 2010;126(5):961–970 [PMID: 20921069].

PREVENTION OF OCULAR INJURIES

Air rifles, paintballs, and fireworks are responsible for many serious eye injuries in children. Golf injuries can be very severe. Bungee cords have been associated with multiple types of severe ocular trauma, including corneal abrasion, iris tears, hyphema, vitreous hemorrhage, retinal detachment, and blindness. Use of these items and associated activities should be avoided or very closely supervised. Safety goggles should be used in laboratories and industrial arts classes, and when operating snow blowers, power lawn mowers, and power tools, or when using hammers and nails.

Sports-related eye injuries can be prevented with protective eyewear. Sports goggles and visors of polycarbonate plastic will prevent injuries in games using fast projectiles such as tennis or racquet balls, or where opponents may swing elbows or poke at the eye.

The one-eyed individual should be specifically advised to always wear polycarbonate eyeglasses and goggles for all sports. High-risk activities such as boxing and the martial arts should be avoided by one-eyed children.

▼ DISORDERS OF THE OCULAR STRUCTURES

DISEASES OF THE EYELIDS

The eyelids can be affected by various dermatologic and infectious conditions.

Blepharitis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Blepharitis is inflammation of the lid margin characterized by crusty debris at the base of the lashes, erythema of eyelid margins, and ocular irritation.

Pathogenesis

Blepharitis is caused by inflammation of the eyelid margin, meibomian gland obstruction, bacterial overgrowth, and tear film imbalance.

Prevention

Eyelid hygiene is essential to prevent or control blepharitis. Eyelid scrubs help decrease the bacterial load on the eyelid margins and lashes. Warm compresses help loosen the secretions of the meibomian glands.

Clinical Findings

Patients may present with dry eye symptoms, red and irritated eyelid margins, conjunctivitis, and decreased vision from corneal erosions or vascularization. When conjunctival injection accompanies blepharitis, the condition is known as *blepharoconjunctivitis*. *Staphylococcus* is the most common bacterial cause.

Differential Diagnosis

Chalazion, hordeolum, and rosacea blepharitis.

Complications

Permanent corneal and eyelid margin scarring in severe cases.

Treatment

Treatment includes lid scrubs with baby shampoo several times a week, warm compresses to the eyelids, and application of a topical antibiotic ointment such as erythromycin or bacitracin at bedtime.

▶ **Prognosis**

Generally good.

Chalazion

> **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
>
> ▶ A chalazion is an inflammation of the meibomian glands, which may produce a tender nodule over the tarsus of the upper or lower lid.
> ▶ Chalazion tends to be recurrent if eyelid hygiene is poor.

▶ **Pathogenesis**

Obstruction of the eyelid margin meibomian glands with resultant inflammation, fibrosis, and granuloma formation.

▶ **Prevention**

See earlier section Blepharitis.

▶ **Clinical Findings**

Eyelid nodule of variable size and localized erythema of the corresponding palpebral conjunctiva that may be associated with a yellow lipogranuloma (Figure 16–11).

▶ **Differential Diagnosis**

Hordeolum, blepharitis.

▶ **Treatment**

See earlier section Blepharitis. Oral flax seed oil may also decrease the risk of recurrent chalazion. If incision and curettage are needed because the lesion is slow to resolve, the child will require a general anesthetic. Topical azithromycin (ophthalmic solution 1%) may also help decrease recurrence of chalazion, but it is still under investigation.

▶ **Prognosis**

Generally good.

VIRAL EYELID DISEASE

> **ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES**
>
> ▶ Viral infections of the eyelids can result in eyelid vesicles or papules.
A
B

▲ **Figure 16–11.** Chalazion. **A:** Right lower lid, external view. **B:** Right lower lid conjunctival surface.

▶ **Pathogenesis**

Herpes simplex virus (HSV) may involve the conjunctiva and lids at the time of primary herpes simplex infection resulting in blepharoconjunctivitis. Vesicular lesions with an erythematous base occur. Herpes zoster causes vesicular disease in association with a skin eruption in the dermatome of the ophthalmic branch of the trigeminal nerve. Molluscum contagiosum lesions are typically umbilicated papules. If near the lid margin, the lesions may cause conjunctivitis.

▶ **Prevention**

Avoid contact with individuals with active viral infections.

▶ **Clinical Findings**

A vesicular rash is the most common sign of herpes viral eyelid infection. Fluorescein dye should be administered topically to the effected eye followed by examination with

a cobalt blue light to determine if corneal or conjunctival involvement is present. Herpes simplex or herpes zoster can be diagnosed by rapid viral culture (24–48 hours) or detection of antigen in skin lesions (3 hours).

▶ Differential Diagnosis

Impetigo.

▶ Complications

Conjunctivitis, keratitis (corneal infection).

▶ Treatment

Primary herpes simplex blepharoconjunctivitis should be treated with systemic acyclovir (a liquid formulation is available), valacyclovir, or famciclovir. When either the conjunctiva or the cornea is involved, treatment should include topical 1% trifluridine or 3% vidarabine.

Treatment of ophthalmic herpes zoster with nucleoside analogues within 5 days after onset may reduce the morbidity. When vesicles are present on the tip of the nose with herpes zoster (Hutchinson sign), ocular involvement, including iritis, is more likely.

Molluscum contagiosum lesions may be treated with cautery or excision.

▶ Prognosis

Generally good unless corneal involvement is present.

MISCELLANEOUS EYELID INFECTIONS

Pediculosis

Pediculosis of the lids (phthiriasis palpebrarum) is caused by *Phthirus pubis*. Nits and adult lice can be seen on the eyelashes when viewed with appropriate magnification. Mechanical removal and application to the lid margins of Phospholine iodide or 1% mercuric oxide ointment can be effective. Other bodily areas of involvement must also be treated if involved. Family members and contacts may also be infected (see Chapter 15).

Papillomavirus

Papillomavirus may infect the lid and conjunctiva. Warts may be recurrent, multiple, and difficult to treat. Treatment modalities include cryotherapy, cautery, carbon dioxide laser, and surgery.

Staphylococcal Infection

Localized staphylococcal infections of the glands of Zeis within the lid cause a sty (hordeolum) (Figure 16–12). When the infection coalesces and points internally or externally, it

▲ **Figure 16–12.** Hordeolum and blepharitis, left upper lid.

may discharge itself or require incision. The lesion is tender and red. Warm compresses help to shorten the acute process. Some practitioners prescribe a topical antibiotic ointment. Any coexisting blepharitis should be treated.

EYELID PTOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Eyelid ptosis results in a droopy eyelid that may be unilateral or bilateral. If the pupil is obstructed, deprivation amblyopia may result.

▶ Pathogenesis

Ptosis—a droopy upper lid (Figure 16–13)—may be congenital or acquired but is usually congenital in children owing to a defective levator muscle. Other causes of ptosis are myasthenia gravis, lid injuries, third nerve palsy, and Horner

▲ **Figure 16–13.** Congenital ptosis of severe degree, left upper lid.

syndrome (see next section). Ptosis may be associated with astigmatism and amblyopia.

▶ Prevention

Injury prevention.

▶ Clinical Findings

An association sometimes seen with congenital ptosis is the Marcus Gunn jaw-winking phenomenon. Intermittent reduction of the ptosis occurs during mastication or sucking, due to a synkinesis or simultaneous firing of the external or internal pterygoid muscle (innervated by the trigeminal nerve) and the levator muscle (innervated by the oculomotor nerve).

▶ Differential Diagnosis

Congenital ptosis, traumatic ptosis, neurogenic ptosis (oculomotor nerve palsy), Horner syndrome.

▶ Complications

Deprivation amblyopia and induced astigmatism.

▶ Treatment

Surgical correction is indicated for moderate to severe ptosis. Mild cases less often require operative management. Cosmesis may be better if surgery is delayed until most of the facial growth has occurred, usually around age 5 years.

▶ Prognosis

The prognosis depends on the presence of amblyopia and whether it is adequately treated.

HORNER SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Horner syndrome, which may be congenital or acquired, presents with signs of unequal pupils (anisocoria), eyelid ptosis, iris heterochromia, and anhidrosis.

▶ Pathogenesis

The syndrome is caused by an abnormality or lesion to the sympathetic chain. The congenital variety is most commonly the result of birth trauma. Acquired cases may occur in children who have had cardiothoracic surgery, trauma, or brainstem vascular malformation. Most worrisome is a Horner syndrome caused by neuroblastoma of the sympathetic chain in the apical lung region.

▲ **Figure 16–14.** Congenital Horner syndrome. Ptosis, miosis, and heterochromia. Lighter colored iris is on the affected left side.

▶ Prevention

Sympathetic chain injury avoidance during cardiothoracic surgery and delivery.

▶ Clinical Findings

Parents may notice unequal pupils or different colored eyes. Penlight examination of the eyes may reveal unequal pupils (anisocoria), iris heterochromia, and eyelid ptosis of the affected eye.

The ptosis is usually mild with a well-defined upper lid crease. This differentiates it from congenital ptosis, which typically has a poorly defined lid crease. Another key finding of congenital Horner syndrome is heterochromia of the two irides, with the lighter colored iris occurring on the same side as the lesion (Figure 16–14). Anhidrosis can occur in congenital and acquired cases. Of note, not all of the three signs must be present to make the diagnosis.

Pharmacologic assessment of the pupils with topical cocaine and hydroxyamphetamine or epinephrine will help determine whether the Horner syndrome is due to a preganglionic or postganglionic lesion of the sympathetic chain. Preliminary studies suggest that topical apraclonidine may be useful in the diagnosis of Horner syndrome. Physical examination, including palpation of the neck and abdomen for masses, and MRI of structures in the head, neck, chest, and abdomen should be considered. An excellent screening test for neuroblastoma is the spot urine vanillylmandelic acid/creatinine ratio.

▶ Differential Diagnosis

Congenital or neurogenic ptosis, physiologic anisocoria.

▶ Complications

Prognosis depends on the etiology. Ptosis associated with Horner syndrome is usually mild and rarely results in amblyopia.

▶ Treatment

Management of any underlying disease is required. The ptosis and vision should be monitored by an ophthalmologist.

Prognosis

Prognosis depends on the etiology. The vision is usually normal.

EYELID TICS

Eyelid tics may occur as a transient phenomenon lasting several days to months. Although a tic may be an isolated finding in an otherwise healthy child, it may also occur in children with multiple tics, attention-deficit/hyperactivity disorder, or Tourette syndrome. Caffeine consumption may cause or exacerbate eyelid tics. If the disorder is a short-lived annoyance, no treatment is needed.

DISORDERS OF THE NASOLACRIMAL SYSTEM

NASOLACRIMAL DUCT OBSTRUCTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Nasolacrimal obstruction occurs in up to 6% of infants.
▶ Most cases clear spontaneously during the first year.

Pathogenesis

Obstruction in any part of the drainage system may result from either incomplete canalization of the duct or membranous obstructions. Nasolacrimal obstruction may also occur in individuals with craniofacial abnormalities or Down syndrome.

Prevention

Not applicable.

Clinical Findings

Nasolacrimal duct obstruction presents with tearing and mucoid discharge from the affected eye. Signs and symptoms include tearing (epiphora), mucoid discharge especially in the morning, erythema of one or both lids, and conjunctivitis (Figure 16–15). Light sensitivity and blepharospasm suggest possible congenital glaucoma and warrant an urgent ophthalmic referral.

Differential Diagnosis

The differential diagnosis of tearing includes nasolacrimal duct obstruction, congenital glaucoma, foreign bodies, nasal disorders, and, in older children, allergies.

▲ **Figure 16–15.** Nasolacrimal obstruction, right eye. Mattering on upper and lower lids.

Complications

Dacryocystitis, orbital cellulitis, sepsis, respiratory distress.

Treatment

Massage over the nasolacrimal sac may empty debris from the nasolacrimal sac and clear the obstruction, although the efficacy of massage in clearing nasolacrimal obstruction is debated. Superinfection may occur, and treatment with topical antibiotics may help decrease the discharge.

The mainstay of surgical treatment is probing, which is successful 80% or more of the time, but the success rate may decrease after the infant reaches 1 year of age. Other surgical procedures, including infraction of the inferior nasal turbinate, balloon dilation, and silicone tube intubation, may be necessary if probing fails. Much less often, dacryocystorhinostomy is required.

Prognosis

Generally good with surgical treatment.

CONGENITAL DACRYOCYSTOCELE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Presence of a nodular enlargement which may be blue in color, occurring shortly after birth over the nasolacrimal sac/medial eyelids.
▶ Dacryocystitis often occurs due to bacterial superinfection.

▲ **Figure 16–16.** Congenital dacryocystocele on the left side. Raised, bluish discolored mass of enlarged nasolacrimal sac. Note superiorly displaced medial canthus.

▶ Pathogenesis

Congenital dacryocystocele is thought to result from obstructions proximal and distal to the nasolacrimal sac.

▶ Prevention

Early intervention with nasolacrimal duct probing may prevent dacryocystitis.

▶ Clinical Findings

At birth, the nasolacrimal sac is distended and has a bluish hue that often leads to an erroneous diagnosis of hemangioma. The tense and swollen sac displaces the medial canthus superiorly (Figure 16–16). Digital pressure over the nodule may result in reflux of tears, mucus, or purulent discharge from the inferior eyelid punctum. An intranasal duct cyst may be present beneath the inferior turbinate at the valve of Hasner. These cysts may be associated with respiratory distress.

▶ Differential Diagnosis

Eyelid hemangioma, basal encephalocele.

▶ Complications

Dacryocystitis, orbital cellulitis, sepsis, respiratory distress.

▶ Treatment

Massage and warm compresses are rarely effective. Nasolacrimal duct probing and endoscopic marsupialization of the intranasal cyst under general anesthesia may be required. Hospital admission and systemic antibiotics are indicated if dacryocystitis is present. Consultation with an ear, nose, and throat specialist is recommended to aid in the diagnosis and treatment of an associated intranasal cyst.

▶ Prognosis

Generally good.

DACRYOCYSTITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Dacryocystitis is an infection of the nasolacrimal sac that causes erythema and edema over the nasolacrimal sac.

▶ Pathogenesis

Acute and chronic dacryocystitis are typically caused by bacteria that colonize the upper respiratory tract, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Streptococcus viridans*, *Moraxella catarrhalis*, and *Haemophilus* species.

▶ Prevention

Treatment of nasolacrimal duct obstruction.

▶ Clinical Findings

Acute dacryocystitis presents with inflammation, swelling, tenderness, and pain over the lacrimal sac (located inferior to the medial canthal tendon). Fever may be present. The infection may point externally (Figure 16–17). A purulent discharge and tearing can be expected, because the cause of infection is almost always nasolacrimal obstruction.

Signs of chronic dacryocystitis are mucopurulent debris on the lids and lashes, tearing, injection of the palpebral conjunctiva, and reflux of pus at the puncta when pressure is applied over the sac. Chronic dacryocystitis and recurrent episodes of low-grade dacryocystitis are caused by nasolacrimal obstruction.

▶ Differential Diagnosis

Dacryocystocele, preseptal cellulitis.

▲ **Figure 16–17.** Acute dacryocystitis in a 11-week-old infant.

Complications

Preseptal cellulitis, orbital cellulitis, sepsis.

Treatment

Severe acute dacryocystitis is treated with intravenous antibiotics after attempts at identifying the offending organism by culture and staining. Oral antibiotics can be tried in milder cases. Topical antibiotic administration is adjunctive and is also used with recurrent chronic infections. Warm compresses are beneficial. After the acute episode subsides—and in chronic cases—the nasolacrimal obstruction must be relieved surgically. If it cannot be drained via the intranasal portion of the nasolacrimal duct, external drainage may be necessary. This should be done as a last resort since a fistula may develop.

Prognosis

Generally good.

▼ DISEASES OF THE CONJUNCTIVA

Conjunctivitis may be infectious, allergic, or associated with systemic disease. Trauma, irritation of the conjunctiva, and intraocular inflammation can cause injection of conjunctival vessels that can be confused with conjunctivitis.

OPHTHALMIA NEONATORUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Ophthalmia neonatorum (conjunctivitis in the newborn) occurs during the first month of life.

Pathogenesis

Pathogenesis may be due to inflammation resulting from silver nitrate prophylaxis given at birth, bacterial infection (gonococcal, staphylococcal, pneumococcal, or chlamydial), or viral infection. In developed countries, *Chlamydia* is the most common cause. Neonatal conjunctivitis may threaten vision if caused by *Neisseria gonorrhoeae*. Herpes simplex is a rare but serious cause of neonatal conjunctivitis, since it may indicate systemic herpes simplex infection.

Prevention

Treatment of maternal infections prior to delivery can prevent ophthalmia neonatorum. Although no single prophylactic

▲ **Figure 16–18.** Ophthalmia neonatorum due to *Chlamydia trachomatis* infection in a 2-week-old infant. Note marked lid and conjunctival inflammation.

medication can eliminate all cases of neonatal conjunctivitis, povidone-iodine may provide broader coverage against the organisms causing this disease than silver nitrate or erythromycin ointment. Silver nitrate is not effective against *Chlamydia*. The choice of prophylactic agent is often dictated by local epidemiology and cost considerations, but erythromycin ophthalmic ointment is most often routinely administered immediately after birth to help prevent ophthalmia neonatorum.

Clinical Findings

Ophthalmia neonatorum is characterized by redness and swelling of the lids and conjunctiva and by discharge (Figure 16–18). Gram staining, polymerase chain reaction amplification for *Chlamydia* and HSV, and bacterial and viral cultures aid in making an etiologic diagnosis.

Differential Diagnosis

Chemical/toxic conjunctivitis, viral conjunctivitis, bacterial conjunctivitis, chlamydial conjunctivitis.

Complications

Chlamydia can cause a delayed-onset pneumonitis. Gonococcal infections can cause blindness through endophthalmitis as well as sepsis.

Treatment

Treatment of these infections requires specific systemic antibiotics because they can cause serious infections in other organs. Parents should be examined and receive treatment when a sexually associated pathogen is present.

▶ Prognosis

Prognosis depends on the infectious agent as well as the rapidity of treatment.

BACTERIAL CONJUNCTIVITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ In general, bacterial conjunctivitis is accompanied by a purulent discharge.

▶ Pathogenesis

Common bacterial causes of conjunctivitis in older children include *Haemophilus* species, *S pneumoniae*, *M catarrhalis*, and *S aureus*.

▶ Prevention

Hand-washing and contact precautions.

▶ Clinical findings

Purulent discharge and conjunctival injection of one or both eyes. These symptoms may be associated with an upper respiratory infection. Regional lymphadenopathy is not a common finding in bacterial conjunctivitis except in cases of oculoglandular syndrome due to *S aureus*, group A β-hemolytic streptococci, *Mycobacterium tuberculosis* or atypical mycobacteria, *Francisella tularensis* (the agent of tularemia), and *Bartonella henselae* (the agent of cat-scratch disease).

▶ Differential Diagnosis

Viral, allergic, traumatic, or chemical/toxic conjunctivitis.

▶ Complications

Bacterial conjunctivitis is usually self-limited unless caused by *Chlamydia trachomatis*, *N gonorrhoeae*, and *Neisseria meningitidis* which may have systemic manifestations.

▶ Treatment

If conjunctivitis is not associated with systemic illness, topical antibiotics such as erythromycin, polymyxin-bacitracin, sulfacetamide, tobramycin, and fluoroquinolones are adequate. Systemic therapy is recommended for conjunctivitis associated with *C trachomatis*, *N gonorrhoeae*, and *N meningitidis*.

▶ Prognosis

Generally good.

Gold RS: Treatment of bacterial conjunctivitis in children. Pediatr Ann 2011;40(2):95–105 [PMID: 21323206].

VIRAL CONJUNCTIVITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Children with viral conjunctivitis usually present with injection of the conjunctiva of one or both eyes and watery ocular discharge.

▶ Pathogenesis

Adenovirus infection is often associated with pharyngitis, a follicular reaction and injection of the palpebral conjunctiva, and preauricular adenopathy (pharyngoconjunctival fever). Epidemics of adenoviral keratoconjunctivitis occur. Conjunctivitis may also be due to enterovirus and can occur as part of an acute measles illness. HSV may cause conjunctivitis or blepharoconjunctivitis.

▶ Prevention

Hand-washing and contact precautions.

▶ Clinical Findings

Watery discharge associated with conjunctival injection of one or both eyes. A vesicular rash involving the eyelids or face suggests HSV.

▶ Differential Diagnosis

Bacterial, allergic, traumatic, or chemical/toxic conjunctivitis.

▶ Complications

Generally, viral conjunctivitis is self-limited. Herpes conjunctivitis may result in keratitis, which can affect visual acuity. This should be treated with antiviral therapy and the patient should be referred to an ophthalmologist.

▶ Treatment

Treatment of adenovirus conjunctivitis is supportive. Children with presumed adenoviral keratoconjunctivitis are considered contagious 10–14 days from the day of onset. They should stay out of school and group activities as long as their eyes are red and tearing. Strict hand-washing precautions are recommended.

Herpes conjunctivitis can be treated with topical trifluridine 1% drops or 3% vidarabine ointment. Oral acyclovir may be used for treatment of the primary infection to decrease the duration and severity of the infection and as prophylaxis to reduce recurrence of herpes simplex ocular disease.

▶ Prognosis

Generally good.

ALLERGIC CONJUNCTIVITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A history of itchy, watery, red eyes, often associated with other allergy symptoms such as sneezing and rhinitis.

▶ Prevention

Decrease exposure to allergens. This may be done by hand washing after handling dogs/cats, washing clothing, and bathing after being outdoors when pollen counts are elevated.

▶ Clinical Findings

The history of itchy, watery, and red eyes is essential in making the diagnosis of allergic conjunctivitis. Redness of the conjunctiva, tearing, and discharge may be part of the history but need not be present on examination to make the diagnosis. Vernal conjunctivitis is a more severe form of allergic conjunctivitis occurring mostly in the spring and summer that is associated with intense tearing, itching, and a stringy discharge. Vernal allergic conjunctivitis is more common in males. Vernal conjunctivitis may present with giant cobblestone papillae (Figure 16–19) on the eyelid conjunctiva, nodules around the corneal limbus, and even sterile corneal ulcers. Contact lens wear may induce a conjunctivitis that appears similar to the palpebral form of vernal conjunctivitis.

▶ Treatment

Topical ophthalmic solutions that combine both an antihistamine and mast cell stabilizers, including olopatadine 0.1%, epinastine HCl 0.05%, and ketotifen fumarate 0.025%, are very effective at treating allergic conjunctivitis. Other agents available include a combination topical vasoconstrictor plus an antihistamine (naphazoline antazoline), a nonsteroidal anti-inflammatory drug (NSAID) such as ketorolac

▲ **Figure 16–19.** Vernal conjunctivitis. Cobblestone papillae in superior tarsal conjunctiva.

tromethamine 0.5%, a mast cell stabilizer such as lodoxamide tromethamine 0.1%, or a corticosteroid such as prednisolone 0.125% (Table 16–2). Corticosteroids should be used with caution because their extended use causes glaucoma or cataracts in some patients. Systemic antihistamines and limitation of exposure to allergens may help reduce symptoms as well.

▶ Prognosis

Generally good.

MUCOCUTANEOUS DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis are systemic conditions that often affect the eyes, as well as the skin, and oral and genitourinary mucosa.
▶ Ocular involvement may result in permanent conjunctival scarring, eyelid malposition, severe dry eye syndrome, and permanent vision loss.

▶ Clinical Findings

Erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis may be caused by medications including: phenytoin, sulfonamides, NSAIDs, and barbiturates or infections such as HSV or *Mycoplasma pneumoniae.*

Table 16–2. Common ocular allergy medications.

Generic Name	Brand Name	Mechanism of Action	Side Effects	Dosage	Indications
Lodoxamide tromethamine 0.1%	Alomide	Mast cell stabilizer	Transient burning or stinging	1 drop 4 times daily—taper	Vernal keratoconjunctivitis
Cromolyn Na 4%	Crolom, Opticrom	Mast cell stabilizer	Transient burning or stinging	1 drop 4–6 times daily	Vernal keratoconjunctivitis
Olopatadine	Patanol, Pataday	Mast cell stabilizer, H_1-receptor antagonist	Headache, burning or stinging	Twice daily (interval 6–8 h)	Itching due to allergic conjunctivitis
Ketorolac tromethamine 0.5%	Acular	Nonsteroidal anti-inflammatory	Transient burning or stinging	1 drop 4 times daily	Itching due to seasonal allergic conjunctivitis
Levocabastine HCl 0.05%	Livostin	H_1-receptor antagonist	Transient burning or stinging, headache	1 drop 4 times daily	Relief of symptoms of seasonal allergic conjunctivitis
Naphazoline HCl 0.1%	AK-Con, Naphcon, Opcon, Vasocon	Ocular decongestant, vasoconstrictor	Mydriasis, increased redness, irritation, discomfort, punctate keratitis, increased intraocular pressure, dizziness, headache, nausea, nervousness, hypertension, weakness, cardiac effects, hyperglycemia	Varies by preparation	Temporary relief of redness due to minor eye irritants
Pheniramine maleate	Component in AKCon A, Opcon-A, Naphcon-A	Antihistamine		1 drop every 3–4 h, as needed	Relief of symptoms of seasonal allergic conjunctivitis

With Stevens-Johnson syndrome, conjunctival changes include erythema and vesicular lesions that frequently rupture. Staining of the conjunctiva and/or cornea with fluorescein suggests severe ocular involvement and high risk for permanent ocular sequela, including symblepharon (adhesions) between the raw edges of the bulbar (eye) and palpebral (lid) conjunctivae.

▶ Differential Diagnosis

Viral or bacterial conjunctivitis if the patient presents prior to cutaneous or mucosal eruptions.

▶ Complications

Severe ocular involvement can result in permanent scarring of the conjunctiva leading to eyelid malposition, trichiasis (eyelashes touching the surface of the eye), and vision loss from chronic ocular irritation and extreme tear film deficiency.

▶ Treatment

Treatment of the underlying disease, including discontinuation of offending medications and use of appropriate antimicrobials is necessary. Management of conjunctivitis associated with mucocutaneous disease depends on its severity. Artificial tears and ointment provide comfort and a topical corticosteroid may help prevent adhesions and dry eye in mild to moderate cases. Lysis of adhesions or use of a scleral ring by an ophthalmologist may be required. Surgical treatment of severe cases with amniotic membrane grafts may prevent visual disability by decreasing the risk of dry eye from tear-producing glands/goblet cell destruction, symblepharon, and trichiasis. Topical cyclosporine may help decrease the inflammatory reaction that leads to the destruction of tear-producing glands/goblet cells and subsequent dry eye syndrome.

▶ Prognosis

Prognosis depends on the severity of the underlying condition. Guarded visual prognosis is made in severe cases.

Gregory DG: Treatment of acute Stevens-Johnson syndrome and toxic epidermal necrolysis using amniotic membrane: a review of 10 consecutive cases. Ophthalmology 2011;118(5):908–914 [PMID: 21440941].

▼ DISORDERS OF THE IRIS

IRIS COLOBOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Iris coloboma is a developmental defect due to incomplete closure of the anterior embryonal fissure.

▶ Iris coloboma may occur as an isolated defect or in association with various chromosomal abnormalities and syndromes.

▶ Clinical Findings

Penlight examination of the pupils reveals a keyhole shape to the pupil rather than the normal round configuration (Figure 16–20). A dilated examination by an ophthalmologist is necessary to determine if the coloboma involves additional structures of the eye including the retina. If the retina is involved, vision may be poor. A genetic evaluation is usually recommended due to the high rate of associated genetic syndromes.

▶ Differential Diagnosis

Microphthalmia, aniridia, previous iris trauma.

▶ Complications

Low vision and rarely a secondary retinal detachment may need surgical intervention.

▲ **Figure 16–20.** Iris coloboma located inferiorly.

▶ Treatment

Patients with coloboma should be monitored by an ophthalmologist for signs of amblyopia, significant refractive errors, and strabismus.

▶ Prognosis

The prognosis depends on whether there are other ocular structures involved. Visual acuity is guarded if a large retinal coloboma is present.

ANIRIDIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Aniridia is a bilateral disorder that results in the absence of the majority of the iris (Figure 16–21).

▶ Pathogenesis

Aniridia may occur as an autosomal dominant disease or in a sporadic form associated with Wilms tumor. The aniridia gene is located within the 11p13 chromosome region. Aniridia, genitourinary abnormalities, and developmental delay have been linked to an 11p deletion.

▶ Clinical Findings

Slit-lamp or penlight examinations reveal little to no visible iris (see Figure 16–21). Photophobia, nystagmus, and poor vision are present in aniridia. Abdominal ultrasonography is indicated in the sporadic form of aniridia to diagnose Wilms tumor. Genetic evaluation is indicated as well. Cataract, corneal changes, macular hypoplasia, and glaucoma are often seen.

▶ Differential Diagnosis

Microphthalmia, iris coloboma, previous iris trauma.

▲ **Figure 16–21.** Bilateral aniridia. Iris remnants present temporally in each eye.

Complications

Low vision, cataracts, and glaucoma.

Treatment

An ophthalmologist should determine if cataracts or glaucoma are present in patients with aniridia. Surgical treatment of cataracts and glaucoma is often indicated.

Prognosis

Patients tend to have low vision.

ALBINISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Albinism is caused by defective melanogenesis, usually as an autosomal recessive disease, but an X-linked form does occur.

Pathogenesis

Tyrosinase is an essential enzyme in the production of melanin. Many cases of complete albinism are caused by mutations of the tyrosinase gene. Albinism with some pigment production, especially in people of African descent, is more commonly caused by mutations of the *p* gene.

Clinical Findings

Affected individuals are usually legally blind and have nystagmus (see later section Nystagmus). Iris, skin, and hair color vary with the type and severity of albinism as well as with race. Iris transillumination is abnormal transmission of light through an iris with decreased pigment which can aid in the diagnosis of albinism. This may be obvious or may require slit-lamp examination with retroillumination to detect focal areas of transillumination. Other ocular abnormalities include foveal hypoplasia, abnormal optic pathway projections, strabismus, and poor stereoacuity.

Differential Diagnosis

Albinism may be associated with other systemic manifestations. Bleeding problems occur in individuals with Hermansky-Pudlak syndrome (chromosome 10q23 or 5q13), in which oculocutaneous albinism is associated with a platelet abnormality. Chédiak-Higashi syndrome (chromosome 1q42–44) is characterized by neutrophil defects, recurrent infections, and oculocutaneous albinism. Other conditions associated with albinism are Waardenburg, Prader-Willi, and Angelman syndromes.

Complications

Low vision, strabismus, high refractive errors, and visual field abnormalities.

Treatment

Children with albinism should be evaluated by a pediatric ophthalmologist in order to optimize their visual function. Low-vision aids such as telescopes, stand magnifiers, and large-print books are often required. Vision teachers in schools and ophthalmic specialists trained in treating low-vision patients can improve the patient's ability to perform activities of daily living and function within society. Affected individuals should use sunscreen and protective clothing to prevent skin cancer.

Prognosis

Vision is subnormal in most individuals.

MISCELLANEOUS IRIS CONDITIONS

Heterochromia, or a difference in iris color, can occur in congenital Horner syndrome, after iritis, or with tumors and nevi of the iris and use of topical prostaglandins. Malignant melanoma of the iris may also cause iris heterochromia. Acquired iris nodules (Lisch nodules), which occur in type 1 neurofibromatosis, usually become apparent by age 8 years. When seen on slit-lamp examination, Lisch nodules are 1–2 mm in diameter. They are often beige in color, although their appearance can vary. Iris xanthogranuloma occurring with juvenile xanthogranuloma can cause hyphema and glaucoma. Patients with juvenile xanthogranuloma should be evaluated by an ophthalmologist for ocular involvement.

▼ GLAUCOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Glaucoma is caused by increased intraocular pressure and results in vision loss due to optic nerve injury, corneal scarring, and amblyopia.
▶ Pediatric glaucoma can be congenital or acquired, pupillary block or angle closure, and unilateral or bilateral.
▶ Glaucoma can be classified on an anatomic basis into two types: open-angle and closed-angle.

Clinical Findings

Signs of glaucoma presenting within the first year of life include enlargement of the globe due to low scleral rigidity in the infant eye (buphthalmos), as well as tearing, photophobia, blepharospasm, corneal clouding due to edema, and optic nerve cupping. After age 3 years, usually only optic nerve changes occur. Findings may be unilateral or bilateral. In general, a red, inflamed eye is not typical of congenital or infantile glaucoma.

Sudden eye pain, redness, corneal clouding, and vision loss suggests possible pupillary block or angle-closure glaucoma. Urgent referral to an ophthalmologist is indicated. Genetic evaluation should be completed if other systemic abnormalities are noted.

Glaucoma also occurs with ocular and systemic syndromes such as aniridia, anterior segment dysgenesis, Sturge-Weber syndrome, the oculocerebrorenal syndrome of Lowe, and the Pierre Robin syndrome. Glaucoma can also occur with a traumatic hyphema, iritis, lens dislocation, intraocular tumor, and ROP.

Differential Diagnosis

Buphthalmos is glaucoma until proven otherwise. The signs and symptoms of glaucoma are quite variable and should be urgently evaluated by an ophthalmologist.

Treatment

Treatment depends on the cause, but surgery is often indicated. Topical medications, which are available to decrease the intraocular pressure, have limited success in pediatric glaucoma.

Prognosis

In general, the prognosis is guarded but is often poor for glaucoma associated with congenital buphthalmos.

Aponte EP, Diehl N, Mohney BG: Medical and surgical outcomes in childhood glaucoma: a population-based study. J AAPOS 2011;15(3):263–267 [PMID: 21652244].

Mandal AK, Chakrabarti D: Update on congenital glaucoma. Indian J Ophthalmol 2011;59 [PMID: 21150027].

▼ UVEITIS

Inflammation of the uveal tract can be subdivided according to the uveal tissue primarily involved (iris, choroid, or retina) or by location (anterior, intermediate, or posterior uveitis). Perhaps the most commonly diagnosed form of uveitis in childhood is traumatic iridocyclitis or iritis.

ANTERIOR UVEITIS/IRIDOCYCLITIS/IRITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Iridocyclitis associated with juvenile idiopathic arthritis may be asymptomatic despite severe ocular inflammation.

Pathogenesis

Iridocyclitis associated with juvenile idiopathic arthritis occurs most often in girls with oligoarticular arthritis and a positive antinuclear antibody test. Inflammatory bowel disease is also associated with iritis—perhaps more commonly with Crohn disease than with ulcerative colitis. Other causes of anterior uveitis in children include syphilis, tuberculosis, sarcoidosis, relapsing fever (borreliosis), and Lyme disease, all but the last also causing posterior uveitis. Juvenile spondyloarthropathies, including ankylosing spondylitis, Reiter syndrome, and psoriatic arthritis, are associated with anterior uveitis. A substantial percentage of cases are of unknown origin.

Clinical Findings

Injection, photophobia, pain, and blurred vision usually accompany iritis (anterior uveitis or iridocyclitis). An exception to this is iritis associated with juvenile idiopathic arthritis (see Chapter 29). The eye in such cases is quiet and asymptomatic, but slit-lamp examination reveals anterior chamber inflammation with inflammatory cells and protein flare. Children with juvenile idiopathic arthritis should be screened according to a schedule recommended by the AAP (http://www.aap.org). Children with Crohn disease or ulcerative colitis should have routine periodic ophthalmologic examinations to detect ocular inflammation, which may be asymptomatic, and to detect cataracts if they have been receiving long-term systemic corticosteroids.

Other ocular findings of the anterior segment include conjunctivitis, episcleritis, and sterile corneal infiltrates. Posterior segment findings may include central serous retinochoroidopathy, panuveitis (inflammation of all uveal tissue), choroiditis, ischemic optic neuropathy, retinal vasculitis, neuroretinitis, and intermediate uveitis (see later section Intermediate Uveitis).

Posterior subcapsular cataracts can develop in patients with or without ocular inflammation. Most, if not all, of these patients have been taking corticosteroids as part of the long-term treatment of their autoimmune disease.

Differential Diagnosis

Iridocyclitis due to autoimmune disorder, trauma, infection, malignancy, or idiopathic etiology.

Complications

Permanent decreased vision due to cataracts, secondary glaucoma, and band keratopathy.

Treatment

Treatment with a topical corticosteroid and a cycloplegic agent is aimed at quieting the inflammation and preventing or delaying the onset of cataract and glaucoma. Methotrexate and other systemic immunosuppressive agents can be used in refractory cases. Systemic antitumor necrosis factor agents such as etanercept, infliximab, and adalimumab show promise in treating refractory cases of uveitis.

Prognosis

Prognosis depends on the severity of ocular inflammation, development of cataracts, and secondary glaucoma.

Qian Y, Acharya NR: Juvenile idiopathic arthritis-associated uveitis. Curr Opin Ophthalmol 2010;21(6):468–472 [PMID: 20729734].

Tugal-Tutkun I: Pediatric uveitis. J Ophthalmic Vis Res 2011; 6(4):259–269 [PMID: 22454749].

POSTERIOR UVEITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ The terms *choroiditis*, *retinitis*, and *retinochoroiditis* denote the tissue layers primarily involved in posterior uveitis. Infectious agents are the most common cause of posterior uveitis in the pediatric population.

Clinical Findings

Children with posterior uveitis often present with systemic manifestations of a congenital infection. Examples include deafness, developmental delay, cataracts, "salt and pepper" retinopathy, and hearing and cardiac disorders seen in congenital rubella.

Serologic analysis and retinal examination by an ophthalmologist are used to identify the cause of posterior uveitis. Active toxoplasmosis (see Chapter 43) produces a white lesion appearing as a "headlight in the fog" owing to the overlying vitreitis. Inactive lesions have a hyperpigmented border. Contiguous white satellite lesions suggest reactivation of disease.

A granular "salt and pepper" retinopathy is characteristic of congenital rubella. In infants, the TORCH complex (toxoplasmosis, other infections, rubella, cytomegalovirus [CMV], and HSV) and syphilis are congenital infections that cause chorioretinitis.

Congenital chorioretinitis caused by lymphocytic choriomeningitis is diagnosed by immunofluorescent antibody or enzyme-linked immunosorbent assay (ELISA) serologic testing. The virus is transmitted to humans by consumption of food contaminated with rodent urine or feces. It most closely resembles congenital toxoplasmosis in presentation. Ocular candidiasis occurs typically in an immune compromised host or a premature infant in the intensive care nursery receiving hyperalimentation. Candidal chorioretinitis, which is evidence of candidemia, appears as multifocal, whitish yellow, fluffy retinal lesions that may spread into the vitreous and produce a so-called cotton or fungus ball vitritis.

Acute retinal necrosis syndrome is caused most often by varicella-zoster virus and occasionally by HSV. Patients may present with vision loss and a red and painful eye. Ophthalmoscopy may show unilateral or bilateral patchy white areas of retina, arterial sheathing, vitreous haze, atrophic retinal scars, retinal detachment, and optic nerve involvement.

CMV infection is the most common cause of retinitis in immune compromised children, especially those with human immunodeficiency virus (HIV) infection. CMV retinitis appears as a white retinal lesion, typically but not always associated with hemorrhage, or as a granular, indolent-appearing lesion with hemorrhage and a white periphery. Cotton-wool spots (nerve fiber layer infarcts) also commonly occur in HIV-positive patients.

In toddlers and young children, *Toxocara canis* or *Toxocara cati* infections (ocular larva migrans; see Chapter 43) occur from ingesting soil contaminated with parasite eggs. The disease is usually unilateral. Common signs and symptoms include a red injected eye, leukocoria, and decreased vision. Funduscopic examination may show endophthalmitis (vitreous abscess) or localized granuloma. Diagnosis is based on the appearance of the lesion and serologic testing using ELISA for *T canis* and *T cati*.

Differential Diagnosis

Posterior uveitis due to autoimmune disorder, trauma, infection, malignancy, or idiopathic etiology.

Complications

Permanent vision loss due to retinal scarring and detachment.

Treatment

Congenital toxoplasmosis infections must be treated with systemic antimicrobials (see Chapter 43). Studies have shown improved ophthalmic and neurologic outcomes with prolonged treatment. Other infectious agents such as *Candida*, varicella, and CMV require systemic and/or intraocular injections of antimicrobial agents, and may require retinal surgery. Treatment of toxocariasis includes periocular corticosteroid injections and vitrectomy.

Prognosis

The prognosis for vision depends on the severity of retinal and systemic involvement.

INTERMEDIATE UVEITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Intermediate uveitis or pars planitis is described as inflammation located in the far anterior periphery of the retina and vitreous base.

Clinical Findings

Patients with pars planitis, inflammation of the anterior edge of the retina, often complain of decreased vision and floaters. They may also have a history of a red eye and ocular discomfort. Patients with intermediate uveitis often have decreased vision. A prolonged duration of the disease can lead to deprivation amblyopia and strabismus.

A dilated examination is required for observation of inflammation of the pars plana and vitritis. Slit-lamp and dilated funduscopic examinations by an ophthalmologist often reveal chronic signs of inflammation associated with intermediate uveitis, including macular edema, cataracts, increased intraocular pressure, irregular pupil, iris adhesion to the lens, and band keratopathy.

Differential Diagnosis

Intermediate uveitis is often idiopathic although there are several known etiologies. *Toxocara* infections with peripheral granuloma can be associated with intermediate uveitis, as can inflammatory bowel disease, multiple sclerosis, and sarcoidosis. Retinoblastoma and other neoplasms can imitate uveitis.

Complications

Decreased vision due to macular edema, vitreous floaters, cataracts, and glaucoma.

Treatment

The most common treatment regimen for intermediate uveitis includes subtenon steroid injections, vitrectomy by a retinal surgeon, and systemic immunosuppression. Secondary glaucoma often requires tube shunt surgery.

Prognosis

The prognosis depends on the severity of the disease and associated secondary complications such as glaucoma and cataracts.

▼ OCULAR MANIFESTATIONS OF AIDS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► The advent of highly active antiretroviral therapy (HAART) has significantly reduced the incidence of CMV retinitis.
► Ocular infections are important manifestations of acquired immunodeficiency syndrome (AIDS) (see Chapter 41).
► Opportunistic ocular infections increase in HIV-infected children as CD4 T-lymphocyte counts fall below 200/μL.

Pathogenesis

Pathogens commonly causing eye infection include CMV and varicella-zoster virus. Acute retinal necrosis syndrome (see earlier section Posterior Uveitis) is a severe necrotizing retinitis that often results in blindness in patients with AIDS. Most cases are thought to be caused by varicella-zoster virus. Other implicated agents are herpes simplex types 1 and 2.

Patients with CD4 counts below 50/μL are at high risk for CMV retinitis and should have a complete ocular evaluation by an ophthalmologist. Various retinal abnormalities may be present which include cotton-wool spots, retinal hemorrhages, microaneurysms, perivasculitis, and decreased visual acuity from ischemic maculopathy.

Immune recovery uveitis associated with antiretroviral therapy may result in decreased vision and require treatment.

Differential Diagnosis

Decreased vision due to immune recovery uveitis, CMV retinitis, or acute retinal necrosis syndrome.

Complications

Retinal scarring, retinal detachment, and blindness.

Treatment

If immune recovery is sufficient with antiretroviral therapy for an extended period, the patient may be able to discontinue anti-CMV therapy. However, active viral retinitis must be treated with antiviral agents. CMV retinitis is treated with intravenous ganciclovir but foscarnet may be required if resistance develops. Intravitreal ganciclovir or ganciclovir implants in conjunction with oral valganciclovir may be required in severe cases or in individuals intolerant to intravenous therapy. Acute retinal necrosis due to HSV or VZV must be treated with intravenous acyclovir, systemic steroids, and intraocular surgery.

Prognosis

Viral retinitis generally has a poor prognosis.

Jabs DA: Cytomegalovirus retinitis and the acquired immuno-deficiency syndrome—bench to bedside: LXVII Edward Jackson Memorial Lecture. Am J Ophthalmol 2011;151(2):198–216 [PMID: 21168815].

Jabs DA et al: Studies of the Ocular Complications of AIDS Research Group. Course of cytomegalovirus retinitis in the era of highly active antiretroviral therapy: five-year outcomes. Ophthalmology 2010;117(11):2152–2161 [PMID: 20673591].

▼ DISORDERS OF THE CORNEA

CLOUDY CORNEA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Corneal clouding can be caused by developmental abnormalities, metabolic disorders, trauma, and infection.

Clinical Findings

The cornea may have a white, hazy appearance on penlight examination. The red reflex may be decreased or absent.

Differential Diagnosis

Corneal clouding, tearing, blepharospasm, and photophobia in a newborn are signs of congenital glaucoma until proven otherwise. Peter anomaly and sclerocornea are congenital malformations of the anterior segment of the eye that are the most common causes of a cloudy cornea at birth. Direct trauma to the cornea during a forceps delivery can result in corneal haze and significant amblyopia. Systemic abnormalities such as developmental delay and liver or kidney failure suggest metabolic disorders such as mucopolysaccharidoses, Wilson disease, and cystinosis. Corneal infiltrates occur with viral infections, staphylococcal lid disease, corneal dystrophies, and interstitial keratitis due to congenital syphilis.

A complete ocular evaluation by an ophthalmologist is required and should be completed urgently when congenital glaucoma is suspected.

Complications

Vision loss is likely due to deprivation amblyopia.

Treatment

Treatment depends on the underlying condition. Surgical treatment of glaucoma and possible corneal transplantation or keratoprosthesis may be required.

Prognosis

Prognosis depends on the amount of corneal involvement and response to surgical treatment. Corneal transplants have a very high frequency of rejection and subsequently a poor prognosis in children.

Lowe MT, Keane MC, Coster DJ, Williams KA: The outcome of corneal transplantation in infants, children, and adolescents. Ophthalmology 2011;118(3):492–497 [PMID: 20932584].

Nallasamy S, Colby K: Keratoprosthesis: procedure of choice for corneal opacities in children? Semin Ophthalmol 2010;25 (5-6):244–248 [PMID: 21091007].

VIRAL KERATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Herpes simplex, herpes zoster, and adenovirus can infect the cornea.
▶ When the corneal epithelium is involved, a dendritic or amoeboid pattern can be seen with fluorescein staining.

Clinical Findings

Patients commonly present with a painful, red eye. Photophobia and decreased vision are also common complaints. Fever,

malaise, and symptoms of upper respiratory tract infection may be present.

Fluorescein administration to the involved cornea will reveal areas of staining when viewed with a blue light if the corneal epithelium is involved. The pattern of epithelium staining may be dendritic (branch-like) or irregular and round if a geographic ulcer is present. Slit-lamp examination may reveal white infiltrates beneath the corneal epithelium as a result of corneal stromal scarring or edema from viral infection of the corneal stromal tissue. Decreased visual acuity, photophobia, and conjunctivitis may also be noted.

▶ Differential Diagnosis

Corneal abrasion, bacterial corneal ulcer, iritis.

▶ Treatment

Topical antivirals such as trifluridine and vidarabine are indicated when herpes simplex infection is limited to the corneal epithelium, although additional systemic therapy is required in newborns. Topical corticosteroids may be a useful addition to antiviral therapy when stromal disease is present. The use of corticosteroids in the presence of herpetic disease should be undertaken only by an ophthalmologist because of the danger of worsening the disease. Oral acyclovir started in the early phase (first 5 days) may be helpful in treating herpes zoster eye disease. Acyclovir prophylaxis is helpful in preventing recurrent herpetic epithelial keratitis (see earlier section Viral Conjunctivitis) and stromal keratitis caused by herpes simplex.

Adenovirus conjunctivitis may progress to keratitis 1–2 weeks after onset. Vision may be decreased. In most cases, no treatment is necessary because adenovirus keratitis is most often self-limiting. However, adenovirus is highly contagious and easily spread (see section Viral Conjunctivitis).

▶ Prognosis

Corneal involvement with herpes simplex can be recurrent and lead to blindness.

CORNEAL ULCERS

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Decreased vision, pain, injection, a white corneal infiltrate or ulcer (Figure 16–22), and hypopyon (pus in the anterior chamber) may all be present.
>
> ▶ Bacterial corneal ulcers in healthy children who are not contact lens wearers are usually secondary to corneal trauma from corneal abrasion or a penetrating foreign body.

▲ **Figure 16–22.** Corneal ulcer. Note white infiltrate located on inferior cornea.

▶ Clinical findings

A corneal ulcer appears as a white spot on the surface of the cornea that stains with fluorescein (see Figure 16–22). Associated symptoms include pain and decreased vision. Signs often include conjunctival injection, photophobia, tearing, and purulent discharge.

▶ Differential Diagnosis

Viral keratitis, corneal abrasion, penetrating foreign body.

▶ Complications

Permanent vision loss may result from corneal scarring. Corneal transplantation may be required.

▶ Treatment

Prompt referral to an ophthalmologist is necessary for evaluation and management.

▶ Prognosis

Prognosis depends on how large the ulcer is and whether the central cornea is involved.

▼ DISORDERS OF THE LENS

Lens disorders involve abnormality of clarity or position. Lens opacification (Figure 16–23) can affect vision depending on its density, size, and position. Visual potential is also influenced by age at onset and the success of amblyopia treatment.

CATARACTS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Cataracts in children may be unilateral or bilateral, may exist as isolated defects, or may be accompanied by other ocular disorders or systemic disease (see Figure 16–23).

▶ Clinical Findings

Leukocoria, poor fixation, and strabismus or nystagmus (or both) may be the presenting complaints. Absence of a red reflex in the newborn may be due to a cataract which requires an urgent referral to an ophthalmologist.

Laboratory investigation for infectious and metabolic causes of congenital cataracts is often indicated. Such investigation would include cultures or serologic tests for toxoplasmosis, rubella, CMV, HSV, and syphilis, as well as evaluation for inborn metabolic errors, such as galactosemia or Lowe syndrome.

▶ Differential Diagnosis

Cloudy cornea, intraocular tumor, retinal detachment.

▶ Complications

Pediatric cataracts are frequently associated with severe deprivation amblyopia.

▶ Treatment

Early diagnosis and treatment are necessary to prevent deprivation amblyopia in children younger than 9 years, because they are visually immature. Cataracts that are visually significant require removal. Visually significant cataracts in infants are usually removed prior to 6 weeks of age to prevent deprivation amblyopia. Rehabilitation of the vision will require

▲ **Figure 16–23.** Cataract causing leukocoria.

the correction of refractive errors and amblyopia treatment. Contact lenses, glasses, and artificial intraocular lenses are used to correct refractive errors after cataract extraction. Treatment of underlying concomitant congenital infections or systemic diseases must be instituted as appropriate.

▶ Prognosis

The ultimate visual acuity depends on when the cataract was diagnosed and treated as well as compliance with amblyopia treatment. Glaucoma is often associated with pediatric cataracts and may result in a poor prognosis if not controlled.

DISLOCATED LENSES/ECTOPIA LENTIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Nontraumatic lens dislocation is usually bilateral.
▶ Subluxation causes refractive errors of large magnitude that are difficult to correct.

▶ Pathogenesis

Systemic diseases, including Marfan syndrome, homocystinuria, Weill-Marchesani syndrome, sulfite oxidase deficiency, hyperlysinemia, syphilis, and Ehlers-Danlos syndrome, are often associated with dislocated lenses.

▶ Clinical Findings

Slit-lamp examination reveals malposition of the intraocular lens. Refraction often reveals significant astigmatism. A complete ophthalmic evaluation, as well as genetic and metabolic evaluation, may be warranted.

▶ Differential Diagnosis

Ectopia lentis due to systemic disease versus trauma.

▶ Complications

Ectopia lentis can cause decreased vision and amblyopia due to induced refractive errors. Another ophthalmologic concern is pupillary block glaucoma, in which a malpositioned unstable lens interferes with the normal flow of aqueous humor from the ciliary body (posterior to the pupil), where it is produced, into the trabecular meshwork (anterior to the pupillary plane).

▶ Treatment

Surgical lensectomy may be required if the visual acuity is not improved significantly with glasses or contact lenses. Underlying metabolic and/or genetic disorders require a multidisciplinary approach.

► Prognosis

Prognosis depends on the severity of the lens dislocation and need for lensectomy.

▼ DISORDERS OF THE RETINA

RETINAL HEMORRHAGES IN THE NEWBORN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ► Retinal hemorrhages are commonly seen in the otherwise healthy newborn.
- ► Retinal hemorrhages occur most often after vaginal delivery but can also be present after suction delivery or cesarean section.

► Clinical Findings

A dilated retinal examination reveals unilateral or bilateral hemorrhages that can be located anywhere in the retina. They may appear as dot, blot, subretinal, or preretinal hemorrhages. They may also break into the vitreous. Examination of the retina of an otherwise healthy newborn infant is not indicated.

► Differential Diagnosis

See earlier section Abusive Head Trauma & Nonaccidental Trauma.

► Treatment

Observation is indicated since retinal hemorrhages of the newborn usually disappear within the first month of life.

► Prognosis

Excellent.

RETINOPATHY OF PREMATURITY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ► Screening examinations are recommended for infants with a birth weight of 1500 g or less or gestational age of 30 weeks or less and selected infants with a birth weight between 1500 and 2000 g or gestational age of greater than 30 weeks with an unstable clinical course.

- ► Cost analysis studies have determined that screening and laser photoablation of retinopathy of prematurity (ROP) are cost-effective medical interventions.
- ► The joint policy statement from the AAP, AAO, and AAPOS on screening examinations of premature infants for ROP is available at http://www.pediatrics.org.

► Pathogenesis

Premature infants with incomplete retinal vascularization are at risk for developing abnormal peripheral retinal vascularization, which may lead to retinal detachment and blindness. The cause of this disorder—including the role of supplemental oxygen in the neonatal period—is still not fully understood. Recent studies suggest that vascular endothelial growth factor (VEGF) may play a key role in ROP development. Other risk factors for severe ROP are bronchopulmonary dysplasia, intraventricular hemorrhage, sepsis, apnea and bradycardia, and mutations of the Norrie disease gene. White males, infants with zone 1 disease, and infants with very low birth weight and gestational age have a higher risk of developing severe ROP that requires treatment.

► Prevention

The risk of vision loss from ROP can be reduced by timely screening of premature infants by an ophthalmologist.

► Clinical Findings

The Cryotherapy for Retinopathy of Prematurity (CRYOROP) study outlined a standard nomenclature to describe the progression and severity of ROP (Table 16–3). Since retinal blood vessels emanate from the optic nerve and do not fully cover the developing retina until term, the optic nerve is used as the central landmark. The most immature zone of the retina, zone 1, is the most posterior concentric imaginary circle around the optic nerve. The next peripheral area is zone 2, and peripheral to that is zone 3. Zone 1 disease by definition is more high-risk than disease in more anterior/peripheral zones.

Table 16–3. Stages of retinopathy of prematurity.

Stage I	Demarcation line or border dividing the vascular from the avascular retina.
Stage II	Ridge. Line of stage I acquires volume and rises above the surface retina to become a ridge.
Stage III	Ridge with extraretinal fibrovascular proliferation.
Stage IV	Subtotal retinal detachment.
Stage V	Total retinal detachment.

Similarly, the stages of the abnormal vessels are numbered from zero (simply incomplete vascularization) through stages I–V.

Recommendations for initiating eye examination are outlined in the joint policy statement issued by the AAP, AAO, and AAPOS and are based on the gestational age and birth weight. Screening examinations are recommended for infants with a birth weight of 1500 g or less or gestational age of 30 weeks or less and selected infants with a birth weight between 1500 and 2000 g or gestational age of greater than 30 weeks with an unstable clinical course. The frequency of follow-up examinations depends on the findings and the risk factors for developing the disease. Most infants are evaluated every 1–2 weeks. ROP often resolves when the infant reaches 40 weeks estimated gestational age. Examinations can be discontinued when the retinas are fully vascularized, or when the infant is 45 weeks' gestational age and has never had prethreshold disease or worse, or is vascularized out to zone 3 and never had zone 1 or 2 disease.

▶ Complications

Low vision, retinal detachment.

▶ Treatment

Surgical treatment of ROP is indicated when there is zone 1 ROP with any stage and plus disease, zone 1 ROP stage III without plus disease, zone 2 ROP with stage II or III and plus disease. The treatment of ROP within 72 hours can reduce the occurrence of bad visual outcomes by 50%. Some patients still progress to a retinal detachment, which can have a very poor prognosis for vision. Surgical treatment for a retinal detachment involves scleral buckling or a lens-sparing vitrectomy by a vitreoretinal specialist. Intraocular injections of anti-VEGF agents such as bevacizumab and ranibizumab have been used in certain severe cases of ROP but long-term effects are still under investigation.

▶ Prognosis

Most cases of ROP do not progress to retinal detachment and require no treatment. However, ROP remains a leading cause of blindness in children. Those with a history of ROP are at a much higher risk of developing strabismus, amblyopia, myopia, and glaucoma than the average child.

Moshfeghi DM, Berrocal AM: Retinopathy of prematurity in the time of bevacizumab: incorporating the BEAT-ROP results into clinical practice. Ophthalmology 2011;118(7):1227–1228 [PMID: 21724044].

RETINOBLASTOMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Retinoblastoma is the most common primary intraocular malignancy of childhood, with an incidence estimated between 1:17,000 and 1:34,000 live births (see Chapter 31).

▶ Most patients present before age 3 years.

▶ Pathogenesis

Inherited forms of retinoblastoma are autosomal dominant with high penetrance. The disease may consist of a solitary mass or multiple tumors in one or both eyes. All bilateral cases and some unilateral cases are caused by germinal mutations; however, most unilateral cases are caused by a somatic retinal mutation. In both situations, the mutation occurs in the retinoblastoma gene (*Rb*) at chromosome 13q14. This is a tumor suppressor gene. One mutated copy may be inherited in an autosomal dominant fashion (germline mutation). If a second mutation spontaneously occurs in any cell, tumorigenesis is likely. Individuals with a germinal mutation are at risk for the development of tumors other than retinoblastoma (pineal tumors, osteosarcoma, and other soft tissue sarcomas). All children with unilateral or bilateral retinoblastoma must be presumed to have the germline form, and followed expectantly for other tumors in the remaining eye and at extraocular sites. Approximately 15% of patients with unilateral disease have germline mutations.

▶ Clinical Findings

The most common presenting sign in a child with previously undiagnosed retinoblastoma is leukocoria (see Figure 16–1). Evaluation of the pupillary red reflex is important, although a normal red reflex does not rule out retinoblastoma. Examination requires indirect ophthalmoscopy with scleral depression and pupillary dilation, performed by an ophthalmologist. Other presentations include strabismus, red eye, glaucoma, or pseudo-hypopyon (appearance of pus-like material in the anterior chamber).

Genetic testing is available for patients with retinoblastoma. Once the causative mutation is found in an affected individual, unaffected members of the family should be tested to determine their personal and reproductive risk.

Differential Diagnosis

Retinal vasculature abnormalities seen in diseases such as Coats disease, uveitis, and endophthalmitis.

Complications

Death if not adequately treated.

Treatment

The goal of treatment is to preserve the eye and as much useful vision as possible. Chemoreduction is used to reduce initial tumor volume. Local treatment with laser photocoagulation, cryotherapy, plaque radiotherapy, or thermotherapy can often preserve vision and spare the patient enucleation and radiation. Ophthalmic artery chemotherapy can be successful in certain cases.

Prognosis

Generally good except in developing countries where children often succumb to their disease due to lack of treatment. Patients with germline mutations need lifelong monitoring for secondary neoplasms such as sarcomas.

Palioura S, Gobin YP, Brodie SE, Marr BP, Dunkel IJ, Abramson DH: Ophthalmic artery chemosurgery for the management of retinoblastoma in eyes with extensive (>50%) retinal detachment. Pediatr Blood Cancer 2012;59(5):859–864 [PMID: 22492689].

Shields CL, Shields JA: Retinoblastoma management: advances in enucleation, intravenous chemoreduction, and intra-arterial chemotherapy. Curr Opin Ophthalmol 2010;21(3):203–212 [PMID: 20224400].

RETINAL DETACHMENT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ A retinal detachment may present as an abnormal or absent red reflex.

▶ Older children may complain of decreased vision, flashes, floaters, or visual field defects.

Pathogenesis

Common causes are trauma and high myopia. Other causes are ROP, Marfan syndrome, and Stickler syndrome.

Clinical Findings

Symptoms of detachment are floaters, flashing lights, and loss of visual field; however, children often cannot appreciate or verbalize their symptoms. A detachment may not be discovered until the child is referred after failing a vision screening examination, strabismus supervenes, or leukocoria is noted.

Differential Diagnosis

Intraocular tumor.

Complications

Vision loss, glaucoma, strabismus.

Treatment

Treatment of retinal detachment is surgical. For children with conditions predisposing to retinal detachment, or a strong family history, examinations under anesthesia by an ophthalmologist, with prophylactic laser treatment, may be recommended.

Prognosis

Prognosis depends on the location and duration of the detachment.

DIABETIC RETINOPATHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Diabetic retinopathy is a specific vascular complication of diabetes mellitus. Patients with type 1, or insulin-dependent, diabetes are at higher risk of developing severe proliferative retinopathy leading to visual loss than are those with type 2, or non–insulin-dependent, diabetes.

▶ The cost-effectiveness of screening examinations for diabetic retinopathy in children requires further evaluation.

Prevention

Control of diabetes is the best way to prevent ocular complications.

Clinical Findings

Acute onset of diabetes may be accompanied by sudden blurred vision due to myopia and cataracts.

In children older than 9 years, referral to an ophthalmologist for screening of retinopathy should occur within 3–5 years after the onset of diabetes. Both conditions may be reversible with good glucose control. Young children with type 1 diabetes should be followed for the Wolfram, or DIDMOD, syndrome, in which diabetes mellitus occurs in conjunction with diabetes insipidus, optic atrophy, and deafness.

▶ Complications

Vision loss due to vitreous hemorrhage, macular edema, neovascular glaucoma, cataracts, or retinal detachment.

▶ Treatment

Severe proliferative diabetic retinopathy requires pan-retinal laser photocoagulation or vitreoretinal surgery (or both). Cataracts often require surgical removal and intraocular lens placement. Intraocular steroid injections have been used to treat macular edema in adults, but their role in children is not well established.

▶ Prognosis

Prognosis depends on the severity of the retinopathy and associated complications.

▼ DISEASES OF THE OPTIC NERVE

OPTIC NEUROPATHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Optic nerve function is evaluated by checking visual acuity, color vision, pupillary response, and visual fields.

▶ Clinical Findings

Poor optic nerve function results in decreased central or peripheral vision, decreased color vision, strabismus, and nystagmus. Optic nerve disorders can be due to congenital malformation, malignancy, inflammation, infection, metabolic disorders, and trauma.

The swinging flashlight test is used to assess function of each optic nerve. It is performed by shining a light alternately in front of each pupil to check for an afferent pupillary defect or Marcus Gunn pupillary defect. An abnormal response in the affected eye is pupillary dilation when the light is directed into that eye after having been shown in the other eye with its healthy optic nerve. This results from poorer conduction along the optic nerve of the affected eye, which in turn results

▲ **Figure 16–24.** Myelinization of the optic nerve.

in less pupillary constriction of both eyes than occurs when the light is shined into the noninvolved eye. Hippus—rhythmic dilating and constricting movements of the pupil—can be confused with an afferent pupillary defect.

The optic nerve is evaluated as to size, shape, color, and vascularity. Occasionally, myelinization past the entrance of the optic nerve head occurs. It appears white, with a feathered edge (Figure 16–24). Myelinization onto the retina can be associated with myopia and amblyopia. Anatomic defects of the optic nerve include colobomatous defects and pits.

▶ Treatment

Management of the underlying condition resulting in the optic neuropathy is necessary.

▶ Prognosis

Prognosis depends on the severity of optic neuropathy and the underlying disease.

OPTIC NERVE HYPOPLASIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Optic nerve hypoplasia may be associated with absence of the septum pellucidum and hypothalamic-pituitary dysfunction, which is known as *septo-optic dysplasia*, or *de Morsier syndrome*.

▶ Children with septo-optic dysplasia and hypocortisolism are at risk for sudden death during febrile illness from thermoregulatory disturbance and dehydration from diabetes insipidus.

▶ Pathogenesis

Optic nerve hypoplasia may occur in infants of diabetic mothers and has also been associated with alcohol use or ingestion of quinine or phenytoin during pregnancy. Anatomically, the optic nerve may range from absent (aplasia) to almost full size, with a segmental defect.

▶ Clinical Findings

Visual function with optic nerve hypoplasia ranges from mildly decreased to absent light perception. If only one eye is involved, the child usually presents with strabismus. If both eyes are affected, nystagmus is usually the presenting sign. Ophthalmoscopy is performed to directly visualize the optic nerves and to determine the severity of the hypoplasia. Neuroimaging of the brain and endocrine consultation should be performed in all patients with bilateral optic nerve hypoplasia.

▶ Treatment

Sensory amblyopia and significant refractive errors should be treated by an ophthalmologist. Strabismus surgery may be necessary in certain patients. Endocrine abnormalities should be managed as necessary.

▶ Prognosis

Severe bilateral optic nerve hypoplasia results in blindness.

PAPILLEDEMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Papilledema (optic nerve edema) is associated with increased intracranial pressure due to any cause, such as tumor, craniosynostosis, or intracranial infection.

▶ Pathogenesis

Papilledema is optic nerve head or optic disc edema associated with increased intracranial pressure. Hydrocephalus and intracranial tumors are common causes of papilledema. In idiopathic intracranial hypertension (pseudotumor cerebri), neuroimaging is normal but papilledema, headaches, and pulsating tinnitus may be present. Papilledema occurs almost equally in boys and girls and sometimes is associated with obesity or upper respiratory tract infection. Other associated causes are viral and other infections, corticosteroid use or withdrawal, sinus infection, trauma, tetracycline use, growth hormone supplementation, and venous sinus thrombosis (see Chapter 25). Early in the illness the patient may not notice a change in vision, although the blind spot may be enlarged. Transient obscuration of vision (amaurosis fugax) may occur as the process becomes more long-standing. Further effects on vision will occur as the papilledema becomes chronic and ultimately leads to optic atrophy. Diplopia (double vision) may occur if increased intracranial pressure results in cranial nerve VI palsy. Workup and treatment are directed toward finding the underlying systemic or central nervous system cause.

▶ Clinical Findings

Direct visualization of the optic nerve by ophthalmoscopy reveals an elevated disc with indistinct margins, increased vessel diameter, vessel tortuosity, and hyperemia. Hemorrhages and exudates are present in more severe cases. Observed changes may be subtle to striking. Optic nerve head changes are usually bilateral and generally symmetrical. Strabismus may occur if a sixth nerve palsy is associated with the underlying condition.

Pseudopapilledema is a normal variant of the optic disc in which the disc appears elevated, with indistinct margins and a normal vascular pattern. Pseudopapilledema sometimes occurs in hyperopic individuals. It is not associated with vision loss, but true papilledema must be ruled out prior to making the diagnosis.

▶ Differential diagnosis

Pseudopapilledema, optic neuritis.

▶ Treatment

Treatment of idiopathic intracranial hypertension may be pharmacologic—for example, using acetazolamide, a carbonic anhydrase inhibitor, or a corticosteroid. Discontinue medications that are suspected of causing papilledema or utilize anticoagulation if venous sinus thrombosis is present. Diagnostic lumbar puncture may also be curative. Optic nerve sheath fenestration and ventriculoperitoneal shunt are surgical interventions used when conservative measures fail. Strabismus surgery, Botox (botulinum toxin type A) injection of extraocular muscles, and amblyopia treatment may be necessary in cases of associated cranial neuropathies resulting in strabismus.

▶ Complications

Optic atrophy and vision loss.

Prognosis

Prognosis depends on the underlying etiology, duration, and control of the increased intracranial pressure.

Honorat R, Marchandot J, Tison C, Cances C, Chaix Y: Treatment and prognosis of idiopathic intracranial hypertension in children. Retrospective study (1995–2009) and literature review. Arch Pediatr 2011;18(11):1139–1147 [PMID: 21992894].

OPTIC NEURITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Papillitis is a form of optic neuritis seen on ophthalmoscopic examination as an inflamed optic nerve head.
▶ Optic neuritis in children may be idiopathic or associated with multiple sclerosis, acute disseminated encephalomyelitis, Devic disease, or cat-scratch disease.

Clinical Findings

Optic neuritis is inflammation of the optic nerve and may have the same appearance as papilledema. Papillitis (inflammation of the optic disc) results in a swollen/elevated nerve head, blurred optic disc margins, hyperemia of the nerve, optic disc hemorrhages, and dilated retinal veins. Retrobulbar optic neuritis (inflammation of the optic nerve posterior to the optic disc) has a normal appearing optic disc on examination by ophthalmoscopy. Optic neuritis may be unilateral, whereas papilledema is almost always bilateral. Optic neuritis is associated with an afferent pupillary defect (Marcus Gunn pupil), decreased visual acuity, decreased color vision, and it may also have pain with eye movements. Other central nervous system (CNS) signs or symptoms may be present so a complete review of systems and neurologic examination are important to complete.

Optic neuritis can be associated with viral and other infections, vaccinations, and CNS inflammatory demyelination diseases such as acute disseminated encephalomyelitis, multiple sclerosis, and neuromyelitis optica (Devic Disease). Neoplasms infiltrating the nerve or orbital infections that compress the optic nerve can also result in optic neuritis.

Workup of the patient with optic neuritis includes lumbar puncture and cerebrospinal fluid analysis. Serology should target infectious and inflammatory markers. Neuromyelitis optica can be diagnosed by detecting neuromyelitis optica immunoglobulin G (IgG). Neuroimaging of the brain and orbits is useful adjunct to the workup.

Differential Diagnosis

Papilledema, pseudopapilledema, systemic immune disorder, infection, or neoplasm.

Complications

Decreased visual acuity, color vision, peripheral vision, and contrast sensitivity. CNS involvement can result in a variety of complications based on the underlying etiology.

Treatment

Treatment of the underlying disease.

Prognosis

Prognosis depends on the underlying disease process.

OPTIC ATROPHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Optic atrophy is pallor of the optic nerve noted on ophthalmoscopy.

Clinical Findings

Optic atrophy is found in children most frequently after neurologic compromise during the perinatal period. An example would be a premature infant who develops an intraventricular hemorrhage. Hydrocephalus, glioma of the optic nerve, craniosynostosis, certain neurologic diseases, and toxins such as methyl alcohol can cause optic atrophy, as can certain inborn errors of metabolism, long-standing papilledema, or papillitis.

Direct examination of the optic nerve by ophthalmoscopy reveals an optic nerve head with a cream or white color and possibly cupping. Neuroimaging is necessary to delineate CNS abnormalities.

Complications

Vision loss, decreased peripheral vision, and contrast sensitivity.

Treatment

Treatment of the underlying condition is indicated.

Prognosis

Prognosis depends on the severity of the optic nerve atrophy and associated neurologic deficits.

DISEASES OF THE ORBIT

PERIORBITAL & ORBITAL CELLULITIS

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ The fascia of the eyelids joins with the fibrous orbital septum to isolate the orbit from the lids.
- ▶ The orbital septum helps decrease the risk of an eyelid infection extending into the orbit.
- ▶ Infections arising anterior to the orbital septum are termed *preseptal.*
- ▶ Orbital cellulitis denotes infection posterior to the orbital septum and may cause serious complications, such as an acute ischemic optic neuropathy or cerebral abscess.

▶ Pathogenesis

Preseptal (periorbital) cellulitis usually arises from a local exogenous source such as an abrasion of the eyelid, from other infections (hordeolum, dacryocystitis, or chalazion), or from infected varicella or insect bite lesions. *S aureus* and *S pyogenes* are the most common pathogens cultured from these sources. Preseptal infections in children younger than 3 years also occur from bacteremia, although this is rare since *Haemophilus influenzae* and *S pneumoniae* vaccines are routinely administered. Bacteremia is still an occasional cause of this infection. Children with periorbital cellulitis from presumed bacteremia must be examined for additional foci of infection.

Orbital cellulitis almost always arises from contiguous sinus infection, because the walls of three sinuses make up portions of the orbital walls and infection can breach these walls or extend by way of a richly anastomosing venous system. The orbital contents can develop a phlegmon (orbital cellulitis), or frank pus can develop in the orbit (orbital abscess). The pathogenic agents are those of acute or chronic sinusitis—respiratory flora and anaerobes. *S aureus* is also frequently implicated.

The frequency of methicillin-resistant *S aureus* preseptal and orbital cellulitis has increased over the past several years.

▶ Clinical Findings

Children with preseptal cellulitis present with erythematous and edematous eyelids, pain, and mild fever. The vision, eye movements, and eye itself are normal. Decreased vision, restricted eye movements, and an afferent pupillary defect suggest orbital cellulitis.

Orbital cellulitis presents with signs of periorbital disease as well as proptosis (a protruding eye), restricted eye movement, and pain with eye movement. Fever is usually high. CT scanning or MRI is required to establish the extent of the infection within the orbit and sinuses.

▶ Differential Diagnosis

Primary or metastatic neoplasm of the orbit, orbital pseudotumor (idiopathic orbital inflammation), and orbital foreign body with secondary infection.

▶ Complications

Preseptal cellulitis can progress to orbital cellulitis. Orbital cellulitis can result in permanent vision loss due to compressive optic neuropathy. Proptosis can cause corneal exposure, dryness, and scarring. Cavernous sinus thrombosis, intracranial extension, blindness, and death can result from severe orbital cellulitis.

▶ Treatment

Therapy for preseptal and orbital cellulitis infection is with systemic antibiotics. Treatment of orbital infections may require surgical drainage for subperiosteal abscess in conjunction with intravenous antibiotics. Drainage of infected sinuses is often part of the therapy.

▶ Prognosis

Most patients do well with timely treatment.

Seltz LB, Smith J, Durairaj VD, Enzenauer R, Todd J: Microbiology and antibiotic management of orbital cellulitis. Pediatrics 2011; 127(3):e566–e572 [PMID: 21321025].

CRANIOFACIAL ANOMALIES

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Craniofacial anomalies can affect the orbit and visual system.
- ▶ Craniofacial anomalies occur with craniosynostoses and midface syndromes such as Treacher Collins and Pierre Robin syndromes.
- ▶ Fetal alcohol syndrome is associated with similar changes of the ocular adnexa.

▶ Clinical Findings

Ocular abnormalities associated with craniofacial abnormalities involving the orbits include visual impairment,

proptosis, corneal exposure, hypertelorism (widely spaced orbits), strabismus, amblyopia, lid coloboma, papilledema, refractive errors, and optic atrophy.

▶ Treatment

Orbital and ocular abnormalities associated with craniofacial anomalies often require a multispecialty approach. Management may require orbital and strabismus surgery. Ophthalmologists also treat amblyopia, refractive errors, and corneal exposure if present.

Taub PJ, Lampert JA: Pediatric craniofacial surgery: a review for the multidisciplinary team. Cleft Palate Craniofac J 2011;48(6): 670–683 [PMID: 21740182].

ORBITAL TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Both benign and malignant orbital lesions occur in children.

▶ The most common benign tumor is capillary hemangioma (Figure 16–25).

▶ The most common primary malignant tumor of the orbit is rhabdomyosarcoma.

▶ Clinical Findings

Capillary hemangiomas may be located superficially in the lid or deep in the orbit and can cause ptosis (see Figure 16–25), refractive errors, and amblyopia. Deeper lesions may cause proptosis. Capillary hemangiomas in infants initially increase in size before involuting at about age 2–4 years.

Orbital dermoid cysts vary in size and are usually found temporally at the brow and orbital rim or supranasally. These lesions are firm, well encapsulated, and mobile. Rupture of the cyst causes a severe inflammatory reaction.

▲ **Figure 16–25.** Right upper lid hemangioma causing ptosis.

Lymphangioma occurring in the orbit is typically poorly encapsulated, increases in size with upper respiratory infection, and is susceptible to hemorrhage. Other benign tumors of the orbit are orbital pseudotumor, neurofibroma, teratoma, and tumors arising from bone, connective tissue, and neural tissue.

Orbital rhabdomyosarcoma (see Chapter 31) grows rapidly and displaces the globe. The average age at onset is 6–7 years. The tumor is often initially mistaken for orbital swelling due to insignificant trauma.

Tumors metastatic to the orbit also occur; neuroblastoma is most common. The patient may exhibit proptosis, orbital ecchymosis (raccoon eyes), Horner syndrome, or opsoclonus (dancing eyes). Ewing sarcoma, leukemia, Burkitt lymphoma, and Langerhans cell histiocytosis may involve the orbit.

Examination of vision, eye movements, eyelids, and orbits often reveals amblyopia, eyelid malposition, strabismus, and proptosis. Neuroimaging with CT or MRI is required to delineate the location and size of orbital tumors.

▶ Differential Diagnosis

Orbital pseudotumor (idiopathic orbital inflammation), orbital cellulitis.

▶ Treatment

Therapy for capillary hemangiomas includes observation and intralesional or systemic corticosteroids. Topical and systemic β-blockers have shown success in treating capillary hemangiomas but optimal dosages and duration of treatment are still under investigation. Treatment is indicated if the lesion is large enough to cause amblyopia. Induced astigmatism or amblyopia (or both) are treated with glasses and patching, respectively. Treatment of orbital dermoids is by excision.

Rhabdomyosarcoma is treated with radiation and chemotherapy after biopsy confirms the diagnosis. With expeditious diagnosis and proper treatment, the survival rate of patients with orbital rhabdomyosarcoma confined to the orbit approaches 90%.

Treatment of metastatic disease requires management by an oncologist and may require chemotherapy and radiation therapy.

▶ Prognosis

Prognosis depends on the underlying disease.

Balma-Mena A et al: Propranolol in the management of infantile hemangiomas: clinical response and predictors. J Cutan Med Surg 2012;16(3):169–173 [PMID: 22713439].

Chakkittakandiyil A et al: Timolol maleate 0.5% or 0.1% gel-forming solution for infantile hemangiomas: a retrospective, multicenter, cohort study. Pediatr Dermatol 2012;29(1):28–31 [PMID: 22150436].

NYSTAGMUS

▶ Nystagmus is a rhythmic oscillation or jiggling of the eyes. It may be unilateral or bilateral, more pronounced in one eye, or gaze-dependent.

▶ Pathogenesis

Nystagmus may be associated with esotropia or may occur with ocular lesions that cause deprivation amblyopia (eg, cataract and eyelid ptosis) or conditions in which the visual pathways are hypoplastic, sometimes referred to as "sensory nystagmus." Nystagmus is seen with optic nerve hypoplasia, macular hypoplasia, aniridia, and albinism. Nystagmus can also occur with normal ocular structures and seemingly normal CNS development, sometimes referred to as "motor nystagmus." In the latter instance, the nystagmus may be blocked in certain positions of gaze, in which case a face turn or torticollis may develop. Latent nystagmus occurs when one eye is occluded. This type of nystagmus occurs in patients with congenital esotropia. An associated amblyopia may be present.

Most nystagmus occurring in childhood is of ocular origin, but CNS disease and, less frequently, inner ear disease are other causes. A CNS cause is likely when the nystagmus is acquired. Patients should be referred to an ophthalmologist for evaluation.

▶ Clinical Findings

Evaluation for iris transillumination defects caused by albinism should be performed since albinism is a common cause of nystagmus.

Spasmus nutans, in which a rapid, shimmering, disconjugate nystagmus occurs with head bobbing and torticollis. Glioma of the hypothalamus can mimic spasmus nutans. Neuroimaging may be necessary to determine if the cause of the nystagmus is due to a CNS disease. An electroretinogram may be required to rule out retinal pathology as the cause of nystagmus if neuroimaging is normal.

▶ Differential Diagnosis

Opsoclonus.

▶ Treatment

Therapy is directed at managing the underlying ocular or CNS disease. An ophthalmologist can optimize vision by correcting significant refractive errors and strabismus. The range of vision varies depending on the cause of the nystagmus. Some patients may benefit from extraocular muscle surgery and contact lenses.

▶ Prognosis

Most affected individuals have subnormal vision but spasmus nutans usually improves with time.

AMBLYOPIA

▶ Amblyopia is a unilateral or bilateral reduction in vision due to strabismus, refractive errors, and/or visual deprivation.
▶ Amblyopia can occur only during the critical period of visual development in the first decade of life when the visual nervous system is plastic.
▶ Approximately 3% of the population is amblyopic.

▶ Pathogenesis

Amblyopia is classified according to its cause. Strabismic amblyopia can occur in the nondominant eye of a strabismic child. Refractive amblyopia can occur in both eyes if significant refractive errors are untreated (ametropic or refractive amblyopia). Another type of refractive amblyopia can occur in the eye with the worse refractive error when imbalance is present between the eyes (anisometropic amblyopia). Deprivation amblyopia occurs when dense cataracts or complete ptosis prevents formation of a formed retinal image. Of the three types of amblyopia, the deprivation form of amblyopia results in the worst vision.

▶ Prevention

Vision screening and referral to an eye care professional if amblyopia is suspected.

▶ Clinical Findings

Screening for amblyopia should be a component of periodic well-child examinations. The single best screening technique to discover amblyopia is obtaining visual acuity in each eye. In preverbal children unable to respond to visual acuity assessment, amblyogenic factors are sought, including strabismus, media opacities, unequal Brückner reflexes (pupillary red reflexes), and a family history suggestive of strabismus, amblyopia, or ocular disease occurring in childhood (see earlier section Ophthalmic Examination).

▶ Treatment

The earlier treatment is begun, the better will be the chance of improving visual acuity. Treatment is usually discontinued after age 9 years. Amblyogenic factors such as refractive errors are addressed. Because of the extreme sensitivity of the visual nervous system in infants, congenital cataracts and media opacities must be diagnosed and treated within the first few weeks of life. Visual rehabilitation and amblyopia treatment must then be started to foster visual development.

After eradicating amblyogenic factors, the mainstay of treatment is patching the sound eye, which causes the visual nervous system to process input from the amblyopic eye and in that way permits the development of useful vision. Other treatment modalities include "fogging" the sound eye with cycloplegic drops (atropine), lenses, and filters.

▶ Prognosis

Prognosis depends on the compliance with treatment but usually good.

STRABISMUS

DIAGNOSIS & TYPICAL FEATURES

▶ Strabismus is misalignment of the eyes.

▶ Its prevalence in childhood is about 2%–3%.

▶ Strabismus is categorized by the direction of the deviation (esotropia, exotropia, hypertropia, hypotropia) and its frequency (constant or intermittent).

▶ Strabismus may cause or be due to amblyopia.

Esotropia (Crossed Eyes)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Pseudoesotropia can result from prominent epicanthal folds that give the appearance of crossed eyes when they are actually straight.

▶ Esotropia is deviation of the eyes toward the nose and may involve one or both eyes.

▶ Pathogenesis

Congenital esotropia (infantile esotropia) has its onset in the first year of life in healthy infants. The deviation of the eyes toward the nose is large and obvious. Esotropia beginning in the first year also occurs in premature infants or children with a complicated perinatal history associated with CNS problems such as intracranial hemorrhage and periventricular leukomalacia. The most frequent type of acquired esotropia is the accommodative type (Figure 16–26). Onset is usually between ages 2 and 5 years. The deviation is variable in magnitude and constancy and is often accompanied by amblyopia. One type of accommodative esotropia is associated with a high hyperopic refraction. In another type, the deviation is worse with near than with distant vision. This type of esodeviation is usually associated with lower refractive errors.

Esotropia is associated with certain syndromes. In Möbius syndrome (congenital facial diplegia), a sixth nerve palsy causing esotropia is associated with palsies of the 7th

A

B
C

▲ **Figure 16–26.** Accommodative esotropia. **A:** Without glasses, esotropic; **B:** with glasses, well aligned at distance; **C:** at near with bifocal correction.

and 12th cranial nerves and limb deformities. Duane syndrome can affect the medial or lateral rectus muscles (or both). It may be an isolated defect or may be associated with a multitude of systemic defects (eg, Goldenhar syndrome). Duane syndrome is often misdiagnosed as a sixth (abducens) nerve palsy. The left eye is involved more commonly, but both eyes can be involved. Girls are affected more frequently. Children with unilateral paretic or restrictive causes of esotropia may develop face turns toward the affected eye to maintain binocularity.

After age 5 years, any esotropia of recent onset should arouse suspicion of CNS disease. Infratentorial masses, hydrocephalus, demyelinating diseases, and idiopathic intracranial hypertension are causes of abducens palsy, which appears as an esotropia, lateral rectus paralysis, and face turn. The face turn is an attempt to maintain binocularity away from the field of action of the paretic muscle. Papilledema is often, but not invariably, present with increased intracranial pressure.

Besides the vulnerability of the abducens nerve to increased intracranial pressure, it is susceptible to infection and inflammation. Otitis media and Gradenigo syndrome (inflammatory disease of the petrous bone) can cause sixth nerve palsy. Less commonly, migraine and diabetes mellitus are considerations in children with sixth nerve palsy.

▶ Clinical Findings

Observation of the reflection of a penlight on the cornea, the corneal light reflex, is an accurate means of determining if the eyes are straight. If strabismus is present, the corneal light reflex will not be centered in both eyes. Observation of eye movements may reveal restriction of eye movements in certain positions of gaze. Alternate cover testing of the eyes while the child is fixating on a near and/or distant target will reveal refixation movements if the eyes are crossed. Motility, cycloplegic refraction, and a dilated funduscopic examination by an ophthalmologist are necessary to determine the etiology of esotropia. Some children require imaging studies and neurologic consultation.

▶ Complications

Amblyopia and poor stereoacuity/depth perception.

▶ Treatment

Surgery is the mainstay of treatment for congenital esotropia. Surgery is typically performed between 6 months and 2 years of age in order to obtain optimal results.

Management of accommodative esotropia includes glasses with or without bifocals, amblyopia treatment, and, in some cases, surgery.

Underlying neurologic disease should be referred to the appropriate specialists for further management.

▶ Prognosis

Usually good.

Exotropia (Wall-Eyed)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Exotropia is a type of strabismus in which the eyes are divergent/wall-eyed (Figure 16–27).
▶ Exotropia may be intermittent or constant and involve one or both eyes.

▶ Clinical Findings

The deviation of the eyes toward the ears most often begins intermittently and occurs after age 2 years (see Figure 16–27). Congenital (infantile) exotropia is extremely rare in an otherwise healthy infant. Early-onset exotropia may occur in infants and children with severe neurologic problems.

Evaluation of the corneal light reflex reveals the penlight's reflection in the deviated eye is displaced nasally.

▲ **Figure 16–27.** Exotropia. **A:** Fixation with left eye. **B:** Fixation with right eye.

All children with constant, congenital exotropia require CNS neuroimaging. Referral to an ophthalmologist is indicated.

▶ Complications

Amblyopia and poor stereoacuity/depth perception.

▶ Treatment

Treatment of exotropia is with surgery, orthoptic exercises, patching, and occasionally glasses.

▶ Prognosis

Generally good.

Granet DB, Khayali S: Amblyopia and strabismus. Pediatr Ann 201; 40(2):89–94 [PMID: 21323205].

▼ UNEXPLAINED DECREASED VISION IN INFANTS & CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Blindness in infants and children is commonly caused by retinal dystrophies, optic nerve disorders, or cortical visual impairment due to significant CNS disease.

▶ Pathogenesis

Occult causes of poor vision and blindness in children may be due to hereditary retinal dystrophies such as Leber congenital amaurosis and optic nerve abnormalities, including optic nerve hypoplasia and atrophy.

Cerebral visual impairment, also known as *cortical blindness*, is manifested as decreased visual attentiveness of varying degree. Cerebral visual impairment can be congenital or acquired. Insults to the optic pathways and higher cortical visual centers are responsible. Asphyxia, trauma, intracranial hemorrhage, and periventricular leukomalacia are some of the causes of cortical visual impairment.

▶ Clinical Findings

Affected infants will have poor eye contact, fail to fixate and follow a visual target, and be unresponsive to visual threat. Wandering or roving eye movements and nystagmus are common. Eye poking is seen in some infants with low vision.

Referral to an ophthalmologist is indicated to determine the etiology of the low vision. Diagnostic tests such as an electroretinogram and visual evoked response may be required. Imaging studies of the brain, genetics, and neurology consultations may be useful.

▶ Differential Diagnosis

Delayed visual maturation, vision loss due to an ocular versus neurologic disease.

▶ Treatment

Low-vision aids enhance remaining vision. Devices used include magnifiers for both distance and near vision, closed-circuit television, and large-print reading materials. Vision rehabilitation specialists and support groups can help teach the affected child and their family how to best use these devices. Clinical trials are underway for treatment of Leber congenital amaurosis with gene therapy.

▶ Prognosis

Generally poor for vision.

Hufnagel RB, Ahmed ZM, Corrêa ZM, Sisk RA: Gene therapy for Leber congenital amaurosis: advances and future directions. Graefes Arch Clin Exp Ophthalmol 2012;250(8):1117–1128 [PMID: 22644094].

▼ LEARNING DISABILITIES & DYSLEXIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Learning disabilities and dyslexia result in poor reading comprehension and writing.
▶ Children often have vague complaints of ocular fatigue, headaches, and difficulty reading.

▶ Clinical Findings

Evaluation of the child with learning disabilities and dyslexia should include ophthalmologic examination to identify any ocular disorders that could cause or contribute to poor school performance. Most children with learning difficulties have no demonstrable problems on ophthalmic examination.

▶ Treatment

A multidisciplinary approach is recommended by the AAP, the AAPOS, and the AAO for evaluating and treating children with learning disabilities. There is no scientific

evidence to support the use of vision therapy, eye exercises, prisms, colored lenses, or filters to treat learning disabilities or dyslexia.

▶ Prognosis

Generally good.

Oral Medicine & Dentistry

Ulrich Klein, DMD, DDS, MS

ISSUES IN PEDIATRIC ORAL HEALTH

Concept of the Dental Home

Analogous to the American Academy of Pediatrics' (AAP) concept of a "medical home," the American Academy of Pediatric Dentistry (AAPD) has promoted the concept of a "dental home." A dental home is best established by referring a child for oral health examination to a dentist who provides care for infants and young children (ie, pediatric dentist) 6 months after the first tooth erupts or by 12 months of age. The primary goal of the dental home is to encourage good oral healthcare habits that will allow the child to grow up free from dental disease. In partnership with the caregivers, the pediatric dentist develops a comprehensive, personalized preventive healthcare program based on an accurate risk assessment for dental disease. The pediatric dentist provides education on age-appropriate oral hygiene techniques and a tooth-friendly diet. Other functions of the dental home include provision of anticipatory guidance on growth and development, provision of comprehensive routine and emergency dental care, and referral to other dental specialists as needed. The dental home has the benefit of promoting continuity of care in a family-centered and culturally appropriate environment, and is associated with fewer emergency visits and reduced treatment costs. A child is less likely to develop dental anxiety if a number of positive experiences precede a less pleasant appointment.

AAPD policies and guidelines: http://www.aapd.org/policies/. Accessed December 26, 2013.
American Academy of Pediatric Dentistry (AAPD): Policy on the dental home. Pediatr Dent 2013;35 (Reference Manual):24–25.

Perinatal Factors & Oral Health

The perinatal period offers a unique opportunity for oral health counseling from various healthcare providers aimed at women's self-care as well as future child care. Mothers may be unaware of the consequences of their own poor oral health or that of their children. Cariogenic bacteria can be transmitted vertically from mother to child by licking a pacifier or sharing eating utensils or horizontally between siblings of similar age, from the father, and from children in day care centers. Colonization of the infant with mutans streptococci (MS) is more likely when maternal salivary MS levels are high. The mother's oral hygiene, snacking habits, and socioeconomic status all have an influence on the infant's colonization with MS. Anticipatory guidance and dental treatment of the expectant mother can significantly reduce the child's risk of acquiring MS. Prenatal dental counseling should include education on the importance of regular dental visits and the role of fluoride in maternal and childhood oral health, counseling on appropriate maternal diet, and advice on reduction of MS colonization. Maternal MS levels and the risk of transmission to infants can be reduced by twice-daily rinsing with chlorhexidine digluconate 0.12% for 2 weeks followed by chewing 100% xylitol gum for 5 minutes 3–5 times/d (total dose of xylitol 6–10 g/d) for several weeks.

Delayed dental development is characteristic of preterm infants and is also seen in infants with global developmental delay. Postnatal environmental tobacco smoke exposure increases susceptibility to childhood caries, an association that is independent of age, family income, geographic region, and frequency of dental visits. It is important to advise expectant mothers about this risk. The risk of oral anomalies is higher in preterm and low-birth-weight infants than in full-term infants. These anomalies may include a narrow palate caused by traumatic laryngoscopy or prolonged endotracheal intubation, hypoplasia of the enamel of primary dentition, and crown dilaceration (an angulation, or a sharp bend or curve, in the root or crown of a formed tooth) of the permanent maxillary incisors. The role of palatal protection plates to prevent palatal "grooving" is not clear.

AAPD: Guideline on perinatal oral health care. Pediatr Dent 2013;35 (Reference Manual):131–136.

Infant Oral Health Care

Infant oral health care is the foundation on which preventive dental care is built. Ideally, this begins before caries develops so preventive measures can be implemented. The primary goals for an infant oral health program are: (1) to establish with parents the goals of oral health; (2) to inform parents of their role in reaching these goals; (3) to motivate parents to learn and practice good preventive dental care; and (4) to initiate a long-term dental care relationship with parents. These goals can be achieved through oral examination of the child, risk assessment for oral disease, anticipatory parental guidance, and regular dental health supervision. This approach advances dental care beyond tooth monitoring toward true health promotion. Because pediatricians encounter new mothers and infants earlier than dentists, it is essential that they be aware of the infectious pathophysiology and risk factors for early childhood caries (ECC).

Pediatricians should incorporate oral health into anticipatory guidance by providing information on oral health in their offices and by referring children with special health-care needs to a pediatric dentist as early as 6 months of age. Referral of healthy infants to establish a dental home should occur no later than 6 months after the first tooth erupts or 12 months of age (whichever comes first).

AAPD: Guideline on infant oral health care. Pediatr Dent 2013;35 (Reference Manual):131–141.

Caries-Risk Assessment

Caries-risk assessment estimates the likelihood of developing carious lesions based on biological and protective factors as well as clinical findings. By 6 months of age, every child should have a caries-risk assessment performed by a pediatric healthcare provider. The Caries Risk Assessment Form (Table 17–1) details risk indicators for the age group 0–3 years old that directly or indirectly influence development of dental caries. Caries management by risk assessment (CAMBRA) is another protocol for a comprehensive evaluation of the child and his/her family and integrates the many factors that contribute to the development of ECC into a practical and individualized strategy for caries control. Although the best predictor of future caries is the incidence of previous caries, this finding is not a practical preventative tool. Additional risk factors include the level of parental education and age of colonization with MS and lactobacilli. The earlier the colonization occurs, the greater the risk of severe decay.

The ultimate purpose of this assessment is to develop a caries management protocol. Based on a child's risk category and extent of parental engagement, interventions include diagnostics (regular recalls and determination of MS levels in saliva), optimization of the protective factors listed above, dietary counseling, and restorative measures as needed.

AAPD: Guideline on caries-risk assessment and management for infants, children, and adolescents. Pediatr Dent 2013;35 (Reference Manual):123–130.

Table 17–1. Caries-risk assessment for 0–3-year-olds.

		High Risk	Moderate Risk	Protective
Biological Factors	Mother/primary caregiver has active caries	Yes		
	Parent/primary caregiver has low socioeconomic status	Yes		
	Child has > 3 between-meal sugar-containing snacks or beverages per day	Yes		
	Child is put to bed with a bottle containing natural or added sugar	Yes		
	Child has special healthcare needs		Yes	
	Child is a recent immigrant		Yes	
Protective Factors	Child receives optimally fluoridated drinking water and fluoride supplements			Yes
	Child has teeth brushed daily with fluoridated toothpaste			Yes
	Child receives topical fluoride from health professional			Yes
	Child has dental home/regular dental care			Yes
Clinical Findings	Child has white spot lesions or enamel defects	Yes		
	Child has visible cavities of fillings	Yes		
	Child is a recent immigrant		Yes

Ramos-Gomez FJ et al: Caries risk assessment appropriate for the age 1 visit (infants and toddlers). J Calif Dent Assoc 2007 Oct; 35:687–702 [PMID: 18044377].

DENTAL CARIES

Dental caries is the most common chronic disease of childhood and the most prevalent unmet health need of US children. Dental caries is largely a disease of poverty. Children and adolescents in low-income families account for 80% of patients with tooth decay.

▶ Pathogenesis

Development of caries requires the interaction of four factors: (1) a host (tooth in the oral environment); (2) a suitable dietary substrate (fermentable carbohydrates); (3) cariogenic microorganisms that adhere to the tooth; and (4) time, measured as the frequency of exposure to fermentable carbohydrates and the duration of acid exposure. The main organisms implicated in the initiation of caries are *Streptococcus mutans* (MS) and *Streptococcus sobrinus*. *Lactobacillus acidophilus* and *Lactobacillus casei* are linked to the progression of caries. MS organisms are most commonly passed vertically from mother to child. A "window of infectivity" between ages 19 and 33 months has been described, but colonization can occur as early as 3 months of age. Earlier colonization increases the risk of caries. Dental plaque is an adherent biofilm on the tooth surface that harbors acidogenic bacteria in close proximity to the enamel. As bacteria metabolize sucrose, they produce lactic acid that solubilizes calcium phosphate in tooth enamel and dentin. Demineralization of the dental enamel occurs below pH 5.5 and is the first step in cariogenesis. The flow rate of saliva and its buffering capacity are important modifiers of demineralization. Demineralization of enamel and dentin can be halted or even reversed by redeposition of calcium, phosphate, and fluoride from saliva. If not halted, the carious process penetrates the enamel, advancing through the dentin toward the pulp of the tooth. In response, blood vessels in the pulp dilate and inflammatory cells begin to infiltrate (pulpitis). If the carious lesion is untreated, pulp exposure will occur, triggering invasion of more inflammatory cells and the eventual formation of a small pulp abscess. If this abscess can drain into the oral cavity, the apical tooth tissue may remain vital. However, if the radical pulp becomes necrotic, a periapical abscess develops (Figure 17–1). Although this process may be asymptomatic, it usually causes severe pain, fever, and swelling.

▶ Clinical Findings & Treatment

The diagnosis of caries is usually made by visual and tactile oral examination. Radiographs are used to visualize caries on the surfaces between teeth. The initial defect observed on enamel beneath the dental plaque is the so-called "white-spot lesion," a white, chalky, decalcified area along the gingival margin or on approximated tooth surfaces. Frank carious lesions are light- to dark-brown spots or cavities of varying size on the tooth. A light shade of brown indicates more rampant decay. Arrested caries are almost black in color. In the early stages of decay, the tooth may be sensitive to temperature changes or sweets. Removing the carious tooth structure and filling the early defect with a restorative material can repair the tooth. As decay progresses deeper into the pulp, inflammation and pain increase. Eventually, the entire pulp becomes necrotic, and a choice must be made between root canal therapy (pulpectomy) or removal of the tooth. In the presence of cellulitis or facial space abscess, extraction and antibiotic therapy are the treatments of choice.

Cavitation is the late phase of disease. Filling cavities does not address the underlying pathologic process responsible for tooth decay. Unlike other infections, dental caries cannot be treated by a course of antibiotics. However, a daily dose of chlorhexidine gluconate rinse 0.12% for 2 weeks can significantly reduce the number of cariogenic bacteria in the mouth and delay recolonization for 3–6 weeks. Such treatment is recommended at 3-month intervals for patients with high levels of bacteria. Improvement in risk of dental caries can only be achieved by a sustained reduction in the number
▲ **Figure 17–1.** Tooth anatomy and progression of caries.

of cariogenic oral bacteria and by the creation of a favorable oral environment. Additionally, all active cavities must be restored to eliminate sources of reinfection. A patient and his/her family must be encouraged to change diet and habits of oral hygiene in an effort to prevent further infection. Motivational interviewing has been shown to be more successful in setting these self-management goals than simple or stern recommendations. Regular dental visits, the periodicity of which should be determined by the risk level for developing carious lesions, must be maintained to monitor and reinforce these goals. The concept of prevention through timely and regular parent education, early diagnosis, and prompt intervention offers greater efficiency, better health outcomes, and lower costs than repeated restoration of diseased teeth.

▶ Caries Prevention

Prevention of dental caries necessitates restoring the delicate balance between pathologic and protective factors. Pathologic factors include cariogenic bacteria and fermentable carbohydrates. Protective factors include salivary flow, and fluoride in food, beverages, drinking water, and oral care products. Saliva provides calcium, phosphate, proteins, antibacterial substances, and buffers to neutralize acid produced by bacteria in plaque.

A. Changes in Lifestyle

Oral hygiene practices should start soon after birth. The infant's gums should be cleaned daily using a moist, soft cloth. Once the teeth erupt, oral hygiene must be practiced in earnest, particularly in children assessed as high risk. A small amount of fluoridated toothpaste ("smear layer") should be used on a small, soft toothbrush designed for infants. Because of a lack of manual dexterity in children younger than 8 years of age, parents need to brush for them twice daily and assist with flossing. Another important parental task is reducing the amount of substrate available to the bacteria by limiting the consumption of sugar-containing infant formulas, beverages, and snacks. Each such exposure produces an acidic oral environment for up to 30 minutes. The primary care physician and his/her team play an invaluable role in disseminating this information during early well-baby visits.

B. Fluorides

Fluorides are safe and effective in caries prevention through three topical mechanisms of action: inhibition of bacterial metabolism by interfering with enzyme activity; inhibition of demineralization; and enhancing remineralization. Fluoride can be applied professionally or by the patient under parental supervision. Although more than half the US population has access to fluoridated community water, an increasing number of families consume processed water with unknown fluoride content. Fluorides affect the dentin

Table 17–2. Dietary fluoride supplementation schedule for children at high caries risk.

Age	Concentration of Fluoride in Water		
	< 0.3 ppm F	0.3–0.6 ppm F	> 0.6 ppm F
Birth–6 mo	None	None	None
6 mo–3 y	0.25 mg	None	None
3–6 y	0.50 mg	0.25 mg	None
6–at least 16 y	1.00 mg	0.50 mg	None

Adapted from Rozier RG et al: Evidence-based clinical recommendations on the prescription of dietary fluoride supplements for caries prevention: a report of the American Dental Association Council on Scientific Affairs. J Am Dent Assoc 2010 Dec;141(12):1480–1489 [PMID: 21158195].

and enamel of both erupted and unerupted teeth. Systemic effects are achieved by oral ingestion from sources such as fluoridated drinking water or fluoride supplements. Fluoridated toothpaste and mouth rinses deliver topical benefits. Table 17–2 shows the current ADA recommendations for dietary fluoride supplementation for children at high caries risk. They should be taken daily to maximize the caries risk prevention benefit. For children at low caries risk, dietary fluoride supplements are not recommended. The child's true exposure to fluoride must be evaluated before supplements are prescribed to avoid the mottled enamel (dental fluorosis) produced by excessive fluoride. Because children younger than 6 years of age cannot expectorate reliably, parents must monitor the use of fluoridated toothpaste, ensuring that only a "pea-sized" amount of the product is used at each brushing. Several factors are associated with a high risk for caries—orthodontic appliances, decreased salivary function, gastroesophageal reflux disease, cariogenic diet, physical inability to properly clean the teeth, mother or siblings with caries, personal history of caries. Children with these risk factors should be considered for additional topical fluoride therapy to supplement oral hygiene measures.

Infants who consume concentrate infant formulas as the main source of nutrition may incur an increased risk for enamel fluorosis in the permanent dentition if those formulas are reconstituted with optimally fluoridated drinking water. It is important that practitioners evaluate all sources of fluoride intake when advising parents about the use of fluoridated toothpastes or prescribing fluoride supplements.

Berg J et al: Evidence-based clinical recommendations regarding fluoride intake from reconstituted infant formula and enamel fluorosis: a report of the American Dental Association Council on Scientific Affairs. J Am Dent Assoc 2011 Jan;142(1):79–87 [PMID: 21243832].

C. Other Adjunctive Measures

Consumption of beverages sweetened with artificial sweeteners instead of sugar can help reduce the intake of fermentable carbohydrates. While chewing gum helps to clean food debris from teeth and increases salivary flow, these beneficial effects are lost when sugar-containing gum is used. The AAP considers chewing gum a choking risk in smaller children. A significant reduction of salivary MS by the polyol sweetener xylitol has been described, but a dose of at least 5–10 g/d for adults and 5–7.5 g/d for toddlers aged 6–36 months with exposure times lasting several minutes three times daily are required to produce this effect. Topical application of 8 g/d xylitol syrup in 9–15-month-old children twice per day for 12 months during primary tooth eruption could prevent up to 70% of dental caries. However, unclear labeling of the ingredients in xylitol-containing products makes the exact determination of the dose difficult and the high cost of foods containing xylitol limits its widespread use.

AAPD: Policy on the use of Xylitol in caries prevention. Pediatr Dent 2013;35 (Reference Manual):45–47.
Featherstone JD: The science and practice of caries prevention. J Am Dent Assoc 2000 Jul;131(7):887–899 [PMID: 10916327].

Early Childhood Caries

Formerly termed "baby bottle tooth decay" or "nursing bottle caries," early childhood caries (ECC) is a particularly virulent and rapidly progressive form of caries that begins on the smooth surfaces of the teeth soon after eruption. Lack of adequate preventive care as well as poor feeding habits, such as the frequent consumption of liquids containing fermentable carbohydrates from a nursing bottle, frequent sipping from a no-spill sippy cup, taking a bottle to bed, and breastfeeding in combination with other carbohydrates, place children at high risk for ECC. It is uncertain whether ad libitum breast-feeding increases the risk for developing caries. ECC typically involves the maxillary incisors but any other teeth may be affected.

ECC is defined as one or more decayed (d), missing (m), or filled (f) tooth surfaces (s) in any primary tooth in a child younger than 71 months of age. Any sign of smooth-surface caries in a child younger than 3 years is termed severe ECC (S-ECC). From 3 to 5 years, one or more decayed, missing, or filled smooth surfaces in maxillary front teeth or a total dmfs score of 4 or higher must be present to make a diagnosis of S-ECC. By age 5 years, a dmfs score of 6 or higher must be present to constitute S-ECC. Children with S-ECC are at higher risk for new carious lesions, more frequent hospitalizations, and emergency department visits. They are absent more often from school, may have below-normal height and weight gain, and have a diminished oral health-related quality of life. Although S-ECC can affect all children, it is

32 times more likely in children who consume sugary foods and whose mothers are of low socioeconomic status and education level.

Parents should be counseled to eliminate saliva-sharing activities and not to put infants to sleep with a bottle containing fermentable carbohydrates. After eruption of the first tooth, ad libitum breast-feeding should be discontinued and regular oral hygiene measures such as twice-daily use of fluoridated toothpaste, both in optimally fluoridated and fluoride-deficient communities, should be implemented. Infants should be weaned from the bottle at about 1 year of age and encouraged to drink from a uncovered cup mainly as part of a snack or meal. Frequent consumption of cariogenic liquids from a bottle or no-spill training cup should be avoided. The AAP recommends limiting juice to 4–6 oz/day for children 1–6 years of age.

Preventive strategies focused on the pregnant woman should start in the prenatal and perinatal periods. Maternal malnutrition during the third trimester, low birth weight, and systemic illness in the neonatal period can lead to tooth hypoplasia, which makes teeth more susceptible to caries. Later, motivational interviewing may help parents to reduce deleterious feeding habits and to adopt lifestyle changes within their family that address the multifactorial etiologies of early childhood caries.

Preventive Dental Treatment (Fluoride Varnish) by Physicians for High-Risk Populations

Since parents are more likely to take their very young child to a physician for well-child visits than to a dentist for oral health counseling, some states have established formal programs to entice medical offices to provide preventive dental services. These include dental screening, risk assessment, and referrals to dentists as needed, parent counseling about their child's oral health, and applications of fluoride varnish (ICD-9-CM Diagnosis Code V07.31: Need for Prophylactic Fluoride Administration). The latter consists of a resin base in which fluoride (5% NaF) is suspended. Its sticky nature allows for extended contact time of the fluoride with the tooth surface. Many studies have demonstrated the safety and efficacy of fluoride varnishes and have described a significant reduction in the decay rate of smooth surfaces

as well as pits and fissures. A report from a medical office-based preventive dental program in North Carolina found that it was successful in reducing caries-related treatments for children up to 6 years of age by 17%. Multiple fluoride varnish applications at the time of tooth emergence seemed to be most beneficial.

The varnish in single-dose packages (0.3–0.5 mL) should be stirred vigorously before application and the contents of larger tubes (5 mL) massaged to redissolve any precipitated fluoride. The former are preferable because consistent availability of fluoride cannot be guaranteed with multidose packages. The average amount of varnish needed depends on the number of teeth present and ranges from 0.1 mL for infants to 0.3 mL for preschool children. Teeth should be dried with gauze before application of the varnish with a small brush. It will set quickly to a dull yellow film upon contact with saliva. Caregivers should be instructed not to brush or floss and to give their child only soft foods until the next morning in order to provide the fluoride enough time for absorption into enamel.

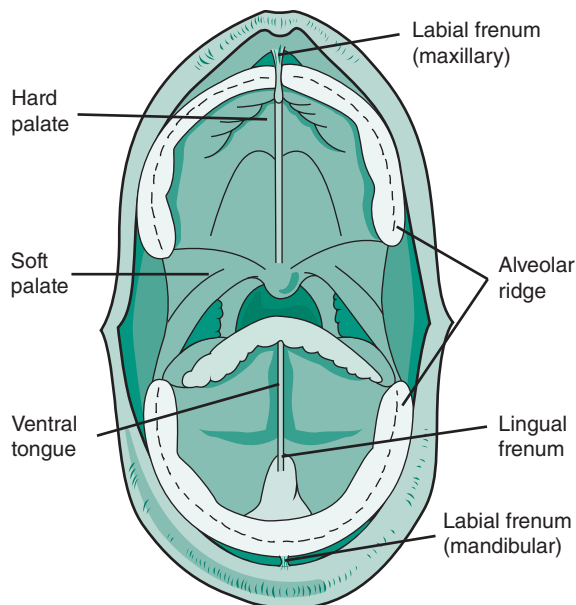
ORAL EXAMINATION OF THE NEWBORN & INFANT

The sagittal and vertical maxillomandibular relationships are different at birth. An anterior open bite is considered physiologic before the onset of tooth eruption. The infant's mouth is more triangularly shaped and its oral cavity is small and totally filled by the tongue due to a small and slightly retrognathic lower jaw. This newborn's pseudo micrognathia is due to ventral positioning of the fetus and will generally correct after birth by physiologic suckling.

Sucking Pads

Frequent breast-feeding can lead in some babies to formation of a lip callus ("sucking or suckling pad") at the midline of the upper lip. Since it does not bother the mother or the child, it should not be removed. It will generally go away within the baby's first year.

Within the cheek of newborns wedged between masseter and buccinator and related to the facial nerve and parotid duct there is a buccal fat pad that is completely enclosed within a distinctive capsule. These "suckling pads" are supposed to strengthen and support the cheek during the act of suckling.


▲ **Figure 17–2.** Normal anatomy of the newborn mouth.

The mouth of the normal newborn is lined with an intact, smooth, moist, shiny mucosa (Figure 17–2). The alveolar ridges are continuous and relatively smooth. Within the alveolar bone are numerous tooth buds, which at birth are mostly primary teeth.

Teeth

Hard tissue formation of primary teeth begins at approximately 4 months' gestation. At birth, all 20 primary teeth are calcified. The central maxillary incisors are almost completely calcified while only the cusp tips of the maxillary and mandibular second molars are calcified. There is a trace of enamel on the first four permanent molars at birth.

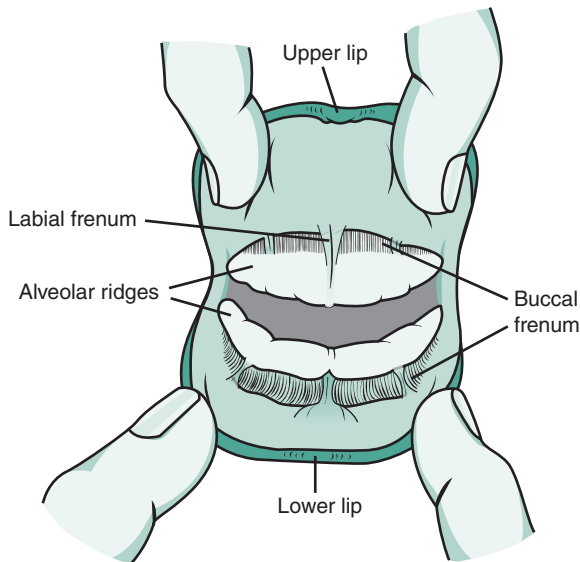
The primary teeth usually begin to erupt at around 7 months of age. On rare occasions (1:3000), natal teeth are present at birth or neonatal teeth erupt within the first month. These are most commonly (85%) mandibular primary incisors. They can be "real" primary teeth (90%) or supernumerary teeth (10%) and should be differentiated radiographically. Although the preferred approach is to leave the tooth in place, supernumerary and hypermobile immature primary teeth should be extracted. On occasion, such teeth must be smoothed or removed if their sharp incisal edge causes laceration of the tongue (Riga-Fede disease). If such teeth cause difficulties with breast-feeding, pumping and bottling the milk is initially recommended while the infant is conditioned not to "bite" during suckling.

Frena

Noticeable but small maxillary and mandibular labial frena should be present (Figure 17–3). The "persisting tectolabial frenum" that is observed in 25% of all children tends to diminish in size with normal development. Its physiological purpose is to provide greater support to the upper lip during breast-feeding. Several small accessory frena may also be present farther posteriorly. In rare cases, as in oral-facial-digital syndrome, there are multiple thick tightly bound frena. Decisions about surgical correction should be based on the ability to maintain the child's gingival health and are best left until the late preteen years. Many thick frena do not require correction.

The tongue is connected to the floor of the mouth by the lingual frenum (Figures 17–3 and 17–4). This connection should not impede the free movement of the tongue.

A **B**

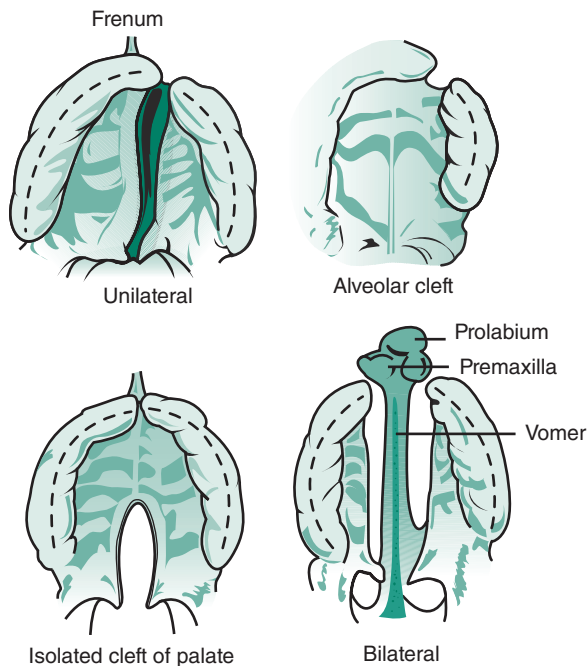
▲ **Figure 17–5.** Ankyloglossia (tongue-tie) in a 6-wk old, before (A) and after (B) the release surgery.


▲ **Figure 17–3.** The frena.
▲ **Figure 17–4.** Normal position of lingual frenum.

If the attachment is tight and high up on the alveolar ridge (Figure 17–5), it may restrict movement and interfere with the child's ability to produce "t," "d," and "l" sounds. This condition is called ankyloglossia (tongue-tie). Surgical correction may be indicated if the tongue cannot touch the maxillary incisors or the roof of the mouth. Earlier intervention (at age 3–4 years) is better than later, but there is usually no urgency for surgery in the neonatal period unless the child has difficulty latching on properly to the mother's nipple and causes her pain during nursing. Frenotomy can be carried out as early as at 10 days of age to provide, in most cases, real, immediate, and sustained improvement in breast-feeding.

Berry J, Griffiths M, Westcott C: A double-blind, randomized, controlled trial of tongue-tie division and its immediate effect on breastfeeding. Breastfeed Med 2012 Jun;7(3):189–193 [PMID: 21999476].

Cleft Lip & Palate

The palate of the newborn should be intact and continuous from the alveolar ridge anteriorly to the uvula (see Figure 17–2). Cleft lip and palate are common defects with an incidence of 0.28–3.74 in 1000 live births globally. Incidence varies widely among races and ranges from 1 in 500 among Navaho Native Americans and Japanese to more than 1 in 800 in Caucasians and 1 in 2000 in African Americans. The cleft of the palate can be unilateral or bilateral (Figure 17–6). It can involve only the alveolar ridge, or the ridge and entire palate. Cleft palate may also present as an isolated submucous cleft or as bifid uvula. Although clefts present superficially as a cosmetic problem, they cause complex functional problems such as oro-antral communication and disruption of the maxillary alveolar ridge with significant associated dental problems, such as irregularities in tooth numbers, delayed eruption, and malocclusion. They disturb the muscle arrangement of the perioral and the soft palate muscles by interrupting their continuity across the midline. As a result, feeding, swallowing, speech, and ventilation of the middle ear are negatively affected.


▲ **Figure 17–6.** Types of clefts.

Children with cleft lip and palate should be referred as soon as possible to a multidisciplinary cleft palate team for comprehensive assessment of their medical status, feeding problems, general development, dental development, hearing, facial esthetics, and overall functioning. The dental needs of children with cleft palate are extensive, and treatment may begin immediately after birth with fabrication of a palatal obturator as a feeding aid. Nasoalveolar molding should be performed to lengthen the columella and to guide the protruding greater segment (in unilateral clefts) or the premaxilla (in bilateral clefts) back into the oral cavity, thus making surgical lip closure easier when it is performed, usually after 10 weeks of age. Palate closure to approximate the muscles of the soft palate, which is intended to restore its proper function and to facilitate the acquisition of normal speech without nasality, follows at 12–18 months of age. The associated scar formation causes significant dentofacial growth disturbance. Orthodontic treatment aims to address the sagittal and transverse maxillary growth deficits as well as the frequent irregularities in tooth eruption and position. Between 8 and 10 years of age, an alveolar bone graft is indicated to add bony support to the central incisor adjacent to the cleft and to enable eruption of the lateral incisor and canine on the cleft side. In some patients, orthognathic surgery to reposition the maxilla anteriorly and mandible posteriorly is needed in late adolescence after cessation of growth to complete their successful rehabilitation.

Other Soft Tissue Variations

Minor oral soft tissue variations can occur in newborns. Small, 1–2 mm round, smooth, white, or grayish lesions are sometimes noted on the buccal and lingual aspects of the alveolar ridges or the midpalatine raphe. The latter, called Epstein pearls, are remnants of epithelial tissue trapped along the raphe during fetal growth. The former, Bohn nodules, are remnants of mucous gland tissue. Both are benign, require no treatment, and usually disappear a few weeks after birth.

Some newborns may have small intraoral lymphangiomas on the alveolar ridge or the floor of the mouth. A dentist familiar with neonates should evaluate these and any other soft tissue variations that are more noticeable or larger than those just described.

ERUPTION OF THE TEETH

Normal Eruption

Primary teeth generally begin to erupt at about 7 months of age, but a gestational age of < 37 weeks or a birth weight < 2500 g increases the mean eruption times by 1 month. The mandibular incisors usually erupt before the maxillary incisors. The first teeth may appear as early as age 3–4 months or as late as age 12–16 months. Many symptoms are ascribed to teething, but any association with fever, upper respiratory infection, or systemic illness is probably coincidental rather than related to the eruption process. Attributing fever to teething without thorough diagnostic evaluation for other sources has resulted in missing serious organic disease.

Common treatment for teething pain is the application of topical anesthetics or teething gels that are available over the counter. Most contain benzocaine or, less commonly, lidocaine. If improperly used, they can cause numbness of the entire oral cavity and pharynx. Suppression of the gag reflex can be a serious side effect. Systemic analgesics such as acetaminophen or ibuprofen are safer and more effective. Chewing on a teething object can be beneficial, if only for distraction purposes.

Occasionally, swelling of the alveolar mucosa overlying an erupting tooth is seen during teething. This condition appears as localized red to purple, round, raised, smooth lesions that may be symptomatic but usually are not. Treatment is rarely needed, as these so-called eruption cysts or eruption hematomas resolve with tooth eruption.

Delayed Eruption

Premature loss of a primary tooth can either accelerate or delay eruption of the underlying secondary tooth. Typically, early eruption occurs when the permanent tooth is in its active eruption stage and the overlying primary tooth is

removed within 6–9 months of its normal exfoliation. If loss of the primary tooth occurs more than 1 year before expected exfoliation, the permanent tooth will likely be delayed in eruption owing to healing, which results in filling in of bone and gingiva over the permanent tooth. The loss of a primary tooth may cause adjacent teeth to tip or drift into the space and lead to space loss for the underlying permanent tooth. Placement of a space maintainer can prevent this.

Other local factors delaying or preventing tooth eruption include supernumerary teeth, cysts, tumors, overretained primary teeth, ankylosed primary teeth, and impaction. A generalized delay in eruption may be associated with global developmental delays, endocrinopathies (hypothyroidism or hypopituitarism), or other systemic conditions (eg, cleidocranial dysplasia, rickets, or trisomy 21).

Ectopic Eruption

If the dental arch provides insufficient room, permanent teeth may erupt ectopically and cause a usually painless partial or complete root resorption in the adjacent primary tooth. This phenomenon is more common in the maxilla, with ectopic eruption of the maxillary first permanent molar being the most frequent. In the mandible, lower incisors may erupt lingually and thus the primary predecessor may be retained. Parental concern about a "double row of teeth" may be the reason for the child's first dental visit. If the primary teeth are not loose, the dentist should remove them to allow their successors to drift into proper position.

Impaction

Impaction occurs when a permanent tooth is prevented from erupting. Although crowding is the most frequent reason, an over-retained primary or supernumerary tooth is another cause. The teeth most often affected in the developing dentition are the maxillary canines. Generally, they are brought into correct alignment through surgical exposure and orthodontic treatment.

Variations in Tooth Number

Failure of teeth to develop—a condition called hypodontia—is rare in the primary dentition, but occurs with an incidence of 5:100 in the permanent dentition. The most frequently missing teeth are the third molars followed by the lateral maxillary incisors and mandibular second premolars. Oligodontia, a condition in which only a few teeth develop, occurs in patients with ectodermal dysplasias. Tooth agenesis is likely caused by several independent defective genes, which can act alone or in combination with other genes. It can occur in isolated cases, but often occurs in combination with cleft lip/cleft palate as part of the phenotype of over 200 syndromes.

Occasionally, supernumerary teeth are present, most typically in the maxillary incisor area, distal to the maxillary molars, or in the mandibular bicuspid region. Mesiodentes are peg-shaped supernumerary teeth situated at the maxillary midline that occur in about 5% of individuals. If they hinder eruption of adjacent permanent incisors, their timely removal is recommended.

Dean JA, Avery DR, McDonald RE: *McDonald and Avery's Dentistry for the Child and Adolescent,* 9th ed. Maryland Heights, MO: Mosby Elsevier.

PERIODONTAL DISEASE

Periodontal disease involves a tooth's supporting structures: bone, gingiva, and periodontal ligaments (Figure 17–7). It begins as inflammation of the gingival tissue adjacent to a tooth. Bacterial accumulation in the gingival sulcus causes irritation and inflammation. This initial phase, called dental plaque-induced disease, is found almost universally in children and adolescents. Systemic conditions, alterations in hormone levels (insulin, gonadotropin), certain medications, and malnutrition can intensify the inflammatory response to plaque. Generally, this condition responds well to removal of bacterial deposits and improved oral hygiene.

Periodontitis is characterized by loss of attachment and destruction of bone. Patients with localized aggressive periodontitis typically have severe alveolar bone loss around permanent first molars and incisors, whereas the generalized form involves other teeth as well. The prevalence is 0.2% in Caucasians, but higher (2.5%) in African Americans, and tends to run in families. Functional defects, such as defects in neutrophil chemotaxis, phagocytosis, and antibacterial activity increase the risk of periodontitis. *Actinobacillus actinomycetemcomitans* in combination with *Bacteroides*-like species are implicated in this disease. Treatment consists of combined surgical and nonsurgical root debridement plus antibiotic therapy.

Periodontitis as a manifestation of systemic disease can be associated with hematological (acquired neutropenia, leukemias) or genetic disorders, such as Down-, Papillon–Lefèvre-, Chediak–Higashi-, hypophosphatasia-, and leukocyte adhesion
▲ **Figure 17–7.** Periodontal disease.

deficiency syndromes. The incidence of necrotizing peri-odontal diseases is lower (1%) in North America than in developing countries (2%–5%). Necrotizing periodontal disease is characterized by interproximal ulceration and necrosis of the dental papillae, rapid onset of dental pain, and often fever. Predisposing factors include viral infections (including human immunodeficiency virus [HIV]), malnu-trition, emotional stress, and systemic disease. The condi-tion usually responds rapidly to treatment consisting of mechanical debridement with ultrasonic scalers, improved oral hygiene, and metronidazole and penicillin for febrile patients.

AAPD: Endorsement; periodontal diseases of children and adolescents. Pediatr Dent 2013;35 (Reference Manual):338–345.

DENTAL EMERGENCIES

Orofacial Trauma

Orofacial trauma most often consists only of abrasions or lac-erations of the lips, gingiva, tongue, or oral mucosa (includ-ing the frena), without damage to the teeth. Lacerations should be cleansed, inspected for foreign bodies, and sutured if necessary. Occasionally, radiographs of the tongue, lips, or cheeks are needed to detect tooth fragments or other foreign bodies. All patients with facial trauma should be evaluated for jaw fractures. Blows to the chin are among the most common childhood orofacial traumas. They are also a lead-ing cause of condylar fracture in the pediatric population. Condylar fracture should be suspected if pain or deviation occurs when the jaw is opened.

Tooth-related trauma affects any or all of the dental hard tissues and the pulp, the alveolar process, and the periodon-tal tissues. The range of luxation injuries includes concus-sion; subluxation; intrusive, extrusive, and lateral luxation; and avulsion. Figure 17–8 demonstrates the different luxa-tion injuries, and Figure 17–9 shows the different degrees of tooth fractures.

The least problematic luxation injuries are concussion (no mobility) and subluxation (mobility without displace-ment). Unless mobility is extensive, this condition can be followed without active intervention, but pulp vitality should be periodically assessed.

Primary Teeth

The peak age for injuries to primary teeth is toddlerhood. Any treatment must include measures to ensure the integrity of the permanent teeth. Parents should be advised of any per-manent tooth complications such as enamel hypocalcification or crown-root dilaceration caused by intrusion injuries of primary maxillary front teeth. An intrusive luxation is usually
▲ **Figure 17–8.** Patterns of luxation injuries.
▲ **Figure 17–9.** Patterns of crown fractures.

observed for a period of time to discern whether the tooth will spontaneously reerupt (see Figure 17–8). Severe luxations in any direction are treated with extraction. Avulsed primary teeth are not replanted. In a root fracture, the crown and apical fragment are generally extracted. The latter should be left for physiologic resorption if its retrieval would result in potential damage to the permanent tooth.

Permanent Teeth

Because the prognosis for viability worsens rapidly as time outside the mouth increases, an avulsed permanent tooth should be replanted into its socket, ideally as soon as pos-sible at or near the accident scene following gentle rinsing with clean water. The patient should seek emergency dental care immediately thereafter. Hank's balanced salt solution is the best storage and transport medium for avulsed teeth that

are to be replanted at a distant emergency clinic. The next best storage media in decreasing order are milk, saline, saliva (buccal vestibule), or water. The commercially available FDA-approved Save-a-Tooth kit should be part of first-aid kits in schools and sports facilities.

Intrusions of permanent teeth are corrected with surgical or orthodontic repositioning. Lateral and extrusive luxations are generally repositioned and splinted for up to 3 weeks. Root canal treatment is necessary in the majority of injuries. Factors to consider during treatment planning are root development (open or closed apex) and the extent of the luxation. Pulp necrosis; surface, inflammatory, and replacement resorption; or ankylosis may occur at any time during the healing process and determine the long-term outcome. All luxated and replanted teeth need to be followed regularly by a dentist.

The Dental Trauma Guide—Your Interactive Tool to Evidence-based Trauma Treatment: http://www.dentaltraumaguide.org/. Accessed March 2013.

Other Dental Emergencies

Dental emergencies other than trauma are usually associated with pain or swelling due to infection resulting from advanced caries. Odontogenic pain usually responds to acetaminophen or ibuprofen. Topical medications are of limited value.

A localized small swelling confined to the gingival tissue associated with a tooth is usually not an urgent situation. This "gumboil" or parulis represents an infection that has spread outward from the root of the tooth through the bone and periosteum. Usually it will drain and leave a fistulous tract. Facial cellulitis results if the infection invades the facial spaces. Elevated temperature (> 38.8°C), difficulty swallowing, and difficulty breathing are signs of more serious infection. Swelling of the midface—especially the bridge of the nose and the lower eyelid—should be urgently evaluated as a potential dental infection. Depending on the clinical situation and the patient's overall health, treatment choices range from treating or extracting the offending tooth/teeth with or without antibiotic coverage to achieve drainage. Occasionally, treatment is delayed for several days while antibiotics are prescribed to contain the spread of the infection. Hospitalization is a prudent choice for younger children with severe facial cellulitis especially if other risk factors are present—dehydration, airway compromise, or possible noncompliance. Inpatient treatment consists of intravenous antibiotics such as clindamycin or ampicillin-sulbactam (Unasyn) with incision, drainage, and removal of the source of infection.

ANTIBIOTICS IN PEDIATRIC DENTISTRY

The antibiotics of choice for odontogenic infection are penicillin and clindamycin. The need for antibiotics—usually a 5- to 7-day course—depends on the severity of the infection and the patient's medical status.

Patients with certain medical conditions are at risk for bacteremia-induced infections and require prophylactic antibiotic coverage prior to invasive dental manipulation. These include children with artificial heart valves, previous infectious endocarditis, certain repaired or nonrepaired congenital heart conditions, or compromised immunity. For nonvalvular devices such as indwelling vascular catheters and cardiovascular implantable electronic devices, antibiotic coverage is indicated only at the time they are placed. Hydrocephalus shunts with vascular access (eg, ventriculoatrial, ventriculocardiac, ventriculovenous) may cause bacteremia-induced infections and therefore require antibiotic prophylaxis, whereas the nonvascular type (ventriculoperitoneal) does not.

Antibiotic prophylaxis is generally not indicated for dental patients with pins, plates, screws, or other orthopedic hardware that is not within a synovial joint. Likewise, most patients with total joint replacements do not routinely require antibiotic prophylaxis, but for them, as well as for the management of patients at high risk and those with Harrington rods or external fixation devices, consultation with the child's physician is advised. Special consideration is also warranted when higher risk dental procedures are performed within 24 months of implant surgery, on immunocompromised patients with total joint arthroplasty, or those who have had previous joint infections.

SPECIAL PATIENT POPULATIONS

Children With Cancer

The most common source of systemic sepsis in the immunosuppressed patient with cancer is the oral cavity. Therefore, a dentist knowledgeable about pediatric oncology should evaluate children with cancer soon after diagnosis. The aim is to educate the patient and caregivers about the importance of good oral hygiene and to remove all existing and potential sources of infection, such as abscessed teeth, extensive caries, teeth that will soon exfoliate, ragged or broken teeth, uneven fillings, and orthodontic appliances, before the child

becomes neutropenic as a consequence of chemotherapy. Younger patients have more oral problems than adults. After an initial evaluation and before the initiation of cancer therapy, a dental treatment plan should be developed in discussion with the medical team. Preventive strategies include reduction of refined sugars, fluoride therapy, lip care, and patient education. Chemotherapeutic drugs and local irradiation are cytotoxic to the oral mucosa, which becomes atrophic and develops mucositis. Oral pain may be severe and often leads to inadequate food and fluid intake, infections in the oral cavity, and an increased risk of septicemia. Meticulous oral hygiene reduces the risk of severe mucositis.

The pediatric oncology patient should be monitored throughout therapy to screen for infection, manage oral bleeding, and control oral pain. These patients can experience spontaneous oral hemorrhage, especially when the platelet count is less than 20,000/µL. Poor oral hygiene or areas of irritation can increase the chances of bleeding. Children receiving radiation therapy to the head and neck may develop xerostomia if salivary glands are in the path of the beam of radiation. Customized fluoride applicators and artificial saliva in combination with close follow-up are used to manage xerostomia aggressively to avoid rapid and extensive destruction of the teeth. Children receiving hematopoietic stem cell transplantation may require longer periods of immunosuppression. During the neutropenic phase of pretransplant conditioning, mucositis, xerostomia, oral pain, oral bleeding, and opportunistic infections may occur. Oral graft-versus-host disease as well as oral fungal and herpes simplex virus infections can be seen during the subsequent initial engraftment and hematopoietic reconstitution period. Long-term dental follow-up includes management of salivary dysfunction and craniofacial growth abnormalities from total body radiation and treatment of oral graft-versus-host disease.

Pediatric oncology patients need regular care by a dentist familiar with young children and their growth and development. Oral and maxillofacial growth disturbances can occur after therapy. Late effects of therapy include such morphologic changes as microdontia, hypocalcification, short and blunted roots, delayed eruption, and alterations in facial bone growth.

da Fonseca MA: Dental care of the pediatric cancer patient. Pediatr Dent 2004;26:53–57 [PMID: 15080359].

Children With Bleeding Disorders

Children with some genetic or acquired disorders of coagulation may require clotting factors before and after invasive dental procedures, including local block anesthesia. Oral surgical procedures on any child with a bleeding disorder should be planned in concert with the child's hematologist. Patients with hemophilia A and factor VIII antibodies (inhibitors) requiring surgery should be admitted to a hospital. Some patients with very mild factor VIII deficiency or von Willebrand disease type 1 may respond to DDAVP (1-deamino-8-D-arginine vasopressin), whereas von Willebrand types 2 and 3 require cryoprecipitate. Antifibrinolytic medications such as ε-aminocaproic and tranexamic acid are used successfully after dental treatment. Topical medications such as Gelfoam and thrombin can be used to control postoperative bleeding. Patients receiving anticoagulant therapy should generally not undergo dosage reduction before surgical dental treatment because the risk of embolic complications is much higher than bleeding complications in those whose anticoagulant therapy is continued. However, the dentist is advised to consult with the hematologist to obtain the most recent INR (international normalized ratio) results and to discuss the most appropriate level of anticoagulation.

Children With Type 1 Diabetes

The incidence of caries is not increased in diabetic children if metabolic control is good. However, they are at higher risk for periodontal disease that usually starts at puberty with mild gingivitis, gum bleeding, and gingival recession. Care must be taken not to disturb the regular cycle of eating and insulin dosage. Anxiety associated with dental appointments can cause a major upset in glycemic control. Postoperative pain or pain from dental abscess can disrupt their routine oral intake, necessitating adjustment of insulin doses.

ORTHODONTIC REFERRAL

A child's dentist usually initiates the referral to an orthodontist. For any child with a cleft palate or other craniofacial growth disorder, referral is indicated when maxillary permanent incisors are starting to erupt. Other localized problems such as anterior and/or posterior crossbites and disturbances associated with the eruption of maxillary and mandibular front teeth should be addressed early to restore proper function and normal craniofacial growth. Significant arch length deficiency that results in severe crowding requires early decisions on how to guide the developing dentition through extractions of multiple primary and permanent teeth (ie, serial extraction sequence). Likewise, pronounced discrepancies in anterior-posterior skeletal jaw relationships warrant early evaluation by an orthodontist.

▼ THE EAR

INFECTIONS OF THE EAR

▶ Otitis Externa

ESSENTIALS OF DIAGNOSIS

- ▶ Edema and erythema of the external auditory canal (EAC) with debris or thick, purulent discharge.
- ▶ Severe ear pain, worsened by manipulation of the pinna.
- ▶ Periauricular and cervical lymphadenopathy may be present.

▶ Differential Diagnosis

Acute otitis media (AOM) with tympanic membrane (TM) rupture, furunculosis of the ear canal, and mastoiditis.

▶ Pathogenesis

Otitis externa (OE) is a cellulitis of the soft tissues of the EAC, which can extend to surrounding structures such as the pinna, tragus, and lymph nodes. Also known as "swimmer's ear," humidity, heat, and moisture in the ear are known to contribute to the development of OE, along with localized trauma to the ear canal skin. Sources of trauma may include digital trauma, earplugs, ear irrigations, and the use of cotton-tipped swabs to clean or scratch the ear canal. Keeping the ear "too clean" can also contribute to the development of OE, since cerumen actually serves as a protective barrier to the underlying skin and its acidic pH inhibits bacterial and fungal growth. The most common organisms in OE are *Staphylococcus aureus* and *Pseudomonas aeruginosa*.

▶ Clinical Findings

Symptoms include pain, aural fullness, decreased hearing, and sometimes itching in the ear. Manipulation of the pinna or tragus causes considerable pain. Discharge may start out as clear then become purulent. It may also cause secondary eczema of the auricle. The ear canal is typically swollen and narrowed, and the patient may resist any attempt to insert an otoscope. Debris is present in the canal and it is usually very difficult to visualize the TM due to canal edema.

▶ Complications

If untreated, facial cellulitis may result. Immunocompromised individuals can develop malignant OE, which is a spread of the infection to the skull base with resultant osteomyelitis. This is a life-threatening condition.

▶ Treatment

Management includes pain control, removal of debris from the canal, topical antimicrobial therapy, and avoidance of causative factors. Fluoroquinolone eardrops are first-line therapy for OE. In the absence of systemic symptoms, children with OE should be treated with antibiotic eardrops only. The topical therapy chosen must be nonototoxic because a perforation or patent tube may be present; if the TM cannot be visualized, then a perforation should be presumed to exist. If the ear canal is too edematous to allow entry of the eardrops, a Pope ear wick (expandable sponge) should be placed to ensure antibiotic delivery. Oral antibiotics are indicated for any signs of invasive infection, such as fever, cellulitis of the face or auricle, or tender periauricular or cervical lymphadenopathy.

In such cases, in addition to the ototopical therapy, cultures of the ear canal discharge should be sent, and an antistaphylococcal antibiotic prescribed while awaiting culture results. The ear should be kept dry until the infection has cleared.

Children with intact TMs who are predisposed to external otitis may be prophylaxed with two to three drops of a 1:1 solution of white vinegar and 70% ethyl alcohol in the ears before and after swimming.

Bullous Myringitis

Bullous myringitis (BM) is inflammation of the TM with hemorrhagic or serous bullae, and has been associated with viral upper respiratory infections and *Streptococcus pneumoniae*. It is often very painful and may be associated with otorrhea and decreased hearing. BM is treated with antibiotics, analgesics, anti-inflammatories, and occasionally steroids.

Acute Otitis Media

Acute otitis media (AOM) is the most common reason why antibiotics are prescribed for children in the United States. It is an acute infection of the middle ear space associated with inflammation, effusion, or, if a patent tympanostomy tube or perforation is present, otorrhea (ear drainage).

ESSENTIALS OF DIAGNOSIS

▶ Moderate to severe bulging of the TM or new otorrhea not associated with OE.

▶ Mild bulging of the TM *and* less than 48 hours of otalgia (ear holding, tugging, or rubbing in a nonverbal child) or intense erythema of the TM.

▶ Middle ear effusion (MEE), proven by pneumatic otoscopy or tympanometry, must be present.

▶ Differential Diagnosis

Otitis media with effusion (OME), BM, acute mastoiditis, and middle ear mass.

▶ Clinical Findings

Two findings are critical in establishing a diagnosis of AOM: a bulging TM and a MEE. The presence of MEE is best determined by visual examination and either pneumatic otoscopy or tympanometry (Figure 18–1). In order to distinguish AOM from OME, signs and symptoms of middle ear inflammation and acute infection must be present. Otoscopic findings specific for AOM include a bulging TM, impaired visibility of ossicular landmarks, yellow or white effusion (pus), an opacified and inflamed eardrum, and sometimes squamous exudate or bullae on the eardrum.

A. Pathophysiology and Predisposing Factors

1. Eustachian tube dysfunction (ETD)—The eustachian tube regulates middle ear pressure and allows for drainage of the middle ear. It must periodically open to prevent the development of negative pressure and effusion in the middle ear space. If this does not occur, negative pressure leads to transudation of cellular fluid into the middle ear, as well as influx of fluids and pathogens from the nasopharynx and adenoids. Middle ear fluid may then become infected, resulting in AOM. The eustachian tube of infants and young children is more prone to dysfunction because it is shorter, floppier, wider, and more horizontal than in adults. Infants with craniofacial disorders, such as Down syndrome or cleft palate, may be particularly susceptible to ETD.

2. Bacterial colonization—Nasopharyngeal colonization with *S pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* increases the risk of AOM, whereas colonization with normal flora such as viridans streptococci may prevent AOM by inhibiting growth of these pathogens.

3. Viral upper respiratory infections (URI)—URIs increase colonization of the nasopharynx with otitis pathogens. They impair eustachian tube function by causing adenoid hypertrophy and edema of the eustachian tube itself.

4. Smoke exposure—Passive smoking increases the risk of persistent MEE by enhancing colonization, prolonging the inflammatory response, and impeding drainage of the middle ear through the eustachian tube. For infants aged 12–18 months, cigarette exposure is associated with an 11% per pack increase in the duration of MEE.

5. Impaired host immune defenses—Immunocompromised children such as those with selective IgA deficiency usually experience recurrent AOM, rhinosinusitis, and pneumonia. However, most children who experience recurrent or persistent otitis only have selective impairments of immune defenses against specific otitis pathogens.

6. Bottle feeding—Breast-feeding reduces the incidence of acute respiratory infections, provides immunoglobulin A (IgA) antibodies that reduce colonization with otitis pathogens, and decreases the aspiration of contaminated secretions into the middle ear space which can occur when a bottle is propped in the crib.

7. Time of year—The incidence of AOM correlates with the activity of respiratory viruses, accounting for the annual surge in otitis media cases during the winter months in temperate climates.

8. Daycare attendance—Children exposed to large groups of children have more respiratory infections and OM. The increased number of children in daycare over the past three decades has undoubtedly played a major role in the increase in AOM in the United States.

9. Genetic susceptibility—Although AOM is known to be multifactorial, and no gene for susceptibility has yet been identified, recent studies of twins and triplets suggest that as much as 70% of the risk is genetically determined.

B. Microbiology of Acute Otitis Media

Bacterial or viral pathogens can be detected in up to 96% of middle ear fluid samples from patients with AOM if sensitive and comprehensive microbiologic methods are used. *S pneumoniae* and *H influenzae* account for 35%–40% and 30%–35% of isolates, respectively. With widespread use of the pneumococcal conjugate vaccine starting in 2000, the incidence of AOM caused by *H influenzae* rose while that of the *S pneumoniae* vaccine serotypes declined. However, there has been an increase in disease caused by *S pneumoniae* serotypes not covered by the vaccine. The third most common pathogen cited is *M catarrhalis*, which causes up to 15%–25% of AOM cases in the United States (Table 18–1). The fourth most common organism in AOM is *Streptococcus pyogenes*, which is found more frequently in school-aged children than in infants. *S pyogenes* and *S pneumoniae* are the predominant causes of mastoiditis.

Drug-resistant *S pneumoniae* is a common pathogen in AOM and strains may be resistant to only one drug class (eg, penicillins or macrolides) or to multiple classes. Children with resistant strains tend to be younger and to have had more unresponsive infections. Antibiotic treatment in the preceding 3 months also increases the risk of harboring resistant pathogens. The prevalence of resistant strains no longer varies significantly among geographic areas within the United States, but it does vary worldwide. Lower incidences are found in countries with less antibiotic use. β-Lactamase resistance is seen in 34%–45% of *H influenzae*, while *M catarrhalis* approaches 100%.

C. Examination Techniques and Procedures

1. Pneumatic otoscopy—AOM is overdiagnosed, leading to inappropriate antibiotic therapy, unnecessary surgical referrals and significant associated costs. Contributing to errors in diagnosis is the temptation to accept the diagnosis without removing enough cerumen to adequately visualize

Table 18–1. Microbiology of acute otitis media (AOM).

Organism	Percentage of AOM cases
Streptococcus pneumoniae	35–40
Haemophilus influenzae	30–35
Moraxella catarrhalis	15–18
Streptococcus pyogenes	4

the TM, and the mistaken belief that a red TM establishes the diagnosis. Redness of the TM is often a vascular flush caused by fever or crying.

A pneumatic otoscope with a rubber suction bulb and tube is used to assess TM mobility. When used correctly, pneumatic otoscopy can improve diagnostic ability by 15%–25%. The largest possible speculum should be used to provide an airtight seal and maximize the field of view. When the rubber bulb is squeezed, the TM should move freely with a snapping motion; if fluid is present in the middle ear space, the mobility of the TM will be absent or resemble a fluid wave. The ability to assess mobility is compromised by failure to achieve an adequate seal with the otoscope, poor visualization due to low light intensity, and mistaking the ear canal wall for the membrane. The bulb should be slightly compressed when placing the speculum to allow gentle retraction of the TM and avoid discomfort. The tip of the speculum should not be advanced past the cartilaginous EAC to avoid pressure on the bony canal, which is painful. Light, rapid squeezes of the bulb should be undertaken to maximize visualization and minimize pain.

2. Cerumen removal—Cerumen (ear wax) removal is an essential skill for anyone who cares for children. Impacted cerumen pushed against the TM can cause itching, pain, or hearing loss. Parents should be advised that cerumen actually protects the ear and usually comes out by itself through the natural sloughing and migration of the skin of the ear canal. Parents should never put anything into the ear canal to remove wax.

Cerumen may be safely removed under direct visualization through the operating head of an otoscope, provided two adults are present to hold the child. A size 0 plastic disposable ear curette may be used. Irrigation can also be used to remove hard or flaky cerumen. Wax can be softened with 1% sodium docusate solution, carbamyl peroxide solutions, or mineral oil before irrigation is attempted. Irrigation with a soft bulb syringe is performed with water warmed to 35–38°C to prevent vertigo. A commercial jet tooth cleanser (eg, Water Pik) can be used, but it is important to set it at low power to prevent damage to the TM. A perforated TM or patent tympanostomy tube is a contraindication to any form of irrigation.

A home remedy for recurrent cerumen impaction is a few drops of oil such as mineral or olive oil a couple of times a week, warmed to body temperature to prevent dizziness. Droppers are available at pharmacies.

3. Tympanometry—Tympanometry can be helpful in assessing middle ear status, particularly when pneumatic otoscopy is inconclusive or difficult to perform. Tympanometry can reveal the presence or absence of a MEE but cannot differentiate between acutely infected fluid (AOM) and a chronic effusion (OME).

Tympanometry measures TM compliance and displays it in graphic form. It also measures the volume of the ear canal, which can help differentiate between an intact and perforated TM. Standard 226-Hz tympanometry is not reliable in infants younger than 6 months. A high-frequency (1000 Hz) probe is used in this age group.

Tympanograms can be classified into four major patterns, as shown in Figure 18–2. The pattern shown in Figure 18–2A, characterized by maximum compliance at normal atmospheric pressure, indicates a normal TM, good eustachian tube function, and absence of effusion. Figure 18–2B identifies a nonmobile TM with normal volume, which indicates MEE. Figure 18–2C indicates an intact, mobile TM with excessively negative middle ear pressure (greater than –150 daPa), indicative of poor eustachian tube function. Figure 18–2D shows a flat tracing with a large middle ear volume, indicative of a patent tube or TM perforation.

▶ **Treatment**

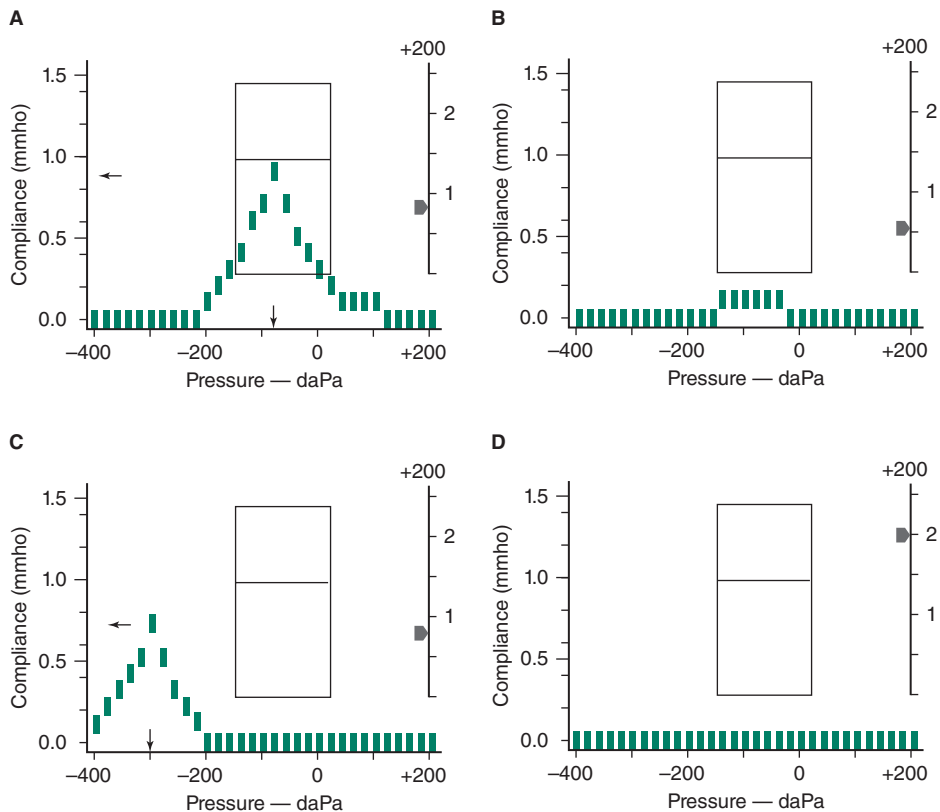
A. Pain Management

Pain is the primary symptom of AOM, and the 2013 clinical practice guidelines emphasize the importance of addressing this symptom. As it may take 1–3 days before antibiotic therapy leads to a reduction in pain, mild to moderate pain should be treated with ibuprofen or acetaminophen. Severe pain should be treated with narcotics, but careful and close observation is required to address possible respiratory depression, altered mental status, gastrointestinal upset and constipation. Topical analgesics have a very short duration and studies do not support efficacy in children younger than 5 years.

B. The Observation Option

Since the release of clinical practice guidelines in 2004, watchful waiting with close observation has been recommended in certain groups of children with AOM. The updated 2013 guidelines modify the initial recommendations, including the laterality of infection and otorrhea as criteria (Table 18–2). The choice to observe is an option in otherwise healthy children without other underlying conditions such as cleft palate, craniofacial abnormalities, immune deficiencies, cochlear implants, or tympanostomy tubes. The decision should be made in conjunction with the parents, and a mechanism must be in place to provide antibiotic therapy if there is worsening of symptoms or lack of improvement within 48–72 hours. For infants younger than 6 months, antibiotics are always recommended on the first visit, regardless of diagnostic certainty.

C. Antibiotic Therapy

High-dose amoxicillin remains the first-line antibiotic for treating AOM, even with a high prevalence of drug-resistant *S pneumoniae*, because data show that isolates of the bacteria remain susceptible to the drug 83%–87% of the time.


▲ **Figure 18–2.** Four types of tympanograms obtained with Welch-Allyn MicroTymp 2. **A:** Normal middle ear. **B:** Otitis media with effusion or acute otitis media. **C:** Negative middle ear pressure due to eustachian tube dysfunction. **D:** Patent tympanostomy tube or perforation in the tympanic membrane. Same as B except for a very large middle ear volume.

Table 18–2. Recommendations for initial management of uncomplicated AOM.[a]

Age	Otorrhea With AOM[a]	Unilateral or Bilateral AOM[a] With Severe Symptoms[b]	Bilateral AOM[a] Without Otorrhea	Unilateral AOM[a] Without Otorrhea
6 mo–2 y	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation
≥ 2 y	Antibiotic therapy	Antibiotic therapy	Antibiotic therapy or additional observation	Antibiotic therapy or additional observation[c]

[a]Applies only to children with well-documented AOM and a high certainty of diagnosis.
[b]A toxic-appearing child, persistent otalgia for more than 48 hours, temperature greater than 39°C (102.2°F) in the past 48 hours, or if there is uncertain access to follow up after the visit.
[c]This plan of initial management provides an opportunity for shared decision making with the child's family for those categories appropriate for initial observation. If observation is offered, a mechanism must be in place to ensure follow-up and begin antibiotics if the child worsens or fails to improve within 48–72 hours of AOM onset.

Amoxicillin is generally considered safe, low-cost, palatable, and has a narrow microbiologic spectrum.

Amoxicillin-clavulanate enhanced strength (ES), with 90 mg/kg/d of amoxicillin dosing (14:1 ratio of amoxicillin:clavulanate), is an appropriate choice when a child has had amoxicillin in the last 30 days, or is clinically failing after 48–72 hours on amoxicillin (Table 18–3). The regular strength formulations of amoxicillin-clavulanate (7:1 ratio) should not be doubled in dosage to achieve 90 mg/kg/d of amoxicillin, because the increased amount of clavulanate will cause diarrhea.

Three oral cephalosporins (cefuroxime, cefpodoxime, and cefdinir) are more β-lactamase–stable and are alternative choices in children who develop a papular rash with amoxicillin (see Table 18–3). Unfortunately, coverage of highly penicillin-resistant pneumococci with these agents is poor and only the intermediate-resistance classes are covered. Of these drugs, cefdinir suspension is most palatable; the other two have a bitter after-taste which is difficult to conceal. Newer flavoring agents may be helpful here.

A second-line antibiotic is indicated when a child experiences symptomatic infection within 1 month of finishing amoxicillin; however, repeat use of high-dose amoxicillin is indicated if more than 4 weeks have passed without symptoms. Macrolides such as azithromycin and clarithromycin are not recommended as second-line agents because *S pneumoniae* is resistant to macrolides in approximately 30% in respiratory isolates, and because virtually all strains of *H influenzae* have an intrinsic macrolide efflux pump, which pumps antibiotic out of the bacterial cell.

Reasons for failure to eradicate a sensitive pathogen include drug noncompliance, poor drug absorption, or vomiting of the drug. If a child remains symptomatic for longer than 3 days while taking a second-line agent, a tympanocentesis is useful to identify the causative pathogen. If a highly resistant pneumococcus is found or if tympanocentesis is not feasible, intramuscular ceftriaxone at 50 mg/kg/dose for 3 consecutive days is recommended. If a child has experienced a severe reaction, such as anaphylaxis, to amoxicillin, cephalosporins should not be substituted. Otherwise, the risk of cross-sensitivity is less than 0.1%. Multi-drug resistant *S pneumoniae* poses a treatment dilemma and newer antibiotics may need to be employed such as fluoroquinolones or linezolid. However, these drugs are not approved by the U.S. Food and Drug Administration (FDA) for the treatment of AOM in children.

Table 18–3. Antibiotic therapies for acute otitis media.

A. Initial Immediate or Delayed Antibiotic Treatment	
First-Line Treatment	**Alternative Treatments (If Penicillin-Allergic)**
Amoxicillin (80–90 mg/kg/d in 2 divided doses) • For children aged < 2 y or children of all ages with severe symptoms, treat for 10 d. • Age 2-6 y with mild-moderate symptoms, treat for 7 d. • Age > 6 y with mild-moderate symptoms, treat for 5 d. or	Cefdinir (14/mg/kg/d in 1 or 2 doses) Cefuroxime (30 mg/kg/d divided BID) Cefpodoxime (10 mg/kg/d in 2 divided doses) Ceftriaxone (50 mg IM or IV per day for 1 or 3 d) • If unable to take oral medications
Amoxicillin-clavulanate (90 mg/kg/d or amoxicillin, with 6.4 mg/kg/d of clavulanate in two divided doses) • For patients who have received amoxicillin in the previous 30 days or who have otitis-conjunctivitis syndrome	For children with severe penicillin allergies (IgE-mediated events): • Trimethoprim–sulfamethoxazole • Macrolides • Clindamycin (30-40 mg/kg/day, divided TID)
B. Antibiotic Treatment After 48-72 h of Failure of Initial Antibiotic	
First-Line Treatment	**Alternative Treatment**
Amoxicillin-clavulanate (90 mg/kg/d or amoxicillin, with 6.4 mg/kg/d of clavulanate in two divided doses) • For patients who have received amoxicillin in the previous 30 days or who have otitis-conjunctivitis syndrome. or Ceftriaxone (50 mg IM or IV per day for 3 d)	Ceftriaxone (50 mg IM or IV per day for 3 d) Clindamycin (30-40 mg/kg/d, divided TID) with or without a 3rd generation cephalosporin Consider tympanocentesis Consult specialist
C. Recurrence > 4 wk After Initial Episode:	
1. A new pathogen is likely, so restart first-line therapy. 2. Be sure diagnosis is not OME, which may be observed for 3–6 mo without treatment.	

In patients with tympanostomy tubes with uncomplicated acute otorrhea, ototopical antibiotics (fluoroquinolone eardrops) are first-line therapy. The eardrops serve two purposes: (1) They treat the infection and (2) they physically "rinse" drainage from the tube which helps prevent plugging of the tube. Oral antibiotics are not indicated in the absence of systemic symptoms.

D. Tympanocentesis

Tympanocentesis is performed by placing a needle through the TM and aspirating the middle ear fluid. The fluid is sent for culture and sensitivity. Indications for tympanocentesis are (1) AOM in an immunocompromised patient, (2) research studies, (3) evaluation for presumed sepsis or meningitis, such as in a neonate, (4) unresponsive otitis media despite courses of two appropriate antibiotics, and (5) acute mastoiditis or other suppurative complications. Tympanocentesis can be performed with an open-headed operating otoscope or a binocular microscope with either a spinal needle and 3-mL syringe, or if available, an Alden-Senturia trap (Storz Instrument Co., St. Louis, MO) or the Tymp-Tap aspirator (Xomed Surgical Products, Jackson, FL) (Figure 18–3).
▲ **Figure 18–3.** Operating head and Alden-Senturia trap for tympanocentesis. Eighteen-gauge spinal needle is attached and bent.

E. Prevention of Acute Otitis Media

1. Antibiotic prophylaxis—Strongly discouraged. Antibiotic resistance is a concern and studies have shown poor efficacy.

2. Lifestyle modifications—Parental education plays a major role in decreasing AOM. These are some items to consider in children with RAOM:

- Smoking is a risk factor both for upper respiratory infection and AOM. Primary care physicians can provide information on smoking cessation programs and measures.

- Breast-feeding protects children from AOM. Clinicians should encourage exclusive breast-feeding for 6 months.

- Bottle-propping in the crib should be avoided. It increases AOM risk due to the reflux of milk into the eustachian tubes.

- Pacifiers are controversial. In Finland, removing pacifiers from infants was shown to reduce AOM episodes by about one-third compared to a control group. The mechanism is uncertain but likely to be related to effects on the eustachian tube. However, the benefit of pacifier use in reducing sudden infant death syndrome (SIDS)–related deaths is also important to consider. Currently, the recommendation from the American Academy of Family Physicians is to wean a pacifier if used after 6 months of age to reduce the risk of AOM.

- Day care is a risk factor for AOM, but working parents may have few alternatives. Possible alternatives include care by relatives or child care in a setting with fewer children.

3. Surgery—Tympanostomy tubes are effective in the treatment of recurrent AOM as well as OME.

4. Immunologic evaluation and allergy testing—While immunoglobulin subclass deficiencies may be more common in children with recurrent AOM, there is no practical immune therapy available. More serious immunodeficiencies, such as selective IgA deficiency, should be considered in children who suffer from a combination of recurrent AOM, rhinosinusitis, and pneumonia. In the school-aged child or preschooler with an atopic background, skin testing may be beneficial in identifying allergens that can predispose to AOM.

5. Vaccines—The pneumococcal conjugate and influenza vaccines are recommended. The seven-valent pneumococcal conjugate vaccine (PCV7) has been used in the United States since 2000, and the 13-valent pneumococcal conjugate vaccine (PCV13) was introduced in 2010. PCV7 was found to produce a 29% reduction in AOM resulting from the seven serotypes found in the vaccine, and overall, PCV7 reduced AOM by 6%–7%, according to a 2009 Cochrane database review. Data are not yet available regarding the effect of

PCV13 on AOM at this time. In recent studies, intranasal influenza vaccine reduced the number of influenza-associated cases of AOM by 30%–55%.

Otitis Media With Effusion

ESSENTIALS OF DIAGNOSIS

▶ MEE with decreased TM mobility.

▶ No signs or symptoms of acute inflammation.

▶ May precede or follow an episode of AOM.

▶ Clinical Findings

Otitis media with effusion (OME) is the presence of fluid in the middle ear space without signs or symptoms of acute inflammation. There may be some discomfort, but acute pain is not characteristic. A retracted or neutral TM with decreased mobility is seen on pneumatic otoscopy. The TM may be opacified or may have a whitish or amber discoloration.

Children with OME can develop AOM if the middle ear fluid should become infected. OME often follows an episode of AOM. After AOM, fluid can remain in the ear for several weeks, with 60%–70% of children still having MEE 2 weeks after successful treatment. This drops to 40% at 1 month and 10%–25% at 3 months after treatment. It is important to distinguish OME from AOM because the former does not benefit from treatment with antibiotics.

▶ Management

An audiology evaluation should be performed after approximately 3 months of continuous bilateral effusion in children younger than 3 years and those at risk of language delay due to socioeconomic circumstances, craniofacial anomalies, or other risk factors. Children with hearing loss or speech delay should be referred to an otolaryngologist for possible tympanostomy tube placement. Antibiotics, antihistamines and steroids have not been shown to be useful in the treatment of OME

Traditionally, OME was observed for 3 months in uncomplicated cases prior to consideration for tympanostomy tube placement. More recent studies have found that longer periods of observation do not necessarily have significant negative effects on literacy, attention, academic achievement, and social skills. Longer periods of observation may be acceptable in children with normal or very mild hearing loss on audiogram, no risk factors for speech and language issues, and no structural changes to the TM. Absolute indications for tympanostomy tubes include hearing loss greater than 40 dB, TM retraction pockets, ossicular erosion, adhesive atelectasis, and cholesteatoma. If a patient clears a persistent MEE, the physician should follow the patient monthly.

▶ Prognosis & Sequelae

Prognosis is variable based on age of presentation. Infants who are very young at the time of first otitis media are more likely to need surgical intervention. Other factors that decrease the likelihood of resolution are onset of OME in the summer or fall, history of prior tympanostomy tubes, presence of adenoids, and hearing loss greater than 30 dB.

The presence of biofilms has been found to explain the "sterile" effusion sometimes present when culturing middle ear fluid in OME. On electron microscopy, biofilms have been found to cover the middle ear mucosa and adenoids in up to 80% of patients with OME. Currently, work is being done to find ways to eradicate biofilms, including physical disruption, reduction, and eradication.

▶ Complications of Otitis Media

A. Tympanosclerosis, Retraction Pockets, Adhesive Otitis

Tympanosclerosis is an acquired disorder of calcification and scarring of the TM and middle ear structures from inflammation. The term *myringosclerosis* applies to calcification of the TM only, and is a fairly common sequela of OME and AOM. Myringosclerosis may also develop at the site of a previous tympanostomy tube; tympanosclerosis is not a common sequela of tube placement. If tympanosclerosis involves the ossicles, a conductive hearing loss may result. Myringosclerosis rarely causes a hearing loss, unless the entire TM is involved ("porcelain eardrum"). Myringosclerosis may be confused with a middle ear mass. However, use of pneumatic otoscopy can often help in differentiation, as the plaque will move with the TM during insufflation.

The appearance of a small defect or invagination of the pars tensa or pars flaccida of the TM suggests a retraction pocket. Retraction pockets occur when chronic inflammation and negative pressure in the middle ear space produce atrophy and atelectasis of the TM.

Continued inflammation can cause adhesions to form between the retracted TM and the ossicles. This condition, referred to as *adhesive otitis*, predisposes one to formation of a cholesteatoma or fixation and erosion of the ossicles.

B. Cholesteatoma

A greasy-looking mass or pearly white mass seen in a retraction pocket or perforation suggests a cholesteatoma (Figure 18–4). If infection is superimposed, serous or purulent drainage will be seen, and the middle ear cavity may contain granulation tissue or even polyps. Persistent, recurrent, or foul smelling otorrhea following appropriate medical management should make one suspect a cholesteatoma.
C. Tympanic Membrane Perforation

Occasionally, an episode of AOM may result in rupture of the TM. Discharge from the ear is seen, and often there is rapid relief of pain. Perforations due to AOM usually heal spontaneously within a couple of weeks. Ototopical antibiotics are recommended for a 10- to 14-day course and patients should be referred to an otolaryngologist 2–3 weeks after the rupture for examination and hearing evaluation.

When perforations fail to heal after 3–6 months, surgical repair may be needed. TM repair is generally delayed until the child is older and eustachian tube function has improved. Procedures include paper patch myringoplasty, fat myringoplasty, and tympanoplasty. Tympanoplasty is generally deferred until around 7 years of age, which is approximately when the eustachian tube reaches adult orientation. In otherwise healthy children, some surgeons perform a repair earlier if the contralateral, nonperforated ear remains free of infection and effusion for 1 year.

In the presence of a perforation, water activities should be limited to surface swimming, preferably with the use of an ear mold.

D. Facial Nerve Paralysis

The facial nerve traverses the middle ear as it courses through the temporal bone to its exit at the stylomastoid foramen. Normally, the facial nerve is completely encased in bone, but occasionally bony dehiscence in the middle ear is present, exposing the nerve to infection and making it susceptible to inflammation during an episode of AOM. The acute onset of a facial nerve paralysis should not be deemed idiopathic Bell palsy until all other causes have been excluded. If middle ear fluid is present, prompt myringotomy and tube placement are indicated. CT is indicated if a cholesteatoma or mastoiditis is suspected.

E. Chronic Suppurative Otitis Media

ESSENTIALS OF DIAGNOSIS

▶ Ongoing purulent ear drainage.
▶ Nonintact TM: perforation or tympanostomy tubes.
▶ May be associated with cholesteatoma.

Chronic suppurative otitis media (CSOM) is present when persistent otorrhea occurs in a child with tympanostomy tubes or TM perforations. It starts with an acute infection

▲ **Figure 18–4.** Attic cholesteatoma, formed from an in-drawing of an attic retraction pocket.

that becomes chronic with mucosal edema, ulceration, and granulation tissue. The most common associated bacteria include *P aeruginosa*, *S aureus*, *Proteus* species, *Klebsiella pneumoniae*, and diphtheroids. Visualization of the TM, meticulous cleaning with culture of the drainage, and appropriate antimicrobial therapy, usually topical, are the keys to management.

Occasionally, CSOM may be a sign of cholesteatoma or other disease process such as foreign body, neoplasm, Langerhans cell histiocytosis, tuberculosis, granulomatosis, fungal infection, or petrositis. If CSOM is not responsive to culture-directed treatment, imaging and biopsy may be needed to rule out other possibilities. Patients with facial palsy, vertigo, or other CNS signs should be referred immediately to an otolaryngologist.

Roland PS, et al: Chronic suppurative otitis media. http://emedicine .medscape.com/article/859501-overview. Accessed January 11, 2014.

F. Labyrinthitis

Suppurative infections of the middle ear can spread into the membranous labyrinth of the inner ear through the round window membrane or abnormal congenital communications. Symptoms include vertigo, hearing loss, fevers, and the child often appears extremely toxic. Intravenous antibiotic therapy is used, and intravenous steroids may also be used to help decrease inflammation. Sequelae can be serious, including a condition known as *labyrinthitis ossificans*, or bony obliteration of the inner ear including the cochlea, leading to profound hearing loss.

▶ Mastoiditis

ESSENTIALS OF DIAGNOSIS

- ▶ AOM otitis media is almost always present.
- ▶ Postauricular pain and erythema.
- ▶ Ear protrusion (late finding).

▶ Pathogenesis

Mastoiditis occurs when infection spreads from the middle ear space to the mastoid portion of the temporal bone, which lies just behind the ear and contains air-filled spaces. Mastoiditis can range in severity from inflammation of the mastoid periosteum to bony destruction of the mastoid air cells (coalescent mastoiditis) with abscess development. Mastoiditis can occur in any age group, but more than 60% of the patients are younger than 2 years. Many children do not have a prior history of recurrent AOM.

▶ Clinical Findings

A. Symptoms and Signs

Patients with mastoiditis usually have postauricular pain, fever, and an outwardly displaced pinna. On examination, the mastoid area often appears indurated and red. With disease progression it may become swollen and fluctuant. The earliest finding is severe tenderness on mastoid palpation. AOM is almost always present. Late findings include a pinna that is pushed forward by postauricular swelling and an ear canal that is narrowed due to pressure on the posterosuperior wall from the mastoid abscess. In infants younger than 1 year, the swelling occurs superior to the ear and pushes the pinna downward rather than outward.

B. Imaging Studies

The best way to determine the extent of disease is by computed tomography (CT) scan. Early mastoiditis may be radiographically indistinguishable from AOM, with both showing opacification but no destruction of the mastoid air cells. With progression of mastoiditis, coalescence of the mastoid air cells is seen.

C. Microbiology

The most common pathogens are *S pneumoniae* followed by *H influenzae* and *S pyogenes.* Rarely, gram-negative bacilli and anaerobes are isolated. Antibiotics may decrease the incidence and morbidity of acute mastoiditis. However, acute mastoiditis still occurs in children who are treated with antibiotics for an acute ear infection. In the Netherlands, where only 31% of AOM patients receive antibiotics, the incidence of acute mastoiditis is 4.2 per 100,000 person-years. In the United States, where more than 96% of patients with AOM receive antibiotics, the incidence of acute mastoiditis is 2 per 100,000 person-years. Moreover, despite the routine use of antibiotics, the incidence of acute mastoiditis has been rising in some cities. The pattern change may be secondary to the emergence of resistant *S pneumoniae.*

▶ Differential Diagnosis

Lymphadenitis, parotitis, trauma, tumor, histiocytosis, OE, and furuncle.

▶ Complications

Meningitis can be a complication of acute mastoiditis and should be suspected when a child has associated high fever, stiff neck, severe headache, or other meningeal signs. Lumbar puncture should be performed for diagnosis. Brain abscess occurs in 2% of mastoiditis patients and may be associated with persistent headaches, recurring fever, or changes in sensorium. Facial palsy, sigmoid sinus thrombosis, epidural

abscess, cavernous sinus thrombosis, and thrombophlebitis may also be encountered.

▶ Treatment

In the preantibiotic era, up to 20% of patients with AOM underwent mastoidectomy for mastoiditis. Now, the occurrence is 5 cases per 100,000 persons with AOM. Intravenous antibiotic treatment alone may be successful if there is no evidence of coalescence or abscess on CT. However, if there is no improvement within 24–48 hours, surgical intervention should be undertaken. Minimal surgical management starts with tympanostomy tube insertion, during which cultures are taken. If a subperiosteal abscess is present, incision and drainage is also performed, with or without a cortical mastoidectomy. Intracranial extension requires complete mastoidectomy with decompression of the involved area.

Antibiotic therapy (intravenous and topical ear drops) is instituted along with surgical management and relies on culture directed antibiotic therapy for 2–3 weeks. An antibiotic regimen should be chosen which is able to cross the blood-brain barrier. After significant clinical improvement is achieved with parenteral therapy, oral antibiotics are begun and should be continued for 2–3 weeks. A patent tympanostomy tube must also be maintained, with continued use of otic drops until drainage abates.

▶ Prognosis

Prognosis for full recovery is good. Children that develop acute mastoiditis with abscess as their first ear infection are not necessarily prone to recurrent otitis media.

ACUTE TRAUMA TO THE MIDDLE EAR

Head injuries, a blow to the ear canal, sudden impact with water, blast injuries, or the insertion of pointed objects into the ear canal can lead to perforation of the TM, ossicular disruption, and hematoma of the middle ear. One study reported that 50% of serious penetrating wounds of the TM were due to parental use of a cotton swab.

Treatment of middle ear trauma consists mainly of watchful waiting. An audiogram may show a conductive hearing loss. Antibiotics are not necessary unless signs of infection appear. The prognosis for normal hearing depends on whether the ossicles have been dislocated or fractured. The patient needs to be followed with audiometry or by an otolaryngologist until hearing has returned to normal, which is expected within 6–8 weeks. A CT scan may be needed to evaluate the middle ear structures. Occasionally, middle ear trauma can lead to a perilymphatic fistula (PLF) which is disruption of the barrier between the middle ear and inner ear, usually in the area of the oval window. PLF can occur from an acute blow to the ear, foreign body, or occasionally from more innocuous mechanisms such as Valsalva or sneezing. Symptoms include sudden hearing loss and vertigo. This requires emergent otolaryngology evaluation.

Traumatic TM perforations should be referred to an otolaryngologist for examination and hearing evaluation. Spontaneous healing may occur within 6 months of the perforation. If the perforation is clean and dry and there is no hearing change, there is no urgency for specialty evaluation. In the acute setting, antibiotic eardrops are often recommended to provide a moist environment which is thought to speed healing.

CERUMEN IMPACTION AND EAR CANAL FOREIGN BODY

Foreign bodies in the ear are common, whether intentional (self-placement, placement by another child) or accidental (eg, insect, broken-off cotton swab after cleaning attempt). Cerumen can also be obstructive, acting like a foreign body. If the cerumen or object is large or difficult to remove with available instruments, otolaryngology referral is recommended, as the child may be traumatized by further removal attempts, and trauma to the ear canal may cause edema, necessitating removal under general anesthesia. Vegetable matter should never be irrigated as it can swell causing increased pain and removal difficulty. An emergency condition exists if the foreign body is a disk-type battery, such as those used in clocks, watches, and hearing aids. An electric current is generated in the moist canal, and a severe burn can occur in less than 4 hours. If the TM cannot be visualized, assume a perforation and avoid irrigation or ototoxic medications.

Sharpe SJ, Rochette LM, Smith GA: Pediatric battery-related emergency department visits in the United States, 1990–2009. Pediatrics 2012 Jun;129(6):1111–1117 [PMID: 22585763].

AURICULAR HEMATOMA

Trauma can result in formation of a hematoma between the perichondrium and cartilage of the pinna. This is different from a bruise, which does not change the ear shape and where the blood is in the soft tissue outside of the perichondrial layer. A hematoma appears as a boggy purple swelling of the cartilaginous auricle, and the normal folds of the ear are obscured. If untreated, pressure necrosis of the underlying cartilage may occur, resulting in "cauliflower ear." To prevent this cosmetic deformity, physicians should urgently refer patients to an otolaryngologist for drainage and application of a carefully molded pressure dressing.

CONGENITAL EAR MALFORMATIONS

Atresia is agenesis of the EAC. This results in conductive hearing loss and should be evaluated within the first 3 months of life by an audiologist and otolaryngologist.

Microtia is the term used for an external ear that is small, collapsed or only has an earlobe present. Often, there is an associated EAC atresia. Reconstruction can be performed in girls around age 6 and in boys around age 8–10 years.

"Lop ears," folded down, or protruding ears ("Dumbo ears") can be a source of much teasing and ridicule. Taping of the ears into correct anatomic position is very effective if performed in the first 72–96 hours of life. Tape is applied over a molding of wax and continued for 2 weeks. If this window of opportunity is missed or taping is unsuccessful, another option for this sort of deformity is an otoplasty procedure.

An ear is considered "low-set" if the upper pole is below eyebrow level. This condition is often associated with other congenital anomalies, and in these patients a genetics evaluation should be considered.

Preauricular tags, ectopic cartilage, fistulas, and cysts require surgical correction primarily for cosmetic reasons. Children exhibiting any of these findings should have their hearing tested. Renal ultrasound should be considered, as external ear anomalies can be associated with renal anomalies, as both structures form during the same period of embryogenesis. Most preauricular pits cause no symptoms but can become infected. If one should become infected, the patient should receive antibiotic therapy and be referred to an otolaryngologist for eventual excision.

IDENTIFICATION & MANAGEMENT OF HEARING LOSS

Hearing loss is classified as being conductive, sensorineural, or mixed in nature. Conductive hearing loss occurs when there is a blockage of sound transmission between the opening of the external ear and the cochlear receptor cells. The most common cause of conductive hearing loss in children is fluid in the middle ear. Sensorineural hearing loss (SNHL) is due to a defect in the neural transmission of sound, arising from a defect in the cochlear hair cells or the auditory nerve. Mixed hearing loss is characterized by elements of both conductive and sensorineural loss.

Hearing is measured in decibels (dB). The threshold, or 0 dB, refers to the level at which a sound is perceived in normal subjects 50% of the time. Hearing is considered normal if an individual's thresholds are within 15 dB of normal. In children, severity of hearing loss is commonly graded as follows: 16–25 dB slight, 26–40 dB mild, 41–55 dB moderate, 56–70 dB moderately severe, 71–90 dB severe, and 91+ dB profound.

Hearing loss can significantly impair a child's ability to communicate, and hinder academic, social, and emotional development. Studies suggest that periods of auditory deprivation may have enduring effects on auditory processing, even after normal hearing is restored. Even a unilateral loss may be associated with difficulties in school and behavioral issues. Early identification and management of any hearing impairment is therefore critical.

Conductive Hearing Loss

The most common cause of childhood conductive hearing loss is otitis media and related conditions such as MEE and eustachian tube dysfunction. Other causes of conductive hearing loss may include EAC atresia or stenosis, TM perforation, cerumen impaction, cholesteatoma, and middle ear abnormalities, such as ossicular fixation or discontinuity. Often, a conductive loss may be corrected with surgery.

MEE may be serous, mucoid, or purulent, as in AOM. Effusions are generally associated with a mild conductive hearing loss that normalizes once the effusion is gone. The American Academy of Pediatrics recommends that hearing and language skills be assessed in children who have recurrent AOM or MEE lasting longer than 3 months.

Sensorineural Hearing Loss

Sensorineural hearing loss (SNHL) arises due to a defect in the cochlear receptor cells or the auditory nerve (cranial nerve VIII). The loss may be congenital (present at birth) or acquired. In both the congenital and acquired categories, the hearing loss may be either hereditary (due to a genetic mutation) or nonhereditary. It is estimated that SNHL affects 2–3 out of every 1000 live births, making this the most common congenital sensory impairment. The incidence is thought to be considerably higher among the neonatal intensive care unit population. Well-recognized risk factors for SNHL in neonates include positive family history of childhood SNHL, birthweight less than 1500 g, low Apgar scores (0–4 at 1 minute or 0–6 at 5 minutes), craniofacial anomalies, hypoxia, in-utero infections (eg, TORCH syndrome), hyperbilirubinemia requiring exchange transfusion, and mechanical ventilation for more than 5 days.

A. Congenital Hearing Loss

Nonhereditary causes account for approximately 50% of congenital hearing loss. These include prenatal infections, teratogenic drugs, and perinatal injuries. The other 50% is

attributed to genetic factors. Among children with hereditary hearing loss, approximately one-third of cases are thought to be due to a known syndrome, while the other two-thirds are considered nonsyndromic.

Syndromic hearing impairment is associated with malformations of the external ear or other organs, or with medical problems involving other organ systems. Over 400 genetic syndromes that include hearing loss have been described. All patients being evaluated for hearing loss should also be evaluated for features commonly associated with these syndromes. These include branchial cleft cysts or sinuses, preauricular pits, ocular abnormalities, white forelock, café au lait spots, and craniofacial anomalies. Some of the more frequently mentioned syndromes associated with hearing loss include the following: Waardenburg, branchio-oto-renal, Usher, Pendred, Jervell and Lange-Nielsen, and Alport.

Over 70% of hereditary hearing loss is nonsyndromic (ie, there are no associated visible abnormalities or related medical problems). The most common known mutation associated with nonsyndromic hearing loss is in the *GJB2* gene, which encodes the protein Connexin 26. The *GJB2* mutation has a carrier rate of about 3% in the general population. Most nonsyndromic hearing loss, including that due to the *GJB2* mutation, is autosomal recessive.

B. Acquired Hearing Loss

Hereditary hearing loss may be delayed in onset, as in Alport syndrome and most types of autosomal dominant nonsyndromic hearing loss. Vulnerability to aminoglycoside-induced hearing loss has also been linked to a mitochondrial gene defect.

Nongenetic etiologies for delayed-onset SNHL include exposure to ototoxic medications, meningitis, autoimmune or neoplastic conditions, noise exposure, and trauma. Infections such as syphilis or Lyme disease have been associated with hearing impairment. Hearing loss associated with congenital cytomegalovirus (CMV) infection may be present at birth, or may have a delayed onset. The loss is progressive in approximately half of all patients with congenital CMV-associated hearing loss. Other risk factors for delayed-onset, progressive loss include a history of persistent pulmonary hypertension and extracorporeal membrane oxygenation therapy.

Identification of Hearing Loss

A. Newborn Hearing Screening

Prior to the institution of universal newborn screening programs, the average age at identification of hearing loss was 30 months. Recognizing the importance of early detection, in 1993, a National Institutes of Health Consensus Panel recommended that all newborns be screened for hearing

impairment prior to hospital discharge. Today, every state and territory in the United States has an Early Hearing Detection and Intervention (EDHI) program, with a goal of hearing loss identification by 3 months of age, and appropriate intervention by the age of 6 months. Subjective testing is not reliable in infants, and therefore objective, physiologic methods are used for screening. Auditory brainstem response and otoacoustic emission testing are the two commonly employed screening modalities.

B. Audiologic Evaluation of Infants and Children

A parent's report of his or her infant's behavior cannot be relied upon for identification of hearing loss. A deaf infant's behavior can appear normal and mislead parents as well as professionals. Deaf infants are often visually alert and able to scan the environment so actively that this can be mistaken for an appropriate response to sound. In children, signs of hearing loss include inconsistent response to sounds, not following directions, speech and language delays, unclear speech, and turning the volume up on equipment such as televisions or radios. If there is any suspicion of hearing loss, it is important to refer the patient for formal audiometric testing by an audiologist who is experienced in testing the pediatric population.

Audiometry subjectively evaluates hearing. There are several different methods used, based on patient age:

- Behavioral observational audiometry (birth to 6 months): Sounds are presented at various intensity levels, and the audiologist watches closely for a reaction, such as change in respiratory rate, starting or stopping of activity, startle, head turn, or muscle tensing. This method is highly tester-dependent and error-prone.

- Visual reinforcement audiometry (6 months to 2.5 years): Auditory stimulus is paired with positive reinforcement. For example, when a child reacts appropriately by turning toward a sound source, the behavior is rewarded by activation of a toy that lights up. After a brief conditioning period, the child localizes toward the tone, if audible, in anticipation of the lighted toy.

- Conditioned play audiometry (2.5–5 years): The child responds to sound stimulus by performing an activity, such as putting a peg into a board.

- Conventional audiometry (5 years and up): The child indicates when he or she hears a sound.

Objective methods such as auditory brainstem response and otoacoustic emission testing may be used if a child cannot be reliably tested using these listed methods.

Referral

A child who fails newborn hearing screening or has a suspected hearing loss should be referred for further audiologic

evaluation, and any child with hearing loss should be referred to an otolaryngologist for further workup and treatment. In addition to the infants who fall into the high-risk categories for SNHL as outlined earlier, hearing should be tested in children with a history of developmental delay, bacterial meningitis, ototoxic medication exposure, neurodegenerative disorders, or a history of infection such as mumps or measles. Children with bacterial meningitis should be referred immediately to an otolaryngologist, as cochlear ossification can occur, necessitating urgent cochlear implantation. Even if a newborn screening was passed, all infants who fall into a high-risk category for progressive or delayed-onset hearing loss should receive ongoing audiologic monitoring for 3 years and at appropriate intervals thereafter to avoid a missed diagnosis.

Prevention

Appropriate care may treat or prevent conditions causing hearing deficits. Aminoglycosides and diuretics, particularly in combination, are potentially ototoxic and should be used judiciously and monitored carefully. Given the association of a certain mitochondrial gene defect and aminoglycoside ototoxicity, use should be avoided, if possible, in patients with a family history of aminoglycoside-related hearing loss. Reduction of repeated exposure to loud noises may prevent high-frequency hearing loss associated with acoustic trauma. Any patient with sudden-onset SNHL should be seen by an otolaryngologist immediately, as in some cases, steroid therapy may reverse the loss if initiated right away.

Management of Hearing Loss

Children with hearing loss should be referred to an otolaryngologist for etiologic workup which may include radiographic imaging and/or laboratory tests. Workup is directed by each individual patient's history, examination, and audiologic results. As discussed previously, hearing loss may be an isolated abnormality or may be part of a larger syndrome. Within the past couple of years, comprehensive genetic testing for syndromic and nonsyndromic hearing loss using next-generation sequencing technology has become widely available to the public.

The importance of early intervention for receptive and expressive development is well-established. The management of hearing loss depends on the type and severity of impairment. Conductive hearing loss is typically correctable by addressing the point in sound transmission at which efficiency is compromised. For example, hearing loss due to chronic effusions usually normalizes once the fluid has cleared, whether by natural means or by the placement of tympanostomy tubes. As of yet, SNHL is not reversible, although cochlear hair cell regeneration is an area of active research. Most sensorineural loss is managed with amplification. Cochlear implantation is an option for some children

with severe-profound loss, and at the time of this writing, is FDA-approved down to the age of 12 months. Unlike hearing aids, cochlear implants do not amplify sound but directly stimulate the cochlea with electrical impulses. Children with hearing loss should receive ongoing audiologic monitoring.

▼ THE NOSE & PARANASAL SINUSES

ACUTE VIRAL RHINITIS (COMMON COLD; SEE ALSO CHAPTER 38)

The common cold (viral upper respiratory infection) is the most common pediatric infectious disease, and the incidence is higher in early childhood than in any other period of life. Children younger than 5 years typically have 6–12 colds per year. Approximately 30%–40% of these are caused by rhinoviruses. Other culprits include adenoviruses, coronaviruses, enteroviruses, influenza and parainfluenza viruses, and respiratory syncytial virus.

ESSENTIALS OF DIAGNOSIS

► Clear or mucoid rhinorrhea, nasal congestion, sore throat.
► Possible fever, particularly in younger children (under 5–6 years).
► Symptoms resolve by 7–10 days.

▶ Differential Diagnosis

Rhinosinusitis (acute or chronic), allergic rhinitis, nonallergic rhinitis, influenza, pneumonia, gastroesophageal reflux disease, asthma, and bronchitis.

▶ Clinical Findings

The patient usually experiences a sudden onset of clear or mucoid rhinorrhea, nasal congestion, sneezing, and sore throat. Cough or fever may develop. Although fever is usually not a prominent feature in older children and adults, in

the first 5 or 6 years of life it can be as high as 40.6°C without superinfection. The nose, throat, and TMs may appear red and inflamed. The average duration of symptoms is about 1 week. Nasal secretions tend to become thicker and more purulent after day 2 of infection due to shedding of epithelial cells and influx of neutrophils. This discoloration should not be assumed to be a sign of bacterial rhinosinusitis, unless it persists beyond 10–14 days, by which time the patient should be experiencing significant symptomatic improvement. A mild cough may persist for 2–3 weeks following resolution of other symptoms.

▶ Treatment

Treatment for the common cold is symptomatic (Figure 18–5). Because colds are vial infections, antibiotics will not cure or shorten their length. Acetaminophen or ibuprofen can be helpful for fever and pain. Humidification may provide relief for congestion and cough. Nasal saline drops and bulb suctioning may be used for an infant or child unable to blow his or her nose.

Available scientific data suggest that over-the-counter cold and cough medications are generally not effective in children. These medications may be associated with serious adverse effects, and it is recommended that they not be used in children under the age of 4 years. Antihistamines have not proven effective in relieving cold symptoms; in rhinoviral colds, increased levels of histamine are not observed. Oral decongestants have been found to provide some symptomatic relief in adults but have not been well-studied in children. Cough suppression at night is the number one goal of many parents; however, studies have shown that antitussives, antihistamines, antihistamine-decongestant combinations and antitussive-bronchodilator combinations are no more effective than placebo. Use of narcotic antitussives is discouraged, as these have been associated with severe respiratory depression.

Education and reassurance may be the most important "therapy" for the common cold. Parents should be informed about the expected nature and duration of symptoms, efficacy and potential side effects of medications, and the signs

U.S. Food and Drug Administration: Using over-the-counter cough and cold products in children. Posted Oct 22, 2008. http://www.fda.gov/ForConsumers/ConsumerUpdates/ucm048515.htm. Accessed January 11, 2014.

RHINOSINUSITIS

The use of the term *rhinosinusitis* has replaced sinusitis. Rhinosinusitis acknowledges that the nasal *and* sinus mucosa are involved in similar and concurrent inflammatory processes.

1. Acute Bacterial Rhinosinusitis

Acute bacterial rhinosinusitis (ABRS) is a bacterial infection of the paranasal sinuses which lasts less than 30 days and in which the symptoms resolve completely. It is almost always preceded by a viral upper respiratory infection (cold). Other predisposing conditions include allergies and trauma. The diagnosis of ABRS is made when a child with a cold does not improve by 10–14 days or worsens after 5–7 days. The maxillary and ethmoid sinuses are most commonly involved. These sinuses are present at birth. The sphenoid sinuses typically form by the age of 5 years, and the frontal sinuses by age 7–8 years. Frontal sinusitis is unusual before age 10 years.

ESSENTIALS OF DIAGNOSIS

► Upper respiratory infection symptoms are present 10 or more days beyond onset, or symptoms worsen within 10 days after an initial period of improvement.

► Symptoms may include nasal congestion, nasal drainage, postnasal drainage, facial pain, headache, and fever.

► Symptoms resolve completely within 30 days.

Pathogenesis

Situations which lead to inflammation of sinonasal mucosa and obstruction of sinus drainage pathways underlie the development of rhinosinusitis. A combination of anatomic, mucosal, microbial, and immune pathogenic factors are believed to be involved. Both viral and bacterial infections play integral roles in the pathogenesis. Viral upper respiratory infections may cause sinus mucosal injury and swelling, resulting in osteomeatal obstruction, loss of ciliary activity, and mucus hypersecretion. The bacterial pathogens that commonly cause acute rhinosinusitis are *S pneumoniae*, *H influenzae* (nontypeable), *M catarrhalis*, and β-hemolytic streptococci.

Clinical Findings

The onset of symptoms in ABRS may be gradual or sudden, and may commonly include nasal drainage, nasal congestion, facial pressure or pain, postnasal drainage, hyposmia or anosmia, fever, cough, fatigue, maxillary dental pain, and ear pressure or fullness. The physical examination is rarely helpful in making the diagnosis, as the findings are essentially the same as those in a child with an uncomplicated cold. Occasionally, sinuses may be tender to percussion, but this is typically seen only in older children and is of questionable reliability.

In complicated or immunocompromised patients, sinus aspiration and culture by an otolaryngologist should be considered for diagnostic purposes and to facilitate culture-directed antibiotic therapy. Gram stain or culture of nasal discharge does not necessarily correlate with cultures of sinus aspirates. If the patient is hospitalized because of rhinosinusitis-related complications, blood cultures should also be obtained.

Imaging of the sinuses during acute illness is not indicated except when evaluating for possible complications, or for patients with persistent symptoms which do not respond to medical therapy. As with the physical examination, the radiographic findings of ABRS, such as sinus opacification, fluid, and mucosal thickening, are indistinguishable from those seen in the common cold.

Complications

Complications of ABRS occur when infection spreads to adjacent structures—the overlying tissues, the eye, or the brain. *S aureus* (including methicillin-resistant *S aureus* [MRSA]) is frequently implicated in complicated ABRS, as well as *Streptococcus anginosus* (*milleri*), which has been found to be a particularly virulent organism.

Orbital complications are the most common, arising from the ethmoid sinuses. These complications usually begin as a preseptal cellulitis, but can progress to postseptal cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis. Associated signs and symptoms include eyelid

edema, restricted extraocular movements, proptosis, chemosis, and altered visual acuity (see Chapter 15).

The most common complication of frontal sinusitis is osteitis of the frontal bone, also known as *Pott's puffy tumor*. Intracranial extension of infection can lead to meningitis and to epidural, subdural, and brain abscesses. Frequently, children with complicated rhinosinusitis have no prior history of sinus infection.

▶ Treatment

For children who are not improving by 10 days, or who have more severe symptoms, with fever of at least 39°C and purulent nasal drainage for at least 3–4 consecutive days, antibiotic therapy is recommended. Although some discrepancy exists, antibiotics are generally thought to decrease duration and severity of symptoms.

To minimize the number of children who receive antimicrobial therapy for uncomplicated viral upper respiratory infections, and to help combat antibiotic resistance, the American Academy of Pediatrics in 2001 issued guidelines for treatment. This algorithm is presented in Figure 18-6. Key decision points include severity of disease and risk factors for resistant organisms

For patients with mild-moderate symptoms, who are not in day care, and have not been on recent antibiotic therapy, high-dose amoxicillin is considered first-line therapy. For those with severe symptoms, in day care, or who were on antibiotics within the past 1–3 months, high-dose amoxicillin–clavulanate is recommended as first-line therapy. Cefuroxime, cefpodoxime, and cefdinir are recommended for patients with a non–type I hypersensitivity to penicillin. Macrolides should be reserved for patients with an anaphylactic reaction to penicillin. Other options for these patients include clindamycin or trimethoprim–sulfamethoxazole. However, it should be remembered that clindamycin is not effective against gram-negative organisms such as *H influenzae*.

Failure to improve after 48–72 hours suggests a resistant organism or potential complication. Second-line therapies should be initiated at this point, or, if the patient is already on amoxicillin–clavulanate or cephalosporin, intravenous antibiotic therapy should be considered. Imaging and referral for sinus aspiration should be strongly considered as well.

Patients who are toxic, or who have evidence of invasive infection or CNS complications, should be hospitalized immediately. Intravenous therapy with nafcillin or clindamycin plus a third-generation cephalosporin such as cefotaxime should be initiated until culture results become available.

Decongestants, antihistamines, and nasal saline irrigations are frequently used in acute rhinosinusitis to promote drainage. To date, there is no evidence-based data supporting their efficacy, and concern has been raised about potential adverse effects related to impaired ciliary function, decreased blood flow to the mucosa, and reduced diffusion of antibiotic into the sinuses with the use of decongestants. Topical nasal decongestants, such as oxymetazoline or phenylephrine sprays, should not be used for more than 3 days due to risk of rebound edema. Patients with underlying allergic rhinitis may benefit from intranasal cromolyn or corticosteroid nasal spray.

2. Recurrent or Chronic Rhinosinusitis

Recurrent rhinosinusitis occurs when episodes of ABRS clear with antibiotic therapy but recur with each or most upper respiratory infections. Chronic rhinosinusitis (CRS) is diagnosed when the child has not cleared the infection in the expected time but has not developed acute complications. Both symptoms and physical findings are required to support the diagnosis, and CT scan may be a useful adjuvant in making the diagnosis. Although recent meta-analysis evaluations have resulted in recommendations for ABRS, there is a paucity of data for the treatment of recurrent or chronic rhinosinusitis. Important factors to consider include allergies, anatomic variations, and disorders in host immunity. Mucosal inflammation leading to obstruction is most commonly caused by allergic rhinitis and occasionally by nonallergic rhinitis. There is a great deal of evidence that allergic rhinitis, rhinosinusitis, and asthma are all manifestations of a systemic inflammatory response. Gastroesophageal reflux has also been implicated in CRS. Less commonly, CRS is caused by anatomic variations, such as septal deviation, polyp, or foreign body.

Allergic nasal polyps are unusual in children younger than 10 years and should prompt a workup for cystic fibrosis. In cases of chronic or recurrent pyogenic pansinusitis, poor host resistance (eg, an immune defect, primary ciliary dyskinesia, or cystic fibrosis)—though rare—must be ruled out by immunoglobulin studies, electron microscopy studies of respiratory cilia, nasal nitric oxide measurements if available, a sweat chloride test, and genetic testing (see Chapters 18 and 31). Anaerobic and staphylococcal organisms are often responsible for CRS. Evaluation by an allergist and an otolaryngologist may be useful in determining the underlying causes.

▶ Treatment

A. Medical Therapy

Antibiotic therapy is similar to that used for ABRS, but the duration is longer, typically 3–4 weeks. Antimicrobial choice should include drugs effective against staphylococcal organisms. Nasal saline irrigations and intranasal steroid sprays

have been shown to be helpful in the reduction of symptoms of CRS.

B. Surgical Therapy

The mainstay of treatment for pediatric CRS is medical management, with appropriate antibiotic therapy and treatment of comorbid conditions such as allergic rhinitis and asthma. Only a small percentage of children will warrant surgical management.

1. Antral lavage—Antral lavage, generally regarded as a diagnostic procedure, may have some therapeutic value. An aspirate or a sample from the maxillary sinus is retrieved under anesthesia. The maxillary sinus is then irrigated. In the very young child, this may be the only procedure performed.

2. Adenoidectomy—Adenoidectomy is thought to be effective in 50%–75% of children with CRS. The adenoids serve as a reservoir of pathogenic bacteria and may also interfere with mucociliary clearance and drainage. Biofilms have been reported in the adenoids of children with CRS, and may explain the resistance of these infections to standard antibiotic therapy.

3. Balloon catheter dilation—This procedure opens up the maxillary sinuses without removal of tissue to promote drainage. Preliminary studies indicate that this may be effective in children who have failed adenoidectomy.

4. Endoscopic sinus surgery—Endoscopic sinus surgery in children was controversial because of concerns regarding facial growth. However, recent studies have not supported this concern. Endoscopic sinus surgery is reported to be effective in over 80% of cases, and may be indicated if adenoidectomy or balloon dilation is not effective.

5. External drainage—External drainage procedures are reserved for complications arising from ethmoid and frontal sinusitis.

CHOANAL ATRESIA

Choanal atresia occurs in approximately 1 in 7000 live births. The female-male ratio is 2:1, as is the unilateral-bilateral ratio. Bilateral atresia results in severe respiratory distress at birth and requires immediate placement of an oral airway or intubation, and otolaryngology consultation for surgical treatment. Unilateral atresia usually appears later as a unilateral chronic nasal discharge that may be mistaken for CRS. Diagnosis may be suspected if a 6-Fr catheter cannot be passed through the nose and is confirmed by axial CT scan. Approximately 50% of patients with bilateral choanal atresia have CHARGE association (**C**oloboma, **H**eart disease, **A**tresia of the choanae, **R**etarded growth and retarded development or CNS anomalies, **G**enital hypoplasia, and **E**ar anomalies or deafness) (see Chapter 35) or other congenital anomalies.

RECURRENT RHINITIS

Recurrent rhinitis is frequently seen in the office practice of pediatrics. The child is brought in with the chief complaint of having "one cold after another," "constant colds," or "always being sick." Approximately two-thirds of these children have recurrent colds; the rest have either allergic rhinitis or recurrent rhinosinusitis.

1. Allergic Rhinitis

Allergic rhinitis is a chronic disorder of the upper airway which is induced by IgE-mediated inflammation secondary to allergen exposure. It is more common in children than in adults and affects up to 40% of children in the United States. It significantly affects quality of life, interfering with physical and social activities, concentration, school performance, and sleep. Allergic rhinitis can contribute to the development of rhinosinusitis, otitis media, and asthma. Symptoms may include nasal congestion, sneezing, rhinorrhea, and itchy nose, palate, throat, and eyes. On physical examination the nasal turbinates are swollen and may be red or pale pink-purple. Several classes of medications have proven effective in treating allergic rhinitis symptoms, including intranasal corticosteroids, oral and intranasal antihistamines, leukotriene antagonists, and decongestants. Ipratropium nasal spray may also be used as an adjunctive therapy. Nasal saline rinses are helpful to wash away allergens. Recent studies have indicated that use of intranasal steroid sprays may not only decrease the impairment caused by allergic rhinitis symptoms, but also help prevent progression to more severe disease and decrease the risk of related comorbidities such as asthma and sleep-disordered breathing.

2. Nonallergic Rhinitis

Nonallergic rhinitis also causes rhinorrhea and nasal congestion, but does not seem to involve an immunologic reaction. Its mechanism is not well understood. Triggers can include sudden changes in environmental temperature, air pollution, and other irritants such as tobacco smoke. Medications can also be associated with nonallergic rhinitis. Nasal decongestant

sprays, when used for long periods of time can cause *rhinitis medicamentosa*, which is a rebound nasal congestion which can be very difficult to treat. Oral decongestants, nasal corticosteroids, antihistamines, and ipratropium spray have all been shown to offer symptomatic relief.

EPISTAXIS

The nose is an extremely vascular structure. In most cases, epistaxis (nosebleed) arises from the anterior portion of the nasal septum (Kiesselbach area). It is often due to dryness, vigorous nose rubbing, nose blowing, or nose picking. Examination of the anterior septum usually reveals a red, raw surface with fresh clots or old crusts. Presence of telangiectasias, hemangiomas, or varicosities should also be noted. If a patient has been using a nasal corticosteroid spray, check the patient's technique to make sure he or she is not directing the spray toward the septum. If proper technique does not reduce the nosebleeds, the spray should be discontinued.

In fewer than 5% of cases, epistaxis is caused by a bleeding disorder such as von Willebrand disease. A hematologic workup is warranted if any of the following is present: family history of a bleeding disorder; medical history of easy bleeding, particularly with circumcision or dental extraction; spontaneous bleeding at any site; bleeding that lasts for more than 30 minutes or blood that will not clot with direct pressure by the physician; onset before age 2 years; or a drop in hematocrit due to epistaxis. High blood pressure may rarely predispose to prolonged nosebleeds in children.

A nasopharyngeal angiofibroma may manifest as recurrent epistaxis. Adolescent boys are affected almost exclusively. CT scan with contrast of the nasal cavity and nasopharynx is diagnostic.

▶ Treatment

The patient should sit up and lean forward so as not to swallow the blood. Swallowed blood may cause nausea and hematemesis. The nasal cavity should be cleared of clots by gentle blowing. The soft part of the nose below the nasal bones is pinched and held firmly enough to prevent arterial blood flow, with pressure over the bleeding site (anterior septum) being maintained for 5 minutes by the clock. For persistent bleeding, a one-time only application of oxymetazoline into the nasal cavity may be helpful. If bleeding continues, the bleeding site needs to be visualized. A small piece of gelatin sponge (Gelfoam) or collagen sponge (Surgicel) can be inserted over the bleeding site and held in place.

Friability of the nasal vessels is often due to dryness and can be decreased by increasing nasal moisture. This can be accomplished by daily application of a water-based ointment to the nose. A pea-sized amount of ointment is placed just inside the nose and spread by gently squeezing the nostrils. Twice-daily nasal saline irrigation and humidifier use may also be helpful. Aspirin and ibuprofen should be avoided, as should nose picking and vigorous nose blowing. Otolaryngology referral is indicated for refractory cases. Cautery of the nasal vessels is reserved for treatment failures.

NASAL INFECTION

A nasal furuncle is an infection of a hair follicle in the anterior nares. Hair plucking or nose picking can provide a route of entry. The most common organism is *S aureus*. A furuncle presents as an exquisitely tender, firm, red lump in the anterior nares. Treatment includes dicloxacillin or cephalexin orally for 5 days to prevent spread. The lesion should be gently incised and drained as soon as it points with a sterile needle. Topical antibiotic ointment may be of additional value. Because this lesion is in the drainage area of the cavernous sinus, the patient should be followed closely until healing is complete. Parents should be advised never to pick or squeeze a furuncle in this location—and neither should the physician. Associated cellulitis or spread requires hospitalization for administration of intravenous antibiotics.

A nasal septal abscess usually follows nasal trauma or a nasal furuncle. Examination reveals fluctuant gray septal swelling, which is usually bilateral. The possible complications are the same as for nasal septal hematoma (see following discussion). In addition, spread of the infection to the CNS is possible. Treatment consists of immediate hospitalization, incision and drainage by an otolaryngologist, and antibiotic therapy.

NASAL TRAUMA

Newborn infants rarely present with subluxation of the quadrangular cartilage of the septum. In this disorder, the top of the nose deviates to one side, the inferior septal border deviates to the other side, the columella leans, and the nasal tip is unstable. This disorder must be distinguished from the more common transient flattening of the nose caused by the birth process. In the past, physicians were encouraged to reduce all subluxations in the nursery. Otolaryngologists are more likely to perform the reduction under anesthesia for more difficult cases.

After nasal trauma, it is essential to examine the inside of the nose in order to rule out hematoma of the nasal septum, as these can cause septal necrosis, leading to permanent nasal deformity. This diagnosis is confirmed by the abrupt

onset of nasal obstruction following trauma and the presence of a boggy, widened nasal septum. The normal nasal septum is only 2–4 mm thick. A cotton swab can be used to palpate the septum. Treatment consists of immediate referral to an otolaryngologist for evacuation of the hematoma and packing of the nose.

Most blows to the nose result in epistaxis without fracture. A persistent nosebleed after trauma, crepitus, instability of the nasal bones, and external deformity of the nose indicate fracture. Septal injury cannot be ruled out by radiography, and can only be ruled out by careful intranasal examination. Patients with suspected nasal fractures should be referred to an otolaryngologist for definitive therapy. Since the nasal bones begin healing immediately, the child must be seen by an otolaryngologist within 48–72 hours of the injury to allow time to arrange for fracture reduction before the bones become immobile.

FOREIGN BODIES IN THE NOSE

If this diagnosis is delayed, unilateral foul-smelling rhinorrhea, halitosis, bleeding, or nasal obstruction often result.

There are many ways to remove nasal foreign bodies. The obvious first maneuver is vigorous nose blowing if the child is old enough. The next step in removal requires nasal decongestion, good lighting, correct instrumentation, and physical restraint. Topical tetracaine or lidocaine may be used for anesthesia in young children. Nasal decongestion can be achieved by topical phenylephrine or oxymetazoline. When the child is properly restrained, most nasal foreign bodies can be removed using a pair of alligator forceps or right-angle instrument through an operating head otoscope. If the object seems unlikely to be removed on the first attempt, is wedged in, or is quite large, the patient should be referred to an otolaryngologist rather than worsening the situation through futile attempts at removal.

Because the nose is a moist cavity, the electrical current generated by disk-type batteries—such as those used in clocks, watches, and hearing aids—can cause necrosis of mucosa and cartilage destruction in less than 4 hours. Batteries constitute a true foreign body emergency.

▼ THE THROAT & ORAL CAVITY

ACUTE STOMATITIS

1. Recurrent Aphthous Stomatitis

Aphthous ulcers, or canker sores, are small painful ulcers (3–10 mm) usually found on the inner aspect of the lips or on the tongue; rarely they may appear on the tonsils or palate. There is usually no associated fever or cervical adenopathy. They can last 1–2 weeks and may recur numerous times

throughout life. The cause is unknown, although an allergic or autoimmune basis is suspected.

A topical corticosteroid, such as triamcinolone dental paste, may reduce duration of the lesion. Pain can also be reduced by eating a bland diet, avoiding salty or acidic foods and juices, and by taking acetaminophen or ibuprofen. A recent Cochrane review was unable to promote a single systemic treatment for those unresponsive to local therapy.

Less common causes of recurrent oral ulcers include Behçet disease, familial Mediterranean fever, and PFAPA syndrome (**P**eriodic **F**ever, **A**phthous stomatitis, **P**haryngitis, and cervical **A**denopathy). PFAPA syndrome was first described in 1987, and its cause is unknown, although an immune etiology is suspected. It usually begins before the age of 5 years, continues through adolescence, and then spontaneously resolves. Fever and other symptoms recur at regular intervals. Episodes last approximately 5 days and are not associated with other URI symptoms or illnesses. Episodes may be dramatically improved with prednisone bursts, but recurrences typically continue. PFAPA may resolve with prolonged cimetidine treatment. Tonsillectomy has been shown to be effective in curing this condition. Otolaryngology referral is appropriate.

A diagnosis of Behçet disease requires two of the following: genital ulcers, uveitis, and erythema nodosum–like lesions. Patients with Mediterranean fever usually have a positive family history, serosal involvement, and recurrent fever.

Brocklehurst P et al: Systemic interventions for recurrent aphthous stomatitis (mouth ulcers). Cochrane Database Syst Rev 2012 Sep 12;9:CD005411. doi: 10.1002/14651858.CD005411.pub2 [Review] [PMID: 22972085].
Licameli G, Lawton M, Kenna M, Dedeoglu F: Long-term surgical outcomes of adenotonsillectomy for PFAPA syndrome. Arch Otolaryngol Head Neck Surg 2012 Oct;138(10):902–906. doi: 10.1001/2013.jamaoto.313 [PMID: 23069819].

2. Herpes Simplex Gingivostomatitis (See also Chapter 38)

In the initial infection with the herpes simplex virus, children usually develop 10 or more small ulcers (1–3 mm) on the buccal mucosa, anterior tonsillar pillars, inner lips, tongue, and gingiva; the posterior pharynx is typically spared. The lesions are associated with fever, tender cervical adenopathy, and generalized oral inflammation which precedes the development of the ulcers. This gingivostomatitis lasts 7–10 days. Exposure to the virus occurs 3–50 days prior to the onset of symptoms. Affected children are commonly younger than 3 years. Treatment is symptomatic, as described earlier for recurrent aphthous stomatitis, with the exception that corticosteroids are contraindicated. Acyclovir therapy may be initiated if the child is seen early in the course. Because of pain, dehydration occasionally develops, requiring hospitalization. Herpetic laryngotracheitis is a rare complication.

3. Thrush (See also Chapter 41)

Oral candidiasis mainly affects infants and occasionally older children in a debilitated state. *Candida albicans* is a saprophyte that normally is not invasive unless the mouth is abraded or the patient is immunocompromised. The use of broad-spectrum antibiotics and systemic or inhaled corticosteroids may be contributing factors. Symptoms include oral pain and refusal of feedings. Lesions consist of white curdlike plaques, predominantly on the buccal mucosa, which cannot be washed away after a feeding. Another less common variation of oral candidal infection is erythematous candidiasis, which produces erythematous patches on the palate and dorsum of the tongue. This condition is associated primarily with patients who are taking broad-spectrum antibiotics or corticosteroids, or are human immunodeficiency virus (HIV) positive.

Treatment consists of nystatin oral suspension. Large plaques may be removed with a moistened cotton swab, and the nystatin may be applied to the lesions with a swab. Patients who do not respond to oral therapy or are immunocompromised may require systemic antifungal agents. Parents should be advised to replace any items, such as a pacifier, that may have become contaminated with *Candida*.

4. Traumatic Oral Ulcers

Mechanical trauma most commonly occurs on the buccal mucosa secondary to biting by the molars. Thermal trauma, from very hot foods, can also cause ulcerative lesions. Chemical ulcers can be produced by mucosal contact with aspirin or other caustic agents. Oral ulcers can also occur with leukemia or on a recurrent basis with cyclic neutropenia.

PHARYNGITIS

Figure 18–7 is an algorithm for the management of a sore throat.

1. Acute Viral Pharyngitis

Over 90% of sore throats and fever in children are due to viral infections. The findings seldom point toward any particular viral agent, but four types of viral pharyngitis are sufficiently distinctive to warrant discussion below.

▶ Clinical Findings

A. Infectious Mononucleosis

Findings include exudative tonsillitis, generalized cervical adenitis, and fever, usually in patients older than 5 years. A palpable spleen or axillary adenopathy increases the likelihood of the diagnosis. The presence of more than 10% atypical lymphocytes on a peripheral blood smear or a positive mononucleosis spot test supports the diagnosis, although these tests are often falsely negative in children younger than age 5 years. Epstein-Barr virus serology showing an elevated IgM-capsid antibody is definitive. Amoxicillin is contraindicated in patients suspected of having mononucleosis because the drug often precipitates a rash.

B. Herpangina

Herpangina ulcers are classically 3 mm in size, surrounded by a halo, and are found on the anterior tonsillar pillars, soft palate, and uvula; the anterior mouth and tonsils are spared. Herpangina is caused by the coxsackie A group of viruses. Enteroviral polymerase chain reaction testing is widely available, but not typically indicated, as herpangina is a self-limited illness.

C. Hand, Foot, and Mouth Disease

This entity is caused by several enteroviruses, one of which (enterovirus 71) can rarely cause encephalitis. Ulcers occur anywhere in the mouth. Vesicles, pustules, or papules may be found on the palms, soles, interdigital areas, and buttocks. In younger children lesions may be seen on the distal extremities and even the face.

D. Pharyngoconjunctival Fever

This disorder is caused by an adenovirus and often is epidemic. Exudative tonsillitis, conjunctivitis, lymphadenopathy, and fever are the main findings. Treatment is symptomatic.

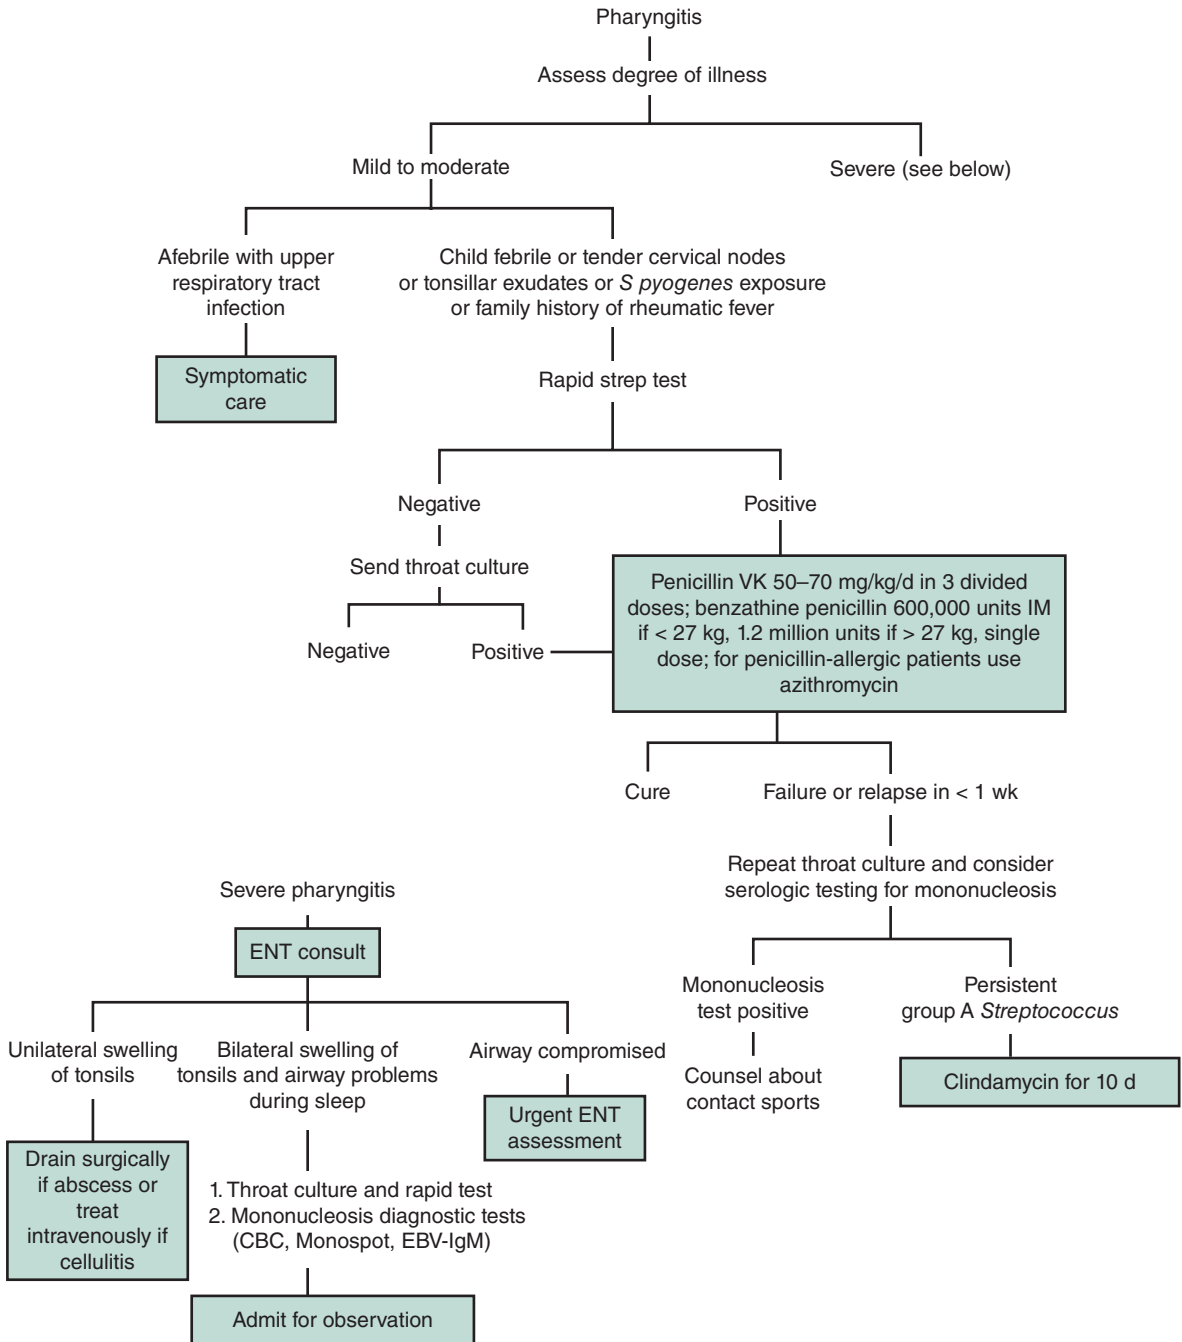
2. Acute Bacterial Pharyngitis

ESSENTIALS OF DIAGNOSIS

▶ Sore throat.
▶ At least one of the following:
 ▶ Cervical lymphadenopathy (lymph nodes tender or > 2 cm)
 ▶ Tonsillar exudates
 ▶ Positive group A β-hemolytic streptococcus culture
 ▶ Fever greater than 38.3°C

▶ Differential Diagnosis

Viral pharyngitis, infectious mononucleosis, bacterial pharyngitis other than streptococcal, diphtheria, and peritonsillar abscess.

Approximately 20%–30% of children with pharyngitis have a group A streptococcal infection. It is most common in


▲ **Figure 18–7.** Algorithm for pharyngitis. CBC, complete blood count; EBV, Epstein-Barr virus; ENT, ear, nose, and throat.

children between 5 and 15 years of age in the winter or early spring. Less common causes of bacterial pharyngitis include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, groups C and G streptococci, and *Arcanobacterium hemolyticum*. Of the five, *M pneumoniae* is by far the most common and may cause over one-third of all pharyngitis cases in adolescents and adults.

▶ Clinical Findings

Sudden onset of sore throat, fever, tender cervical adenopathy, palatal petechiae, a beefy-red uvula, and a tonsillar exudate suggest streptococcal infection. Other symptoms may include headache, stomachache, nausea, and vomiting. The only way to make a definitive diagnosis is by throat culture or rapid antigen test. Rapid antigen tests are very specific, but have a sensitivity of only 85%–95%. Therefore, a positive test indicates *S pyogenes* infection, but a negative result requires confirmation by performing a culture. Diagnosis is important because untreated streptococcal pharyngitis can result in acute rheumatic fever, glomerulonephritis, and suppurative complications (eg, cervical adenitis, peritonsillar abscess, otitis media, cellulitis, and septicemia). The presence of conjunctivitis, cough, hoarseness, symptoms of upper respiratory infection, anterior stomatitis, ulcerative lesions, viral rash, and diarrhea should raise suspicion of a viral etiology.

Occasionally, a child with group A streptococcal infection develops scarlet fever within 24–48 hours after the onset of symptoms. Scarlet fever is a diffuse, finely papular, erythematous eruption producing a bright red discoloration of the skin, which blanches on pressure. The rash is more intense in the skin creases. The tongue has a strawberry appearance.

A controversial but possible complication of streptococcal infections is pediatric autoimmune neuropsychiatric disorders associated with *Streptococcus* (PANDAS). PANDAS is a relatively newly recognized condition. It describes a subset of pediatric patients who experience a sudden onset of obsessive-compulsive disorder and/or tics, or worsening of such symptoms in children who previously had these, following a strep infection.

▶ Treatment

Suspected or proven group A streptococcal infection should be treated with penicillin (oral or intramuscular) or amoxicillin as outlined in Table 18–4. For patients allergic to penicillin, alternative treatments include cephalexin, azithromycin, and clindamycin.

Repeat culture after treatment is not recommended and is indicated only for those who remain symptomatic, have a recurrence of symptoms, or have had rheumatic fever. Of note, children who have had rheumatic fever are at a

Table 18–4. Treatment of group A streptococcal pharyngitis.[a]

Treatment of Acute Group A Strep Pharyngitis		
Antibiotic	**Dose**	**Notes**
Penicillin	**Penicillin V** 250 mg 2–3 times per day for 10 d if < 27 kg; 500 mg 2–3 times per day for 10 d if > 27 kg **Benzathine penicillin** 600,000 units IM single dose if < 27 kg; 1.2 million units IM single dose if > 27kg	Resistance to penicillin, amoxicillin, and first-generation cephalosporins has not been reported. Each is equally effective if compliance is assured.
Amoxicillin	50 mg/kg/d once daily for 10 d (max 1200 mg)	
Cephalexin	25–50 mg/kg/d in 2 divided doses for 10 d	
Clindamycin	20 mg/kg/d in 3 divided doses for 10 d	Rare resistance reported in US
Azithromycin	12 mg/kg once daily for 5 d (max 500 mg/d)	Some resistance reported in US
Eradication of carrier state		
Clindamycin	20 mg/kg/d in 3 divided doses for 10 d	Most effective
Cephalexin	25–50 mg/kg/d in 2 divided doses for 10 d	Also effective
Penicillin + rifampin	See above penicillin doses; rifampin 20 mg/kg/d twice daily for final 4 days	

[a]Tetracyclines, sulfonamides (including trimethoprim-sulfamethoxazole), and quinolones should not be used for treating GAS infections. Table reproduced and adapted, courtesy of Todd J: Update on group A streptococcal pharyngitis. Contagious Comments, Children's Hospital Colorado, 2013; XXVIII(1).

high risk of recurrence if future group A strep infections are inadequately treated. In this group of patients, long-term antibiotic prophylaxis is recommended, sometimes life-long in patients with residual rheumatic heart disease. (See Chapter 20.)

In general, the carrier state is harmless, self-limited (2–6 months), and not contagious. An attempt to eradicate the carrier state is warranted only if the patient or another family member has frequent streptococcal infections, or if a family member or patient has a history of rheumatic fever or glomerulonephritis. If eradication is chosen, a course of clindamycin for 10 days or rifampin for 5 days should be used.

In the past, daily penicillin prophylaxis was occasionally recommended; however, because of concerns about the development of drug resistance, tonsillectomy is now preferred for patients with recurrent streptococcal tonsillitis.

Web Resources

National Institute of Mental Health PANDAS information: http://intramural.nimh.nih.gov/pdn/web.htm. Accessed January 11, 2014.

PERITONSILLAR CELLULITIS OR ABSCESS (QUINSY)

ESSENTIALS OF DIAGNOSIS

► Severe sore throat.
► Unilateral tonsillar swelling.
► Deviation of the uvula.
► Trismus (limited mouth opening).

Tonsillar infection occasionally penetrates the tonsillar capsule, spreading to the surrounding tissues, causing peritonsillar cellulitis. If untreated, necrosis occurs and a peritonsillar abscess forms. The most common pathogen is β-hemolytic streptococcus, but others include group D streptococcus, S pneumoniae, and anaerobes.

The patient complains of a severe sore throat even before the physical findings become marked. A high fever is usually present, and the process is almost always unilateral. The tonsil bulges medially, and the anterior tonsillar pillar is prominent. The soft palate and uvula on the involved side are edematous and displaced toward the uninvolved side. As the infection progresses, trismus, ear pain, dysphagia, and drooling may occur. The most serious complication of untreated peritonsillar abscess is a lateral pharyngeal abscess.

It is often difficult to differentiate peritonsillar cellulitis from abscess. In some children, it is possible to aspirate the peritonsillar space to diagnose and treat an abscess. However, it is reasonable to admit a child for 12–24 hours of intravenous antimicrobial therapy, because aggressive treatment of cellulitis can usually prevent suppuration. Therapy with a penicillin or clindamycin is appropriate. Failure to respond to therapy during the first 12–24 hours indicates a high probability of abscess formation. An otolaryngologist should be consulted for incision and drainage or for aspiration under local or general anesthesia.

Recurrent peritonsillar abscesses are so uncommon (7%) that routine tonsillectomy for a single incident is not indicated unless other tonsillectomy indications exist. Hospitalized patients can be discharged on oral antibiotics when fever has resolved for 24 hours and dysphagia has improved.

RETROPHARYNGEAL ABSCESS

Retropharyngeal lymph nodes, which drain the adenoids, nasopharynx, and paranasal sinuses, can become infected, commonly due to β-hemolytic streptococci and S aureus. If this pyogenic adenitis goes untreated, a retropharyngeal abscess forms. This occurs most commonly during the first 2 years of life. After this age, the most common cause of retropharyngeal abscess is superinfection of a penetrating injury of the posterior wall of the oropharynx.

The diagnosis of retropharyngeal abscess should be strongly suspected in a child with fever, respiratory symptoms, and neck hyperextension. Dysphagia, drooling, dyspnea, and gurgling respirations are also found. Prominent swelling on one side of the posterior pharyngeal wall is characteristic. Swelling usually stops at the midline because a medial raphe divides the prevertebral space. On lateral neck x-ray, the retropharyngeal tissues are wider than the C4 vertebral body. But plain films are not specific; a CT scan with contrast is more helpful.

Although a retropharyngeal abscess is a surgical emergency, frequently it cannot be distinguished from retropharyngeal adenitis. Immediate hospitalization and intravenous antimicrobial therapy with a semisynthetic penicillin or clindamycin is the first step for most cases. Immediate surgical drainage is required when a definite abscess is seen radiographically or when the airway is compromised. In most instances, a period of 12–24 hours of antimicrobial therapy will help differentiate the two entities. In the child with adenitis, fever will decrease and oral intake will increase. A child with retropharyngeal abscess will not improve and may continue to deteriorate. A surgeon should incise and drain the abscess under general anesthesia to prevent its extension.

LUDWIG ANGINA

Ludwig angina is a rapidly progressive cellulitis of the sub-mandibular space that can cause airway obstruction and death. The submandibular space extends from the mucous membrane of the floor of the mouth to the muscular and fascial attachments of the hyoid bone. This infection is unusual in infants and children. The initiating factor in over 50% of cases is dental disease, including abscesses and extraction. Some patients have a history of injury to the floor of the mouth. Group A strep is the most common organism identified.

Symptoms include fever and tender swelling of the floor of the mouth. The tongue can become tender and inflamed. Upward displacement of the tongue may cause dysphagia, drooling, and airway obstruction.

Treatment consists of high-dose intravenous clindamycin or ampicillin plus nafcillin until the culture results and sensitivities are available. Because the most common cause of death in Ludwig angina is sudden airway obstruction, the patient must be monitored closely in the intensive care unit and intubation provided for progressive respiratory distress. An otolaryngologist should be consulted for airway evaluation and management, and to perform a drainage procedure if needed.

ACUTE CERVICAL ADENITIS

Local infections of the ear, nose, and throat can involve a regional lymph node and cause abscess formation. The typical case involves a unilateral, solitary, anterior cervical node. About 70% of these cases are due to β-hemolytic streptococcal infection, 20% to staphylococci, and the remainder to viruses, atypical mycobacteria, and *Bartonella henselae*. MRSA must also be considered.

The initial evaluation of cervical adenitis should generally include a rapid group A streptococcal test, and a complete blood count with differential looking for atypical lymphocytes. A purified protein derivative skin test, looking for nontuberculous mycobacteria, should also be considered. If multiple enlarged nodes are found, a rapid mononucleosis test is useful. Early treatment with antibiotics prevents many cases of adenitis from progressing to suppuration. However, once abscess formation occurs, antibiotic therapy alone is often insufficient and a drainage procedure may be necessary. Because of the increase in community-acquired MRSA, it is a prudent to send a specimen for culture and sensitivity.

Cat-scratch disease, caused by *B henselae*, causes indolent ("cold") adenopathy. The diagnosis is supported if a primary papule is found at the scratch site on the face. In over 90% of patients, there is a history of contact with kittens. The node is usually only mildly tender but may, over a month or more, suppurate and drain. About one-third of children have fever and malaise; rarely neurologic sequelae and prolonged fever occur. Cat-scratch disease can be diagnosed by serologic testing, but testing is not always confirmatory. Blood should be drawn 2–8 weeks after onset of symptoms. Because most enlarged lymph nodes infected with *B henselae* spontaneously regress within 1–3 months, the benefit of antibiotics is controversial. In a placebo-controlled trial, azithromycin for 5 days caused a more rapid decrease in node size. Other drugs likely to be effective include rifampin, trimethoprim-sulfamethoxazole, erythromycin, clarithromycin, doxycycline, ciprofloxacin, and gentamicin.

Cervical lymphadenitis can also be caused by nontuberculous mycobacterial species or *Mycobacterium avium* complex. Mycobacterial disease is unilateral and may involve several matted nodes. A characteristic violaceous appearance may develop over a prolonged period of time without systemic signs or much local pain. Atypical mycobacterial infections are often associated with positive purified protein derivative skin test reactions less than 10 mm in diameter, and a second-strength (250-test-unit) purified protein derivative skin test is virtually always positive.

▶ Differential Diagnosis

A. Neoplasms and Cervical Nodes

Malignant tumors usually are not suspected until adenopathy persists despite antibiotic treatment. Classically, malignant lymph nodes are painless, nontender, and firm to hard in consistency. They may be fixed to underlying tissues. They may occur as a single node, as unilateral nodes in a chain, bilateral cervical nodes, or as generalized adenopathy. Common malignancies that may manifest in the neck include lymphoma, rhabdomyosarcoma, and thyroid carcinoma.

B. Imitators of Adenitis

Several structures in the neck can become infected and resemble a lymph node. The first three masses are of congenital origin.

1. Thyroglossal duct cyst—These are in the midline of the neck, usually located near the level of the hyoid bone. Thyroglossal duct cysts move upward when the tongue is protruded or with swallowing. Occasionally, a thyroglossal duct cyst may have a sinus tract with an opening just lateral to the midline. When infected, these can become acutely swollen and inflamed.

2. Branchial cleft cyst—These masses are found along the anterior border of the sternocleidomastoid muscle and are smooth and fluctuant. Sometimes a branchial cleft cyst may be attached to the overlying skin by a small dimple or

a draining sinus tract. When infected, they can become a tender mass 3–5 cm in diameter.

3. Lymphatic malformation—Most lymphatic cysts are located in the posterior triangle just above the clavicle. These are soft and compressible and can be transilluminated. Over 60% of lymphatic malformations are noted at birth; the remaining malformations are usually seen by the age of 2 years. If these become large enough, they can compromise the patient's ability to swallow and breathe.

4. Parotitis—The most common pitfall is mistaking parotitis for cervical adenitis. The parotid salivary gland crosses the angle of the jaw. Parotitis may be bacterial or viral and may occur unilaterally or bilaterally. Mumps was once the most common cause of viral parotitis, but because of routine vaccinations, parainfluenza is the primary viral cause in the United States. An amylase level will be elevated in parotitis.

5. Ranula—A ranula is a cyst in the floor of the mouth caused by obstruction of the sublingual salivary gland. A "plunging" ranula extends through the mylohyoid muscle and can present as a neck mass.

6. Sternocleidomastoid muscle hematoma—Also known as *fibromatosis colli*, these are noted at age 2–4 weeks. On examination, the mass is found to be part of the muscle body and not movable. An associated torticollis usually confirms the diagnosis. A neck ultrasound can help confirm the diagnosis. Treatment involves physical therapy, with range of motion exercises.

SNORING, MOUTH BREATHING, & UPPER AIRWAY OBSTRUCTION

The American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) defines sleep-disordered breathing (SDB) as an abnormal respiratory pattern during sleep that includes snoring, mouth breathing, and pauses in breathing. SDB encompasses a spectrum of disorders that ranges in severity from snoring to obstructive sleep apnea. SDB is a presumptive diagnosis; OSA can be diagnosed only by polysomnogram (PSG).

In 2012, the American Academy of Pediatrics (AAP) updated their clinical practice guideline for the diagnosis and management of uncomplicated childhood obstructive sleep apnea syndrome. The guideline emphasizes that pediatricians should screen all children for snoring. If the child exhibits additional signs and symptoms of SDB, referral for a sleep study is recommended, but referral to an otolaryngologist or sleep specialist is also an option. The American Academy of Sleep Medicine (AASM) has similar recommendations.

Polysomnography

The gold standard for diagnosis of OSA is a polysomnogram (PSG), commonly called a "sleep study". A patient's history and clinical examination cannot predict the presence or severity of OSA. Similarly, an overnight oximetry study is a poor screening test for OSA, as it may detect patients with severe disease but miss those with milder forms, since obstructive respiratory events can occur without oxygen desaturations. The criteria for diagnosing OSA differ between children and adults. An obstructive event occurs when airflow stops despite persistence of respiratory effort. A hypopnea is counted when airflow and respiratory effort decrease with an associated oxygen desaturation or arousal. Normative values for children are just being established. The AASM states that for children, the occurrence of more than one apneic or hypopneic event per hour with duration of at least two respiratory cycles is abnormal. However, the AASM has qualified its recommendation, stating that the criteria may be modified once more comprehensive data become available. One study of children aged 6–11 years found that a respiratory disturbance index of at least one event per hour, when associated with a 3% oxygen desaturation, was associated with daytime sleepiness and learning problems. If oxygen desaturations were absent, a respiratory disturbance index of five events per hour was associated with clinical symptoms.

Although an obstructive apnea index greater than one event per hour may be statistically significant, whether it is clinically relevant remains unclear. Children with an apnea-hypopnea index of greater than five events per hour appear to have clinically significant OSA. The dilemma is how to manage children with an apnea-plus-hypopnea index of more than one but fewer than five events per hour, as some of these children experience neurocognitive symptoms. Of note, many research studies have shown little correlation between the severity of OSA by PSG and neuropsychological morbidity.

▶ Clinical Evaluation & Management

The AAO-HNS has developed clinical guidelines to help otolaryngologists determine when to proceed with surgical treatment (usually adenotonsillectomy) or request a polysomnogram. A PSG is generally recommended for children with suspected sleep apnea if they have any of the following comorbid conditions: obesity, Down syndrome, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidoses. PSG is also recommended for children without the above comorbidities if the need for surgery is uncertain, or if there is discordance between tonsillar size on physical examination and the reported severity of symptoms.

Most pediatric otolaryngologists perform adenotonsillectomy in healthy patients with SDB without obtaining a PSG.

An adenotonsillectomy without PSG is usually recommended in a healthy child if the following are present:

1. Nighttime symptoms: habitual snoring along with gasping, pauses, or labored breathing. Other symptoms which may be related to SDB include night terrors, sleep walking, and secondary enuresis.

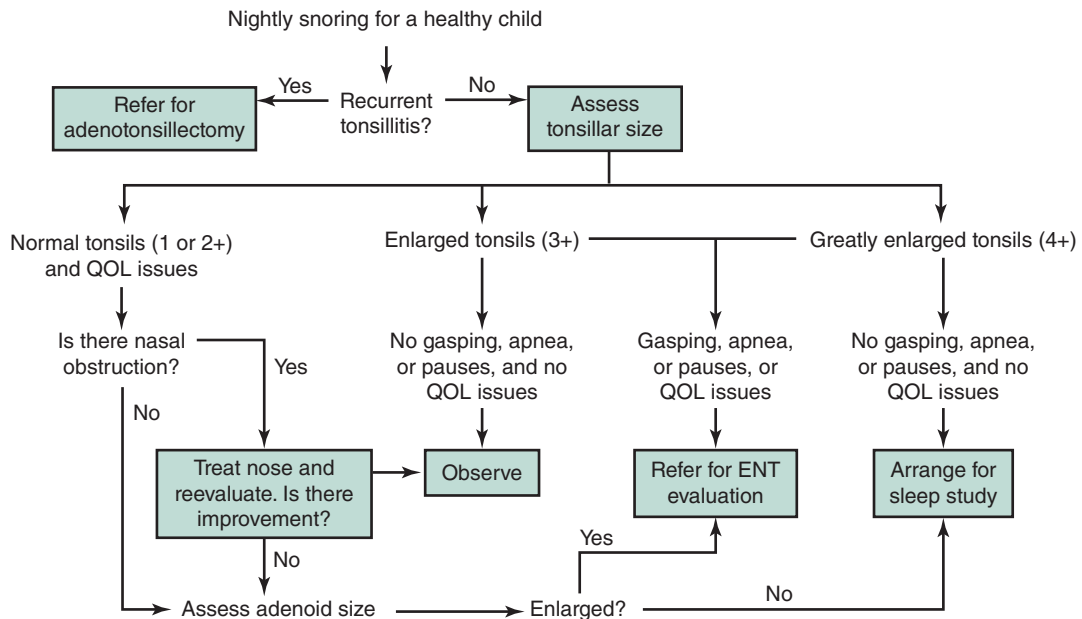
2. Daytime symptoms: unrefreshed sleep, attention deficit, hyperactivity, emotional lability, temperamental behavior, poor weight gain, and daytime fatigue. Other signs include daytime mouth breathing or dysphagia.

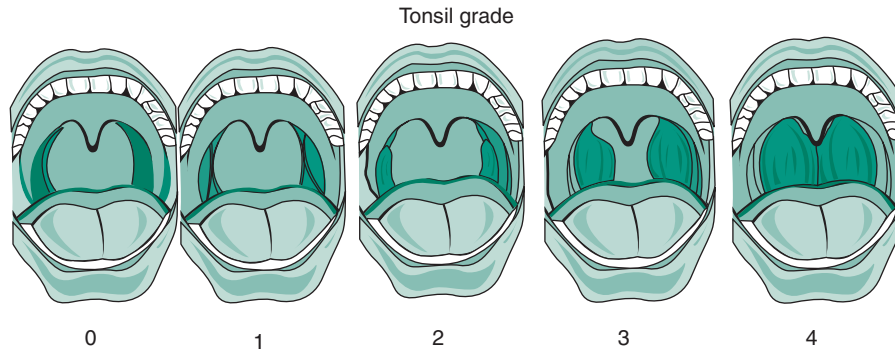
3. Enlarged tonsils.

If the three findings cannot be confirmed, but the child has other indications for an adenotonsillectomy—that is, recurrent tonsillitis or markedly enlarged (4+) tonsils with dysphagia—surgery is also warranted.

Figure 18–8 is an algorithm for management of SDB complaints in an otherwise healthy child. The pathway relies on clinical symptoms and tonsil size. Of note, tonsil size alone does not predict the presence of significant SDB. Children without significant tonsil hypertrophy may still have SDB. Factors such as low muscle tone can contribute to an individual's propensity to experience SDB. Although the pathway states that an asymptomatic child with markedly enlarged tonsils (4+) should undergo PSG, a period of observation is reasonable. One's clinical suspicion of SDB should be heightened if a child has enlarged tonsils, especially if the parents cannot provide a reliable history. If the child has no clinical symptoms and the tonsils are only moderately enlarged (3+), observation is appropriate. Educating the parents about the risks of SDB and what to look for is paramount.

A polysomnographic study is recommended for a child who has no adenotonsillar hypertrophy or nasal obstruction, but has significant symptoms of SDB. Other conditions, especially a periodic limb movement disorder, may mimic the daytime symptoms of SDB. If a polysomnogram indicates OSA in a child without tonsillar hypertrophy, a complete evaluation of the upper airway by awake flexible laryngoscopy should be performed to look for other possible sites of obstruction: nose, nasopharynx (adenoid), hypopharynx (base of tongue or lingual tonsils), and larynx. The adenoid can also be assessed with a lateral neck x-ray. Alternative methods to evaluate a child for anatomical sites of obstruction include sedated ciné MRI of the upper airway or sleep endoscopy.

As for postoperative PSG, the AASM and AAP agree that a child with mild OSA (typically fewer than five obstructive events an hour) does not require a follow-up study. However, those with persistent symptoms, more severe OSA, obesity, or other comorbidities should routinely have a postoperative study.


▲ **Figure 18–8.** Algorithm for evaluation of snoring in a healthy child.


Tonsil grade

▲ **Figure 18–9.** A grading scale for tonsil size that ranges from 0 to 4. With grade 0 the tonsils are small and contained within the tonsillar fossa; in grade 4 the tonsils are so large they almost touch ("kissing"). (Reprinted, with permission, from Brodksy L: Modern assessment of tonsils and adenoids. Pediatr Clin North Am 1989;36:1551.)

Allergic rhinitis is a common cause of nasal obstruction. If allergy is the suspected cause of SDB, a trial of intranasal corticosteroid spray is indicated. If enlarged tonsils (Figure 18–9) or adenoids are present, a referral to an otolaryngologist or a pediatric sleep laboratory is appropriate.

▶ Complications & Sequelae

The importance of diagnosing SDB in children cannot be underestimated. SDB has been associated with problems in a multitude of realms, including social, behavioral, and neurocognitive. It has been shown to significantly impact quality of life and has been associated with growth impairment and cardiovascular complications. Recent studies also suggest that SDB is associated with systemic inflammation.

TONSILLECTOMY & ADENOIDECTOMY

Tonsillectomy

A tonsillectomy, with or without adenoidectomy, is most often performed for either hypertrophy or recurrent infections. The most common indication for adenotonsillectomy is adenotonsillar hypertrophy associated with an obstructive breathing pattern during sleep (see earlier discussion of OSA and SDB). Adenotonsillar hypertrophy may also cause dysphagia or dental malocclusion. Rarely, hypertrophied tonsils may lead to pulmonary hypertension or cor pulmonale.

Recurrent tonsillitis is the second most common reason for tonsillectomy. Tonsillitis is considered "recurrent" when a child has seven or more documented infections in 1 year, five per year for 2 years, or three per year for 3 years. For an infection to be considered clinically significant, there must be a sore throat and at least one of the following clinical features: cervical lymphadenopathy (tender lymph nodes or > 2 cm), OR tonsillar exudate, OR positive culture for group A β-hemolytic streptococcus, OR temperature greater than 38.3°C.

Tonsillectomy is reasonable with fewer infections if the child has missed multiple school days due to infection, has a complicated course, or under other circumstances such as recurrent peritonsillar abscess, persistent streptococcal carrier state, or multiple antibiotic allergies. Unless neoplasm is suspected, tonsil asymmetry is not an indication.

A new indication for tonsillectomy is PFAPA syndrome (see section on Recurrent Aphthous Stomatitis, earlier), in which fever recurs predictably, typically every 4–8 weeks. Tonsillectomy has been shown to be an effective treatment.

Baugh RF et al; American Academy of Otolaryngology-Head and Neck Surgery Foundation: Clinical practice guideline: tonsillectomy in children. Otolaryngol Head Neck Surg 2011 Jan;144(1 Suppl):S1-S0. doi: 10.1177/0194599810389949 [PMID: 21493257].

Adenoidectomy

The adenoids, composed of lymphoid tissue in the nasopharynx, are a part of the Waldeyer ring of lymphoid tissue, which also includes the palatine and lingual tonsils. Enlarged adenoids, with or without infection, can obstruct the nose, alter normal orofacial growth, and interfere with speech, swallowing, and eustachian tube function. Children who are persistent mouth breathers can develop dental malocclusion and "adenoid facies," where the face is pinched and the maxilla narrowed because the molding pressures of the orbicularis oris and buccinator muscles are unopposed by the tongue. The adenoids can also harbor biofilms, which have been associated with CRS and otitis media.

Indications for adenoidectomy with or without tonsillectomy include upper airway obstruction, orofacial conditions such as mandibular growth abnormalities and dental malocclusion, speech abnormalities, persistent MEE, recurrent otitis media, and CRS.

Complications of Tonsillectomy & Adenoidectomy

The mortality rate associated with tonsillectomy and adenoidectomy is reported to approximate that of general anesthesia alone. The rate of hemorrhage varies between 0.1% and 8.1%, depending on the definition of hemorrhage; the rate of postoperative transfusion is 0.04%. Other potential complications include permanently hypernasal speech (< 0.01%) and, more rarely, nasopharyngeal stenosis, atlantoaxial subluxation, mandibular condyle fracture, and psychological trauma.

Contraindications to Tonsillectomy & Adenoidectomy

A. Palatal Abnormalities

Adenoids should not be removed completely in a child with a cleft palate or submucous cleft palate because of the risk of velopharyngeal incompetence which may cause hypernasal speech and nasal regurgitation. If needed, a partial adenoidectomy can be performed in at-risk children. A bifid uvula can be a sign of a palatal abnormality.

B. Bleeding Disorder

When suspected, bleeding disorders must be diagnosed and treated prior to surgery.

C. Acute Tonsillitis

An elective tonsillectomy and adenoidectomy can often be postponed until acute tonsillitis is resolved. Urgent tonsillectomy may occasionally be required for tonsillitis unresponsive to medical therapy.

DISORDERS OF THE LIPS

1. Labial Sucking Tubercle

A young infant may present with a small callus in the mid-upper lip. It usually is asymptomatic and disappears after cup feeding is initiated.

2. Cheilitis

Dry, cracked, scaling lips are usually caused by sun or wind exposure. Contact dermatitis from mouthpieces or various woodwind or brass instruments has also been reported. Licking the lips exacerbates cheilitis. Liberal use of lip balm gives excellent results.

3. Inclusion Cyst

Inclusion or mucous retention cysts are due to obstruction of mucous glands or other mucous membrane structures, such as minor salivary glands. In the newborn, they occur on the hard palate or gums and are called *Epstein pearls*. These resolve spontaneously in 1–2 months. In older children, inclusion cysts usually occur on the palate, uvula, or tonsillar pillars. They appear as taut yellow sacs varying in size from 2 to 10 mm. Inclusion cysts that do not resolve spontaneously may undergo incision and drainage. Occasionally a mucous cyst on the lower lip (mucocele) will require excision for cosmetic reasons.

DISORDERS OF THE TONGUE

1. Geographic Tongue (Benign Migratory Glossitis)

This condition of unknown etiology occurs in 1%–2% of the population with no age, sex, or racial predilection. It is characterized by irregularly shaped patches on the tongue that are devoid of papillae and surrounded by parakeratotic

reddish borders. The pattern changes as alternating regeneration and desquamation occurs. The lesions are generally asymptomatic and require no treatment.

2. Fissured Tongue (Scrotal Tongue)

This condition is marked by numerous irregular fissures on the dorsum of the tongue. It occurs in approximately 1% of the population and is usually a dominant trait. It is also frequently seen in children with trisomy 21.

3. Coated Tongue (Furry Tongue)

The tongue becomes coated if mastication is impaired and the patient is limited to a liquid or soft diet. Mouth breathing, fever, or dehydration can accentuate the process.

4. Macroglossia

Tongue hypertrophy and protrusion may be due to trisomy 21, Beckwith-Wiedemann syndrome, glycogen storage diseases, cretinism, mucopolysaccharidoses, lymphangioma, or hemangioma. Tongue reduction procedures should be considered in otherwise healthy subjects if macroglossia affects airway patency.

HALITOSIS

Bad breath is usually due to acute stomatitis, pharyngitis, rhinosinusitis, nasal foreign body, or dental hygiene problems. In older children and adolescents, halitosis can be a manifestation of CRS, gastric bezoar, bronchiectasis, or lung abscess. The presence of orthodontic devices or dentures can cause halitosis if good dental hygiene is not maintained. Halitosis can also be caused by decaying food particles embedded in cryptic tonsils. Mouthwashes and chewable breath fresheners give limited improvement. Treatment of the underlying cause is indicated, and a dental referral may be in order.

SALIVARY GLAND DISORDERS

1. Parotitis

A first episode of parotitis may safely be considered to be of viral origin, unless fluctuance is present. Mumps was the leading cause until adoption of vaccination; now the leading viruses are parainfluenza and Epstein-Barr virus. HIV infection should be considered if the child is known to be at risk.

2. Suppurative Parotitis

Suppurative parotitis occurs chiefly in newborns and debilitated elderly patients. The parotid gland is swollen, tender, and often erythematous, usually unilaterally. The diagnosis is made by expression of purulent material from Stensen duct.

The material should be cultured. Fever and leukocytosis may be present. Treatment includes hospitalization and intravenous antibiotic therapy. *S aureus* is the most common causative organism.

3. Juvenile Recurrent Parotitis

Some children experience recurrent nonsuppurative parotid inflammation with swelling or pain and fever. Juvenile recurrent parotitis (JRP) is most prevalent between the ages of 3 and 6 years, and it generally decreases by adolescence. The cause is unknown, but possible etiologic factors include ductal anomaly, autoimmune, allergy, and genetic. It usually occurs unilaterally. Treatment includes analgesics and some recommend an antistaphylococcal antibiotic for prophylaxis of bacterial infection and quicker resolution. Recently, endoscopy of Stensen duct has been investigated not only to confirm the diagnosis but also to provide treatment.

4. Tumors of the Parotid Gland

Mixed tumors, hemangiomas, sarcoidosis, and leukemia can manifest in the parotid gland as a hard or persistent mass. A cystic mass or multiple cystic masses may represent an HIV infection. Workup may require consultation with oncology, infectious disease, hematology, and otolaryngology.

5. Ranula

A ranula is a retention cyst of a sublingual salivary gland. It occurs on the floor of the mouth to one side of the lingual frenulum. It is thin-walled and can appear bluish. Refer to an otolaryngologist for surgical management.

CONGENITAL ORAL MALFORMATIONS

1. Tongue-Tie (Ankyloglossia)

A short lingual frenulum can hinder both protrusion and elevation of the tongue. Puckering of the midline tongue tip is noted with tongue movement. Ankyloglossia can cause feeding difficulties in the neonate, speech problems, and dental problems. If the tongue cannot protrude past the teeth or alveolar ridge or move between the gums and cheek, referral to an otolaryngologist is indicated. A frenulectomy should be performed in the neonatal period if the infant is having difficulty breast-feeding. In our practice, neonatal frenulectomy is performed in clinic. Early treatment is favored, as when an infant is even several months old, general anesthesia is required for the procedure to be performed safely.

Buryk M et al: Efficacy of neonatal release of ankyloglossia: a randomized trial. Pediatrics 2011 Aug;128(2):280–288 [PMID: 21768318].

2. Torus Palatini

Torus palatini are hard, midline, palate masses which form at suture lines of the bone. They are usually asymptomatic and require no therapy, but they can be surgically reduced if necessary.

3. Cleft Lip & Cleft Palate (See Chapter 35)

A. Submucous Cleft Palate

A bifid uvula is present in 3% of healthy children. However, a close association exists between bifid uvula and submucous cleft palate. A submucous cleft can be diagnosed by noting a translucent zone in the middle of the soft palate (zona pellucida). Palpation of the hard palate reveals absence of the posterior bony protrusion. Affected children have a 40% risk of developing persistent MEE. They are at risk for velopharyngeal incompetence, or an inability to close the palate against the posterior pharyngeal wall, resulting in hypernasal speech. During feeding, some of these infants experience nasal regurgitation of food. Children with submucous cleft palate causing abnormal speech or significant nasal regurgitation of food should be referred for possible surgical repair.

B. High-Arched Palate

A high-arched palate is usually a genetic trait of no consequence. It also occurs in children who are chronic mouth breathers and in premature infants who undergo prolonged oral intubation. Some rare causes of high-arched palate are congenital disorders such as Marfan syndrome, Treacher Collins syndrome, and Ehlers-Danlos syndrome.

C. Pierre Robin Sequence

This group of congenital malformations is characterized by the triad of micrognathia, cleft palate, and glossoptosis. Affected children present as emergencies in the newborn period because of infringement on the airway by the tongue. The main objective of treatment is to prevent asphyxia until the mandible becomes large enough to accommodate the tongue. In some cases, this can be achieved by leaving the child in a prone position when unattended. Other airway manipulations such as a nasal trumpet may be necessary. Recently, distraction osteogenesis has been used to avoid tracheostomy. In severe cases, a tracheostomy is required. The child requires close observation and careful feeding until the problem is outgrown.

Mackay DR: Controversies in the diagnosis and management of the Robin sequence. J Craniofac Surg 2011 Mar;22(2):415–420 [PMID: 21403570].

▼ RESPIRATORY TRACT

Pediatric pulmonary diseases account for almost 50% of deaths in children younger than age 1 year and about 20% of all hospitalizations of children younger than age 15 years. Approximately 7% of children have a chronic disorder of the lower respiratory system. Understanding the pathophysiology of many pediatric pulmonary diseases requires an appreciation of the normal growth and development of the lung.

▼ GROWTH & DEVELOPMENT

The lung has its origins from an outpouching of the foregut during the fourth week of gestation. The development of the lung is divided into five overlapping stages.

1. *Embryonic stage* (3–7 weeks' gestation): During this stage, the primitive lung bud undergoes asymmetrical branching and then subsequent dichotomous branching, leading to the development of the conducting airways. This stage of lung development is dependent on a complex interaction of various growth factors originating in both the pulmonary epithelium and the splanchnic mesenchyme. It also sees the development of the large pulmonary arteries from the sixth aortic arch and the pulmonary veins as outgrowths of the left atrium. Abnormalities during this stage result in congenital abnormalities such as lung aplasia, tracheoesophageal fistula, and congenital pulmonary cysts.

2. *Pseudoglandular stage* (5–17 weeks' gestation): During this stage, which overlaps with the embryonic stage, the lung has a glandular appearance. The conducting airways (bronchi and bronchioles) form over these 12 weeks. The respiratory epithelium of these airways begins to differentiate, and the presence of cartilage, smooth muscle cells, and mucus glands are first seen.

In addition, the pleuroperitoneal cavity divides into two distinct compartments. Abnormalities during this stage lead to pulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia.

3. *Canalicular stage* (16–26 weeks' gestation): This stage witnesses the delineation of the pulmonary acinus. The alveolar type II cells differentiate into type I cells, the pulmonary capillary network develops, and the alveolar type I cells closely approximate with the developing capillary network. Abnormalities of development during this stage include neonatal respiratory distress syndrome and lung hypoplasia.

4. *Saccular stage* (26–36 weeks' gestation): During this stage further branching of the terminal saccules takes place as well as a thinning of the interstitium and fusion of the type I cell and capillary basement membrane in preparation for the lungs' function as a gas-exchange organ. This stage sees the beginning of an exponential increase in the epithelial surface area for gas exchange. During this stage of lung development the lung is able to fulfill its function, in terms of a gas-exchange organ.

5. *Alveolar stage* (36 weeks' gestation to 3–8 years of age): Controversy surrounds the length of this stage of lung development. During this stage, secondary alveolar septa form to increase the surface area for gas exchange, the capillary network has a rapid phase of growth, and true alveoli develop. Abnormalities during this stage lead to lung hypoplasia and can result in the development of bronchopulmonary dysplasia (BPD).

At birth, the lung assumes the gas-exchanging function served by the placenta in utero, placing immediate stress on all components of the respiratory system. Any abnormality in the lung, respiratory muscles, chest wall, airway, central respiratory control, or pulmonary circulation may therefore

lead to problems at birth. For example, infants who are homozygous for an abnormality in the surfactant protein B gene will develop lethal pulmonary disease. Persistent pulmonary hypertension of the newborn due to a failure of the normal transition to a low-resistance pulmonary circulation at birth can complicate neonatal respiratory diseases. There is also mounting evidence that abnormalities during fetal and neonatal growth and development of the lung have long-standing effects into adulthood, such as reduced gas exchange, exercise intolerance, asthma, and an increased risk of chronic obstructive pulmonary disease.

▼ DIAGNOSTIC AIDS

PHYSICAL EXAMINATION OF THE RESPIRATORY TRACT

The four components of a complete pulmonary examination include inspection, palpation, auscultation, and percussion. *Inspection* of respiratory rate, depth, ease, symmetry, and rhythm of respiration is critical to the detection of pulmonary disease. In young children, an elevated respiratory rate may be an initial indicator of pneumonia or hypoxemia. In a study of children with respiratory illnesses, abnormalities of attentiveness, inconsolability, respiratory effort, color, and movement had a good diagnostic accuracy in detecting hypoxemia. *Palpation* of tracheal position, symmetry of chest wall movement, and vibration with vocalization can help in identifying intrathoracic abnormalities. For example, a shift in tracheal position can suggest pneumothorax or significant atelectasis. Tactile fremitus may change with consolidation or air in the pleural space. *Auscultation* should assess the quality of breath sounds and detect the presence of abnormal sounds such as fine or coarse crackles, wheezing, or rhonchi. Wheezing or prolonged expiratory compared to inspiratory time suggests intrathoracic airways obstruction. Tachypnea with an equal inspiratory and expiratory time suggests decreased lung compliance. Transmitted voice sounds in egophony and whispered pectoriloquy change with lung consolidation. It is important to know the lung anatomy in order to identify the location of abnormal findings (Figure 19–1). In older patients, unilateral crackles are the most valuable examination finding in pneumonia. *Percussion* may identify tympanic or
▲ **Figure 19–1.** Projections of the pulmonary lobes on the chest surface. The upper lobes are white, the right-middle lobe is the darker color, and the lower lobes are the lighter color.

dull sounds that can help define an intrathoracic process. (This component of the examination can prove challenging in young children, who may not cooperate.) Although chest radiography has replaced the utility of these tests, they can be helpful when imaging is not available.

Extrapulmonary manifestations of pulmonary disease include acute findings such as cyanosis and altered mental status and signs of chronic respiratory insufficiency such as growth failure, clubbing, and osteoarthropathy. Evidence of cor pulmonale (loud pulmonic component of the second heart sound, hepatomegaly, elevated neck veins, and rarely, peripheral edema) signifies pulmonary hypertension and may accompany advanced lung disease.

Respiratory disorders can be secondary to disease in other systems. It is therefore important to look for other conditions such as metabolic acidosis, congenital heart disease, neuromuscular disease, immunodeficiency, autoimmune disease, and occult malignancy (arthritis or hepatosplenomegaly). Children with an elevated body mass index are more likely to present with respiratory symptoms and need to be evaluated for pulmonary pathology versus deconditioning or dyspnea.

PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) are objective measures of lung and airway physiology that can help differentiate obstructive from restrictive lung diseases, measure disease severity, measure disease progression, and evaluate response to therapy. Because the range of predicted normal values changes with growth, serial determinations of lung function are often more informative than a single determination. Patient cooperation and consistent effort is essential for almost all standard physiologic assessments. With a well-trained technician in a comfortable environment aided by visual incentives, and an interactive computer-animated system, most children age 3 years and older can produce satisfactory results. Lung function measurements in infants and toddlers are available at centers with specialized equipment and expertise. Despite these limitations, tests of lung function are valuable in the care of children. Children with cystic fibrosis perform pulmonary function testing routinely as early as they can cooperate. The Expert Panel Report (3) recommends pulmonary function testing be performed routinely for evaluation and management of asthmatic children age 5 and older. Current spirometers use a pneumotachograph to record flow over time and produce a volume-time tracing (spirogram) or a flow-volume curve. The patient inhales maximally, holds his or her breath for a short period, and then exhales as fast and hard as possible until they reach residual volume or for at least 3 seconds. The values reported include: the forced vital capacity (FVC), which is the total volume of air that is exhaled; the forced expiratory volume in the first second of the exhalation (FEV_1); the ratio of the FEV_1/FVC; the forced expiratory flow at the middle of the vital capacity (FEF_{25-75}); and the peak expiratory flow rate (PEFR). A suggested range of normal for these measurements are included in Table 19–1 and examples are shown in the figures. Obstructive processes include asthma, bronchopulmonary dysplasia (BPD), and cystic fibrosis (CF). Restrictive lung disease can be caused by chest wall deformities that limit lung expansion, muscle weakness, and interstitial lung diseases such as collagen-vascular diseases, hypersensitivity pneumonitis, and interstitial fibrosis. Confirmation of restrictive lung or chest wall physiology requires lung volume measurements (eg, total lung capacity, residual volume, and functional residual capacity) because poor effort can mimic restrictive physiology. Lung volume measurements are usually only available at specialized centers. (For examples of pulmonary function tests, see Figures 19–2 to 19–4.)

The peak expiratory flow rate, the maximal flow recorded during an FVC maneuver, can be assessed by handheld devices. These devices are not as well calibrated as spirometers and the PEFR measurement can vary greatly with patient effort, so they are not good substitutes for actual spirometry. However, peak flow monitoring can be helpful in a patient with asthma that is difficult to control or for patients with poor perception of their airflow obstruction

ASSESSMENT OF OXYGENATION & VENTILATION

Arterial blood gas measurements define the acid-base balance between respiration at the tissue level and that in the lungs. Blood gas measurement is essential in critically ill children to evaluate hypoxemia, acidosis, and hypercarbia. Blood gas measurements can be used to categorize acid-base disturbances as respiratory, metabolic, or mixed. Blood gas measurements are affected by abnormalities of respiratory control, gas exchange, respiratory mechanics, and the circulation. In pediatrics, hypoxemia (low partial pressure of arterial oxygen [Pao_2]) most commonly results from ventilation (V') and perfusion (Q') mismatch. Common pediatric diseases that may be associated with hypoxemia due to V'/Q' mismatch include acute asthma, cystic fibrosis (CF), pneumonia, bronchiolitis, and bronchopulmonary dysplasia (BPD). Other causes of hypoxemia include hypoventilation, shunts, and diffusion barrier for oxygen. Hypercapnia (elevated partial pressure of arterial carbon dioxide [$Paco_2$]) results from inadequate alveolar ventilation (ie, inability to clear the CO_2 produced). This is termed *hypoventilation*. Causes include decreased central respiratory drive, respiratory muscle weakness, and low-tidal-volume breathing as seen in restrictive lung diseases, severe scoliosis, or chest wall trauma. Hypercapnea can also occur when severe V'/Q' mismatch is present which may occur with severe CF or BPD. Table 19–2 gives normal values for arterial pH, Pao_2, and $Paco_2$ at sea level and at 5000 ft.

▲ **Figure 19–3.** Flow volume loops from a child with asthma (obstructive pattern).

Venous blood gas analysis or capillary blood gas analysis can be useful for the assessment of P_{CO_2} and pH, but not P_{O_2} or saturation. Noninvasive assessment of oxygenation can be achieved with pulse oximetry (measuring light absorption by transilluminating the skin). Oxygenated hemoglobin absorbs light at different wavelengths than deoxygenated hemoglobin. Measurement during a systolic pulse allows estimation of arterial oxygen saturation. No heating of the skin is necessary. Values of oxygen saturation are reliable as low as 80%. The pulse oximeter has reduced reliability during conditions causing reduced arterial pulsation such as hypothermia, hypotension, or infusion of vasoconstrictor drugs. Carbon monoxide bound to hemoglobin results in falsely high oxygen saturation readings. Transcutaneous assessment of Pa_{O_2} is not commonly utilized because of the multiple factors that can interfere with accurate measurements.

Exhaled or end-tidal CO_2 monitoring can be used to noninvasively estimate arterial CO_2 content. It is used to monitor alveolar ventilation and is most accurate in patients without significant lung disease, particularly those with a good match of ventilation and perfusion and without airway obstruction. Monitoring of exhaled or end-tidal CO_2 is commonly used during a polysomnogram and by anesthesia. Transcutaneous P_{CO_2} monitoring is also feasible but may be less reliable than transcutaneous P_{O_2} monitoring and should be used with caution if at all.

DIAGNOSIS OF RESPIRATORY TRACT INFECTIONS

Respiratory tract infections may be caused by bacteria, viruses, atypical bacteria (eg, *Mycoplasma pneumonia* and *Chlamydia pneumoniae*), *Mycobacterium tuberculosis,* nontuberculous mycobacterium, or fungi (eg, *Aspergillus and Pneumocystis jiroveci)*. The type of infection suspected and appropriate diagnostic tests vary depending on host factors such as underlying lung disease, immune function, and geographic region. Sources of respiratory tract secretions for diagnostic testing include nasopharyngeal and oropharyngeal swabs; expectorated and induced sputum; tracheal aspirates; direct lung or pleural fluid sampling; bronchoalveolar lavage fluid; and gastric aspirates, specifically for *M tuberculosis*. Blood and urine samples may also be used for serologic and antigen testing. Spontaneously expectorated sputum is the least invasive way to collect a sample for diagnostics, though it is rarely available from patients younger than age 6 years. Sputum

induction, performed by inhaling aerosolized hypertonic saline, is a relatively safe, noninvasive means of obtaining lower airway secretions. Sputum induction has been used in patients with CF and may be useful in patients with suspected *M tuberculosis, P jiroveci* pneumonia, or complicated community-acquired pneumonia. Tracheal aspirates can be obtained easily from patients with endotracheal or tracheostomy tubes. Culture of respiratory tract samples is the most commonly used approach to detect and identify airway pathogens. Molecular diagnostic tests, based on PCR amplification and detection of nucleic material from microbes, may offer more rapid and sensitive testing for microbes. Molecular assays are used for detection of viruses and atypical bacteria in many laboratories. PCR is also used as an adjunct to culture for identification of *M tuberculosis,* nontuberculous mycobacteria, and some fastidious bacteria. Molecular approaches to the diagnosis of *M tuberculosis* and *P jiroveci* are also available and their use is likely to become more widespread.

IMAGING OF THE RESPIRATORY TRACT

The plain chest radiograph remains the foundation for investigating the pediatric thorax. Both frontal (posterior-anterior) and lateral views should be obtained if feasible. The radiograph is useful for evaluating chest wall abnormalities, heart size and shape, mediastinum, diaphragm, and lung parenchyma. When pleural fluid is suspected, lateral decubitus radiographs may be helpful in determining the extent and mobility of the fluid. When a foreign body is suspected, forced expiratory radiographs may show focal air trapping and shift of the mediastinum to the contralateral side. Lateral neck radiographs can be useful in assessing the size of adenoids and tonsils and also in differentiating croup from epiglottitis, the latter being associated with the "thumbprint" sign.

Barium swallow is indicated for detection of swallowing dysfunction in patients with suspected aspiration, tracheoesophageal fistula, gastroesophageal reflux, vascular rings and slings, and achalasia. Airway fluoroscopy assesses both fixed airway obstruction (eg, tracheal stenosis, masses, or tracheal compression) and dynamic airway obstruction (eg, tracheomalacia). Fluoroscopy or ultrasound of the diaphragm can detect paralysis by demonstrating paradoxic movement of the involved hemidiaphragm.

Chest CT is useful in evaluation of congenital lung lesions, pleural disease (eg, effusion or recurrent pneumothorax), mediastinum (eg, lymphadenopathy), pulmonary nodules or masses. High-resolution CT is best for evaluating interstitial lung disease (ILD) or bronchiectasis while decreasing radiation exposure compared to a standard CT. Magnetic resonance imaging (MRI) is useful for defining vascular or bronchial anatomical abnormalities. Ventilation-perfusion scans can provide information about regional ventilation and perfusion and can help detect vascular malformations and pulmonary emboli. Pulmonary angiography is occasionally necessary to define the pulmonary vascular bed more precisely. Recent concerns about radiation exposure in children led to the *Image Gently* campaign, an initiative of The Alliance for Radiation Safety in Pediatric Imaging, dedicated to increasing awareness of the need for radiation protection for children. Identified challenges include the need for continued education particularly at adult-focused hospitals, increased emphasis on appropriateness of pediatric imaging and outcomes research to validate the use of CT, and establishing ranges of optimal CT technique when imaging children.

LARYNGOSCOPY & BRONCHOSCOPY

Direct visualization of the airways may be necessary to establish the etiology of the respiratory problem despite an extensive history and physical and sophisticated imaging. This can be achieved with rigid or flexible instrumentation. Indications for laryngoscopy include hoarseness, stridor, symptoms of obstructive sleep apnea, and laryngeal wheezing. Indications for bronchoscopy include wheezing, suspected foreign body, recurrent pneumonia, persistent atelectasis, chronic cough, and hemoptysis. A flexible bronchoscope can also be used to assess placement and patency of an endotracheal tube. In general, the more specific the indication, the higher the diagnostic yield. Each method, rigid or flexible, has advantages and for some patients both should be employed sequentially under the same anesthesia.

The rigid, open tube instruments have the best optics and allow surgical intervention to be easily achieved such as removal of a foreign body. Rigid bronchoscopy is done with general anesthesia. Flexible laryngoscopy may be done with topical anesthesia or light sedation and flexible bronchoscopy can be done with either conscious sedation or general anesthesia. The flexible bronchscopy is of a smaller caliber and allows more distal examination of the airways. Because

it is smaller, the flexible bronchoscope does not stent the airway open during the procedure and often dynamic airway collapse is more easily documented by the flexible procedure. Bronchoalveolar lavage is useful to sample the alveolar space for infection, inflammation, hemorrhage, or aspiration. Although removal of foreign bodies has been achieved with the flexible bronchoscope in larger children, the standard of care in most institutions is to remove foreign bodies via the rigid bronchoscope.

Transbronchial biopsy in children is limited to evaluation of infection and rejection in lung transplant patients. There is low diagnostic yield in most conditions. Transbronchial biopsy may have a role in sarcoidosis. Video-assisted thoracoscopic lung biopsy (VATS) provides a more substantial specimen for pathologic assessment.

◥ GENERAL THERAPY OF PEDIATRIC LUNG DISEASES

OXYGEN THERAPY

The goal of supplemental oxygen (O_2) therapy is to relieve hypoxemia. Supplemental oxygen can reduce the work of breathing, resulting in fewer respiratory symptoms; relax the pulmonary vasculature, lessening the potential for pulmonary hypertension and congestive heart failure; and improve feeding. Patients breathing spontaneously can be treated by nasal cannula, head hood, or mask (including simple, rebreathing, nonrebreathing, or Venturi masks). The goal of O_2 therapy is to achieve an arterial oxygen tension of 65–90 mm Hg or an oxygen saturation above 92%, although lower Pao_2 or Spo_2 levels may be acceptable in certain situations. The actual O_2 concentration achieved by nasal cannula or mask depends on the flow rate, the type of mask used, and the patient's age. Small changes in flow rate during oxygen administration by nasal cannula can lead to substantial changes in inspired oxygen concentration in young infants. The amount of oxygen required to correct hypoxemia may vary according to the child's activity. It is not unusual, for example, for an infant with chronic lung disease to require 0.75 L/min while awake but 1 L/min while asleep or feeding.

Although the head hood is an efficient device for delivery of oxygen in young infants, the nasal cannula is used more often because it allows greater mobility. The cannula has nasal prongs that are inserted in the nares. Flow through the cannula should generally not exceed 3 L/min to avoid excessive drying of the mucosa. Even at high flow rates, oxygen by nasal cannula rarely delivers inspired oxygen concentrations greater than 40%–45%. In contrast, partial rebreathing and nonrebreathing masks or head hoods achieve inspired oxygen concentrations as high as 90%–100%. Heated high-flow nasal cannulas have been developed recently to deliver a high flow rate without a high Fio_2.

Physical findings of hypoxemia are subtle. Adequate oxygenation should be measured by the arterial oxygen tension or pulse oximetry. The advantages of the latter noninvasive method include the ability to obtain continuous measurements during normal activities and to avoid artifacts caused by crying or breath-holding during arterial puncture. For children with cardiopulmonary disorders that require chronic supplemental oxygen therapy (eg, bronchopulmonary dysplasia or cystic fibrosis), frequent noninvasive assessments are essential to ensure the safety and adequacy of O_2 treatment.

Ralston M et al (eds): *Pediatric Advanced Life Support Provider Manual.* American Heart Association and American Academy of Pediatrics; 2006.

INHALATION OF MEDICATIONS

Inhalation of medications is a mainstay of therapy for pediatric respiratory conditions and are routinely used in patients with chronic diseases such as cystic fibrosis (CF), bronchopulmonary dysplasia (BPD), and asthma, as well as in acute illnesses such as infectious laryngotracheobronchitis and bronchiolitis (Table 19–3). Short-acting β-agonists and anticholinergics provide acute bronchodilation (relievers), whereas inhaled corticosteroids and cromones provide anti-inflammatory effects (controllers). Nebulized antibiotics have documented benefit in CF and nebulized mucolytic medications are used in CF and other conditions with impaired secretion control such as non-CF bronchiectasis.

The medications can be delivered by pressurized metered dose inhaler (pMDI), dry powder inhaler (DPI), or compressed air-driven wet nebulization. Careful attention to delivery technique is critical to optimize medication delivery to the airways. A valved holding chamber or similar spacer should be used with pMDI use, and this technique has been shown to be effective in infants as young as 4 months of age. A face-mask interface is recommended for both pMDI and wet nebulization in infants and toddlers; a simple mouth piece suffices for older children who can form a seal around the mouth piece. Delivery technique should be assessed and reviewed at each clinical visit.

Table 19–3. Common uses for inhaled medications in pediatric respiratory illness.

Disease Process	Short-Acting Bronchodilator	Anticholinergic Bronchodilator	Inhaled Steroid	Other
Asthma	Acute relief prior to exercise	Acute relief	Chronic use for control	Inhaled corticosteroid + long-acting bronchodilator for control
Bronchopulmonary dysplasia	Acute relief	Acute relief	Control if bronchial reactivity is present	
Cystic fibrosis	Prior to airway clearance	Limited data	Control if bronchial reactivity is present	Mucolytics and inhaled antibiotics
Infectious laryngotracheo-bronchitis (croup)	Acute relief (racemic epinephrine)		Acute relief (nebulized steroid)	
Bronchiolitis (acute infectious)	Acute relief (may have limited benefit)			Recent interest in inhaled epinephrine and hypertonic saline

Janssens HM, Tiddens HA: Aerosol therapy: the special needs of young children. Paediatr Respir Rev 2006;7(Suppl 1) [PMID: 16798606].

AIRWAY CLEARANCE THERAPY

Chest physical therapy, with postural drainage, percussion, and forced expiratory maneuvers, has been widely used to improve the clearance of lower airway secretions in children with CF, bronchiectasis, and neuromuscular disorders. Currently available airway clearance techniques include: chest physiotherapy, autogenic drainage, blowing therapies (bubbles, pinwheels), active coughing, positive expiratory pressure (PEP) with handheld devices, intrapulmonary percussive ventilation, or high-frequency chest compression. The decision about which technique to use should be based on the patient's age and preference after trying different approaches. Daily exercise is an important adjunctive therapy for airway clearance and overall lung health. Cough assist devices (eg, mechanical insufflator-exsufflators) are useful for children with a weak cough. For example, they are useful for children with neuromuscular disorders such as muscular dystrophy and spinal muscular atrophy. Bronchodilators or mucolytic medications may be given prior to or during airway clearance therapy. Inhaled corticosteroids and inhaled antibiotics should be given after airway clearance therapy so that the airways are first cleared of secretions, allowing the medications to maximally penetrate into the lung. Airway clearance has not been shown to be beneficial for patients with acute respiratory illnesses such as pneumonia, bronchiolitis, and asthma.

AVOIDANCE OF ENVIRONMENTAL HAZARDS

Environmental insults can aggravate existing lung diseases and impair pulmonary function, and probably cause lung disease in children. Outdoor air pollution (ozone and particulates), indoor pollution, diesel exhaust, and household fungi are examples. Environmental tobacco poisoning, either second or third hand, dramatically increases childhood pulmonary morbidity. Many adolescents personally abuse tobacco and become addicted. Public health policies that limit smoke exposure and reduce advertising to children have had a positive impact. Smoking family members should be admonished to quit smoking and do everything possible to minimize environmental smoke exposure to the children around them. Homes with mold should have remediation, particularly if children with lung disease are in residence. Ozone exposure can be limited by avoiding outdoor activities during the height of daily ozone levels, but additional public policy changes will be required to further reduce ozone pollutants in the air.

For children with asthma, family pets may be a significant trigger as can household cockroach infestation. Despite the known risk, many families are reluctant to eliminate risk of exposure to the pet. Families should also be counseled about risks of foreign body aspiration in curious toddlers.

DISORDERS OF THE CONDUCTING AIRWAYS

The conducting airways include the nose, mouth, pharynx, larynx, trachea, bronchi, and terminal bronchioles. These airways direct inspired air to the gas-exchange units of the lung but do not participate in gas exchange. Airflow obstruction in the conducting airways can occur at extrathoracic sites (eg, above the thoracic inlet) or at intrathoracic sites (eg, below the thoracic inlet). Extrathoracic or upper airway obstruction disrupts the inspiratory phase of respiration and is often manifest by stridor or "noisy breathing." Intrathoracic obstruction disrupts the expiratory phase of respiration and is often manifest by wheezing and prolongation of the expiratory phase. After assessing whether the obstruction is extrathoracic or intrathoracic the next challenge is to determine if the obstruction is fixed or variable. Fixed obstructions disrupt each breath and the abnormal sounds are consistently heard. Fixed obstructions can be intrinsic to the airway or due to airway compression (extrinsic). They are often associated with anatomic abnormalities that may be amenable to surgical correction (Table 19–4).

Variable obstruction leads to abnormal sounds with breathing that are softer or absent with normal quiet breathing and may sound different with every breath. Variable obstructions are often due to dynamic changes in airway caliber that occurs with laryngomalacia, tracheomalacia, or bronchomalacia. The onset and progression of the obstruction can provide important clues as to the etiology and help determine the urgency of evaluation and management. Obstructions due to dynamic airway collapse often improve with age, whereas fixed obstructions typically progress or fail to improve with age. Acute onset extrathoracic obstruction is often infectious. Clinical indications that the obstruction is severe include high-pitched stridor or wheezing, biphasic stridor, drooling or dysphagia, poor-intensity breath sounds, severe retractions, and poor color or cyanosis.

Helpful diagnostic studies in the evaluation of extrathoracic obstruction include chest and lateral neck radiographs, airway fluoroscopy, and barium swallow. Patients who have symptoms of severe chronic obstruction should have an electrocardiogram and/or ECHO to evaluate for right ventricular hypertrophy and pulmonary hypertension. Patients suspected to have obstructive sleep apnea should have polysomnography (see section on Sleep Disordered Breathing). Diagnostic studies for intrathoracic obstruction include two-view chest radiographs, a sweat test, and pulmonary function tests. Other diagnostic studies are dictated by the history and physical findings. If asthma is suspected, a trial of bronchodilators and/or anti-inflammatories should be considered. If noninvasive studies are unable to establish the cause of airway obstruction, laryngoscopy and bronchoscopy remain the procedures of choice to establish the precise diagnosis. In older children, pulmonary function tests can differentiate fixed from variable airflow obstruction and may identify the site of obstruction. Treatment should be directed at relieving airway obstruction and correcting the underlying condition if possible.

Table 19–4. Classification and causes of upper airway obstruction.

Fixed, Extrathoracic, Not Acute	Fixed, Extrathoracic, Acute	Fixed Intrathoracic, Intrinsic	Fixed, Intrathoracic, Extrinsic
Vocal cord paralysis	Infectious laryngotracheobronchitis	Tracheal stenosis	Tumor (compressing the airways)
Laryngeal atresia/web	Epiglottitis	Complete tracheal rings	Vascular ring or sling
Laryngocele/cyst	Bacterial tracheitis	Foreign body aspiration	Bronchogenic cyst
Laryngeal papillomas	Anaphylaxis	Endobronchial tumor	Congenital pulmonary airway malformation
Subglottic hemangioma	Angioneurotic edema		Esophageal duplication
Tracheal web	Foreign body aspiration		Congenital lobar overdistention
Peritonsillar abscess			
Choanal atresia			
Retropharyngeal abscess			

LARYNGOMALACIA & CONGENITAL DISORDERS OF THE EXTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Presentation from birth or within the first few months of life.
▶ Intermittent, high-pitched, inspiratory stridor.
▶ Moderate to severe symptoms require visualization of the airway.

LARYNGOMALACIA

Laryngomalacia is a benign congenital disorder in which the cartilaginous support for the supraglottic structures is underdeveloped. It is the most common cause of variable extrathoracic airway obstruction and manifests as **intermittent stridor** in infants and usually is seen in the first 6 weeks of life. Stridor has been reported to be worse in the supine position, with increased activity, with upper respiratory infections, and during feeding; however, the clinical presentation can be variable. Patients may have slight oxygen desaturation during sleep. The condition usually improves with age and resolves by the time the child is 2 years old, but in some cases symptoms persist for years. The diagnosis is established by direct laryngoscopy, which shows inspiratory collapse of an omega-shaped epiglottis (with or without long, redundant arytenoids). In mildly affected patients with no stridor at rest and no retractions, treatment is not usually needed. Patients with either severe symptoms of airway obstruction such as stridor with each breath, retractions, and increased work of breathing or more chronic signs such as feeding difficulties, failure to thrive, obstructive sleep apnea, hypoxemia, or severe dyspnea may benefit from surgical epiglottoplasty.

Meier JD et al: Improved growth curve measurements after supraglottoplasty. The Laryngoscope 2011;121(7):1574 [PMID: 21647914].
Thompson DM et al: Laryngomalacia: factors that influence disease severity and outcomes of management. Curr Opin Otolaryngol Head Neck Surg 2010;18(6):564 [PMID: 20962644].

OTHER CAUSES OF CONGENITAL EXTRATHORACIC OBSTRUCTION

Other congenital lesions of the larynx such as laryngeal atresia, laryngeal web, laryngocele and cyst of the larynx, subglottic hemangioma, and laryngeal cleft usually present as fixed extrathoracic obstruction and are best evaluated by direct laryngoscopy.

Laryngeal atresia presents at birth with severe respiratory distress and is usually fatal. Laryngeal web, representing fusion of the anterior portion of the true vocal cords, is associated with hoarseness, aphonia, and stridor. Surgical correction is usually necessary. Laryngeal cysts and lanryngocoeles present with stridor and significant airway obstruction. Laryngeal cysts are superficial and are generally fluid filled. Laryngoceles communicate with the interior of the larynx and may be either air- or fluid-filled. Both require surgery or laser therapy.

Subglottic hemangiomas are a rare cause of upper airway obstruction in infants and are associated with cutaneous vascular lesions of the skin in 50%–60% of patients. Although vascular malformations regress spontaneously, airway obstruction usually necessitates intervention. Medical management options include propranolol, systemic steroids, or intralesional steroids. Surgical intervention with laser ablation is usually successful, but rarely tracheostomy is required. Laryngeal cleft is an uncommon condition resulting from failure of posterior cricoid fusion. Patients present with stridor, dysphagia, or silent aspiration. A type 1 laryngeal cleft (above the vocal cords) may not show aspiration on a modified barium swallow while more severe type 2 and 3 laryngeal clefts almost always do. All types of clefts may result in recurrent or chronic pneumonia and failure to thrive. The diagnosis is made by direct laryngoscopy with attention to spreading the glottis structures apart and assessing for the absence of tissue above the vocal folds. The decision to correct type 1 clefts should be made after multidisciplinary consideration of the pulmonary complications and other comorbidities. Repair of type 1 clefts may be addressed surgically or with an injection laryngoplasty. More severe clefts require surgical repair and may require tracheostomy. Normal swallow function without aspiration may take months to occur, even after repair.

ACQUIRED DISORDERS OF THE EXTRATHORACIC AIRWAY

Acquired disorders of the extrathoracic airway can present acutely or with recurrent symptoms of upper airway obstruction. Children with acquired disorders of the extrathoracic airway present with inspiratory sounds consistent

with stridor. The pitch of the sound varies depending on the diagnosis. Upper airway obstruction can progress quickly and may be life-threatening, requiring close observation.

FOREIGN BODY ASPIRATION IN THE EXTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Sudden onset of coughing or respiratory distress.
▶ Difficulty vocalizing.

Aspiration of a foreign body into the respiratory tract is a significant cause of accidental death each year.

The foreign body can lodge anywhere along the respiratory tract. Foreign bodies that lodge in the esophagus may compress the airway and cause respiratory distress. More typically, the foreign body lodges in the supraglottic airway, triggering protective reflexes that result in laryngospasm. Small objects such as coins may pass through the glottis and obstruct the trachea. Objects that pass into the lower airway cause coughing but more variable respiratory distress (see section Acquired Causes of Intrathoracic Airway Obstruction).

Foreign body aspiration is commonly seen with small, round foods such as nuts and seeds, berries, corn/popcorn, hot dogs, and beans. Children 6 months to 4 years are at highest risk. Homes and child care centers in which an older sibling or child feeds age-inappropriate foods (eg, peanuts, hard candy, or carrot slices) to the younger child are typical. Without treatment, progressive cyanosis, loss of consciousness, seizures, bradycardia, and cardiopulmonary arrest can follow.

▶ Clinical Findings

Signs at the time of ingestion can include coughing, choking, or wheezing. Onset is generally abrupt, with a history of the child running with food in the mouth or playing with seeds, small coins, or toys.

The diagnosis is established by acute onset of choking along with *inability* to vocalize or cough and cyanosis with marked distress (complete obstruction), or with drooling, stridor, and *ability* to vocalize (partial obstruction). Chest x-rays and other imaging studies have been used to evaluate for foreign body ingestion. However, rigid bronchoscopy is the gold standard for diagnosis.

▶ Treatment

The emergency treatment of upper airway obstruction due to foreign body aspiration has changed over the last few years. If *complete* obstruction is present, then one must intervene immediately. If partial obstruction is present, then the choking subject should be allowed to use his or her own cough reflex to remove the foreign body. If, after a brief observation period, the obstruction increases or the airway becomes completely obstructed, acute intervention is required. The American Academy of Pediatrics and the American Heart Association distinguish between children younger than and older than 1 year of age. In an awake child younger than 1 year of age with a complete obstruction, the child should be placed face down over the rescuer's arm. Five measured back blows are delivered rapidly followed by rolling the infant over and delivering 5 rapid chest thrusts. This sequence is repeated until the obstruction is relieved. In a choking child older than 1 year of age, abdominal thrusts (Heimlich maneuver) should be performed, with special care in younger children because of concern about possible intra-abdominal organ injury. If the child of any age becomes unresponsive, cardiopulmonary resuscitation is recommended. Chest compressions may help to dislodge the foreign body.

Blind finger sweeps should *not* be performed in infants or children because the finger may push the foreign body further into the airway causing worse obstruction. The airway may be opened by jaw thrust, and if the foreign body can be directly visualized, careful removal with the fingers or instruments should be attempted. Patients with persistent apnea and inability to achieve adequate ventilation may require emergency intubation, tracheotomy, or needle cricothyrotomy, depending on the setting and the rescuer's skills. Foreign body removal is most successfully performed using a rigid bronchoscopy under general anaesthesia.

Berg MD et al: Pediatric basic life support: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Pediatrics 2010 Nov;126(5):e1345-60. doi: 10.1542/peds.2010-2972C. Epub 2010 Oct 18 [PMID:20956430].

Fiedkowski CW, Zheng H, Firth PG: The anesthetic considerations of tracheobronchial foreign bodies in children: a literature review of 12,979 cases. Anesth Analg 2010;111(4):1016–1025 [PMID: 20802055].

CROUP SYNDROMES

Croup describes acute inflammatory diseases of the larynx, including viral croup (laryngotracheobronchitis), epiglottitis (supraglottitis), and bacterial tracheitis. These are the main entities in the differential diagnosis for patients presenting with acute stridor, although spasmodic croup, angioedema, laryngeal or esophageal foreign body, and retropharyngeal or peritonsillar abscess should be considered as well.

1. Viral croup

Viral croup generally affects young children 6 months to 5 years of age in the fall and early winter months and is

most often caused by parainfluenza virus serotypes. Other organisms causing croup include respiratory syncytial virus (RSV), human coronavirus NL63, rhinovirus, human meta-pneumovirus, influenza virus A&B, rubeola virus, adenovirus, and *M pneumoniae*. Although inflammation of the entire airway is usually present, edema formation in the subglottic space accounts for the predominant signs of upper airway obstruction.

▶ Clinical Findings

A. Symptoms and Signs

Usually a prodrome of upper respiratory tract symptoms is followed by a barking cough and stridor. Fever is usually absent or low-grade but may on occasion be high-grade. Patients with mild disease may have stridor when agitated. As obstruction worsens, stridor occurs at rest, accompanied in severe cases by retractions, air hunger, and cyanosis. On examination, the presence of cough and the absence of drooling favor the diagnosis of viral croup over epiglottitis.

B. Imaging

Anteroposterior and lateral neck radiographs in patients with classic presentations are not required but can be diagnostically supportive if the x-ray shows subglottic narrowing (the steeple sign) without the irregularities seen in tracheitis and a normal epiglottis. However, a severely ill patient should never be left unattended in the imaging suite.

▶ Treatment

Treatment of viral croup is based on the symptoms. Mild croup, signified by a barking cough and no stridor at rest, requires supportive therapy with oral hydration and minimal handling. Mist therapy has historically been used but clinical studies do not demonstrate effectiveness. Conversely, patients with stridor at rest require active intervention. Oxygen should be administered to patients with oxygen desaturation. Nebulized racemic epinephrine (0.5 mL of 2.25% solution diluted in sterile saline) is commonly used because it has a rapid onset of action within 10–30 minutes. Both racemic epinephrine and epinephrine hydrochloride (L-epinephrine, an isomer) are effective in alleviating symptoms and decreasing the need for intubation.

The efficacy of glucocorticoids in croup is now firmly established. Dexamethasone, 0.6 mg/kg intramuscularly as one dose, improves symptoms, reduces the duration of hospitalizations and frequency of intubations, and permits earlier discharge from the emergency department. Oral dexamethasone (0.15 mg/kg) may be equally effective for mild to moderate croup. Inhaled budesonide (2–4 mg) also improves symptoms and decreases hospital stay and may be as effective as dexamethasone. Dexamethasone has also been shown to be more effective than prednisolone in equivalent doses.

If symptoms resolve within 3 hours of glucocorticoids and nebulized epinephrine, patients can safely be discharged without fear of a sudden rebound in symptoms. If, however, recurrent nebulized epinephrine treatments are required or if respiratory distress persists, patients require hospitalization for close observation, supportive care, and nebulization treatments as needed. In patients with impending respiratory failure, an airway must be established. Intubation with an endotracheal tube of slightly smaller diameter than would ordinarily be used is reasonably safe. Extubation should be accomplished within 2–3 days to minimize the risk of laryngeal injury. If the patient fails extubation, tracheostomy may be required. Other underlying causes should be considered in hospitalized patients with persistent symptoms over 3–4 days despite treatment.

▶ Prognosis

Most children with viral croup have an uneventful course and improve within a few days. Some evidence suggests that patients with a history of croup associated with wheezing may have airway hyperreactivity. It is not always clear if the hyperreactivity was present prior to the croup episode or if the viral infection causing croup altered airway function.

Bjornson CL, Johnson DW: Croup. The Lancet 2008;371(9609):329 [PMID: 18295000].

2. Epiglottitis

With the introduction of the *Haemophilus influenzae* conjugate vaccine, the incidence of epiglottitis has dramatically decreased and epiglottitis is rare in countries with immunization programs. If disease occurs, it is likely to be associated with *H influenzae* in unimmunized children, or another organism such as nontypeable *H influenzae, Neisseria meningitides,* or *Streptococcus* species in immunized populations.

▶ Clinical Findings

A. Symptoms and Signs

The classic presentation is a sudden onset of high fever, dysphagia, drooling, muffled voice, inspiratory retractions, cyanosis, and soft stridor. Patients often sit in the so-called sniffing dog position, with the neck hyperextended and the chin stretched forward, which gives them the best airway possible under the circumstances. Progression to total airway obstruction may occur and result in respiratory arrest. The definitive diagnosis is made by direct inspection of the epiglottis, a procedure that should be done by an experienced airway specialist under controlled conditions (typically in the operating room during intubation). The typical findings are a cherry-red and swollen epiglottis and swollen arytenoids.

B. Imaging

Diagnostically, lateral neck radiographs may be helpful in demonstrating a classic "thumbprint" sign caused by the swollen epiglottis. Obtaining radiographs, however, may delay important airway intervention.

▶ Treatment

Once the diagnosis of epiglottitis is made, endotracheal intubation must be performed immediately in children but not necessarily in adult populations. Most anesthesiologists prefer general anesthesia (but not muscle relaxants) to facilitate intubation. After an airway is established, cultures of the blood and epiglottis should be obtained and the patient should be started on appropriate intravenous antibiotics to cover *H influenzae* and *Streptococcus* species (ceftriaxone sodium or an equivalent cephalosporin). Extubation can usually be accomplished in 24–48 hours, when direct inspection shows significant reduction in the size of the epiglottis. Intravenous antibiotics should be continued for 2–3 days, followed by oral antibiotics to complete a 10-day course.

▶ Prognosis

Prompt recognition and appropriate treatment usually results in rapid resolution of swelling and inflammation. Recurrence is unusual.

Guardiani E et al: Supraglottitis in the era following widespread immunization against *Haemophilus influenzae* type B: evolving principles in diagnosis and management. The Laryngoscope 2010;120(11):2183 [PMID: 20925091].

Tibballs J et al: Symptoms and signs differentiating croup and epiglottitis. J Paediatr Child Health 2011;47(3):77 [PMID: 21091577].

3. Bacterial Tracheitis

Bacterial tracheitis (pseudomembranous croup) is a severe life-threatening form of laryngotracheobronchitis. As the management of severe viral croup has been improved with the use of dexamethasone and vaccination has decreased the incidence of epiglottitis, tracheitis is a more common cause of a pediatric airway emergency requiring admission to the pediatric intensive care unit. This diagnosis must be high in the differential when a patient presents with severe upper airway obstruction and fever. The organism most often isolated is *Staphylococcus aureus,* but organisms such as *H influenzae,* group A *Streptococcus pyogenes, Neisseria* species, *Moraxella catarrhalis,* and others have been reported. A viral prodrome is common. Viral coinfections are described and should be treated especially in Influenza A and H1N1. The disease probably represents localized mucosal invasion of bacteria in patients with primary viral croup, resulting in inflammatory edema, purulent secretions, and pseudomembranes. Although cultures of the tracheal secretions are frequently positive, blood cultures are almost always negative.

▶ Clinical Findings

A. Symptoms and Signs

The early clinical picture is similar to that of viral croup. However, instead of gradual improvement, patients develop higher fever, toxicity, and progressive or intermittent severe upper airway obstruction that is unresponsive to standard croup therapy. The incidence of sudden respiratory arrest or progressive respiratory failure is high; in such instances, airway intervention is required. Findings of toxic shock and the acute respiratory distress syndrome may also be seen. Recently, subsets of patients with tracheal membranes have been reported with a less severe initial clinical presentation. Nevertheless, these patients are still at risk for life-threatening airway obstruction. Aggressive medical treatment and debridement still must occur in these patients.

B. Laboratory Findings and Imaging

The white cell count is usually elevated with a left shift. Cultures of tracheal secretions usually demonstrate one of the causative organisms. Lateral neck radiographs show a normal epiglottis but severe subglottic and tracheal narrowing. Irregularity of the contour of the proximal tracheal mucosa can frequently be seen radiographically and should elicit concern for tracheitis. Bronchoscopy showing a normal epiglottis and the presence of copious purulent tracheal secretions and membranes confirms the diagnosis.

▶ Treatment

Patients with suspected bacterial tracheitis will require direct visualization of the airway in a controlled environment and debridement of the airway. Most patients will be intubated because the incidence of respiratory arrest or progressive respiratory failure and respiratory arrest is high. Patients may also require further debridement, humidification, frequent suctioning, and intensive care monitoring to prevent endotracheal tube obstruction by purulent tracheal secretions. Intravenous antibiotics to cover *S aureus, H influenzae,* and the other organisms are indicated. Thick secretions persist for several days, usually resulting in longer periods of intubation for bacterial tracheitis than for epiglottitis or croup. Despite the severity of this illness, the reported mortality rate is very low if it is recognized and treated promptly.

Tebruegge M et al: Bacterial tracheitis: a multi-centre perspective. Scand J Infect Dis 2009;41(8):548-557. [PMID: 19401934].

VOCAL CORD PARALYSIS

Unilateral or bilateral vocal cord paralysis may be congenital, or more commonly may result from injury to the recurrent laryngeal nerves. Risk factors for acquired paralysis include difficult delivery (especially face presentation), neck and thoracic surgery (eg, ductal ligation or repair of tracheoesophageal fistula), trauma, mediastinal masses, and central nervous system disease (eg, Arnold-Chiari malformation). Patients may present with varying degrees of hoarseness, aspiration, or high-pitched stridor. Unilateral cord paralysis is more likely to occur on the left because of the longer course of the left recurrent laryngeal nerve and its proximity to major thoracic structures. Patients with unilateral paralysis are usually hoarse but rarely have stridor. With bilateral cord paralysis, the closer to midline the cords are positioned, the greater the airway obstruction; the more lateral the cords are positioned, the greater the tendency to aspirate and experience hoarseness or aphonia. If partial function is preserved (paresis), the adductor muscles tend to operate better than the abductors, with a resultant high-pitched inspiratory stridor and normal voice.

Airway intervention (tracheostomy) is rarely indicated in unilateral paralysis but is often necessary for bilateral paralysis. Clinically, paralysis can be assessed by direct visualization of vocal cord function with laryngoscopy or more invasively by recording the electrical activity of the muscles (electromyography). Electromyogram recordings can differentiate vocal fold paralysis from arytenoid dislocation, which has prognostic value. Recovery is related to the severity of nerve injury and the potential for healing.

Khariwala SS et al: Laryngotracheal consequences of pediatric cardiac surgery. Arch Otolaryngol Head Neck Surg 2005;131:336 [PMID: 15837903].

SUBGLOTTIC STENOSIS

Subglottic stenosis may be congenital, or more commonly may result from endotracheal intubation. Neonates and infants are particularly vulnerable to subglottic injury from intubation. The subglottis is the narrowest part of an infant's airway, and the cricoid cartilage, which supports the subglottis, is the only cartilage that completely encircles the airway. This area is therefore susceptible to injury while patients have an endotracheal tube inserted. The clinical presentation may vary from totally asymptomatic to the typical picture of severe upper airway obstruction. Patients with signs of stridor who repeatedly fail extubation are likely to have subglottic stenosis. Subglottic stenosis should also be suspected in children with multiple, prolonged, or severe episodes of croup. Diagnosis is made by direct visualization of the subglottic space with bronchoscopy and maneuvers to size the airway. Tracheostomy is often required when airway compromise is severe. Surgical intervention is ultimately required to correct the stenosis. Laryngotracheal reconstruction in which a cartilage graft from another source (eg, rib) is used to expand the airway has become the standard procedure for symptomatic subglottic stenosis in children.

▼ CONGENITAL CAUSES OF INTRATHORACIC AIRWAY OBSTRUCTION

MALACIA OF AIRWAYS

⌘ ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Chronic monophonic wheeze with or without a barking cough.

▶ Respiratory symptoms do not respond to bronchodilators.

▶ Pathogenesis

Tracheomalacia or bronchomalacia exists when the cartilaginous framework of the airway is inadequate to maintain airway patency. Airway collapse is dynamic and can lead to airway obstruction. Because the cartilage of the infant airway is normally soft, all infants may have some degree of dynamic collapse of the central airway when pressure outside the airway exceeds intraluminal pressure.

Tracheomalacia and bronchomalacia can be congenital or acquired. Congenital tracheomalacia and bronchomalacia are associated with developmental abnormalities such as tracheoesophageal fistula, vascular ring, or cardiac anomalies causing extrinsic airway compression during development. Tracheomalacia is also associated with various syndromes. Congenital tracheomalacia may be localized to part of the trachea, but can also involve the entire trachea as well as the remainder of the conducting airways (bronchomalacia). Acquired tracheomalacia has been associated with long-term ventilation of premature newborns, severe tracheobronchitis, surgical repair of airways anomalies such as tracheoesophageal fistula and complete tracheal rings, and airway compression due to tumors, abscess or infection, and cysts.

▶ Clinical Findings

Coarse wheezing, cough, stridor, recurrent illnesses, recurrent wheezing that does not respond to bronchodilators, or

radiographic changes are common findings. Symptoms classically present insidiously over the first few months of life and can increase with agitation, excitement, activity, or upper respiratory tract infections. Diagnosis can be made by airway fluoroscopy or bronchoscopy.

▶ Treatment

Conservative treatment is usually indicated for the isolated condition, which generally improves over time with growth. Coexisting lesions such as tracheoesophageal fistulas and vascular rings need primary repair. In severe cases of tracheomalacia, intubation or tracheostomy may be necessary. Unfortunately, tracheostomy alone is seldom satisfactory because airway collapse continues to exist below the tip of the artificial airway. Positive pressure ventilation may be required to stent the collapsing airway. Surgical approaches to the problem (tracheopexy or aortopexy) may be considered as alternatives prior to or in an effort to wean off ventilatory support.

Carden KA et al: Tracheomalacia and tracheobronchomalacia in children and adults: an in-depth review. Chest 2005;127:984 [PMID: 15764786].
Goyal V, Masters IB, Chang AB: Interventions for primary (intrinsic) tracheomalacia in children. Cochrane Database Syst Rev 2012; CD005304 [PMID: 23076914].

VASCULAR RINGS AND SLINGS

The most common vascular anomaly to compress the trachea or esophagus is a vascular ring. A vascular ring can be formed by a double aortic arch or a right aortic arch with left ligamentum arteriosum or a patent ductus arteriosus. The pulmonary sling is created when the left pulmonary artery branches off the right pulmonary artery. Other common vascular anomalies include an anomalous innominate artery, a left carotid artery, and an aberrant right subclavian artery. All but the right subclavian artery can cause tracheal compression. The pulmonary sling may compress the trachea but can also compress the right upper lobe bronchus or the right mainstem takeoff. Of note, a pulmonary sling is associated with long segment tracheal stenosis 50% of the time.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of chronic airway obstruction (stridor, coarse wheezing, and croupy cough) are often worse in the supine position. Respiratory compromise is most severe with double aortic arch and may lead to apnea, respiratory arrest, or even death. Esophageal compression, present in all but anomalous innominate or carotid artery, may result in feeding difficulties. Barium swallow showing esophageal compression is the mainstay of diagnosis. Chest radiographs and echocardiograms may miss abnormalities. Anatomy can be further defined by angiography, chest CT with contrast, MRI or magnetic resonance angiography, or bronchoscopy.

▶ Treatment

Patients with significant symptoms require surgical correction, especially those with double aortic arch. Patients usually improve following correction but may have persistent but milder symptoms of airway obstruction due to associated tracheomalacia.

Humphrey C et al: Decade of experience with vascular rings at a single institution. Pediatrics 2006;117:e903 [PMID: 16585275].
McLaren CA, Elliott MJ, Roebuck DJ: Vascular compression of the airway in children. Paediatr Respir Rev 2008;9(2):85–94 [PMID: 18513668].

BRONCHOGENIC CYSTS

Bronchogenic cysts generally occur in the middle mediastinum (see section Mediastinal Masses) near the carina and adjacent to the major bronchi but can be found elsewhere in the lung. They range in size from 2 to 10 cm. Cyst walls are thin and may contain air, pus, mucus, or blood. Cysts develop from abnormal lung budding of the primitive foregut. They can be seen in conjunction with other congenital pulmonary malformations such as pulmonary sequestration or lobar emphysema.

▶ Clinical Findings

Bronchogenic cysts can present acutely with respiratory distress in early childhood due to airway compression or with symptoms of infection. Other patients present with chronic symptoms such as chronic wheezing, cough, intermittent tachypnea, recurrent pneumonia, or recurrent stridor, depending on the location and size of the cysts and the degree of airway compression. Still other patients remain asymptomatic until adulthood. However, all asymptomatic cysts will eventually become symptomatic with chest pain being the most common presenting complaint. The physical examination is often normal. Positive examination findings might include tracheal deviation from the midline and decreased breath sounds; percussion over involved lobes may be hyperresonant due to air trapping.

A. Laboratory Findings and Imaging Studies

The choice of diagnostic studies for bronchogenic cysts is controversial. Chest radiographs can show air trapping and

hyperinflation of the affected lobes or may show a spherical lesion with or without an air-fluid level. However, smaller lesions may not be seen on chest radiographs. CT scan is the preferred imaging study and can differentiate solid versus cystic mediastinal masses and define the cyst's relationship to the airways and the rest of the lung. A barium swallow can help determine whether the lesion communicates with the gastrointestinal tract. MRI and ultrasound are other imaging modalities used.

▶ Treatment

Treatment is surgical resection. Resection should be performed as soon as the cyst is detected to avoid future complications including infection. Postoperatively, vigorous pulmonary physiotherapy is required to prevent complications (atelectasis or infection of the lung distal to the site of resection of the cyst).

▼ ACQUIRED CAUSES OF INTRATHORACIC AIRWAY OBSTRUCTION

FOREIGN BODY ASPIRATION IN THE INTRATHORACIC AIRWAY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Sudden onset of coughing, wheezing, or respiratory distress.

▶ Asymmetrical physical findings of decreased breath sounds or localized wheezing.

▶ Asymmetrical radiographic findings, especially with forced expiratory view.

▶ Clinical Findings

A. Symptoms and Signs

Respiratory symptoms and signs vary depending on the site of obstruction and the duration following the acute episode. (See section Foreign Body Aspiration in the Intrathoracic Airway.) For example, a large or central airway obstruction may cause marked distress. The acute cough or wheezing caused by a foreign body in the lower respiratory tract may diminish over time only to recur later as chronic cough or persistent wheezing, monophonic wheezing, asymmetrical breath sounds on chest examination, or recurrent pneumonia in one location. Foreign body aspiration should be suspected in children with chronic cough, persistent wheezing, or recurrent pneumonia. Long-standing foreign bodies may lead to bronchiectasis or lung abscess. Hearing asymmetrical breath sounds or localized wheezing also suggests a foreign body.

B. Laboratory Findings and Imaging Studies

Inspiratory and forced expiratory (obtained by manually compressing the abdomen during expiration) chest radiographs should be obtained if foreign body aspiration is suspected. Chest radiographs may be normal up to 17% of the time. A positive forced expiratory study shows unilateral hyperinflation and there may be a mediastinal shift away from the affected side. If airway obstruction is complete, atelectasis and related volume loss will be the major radiologic findings. Virtual broncscopy and computerized tomography are alternative approaches for detecting a foreign body.

▶ Treatment

When a foreign body is highly suspected, a normal chest radiograph should not rule out the possibility of an airway foreign body. If clinical suspicion persists based on two of three findings—history of possible aspiration, focal abnormal lung examination, or an abnormal chest radiograph—then a bronchoscopy is indicated. Rigid bronchoscopy under general anesthesia is recommended. Flexible bronchoscopy may be helpful for follow-up evaluations (after the foreign object has been removed).

Children with suspected acute foreign body aspiration should be admitted to the hospital for evaluation and treatment. Chest postural drainage is no longer recommended because the foreign body may become dislodged and obstruct a major central airway. Bronchoscopy should not be delayed in children with respiratory distress but should be performed as soon as the diagnosis is made—even in children with more chronic symptoms. Following the removal of the foreign body, β-adrenergic nebulization treatments followed by chest physiotherapy are recommended to help clear related mucus or treat bronchospasm. Failure to identify a foreign body in the lower respiratory tract can result in bronchiectasis or lung abscess. This risk justifies an aggressive approach to suspected foreign bodies in suspicious cases.

Fiedkowski CW, Zheng H, Firth PG: The anesthetic considerations of tracheobronchial foreign bodies in children: a literature review of 12,979 cases. Anesth Analg 2010;111(4):1016–1025 [PMID: 20802055].

▼ DISORDERS OF MUCOCILIARY CLEARANCE

Mucociliary clearance is the primary defense mechanism for the lung. Inhaled particles including microbial pathogens are also entrapped in mucus on the airway surface, then cleared by the coordinated action of cilia. The volume and composition of airway surface liquid influence the efficiency of ciliary function and mucus clearance. Mucous that cannot be cleared normally can obstruct the airways. If mucociliary clearance is not normal, bacteria that are not cleared can lead to a vicious cycle of infection and inflammation and increased mucous production. The two main genetic diseases of mucociliary clearance involve disorders of ion transport (cystic fibrosis [CF]) and disorders in ciliary function (primary ciliary dyskinesia [PCD]).

CYSTIC FIBROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Greasy, bulky, malodorous stools; failure to thrive.

▶ Recurrent respiratory infections.

▶ Digital clubbing on examination.

▶ Bronchiectasis on chest imaging.

▶ Sweat chloride > 60 mmol/L.

▶ Pathogenesis

Cystic fibrosis (CF), an autosomal recessive disease, results in a syndrome of chronic sinopulmonary infections, malabsorption, and nutritional abnormalities. It is one of the most common lethal genetic diseases in the United States, with an incidence of approximately 1:3000 among Caucasians and 1:9200 in the US Hispanic population. Although abnormalities occur in the hepatic, gastrointestinal, and male reproductive systems, lung disease is the major cause of morbidity and mortality. Most individuals with CF develop obstructive lung disease associated with chronic infection that leads to progressive loss of pulmonary function.

The cause of CF is a defect in a single gene on chromosome 7 that encodes an epithelial chloride channel called the CF transmembrane conductance regulator (CFTR) protein. The most common mutation is ΔF508, although approximately 1500 other disease-causing mutations in the CF gene have been identified. Gene mutations lead to defects or deficiencies in CFTR, causing problems in salt and water movement across cell membranes, resulting in abnormally thick secretions in various organ systems and critically altering host defense in the lung.

▶ Clinical Findings

A. Symptoms and Signs

All states in the United States and many other countries now perform newborn screening for CF by measuring immuno-reactive trypsin (IRT), a pancreatic enzyme, in blood with or without concurrent DNA testing. Most infants with CF have elevated IRT in the newborn period, although false negative results are possible. In newborns with positive newborn screen, the diagnosis of CF must be confirmed by sweat testing, mutation analysis, or both (http://www.cff.org/AboutCF/Testing/NewbornScreening/).

Approximately 15% of newborns with CF present at birth with meconium ileus, a severe intestinal obstruction resulting from inspissation of tenacious meconium in the terminal ileum. Meconium ileus is virtually diagnostic of CF, so the infant should be treated presumptively as having CF until a sweat test or genotyping can be obtained.

During infancy and beyond, a common presentation of CF is failure to thrive due to malabsorption from exocrine pancreatic insufficiency. These children fail to gain weight despite good appetite and typically have frequent, bulky, foul-smelling, oily stools. These symptoms are the result of severe exocrine pancreatic insufficiency, the failure of the pancreas to produce sufficient digestive enzymes to allow breakdown and absorption of fats and protein. Pancreatic insufficiency occurs in more than 85% of persons with CF. (Chapter 22 describes gastrointestinal and hepatobiliary manifestations of CF; see also Table 22–12.) Infants with undiagnosed CF may also present with hypoproteinemia with or without edema, anemia, and deficiency of the fat-soluble vitamins A, D, E, and K, because of ongoing steatorrhea.

CF should also be considered in infants and children who present with severe dehydration and hypochloremic alkalosis. Other findings that should prompt a diagnostic evaluation for CF include unexplained bronchiectasis, rectal prolapse, nasal polyps, chronic sinusitis, and unexplained pancreatitis or cirrhosis. From a respiratory standpoint, clinical manifestations include productive cough, wheezing, recurrent pneumonias, progressive obstructive airways disease, exercise intolerance, dyspnea, and hemoptysis. Chronic airway infection with bacteria, including *S aureus* and *H influenzae,* often begins in the first few months of life, even in asymptomatic infants. Eventually, *Pseudomonas aeruginosa* and other gram-negative opportunistic bacteria

becomes the predominant pathogen. Chronic infection leads to airflow obstruction and progressive airway and lung destruction resulting in bronchiectasis. There is increasing appreciation that bacterial communities (or microbiota) in CF airways are diverse and that these communities may also contribute to lung health and disease.

An acute change in respiratory signs and symptoms from the subject's baseline is generically termed a pulmonary exacerbation. Clinically, an exacerbation is typically manifested by increased cough and sputum production, decreased exercise tolerance, malaise, and anorexia. These symptoms are usually associated with decreased measures of lung function. Treatment for pulmonary exacerbations generally consists of antibiotics and augmented airway clearance.

CF should also be considered in infants and children who present with severe dehydration and hypochloremic alkalosis. Other findings that should prompt a diagnostic evaluation for CF include unexplained bronchiectasis, rectal prolapse, nasal polyps, chronic sinusitis, and unexplained pancreatitis or cirrhosis.

B. Laboratory Findings and Imaging Studies

The diagnosis of CF is made by a sweat chloride concentration greater than 60 mmol/L in the presence of one or more typical clinical features (chronic sinopulmonary disease, pancreatic insufficiency, salt loss syndromes) or an appropriate family history (sibling or first cousin who has CF). Sweat tests should be performed at a CF Foundation–accredited laboratory. A diagnosis can also be confirmed by genotyping that reveals two disease-causing mutations. Intermediate sweat chloride values of 30–60 may be associated with mild CFTR mutations or CFTR-related metabolic syndrome (CFRM). Patients with mild CFTR mutations typically have adequate pancreatic exocrine function, but are still at risk for severe lung disease. CFRM patients appear to have even milder disease phenotypes, but the natural history of this condition is still being defined.

▶ Treatment

It is strongly recommended that individuals with CF be followed at a CF Foundation–accredited CF care center (http://www.cff.org).

The cornerstone of gastrointestinal treatment is pancreatic enzyme supplementation combined with a high calorie, high protein, and high fat diet. Persons with CF are required to take pancreatic enzyme capsules immediately prior to each meal and with snacks. Individuals should also take daily multivitamins that contain vitamins A, D, E, and K. Caloric supplements are often added to the patient's diet to optimize growth. Daily salt supplementation also is recommended to prevent hyponatremia, especially during hot weather

Airway clearance therapy and aggressive antibiotic use form the mainstays of treatment for CF lung disease.

Antibiotic therapy appears to be one of the primary reasons for the increased life expectancy of persons with CF. Respiratory treatments typically include recombinant human DNAse (Pulmozyme), inhaled hypertonic saline, and for those with chronic *Pseudomonas* infection, inhaled tobramycin (TOBI) or inhaled aztreonam, and chronic oral azithromycin. These therapies have been shown to maintain lung function and reduce the need for hospitalizations and intravenous antibiotics. Early detection of *P aeruginosa* and treatment with inhaled tobramycin can often eradicate the bacteria and delay chronic infection. Bronchodilators and anti-inflammatory therapies are also frequently used. Recent clinical trials using protein-rescue therapies to improve CFTR function have shown encouraging results, and the first small-molecule drug that directly addresses the underlying defect in CF was approved by the FDA in 2012. This drug, ivacaftor, is currently approved for use in patients with the G551D CFTR mutation which affects about 4% of CF patients. Ongoing trials of this drug with others in combination regimens may extend its use to patients who are F508del homozygous or have other mutations.

▶ Prognosis

A few decades ago, CF was fatal in early childhood. Now the median life expectancy is around 35 years of age. The rate of lung disease progression usually determines survival. Lung transplantation may be performed in those with end-stage lung disease. In addition, new treatments, including gene therapy trials and agents that modulate CFTR protein function, are being developed based on improved understanding of the disease at the cellular and molecular levels.

PRIMARY CILIARY DYSKINESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Chronic cough, sinusitis, and otitis.

▶ Unexplained respiratory distress in the newborn period.

▶ Situs inversus in approximately 50% of cases

▶ Diagnosis confirmed by identifying a ciliary ultrastructural abnormality on electron microscopy or mutations in PCD genes.

Primary ciliary dyskinesia (PCD), also known as immotile cilia syndrome, is a rare, inherited, usually autosomal recessive disorder with impaired ciliary function leading to progressive sinopulmonary disease. It is believed to occur in approximately 1 in 15,000 births. Almost half of patients with PCD have situs abnormalities, and men are usually infertile. The triad of situs inversus totalis, bronchiectasis, and chronic sinusitis is known as Kartagener syndrome.

▶ Clinical Findings

A. Symptoms and Signs

Situs inversus totalis occurs in approximately 50% of patients with PCD. Conversely, 20% of children with situs inversus totalis have PCD. Upper and lower respiratory tract manifestations are cardinal features of PCD. The majority of children with PCD present in the immediate newborn period with respiratory distress (commonly diagnosed as neonatal pneumonia or transient tachypnea of the newborn). Upper respiratory tract problems include chronic year-around nasal drainage that may begin in the first weeks of life, chronic sinusitis, nasal polyps, and chronic serous otitis media. Conductive hearing loss with chronic middle ear effusion is common. If myringotomy tubes are placed, chronic otorrhea often ensues. Lower respiratory tract features include chronic productive cough, chronic and recurrent bronchitis, and recurrent pneumonia. They are at risk to develop obstructive lung disease and bronchiectasis.

Nonrespiratory ciliopathies have been associated with PCD and include heterotaxy, asplenia, polysplenia, congenital heart disease, autosomal dominant polycystic kidney disease, retinitis pigmentosa, biliary atresia, and hydrocephalus.

B. Laboratory Findings and Imaging Studies

The diagnosis of PCD currently requires a compatible clinical phenotype and identification of ultrastructural and/or functional defects of the cilia. Examination of ciliary ultrastructure by transmission electron microscopy remains the cornerstone test for PCD. Cilia samples may be obtained from either the upper airways (nasal passage) or lower airways (trachea). Semen collection from older male patients can also be obtained to analyze sperm tails, which have the same ultrastructure as cilia. Significant expertise is required to produce high-quality transmission electron micrographs of cilia, and to distinguish primary (genetic) defects from secondary (acquired) defects in ciliary ultrastructure. Ciliary beat frequency or airway epithelium cultures are also used in some settings. In patients with a compatible clinical history but without visible ultrastructural defects, measurement of nasal nitric oxide has proven to be a useful screening and adjunctive diagnostic test in children ages 5 and older based on very low levels in PCD. Genetic testing is emerging for PCD and demonstrates extensive genetic heterogeneity. Some genes and gene mutations involved in PCD have been defined. Approximately 60% PCD cases have identifiable gene mutations in one of 14 known PCD genes.

▶ Treatment

At present, no specific therapies are available to correct the ciliary dysfunction in PCD. Treatment is not evidence-based and recommendations are largely extrapolated from CF and other suppurative lung diseases. Respiratory management includes routine pulmonary monitoring (lung function testing, respiratory cultures, chest imaging), airway clearance by combinations of physiotherapy and physical exercise, and aggressive treatment of upper and lower airways infections.

▶ Prognosis

The progression of lung disease in PCD is quite variable. Importantly, persons with PCD are at risk for chronic obstructive lung disease with bronchiectasis. With monitoring and aggressive treatment during times of illness, most individuals with PCD should experience a normal or near-normal life span.

BRONCHIOLITIS OBLITERANS

Bronchiolitis obliterans is a rare chronic obstructive lung disease characterized by complete obliteration of the small airways following a severe insult. The most common form in children is post-infectious, following a lower airway tract infection with adenovirus, although influenza, rubeola, *Bordetella,* and *Mycoplasma* are also implicated. Other causes include connective tissue diseases, chronic aspiration, Stevens-Johnson syndrome, post-transplantation (lung or bone marrow) and inhalational injury. Many cases of bronchiolitis obliterans are idiopathic. Adenovirus-induced bronchiolitis obliterans occurs more frequently in the Native

American population. Mechanical ventilation for severe adenoviral respiratory infection is a strong risk factor for development of bronchiolitis obliterans.

▶ Clinical Findings

A. Symptoms and Signs

Persons with bronchiolitis obliterans usually experience dyspnea, coughing, and exercise intolerance. This diagnosis should be considered in children with persistent cough, wheezing, crackles, or hypoxemia persisting longer than 60 days following a lower respiratory tract infection.

B. Laboratory Findings and Imaging Studies

Chest radiograph abnormalities include evidence of heterogeneous air trapping and airway wall thickening. Traction bronchiectasis can occur as the disease progresses. Classic findings on chest high-resolution CT include a mosaic perfusion pattern, vascular attenuation, and central bronchiectasis. This finding along with pulmonary function testing showing airway obstruction unresponsive to bronchodilators may be diagnostic in some patients with the appropriate clinical history. Although not typically required for diagnosis, ventilation-perfusion scans may show a pattern of ventilation and perfusion mismatch. Pulmonary angiograms reveal decreased vasculature in involved lung, and bronchograms show marked pruning of the bronchial tree.

▶ Differential Diagnosis

Poorly treated asthma, CF, and BPD must be considered in children with persistent airway obstruction. A trial of medications (including bronchodilators and corticosteroids) may help to determine the reversibility of the process when the primary differential is between asthma and bronchiolitis obliterans. Others without classic findings on CT scan and lung function testing may require a lung biopsy.

▶ Complications

Sequelae of bronchiolitis obliterans include persistent airway obstruction, recurrent wheezing, bronchiectasis, chronic atelectasis, recurrent pneumonia, and unilateral hyperlucent lung syndrome.

▶ Treatment

Supportive care including supplemental oxygen for hypoxemia, routine vaccination, avoidance of environmental irritant exposure, exercise and nutritional support should be provided. Ongoing airway damage due to problems such as aspiration should be prevented. Inhaled bronchodilators may reverse airway obstruction if the disease has a reactive component. Corticosteroids (inhaled, daily, or pulse dosing) may help reverse the obstruction or prevent ongoing

damage. Antibiotics should be used as indicated for pneumonia. Azithromycin has been shown to have therapeutic properties for airway injury in CF, diffuse panbronchiolitis, and in bronchiolitis obliterans syndrome (BOS) after lung transplantation, providing some rationale for a trial of this medication for bronchiolitis obliterans. Lung transplant may be an option for patients with severe, progressive disease. Early research in animal models suggests that TNF-α blockers may be useful in prevention progression of bronchiolitis obliterans.

▶ Prognosis

Prognosis depends in part on the underlying cause as well as the age of onset. Postinfectious bronchiolitis obliterans tends to be nonprogressive with low mortality and the possibility of slow improvement with time. Conversely, posttransplantation or Stevens-Johnson Syndrome related bronchiolitis obliterans may have a rapidly progressive course leading to death or need for lung transplantation.

BRONCHIECTASIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Chronic cough with sputum production.
▶ Rhonchi or wheezes (or both) on chest auscultation.
▶ Diagnosis is confirmed by high-resolution CT scan.

▶ Pathogenesis

Bronchiectasis is the permanent dilation of bronchi resulting from airway obstruction by retained mucus secretions or inflammation in response to chronic or repeated infection. It occurs either as a consequence of a preceding illness (severe pneumonia or foreign body aspiration) or as a manifestation of an underlying systemic disorder (CF, PCD, chronic aspiration or immunodeficiency).

▶ Clinical Findings

A. Symptoms and Signs

Persons with bronchiectasis will typically have chronic cough, purulent sputum, fever, and weight loss. Recurrent

respiratory infections and dyspnea on exertion are also common. Hemoptysis occurs less frequently in children than in adults with bronchiectasis. On physical examination, finger clubbing may be seen. Rales, rhonchi, and decreased air entry are often noted over the bronchiectatic areas.

B. Laboratory Findings and Imaging Studies

The most common bacteria detected in cultures from the lower respiratory tract include *S pneumoniae, S aureus,* nontypeable *H influenzae,* and *P aeruginosa.* Nontuberculous mycobacterial species may also be detected in patients with bronchiectasis.

Chest radiographs may be mildly abnormal with slightly increased bronchovascular markings or areas of atelectasis, or they may demonstrate cystic changes in one or more areas of the lung. The extent of bronchiectasis is best defined by high-resolution CT scan of the lung, which often reveals far wider involvement of lung than expected from the chest radiograph. Airflow obstruction and air trapping often is seen on pulmonary function testing. Evaluation of lung function after use of a bronchodilator is helpful in assessing the benefit a patient may have from bronchodilators. Serial assessments of lung function help define the progression or resolution of the disease.

▶ Differential Diagnosis

Bronchiectasis has numerous causes. It can occur following severe respiratory tract infections by bacteria (*S aureus, Bordetella pertussis*), viruses (adenovirus), or other organisms (*M tuberculosis*). Bronchiectasis can also be due to persistent inflammation and is commonly seen in persons with recurrent aspiration pneumonia, CF, PCD, immunodeficiency, surfactant deficiencies, and collagen-vascular conditions. Other diagnostic considerations include foreign body aspiration and allergic bronchopulmonary aspergillosis.

▶ Treatment

Aggressive antibiotic therapy during pulmonary exacerbations and routine airway clearance are mainstays of treatment. Inhaled hyperosmolar agents (hypertonic saline) were shown in small clinical trials to improve lung function and secretion clearance in non-CF bronchiectasis. Chronic antibiotic use, anti-inflammatory therapy, hyperosmolar agents (hypertonic saline), and bronchodilators have not been proven effective in non-CF bronchiectasis, although individual patients may benefit. Chronic azithromycin was recently shown to reduce exacerbations in adults with non-CF bronchiectasis. Conversely, a large study in adults with idiopathic bronchiectasis concluded that those who received dornase alpha twice a day had more frequent exacerbations,

hospitalizations, and lower lung function compared to placebo; thus, dornase alpha is not indicated in adult idiopathic bronchiectasis. Whether these results translate to children with idiopathic bronchiectasis is not known.

Surgical removal of an area of lung affected with severe bronchiectasis is considered when the response to medical therapy is poor. Other indications for operation include severe localized disease, repeated hemoptysis, and recurrent pneumonia in one area of lung. If bronchiectasis is widespread, surgical resection offers little advantage.

▶ Prognosis

The prognosis depends on the underlying cause and severity of bronchiectasis, the extent of lung involvement, and the response to medical management. Good pulmonary hygiene and avoidance of infectious complications in the involved areas of lung may reverse cylindric bronchiectasis.

▼ CONGENITAL MALFORMATIONS OF THE LUNG PARENCHYMA

What follows is a brief description of selected congenital pulmonary malformations.

PULMONARY AGENESIS & HYPOPLASIA

In unilateral pulmonary agenesis (complete absence of one lung), the trachea continues into a main bronchus and often has complete tracheal rings. The left lung is affected more often than the right. With compensatory postnatal growth, the remaining lung often herniates into the contralateral chest. Chest radiographs show a mediastinal shift toward the affected side, and vertebral abnormalities may be present. Absent or incomplete lung development may be associated with other congenital abnormalities, such as absence of one or both kidneys or fusion of ribs, and the outcome is primarily related to the severity of associated lesions. About 50% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung. This difference is probably not related to the higher incidence of associated anomalies but rather to a greater shift in the mediastinum that leads to tracheal compression and distortion of vascular structures.

Pulmonary hypoplasia is incomplete development of one or both lungs, characterized by a reduction in alveolar number and a reduction in airway branches. Pulmonary hypoplasia is present in up to 10%–15% of perinatal autopsies. The hypoplasia can be a result of an intrathoracic mass, resulting in lack of space for the lungs to grow; decreased size of the thorax; decreased fetal breathing movements; decreased blood flow to the lungs; or possibly a primary mesodermal defect affecting multiple organ systems. Congenital diaphragmatic hernia is the most common cause, with an incidence of 1:2200 births. Other causes include extralobar sequestration, diaphragmatic eventration or hypoplasia, thoracic neuroblastoma, fetal hydrops, and fetal hydrochylothorax. Chest cage abnormalities, diaphragmatic elevation, oligohydramnios, chromosomal abnormalities, severe musculoskeletal disorders, and cardiac lesions may also result in hypoplastic lungs. Postnatal factors may play important roles. For example, infants with advanced BPD can have pulmonary hypoplasia.

▶ Clinical Findings

A. Symptoms and Signs

The clinical presentation is highly variable and is related to the severity of hypoplasia as well as associated abnormalities. Lung hypoplasia is often associated with pneumothorax in newborns. Some newborns present with perinatal stress, severe acute respiratory distress, and persistent pulmonary hypertension of the newborn secondary to primary pulmonary hypoplasia (without associated anomalies). Children with lesser degrees of hypoplasia may present with chronic cough, tachypnea, wheezing, and recurrent pneumonia.

B. Laboratory Findings and Imaging Studies

Chest radiographic findings include variable degrees of volume loss in a small hemithorax with mediastinal shift. Pulmonary agenesis should be suspected if tracheal deviation is evident on the chest radiograph. The chest CT scan is the optimal diagnostic imaging procedure if the chest radiograph is not definitive. Ventilation-perfusion scans, angiography, and bronchoscopy are often helpful in the evaluation, demonstrating decreased pulmonary vascularity or premature blunting of airways associated with the maldeveloped lung tissue. The degree of respiratory impairment is defined by analysis of arterial blood gases.

▶ Treatment & Prognosis

Treatment is supportive. The outcome is determined by the severity of underlying medical problems, the extent of the hypoplasia, and the degree of pulmonary hypertension.

PULMONARY SEQUESTRATION

Pulmonary sequestration is nonfunctional pulmonary tissue that does not communicate with the tracheobronchial tree and receives its blood supply from one or more anomalous systemic arteries. This abnormality originates during the embryonic period of lung development. It is classified as either extralobar or intralobar. Extralobar sequestration is a mass of pulmonary parenchyma anatomically separate from the normal lung, with a distinct pleural investment. Its blood supply derives from the systemic circulation (more typical), from pulmonary vessels, or from both. Rarely, it communicates with the esophagus or stomach. Pathologically, extralobar sequestration appears as a solitary thoracic lesion near the diaphragm. Abdominal sites are rare. Size varies from 0.5 to 12 cm. The left side is involved in more than 90% of cases. In contrast to intralobar sequestrations, venous drainage is usually through the systemic or portal venous system.

Histologic findings include uniformly dilated bronchioles, alveolar ducts, and alveoli. Occasionally the bronchial structure appears normal; however, often the cartilage in the wall is deficient, or no cartilage-containing structures can be found. Lymphangiectasia is sometimes found within the lesion. Extralobar sequestration can be associated with other anomalies, including bronchogenic cysts, heart defects, and diaphragmatic hernia, the latter occurring in over half of cases.

Intralobar sequestration is an isolated segment of lung within the normal pleural investment that often receives blood from one or more arteries arising from the aorta or its branches. Intralobar sequestration is usually found within the lower lobes (98%), two-thirds are found on the left side, and it is rarely associated with other congenital anomalies (< 2% vs 50% with extralobar sequestration). It rarely presents in the newborn period (unlike extralobar sequestration). Some researchers have hypothesized that intralobar sequestration is an acquired lesion secondary to chronic infection. Clinical presentation includes chronic cough, wheezing, or recurrent pneumonias. Rarely, patients with intralobar sequestration can present with hemoptysis. Diagnosis is often made by angiography, which shows large systemic arteries perfusing the lesion. Recently spiral CT

scans with contrast or magnetic resonance angiography have proved useful in identifying anomalous systemic arterial supply to the lung. Treatment is usually by surgical resection.

CONGENITAL LOBAR EMPHYSEMA

Patients with congenital lobar emphysema—also known as infantile lobar emphysema, congenital localized emphysema, unilobar obstructive emphysema, congenital hypertrophic lobar emphysema, or congenital lobar overinflation—present most commonly with severe neonatal respiratory distress or progressive respiratory impairment during the first year of life. Rarely the mild or intermittent nature of the symptoms in older children or young adults results in delayed diagnosis. Most patients are white males. Although the cause of congenital lobar emphysema is not well understood, some lesions show bronchial cartilaginous dysplasia due to abnormal orientation or distribution of the bronchial cartilage. This leads to expiratory collapse, producing obstruction and the symptoms outlined in the following discussion.

▶ Clinical Findings

A. Symptoms and Signs

Clinical features include respiratory distress, tachypnea, cyanosis, wheezing, retractions, and cough. Breath sounds are reduced on the affected side, perhaps with hyperresonance to percussion, mediastinal displacement, and bulging of the chest wall on the affected side.

B. Imaging Studies

Radiologic findings include overdistention of the affected lobe (usually an upper or middle lobe; > 99%), with wide separation of bronchovascular markings, collapse of adjacent lung, shift of the mediastinum away from the affected side, and a depressed diaphragm on the affected side. The radiographic diagnosis may be confusing in the newborn because of retention of alveolar fluid in the affected lobe causing the appearance of a homogeneous density. Other diagnostic studies include chest radiograph with fluoroscopy, ventilation-perfusion study, and chest CT scan followed by bronchoscopy, angiography, and exploratory thoracotomy.

▶ Differential Diagnosis

The differential diagnosis of congenital lobar emphysema includes pneumothorax, pneumatocele, atelectasis with compensatory hyperinflation, diaphragmatic hernia, and congenital cystic adenomatoid malformation. The most common site of involvement is the left upper lobe (42%) or right middle lobe (35%). Evaluation must differentiate regional obstructive emphysema from lobar hyperinflation secondary to an uncomplicated ball-valve mechanism due to extrinsic compression from a mass (ie, bronchogenic cyst, tumor, lymphadenopathy, foreign body, pseudotumor or plasma cell granuloma, or vascular compression) or intrinsic obstruction from a mucus plug due to infection and inflammation from various causes.

▶ Treatment

When respiratory distress is marked, a segmental or complete lobectomy is usually required. Less symptomatic older children may do equally well with or without lobectomy.

Biyyam DR, Chapman T, Ferguson MR, Deutsch G, Dighe MK: Congenital lung abnormalities: embryologic features, prenatal diagnosis, and postnatal radiologic-pathologic correlation. Radiographics 2010;30(6):1721–1738. doi:10.1148/rg.306105508 [PMID: 21071385].

CONGENITAL PULMONARY AIRWAY MALFORMATION (CYSTIC ADENOMATOID MALFORMATION)

Congenital pulmonary adenomatoid malformations (CPAMs; previously known as congenital cystic adenomatoid malformations) are unilateral hamartomatous lesions which generally present with marked respiratory distress within the first days of life. This disorder accounts for 95% of cases of congenital cystic lung disease.

Right and left lungs are involved with equal frequency. These lesions originate in the first 5–22 weeks of gestation during the embryonic period of lung development. They appear as glandlike, space-occupying masses or have an increase in terminal respiratory structures, forming intercommunicating cysts of various sizes, lined by cuboidal or ciliated pseudostratified columnar epithelium. The lesions may have polypoid formations of mucosa, with focally increased elastic tissue in the cyst wall beneath the bronchial type of epithelium. Air passages appear malformed and tend to lack cartilage.

There are five types of such malformations.

1. Type 0, also known as acinar dysplasia or agenesis istracheal or bronchial in origin and is rare and incompatible

with life. The lungs are small, firm and microscopically are made up entirely of irregular bronchial type structures.

2. Type 1, a large cyst lesion (bronchial or bronchiolar origin), is most common (50%–65%) and consists of single or multiple large cysts (> 2 cm in diameter) with features of mature lung tissue, including a pseudostratified epithelium. Type 1 is amenable to surgical resection. A mediastinal shift is evident on examination or chest radiograph in 80% of patients and can mimic infantile lobar emphysema. Approximately 75% of type 1 lesions are on the right side. A survival rate of 90% is generally reported. There are some reports of bronchioloalveolar carcinoma in patients with type 1 CPAM although this does not necessitate urgent resection.

3. Type 2 lesions, small cyst lesions (bronchiolar origin) and (10%–40% of cases), consist of multiple small cysts (< 2 cm) resembling dilated simple bronchioles and are often (60%) associated with other anomalies, especially renal agenesis or dysgenesis, cardiac malformations, extralobar sequestration and intestinal atresia. Approximately 60% of type 2 lesions are on the left side. Mediastinal shift is evident less often (10%) than in type 1, and the survival rate is worse (40%). Microscopically the lesion is composed of dilated bronchioles lined by cuboidal to low columnar epithelium and separated by alveolar duct-like structures.

4. Type 3 lesions, adenomatoid lesion (bronchiolar/alveolar duct origin) and (5%–10% of cases), consist of small cysts (< 0.5 cm). These are the "classic" CPAM (or CCAM). They appear as bulky, firm masses with mediastinal shift and carry the risk of hydrops from mass shift resulting in caval obstruction and cardiac compression (80% of cases). The lesion will often involve the entire lobe and microscopically random bronchiolar/alveolar duct-like structures are seen. There is a striking absence of any small, medium or large pulmonary arteries within the lesion. Often the adjacent or uninvolved lung is hypoplastic. The reported survival rate is 50%.

5. Type 4 lesions, "unlined" cyst (distal acinar origin) and (10%–15% of cases), appear to be a hamartomatous malformation of the distal acinus. The cysts are large thin walled and found at the periphery of the lung. The cysts are lined by flattened epithelial (type I) cells.

▶ Clinical Findings

A. Symptoms and Signs

Clinically, respiratory distress is noted soon after birth. Expansion of the cysts occurs with the onset of breathing and produces compression of normal lung areas with mediastinal herniation. Breath sounds are decreased. With type 3 lesions, dullness to percussion may be present. Older patients can present with a spontaneous pneumothorax or with pneumonia-like symptoms. Recently more patients are diagnosed with these lesions on prenatal ultrasound

B. Laboratory Findings and Imaging Studies

With type 1 lesions, chest radiographs show an intrapulmonary mass of soft tissue density with scattered radiolucent areas of varying sizes and shapes, usually with a mediastinal shift and pulmonary herniation. Placement of a radiopaque feeding tube into the stomach helps in the differentiation from diaphragmatic hernia. Type 2 lesions appear similar except that the cysts are smaller. Type 3 lesions may appear as a solid homogeneous mass filling the hemithorax and causing a marked mediastinal shift. Type 4 lesions are large air-filled cysts localized to one lobe. Differentiation from sequestration is not difficult because congenital CPAM have no systemic blood supply.

▶ Treatment

In cases of prenatal diagnosis, the treatment of these lesions is variable and does not need antenatal intervention. Up to 6%–10% of these have regressed spontaneously and thus they need to be followed serially, prenatally. Attention must be paid to the development of hydrops as a complication of these lesions. Postnatal treatment of types 1 and 3 lesions involves surgical removal of the affected lobe. Resection is often indicated because of the risk of infection and air trapping, since the malformation communicates with the tracheobronchial tree but mucous clearance is compromised. Because type 2 lesions are often associated with other severe anomalies, management may be more complex. Segmental resection is not feasible because smaller cysts may expand after removal of the more obviously affected area. CPAM have been reported to have malignant potential; therefore, expectant management with observation alone should proceed with caution. Recent development of intrauterine surgery for congenital malformations has led to promising results.

▼ ACQUIRED ABNORMALITIES OF THE LUNG PARENCHYMA

BRONCHOPULMONARY DYSPLASIA

▶ Acute respiratory distress in the first week of life.

▶ Required oxygen therapy or mechanical ventilation, with persistent oxygen requirement at 36 weeks' gestational age or 28 days of life.

▶ Persistent respiratory abnormalities, including physical signs and radiographic findings.

Bronchopulmonary dysplasia (BPD) remains one of the most significant sequelae of acute respiratory distress in the neonatal intensive care unit, with an incidence of about 30% for infants with a birth weight of less than 1000 g. This disease was first characterized in 1967 when Northway reported the clinical, radiologic, and pathologic findings in a group of preterm newborns that required prolonged mechanical ventilation and oxygen therapy to treat hyaline membrane disease (HMD). The progression from acute HMD to chronic lung disease was divided into four stages: acute respiratory distress shortly after birth, (stage I); clinical and radiographic worsening of the acute lung disease, often due to increased pulmonary blood flow secondary to a patent ductus arteriosus (stage II); and progressive signs of chronic lung disease (stages III and IV).

The pathologic findings and clinical course of BPD in recent years have changed due to a combination of new therapies (artificial surfactants, prenatal glucocorticoids, and protective ventilatory strategies) and increased survival of infants born at earlier gestational ages. Although the incidence of BPD has not changed, the severity of the lung disease has decreased. Pathologically this "new" BPD is a developmental disorder of the lung characterized by decreased surface area for gas exchange, reduced inflammation, and a dysmorphic vascular structure.

▶ Pathogenesis

The precise mechanism that results in the development of BPD is unclear. Current studies indicate that these babies have abnormal lung mechanics due to structural immaturity of the alveolar-capillary network, surfactant deficiency, atelectasis, and pulmonary edema. Furthermore, mechanical ventilation causes barotrauma and supplemental oxygen may lead to toxic oxygen metabolites in a child whose antioxidant defense mechanisms are not sufficiently mature. The ongoing injuries may lead to a vicious cycle of ventilator and oxygen dependence. As a result, the lungs of extremely preterm newborns with BPD show simplified histology with fewer alveoli, early inflammation, and hypercellularity followed by healing with fibrosis. Excessive fluid administration, patent ductus arteriosus, pulmonary interstitial emphysema, pneumothorax, infection, pulmonary hypertension, and inflammatory stimuli secondary to lung injury or infection also play important roles in the pathogenesis of the disease.

▶ Clinical Findings

A recent summary of a National Institutes of Health workshop on BPD proposed a definition of the disease that includes oxygen requirement for more than 28 days, a history of positive pressure ventilation or continuous positive airway pressure, and gestational age. The new definition accommodates several key observations regarding the disease, as follows: (1) although most of these children were born preterm and had hyaline membrane disease, full-term newborns with such disorders as meconium aspiration, diaphragmatic hernia, or persistent pulmonary hypertension also can develop BPD; (2) some extremely preterm newborns require minimal ventilator support yet subsequently develop a prolonged oxygen requirement despite the absence of severe acute manifestations of respiratory failure; (3) newborns dying within the first weeks of life can already have the aggressive, fibroproliferative pathologic lesions that resemble BPD; and (4) physiologic abnormalities (increased airway resistance) and biochemical markers of lung injury (altered protease-antiprotease ratios and increased inflammatory cells and mediators) which may be predictive of BPD are already present in the first week of life.

The clinical course of infants with BPD ranges from an oxygen requirement that gradually resolves over a few months to more severe disease requiring chronic tracheostomy and mechanical ventilation for the first few years of life. In general, patients show slow, steady improvements in oxygen or ventilator requirements but can have respiratory exacerbations leading to frequent and prolonged hospitalizations. Clinical management generally includes careful attention to growth, nutrition (infants with oxygen dependence and respiratory have high caloric requirements), metabolic status, developmental and neurologic status, along with the associated cardiopulmonary abnormalities.

▶ Treatment

A. Medical Therapy

Early use of surfactant therapy with adequate lung recruitment increases the chance for survival without BPD, reduces the need for mechanical ventlaton, and can decrease the overall mortality. Short courses of postnatal glucocorticoid

therapy have been helpful in increasing the success of weaning from the ventilator. Longer courses of postnatal glucocorticoids have been linked to an increased incidence of cerebral palsy. Inhaled corticosteroids together with occasional use of β-adrenergic agonists are commonly part of the treatment plan but the overall effect on the course of BPD is not clear.

Salt and water retention secondary to chronic hypoxemia, hypercapnia, or other stimuli may be present. Chronic or intermittent diuretic therapy is commonly used if rales or signs of persistent pulmonary edema are present; clinical studies show acute improvement in lung function with this therapy. Unfortunately, diuretics often have adverse effects, including volume contraction, hypokalemia, alkalosis, hyponatremia, and nephrocalcinosis. Potassium and arginine chloride supplements may be required.

B. Airway Evaluation

Children with significant stridor, sleep apnea, chronic wheezing, or excessive respiratory distress need diagnostic bronchoscopy to evaluate for structural lesions (eg, subglottic stenosis, vocal cord paralysis, tracheal or bronchial stenosis, tracheobronchomalacia, or airway granulomas). The contribution of gastroesophageal reflux and aspiration should be considered in the face of worsening chronic lung disease.

C. Management of Pulmonary Hypertension

Infants with BPD are at risk of developing pulmonary hypertension. In many of these children even mild hypoxemia can cause significant elevations of pulmonary arterial pressure. To minimize the harmful effects of hypoxemia, the arterial oxygen saturation should be kept above 93% in children with pulmonary hypertension, with care to avoid hyperoxia during retinal vascular development. Electrocardiographic and echocardiographic studies should be performed to monitor for the development of right ventricular hypertrophy. Management of neonatal pulmonary hypertension should involve expert consultation with a pulmonary hypertension specialist. If right ventricular hypertrophy persists or if it develops when it was not previously present, intermittent hypoxemia should be considered and further assessments of oxygenation pursued, especially while the infant sleeps. Cardiac catheterization may be necessary to diagnose unsuspected cardiac or pulmonary lesions and to measure the response of the pulmonary vasculature to vasodilators such as nitric oxide before chronic therapy is initiated. Infants with a history of intubation can develop obstructive sleep apnea secondary to a high-arched palate or subglottic narrowing. Barium esophagram, esophageal pH/impedence studies, and bronchoscopy may aid in diagnosing gastroesophageal reflux, aspiration, and airway abnormalities that contribute to the underlying pathophysiology. In infants with severe BPD, prophylactic fundoplication at the tme of gastrostomy tube placement may prevent catastrophic aspiration events that could be life threatening. Long-term care also should include monitoring for systemic hypertension and the development of left ventricular hypertrophy.

D. Nutrition and Immunizations

Nutritional problems in infants with BPD may be due to increased oxygen consumption, feeding difficulties, gastroesophageal reflux, and chronic hypoxemia. Hypercaloric formulas and gastrostomy tubes are often required to ensure adequate intake while avoiding overhydration. Routine vaccinations including the influenza vaccine are recommended. With the onset of acute wheezing secondary to suspected viral infection, rapid diagnostic testing for RSV infection may facilitate early treatment. Immune prophylaxis of RSV reduces the morbidity of bronchiolitis in infants with BPD. In children older than 2 years of age with severe BPD, pneumococcal polysaccharide 23-valent vaccine should be considered in addition to standard pneumococcal vaccination.

E. Ventilation

For children with BPD who remain ventilator-dependent, attempts should be made to maintain $Paco_2$ below 60 mm Hg—even when pH is normal—because of the potential adverse effects of hypercapnia on salt and water retention, cardiac function, and perhaps pulmonary vascular tone. Changes in ventilator settings in children with severe lung disease should be slow, because the effects of many of the changes may not be apparent for days.

▶ Differential Diagnosis

The differential diagnosis of BPD includes meconium aspiration syndrome, congenital infection (eg, with cytomegalovirus or *Ureaplasma*), cystic adenomatoid malformation, recurrent aspiration, pulmonary lymphangiectasia, total anomalous pulmonary venous return, overhydration, and idiopathic pulmonary fibrosis.

▶ Prognosis

Surfactant replacement therapy has had a significantly and markedly beneficial effect on reducing morbidity and mortality from BPD. Infants of younger gestational age are surviving in greater numbers. Surprisingly, the effect of neonatal care has not significantly decreased the incidence of BPD. The disorder typically develops in the most immature infants. The long-term outlook for most survivors is favorable. Follow-up studies suggest that lung function may be altered for life. Hyperinflation and damage to small airways has been reported in children 10 years after the first signs of BPD. In addition, these infants are at a risk for developing such sequelae as hypoxemia, airway hyperreactivity, exercise intolerance, pulmonary hypertension, chronic obstructive pulmonary disease, and abnormal lung

growth. As smaller, more immature infants survive, abnormal neurodevelopmental outcomes become more likely. The incidence of cerebral palsy, hearing/visual impairment, and developmental delays is increased. Feeding abnormalities, behavior difficulties, and increased irritability have also been reported. A focus on good nutrition and prophylaxis against respiratory pathogens and airway hyperreactivity provide the best outcomes. Family support, developmental therapies (physical, occupational, and speech), and attention to cognitive function and learning issues help to improve the long-term outlook.

COMMUNITY-ACQUIRED BACTERIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever, cough, dyspnea.
- ▶ Abnormal chest examination (crackles or decreased breath sounds).
- ▶ Abnormal chest radiograph (infiltrates, hilar adenopathy, pleural effusion).

Lower respiratory tract infections (LRTIs) are a major cause of childhood mortality in disadvantaged areas of the world. The infectious etiologies vary widely by geographic region and by the age of the child. In developed countries the majority of pneumonias are caused by viral agents and bacterial pneumonia is a less common cause. Discrimination between viral and bacterial pneumonia is challenging as neither the white blood cell count nor differential nor the chest radiograph are strong predictors. In areas where the technology is readily available chest radiography is recommended to establish with certainty the presence of pneumonia. The most common cause of bacterial pneumonia in children of all ages is *S pneumoniae*. Bacterial pneumonia usually follows a viral lower respiratory tract infection. Children at

high risk for bacterial pneumonia are those with compromised pulmonary defense systems. For example, children with abnormal mucociliary clearance, immunocompromised children, children who aspirate their own secretions or who aspirate while eating, and malnourished children are at increased risk for bacterial pneumonia.

▶ Clinical Findings

A. Symptoms and Signs

The pathogen, severity of the infection, and age of the patient may cause substantial variations in the presentation of community-acquired pneumonia (CAP). Fevers (over 39°C), tachypnea, and cough are hallmarks of CAP. Chest auscultation may reveal crackles or decreased breath sounds in the setting of consolidation or an associated pleural effusion. Some patients may have additional extrapulmonary findings, such as meningismus or abdominal pain, due to pneumonia itself. Others may have evidence of infection at other sites due to the same organism causing their pneumonia: meningitis, otitis media, sinusitis, pericarditis, epiglottitis, or abscesses.

B. Laboratory Findings and Imaging Studies

An elevated peripheral white blood cell count with a left shift may be a marker of bacterial pneumonia. A low white blood count ($< 5000/\mu L$) can be an ominous finding in this disease. Blood cultures should be obtained in children admitted to the hospital with pneumonia, although approximately 10% or less will be positive, even with known bacterial pneumonia. Sputum cultures may be helpful in older children capable of providing a satisfactory sample. Invasive diagnostic procedures (bronchial brushing or washing, lung puncture, or open or thoracoscopic lung biopsy) should be undertaken in critically ill patients when other means do not adequately identify the cause (see section Diagnosis of Respiratory Tract Infections).

The spectrum of potential pathogens to be considered includes aerobic, anaerobic, and acid-fast bacteria as well as *Chlamydia trachomatis, C Pneumoniae, C psittaci, Coxiella burnetii* (Q fever), *P jiroveci, B pertussis, M pneumoniae, Legionella pneumophila,* and respiratory viruses. *S pneumoniae* is the most prevalent bacterial pathogen. Viral antigen immunofluorescent staining (DFA) and polymerase chain reactivity (PCR) technology has improved the ability to detect a wide variety of viral infections.

Air space disease or consolidation in a lobar distribution on chest x-ray suggests bacterial pneumonia; interstitial or peribronchial infiltrates suggest a viral infection. Severity of the infection may not correlate with radiographic findings and clinical improvement precedes radiographic resolution. If a pleural effusion is suspected, radiographs should be taken in the lateral decubitus position. A diagnostic (and

possibly therapeutic) thoracocentesis should also be performed in a child with a pleural effusion.

▶ Differential Diagnosis

Noninfectious pulmonary disease (including gastric aspiration, foreign body aspiration, atelectasis, congenital malformations, congestive heart failure, malignancy, tumors such as plasma cell granuloma, chronic ILD, and pulmonary hemosiderosis) should be considered in the differential diagnosis of localized or diffuse infiltrates. When effusions are present, additional noninfectious disorders such as collagen diseases, neoplasm, and pulmonary infarction should also be considered.

▶ Complications

Empyema can occur frequently with staphylococcal, pneumococcal, and group A β-hemolytic streptococcal pneumonia. Distal sites of infection—meningitis, otitis media, sinusitis (especially of the ethmoids), and septicemia—may be present, particularly with disease due to *S pneumoniae* or *H influenzae*. Certain immunocompromised patients, such as those who have undergone splenectomy or who have hemoglobin SS or SC disease or thalassemia, are especially prone to overwhelming sepsis with these organisms.

▶ Treatment

If a bacterial pneumonia is suspected, empiric antibiotic therapy should be considered. Children less than 4 weeks of age should be treated with ampicillin and an aminoglycoside. Infants 4–12 weeks of age should be treated with IV ampicillin for 7–10 days. Children 3 months to 5 years of age should be treated with oral amoxicillin (50–90 mg/kg/dose) for 7–10 days. Children older than 5 years should be treated with a macrolide antibiotic or amoxicillin or penicillin G depending on the suspected etiology. When possible, therapy can be guided by the antibiotic sensitivity pattern of the organisms isolated. (For further discussion, see Chapter 39.) An appropriate antiviral (eg, amantadine, rimantidine, osetamivir, zanamivir) should be considered for the child with pneumonia due to Influenza. Whether a child should be hospitalized depends on his or her age, the severity of illness, the suspected organism, and the anticipated reliability of adherence to the treatment regimen at home. All children younger than 3 months of age should be admitted for treatment. Moderate to severe respiratory distress, apnea, hypoxemia, poor feeding, clinical deterioration on treatment, or associated complications (large effusions, empyema, or abscess) indicate the need for immediate hospitalization in older children. Careful outpatient follow-up within 12 hours to 5 days is often indicated in those not admitted.

Additional therapeutic considerations include oxygen, humidification of inspired gases, hydration and electrolyte supplementation, and nutrition. Removal of pleural fluid for diagnostic purposes is indicated initially to guide antimicrobial therapy. Removal of pleural fluid for therapeutic purposes may also be indicated.

▶ Prognosis

In developed countries, for the immunocompetent host in whom bacterial pneumonia is adequately recognized and treated, the survival rate is high. For example, the mortality rate from uncomplicated pneumococcal pneumonia is less than 1%. If the patient survives the initial illness, persistently abnormal pulmonary function following empyema is surprisingly uncommon, even when treatment has been delayed or inappropriate.

PARAPNEUMONIC EFFUSION & EMPYEMA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Respiratory distress and chest pain.

▶ Fever.

▶ Chest x-ray showing a meniscus or layering fluid on a lateral decubitus film.

Bacterial pneumonia is often accompanied by pleural effusion. Some of these effusions harbor infection, and others are inflammatory reactions to pneumonia. The nomenclature in this area is somewhat confusing. Some authors use the term *empyema* for grossly purulent fluid and *parapneumonic effusion* for nonpurulent fluid. It is clear, however, that some nonpurulent effusions will also contain organisms and represent either partially treated or early empyema. It is probably best to refer to all effusions associated with pneumonia as parapneumonic effusions, some of which are infected and some not.

The most common organism associated with empyema is *S pneumoniae*. Other common organisms include *H influenzae* and *S aureus*. Less common causes are group A streptococci, gram-negative organisms, anaerobic organisms, and *M pneumoniae*. Effusions associated with tuberculosis are almost always sterile and constitute an inflammatory reaction.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually present with typical signs of pneumonia, including fever, tachypnea, and cough. They may have chest pain, decreased breath sounds, and dullness to percussion on the affected side and may prefer to lie on the affected side. With large effusions, there may be tracheal deviation to the contralateral side. According to a study in Canada, empyema is more likely to occur in children less than 5 years.

B. Diagnostic Studies

The white blood cell count is often elevated, with left shift. Blood cultures are sometimes positive. The tuberculin skin test is positive in most cases of tuberculosis. Thoracentesis reveals findings consistent with an exudate. Cells in the pleural fluid are usually neutrophils in bacterial disease and lymphocytes in tuberculous effusions. In bacterial disease, pleural fluid pH and glucose are often low. A pH less than 7.2 suggests active bacterial infection. The pH of the specimen should be determined in a blood gas syringe sent to the laboratory on ice. Extra heparin should not be used in the syringe as it can falsely lower the pH. Although in adults the presence of low pH and glucose indicates the need for aggressive and thorough drainage procedures, the prognostic significance of these findings in children is unknown. Gram stain, cultures, and counterimmunoelectrophoresis are often positive for the offending organism.

The presence of pleural fluid is suggested by a homogeneous density that obscures the underlying lung on chest radiograph. Large effusions may cause a shift of the mediastinum to the contralateral side. Small effusions may only blunt the costophrenic angle. Lateral decubitus radiographs may help to detect freely movable fluid by demonstrating a layering-out effect. If the fluid is loculated, no such effect is perceived. Ultrasonography can be extremely valuable in localizing the fluid and detecting loculations, especially when thoracentesis is contemplated, but availability may be limited. Chest CT scan can help determine whether the fluid is intraparenchymal or extraparenchymal and can direct further care of complicated pneumonias.

▶ Treatment

After initial thoracentesis and identification of the organism, appropriate intravenous antibiotics and adequate drainage of the fluid remain the mainstay of therapy, but the approach is debated. Although there is a trend toward managing smaller pneumococcal empyemas without a chest tube, larger effusions require chest tube drainage. Evidence of early interventions using thoracoscopic techniques such as VATS may reduce morbidity and has been shown to shorten length of hospital stay when done by an experienced surgeon. While there is growing use of VATS as first-line therapy, it is not standard of care. Studies in adults show that aggressive management with drainage of pleural cavity fluid and release of adhesions with fibrinolytics is cost effective and decreases the length of stay. There are limited studies of fibrinolytics in children. The therapeutic choice will vary depending on the resources available and the preferences of the clinician.

▶ Prognosis

The prognosis is related to the severity of disease but is generally excellent, with complete or nearly complete recovery expected in most instances.

▼ ATYPICAL PNEUMONIAS

VIRAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Upper respiratory infection prodrome (fever, coryza, cough, hoarseness).

▶ Wheezing or rales.

▶ Myalgia, malaise, headache (older children).

Viral infection is a common cause of community-acquired pneumonia in children. Viral pneumonia is most common in children younger than 2 years of age. RSV, parainfluenza (1, 2, and 3) viruses, influenza (A and B) viruses, and human metapneumovirus are responsible for the large majority of cases. Severity of disease, severity of fever, radiographic findings, and the characteristics of cough or lung sounds do not reliably differentiate viral from bacterial pneumonias. Furthermore, such infections may coexist. However, substantial pleural effusions, pneumatoceles, abscesses, lobar consolidation with lobar volume expansion, and "round" pneumonias are generally inconsistent with viral disease.

▶ Clinical Findings

A. Symptoms and Signs

An upper respiratory infection frequently precedes the onset of lower respiratory disease due to viruses. Although wheezing or stridor may be prominent in viral disease, cough, signs of respiratory distress (tachypnea, retractions, grunting, and nasal flaring), and physical findings (rales and decreased breath sounds) may not be distinguishable from those in bacterial pneumonia.

B. Laboratory Findings

The peripheral white blood cell count can be normal or slightly elevated and is not useful in distinguishing viral from bacterial disease.

Rapid viral diagnostic methods such as fluorescent antibody tests or enzyme-linked immunosorbent assay and/or polymerase chain reaction (PCR) should be performed on nasopharyngeal secretions to confirm this diagnosis in high-risk patients and for epidemiology or infection control. Rapid diagnosis of RSV infection does not preclude the possibility of concomitant infection with other pathogens.

C. Imaging Studies

Chest radiographs frequently show perihilar streaking, increased interstitial markings, peribronchial cuffing, or patchy bronchopneumonia. Lobar consolidation or atelectasis may occur, however. Hyperinflation of the lungs may occur when involvement of the small airways is prominent.

▶ Differential Diagnosis

The differential diagnosis of viral pneumonia is the same as for bacterial pneumonia. Patients with prominent wheezing may have asthma, airway obstruction caused by foreign body aspiration, acute bacterial or viral tracheitis, or parasitic disease.

▶ Complications

Viral pneumonia or laryngotracheobronchitis may predispose the patient to subsequent bacterial tracheitis or pneumonia as immediate sequelae. Bronchiolitis obliterans or severe chronic respiratory failure may follow adenovirus pneumonia. The results of studies evaluating the development of asthma after a viral pneumonia are variable. Bronchiectasis, chronic ILD, and unilateral hyperlucent lung (Sawyer-James syndrome) may follow measles, adenovirus, and influenza pneumonias.

▶ Treatment

General supportive care for viral pneumonia does not differ from that for bacterial pneumonia. Patients can be quite ill and should be hospitalized according to the level of their illness. Because bacterial disease often cannot be definitively excluded, antibiotics may be indicated.

Patients at risk for life-threatening RSV infections (eg, those with BPD or other severe pulmonary conditions, congenital heart disease, or significant immunocompromise) should be hospitalized and ribavirin should be considered. Rapid viral diagnostic tests may be a useful guide for such therapy.

All children with influenza should be treated with the appropriate therapy for the specific type of influenza (A, B, H1N1). When available epidemiologic data indicate an active influenza infection in the community, rimantadine, amantadine hydrochloride, or oseltamivir phosphate should be considered early for high-risk infants and children who appear to be infected. Children with suspected viral pneumonia should be placed in respiratory isolation.

▶ Prognosis

Although most children with viral pneumonia recover uneventfully, worsening asthma, abnormal pulmonary function or chest radiographs, persistent respiratory insufficiency, and even death may occur in high-risk patients such as newborns or those with underlying lung, cardiac, or immunodeficiency disease. Patients with adenovirus infection or those concomitantly infected with RSV and second pathogens such as influenza, adenovirus, cytomegalovirus, or *P jiroveci* also have a worse prognosis.

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Clinical syndrome characterized by one or more of the following findings: coughing, tachypnea, labored breathing, and hypoxia.

► Irritability, poor feeding, vomiting.

► Wheezing and crackles on chest auscultation.

Bronchiolitis is the most common serious acute respiratory illness in infants and young children. The diagnosis of bronchiolitis is based upon clinical findings including an upper respiratory infection that has progressed to cough, tachypnea, respiratory distress, and crackles or wheeze by physical examination. In most literature from the United States, this definition of bronchiolitis specifically applies to children younger than 2 years old. One to 3% of infants with bronchiolitis will require hospitalization, especially during the winter months. RSV is by far the most common viral cause of acute bronchiolitis. Parainfluenza, human metapneumovirus, influenza, adenovirus, *Mycoplasma, Chlamydia, Ureaplasma, Bocavirus,* and *Pneumocystis* are less common causes of bronchiolitis during early infancy.

Prevention

The most effective preventions against RSV infection are proper handwashing techniques and reducing exposure to potential environmental risk factors. Major challenges have impeded the development of an RSV vaccine, but a licensed product may be expected in the near future. Prophylaxis with a monoclonal antibody (palivizumab) has proven effective in reducing the rate of hospitalization and associated morbidities in high-risk premature infants and those with chronic cardiopulmonary conditions.

Clinical Findings

A. Symptoms and Signs

The usual course of RSV bronchiolitis is 1–2 days of fever, rhinorrhea, and cough, followed by wheezing, tachypnea, and respiratory distress. Typically the breathing pattern is shallow, with rapid respirations. Nasal flaring, cyanosis, retractions, and rales may be present, along with prolongation of the expiratory phase and wheezing, depending on the severity of illness. Some young infants present with apnea and few findings on auscultation but may subsequently develop rales, rhonchi, and expiratory wheezing.

B. Laboratory Findings and Imaging Studies

A viral nasal wash may be performed to identify the causative pathogen but is not necessary to make the diagnosis of bronchiolitis. The peripheral white blood cell count may be normal or may show a mild lymphocytosis. Chest radiographs are not indicated in children who have bilateral, symmetrical findings on examination, who are not in significant respiratory distress, and who do not have elevated temperature for the child's age. If obtained, chest radiograph findings are generally nonspecific and typically include hyperinflation, peribronchial cuffing, increased interstitial markings, and subsegmental atelectasis.

Complications

The most common complication of bronchiolitis is superinfection with a bacterial pathogen such as *Streptococcus pneumoniae* leading to pneumonia. The results of studies investigating the risk for the subsequent development of chronic airway hyperreactivity (asthma) are variable. Bronchiolitis due to RSV infection contributes substantially to morbidity and mortality in children with underlying medical disorders, including chronic lung disease of prematurity, CF, congenital heart disease, and immunodeficiency.

Treatment

Although most children with RSV bronchiolitis are readily treated as outpatients, hospitalization is required in infected children with hypoxemia on room air, a history of apnea, moderate tachypnea with feeding difficulties, and marked respiratory distress with retractions. Children at high risk for hospitalization include infants (younger than 6 months of age), especially with any history of prematurity, and those with underlying chronic cardiopulmonary disorders. While in the hospital, treatment should include supportive strategies such as frequent suctioning and providing adequate fluids to maintain hydration. If hypoxemia is present, supplemental oxygen should be administered. There is no evidence to support the use of antibiotics in children with bronchiolitis unless there is evidence of an associated bacterial pneumonia. Bronchodilators and corticosteroids have not been shown to change the severity or the length of the illness in bronchiolitis and therefore are not recommended. Studies evaluating the effectiveness of hypertonic saline and the combination of oral dexamethasone and inhaled epinephrine in children with bronchiolitis seen in the emergency department and inpatient setting are ongoing.

Patients at risk for life-threatening RSV infections (eg, children younger than 24 months of age whose gestational age is less than 35 weeks, children younger than 24 months of age with other severe pulmonary conditions, congenital heart disease, neuromuscular disease, or significant immunocompromise) should be considered for RSV prophylaxis therapy. For more detail, refer to the American Academy of Pediatrics 2009 guidelines. High-risk patients with RSV bronchiolitis may need to be hospitalized and treated with ribavirin.

Prognosis

The prognosis for the majority of infants with acute bronchiolitis is very good. With improved supportive care and prophylaxis with palivizumab, the mortality rate among high-risk infants has decreased substantially.

MYCOPLASMA PNEUMONIA (SEE ALSO CHAPTER 42)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Fever.
► Cough.
► Most common in children older than 5 years of age.

M pneumoniae is a common cause of symptomatic pneumonia in older children although it may be seen in children younger than 5 years of age. Endemic and epidemic infection can occur. The incubation period is long (2–3 weeks), and the onset of symptoms is slow. Although the lung is the primary infection site, extrapulmonary complications sometimes occur.

► Clinical Findings

A. Symptoms and Signs

Fever, cough, headache, and malaise are common symptoms as the illness evolves. Although cough is usually dry at the onset, sputum production may develop as the illness progresses. Sore throat, otitis media, otitis externa, and bullous myringitis may occur. Rales and chest pain are frequently present on chest examination; decreased breath sounds or dullness to percussion over the involved area may be present.

B. Laboratory Findings and Imaging Studies

The total and differential white blood cell counts are usually normal. Enzyme immunoassay (EIA) and complement fixation are sensitive and specific for *M pneumoniae.* The cold hemagglutinin titer may be elevated during the acute presentation. A titer of 1:64 or higher supports the diagnosis. Acute and convalescent titers for *M pneumoniae* demonstrating a fourfold or greater rise in specific antibodies confirm the diagnosis. Diagnosis of mycoplasmal pneumonia by polymerase chain reaction is also available.

Chest radiographs usually demonstrate interstitial or bronchopneumonic infiltrates, frequently in the middle or lower lobes. Pleural effusions are extremely uncommon.

► Complications

Extrapulmonary involvement of the blood, central nervous system, skin, heart, or joints can occur. Direct Coombs–positive autoimmune hemolytic anemia, occasionally a life-threatening disorder, is the most common hematologic abnormality that can accompany *M pneumoniae* infection. Coagulation defects and thrombocytopenia can also occur. Cerebral infarction, meningoencephalitis, Guillain-Barré syndrome, cranial nerve involvement, and psychosis all have been described. A wide variety of skin rashes, including erythema multiforme and Stevens-Johnson syndrome, can occur. Myocarditis, pericarditis, and a rheumatic fever–like illness can also occur.

► Treatment

Antibiotic therapy with a macrolide for 7–10 days may shorten the course of illness. Ciprofloxacin is a possible alternative. Supportive measures, including hydration, antipyretics, and bed rest, are helpful.

► Prognosis

In the absence of the less common extrapulmonary complications, the outlook for recovery is excellent. The extent to which *M pneumoniae* can initiate or exacerbate chronic lung disease is not well understood.

Don M, Canciani M, Korppi M: Community acquired pneumonia in children: what's old? what's new? Acta Paediatr 2010;99(11):1602–1608 [PMID: 20573146].

TUBERCULOSIS (SEE ALSO CHAPTER 42)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Positive tuberculin skin test or anergic host.
► Positive culture for *M tuberculosis*.
► Symptoms of active disease (if present): chronic cough, anorexia, weight loss or poor weight gain, fever, night sweats.

Tuberculosis is a widespread and deadly disease resulting from infection with *M tuberculosis*. The clinical spectrum of disease includes asymptomatic primary infection, calcified nodules, pleural effusions, progressive primary cavitating lesions, contiguous spread into adjacent thoracic structures, acute miliary tuberculosis, and acute respiratory distress syndrome, overwhelming reactivation infection in the immunocompromised host, occult lymphohematogenous spread, and metastatic extrapulmonary involvement at almost any site. Because transmission is usually through respiratory droplets, isolated pulmonary parenchymal tuberculosis constitutes more than 85% of presenting cases. Pulmonary tuberculosis is the focus of discussion here; additional manifestations of tuberculosis are discussed in Chapter 42.

Following resurgence in the 1980s and early 1990s, tuberculosis has declined among all age groups in the United States, including children. This trend has continued through 2006, the most recent year for which data are available. However, the disease remains a significant cause of morbidity and mortality worldwide.

▶ Clinical Findings

A. Symptoms and Signs

Most children with tuberculosis are asymptomatic and present with a positive tuberculin skin test. Symptoms of active disease, if present, might include chronic cough, anorexia, weight loss or poor weight gain, fever, and night sweats. Children can also present with symptoms of airway obstruction, with secondary bacterial pneumonia or airway collapse resulting from hilar adenopathy.

Because most children infected with tuberculosis are asymptomatic, a clue to infection may be contact with an individual with tuberculosis—often an elderly relative, a caregiver, or a person previously residing in a region where tuberculosis is endemic—or a history of travel to or residence in such an area. Homeless and extremely impoverished children are also at high risk, as are those in contact with high-risk adults (patients with AIDS, residents or employees of correctional institutions or nursing homes, drug users, and healthcare workers). Once exposed, pediatric patients at risk for developing active disease include infants and those with malnutrition, AIDS, diabetes mellitus, or immunosuppression (cancer chemotherapy or corticosteroids).

The symptoms of active disease listed previously most often occur during the first year of infection. Thereafter, infection remains quiescent until adolescence, when reactivation of pulmonary tuberculosis is common. At any stage, chronic cough, anorexia, weight loss or poor weight gain, and fever are useful clinical signs of reactivation. Of note, except in patients with complications or advanced disease, physical findings are few.

B. Laboratory Findings and Imaging Studies

A positive tuberculin skin test is defined by the size of induration as measured by a medical provider 48–72 hours after intradermal injection of 5 tuberculin units of purified protein derivative (PPD). A positive test is defined as an induration greater than or equal to 5 mm in patients who are at high risk for developing active disease (ie, immunocompromised, those with a history of a positive test or radiograph, children younger than 4 years, and those known to have close contact with someone with active disease); greater than 10 mm in patients from or exposed to high-risk populations (ie, born in countries with a high prevalence, users of injected drugs, having poor access to health care, or living in facilities such as jails, homeless shelters, or nursing homes); and greater than 15 mm in those who are at low risk. Tine tests should not be used. Appropriate control skin tests, such as those for hypersensitivity to diphtheria-tetanus, mumps, or *Candida albicans,* should be applied in patients with suspected or proven immunosuppression or in those with possible severe disseminated disease. If the patient fails to respond to PPD, the possibility of tuberculosis is not excluded. In suspected cases, the patient, immediate family, and suspected carriers should also be tuberculin-tested. Because healing—rather than progression—is the usual course in the uncompromised host, a positive tuberculin test may be the only manifestation. The primary focus (usually single) and associated nodal involvement may not be seen radiographically. For patients born outside the United States or those who have received a previous bacillus Calmette-Guérin immunization, induration greater than 5 mm should be considered positive and further evaluated.

There are new serum immunological tests that are currently being studied in adults and children. For example, T-spot. TB (Oxford Immunotec, UK) and Quantiferon-TB Gold (Cellestis, Australia) are now being used in adults. Guidelines for interpretation of the tests in pediatrics are not available. In addition, it is not clear how to distinguish new infection from latent infections using these immunological assays.

C. Imaging Studies

Anteroposterior and lateral chest radiographs should be obtained in all suspected cases. Culture for *M tuberculosis* is critical for proving the diagnosis and for defining drug susceptibility. Early morning gastric lavage following an overnight fast should be performed on three occasions in infants and children with suspected active pulmonary tuberculosis before treatment is started, when the severity of illness allows. Although stains for acid-fast bacilli on this material are of little value, this is the ideal culture site. Despite the increasing importance of isolating organisms because of multiple drug resistance, only 40% of children will yield positive cultures.

D. Special Tests

Sputum cultures from older children and adolescents can also be useful. Stains and cultures of bronchial secretions can be obtained using bronchoscopy. When pleural effusions are present, pleural biopsy for cultures and histopathologic examination for granulomas or organisms provide diagnostic information. Meningeal involvement is also possible in young children, and lumbar puncture should be considered in their initial evaluation.

▶ Differential Diagnosis

Fungal diseases that affect mainly the lungs, such as histoplasmosis, coccidioidomycosis, cryptococcosis, and North American blastomycosis, may resemble tuberculosis and in cases where the diagnosis is unclear, should be excluded by biopsy or appropriate serologic studies. Atypical tuberculous organisms may involve the lungs, especially in the immunocompromised patient. Depending on the presentation, diagnoses such as lymphoreticular and other malignancies, collagen-vascular disorders, or other pulmonary infections may be considered.

▶ Complications

In addition to those complications listed in the sections on general considerations and clinical findings, lymphadenitis, meningitis, osteomyelitis, arthritis, enteritis, peritonitis, and renal, ocular, middle ear, and cutaneous disease may occur. Infants born to parents infected with *M tuberculosis* are at great risk for developing illness. The possibility of life-threatening airway compromise must always be considered in patients with large mediastinal or hilar lesions.

▶ Treatment

Because the risk of hepatitis due to isoniazid is extremely low in children, this drug is indicated in those with a positive tuberculin skin test. This greatly reduces the risk of subsequent active disease and complications with minimal morbidity. Isoniazid plus rifampin treatment for 6 months, plus pyrazinamide during the first 2 months, is indicated when the chest radiograph is abnormal or when extrapulmonary disease is present. Without pyrazinamide, isoniazid plus rifampin must be given for 9 months. In general, the more severe tuberculous complications are treated with a larger number of drugs (see Chapter 42). Enforced, directly observed therapy (twice or three times weekly) is indicated when nonadherence is suspected. Recommendations for antituberculosis chemotherapy based on disease stage are continuously being updated. The most current edition of the American Academy of Pediatrics *Red Book* is a reliable source for these protocols.

Corticosteroids are used to control inflammation in selected patients with potentially life-threatening airway compression by lymph nodes, acute pericardial effusion, massive pleural effusion with mediastinal shift, or miliary tuberculosis with respiratory failure.

▶ Prognosis

In patients with an intact immune system, modern antituberculous therapy offers good potential for recovery. The outlook for patients with immunodeficiencies, organisms resistant to multiple drugs, poor drug adherence, or advanced complications is guarded. Organisms resistant to multiple drugs are increasingly common. Resistance emerges either because the physician prescribes an inadequate regimen or because the patient discontinues medications. When resistance to or intolerance of isoniazid and rifampin prevents their use, cure rates are 50% or less.

Powell DA, Hunt WG: Tuberculosis in children: an update. Adv Pediatr 2006;53:279 [PMID: 17089872].

ASPIRATION PNEUMONIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► History of recurrent aspiration or an aspiration event.
► New-onset respiratory distress, oxygen requirement, or in some children, fever, after the aspiration or in a child with known aspiration.
► Focal findings on physical examination (usually in the side).

Patients whose anatomic defense mechanisms are impaired are at risk of aspiration pneumonia (Table 19–5). Acute disease is commonly caused by bacteria present in the mouth (especially gram-negative anaerobes). Chronic aspiration often causes recurrent bouts of acute febrile pneumonia. It may also lead to chronic focal infiltrates, atelectasis, an illness resembling asthma or ILD, bronchiectasis, or failure to thrive.

▶ Clinical Findings

A. Symptoms and Signs

Acute onset of fever, cough, respiratory distress, or hypoxemia in a patient at risk suggests aspiration pneumonia.

Table 19–5. Risk factors for aspiration pneumonia.

Seizures
Depressed sensorium
Recurrent gastroesophageal reflux, emesis, or gastrointestinal
    obstruction
Neuromuscular disorders with suck-swallow dysfunction
Anatomic abnormalities (laryngeal cleft, tracheoesophageal fistula,
    vocal cord paralysis)
Debilitating illnesses
Occult brainstem lesions
Near-drowning
Nasogastric, endotracheal, or tracheostomy tubes
Severe periodontal disease

Chest physical findings, such as rales, rhonchi, or decreased breath sounds, may initially be limited to the lung region into which aspiration occurred. Although any region may be affected, the right side—especially the right upper lobe in the supine patient—is commonly affected. In patients with chronic aspiration, diffuse wheezing may occur. Generalized rales may also be present. Such patients may not develop acute febrile pneumonias.

B. Laboratory Findings and Imaging Studies

Chest radiographs may reveal lobar consolidation or atelectasis and focal or generalized alveolar or interstitial infiltrates. In some patients with chronic aspiration, perihilar infiltrates with or without bilateral air trapping may be seen.

In severely ill patients with acute febrile illnesses, and especially when the pneumonia is complicated by a pleural effusion, a bacteriologic diagnosis should be made. In addition to blood cultures and cultures of the pleural fluid, cultures of tracheobronchial secretions and bronchoalveolar lavage specimens may be considered (see section Diagnosis of Respiratory Tract Infections).

In patients with chronic aspiration pneumonitis, documentation of aspiration as the cause of illness may be elusive. Barium contrast studies using liquids of increasing consistency may provide evidence of suck-swallow dysfunction or laryngeal cleft. Bolus barium swallow studies with good distention of the esophagus may help to identify an occult tracheoesophageal fistula. Gastroesophageal reflux may be a risk factor for aspiration while the child is sleeping, and an overnight or 24-hour esophageal pH probe studies may also help establish the diagnosis of gastroesophageal reflux. Although radionuclide scans are commonly used, the yield from such studies is disappointingly low. Rigid bronchoscopy in infants or flexible bronchoscopy in older children can be used to identify anatomic abnormalities such as tracheal cleft and tracheoesophageal fistula. Flexible bronchoscopy and bronchoalveolar lavage specimens to search for lipid-laden macrophages can also suggest chronic aspiration.

▶ Differential Diagnosis

In the acutely ill patient, bacterial and viral pneumonias should be considered. In the chronically ill patient, the differential diagnosis may include disorders causing recurrent pneumonia (eg, immunodeficiencies, ciliary dysfunction, or foreign body), chronic wheezing, or interstitial lung disorders (see next section), depending on the presentation.

▶ Complications

Empyema or lung abscess may complicate acute aspiration pneumonia. Chronic aspiration may also result in bronchiectasis.

▶ Treatment

Aspiration pneumonia leads to a chemical pneumonitis and, in some cases, supportive treatment is the only recommended therapy. Antimicrobial therapy for patients who are acutely ill from aspiration pneumonia includes coverage for gram-negative anaerobic organisms. In general, clindamycin is appropriate initial coverage. However, in some hospital-acquired infections, additional coverage for multiple resistant *P aeruginosa,* streptococci, and other organisms may be required

Treatment of recurrent and chronic aspiration pneumonia may include the following: surgical correction of anatomic abnormalities; improved oral hygiene; improved hydration; and inhaled bronchodilators, chest physical therapy, and suctioning. In patients with compromise of the central nervous system, exclusive feeding by gastrostomy and (in some) tracheostomy may be required to control airway secretions. Gastroesophageal reflux, if present in these patients, also often requires surgical correction.

▶ Prognosis

The outlook is directly related to the disorder causing aspiration.

Boesch RP et al: Advances in the diagnosis and management of chronic pulmonary aspiration in children. Eur Respir J 2006; 28(4):847–861 [PMID: 17012631].

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST

An immunocompromised state must be considered in patients following solid organ or hematopoietic stem cell transplants, those with congenital or acquired immune

deficits or autoimmune disorders, and those on chemotherapy or immunosuppressant therapy. Pulmonary infection is the most common form of infection in these hosts and can present with focal pneumonia or ILD. The underlying cause of the immunocompromised state often determines the spectrum of infectious agents responsible for disease (see also Chapter 33). Pneumonia in an immunocompromised host may be due to any common bacteria (streptococci, staphylococci, or *M pneumoniae*) or less common pathogens such as *Toxoplasma gondii, P jiroveci, Aspergillus* species, *Mucor* species, *Candida* species, *Cryptococcus neoformans,* gram-negative enteric and anaerobic bacteria, *Nocardia* species, *L pneumophila,* mycobacteria, and viruses (cytomegalovirus, varicella-zoster, herpes simplex, influenza virus, respiratory syncytial virus, human metapneumovirus, or adenovirus). Multiple organisms are common and disseminated disease is possible.

▶ Clinical Findings

A. Symptoms and Signs

Patients often present with subtle signs such as mild cough, tachypnea, or low-grade fever that can rapidly progress to high fever, respiratory distress, and hypoxemia or chILD syndrome. An obvious portal of infection, such as an intravascular catheter, may predispose to bacterial or fungal infection.

B. Laboratory Findings and Imaging Studies

Fungal, parasitic, or bacterial infection, especially with antibiotic-resistant bacteria, should be suspected in the neutropenic child. Cultures of peripheral blood, sputum, tracheobronchial secretions, urine, nasopharynx or sinuses, bone marrow, pleural fluid, biopsied lymph nodes, or skin lesions or cultures through intravascular catheters should be obtained as soon as infection is suspected. Currently, serum and bronchoalveolar lavage (BAL) galactomannan assays for invasive pulmonary aspergillosis are being used in some centers to help guide therapy.

Invasive methods are commonly required to make a diagnosis. Appropriate samples should be obtained soon after a patient with pneumonia fails to respond to initial treatment. The results of these procedures usually lead to important changes in empiric therapy. Sputum is often unavailable. Bronchoalveolar lavage frequently provides the diagnosis of one or more organisms and should be done early in evaluation. The combined use of a wash, brushing, and lavage has a high yield. In patients with rapidly advancing, or more peripheraldisease, lung biopsy becomes more urgent. The morbidity and mortality of this procedure can be reduced by a surgeon skilled in video-assisted thoracoscopic surgical (VATS) techniques. Because of the multiplicity of organisms

that may cause disease, a comprehensive set of studies should be done on lavage and biopsy material. These consist of rapid diagnostic studies, including fluorescent antibody studies for *Legionella;* rapid culture and antigen detection for viruses; Gram, acid-fast, and fungal stains; cytologic examination for viral inclusions; cultures for viruses, anaerobic and aerobic bacteria, fungi, mycobacteria, and *Legionella;* and rapid immunofluorescent studies for *P jiroveci.*

Chest radiographs and increasingly high-resolution CT scans may be useful in identifying the pattern and extent of disease. In *P jiroveci* pneumonia, dyspnea and hypoxemia may be marked despite minimal radiographic abnormalities.

▶ Differential Diagnosis

The organisms causing disease vary with the type of immunocompromise present. For example, the splenectomized or sickle cell disease patient may be overwhelmed by infection with encapsulated bacteria. The child with HIV/AIDS or receiving immunosuppressant therapy or chemotherapy is more likely to have *P jiroveci* infection. The febrile neutropenic child who has been receiving adequate doses of intravenous broad-spectrum antibiotics or systemic steroid therapy may have fungal disease. The key to diagnosis is to consider all possibilities of infection.

Depending on the form of immunocompromise, perhaps only half to two-thirds of new pulmonary infiltrates in such patients represent infection. The remainder are caused by pulmonary toxicity of radiation, chemotherapy, or other drugs; pulmonary disorders, including hemorrhage, embolism, atelectasis, or aspiration; idiopathic pneumonia syndrome or acute respiratory distress syndrome in bone marrow transplant patients; recurrence or extension of primary malignant growths or immunologic disorders; transfusion reactions, leukostasis, or tumor cell lysis; or ILD, such as lymphocytic interstitial pneumonitis with HIV infection.

▶ Complications

Necrotizing pneumonia, lung abscesses, and parapneumonic effusions can develop. Progressive respiratory failure, shock, multiple organ damage, disseminated infection, and death commonly occur in the infected immunocompromised host if the primary etiology is not treated effectively.

▶ Treatment

Early use of broad-spectrum intravenous antibiotics is indicated early in febrile, neutropenic, or immunocompromised children. Trimethoprim-sulfamethoxazole (for *Pneumocystis*) and macrolides (for *Legionella*) are also indicated early in the treatment of immunocompromised children before an organism is identified. Further therapy should be based on studies of specimens obtained from

bronchoalveolar lavage or lung biopsy. Recent data suggest that use of noninvasive ventilation strategies early in the course of pulmonary insufficiency or respiratory failure may decrease mortality.

Prognosis

Prognosis is based on the severity of the underlying immunocompromise, appropriate early diagnosis and treatment, and the infecting organisms. Intubation and mechanical ventilation have been associated with high mortality rates, especially in hematopoietic stem cell transplant patients.

Collaco J, Michael et al: Pulmonary dysfunction in pediatric hematopoietic stem cell transplant patients: overview, diagnostic considerations, and infectious complications. Pediatr Blood Cancer 2007;49(2):117 [PMID: 17029246].

Nouér Simone A et al: Earlier response assessment in invasive aspergillosis based on the kinetics of serum Aspergillus galactomannan: proposal for a new definition. Clin Infect Dis 2011;53(7):671 [PMID: 21846834].

LUNG ABSCESS

Pathogensis

Lung abscesses are thick-walled cavities that form from inflammation and central necrosis following an initial pulmonary infection. A primary lung abscess occurs in a previously well child or one prone to aspiration, while secondary lung abscesses develop in children with immunosuppression, underlying lung or systemic disease. Lung abscesses may also occur via embolic spread. Although organisms such as *S aureus, S pneumoniae,* and other staphylococci and streptococci more commonly affect the healthy host, anaerobic and gram-negative organisms as well as *Nocardia, Legionella* species, and fungi (*Candida* and *Aspergillus*) should also be considered in the immunocompromised host or in patients not responding to treatment.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs referable to the chest may or may not be present. High fever, malaise, and weight loss are often present. In infants, evidence of respiratory distress can be present.

B. Laboratory Findings and Imaging Studies

Elevated peripheral white blood cell count with a neutrophil predominance or an elevated erythrocyte sedimentation rate or C-reactive protein may be present. Blood cultures are rarely positive except in the overwhelmed host.

Chest radiographs usually reveal single or multiple thick-walled lung cavities. Air-fluid levels can be present. Local compressive atelectasis, pleural thickening, or adenopathy may also occur. Chest CT scan may provide better localization and understanding of the lesions.

In patients producing sputum, stains, and cultures may provide the diagnosis. Direct percutaneous aspiration of material for stains and cultures guided by fluoroscopy or ultrasonography or CT imaging should be considered in the severely compromised or ill.

Differential Diagnosis

Loculated pyopneumothorax, an *Echinococcus* cyst, neoplasms, plasma cell granuloma, and infected congenital cysts and sequestrations should be considered. Pneumatoceles, non–fluid-filled cysts, are common in children with empyema and usually resolve over time.

Complications

Although complications due to abscesses are now rare, mediastinal shift, tension pneumothorax, and spontaneous rupture can occur. Diagnostic maneuvers such as radiology-guided lung puncture to drain and culture the abscess may also cause a pneumothorax or a bronchopulmonary fistula.

Treatment

Because of the risks of lung puncture, uncomplicated abscesses are frequently conservatively treated in the uncompromised host with appropriate broad-spectrum intravenous antibiotics directed at *S aureus, S pneumonia, and other staphylococci* and streptococci. Additional coverage for anaerobic gram-negative organisms and fungi should be provided for others. Prolonged therapy with 2–3 weeks of intravenous antibiotics followed by oral therapy may be required. Attempts to drain abscesses via bronchoscopy have caused life-threatening airway compromise. Surgical drainage or lobectomy is occasionally required, primarily in immunocompromised patients. However, such procedures may themselves cause life-threatening complications.

Prognosis

Although radiographic resolution may be very slow (6 weeks–5 years), resolution occurs in most patients without risk factors for lower respiratory tract infections or loss of pulmonary function. In the immunocompromised or medically complex host, the outlook depends on the underlying disorder.

CHILDREN'S INTERSTITIAL LUNG DISEASE SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▸ Occurs acutely in the neonatal period or subacutely in infancy or childhood.

▸ Infants and young children have different diagnoses than adolescents and adults.

▸ Presence of three to five of the following criteria in the absence of any identified primary etiology is suggestive of an interstitial lung disease (ILD) syndrome:

▸ Symptoms of impaired respiratory function (cough, tachypnea, retractions, exercise intolerance).

▸ Evidence of impaired gas exchange (resting hypoxemia or hypercarbia, desaturation with exercise).

▸ Diffuse infiltrates on imaging.

▸ Presence of adventitious sounds (crackles, wheezing).

▸ Abnormal spirometry, lung volumes, or carbon monoxide diffusing capacity.

▸ History of exposure (eg, birds, organic dusts, drug therapy, hot tubs, molds), previous lung disease, immunosuppression, symptoms of connective tissue disease; family history of familial lung disease (especially ILD) or early infant death from lung disease.

Children's **I**nterstitial **L**ung **D**isease (chILD) syndrome is a constellation of signs and symptoms and not a specific diagnosis. Once recognized, chILD syndrome should elicit a search for a more specific diagnosis. Known disorders can present as chILD syndrome and must be excluded as the primary cause of symptoms. These disorders include CF, cardiac disease, asthma, acute infection, immunodeficiency, neuromuscular disease, scoliosis, thoracic cage abnormality, typical BPD or premature respiratory distress syndrome, and confirmed significant aspiration on a swallow study. However, if patients present with symptoms out of proportion to the diagnosis, consideration should be given to other ILD disorders.

▸ Clinical Findings

A. Symptoms and Signs

chILD syndrome may present acutely in the newborn period with respiratory failure or gradually over time with a chronic dry cough or a history of dyspnea on exertion. The child with more advanced disease may have dyspnea, resting tachypnea, retractions, hypoxemia, cyanosis, barrel chest, clubbing, failure to thrive, or weight loss.

B. Laboratory Findings

Initial evaluations should be directed at ruling out known conditions. Depending on the age and presentation, this should include the following: chest radiographs, modified barium swallow, pulmonary function tests, and skin tests (see section Tuberculosis); complete blood count and erythrocyte sedimentation rate; sweat chloride test for CF; electrocardiogram or echocardiogram; serum immunoglobulins and other immunologic evaluations; sputum studies (see section Pneumonia in the Immunocompromised Host); and possibly studies for Epstein-Barr virus, cytomegalovirus, *M pneumoniae, Chlamydia, Pneumocystis,* and *Ureaplasma urealyticum.*

C. Imaging Studies

Chest radiographs are normal in up to 10%–15% of patients. Frequently, specific chILD disorders can be suspected by findings on controlled volume inspiratory and expiratory high-resolution CT. Diagnoses of bronchiolitis obliterans (BO) and neuroendocrine cell hyperplasia of infancy (NEHI) can be made using CT findings in the right clinical context. Infants and children younger than age 5 years require sedation, which allows either infant pulmonary function testing or bronchoscopy to be completed at the same time. The lowest possible dose of radiation should always be used and this point should be emphasized at centers not specialized in pediatric care.

D. Special Tests

Depending on the specific ILD, pulmonary function tests may show (1) a restrictive pattern of decreased lung volumes, compliance, and carbon monoxide diffusing capacity, (2) an obstructive pattern with hyperinflation, or (3) a mixed obstructive-restrictive pattern. Exercise-induced or nocturnal hypoxemia is often the earliest detectable abnormality of lung function in children.

During the second evaluation phase, bronchoscopy is performed to exclude anatomic abnormalities, and obtain bronchoalveolar lavage for microbiologic and cytologic testing. Nasal brushings to evaluate for primary ciliary dyskinesia (see section Primary Ciliary Dyskinesia) may be obtained if this diagnosis is suspected.

In patients with static or slowly progressing disease, one can then await results of bronchoscopic studies. In patients with acute, rapidly progressive disease, this stage should be combined with video-assisted thoracoscopic lung biopsy. Lung biopsy is the most reliable method for definitive diagnosis when analyzed by pathologists experienced in chILD

disorders. A new chILD histology classification has been proposed to improve diagnostic yields. Tissue should be processed in a standard manner for special stains and cultures, electron microscopy, and immunofluorescence for immune complexes if indicated. Although transbronchial biopsy may be useful in diagnosing a few diffuse disorders and graft rejection in transplantation (eg, sarcoidosis), its overall usefulness in chILD is limited at this time.

E. Special Examinations: Genetic Testing

Genomic mutational analysis of tissue or blood for surfactant proteins B and C (SP-B, SP-C) and *ABCA3* is now offered in clinical laboratories and should be considered in children with diffuse lung disease or a strong family history of ILD. Recently other genetic mutations have been reported for rare chILD that offer diagnostic information. A newly recognized disorder associated with the thyroid transcription factor–1 protein (NKX2.1 gene) can result in variable phenotypes of brain, thyroid, and lung syndrome. Children with unexplained lung disease and hypotonia or developmental delays with or without hypothyroidism and newborns with severe RDS and congenital hypothyroidism should be screened for this disorder. Other genetic disorders that cause ILD include alveolar capillary dysplasia (FOXF1 found in 30% of patients), pulmonary alveolar proteinosis (GCSF [granulocyte colony-stimulating factor] receptor mutations or autoantibodies), pulmonary alveolar microlithiasis (SLC34A2), and lysinuric protein intolerance (SLC7A7).

▶ Differential Diagnosis

chILD syndrome is composed of a group of diverse conditions that differ from adult ILD conditions. Common adult causes of ILD such as idiopathic pulmonary fibrosis, which is associated with a high mortality rate, and respiratory bronchiolitis, associated with smoking, have not been found in children. Conversely, newly identified conditions unique to infancy such as neuroendocrine cell hyperplasia of infancy (NEHI) or pulmonary interstitial glycogenosis (PIG), have not been described in adults. Other chILD conditions include the genetically recognized surfactant dysfunction mutations SP-B, SP-C, *ABCA3,* and *NKX2.1;* developmental abnormalities; and growth disorders, especially in younger children. Older children are more likely to have SP-C or *ABCA3* surfactant mutations, hypersensitivity pneumonitis, or collagen-vascular disease. Other known conditions must also be ruled out.

▶ Complications

Respiratory failure or pulmonary hypertension may occur. Somatic growth deficiencies often require nutritional supplementation. Mortality and morbidity can be significant in and vary by specific diagnosis.

▶ Treatment

Therapy for known causes of ILD such as infection, aspiration, or cardiac disorders should be directed toward the primary disorder. It must be recognized that treatment for chILD conditions is anecdotal and based on case reports and small case series. In noninflammatory chILD syndrome conditions such as NEHI or developmental or growth abnormalities, treatment is supportive and may not require corticosteroids. For surfactant dysfunction mutations, PIG, hypersensitivity pneumonitis, and systemic collagen-vascular disease, patients are frequently treated initially with glucocorticoids. Other conditions may require oral glucocorticoids (2 mg/kg/d for 6 weeks) or monthly pulse glucocorticoids (IV doses of 10–30 mg/kg for 1–3 days). Many patients require even more protracted therapy with alternate-day prednisone. Chloroquine (5–10 mg/kg/d) may be useful in selected disorders such as desquamative interstitial pneumonitis, surfactant dysfunction mutations, or refractory disease. Cyclophosphamide is used in severe cases of diffuse alveolar hemorrhage associated with pulmonary capillaritis. In refractory cases, immunomodulatory therapies (plasmapheresis, intravenous immunoglobulin, azathioprine, cyclophosphamide, and rituximab) have been used. Finally, some patients with severe disease may require long-term mechanical ventilation or lung transplantation for survival. Children with ILD should be evaluated and cared for by an experienced multidisciplinary team. The chILD Family Foundation can provide further supportive resources for families (http://www.childfoundation.us).

▶ Prognosis

Prognosis is guarded in children with ILD due to collagen-vascular disease, surfactant dysfunction mutations, and lung development disorders. Mortality has been reported in PIG, usually in association with a concurrent lung growth abnormality. Deaths have not been reported in NEHI.

HYPERSENSITIVITIY PNEUMONITIS

Hypersensitivity pneumonitis, or extrinsic allergic alveolitis, is a T-cell–mediated disease involving the peripheral airways, interstitium, and alveoli and presents as a distinct

form of chILD. Both acute and chronic forms may occur. In children, the most common forms are brought on by exposure to domestic and occasionally wild birds or bird droppings (eg, pigeons, parakeets, parrots, or doves) also known as bird fanciers lung. Intensity, duration, and genetic predisposition are all important factors. However, inhalation of almost any organic dust (moldy hay, compost, logs or tree bark, sawdust, or aerosols from humidifiers or hot tubs) can cause disease. Methotrexate-induced hypersensitivity has also been described in a child with juvenile rheumatoid arthritis. Hot tub lung can be caused by exposure to aerosolized *Mycobacterium avium* complex. A high level of suspicion and a thorough history with attention to environmental exposures are required for diagnosis.

▶ Clinical Findings

A. Symptoms and Signs

Episodic cough and fever can occur with acute exposures. Chronic exposure results in weight loss, fatigue, dyspnea, cyanosis, and, ultimately, respiratory failure.

B. Laboratory Findings

Acute exposure may be followed by polymorphonuclear leukocytosis with eosinophilia and evidence of airway obstruction on pulmonary function testing. Chronic disease results in a restrictive picture on lung function tests.

The serologic key to diagnosis is the finding of precipitins (precipitating IgG antibodies) to the organic materials that contain avian proteins or fungal or bacterial antigens. Ideally, to identify avian proteins, the patient's sera should be tested with antigens from droppings of the suspected species of bird. However, exposure may invoke precipitins without causing disease.

When serologic investigations are not diagnostic, lung biopsy may be necessary. Histopathology is characterized by lymphocyte predominant interstitial infiltrates, cellular bronchiolitis, and peribronchiolar noncaseating granulomas.

Chest x-ray findings are variable and may include normal lung fields, air-space consolidation, nodular, or reticulonodular patterns. High-resolution CT of the chest is more sensitive, with classic findings of centrilobular nodules, ground-glass opacities, and air-trapping. Pulmonary fibrosis is seen in chronic disease. Lymphocytosis or *M avium* complex on bronchoalveolar lavage may be suggestive.

▶ Differential Diagnosis

Patients with mainly acute symptoms must be differentiated from those with atopic asthma. Patients with chronic symptoms must be distinguished from those with collagen-vascular, immunologic, or primary interstitial lung disease.

▶ Complications

Prolonged exposure to offending antigens may result in pulmonary hypertension due to chronic hypoxemia, irreversible restrictive lung disease due to pulmonary fibrosis, or respiratory failure.

▶ Treatment & Prognosis

Complete elimination of exposure to the offending antigens is required. If drug-induced hypersensitivity pneumonitis is suspected, discontinuation is required. Corticosteroids may hasten recovery. With appropriate early diagnosis and identification and avoidance of offending antigens, the prognosis is excellent.

Venkatesh P, Wild L: Hypersensitivity pneumonitis in children: clinical features, diagnosis, and treatment. Paediatr Drugs 2005; 7(4):235–244 [PMID: 16117560].

▼ DISEASES OF THE PULMONARY CIRCULATION

PULMONARY HEMORRHAGE

Pulmonary hemorrhage can be caused by a spectrum of disorders affecting the large and small airways and alveoli. It can occur as an acute or chronic process. If pulmonary hemorrhage is subacute or chronic, hemosiderin-laden macrophages can be found in the sputum and tracheal or gastric aspirate 48–72 hours after the bleeding begins. Many cases are secondary to bacterial, mycobacterial, parasitic, viral, or fungal infections (such as the toxigenic mold *Stachybotrys chartarum*. Lung abscess, bronchiectasis (CF or other causes), foreign body, coagulopathy (often with overwhelming sepsis), or elevated pulmonary venous pressure (secondary to congestive heart failure, anatomic heart lesions, or ascent to high altitude) may also cause pulmonary hemorrhage. Other causes include lung contusion from trauma, pulmonary embolus with infarction, arteriovenous fistula or telangiectasias, autoimmune vasculitis, hypersensitivity pneumonitis pulmonary sequestration, agenesis of a single pulmonary artery, and esophageal duplication or bronchogenic cyst. In children, pulmonary hemorrhage due to airway tumors (eg, bronchial adenoma or left atrial myxoma) is quite rare.

Hemorrhage involving the alveoli is termed diffuse alveolar hemorrhage. Diffuse alveolar hemorrhage may be idiopathic or drug-related or may occur in Goodpasture syndrome, rapidly progressive glomerulonephritis, and systemic vasculitides (often associated with such collagen-vascular diseases as systemic lupus erythematosus, rheumatoid arthritis, Wegener granulomatosis, polyarteritis nodosa,

Henoch-Schönlein purpura, and Behçet disease). Idiopathic pulmonary hemosiderosis refers to the accumulation of hemosiderin in the lung, especially the alveolar macrophage, as a result of chronic or recurrent hemorrhage (usually from pulmonary capillaries) that is not associated with the previously listed causes. Children and young adults are mainly affected, with the age at onset ranging from 6 months to 20 years.

▶ Clinical Findings

A. Symptoms and Signs

Large airway hemorrhage presents with hemoptysis and symptoms of the underlying cause, such as infection, foreign body, or bronchiectasis in CF. Hemoptysis from larger airways is often bright red or contains clots. Children with diffuse alveolar hemorrhage may present with massive hemoptysis, marked respiratory distress, stridor, or a pneumonia-like syndrome. However, most patients with diffuse alveolar hemorrhage and idiopathic pulmonary hemosiderosis present with nonspecific respiratory symptoms (cough, tachypnea, and retractions) with or without hemoptysis, poor growth, and fatigue. Fever, abdominal pain, digital clubbing, and chest pain may also be reported. Jaundice and hepatosplenomegaly may be present with chronic bleeding. Physical examination often reveals decreased breath sounds, rales, rhonchi, or wheezing.

B. Laboratory Findings and Imaging Studies

Laboratory studies depend on the cause of hemorrhage. When gross hemoptysis is present, large airway bronchiectasis, epistaxis, foreign body, and arteriovenous malformations should be considered. Flexible bronchoscopy and imaging (MRI or CT-assisted angiography) can be used to localize the site of bleeding. Alveolar bleeding with hemoptysis is often frothy and pink. Long-standing idiopathic pulmonary hemorrhage may cause iron deficiency anemia and heme-positive sputum. Nonspecific findings may include lymphocytosis and an elevated erythrocyte sedimentation rate. Peripheral eosinophilia is present in up to 25% of patients. Chest radiographs may demonstrate perihilar infiltrates, fluffy alveolar infiltrates with or without atelectasis, and mediastinal adenopathy. Pulmonary function testing generally reveals restrictive impairment, with low lung volumes, poor compliance, and an increased diffusion capacity. Hemosiderin-laden macrophages are found in tracheal or gastric aspirates. The diagnostic usefulness of lung biopsy is controversial.

Patients with diffuse alveolar hemorrhage with an underlying systemic disease may need a lung biopsy. In patients with systemic lupus erythematosus, Wegener granulomatosis, and occasionally Goodpasture syndrome diffuse alveolar hemorrhage can occur with the histologic entity known as necrotizing pulmonary capillaritis. Lung biopsy reveals alveolar septa infiltrated with neutrophils, edema, or necrosis in addition to alveolar hemorrhage. In idiopathic pulmonary hemosiderosis, a mild form of capillaritis is associated with focal or diffuse alveolar hemorrhage. An immune-mediated process may cause idiopathic pulmonary hemosiderosis and capillaritis by biopsy in the absence of an identifiable serologic marker. Although capillaritis has been described without evidence of underlying systemic disease, the search for collagen-vascular disease, vasculitis, or pulmonary fibrosis should be exhaustive.

Serologic studies such as circulating antineutrophilic cytoplasmic autoantibodies for Wegener granulomatosis, perinuclear antineutrophilic cytoplasmic autoantibodies for microscopic polyangiitis, antinuclear antibodies for systemic lupus erythematosus, and anti–basement membrane antibodies for Goodpasture syndrome should be obtained. α_1-Antitrypsin deficiency should also be considered.

Cow's milk–induced pulmonary hemosiderosis (Heiner syndrome) can be confirmed by high titers of serum precipitins to multiple constituents of cow's milk and positive intradermal skin tests to cow's milk proteins. Improvement after eliminating cow's milk also supports the diagnosis.

▶ Differential Diagnosis

Bleeding from the nose or mouth can present as hemoptysis. Therefore, a complete examination of the nose and mouth is required before confirming the diagnosis of intrapulmonary bleeding. Hematemesis can also be confused with hemoptysis; confirming that the blood was produced after coughing and not with emesis should also be part of the initial evaluations. A complete past medical history including underlying systemic illness and cardiovascular anomalies may direct the search for the site of respiratory bleeding.

▶ Treatment

Therapy should be aimed at direct treatment of the underlying disease. In severe bleeding, intubation with application of positive pressure during mechanical ventilation and/or endotracheal administration of epinephrine may help attenuate bleeding. Patients with cystic fibrosis or bronchiectasis from other causes who develop massive (> 240 mL) or recurrent hemoptysis, bronchial artery embolization may be necessary. An experienced interventional radiologist should be consulted immediately. Although its use requires anticoagulation, extracorporal life support has resulted in the survival of children with severe pulmonary hemorrhage. For more chronic bleeding, supportive measures, including iron therapy, supplemental oxygen, and blood transfusions, may be needed. A diet free of cow's milk should be tried in infants. Systemic corticosteroids have been used for various causes of diffuse alveolar hemorrhage and have been particularly successful in those secondary to collagen-vascular

disorders and vasculitis. Case reports have been published describing the variable effectiveness of steroids, chloroquine, cyclophosphamide, and azathioprine for idiopathic pulmonary hemosiderosis.

▶ Prognosis

The outcome of pulmonary hemorrhage depends on the cause of the bleeding and how much blood has been lost. The course of idiopathic pulmonary hemosiderosis is variable, characterized by a waxing and waning course of intermittent intrapulmonary bleeds and the gradual development of pulmonary fibrosis over time. The severity of the underlying renal disease contributes to the mortality rates associated with Goodpasture syndrome and Wegener granulomatosis. Diffuse alveolar hemorrhage is considered a lethal pulmonary complication of systemic lupus erythematosus.

Sherman J et al: Time course of Hemosiderin production and clearance by human pulmonary macrophages. Chest 1984;86:409 [PMID: 6468000].

PULMONARY EMBOLISM

Pulmonary embolism is a rare, but severe cause of respiratory distress in children. It is commonly caused by sickle cell anemia as part of the acute chest syndrome, malignancy, rheumatic fever, infective endocarditis, schistosomiasis, bone fracture, dehydration, polycythemia, nephrotic syndrome, atrial fibrillation, and other conditions. A majority of children with pulmonary emboli referred for hematology evaluation have coagulation regulatory protein abnormalities and antiphospholipid antibodies. Emboli may result in clinical signs and symptoms dependent on the severity of pulmonary vascular obstruction. In children, tumor emboli are a more common cause of massive pulmonary embolism than embolization from a lower extremity deep venous thrombosis.

▶ Clinical Findings

A. Symptoms and Signs

Pulmonary embolism usually presents as an acute onset of dyspnea and tachypnea. Heart palpitations, pleuritic chest pain, and a sense of impending doom may be reported.

Hemoptysis is rare, but may occur along with splinting, cyanosis, and tachycardia. Massive emboli may be present with syncope and cardiac arrhythmias. Physical examination is usually normal (except for tachycardia and tachypnea) unless the embolism is associated with an underlying disorder. Mild hypoxemia, rales, focal wheezing, or a pleural friction rub may be found.

B. Laboratory Findings and Imaging Studies

Radiographic findings may be normal, but a peripheral infiltrate, small pleural effusion, or elevated hemidiaphragm can be present. If the emboli are massive, differential blood flow and pulmonary artery enlargement may be appreciated. The electrocardiogram is usually normal unless the pulmonary embolus is massive. Echocardiography is useful in detecting the presence of a large proximal embolus. A negative D-dimer has a more than 95% negative predictive value for an embolus. Ventilation-perfusion scans show localized areas of ventilation without perfusion.

Spiral CT with contrast may be helpful, but pulmonary angiography is the gold standard. A recent case series suggests that bedside chest ultrasound may aid in diagnosing pulmonary emboli, particularly in critically ill children. Further evaluation may include Doppler ultrasound studies of the legs to search for deep venous thrombosis. Coagulation studies, including assessments of antithrombin III, fibrinogen, antiphospholipid antibodies, homocystine, coagulation regulatory proteins (proteins C and S, and factor V Leiden), and the prothrombin G20210A mutation are abnormal in up to 70% of pediatric patients with pulmonary embolism.

▶ Treatment

Acute treatment includes supplemental oxygen, and anticoagulation. Current recommendations include heparin therapy to maintain an activated partial thromboplastin time of greater than 1.5 times the control value for the first 24 hours. Urokinase or tissue plasminogen activator can be used to help dissolve the embolus. These therapies should be followed by warfarin therapy for at least 6 weeks with an international normalized ratio (INR) greater than 2.

Konstantinides S et al: Heparin plus alteplase compared with heparin alone in patients with submassive pulmonary embolism. N Engl J Med 2002;347:1143 [PMID: 12374874].

PULMONARY EDEMA

▶ Pathogenesis

Pulmonary edema is excessive accumulation of extravascular fluid in the lung. This occurs when fluid is filtered into the lungs faster than it can be removed, leading to changes in lung mechanics such as decreased lung compliance, worsening

hypoxemia from ventilation-perfusion mismatch, bronchial compression, and if advanced, decreased surfactant function. There are two basic types of pulmonary edema: increased pressure (cardiogenic or hydrostatic) and increased permeability (noncardiogenic or primary). Hydrostatic pulmonary edema is usually due to excessive increases in pulmonary venous pressure, which is most commonly due to congestive heart failure from multiple causes. Postobstructive pulmonary edema occurs when airway occlusion (or its sudden relief) causes a sudden drop in airway pressure which leads to increased venous return and decreased left heart blood flow. These changes result in elevated hydrostatic pressures and transudation of fluid from the pulmonary capillaries to the alveolar space.

In contrast, many lung diseases, especially acute respiratory distress syndrome, are characterized by the development of pulmonary edema secondary to changes in permeability due to injury to the alveolocapillary barrier. In these settings, pulmonary edema occurs independently of the elevations of pulmonary venous pressure.

▶ Clinical Findings

A. Symptoms and Signs

Cyanosis, tachypnea, tachycardia, and respiratory distress are commonly present. Physical findings include rales, diminished breath sounds, and (in young infants) expiratory wheezing. More severe disease is characterized by progressive respiratory distress with marked retractions, dyspnea, and severe hypoxemia.

B. Imaging Studies

Chest radiographic findings depend on the cause of the edema. Pulmonary vessels are prominent, often with diffuse interstitial or alveolar infiltrates. Heart size is usually normal in permeability edema but enlarged in hydrostatic edema.

▶ Treatment

Although specific therapy depends on the underlying cause, supplemental oxygen therapy, and ventilator support may be indicated. Diuretics, digoxin, and vasodilators may be indicated for congestive heart failure along with restriction of salt and water. Loop diuretics, such as furosemide, are primarily beneficial because they increase systemic venous capacitance, not because they induce diuresis. Improvement can even be seen in anuric patients. Recommended interventions for permeability edema are reduction of vascular volume and maintenance of the lowest central venous or pulmonary arterial wedge pressure possible without sacrificing cardiac output or causing hypotension (see following discussion). β-Adrenergic agonists such as terbutaline have been shown to increase alveolar clearance of lung water, perhaps through the action of a sodium-potassium channel

pump. Maintaining normal albumin levels and a hematocrit concentration above 30 maintains the filtration of lung liquid toward the capillaries, avoiding low oncotic pressure.

High-altitude pulmonary edema (HAPE) occurs when susceptible individuals develop noncardiogenic edema after rapid ascent to altitudes above 3000 m. Children may develop HAPE with variation in severity. Oxygen therapy and prompt descent are the cornerstones of therapy for this illness.

CONGENITAL PULMONARY LYMPHANGIECTASIA

Structurally, congenital pulmonary lymphangiectasia appears as dilated subpleural and interlobular lymphatic channels and may present as part of a generalized lymphangiectasis (in association with obstructive cardiovascular lesions—especially total anomalous pulmonary venous return) or as an isolated idiopathic lesion. Pathologically, the lung appears firm, bulky, and noncompressible, with prominent cystic lymphatics visible beneath the pleura. On cut section, dilated lymphatics are present near the hilum, along interlobular septa, around bronchovascular bundles, and beneath the pleura. Histologically, dilated lymphatics have a thin endothelial cell lining overlying a delicate network of elastin and collagen.

▶ Clinical Findings

Congenital pulmonary lymphangiectasia is a rare, usually fatal disease that generally presents as acute or persistent respiratory distress at birth. Although most patients do not survive the newborn period, some survive longer, and there are case reports of its diagnosis later in childhood. Congenital pulmonary lymphangiectasia may be associated with Noonan syndrome, asplenia, total anomalous pulmonary venous return, septal defects, atrioventricular canal, hypoplastic left heart, aortic arch malformations, and renal malformations. Chylothorax has been reported. Chest radiographic findings include a ground-glass appearance, prominent interstitial markings suggesting lymphatic distention, diffuse hyperlucency of the pulmonary parenchyma, and hyperinflation with depression of the diaphragm.

▶ Prognosis

Although the onset of symptoms may be delayed for as long as the first few months of life, prolonged survival is rare.

Most deaths occur within weeks after birth. However, more recent studies have shown that respiratory symptoms do improve after the first year of life suggesting that maximal medical treatment remains warranted. In those with the most severe disease, rapid diagnosis is essential in order to expedite the option of lung transplantation.

▼ DISORDERS OF THE CHEST WALL & DIAPHRAGM

SCOLIOSIS

Scoliosis is defined as lateral curvature of the spine and is commonly categorized as idiopathic, congenital, or neuromuscular. No pulmonary impairment is typically seen with a Cobb angle showing thoracic curvature of less than 35 degrees. Most cases of idiopathic scoliosis occur in adolescent girls and are corrected before significant pulmonary impairment occurs. Congenital scoliosis of severe degree or with other major abnormalities carries a more guarded prognosis. Patients with progressive neuromuscular disease, such as Duchenne muscular dystrophy, can be at risk for respiratory failure due to severe scoliosis and restrictive lung disease. Severe scoliosis can also lead to impaired lung function and, if uncorrected, possible death from cor pulmonale. (See also Chapter 26.) Small studies indicate that surgical correction of neuromuscular scoliosis may lead to improved quality of life, although pulmonary function may not improve.

Greiner KA: Adolescent idiopathic scoliosis: Radiologic decision-making. Am Fam Physician 2002;65:1817 [PMID: 12018804].
Johnston CE et al: Correlation of preoperative deformity magnitude and pulmonary function tests in adolescent idiopathic scoliosis. Spine 2011;36:1096–1102 [PMID: 21270699].

PECTUS CARINATUM

Pectus carinatum is a protrusion of the upper or lower (more common) portion of the sternum, more commonly seen in males. Impedance of cardiopulmonary function due to pectus carinatum is debated. The decision to repair this deformity is often based upon cosmetic concerns. Research has shown that those with reduced endurance or dyspnea with mild exercise experienced marked improvement within 6 months following repair, suggesting possible physiologic indications. Pectus carinatum may be associated with systemic diseases such as the mucopolysaccharidoses and congenital heart disease.

Lawson ML et al: Impact of pectus excavatum on pulmonary function before and after repair with the Nuss procedure. J Pediatr Surg 2005;40:174 [PMID: 15868581].
Malek MH et al: Ventilatory and cardiovascular responses to exercise in patients with pectus excavatum. Chest 2003;124:870 [PMID: 12970011].

PECTUS EXCAVATUM

Pectus excavatum is anterior depression of the chest wall that may be symmetrical or asymmetrical with respect to the midline. Its presence can be psychologically difficult for the patient. Whether or not it is cause for cardiopulmonary limitations is controversial. While subjective exertional dyspnea can be reported and may improve with repair, objective cardiopulmonary function may not change postoperatively. Therefore, the decision to repair the deformity may be based on cosmetic or physiologic considerations. Surgical literature provides more information regarding long-term outcomes following repair. Timing of repair is critical in light of growth plate maturation. Pectus excavatum may be associated with congenital heart disease.

Fonkalsrud EW, Anselmo DM: Less extensive techniques for repair of pectus carinatum: the undertreated chest deformity. J Am Coll Surg 2004;198:898 [PMID: 15194071].
Williams AM, Crabbe DC: Pectus deformities of the anterior chest wall. Paediatr Respir Rev 2003;4:237 [PMID: 12880759].

▼ NEUROMUSCULAR DISORDERS

Neuromuscular disorders are discussed in detail in Chapter 25. Weakness of the respiratory and pharyngeal muscles leads to chronic or recurrent pneumonia secondary to weak cough and poor mucous clearance, aspiration and infection, persistent atelectasis, hypoventilation, and respiratory failure in severe cases. Scoliosis, which frequently accompanies longstanding neuromuscular disorders, may further compromise respiratory function. Children born with significant neuromuscular weakness may present with signs and symptoms of respiratory compromise early in life. The time to presentation for children with progressive or acquired neuromuscular disease will depend upon the progression of their disease. Typical examination findings in children at increased risk for pulmonary disease are a weak cough, decreased air exchange, crackles, wheezing, and dullness to percussion. The child also may have symptoms of obstructive sleep apnea and decreased lung function by spirometry and/or lung volume analysis. Signs of cor pulmonale (loud

pulmonary component to the second heart sound, hepatomegaly, and elevated neck veins) may be evident in advanced cases. Chest radiographs generally show small lung volumes. If chronic aspiration is present, increased interstitial infiltrates and areas of atelectasis or consolidation may be present. Arterial blood gases demonstrate hypoxemia in the early stages and compensated respiratory acidosis in the late stages. Typical pulmonary function abnormalities include low lung volumes and decreased inspiratory force generated against an occluded airway.

Treatment is supportive and includes vigorous pulmonary toilet, antibiotics with infection, and oxygen to correct hypoxemia. Consideration of bilevel positive airway pressure and mechanical airway clearance support, like mechanical inexsufflation, should be introduced before respiratory failure is present. Unfortunately, despite aggressive medical therapy, many neuromuscular conditions progress to respiratory failure and death. The decision to intubate and ventilate is a difficult one; it should be made only when there is real hope that deterioration, though acute, is potentially reversible or when chronic ventilation is wanted. Chronic mechanical ventilation using either noninvasive or invasive techniques is being used more frequently in patients with chronic respiratory insufficiency.

Panitch HB: The pathophysiology of respiratory impairment in pediatric neuromuscular diseases. Pediatric 2009;123(Suppl 4): S215–S218 [PMID: 19420146].

EVENTRATION OF THE DIAPHRAGM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Respiratory distress in a newborn.
▶ Recurrent pneumonia.
▶ Persistent elevation of the diaphragm by chest x-ray.

Eventration of the diaphragm occurs when striated muscle is replaced with connective tissue and is demonstrated on radiograph by elevation of a part or whole of the diaphragm. There are two types: congenital and acquired. The congenital type is thought to represent incomplete formation of the diaphragm in utero. The acquired type is related to atrophy of diaphragm muscles secondary to prenatal or postnatal phrenic nerve injury. The differential diagnosis of eventration includes phrenic nerve injury and partial diaphragmatic hernia.

▶ Clinical Findings

A. Symptoms and Signs

The degree of respiratory distress depends on the amount of paradoxical motion of the diaphragm. When the diaphragm moves upward during inspiration, instability of the inferior border of the chest wall increases the work of breathing and can lead to respiratory muscle fatigue and potential failure when stressed. Symptoms include persistent increased work of breathing, particularly with feeding or failure to extubate.

B. Laboratory Findings and Imaging Studies

Small eventrations may be an incidental finding on a chest radiograph, commonly seen on the right side. Ultra-sound provides useful information to further define a suspected eventration. When defects are small, there is no paradoxical movement of the diaphragm and little symptomatology. When defects are large, paradoxical movement of the diaphragm may be present.

▶ Treatment

Treatment is based on severity of symptoms. If symptoms persist for 2–4 weeks, the diaphragm is surgically plicated, which stabilizes it. Function returns to the diaphragm in about 50% of cases of phrenic nerve injury whether or not plication was performed. Recovery periods of up to 100 days have been reported in these cases.

Eren S et al: Congenital diaphragmatic eventration as a cause of anterior mediastinal mass in children: imaging modalities and literature review. Eur J Radiol 2004;51:85 [PMID: 15186890].

▼ DISORDERS OF THE PLEURA & PLEURAL CAVITY

The *parietal* pleura covers the inner surface of the chest wall. The *visceral* pleura covers the outer surface of the lungs. Disease processes can lead to accumulation of air or fluid or both in the pleural space. Pleural effusions are classified as transudates or exudates. Transudates occur when there is imbalance between hydrostatic and oncotic pressure, so that fluid filtration exceeds reabsorption (eg, congestive heart failure). Exudates form as a result of inflammation of the pleural surface leading to increased capillary permeability (eg, parapneumonic effusions). Other pleural effusions include chylothorax and hemothorax.

Thoracentesis is helpful in characterizing the fluid and providing definitive diagnosis. Recovered fluid is considered

an exudate (as opposed to a transudate) if any of the following are found: a pleural fluid–serum protein ratio greater than 0.5, a pleural fluid–serum lactate dehydrogenase ratio greater than 0.6, or a pleural fluid lactate dehydrogenase level greater than 200 U/L. Important additional studies on pleural fluid include cell count; pH and glucose; Gram stain, acid-fast and fungal stains; aerobic and anaerobic cultures; counterimmunoelectrophoresis for specific organisms; and occasionally, amylase concentration. Cytologic examination of pleural fluid should be performed to rule out leukemia or other neoplasm.

Hilliard TN et al: Management of parapneumonic effusion and empyema. Arch Dis Child 2003;88:915 [PMID: 14500314].

HEMOTHORAX

Accumulation of blood in the pleural space can be caused by surgical or accidental trauma, coagulation defects, and pleural or pulmonary tumors. A parapneumonic effusion is defined as a hemothorax when the hematocrit of the fluid is more than 50% of the peripheral blood. With blunt trauma, hemopneumothorax may be present. Symptoms are related to blood loss and compression of underlying lung parenchyma. There is some risk of secondary infection, resulting in empyema.

▶ Treatment

Drainage of a hemothorax is required when significant compromise of pulmonary function is present, as with hemopneumothorax. In uncomplicated cases, observation is indicated because blood is readily absorbed spontaneously from the pleural space.

VATS has been used successfully in the management of hemothorax. Chest CT scan is helpful to select patients who may require surgery, as identification of blood and the volume of blood may be more predictive by this method than by chest radiograph.

Muzumdar H, Arens R: Pleural fluid. Pediatr Rev 2007; 28(12):462–464 [PMID: 18055645].

CHYLOTHORAX

Accumulation of chyle, fluid of intestinal origin containing fat digestion products (mostly lipids), in the pleural space usually results from accidental or surgical trauma to the thoracic duct. The most common cause of a pleural effusion in the first few days of life is a chylothorax. In a newborn, chylothorax can be due to congenital abnormalities of the lymph vessels or secondary to birth trauma. In an older child, chylothoracies can be due to: laceration or obstruction of the thoracic duct due to trauma or any surgery involving the chest wall (cardiac surgery, scoliosis repair etc); obstruction of the vessels due to a benign or malignant mass or lymphadenopathy; or increased venous pressure due to obstruction or left ventricular failure. Symptoms of chylothorax are related to the amount of fluid accumulation and the degree of compromise of underlying pulmonary parenchyma. Thoracentesis reveals typical milky fluid (unless the patient has been fasting) containing chiefly T lymphocytes.

▶ Treatment

Treatment should be conservative because many chylothoraces resolve spontaneously. Oral feedings with medium-chain triglycerides reduce lymphatic flow through the thoracic duct. Recent literature has shown somatostatin or the long-acting somatostain analogue, octreotide, as viable therapeutic options. Drainage of chylous effusions should be performed only for respiratory compromised because the fluid often rapidly reaccumulates. Repeated or continuous drainage may lead to protein malnutrition and T-cell depletion, rendering the patient relatively immunocompromised. If reaccumulation of fluid persists, surgical ligation of the thoracic duct or sclerosis of the pleural space can be attempted, although the results may be less than satisfactory.

Helin RD, Angeles ST, Bhat R: Octreotide therapy for chylothorax in infants and children: a brief review. Pediatr Crit Care Med 2006 Nov;7(6):576–579 [PMID: 16878051].
Soto-Martinez M, Massie J: Chylothorax: diagnosis and management in children. Paediatr Respir Rev 2009;10(4):199–207 [PMID: 19879510].

PNEUMOTHORAX & RELATED AIR LEAK SYNDROMES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Sudden onset shortness of breath.
- ▶ Focal area of absent breath sounds on chest auscultation.
- ▶ Shift of the trachea away from the area with absent breath sounds.

Pneumothorax can occur spontaneously in newborns and in older children, or more commonly, as a result of birth trauma, positive pressure ventilation, underlying obstructive or restrictive lung disease, or rupture of a congenital or acquired lung cyst. Pneumothorax can also occur as an acute complication of tracheostomy. Air usually dissects from the alveolar spaces into the interstitial spaces of the lung.

Migration to the visceral pleura ultimately leads to rupture into the pleural space. Associated conditions include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. These conditions are more commonly associated with dissection of air into the interstitial spaces of the lung with retrograde dissection along the bronchovascular bundles toward the hilum.

Clinical Findings

A. Symptoms and Signs

The clinical spectrum can vary from asymptomatic to severe respiratory distress. Associated symptoms include cyanosis, chest pain, and dyspnea. Physical examination may reveal decreased breath sounds and hyperresonance to percussion on the affected side with tracheal deviation to the opposite side. When pneumothorax is under tension, cardiac function may be compromised, resulting in hypotension or narrowing of the pulse pressure. Pneumopericardium is a life-threatening condition that presents with muffled heart tones and shock. Pneumomediastinum rarely causes other than chest pain symptoms by itself.

B. Diagnostic Studies

Chest radiographs usually demonstrate the presence of free air in the pleural space. If the pneumothorax is large and under tension, compressive atelectasis of the underlying lung and shift of the mediastinum to the opposite side may be demonstrated. Cross-table lateral and lateral decubitus radiographs can aid in the diagnosis of free air. Pneumopericardium is identified by the presence of air completely surrounding the heart, whereas in patients with pneumomediastinum, the heart and mediastinal structures may be outlined with air, but the air does not involve the diaphragmatic cardiac border. Chest CT scan may be helpful with recurrent spontaneous pneumothoraces to look for subtle pulmonary disease not seen on chest radiograph, but this is debated.

Differential Diagnosis

Acute deterioration of a patient on a ventilator can be caused by tension pneumothorax, obstruction or dislodgment of the endotracheal tube, or ventilator failure. Radiographically, pneumothorax must be distinguished from diaphragmatic hernia, lung cysts, congenital lobar emphysema, and cystic adenomatoid malformation, but this task is usually not difficult.

Treatment

Small (< 15%) or asymptomatic pneumothoraces usually do not require treatment and can be managed with close observation. Larger or symptomatic pneumothoraces require drainage, although inhalation of 100% oxygen to wash out blood nitrogen can be tried. Needle aspiration should be used to relieve tension acutely, followed by chest tube or pigtail catheter placement. Pneumopericardium requires immediate identification, and if clinically symptomatic, needle aspiration to prevent death, followed by pericardial tube placement.

Prognosis

In older patients with spontaneous pneumothorax, recurrences are common; sclerosing and surgical procedures are often required.

▼ MEDIASTINUM

MEDIASTINAL MASSES

Children with mediastinal masses may present because of symptoms produced by pressure on the esophagus, airways, nerves, or vessels within the mediastinum, or the masses may be discovered on a routine chest radiograph. Once the mass is identified, localization to one of four mediastinal compartments aids in the differential diagnosis. The superior mediastinum is the area above the pericardium that is bordered inferiorly by an imaginary line from the manubrium to the fourth thoracic vertebra. The anterior mediastinum is bordered by the sternum anteriorly and the pericardium posteriorly, and the posterior mediastinum is defined by the pericardium and diaphragm anteriorly and the lower eight thoracic vertebrae posteriorly. The middle mediastinum is surrounded by these three compartments.

Clinical Findings

A. Symptoms and Signs

Respiratory symptoms, when present, are due to pressure on an airway (cough or wheezing) or an infection (unresolving pneumonia in one area of lung). Hemoptysis can also occur but is an unusual presenting symptom. Dysphagia may occur secondary to compression of the esophagus. Pressure on the recurrent laryngeal nerve can cause hoarseness due to paralysis of the left vocal cord. Superior vena caval

syndrome presents with dilation of neck vessels and other signs and symptoms of venous obstruction from the head and neck: superior mediastinal syndrome presents similarly but includes tracheal compression.

B. Laboratory Findings and Imaging

The mass is initially defined by frontal and lateral chest radiographs together with thoracic CT scans or MRI. A barium esophagram may also help define the extent of a mass. Other studies that may be required include angiography (to define the blood supply to large tumors), electrocardiography, echocardiography, ultrasound of the thorax, fungal and mycobacterial skin tests, and urinary catecholamine assays. MRI or myelography may be necessary in children suspected of having a neurogenic tumor in the posterior mediastinum. Mediastinal masses, particularly anterior masses, can cause life-threatening airway compromise during sedation even in patients with mild symptoms; thus, any sedation or anesthesia should be avoided if possible and performed cautiously if absolutely necessary.

▶ Differential Diagnosis

The differential diagnosis of mediastinal masses is determined by their location. Within the superior mediastinum, one may find cystic hygromas, vascular or neurogenic tumors, thymic masses, teratomas, intrathoracic thyroid tissue, mediastinal abscess, and esophageal lesions. Within the anterior mediastinum, thymic tissue (thymomas, hyperplasia, cysts and intrathoracic thyroid) and teratomas, vascular tumors, and lymphatic tissue (lymphomas, leukemia, or reactive lymphadenopathy) give rise to masses. Within the middle mediastinum one may again find lymphomas and hypertrophic lymph nodes, granulomas, bronchogenic or enterogenous cysts, metastases, and pericardial cysts. Abnormalities of the great vessels and aortic aneurysms may also present as masses in this compartment. Within the posterior mediastinum, neurogenic tumors, enterogenous cysts, thoracic meningoceles, or aortic aneurysms may be present.

In some series, more than 50% of mediastinal tumors occur in the posterior mediastinum and are mainly neurogenic tumors or enterogenous cysts. Most neurogenic tumors in children younger than age 4 years are malignant (neuroblastoma or neuroganglioblastoma), whereas a benign ganglioneuroma is the most common histologic type in older children. In the middle and anterior mediastinum, lymphoma and leukemia are the primary concern. Definitive diagnosis in most instances relies on surgery to obtain the mass or a part of the mass for histologic examination.

▶ Treatment & Prognosis

The appropriate therapy and the response to therapy depend on the cause of the mediastinal mass.

▼ SLEEP-DISORDERED BREATHING

Sleep apnea is recognized as a major public health problem in adults, with the risk of excessive daytime sleepiness, driving accidents, poor work performance, and effects on mental health. Pediatric sleep disorders are less commonly recognized because of a lack of training in sleep problem recognition and the presentation, risks, and outcome all differ from those in adults. The spectrum of sleep-disordered breathing includes obstructive sleep apnea, upper airway resistance disorder, and primary snoring. Sleep apnea is defined as cessation of breathing and can be classified as obstructive (the attempt to breathe through an obstructed airway) or central (the lack of effort to breathe). Snoring, mouth breathing, and upper airway obstruction are discussed in Chapter 18.

OBSTRUCTIVE & CENTRAL SLEEP APNEA

▶ Clinical Findings and Differential Diagnosis

Obstructive sleep apnea (OSA) occurs in normal children with an incidence of about 2%, increasing in children with craniofacial abnormalities, neuropathies, or other medical problems. The incidence also increases when children are medicated with hypnotics, sedatives, or anticonvulsants. While not all children who snore have sleep apnea, there is evidence that that snoring without gas exchange abnormalities has neurobehavioral consequences. Obstructive sleep apnea should be suspected whenever a child presents with frequent or habitual snoring, witnessed apnea, labored breathing, frequent nighttime arousals, failure to thrive, oxygen desaturations, life-threatening events, behavior abnormalities, obesity, or craniofacial abnormalities. Upper airway resistance syndrome is characterized by daytime fatigue or sleepiness in the presence of a snoring without gas exchange abnormalities on the polysomnogram. Symptoms are similar to obstructive sleep apnea, including snoring, change in appetite, poor performance in school, and problems with behavior. This chronic flow limitation often improves with treatment. In children, airway obstruction is often associated with adenotonsillar hypertrophy. Tonsillar hypertrophy is most common between the ages of two and seven years. Obesity is widely recognized as an etiologic component in adult OSA and has been similarly cited in children. In children, consequences of sleep apnea include failure to thrive, pulmonary hypertension, deficits of cognition, poor school performance, and psychiatric or behavioral problems.

Central apneas are seen in infants and children. These are pauses in breathing without concomitant effort. Clinical significance is uncertain, but they may be relevant if they occur frequently or gas exchange problems or sleep fragmentation occur. Healthy children have been shown to have central apneas lasting 25 seconds without clear consequences. In comparison, central hypoventilation syndrome patients have intact voluntary control of ventilation, but lack automatic control. During sleep, they will hypoventilate to the point at which they need ventilatory support that may require treatment with positive airway pressure and a rated tidal volume via a noninvasive mask or tracheostomy. Central hypoventilation may occur with low tidal volume breathing and not discreet central apneas, and requires treatment of gas exchange problems.

▶ Diagnostic Studies

Several studies have shown that clinical history and physical examination alone are not enough to identify children with OSA and that polysomnography should be performed in all suspected cases. This test measures sleep state with electroencephalogram leads and electromyography, airflow at the nose, chest and abdominal muscle movement, heart rate and rhythm, gas exchange (CO_2 and oxygenation), and leg movements, along with other potential data including body position, vibrations representing snoring, and esophageal pH/impedence. Polysomnography allows diagnosis of various forms of apnea, sleep fragmentation, periodic limb movement disorder, or other sleep disorders of children. Overnight oximetry is not an ideal study to diagnose obstructive sleep apnea. While it may identify subjects with severe obstructive sleep apnea, its sensitivity is low. Literature has shown normal oximetry studies in half a population of subjects with polysomnographically confirmed obstructive sleep apnea.

▶ Treatment

First-line therapy for obstructive sleep apnea in children is adenotonsillectomy, which improves the clinical status for most children with normal craniofacial structure. Even children with craniofacial anomalies or neuromuscular disorders may benefit, although additional treatment with continuous positive airway pressure may be indicated (Roland et al: S1–15). Down syndrome presents unique challenges: up to half of these children can still have obstructive sleep apnea despite adenotonsillectomy. Treatment of young or developmentally delayed children with apnea also presents several challenges. (See Chapter 18 for additional discussion.) Other therapies, such as, nasal steroids, leukotriene modifiers (Goldbart et al: 364–370), oral appliances, rapid maxillary expanders, and weight loss have their roles in select patient populations.

Because the presentation of sleep apnea is quite varied among children, pediatric sleep disorder centers are the referral of choice for testing and initiation of therapy.

▼ APPARENT LIFE-THREATENING EVENTS

Apparent life-threatening events (ALTEs) are characterized as being frightening to the observer and commonly include some combination of apnea, color change (usually cyanosis or pallor), a marked change in muscle tone (usually extreme limpness), choking, or gagging. The observer sometimes fears the infant has died. The most frequent problems associated with an ALTE are gastrointestinal (~50%), neurologic (30%), respiratory (20%), cardiovascular (5%), metabolic and endocrine (< 5%), or diverse other problems, including child abuse. Up to 50% of ALTEs remain unexplained and are referred to as apnea of infancy. The relationship between ALTE and future risk of sudden infant death syndrome (SIDS) is not clear, as ALTE infants tend to be slightly younger and found more often while the caretaker is awake. The term *apparent life-threatening event* replaced "near-miss SIDS" in order to distance the event from a direct association with SIDS. Literature has reported an increased risk when extreme cardiopulmonary events were present at the time of the ALTE. About 12%–15% of both SIDS victims and infants dying unexpectedly of a known cause (SUDI) have had a prior history of ALTE, but most do not.

The mechanism for ALTEs is unknown, but because they do not occur after infancy, immaturity is felt to play a major role. Classic studies on the nervous system, reflexes, or responses to apnea or gastroesophageal reflux during sleep in infants and immature animals show profound cardiovascular changes during stimulation of the vagus nerve where adults would not be affected. More recently, an association of endogenous opioids and opioid-induced respiratory depression has been implicated as an association with ALTE in infants, and is an area of exciting research. The following section describes an approach to the patient who has undergone an ALTE, taking note of the very broad differential diagnosis and uncertainties in both evaluation and treatment.

▶ Clinical Findings and Differential Diagnosis

A. Symptoms and Signs

Table 19–6 classifies disorders associated with ALTEs. As seen from the outset, the causes of ALTEs are multifactorial, but it is the response to the trigger that creates a symptom cluster unique to infants. A careful history is often the most helpful part of the evaluation. In a large epidemiological study of infants who later died of SIDS or SUDI, a careful history using a "baby check" score was useful in identifying infants who were seriously ill. It is useful to determine whether the infant has been ill or essentially well. A history of several days of poor feeding, temperature instability, or respiratory or gastrointestinal symptoms suggests an infectious process. Reports of "struggling to breathe" or "trying to breathe" imply airway obstruction. Association of the episodes with feeding implies discoordinated swallowing, gastroesophageal reflux, or delayed gastric emptying, or may imply an airway abnormality, but these awake episodes may lead to very different diagnoses than those episodes occurring during sleep. Episodes that typically follow crying may be related to breath-holding. Association of episodes with sleeping may also suggest seizure, gastroesophageal reflux, apnea of infancy, or sleep-disordered breathing. Attempts should be made to determine the duration of the episode, but this is often difficult. It is helpful to role-play the episode with the family. Details regarding the measures taken to resuscitate the infant and the infant's recovery from the episode may be useful in determining severity.

The physical examination provides further direction in pursuing the diagnosis. Fever or hypothermia suggests infection. An altered state of consciousness implies a postictal state or drug overdose. Respiratory distress implies cardiac or pulmonary lesions.

Apneic episodes have been linked to child abuse in several ways. Head injury following nonaccidental trauma may be first brought to medical attention because of apnea. Other signs of abuse are usually immediately apparent in such cases. Drug overdose, either accidental or intentional, may also present with apnea. Several series document that apneic episodes may be falsely reported by parents seeking attention (ie, Munchausen syndrome by proxy). Parents may physically interfere with a child's respiratory efforts, in which case pinch marks on the nares are sometimes found.

B. Laboratory Findings

Most patients are hospitalized for observation in order to reduce stress on the family and allow prompt completion of the evaluation. Laboratory evaluation includes a complete blood count for evidence of infection. Diagnostic testing should be based very heavily on the history and physical examination. Laboratory evaluation might include a complete blood count, blood culture with urinalysis and urine culture for evidence of infection, especially in the face of fever, hypothermia, or an abnormal physical examination. Serum electrolytes might be considered as elevations in serum bicarbonate suggest chronic hypoventilation, whereas decreases suggest acute acidosis, perhaps due to hypoxia during the episode. Chronic acidosis suggests an inherited metabolic disorder. Arterial blood gas studies provide an initial assessment of oxygenation and acid-base status, and low Pao_2 or elevated $Paco_2$ (or both) implies cardiorespiratory disease. A significant base deficit suggests that the episode was accompanied by hypoxia or circulatory impairment. Oxygen saturation measurements in the hospital assess oxygenation status during different activities and are more comprehensive than a single blood gas sample. Because apnea has been associated with respiratory infections, diagnostic studies for RSV and other viruses, pertussis, and *Chlamydia* may help with diagnosis. Apnea occurring with infection often precedes other physical findings.

C. Imaging Studies

The chest radiograph is examined for infiltrates suggesting acute infection or chronic aspiration and for cardiac size

Table 19–6. Potential causes of apparent life-threatening events.

Infectious	Viral: respiratory syncytial virus and other respiratory *viruses* Bacterial: sepsis, pertussis, Chlamydia
Gastrointestinal	Gastroesophageal reflux with or without obstructive apnea
Respiratory	Airway abnormality; vascular rings, pulmonary slings, tracheomalacia Pneumonia
Neurologic	Seizure disorder Central nervous system infection: meningitis, encephalitis Vasovagal response Leigh encephalopathy Brain tumor
Cardiovascular	Congenital malformation Dysrhythmias Cardiomyopathy
Nonaccidental trauma	Battering Drug overdose Munchausen syndrome by proxy
No definable cause	Apnea of infancy

as a clue to intrinsic cardiac disease. If the episode might have involved airway obstruction, the airway should be examined either directly by fiberoptic bronchoscopy or radiographically by CT or barium swallow. Barium swallow is a useful tool to rule out the possibility of anatomic abnormalities such as vascular ring and tracheoesophageal fistula. Esophageal pH monitoring is only helpful if the infant has sufficiently acidified the stomach, and can underestimate the degree of reflux for nonacid events. Impedence monitors improve this interpretation. Gastroesophageal reflux is one of the most common findings in infants with ALTE; however, it may be a marker of autonomic immaturity as opposed to a diagnosis for the event. Most infants with reflux and apnea can be given medical antireflux treatment. Infants with reflux and repeated episodes of apnea may benefit from a surgical antireflux procedure.

D. Special Tests: Polysomnography and Other Studies

ALTEs occur in the same age group as infants who die of sudden death (2–4 months is the peak age). Sleep-disordered breathing has been implicated as a possible cause of ALTEs and perhaps sudden death. Depending on the discretion of the clinician in appropriate scenarios, polysomnograms can be useful to determine abnormalities of cardiorespiratory function, sleep state, oxygen saturation, CO_2 retention, and seizure activity. They can be used in conjunction with pH monitoring to determine the contribution of reflux to apnea. Esophageal pressure manometry can be useful to detect subtle changes in respiratory effort related to partial obstructive breathing (hypopnea). Infants may be at more risk of adverse events from sleep-disordered breathing due to their immature nervous system.

There are several neurologic causes of ALTEs, and seizure disorder has been found to be a cause of ALTE in a significant number of cases. Apnea as the sole manifestation of a seizure disorder is unusual but may occur. In cases of repeated episodes, 24-hour electroencephalographic monitoring may be helpful in detecting a seizure disorder.

▶ Treatment

Therapy is directed at the underlying cause if one is found. After blood cultures are taken, antibiotics should be given to infants who appear toxic. Seizure disorders are treated with anticonvulsants. Gastroesophageal reflux should be treated, but may not prevent future episodes of ALTE. Vascular rings and pulmonary slings must be corrected surgically because of severe morbidity and high mortality rates when untreated.

The approach to care of infants with ALTEs where no definable cause can be ascertained is controversial. Home monitoring has been used in the past as treatment, but the efficacy of monitoring has not been demonstrated in controlled trials. With more than 30 years of home monitoring,

the sudden infant death rate did not change due to this intervention. Although monitors can detect central apnea or bradycardia, they do not predict which children will have future ALTEs, and they do not detect obstructive forms of breathing a common form of apnea in infants. Apnea monitors are prone to frequent false alarms, and it must be noted that many parents cannot handle the stress associated with having a monitor in the home. Parents should be taught cardiopulmonary resuscitation prior to discharge and should prevent modifiable risk factors for infant death discussed below. The decision to monitor these infants involves the participation of the family. Infants with severe initial episodes or repeated severe episodes are now thought to be at significantly increased risk. A monitor with an oxygen saturation detection capability may identify episodes earlier. The caregiver responsible for prescribing a monitor should have a plan for the data acquisition, and the discontinuation of the monitor so that the parents can be prepared. Oxygen has been used as therapy for ALTEs for several reasons. Oxygen reduces periodic breathing of infancy, an immature pattern of breathing that can cause some degree of oxygen desaturation. Second, infants have small chest capacities with increased chest wall compliance that reduces lung volume. Oxygen can increase the baseline saturation, reducing the severity of desaturation with short apneas. Respiratory stimulants such as caffeine and aminophylline have been used in specific cases of central apnea or periodic breathing.

Any infant younger than 1 year of age should be evaluated for the presence of modifiable SIDS risk factors by a caregiver. Parents should be educated on how to avoid these risk factors, especially in infants at increased risk such as former preterm infants, children exposed to cigarette smoke environmentally or prior to birth, African American or Native American infants, and infants in poor socioeconomic areas. Updates on recommendations for the prevention of unexpected death in infants was recently published by the American Academy of Pediatrics (SIDS and other sleep-related infant deaths: expansion of recommendations for a safe infant sleeping environment: 1030–1039) and especially applies to infants after an ALTE. The reference should be read in full, but new recommendations include:

- Always place a baby on its back to sleep (this includes a baby with reflux).
- A baby should always sleep in its own space such as a crib, bassinette, or pack & play. A baby should not sleep on an adult bed, couch, armchair, futon, or other soft surface. Use a firm mattress designed for the crib, bassinet, or pack & play with a tight fitting sheet. The mattress should be flat, not elevated, and with no soft bedding underneath or on top.
- Share a room, but not a bed, with a baby.
- There should be nothing in a baby's sleep space, other than the baby. Avoid overheating, overwrapping, and

covering the face and head; use appropriate baby sleep clothing or sleep sack.

- Breast-feeding a baby is recommended.
- Consider offering a pacifier to a baby at nap and sleep time.
- Avoid or limit a baby's exposure to cigarette smoke.
- Car seats, swings, and baby slings should NOT be used for sleep.
- Avoid the use of adult beds, bed rails, and in-bed co-sleepers, which increase the risk of suffocation and entrapment.

SUDDEN INFANT DEATH SYNDROME

SIDS is defined as the sudden death of an infant younger than age 1 year that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history. The postmortem examination is an important feature of the definition because approximately 20% of cases of sudden death can be explained by autopsy findings. The incidence of SIDS in the United States has declined to less than 1 in 1000 live births over the last 15 years; however, it has leveled off. Reduction of prone sleeping after the "Back to Sleep" campaign was in large part responsible for the reduction of SIDS from a high of 2 infants per 1000 births, but new evidence shows the increase of sudden unexpected deaths of infants (SUDI) due to accidental suffocation and unsafe sleep surfaces.

▶ Epidemiology and Pathogenesis

Epidemiologic and pathologic data constitute most of what is known about SIDS. The number of deaths peaks between ages 2 and 4 months. Most deaths occur between midnight and 8 AM, while the infant and often the caregiver are sleeping. In fact, the only unifying features of all SIDS cases are age and sleep. SIDS is more common among ethnic and racial minorities and socioeconomically disadvantaged populations. Racial disparity in the prevalence of prone positioning or especially in cosleeping (Fu, Moon, and Hauck: 376–382) may also be contributing to the continued disparity in SIDS rates between black and white infants. There is a 3:2 male predominance in most series. Other risk factors include low birth weight, teenage or drug-addicted mothers, multiparity, crowded living conditions, maternal smoking, and a family history of SIDS. Most of these risk factors are associated with a two- to threefold elevation of incidence but are not specific enough to be useful in predicting which infants will die unexpectedly. Recent immunization is not a risk factor.

The most consistent pathologic findings are intrathoracic petechiae and mild inflammation and congestion of the respiratory tract. More subtle pathologic findings include brainstem gliosis, extramedullary hematopoiesis, and increases in peri-adrenal brown fat. These latter findings suggest that infants who succumb to SIDS have had intermittent or chronic hypoxia before death.

The mechanism or mechanisms of death in SIDS are unknown. For example, it is unknown whether the initiating event at the time of death is cessation of breathing, cardiac arrhythmia, or asystole. Hypotheses have included upper airway obstruction, catecholamine excess, and increased fetal hemoglobin. However, maldevelopment or delay in maturation of the brainstem, which is responsible for arousal, remains the predominant theory. A history of mild symptoms of upper respiratory infection before death is not uncommon, and SIDS victims are sometimes seen by physicians a day or so before death. The postmortem examination is essential for the diagnosis of SIDS and may help the family by excluding other possible causes of death. A death scene investigation is also important in determining the cause of sudden unexpected deaths in infancy.

Families must be supported following the death of an infant. The National SIDS Resource Center (http://www.sidscenter.org) provides information about psychosocial support groups and counseling for families of SIDS victims.

▶ Prevention

Since 1990, SIDS rates have declined more than 60% worldwide. Population studies in New Zealand and Europe identified risk factors, which when changed had a major effect on the incidence of SIDS. Since 1994 the American Academy of Pediatrics' "Back-to-Sleep" campaign has promoted education about SIDS risk factors in the United States. The new updated recommendations are printed above and are available on line (SIDS and other sleep-related infant deaths: expansion of recommendations for a safe infant sleeping environment: 1030–1039). Modifiable risk factors include sleeping position, bottle feeding, maternal smoking, and infant overheating. The prone sleep position could contribute to SIDS through decreased arousal or rebreathing of exhaled gases. The side position, often used in hospitals and then mimicked at home, increases risk of SIDS compared with the supine position. Maternal smoking, especially prenatal maternal smoking, increases the risk of SIDS. Investigations of tobacco effects on the autonomic nervous system of the developing fetus, pulmonary growth and function of the newborn, or its combination with viral infection all point to differences in SIDS compared with control subjects. New data demonstrates decreased risk of SIDS with the use of pacifiers and breast feeding.

The healthcare provider is instrumental in parental education regarding the modifiable risk factors for SIDS (Table 19–7). The healthcare provider should screen all infants for SIDS risk factors, and include awareness of

Table 19–7. American Academy of Pediatrics recommendations regarding sudden infant death syndrome (SIDS) risk reduction.

"Back-to-sleep" (supine sleeping position)
Firm sleep surface designed for infant sleep
Pillows/loose bedding, loose blankets should be out of the crib
Share a room, not a bed with the infant
Do not smoke during pregnancy, and smoke-free environment after birth
Consider offering a pacifier at nap and bed time
Avoid overheating, overwrapping, and head covering
Avoid commercial devices marketed to reduce the risk of SIDS
Do not use home monitors as a strategy to reduce the risk of SIDS
Encourage tummy time while awake

the child care setting, as many parents rely on others to watch their children, where the importance of risk factors may not be recognized. Hospitals should set an example by placing infants in the supine position with no blankets in the bed prior to discharge. At present, the data shows that the environment is key to the safety of the infant, and unsafe sleep environments are responsible for the recent increase in accidental suffocation, asphyxia, and entrapment.

Cardiovascular Diseases

Jeffrey R. Darst, MD
Kathryn K. Collins, MD
Shelley D. Miyamoto, MD

Eight in 1000 infants are born with a congenital heart defect. Advances in medical and surgical care allow more than 90% of such children to enter adulthood. Pediatric cardiac care includes not only the diagnosis and treatment of congenital heart disease but also the prevention of risk factors for adult cardiovascular disease—obesity, smoking, and hyperlipidemia. Acquired and familial heart diseases such as Kawasaki disease, viral myocarditis, cardiomyopathies, and rheumatic heart disease are also a significant cause of morbidity and mortality in children.

▼ DIAGNOSTIC EVALUATION

HISTORY

Symptoms related to congenital heart defects primarily vary according to the alteration in pulmonary blood flow (Table 20–1). The presence of other cardiovascular symptoms such as palpitations and chest pain should be determined by history in the older child, paying particular attention to the timing (at rest or activity-related), onset, and termination (gradual vs sudden), as well as precipitating and relieving factors.

PHYSICAL EXAMINATION

General

The examination begins with a visual assessment of mental status, signs of distress, perfusion, and skin color. Documentation of heart rate, respiratory rate, blood pressure (in all four extremities), and oxygen saturation is essential. Many congenital cardiac defects occur as part of a genetic syndrome (Table 20–2), and complete assessment includes evaluation of dysmorphic features that may be clues to the associated cardiac defect.

Cardiovascular Examination

A. Inspection and Palpation

Chest conformation should be noted in the supine position. A precordial bulge indicates cardiomegaly. Palpation may reveal increased precordial activity, right ventricular lift, or left-sided heave; a diffuse point of maximal impulse; or a precordial thrill caused by a grade IV/VI or greater murmur. The thrill of aortic stenosis is found in the suprasternal notch. In patients with severe pulmonary hypertension, a palpable pulmonary closure (P_2) is frequently noted at the upper left sternal border.

B. Auscultation

1. Heart sounds—The first heart sound (S_1) is the sound of atrioventricular (AV) valve closure. It is best heard at the lower left sternal border and is usually medium-pitched. Although S_1 has multiple components, only one of these (M_1—closure of the mitral valve) is usually audible.

The second heart sound (S_2) is the sound of semilunar valve closure. It is best heard at the upper left sternal border. S_2 has two component sounds, A_2 and P_2 (aortic and pulmonic valve closure). Splitting of S_2 varies with respiration, widening with inspiration and narrowing with expiration. Abnormal splitting of S_2 may be an indication of cardiac disease (Table 20–3). A prominent or loud P_2 is associated with pulmonary hypertension.

The third heart sound (S_3) is the sound of rapid left ventricular filling. It occurs in early diastole, after S_2, and is medium- to low-pitched. In healthy children, S_3 diminishes or disappears when going from supine to sitting or standing. A pathologic S_3 is often heard in the presence of poor cardiac function or a large left-to-right shunt. The fourth heart sound (S_4) is associated with atrial contraction and increased atrial pressure, and has a low pitch similar to that of S_3.

Table 20–1. Symptoms of increased and decreased pulmonary blood flow.

Decreased Pulmonary Blood Flow	Increased Pulmonary Blood Flow
Infant/toddler	
Cyanosis	Tachypnea with activity/feeds
Squatting	Diaphoresis
Loss of consciousness	Poor weight gain
Older child	
Dizziness	Exercise intolerance
Syncope	Dyspnea on exertion, diaphoresis

Table 20–2. Cardiac defects in common syndromes.

Genetic Syndrome	Commonly Associated Cardiac Defect
Down syndrome	AVSD
Turner syndrome	Bicuspid aortic valve, coarctation, dilated aortic root, hypertension
Noonan syndrome	Dysplastic pulmonic valve, HCM
Williams-Beuren syndrome	Supravalvular aortic stenosis, PPS, coronary ostial stenosis
Marfan syndrome	MVP, MR, dilated aortic root
Fetal alcohol syndrome	VSD, ASD
Maternal rubella Loeys-Dietz Syndrome	PDA, PPS Aneurysmal PDA, dilated aortic root, tortuous arteries throughout the body

ASD, atrial septal defect; AVSD, atrioventricular septal defect; HCM, hypertrophic cardiomyopathy; MR, mitral regurgitation; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; PPS, peripheral pulmonary stenosis; VSD, ventricular septal defect.

Table 20–3. Abnormal splitting of S_2.

Causes of wide split S_2
RV volume overload: ASD, anomalous pulmonary venous return, PI
RV pressure overload: Pulmonary valve stenosis
Delayed RV conduction: RBBB
Causes of narrow split S_2
Pulmonary hypertension
Single semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus)

ASD, atrial septal defect; PI, pulmonic insufficiency; RBBB, right bundle branch block; RV, right ventricle.

It occurs just prior to S_1 and is not normally audible. It is heard in the presence of atrial contraction into a noncompliant ventricle as in hypertrophic or restrictive cardiomyopathy or from other causes of diastolic dysfunction.

Ejection clicks are usually related to dilate great vessels or valve abnormalities. They are heard during ventricular systole and are classified as early, mid, or late. Early ejection clicks at the mid left sternal border are from the pulmonic valve. Aortic clicks are typically best heard at the apex. In contrast to aortic clicks, pulmonic clicks vary with respiration, becoming louder during inspiration. A mid to late ejection click at the apex is most typically caused by mitral valve prolapse.

2. Murmurs—A heart murmur is the most common cardiovascular finding leading to a cardiology referral. Innocent or functional heart murmurs are common, and 40%–45% of children have an innocent murmur at some time during childhood.

A. Characteristics—All murmurs should be described based on the following characteristics:

(1) Location and radiation—Where the murmur is best heard and where the sound extends.

(2) Relationship to cardiac cycle and duration—Systolic ejection (immediately following S_1 with a crescendo/decrescendo change in intensity), pansystolic (occurring throughout most of systole and of constant intensity), diastolic, or continuous. The timing of the murmur provides valuable clues as to underlying pathology (Table 20–4).

(3) Intensity—Grade I describes a soft murmur heard with difficulty; grade II, soft but easily heard; grade III, loud but without a thrill; grade IV, loud and associated with a precordial thrill; grade V, loud, with a thrill, and audible with the edge of the stethoscope; grade VI, very loud and audible with the stethoscope off the chest.

(4) Quality—Harsh, musical, or rough; high, medium, or low in pitch.

(5) Variation with position—Audible changes in murmur when the patient is supine, sitting, standing, or squatting.

B. Innocent Murmurs—The six most common innocent murmurs of childhood are

(1) Newborn murmur—Heard in the first few days of life, this murmur is at the lower left sternal border, without significant radiation. It has a soft, short, vibratory grade I–II/VI quality that often subsides when mild pressure is applied to the abdomen. It usually disappears by age 2–3 weeks.

(2) Peripheral pulmonary artery stenosis (PPS)—This murmur, often heard in newborns, is caused by the normal branching of the pulmonary artery. It is heard with equal intensity at the upper left sternal border, at the back, and in one or both axillae. It is a soft, short, high-pitched, grade I–II/VI systolic ejection murmur and usually disappears by age 2. This murmur must be differentiated from true peripheral pulmonary stenosis (Williams syndrome,

Table 20–4. Pathologic murmurs.

Systolic Ejection	Pansystolic	Diastolic	Continuous
Semilunar valve stenosis (AS/PS/truncal stenosis)	VSD	Semilunar valve regurgitation	Runoff lesions
ASD	AVVR (MR/TR)	AI/PI/truncal insufficiency	PDA/AVM/aortopulmonary collaterals
Coarctation		AV valve stenosis (MS/TS)	

AI/PI, aortic insufficiency/pulmonic insufficiency; AS/PS, aortic stenosis/pulmonic stenosis; ASD, atrial septal defect; AV, atrioventricular; MS/TS, mitral stenosis/tricuspid stenosis; AVVR, atrioventricular valve regurgitation; MR/TR, mitral regurgitation/tricuspid regurgitation; PDA/AVM, patent ductus arteriosus/arteriovenous malformation; VSD, ventricular septal defect.

Alagille syndrome, or rubella syndrome), coarctation of the aorta, and valvular pulmonary stenosis. Characteristic facial features, extracardiac physical exam findings, history, and laboratory abnormalities suggestive of the syndromes listed above are the best way to differentiate true peripheral pulmonary stenosis from benign PPS of infancy as the murmurs can be similar.

(3) Still murmur—This is the most common innocent murmur of early childhood. It is typically heard between 2 and 7 years of age. It is the loudest midway between the apex and the lower left sternal border. Still murmur is a musical or vibratory, short, high-pitched, grade I–III early systolic murmur. It is loudest when the patient is supine. It diminishes or disappears with inspiration or when the patient is sitting. The Still murmur is louder in patients with fever, anemia, or sinus tachycardia from any reason.

(4) Pulmonary ejection murmur—This is the most common innocent murmur in older children and adults. It is heard from age 3 years onward. It is usually a soft systolic ejection murmur, grade I–II in intensity at the upper left sternal border. The murmur is louder when the patient is supine or when cardiac output is increased. The pulmonary ejection murmur must be differentiated from murmurs of pulmonary stenosis, coarctation of the aorta, atrial septal defect (ASD), and peripheral pulmonary artery stenosis.

(5) Venous hum—A venous hum is usually heard after age 2 years. It is located in the infraclavicular area on the right. It is a continuous musical hum of grade I–III intensity and may be accentuated in diastole and with inspiration. It is best heard in the sitting position. Turning the child's neck, placing the child supine, and compressing the jugular vein obliterates the venous hum. Venous hum is caused by turbulence at the confluence of the subclavian and jugular veins.

(6) Innominate or carotid bruit—This murmur is more common in the older child and adolescents. It is heard in the right supraclavicular area. It is a long systolic ejection murmur, somewhat harsh and of grade II–III intensity. The bruit can be accentuated by light pressure on the carotid artery and must be differentiated from all types of aortic stenosis.

The characteristic findings of aortic stenosis are outlined in more detail later in this chapter.

When innocent murmurs are found in a child, the physician should assure the parents that these are normal heart sounds of the developing child and that they do not represent heart disease.

Extracardiac Examination

A. Arterial Pulse Rate and Rhythm

Cardiac rate and rhythm vary greatly during infancy and childhood, so multiple determinations should be made. This is particularly important for infants (Table 20–5) whose heart rates vary with activity. The rhythm may be regular or there may be a normal phasic variation with respiration (sinus arrhythmia).

B. Arterial Pulse Quality and Amplitude

A bounding pulse is characteristic of run-off lesions, including patent ductus arteriosus (PDA), aortic regurgitation, arteriovenous malformation, or any condition with a low diastolic pressure (fever, anemia, or septic shock). Narrow or thready pulses occur in patients with conditions reducing cardiac output such as decompensated heart failure pericardial tamponade, or severe aortic stenosis. A reduction in pulse amplitude or blood pressure (> 10 mm Hg) with inspiration is referred to as pulsus paradoxus and is a telltale sign

Table 20–5. Resting heart rates.

Age	Low	High
< 1 mo	80	160
1–3 mo	80	200
2–24 mo	70	120
2–10 y	60	90
11–18 y	40	90

of pericardial tamponade. The pulses of the upper and lower extremities should be compared. The femoral pulse should be palpable and equal in amplitude and simultaneous with the brachial pulse. A femoral pulse that is absent or weak, or that is delayed in comparison with the brachial pulse, suggests coarctation of the aorta.

C. Arterial Blood Pressure

Blood pressures should be obtained in the upper and lower extremities. Systolic pressure in the lower extremities should be greater than or equal to that in the upper extremities. The cuff must cover the same relative area of the arm and leg. Measurements should be repeated several times. A lower blood pressure in the lower extremities suggests coarctation of the aorta.

D. Cyanosis of the Extremities

Cyanosis results from an increased concentration (> 4–5 g/dL) of reduced hemoglobin in the blood. Bluish skin color is usually, but not always, a sign. Visible cyanosis also accompanies low cardiac output, hypothermia, and systemic venous congestion, even in the presence of adequate oxygenation. Cyanosis should be judged by the color of the mucous membranes (lips). Bluish discoloration around the mouth (acrocyanosis) does not correlate with cyanosis.

E. Clubbing of the Fingers and Toes

Clubbing is often associated with severe cyanotic congenital heart disease. It usually appears after age 1 year. Hypoxemia with cyanosis is the most common cause, but clubbing also occurs in patients with endocarditis, chronic liver disease, inflammatory bowel diseases, chronic pulmonary disease, and lung abscess. Digital clubbing may be a benign genetic variant.

F. Edema

Edema of dependent areas (lower extremities in the older child and the face and sacrum in the younger child) is characteristic of elevated right heart pressure, which may be seen with tricuspid valve pathology or heart failure.

G. Abdomen

Hepatomegaly is the cardinal sign of right heart failure in the infant and child. Left heart failure can ultimately lead to right heart failure and therefore, hepatomegaly may also be seen in the child with pulmonary edema from lesions causing left-to-right shunting (pulmonary overcirculation) or left ventricular failure. Splenomegaly may be present in patients with long-standing heart failure (HF), and is also a characteristic of infective endocarditis. Ascites is a feature of chronic right heart failure. Examination of the abdomen may reveal shifting dullness or a fluid wave.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) is essential in the evaluation of the cardiovascular system. The heart rate should first be determined, then the cardiac rhythm (Is the patient in a normal sinus rhythm or other rhythm as evidenced by a P wave with a consistent PR interval before every QRS complex?), and then the axis (Are the P and QRS axes normal for patient age?). Finally, assessment of chamber enlargement, cardiac intervals, and ST segments should be performed.

Age-Related Variations

The ECG evolves with age. The heart rate decreases and intervals increase with age. RV dominance in the newborn changes to LV dominance in the older infant, child, and adult. The normal ECG of the 1-week-old infant is abnormal for a 1-year-old child, and the ECG of a 5-year-old child is abnormal for an adult.

Electrocardiographic Interpretation

Figure 20–1 defines the events recorded by the ECG.

A. Rate

The heart rate varies markedly with age, activity, and state of emotional and physical well-being (Table 20-5).

B. Rhythm

Sinus rhythm should always be present in healthy children. Extra heart beats representing premature atrial and ventricular contractions are common during childhood, with atrial ectopy predominating in infants and ventricular ectopy during adolescence. Isolated premature beats in patients with normal heart structure and function are usually benign.

C. Axis

1. P-wave axis—The P wave is generated from atrial contraction beginning in the high right atrium at the site of the sinus node. The impulse proceeds leftward and inferiorly, thus leading to a positive deflection in all left-sided and inferior leads (II, III, and aVF) and negative in lead aVR.
▲ **Figure 20–1.** Complexes and intervals of the electrocardiogram.

2. QRS axis—The net voltage should be positive in leads I and aVF in children with a normal axis. In infants and young children, RV dominance may persist, leading to a negative deflection in lead I. Several congenital cardiac lesions are associated with alterations in the normal QRS axis (Table 20–6).

D. P Wave

In the pediatric patient, the amplitude of the P wave is normally no greater than 3 mm and the duration no more than 0.08 second. The P wave is best seen in leads II and V_1.

Table 20–6. QRS axis deviation.

Right Axis Deviation	Left Axis Deviation
Tetralogy of Fallot	Atrioventricular septal defect
Transposition of the great arteries	Pulmonary atresia with intact ventricular septum
Total anomalous pulmonary venous return	Tricuspid atresia
Atrial septal defect	

E. PR Interval

The PR is measured from the beginning of the P wave to the beginning of the QRS complex. It increases with age and with slower rates. The PR interval ranges from a minimum of 0.10 second in infants to a maximum of 0.18 second in older children with slow rates. Rheumatic heart disease, digitalis, β-blockers and calcium channel blockers can prolong the PR interval.

F. QRS Complex

This represents ventricular depolarization, and its amplitude and direction of force (axis) reveal the relative ventricular mass in hypertrophy, hypoplasia, and infarction. Abnormal ventricular conduction (eg, right or left bundle-branch block) is also revealed.

G. QT Interval

This interval is measured from the beginning of the QRS complex to the end of the T wave. The QT duration may be prolonged as a primary condition or secondarily due to drugs or electrolyte imbalances (Table 20–7). The normal

Table 20–7. Causes of QT prolongation.[a]

Cardiac medications
    Antiarrhythmics: Class IA (quinidine, procainamide, disopyramide)
        class III (amiodarone, sotalol)
    Inotropic agents: dobutamine, dopamine, epinephrine,
        isoproterenol
Noncardiac medications
    Antibiotics/antivirals: azithromycin, clarithromycin, levofloxacin,
        amantadine
    Antipsychotics: risperidol, thioridazine, lithium, haloperidol
    Sedatives: chloral hydrate, methadone
    Other: albuterol, levalbuterol, ondansetron, phenytoin,
        pseudoephedrine
Electrolyte disturbances: hypokalemia, hypomagnesemia,
    hypocalcemia

[a]Partial list only.

QT duration is rate-related and must be corrected using the Bazett formula:

$$QTc = \frac{QT \text{ intervals (s)}}{\sqrt{R\text{-}R \text{ intervals (s)}}}$$

The normal QTc is less than or equal to 0.44 second.

H. ST Segment

This segment, lying between the end of the QRS complex and the beginning of the T wave, is affected by drugs, electrolyte imbalances, or myocardial injury.

I. T Wave

The T wave represents myocardial repolarization and is altered by electrolytes, myocardial hypertrophy, and ischemia.

J. Impression

The ultimate impression of the ECG is derived from a systematic analysis of all the features above as compared with expected normal values for the child's age.

O'Connor M, McDaniel N, Brady WJ: The pediatric electrocardiogram. Part I: age-related interpretation. Am J Emerg Med 2008 May;26(4):506–512 [PMID: 18416018].

CHEST RADIOGRAPH

Evaluation of the chest radiograph for cardiac disease should focus on (1) position of the heart, (2) position of the abdominal viscera, (3) cardiac size, (4) cardiac configuration, and (5) character of the pulmonary vasculature. The standard posteroanterior and left lateral chest radiographs are used (Figure 20–2).
▲ **Figure 20–2.** Position of cardiovascular structures in principal radiograph views. AO, aorta; IVC, inferior vena cava; LA, left atrium; LA APP, left atrial appendage; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Cardiac position is either levocardia (heart predominantly in the left chest), dextrocardia (heart predominantly in the right chest), or mesocardia (midline heart). The position of the liver and stomach bubble is either in the normal position (abdominal situs solitus), inverted with the stomach bubble on the right (abdominal situs inversus), or variable with midline liver (abdominal situs ambiguous). The heart appears relatively large in normal newborns at least in part due to a prominent thymic shadow. The heart size should be less than 50% of the chest diameter in children older than age 1 year. The cardiac configuration on chest radiograph may provide useful diagnostic information (Table 20–8). Some congenital cardiac lesions have a characteristic radiographic appearance that suggests the diagnosis but should not be viewed as conclusive (Table 20–9). The pulmonary vasculature should be assessed. The presence of increased or decreased pulmonary blood flow suggests a possible congenital cardiac diagnosis, particularly in the cyanotic infant (Table 20–10).

Laya BF et al: The accuracy of chest radiographs in the detection of congenital heart disease and in the diagnosis of specific congenital cardiac lesions. Pediatr Radiol 2006;36:677–681 [PMID: 16547698].

Table 20–8. Radiographic changes with cardiac chamber enlargement.

Chamber Enlarged	Change in Cardiac Silhouette on Anteroposterior Film
Right ventricle	Apex of the heart is tipped upward
Left ventricle	Apex of the heart is tipped downward
Left atrium	Double shadow behind cardiac silhouette Increase in subcarinal angle
Right atrium	Prominence of right atrial border of the heart

Table 20–9. Lesion-specific chest radiographic findings.

Diagnosis	Chest Radiograph Appearance
D-transposition of the great arteries	Egg on a string
Tetralogy of Fallot	Boot-shaped heart
Unobstructed total anomalous pulmonary venous drainage	Snowman
Obstructed total anomalous pulmonary venous drainage	Small heart with congested lungs
Coarctation	Figure 3 sign + rib notching

Table 20–10. Alterations in pulmonary blood flow in cyanotic cardiac lesions.

Increased Pulmonary Blood Flow	Decreased Pulmonary Blood Flow
Total anomalous pulmonary venous return	Pulmonic stenosis
Tricuspid atresia with large ventricular septal defect	Tricuspid atresia/restrictive ventricular septal defect
Transposition of the great arteries	Tetralogy of Fallot
Truncus arteriosus	Pulmonary atresia with intact ventricular septum

Dextrocardia

Dextrocardia is a radiographic term used when the heart is on the right side of the chest. When dextrocardia occurs with reversal of position of the other important organs of the chest and abdomen (eg, liver, lungs, and spleen), the condition is called situs inversus totalis, and the heart is usually normal. When dextrocardia occurs with the other organs normally located (situs solitus), the heart usually has severe defects.

Other situs abnormalities include situs ambiguous with the liver central and anterior in the upper abdomen and the stomach pushed posteriorly; bilateral right-sidedness (asplenia syndrome); and bilateral left-sidedness (polysplenia syndrome). In virtually all cases of situs ambiguous, congenital heart disease is present.

ECHOCARDIOGRAPHY

Echocardiography is a fundamental tool of pediatric cardiology. Using multiple ultrasound modalities (two-dimensional imaging, Doppler, and M-mode), cardiac anatomy, blood flow, intracardiac pressures, and ventricular function can be assessed. Echocardiography is based on the physical principles of sound waves. The ultrasound frequencies utilized in cardiac imaging range from 2 to 10 million cycles/s.

M-mode echocardiography uses short bursts of ultrasound sent from a transducer. At acoustic interfaces, sound waves are reflected back to the transducer. The time it takes for the sound wave to return to the transducer is measured and the distance to the interface is calculated. That calculated distance is displayed against time, and a one-dimensional image is constructed that demonstrates cardiac motion. **Two-dimensional imaging** extends this technique by sending a rapid series of ultrasound bursts across a 90-degree sector, which allows construction of a two-dimensional image of the heart. **Doppler ultrasound** measures blood flow. The ultrasound transducer sends out a known frequency of sound which reflects off moving red blood cells. The transducer receives the reflected frequency and compares it with the transmitted frequency. The blood flow velocity can be calculated from the measured frequency shift. This information is used to estimate pressure gradients by the simplified Bernouli equation, in which the pressure gradient is equal to four times the calculated velocity (Pressure gradient $= 4(V^2)$).

A transthoracic echocardiogram is obtained by placing the transducer on areas of the chest where there is minimal lung interference. At each transducer position, the beam is swept through the heart and a two-dimensional image appears on the screen. Complex intracardiac anatomy and spatial relationships can be described, making possible the accurate diagnosis of congenital heart disease. In addition to structural details, Doppler gives information about intracardiac blood flow and pressure gradients. Commonly used Doppler techniques include color flow imaging, pulsed-wave, and continuous-wave Doppler. Color flow imaging gives general information on the direction and velocity of flow. Pulsed- and continuous-wave Doppler imagings give more precise measurements of blood velocity. The role of M-mode in the ultrasound examination has decreased as other ultrasound modalities have been developed. M-mode is still used to measure LV end-diastolic and end-systolic dimensions and permits calculation of the LV-shortening fraction, a standard estimate of LV function (SF = LV end-diastolic volume – LV systolic volume/LV end-diastolic volume). Three-dimensional echocardiography, tissue Doppler, strain, and strain rate imaging are newer modalities that provide more sophisticated assessment of systolic and diastolic function and can detect early changes in myocardial function.

A typical transthoracic echocardiogram performed by a skilled sonographer takes about 30 minutes, and patients must be still for the examination. Frequently infants and children cannot cooperate for the examination and sedation is required. Transesophageal echocardiography requires general anesthesia in infants and children and is primarily used to guide interventional procedures and surgical repair

of congenital heart disease. In cases of difficult imaging windows due to patient size, air interference or when looking for evidence of vegetations on cardiac valves, transesophageal echocardiography may be necessary.

It is important to note that fetal echocardiography plays an important role in the prenatal diagnosis of congenital heart disease. A fetal echocardiogram is recommended if the fetus is considered high risk for the development of congenital heart disease or if there is suspicion for structural heart disease or fetal arrhythmias based on the obstetric fetal ultrasound. In utero management of fetal arrhythmias and post-delivery planning for the fetus with complex heart disease has resulted in improved outcomes for this challenging group of patients.

Elkiran O et al: Tissue Doppler, strain, and strain rate measurements assessed by two-dimensional speckle-tracking echocardiography in healthy newborns and infants. Cardiol Young 2013 Feb 6:1–11 [PMID: 23388082].

Friedberg MK et al: Validation of 3D echocardiographic assessment of left ventricular volumes, mass, and ejection fraction in neonates and infants with congenital heart disease: a comparison study with cardiac MRI. Circ Cardiovasc Imaging 2010;3(6):735–742 [PMID: 20855861].

NUCLEAR CARDIOLOGY

Nuclear imaging is not commonly used in pediatric cardiology, but can be a useful adjunct to cardiopulmonary exercise testing in assessing both fixed and reversible areas of myocardial ischemia. It is valuable in evaluating myocardial perfusion in patients with Kawasaki disease, repaired anomalous left coronary artery or other coronary anomalies, myocardial bridging in the setting of hypertrophic cardiomyopathy (HCM), or chest pain in association with ECG changes with exercise.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) of the heart is valuable for evaluation and noninvasive follow-up of many congenital heart defects. It is particularly useful in imaging the thoracic vessels, which are difficult to image by transthoracic echocardiogram. Cardiac gated imaging allows dynamic evaluation of structure and blood flow of the heart and great vessels. Cardiac MRI provides unique and precise imaging in patients with newly diagnosed or repaired aortic coarctation and defines the aortic dilation in Marfan, Turner, and Loeys-Dietz syndromes. Cardiac MRI can quantify regurgitant lesions such as pulmonary insufficiency (PI) after repair of tetralogy of Fallot (ToF) and can define ventricular function, chamber size, and wall thickness in patients with inadequate echocardiographic images or cardiomyopathies. MRI is especially useful to characterize right ventricular size and function as this chamber is often difficult to image

comprehensively by echocardiogram. Because it allows computer manipulation of images of the heart and great vessels, three-dimensional MRI is an ideal noninvasive way of obtaining accurate reconstructions of the heart. General anesthesia is often required to facilitate cardiac MRI performance in children less than 8 years.

Van der Hulst AE et al: Cardiac MRI in postoperative congenital heart disease patients. J Magn Reson Imaging 2012;36(3): 511–528 [PMID: 2290365].

CARDIOPULMONARY STRESS TESTING

Most children with heart disease are capable of normal activity. Data on cardiac function after exercise are essential to prevent unnecessary restriction of activities. The response to exercise is helpful in determining the need for and the timing of cardiovascular surgery and is a useful objective outcome measure of the results of medical and surgical interventions.

Bicycle ergometers or treadmills can be used in children as young as age 5 years. The addition of a metabolic cart enables one to assess whether exercise impairment is secondary to cardiac limitation, pulmonary limitation, deconditioning, or lack of effort. Exercise variables include the ECG, blood pressure response to exercise, oxygen saturation, ventilation, maximal oxygen consumption, and peak workload attained. Cardiopulmonary stress testing is routine in children with congenital cardiac lesions to ascertain limitations, develop exercise programs, assess the effect of therapies, and decide on the need for cardiac transplantation. Stress testing is also employed in children with structurally normal hearts with complaints of exercise-induced symptoms in order to rule out cardiac or pulmonary pathology. Significant stress ischemia or dysrhythmias warrant physical restrictions or appropriate therapy. Children with poor performance due to suboptimal conditioning benefit from a planned exercise program.

Arvidsson D, Slinde F, Hulthén L, Sunnegårdh J: Physical activity, sports participation and aerobic fitness in children who have undergone surgery for congenital heart defects. Acta Paediatr 2009 Sep;98(9):1475–1482 [PMID: 19489769].

ARTERIAL BLOOD GASES

Quantitating the partial oxygen pressure (Po_2) or O_2 saturation during the administration of 100% oxygen is the most useful method of distinguishing cyanosis produced primarily by heart disease or by lung disease in sick infants. In cyanotic heart disease, the partial arterial oxygen pressure (Pao_2) increases very little when 100% oxygen is administered over the values obtained while breathing room air. However, Pao_2 usually increases significantly when oxygen is administered to a patient with lung disease. Table 20–11 illustrates the

Table 20–11. Examples of responses to 10 minutes of 100% oxygen in lung disease and heart disease.

	Lung Disease		Heart Disease	
	Room Air	100% O$_2$	Room Air	100% O$_2$
Color	Blue $\rightarrow$ Pink		Blue $\rightarrow$ Blue	
Oximetry	60% $\rightarrow$ 99%		60% $\rightarrow$ 62%	
Pao$_2$ (mm Hg)	35 $\rightarrow$ 120		35 $\rightarrow$ 38	

Pao$_2$, partial arterial oxygen pressure.
Data from Mahle WT et al: Role of pulse oximetry in examining newborns for congenital heart disease: A scientific statement from the AHA and AAP. Pediatrics 2009;124:823–836 [PMID: 19581259].

responses seen in patients with heart or lung disease during the hyperoxic test. Although the US Department of Health and Human Services recommended newborn screening for critical congenital heart disease in 2010, implementation of comprehensive pulse oximetry screening programs are challenged by variable infrastructure and access to expert interpretation.

Kember AR et al: Strategies for implementing screening for critical congenital heart disease. Pediatrics 2011 Nov;128(5): e1259–e1267 [PMID: 21987707].

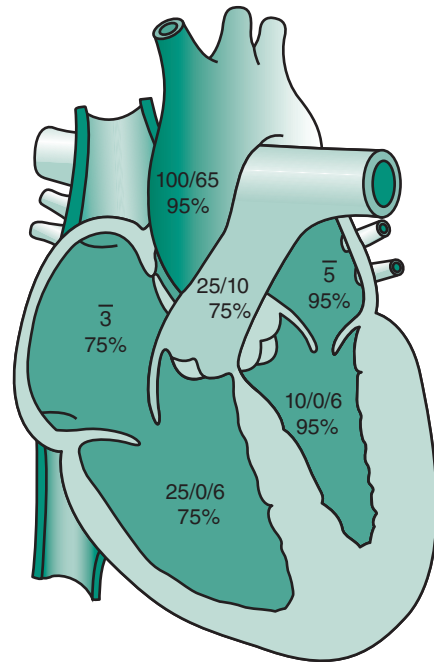
CARDIAC CATHETERIZATION & ANGIOCARDIOGRAPHY

Cardiac catheterization is an invasive method to evaluate anatomic and physiologic conditions in congenital or acquired heart disease. Management decisions may be made based on oximetric, hemodynamic or angiographic data obtained through a catheterization. In an increasing number of cases, intervention may be performed during a catheterization that may palliate, or even cure, a congenital heart defect without open heart surgery.

Cardiac Catheterization Data

Figure 20–3 shows oxygen saturation (in percent) and pressure (in millimeters of mercury) values obtained at cardiac catheterization from the chambers and great arteries of the heart. These values represent the normal range for a school age child.

A. Oximetry, Shunts, and Cardiac Output

Measurement of oxygen levels throughout the heart and surrounding blood vessels can provide a wealth of information about a patient's physiology. The difference between systemic saturation (in the aorta) and mixed venous saturation (usually in the superior vena cava [SVC]) is usually inversely


▲ **Figure 20–3.** Pressures (in millimeters of mercury) and oxygen saturation (in percent) obtained by cardiac catheterization in a healthy child. 3, mean pressure of 3 mm Hg in the right atrium; 5, mean pressure of 5 mm Hg in the left atrium.

proportional to the overall cardiac output. Cardiac output is determined by saturation difference across a vascular bed, taking into account oxygen consumption and hemoglobin. This is known as the Fick principle. Cardiac output in a healthy heart varies directly with the body's oxygen consumption and is inversely proportional to hemoglobin. The circulatory system of patients who are anemic usually tries to generate a higher cardiac output to maintain oxygen delivery to the cells of the body.

An *increase* in saturation across the *right* side of the heart (anywhere between SVC and pulmonary arteries) represents a left-to-right shunt. If oxygenated blood can mix with venous blood, the saturation rises—the degree of which correlates with the size of the shunt. Conversely, a *fall* in saturation across the *left* heart, between the pulmonary veins and the aorta, is abnormal. This represents the addition of deoxygenated blood to oxygenated blood—a right-to-left shunt.

A commonly referenced ratio in pediatric cardiology is the Qp:Qs. In a normal heart, systemic cardiac output (Qs) and pulmonary blood flow (Qp) are equal, or Qp:Qs = 1. If a step-up in saturation is noted across the right heart, suggesting a left-to-right shunt, pulmonary blood flow will exceed systemic blood flow. This can result, in cases of large shunts,

in a Qp:Qs of as high as 3:1 or more. This level of shunt is usually poorly tolerated, but small shunts (such as 1.5:1) may be well tolerated for months or years. In cases of right-to-left shunts, Qs will exceed Qp. In these cyanotic patients, the Qp:Qs may be 0.7 or 0.8.

B. Pressures

Pressures should be determined in all chambers and major vessels entered. Systolic pressure in the right ventricle should be equal to the systolic pressure in the pulmonary artery. Likewise, the systolic pressure in the left ventricle should be equal to the systolic pressure of the aorta. The mean pressure in the atria should be nearly equal to (or a point or two lower than) the end-diastolic pressure of the ventricles. If a gradient in pressure exists, an obstruction is present, and the severity of the gradient is one criterion for the necessity of intervention.

For example, a left ventricular systolic pressure in a small child of 140 mm Hg and an aortic systolic pressure of 80 mm Hg, a gradient of 60 mm Hg, would classify as severe aortic valve stenosis. Balloon aortic valvuloplasty would be indicated at the time of the catheterization.

C. Vascular Resistance

In addition to pressure and flow, resistance completes the "concept triad" of congenital heart physiology. Resistance is related to pressure and flow as described in the below equation:

$$\text{Resistance} = \frac{\text{Pressure}}{\text{Flow}}$$

The resistance across a vascular bed can be concretely calculated. The most common clinically relevant example is pulmonary vascular resistance. Patients with congenital heart disease or pulmonary vascular disease may have elevation in pulmonary vascular resistance, which can adversely impact circulation and heart function. To calculate pulmonary vascular resistance, the pressure drop from the pulmonary arteries to the left atrium is divided by pulmonary blood flow (Qp) to obtain a value in units. For example, a patient with a mean pulmonary artery pressure of 15 mm Hg and a left atrial pressure of 9 mm Hg, with a Qp of 3 L/min/m^2, has a pulmonary vascular resistance of 2 U/m^2.

Normal pulmonary vascular resistance is less than 3 U/m^2. Systemic vascular resistance normally covers a wider range, usually from 10 to 30 U/m^2. The ratio of pulmonary to systemic vascular resistance is usually less than 0.3. High pulmonary resistance, or a high ratio of resistance, denotes abnormal pulmonary vasculature. It often represents increased risk in patients with congenital heart disease or pulmonary hypertension and results in higher risk of death in severely affected patients.

Cardiac catheterization can be performed to evaluate the effects of pharmaceutical therapy. An example of this use of catheterization is monitoring changes in pulmonary vascular resistance during the administration of nitric oxide or prostacyclin in a child with primary pulmonary hypertension.

Angiography

In the past, angiography was a mainstay of the initial diagnostic methods for congenital heart disease. It is still used for diagnostic purposes in selected cases, but currently is used more frequently to plan interventions or evaluate postsurgical anatomy that is poorly seen by noninvasive methods. Injection of contrast liquid via a well-positioned catheter can illuminate detailed intracardiac and intravascular anatomy more clearly than any other method. Cardiac function can be observed, and anatomic abnormalities may be easily identified. In a growing number of centers, three-dimensional reconstruction of angiograms can provide exquisite delineation of cardiac and vascular structures.

Interventional Cardiac Catheterization

Various procedures are commonly performed in the catheterization laboratory that can improve or cure congenital malformations. Lesions that result in abnormal flow near or within the heart can be occluded, such as a patent ductus arteriosus, atrial septal defect, or ventricular septal defect. Obstruction of heart valves can be addressed through balloon valvuloplasty. Intervention may also be performed on vascular obstruction through angioplasty or stent placement in pulmonary arteries or the aorta. Systemic and pulmonary veins can be modified in a similar fashion, unfortunately with often minimal success in the latter. Devices are now available to allow patients to undergo replacement of failing heart valves without open heart surgery, and an increasing armamentarium of devices are becoming available for treatment of other defects and abnormal vasculature.

With the progression of improved noninvasive imaging, fewer diagnostic cardiac catheterization studies are performed today. The number of interventional procedures, however, is on the rise. Although the risks of cardiac catheterization are very low for elective studies in older children (< 1%), the risk of major complications in distressed or small patients is higher. Interventional procedures, particularly in unstable babies and children, increase these risks further. Increased use of registries is currently being employed to better understand efficacy rates and risks of these procedures, with the hope of optimizing the care of infants and children in the catheterization laboratory.

▼ PERINATAL & NEONATAL CIRCULATION

At birth, two events affect the cardiovascular and pulmonary system: (1) the umbilical cord is clamped, removing the placenta from the maternal circulation; and (2) breathing commences. As a result, marked changes in the circulation occur. During fetal life, the placenta offers low resistance to blood flow. In contrast, the pulmonary arterioles are markedly constricted and there is high resistance to blood flow in the lungs. Therefore, the majority of blood entering the right side of the heart travels from the right atrium into the left atrium across the foramen ovale (right-to-left shunt). In addition, most of the blood that makes its way into the right ventricle and then pulmonary arteries will flow from the pulmonary artery into the aorta through the ductus arteriosus (right-to-left shunt). Subsequently, pulmonary blood flow accounts for only 7%–10% of the combined in utero ventricular output. At birth, pulmonary blood flow dramatically increases with the fall in pulmonary vascular resistance and pressure. The causes of prolonged high pulmonary vascular resistance include physical factors (lack of an adequate air-liquid interface or ventilation), low oxygen tension, and vasoactive mediators such as elevated endothelin peptide levels or leukotrienes. Clamping the umbilical cord produces an immediate increase in resistance to flow in the systemic circuit.

As breathing commences, the Po_2 of the small pulmonary arterioles increases, resulting in a decrease in pulmonary vascular resistance. Increased oxygen tension, rhythmic lung distention, and production of nitric oxide as well as prostacyclin play major roles in the fall in pulmonary vascular resistance at birth. The pulmonary vascular resistance falls below that of the systemic circuit, resulting in a reversal in direction of blood flow across the ductus arteriosus and marked increase in pulmonary blood flow.

Functional closure of the ductus arteriosus begins shortly after birth. The ductus arteriosus usually remains patent for 1–5 days. During the first hour after birth, a small right-to-left shunt is present (as in the fetus). However, after 1 hour, bidirectional shunting occurs, with the left-to-right direction predominating. In most cases, right-to-left shunting disappears completely by 8 hours. In patients with severe hypoxia (eg, in the syndrome of persistent pulmonary hypertension of the newborn), pulmonary vascular resistance remains high, resulting in a continued right-to-left shunt. Although flow through the ductus arteriosus usually is gone by 5 days of life, the vessel does not close anatomically for 7–14 days.

In fetal life, the foramen ovale serves as a one-way valve shunting blood from the inferior vena cava through the right atrium into the left atrium. At birth, because of the changes in the pulmonary and systemic vascular resistance and the increase in the quantity of blood returning from the pulmonary veins to the left atrium, the left atrial pressure rises above that of the right atrium. This functionally closes the flap of the foramen ovale, preventing flow of blood across the septum. The foramen ovale remains probe patent in 10%–15% of adults.

Persistent pulmonary hypertension is a clinical syndrome of full-term infants. The neonate develops tachypnea, cyanosis, and pulmonary hypertension during the first 8 hours after delivery. These infants have massive right-to-left ductal and/or foramen shunting for 3–7 days because of high pulmonary vascular resistance. Progressive hypoxia and acidosis will cause early death unless the pulmonary resistance can be lowered. Postmortem findings include increased thickness of the pulmonary arteriolar media. Increased alveolar Po_2 with hyperventilation, alkalosis, paralysis, surfactant administration, high-frequency ventilation, and cardiac inotropes can usually reverse this process. Inhaled nitric oxide selectively dilates pulmonary vasculature, produces a sustained improvement in oxygenation, and has resulted in improved outcomes.

In the normal newborn, pulmonary vascular resistance and pulmonary arterial pressure continue to fall during the first weeks of life as a result of demuscularization of the pulmonary arterioles. Adult levels of pulmonary resistance and pressure are normally achieved by 4–6 weeks of age. It is at this time typically that signs of pulmonary overcirculation associated with left-to-right shunt lesions (VSD or atrioventricular septal defect [AVSD]) appear.

▼ HEART FAILURE

Heart failure (HF) is the clinical condition in which the heart fails to meet the circulatory and metabolic needs of the body. The term *congestive heart failure* is not always accurate, as some patients with significant cardiac dysfunction have symptoms of exercise intolerance and fatigue without evidence of congestion. Right and left heart failure can result from volume or pressure overload of the respective ventricle or an intrinsic abnormality of the ventricular myocardium. Causes of right ventricular volume overload include an ASD, pulmonary insufficiency, or anomalous pulmonary venous return.

Left ventricular volume overload occurs with any left-to-right shunting lesion (eg, VSD, PDA), aortic insufficiency, or a systemic arteriovenous malformation. Causes of right ventricular failure as a result of pressure overload include pulmonary hypertension, valvar pulmonary stenosis, or severe branch pulmonary artery stenosis. Left ventricular pressure overload results from left heart obstructive lesions such as aortic stenosis (subvalvar, valvar, or supravalvar) or coarctation of the aorta. Abnormalities of the right ventricular myocardium that can result in right heart failure include Ebstein's anomaly (atrialization of the right ventricle) and arrhythmogenic right ventricular dysplasia (a genetic disorder where the right ventricular myocardium is replaced by fat). Abnormalities of the left ventricular myocardium are more common and include dilated cardiomyopathy, myocarditis, or hypertrophic cardiomyopathy. As a result of elevated left atrial pressure and impaired relaxation of the left ventricle, left heart failure can lead to right heart failure. Other causes of HF in infants include AV septal defect, coronary artery anomalies, and chronic atrial tachyarrhythmias. Metabolic, mitochondrial, and neuromuscular disorders with associated cardiomyopathy present at various ages depending on the etiology. HF due to acquired conditions such as myocarditis can occur at any age. Children with HF may present with irritability, diaphoresis with feeds, fatigue, exercise intolerance, or evidence of pulmonary congestion (see Table 20–1).

Treatment of Heart Failure

The therapy of HF should be directed toward the underlying cause as well as the symptoms. Regardless of the etiology, neurohormonal activation occurs early when ventricular systolic dysfunction is present. Plasma catecholamine levels (eg, norepinephrine) increase causing tachycardia, diaphoresis, and, by activating the renin-angiotensin system, peripheral vasoconstriction and salt and water retention. There is no gold standard diagnostic or therapeutic approach to HF

in children. Treatment must be individualized and therapies should be aimed at improving cardiac performance by targeting the three determinants of cardiac performance: (1) preload, (2) afterload, and (3) contractility.

Inpatient Management of Heart Failure

Patients with cardiac decompensation may require hospitalization for initiation or augmentation of HF therapy. Table 20–12 demonstrates intravenous inotropic agents used to augment cardiac output and their relative effect on heart rate, systemic vascular resistance, and cardiac index. The drug used will depend in part on the cause of the HF.

A. Inotropic and Mechanical Support

1. Afterload reduction

A. MILRINONE—This phosphodiesterase-3 inhibitor increases cyclic adenosine monophosphate, thereby improving the inotropic state of the heart. In addition to a dose-dependent increase in cardiac contractility, milrinone is a systemic and pulmonary vasodilator and thus an effective agent in both right and left ventricular systolic dysfunction. Milrinone reduces the incidence of low cardiac output syndrome following open-heart surgery. The usual dosage range is 0.25–0.75 mcg/kg/min.

B. NITROGLYCERIN—Nitroglycerin functions primarily as a dilator of venous capacitance vessels and causes a reduction of right and left atrial pressure. Systemic blood pressure may also fall, and reflex tachycardia may occur. Nitroglycerin is used to improve coronary blood flow and may be especially useful when cardiac output is reduced because of coronary under-perfusion following congenital heart surgery. The usual intravenous dosage range is 1–3 mcg/kg/min.

2. Enhancement of contractility

A. DOPAMINE—This naturally occurring catecholamine increases myocardial contractility primarily via cardiac

Table 20–12. Intravenous inotropic agents.

Drug	Dose	Renal Perfusion	Heart Rate	Cardiac Index	SVR
Dopamine	2–5 mcg/kg/min	↑ via vasodilation	0	0	0
	5–10	↑/↓ - depending on balance of ↑ cardiac index and ↑SVR	↑	↑	↑↓
	> 10	↓	↑	↑	↑
Dobutamine	2.5–10 mcg/kg/min	↑ via ↑ cardiac index	↑	↑	↑↓
Epinephrine	0.2–2.0 mcg/kg/min	↓	↑	↑	↓
Norepinephrine	0.05–0.1 mcg/kg/min	↓	0	↑	↑↑
Isoproterenol	0.05–2.0 mcg/kg/min	0	↑↑	↑	↓↓

SVR, systemic vascular resistance.

β-adrenergic activation. Dopamine also directly acts on renal dopamine receptors to improve renal perfusion. The usual dose range for HF is 3–10 mcg/kg/min.

b. Dobutamine—This synthetic catecholamine increases myocardial contractility secondary to cardiospecific β-adrenergic activation and produces little peripheral vasoconstriction. Dobutamine does not usually cause marked tachycardia, which is a distinct advantage. However, the drug does not selectively improve renal perfusion as does dopamine. The usual dose range is essentially the same as for dopamine.

3. Mechanical circulatory support—Mechanical support is indicated in children with severe, refractory myocardial failure secondary to cardiomyopathy, myocarditis, or following cardiac surgery. Mechanical support is used for a limited time while cardiac function improves or as a bridge to cardiac transplantation.

a. Extracorporeal membrane oxygenation (ecmo)— ECMO is a temporary means of providing oxygenation, carbon dioxide removal, and hemodynamic support to patients with cardiac or pulmonary failure refractory to conventional therapy. The blood removed from the patient via a catheter positioned in the venous system (eg, superior vena cava or right atrium) passes through a membrane oxygenator and then is delivered back to the patient through a catheter in the arterial system (eg, aorta or common carotid artery). Flow rates are adjusted to maintain adequate systemic perfusion, as judged by mean arterial blood pressure, acid-base status, end-organ function, and mixed venous oxygen saturation. The patient is monitored closely for improvement in cardiac contractility. Risks are significant and include severe internal and external bleeding, infection, thrombosis, and pump failure.

b. Ventricular assist devices—Use of ventricular assist devices is increasing in children as device development has progressed. These devices allow for less invasive hemodynamic support than ECMO. A cannula is usually positioned in the apex of the ventricle and removes blood from the ventricle using a battery-operated pump. Blood is then returned to the patient through a separate cannula positioned in the aorta or pulmonary artery, depending on the ventricle being supported. Biventricular support can be done if necessary. Ventricular assist carries lower risk of pump failure than ECMO, but the risk of infection, thrombosis, and bleeding complications remains.

Outpatient Management of Heart Failure

A. Medications

1. Afterload-reducing agents—Oral afterload-reducing agents improve cardiac output by decreasing systemic vascular resistance. Angiotensin-converting enzyme (ACE) inhibitors (captopril, enalapril, and lisinopril) are first-line therapy in children with HF requiring long-term treatment. These agents block angiotensin II–mediated systemic vasoconstriction and are particularly useful in children with structurally normal hearts but reduced LV myocardial function (eg, myocarditis or dilated cardiomyopathies [DCMs]). They are also useful in ameliorating mitral and aortic insufficiency and have a role in controlling refractory HF in patients with large left-to-right shunts in whom systemic vascular resistance is elevated.

2. β-Blockade—Although clearly beneficial in adults with HF, a randomized, controlled study of the use of a β-blocker (carvedilol) in children with HF did not demonstrate any significant improvement compared to placebo. However, β-blockers may still be useful adjunctive therapy in some children with refractory HF already taking ACE inhibitors. In the setting of HF, excessive circulating catecholamines are present due to activation of the sympathetic nervous system. Although beneficial acutely, this compensatory response over time produces myocardial fibrosis, myocyte hypertrophy, and myocyte apoptosis that contribute to the progression of HF. β-Blockers (eg, carvedilol and metoprolol) antagonize this sympathetic activation and may offset these deleterious effects. Side effects of β-blockers are significant and include bradycardia, hypotension, and worsening HF in some patients.

3. Diuretics—Diuretic therapy may be necessary in HF to maintain the euvolemic state and control symptoms related to pulmonary or hepatic congestion.

a. Furosemide—This rapid-acting loop diuretic may be given intravenously or orally. It removes large amounts of potassium and chloride from the body, producing hypochloremic metabolic alkalosis when used chronically. Electrolytes should be monitored during long-term therapy.

b. Thiazides—Thiazides are distal tubular diuretics used to complement furosemide in severe cases of HF.

c. Spironolactone—Spironolactone is a potassium-sparing aldosterone inhibitor. It is used frequently in conjunction with furosemide or thiazides for its enhanced diuretic function. Because it spares potassium, supplemental potassium may be avoided. Spironolactone has benefit in adults with HF regardless of its diuretic effect as aldosterone is associated with the development of fibrosis, sodium retention, and vascular dysfunction. This effect has not been proven in children.

4. Digitalis—Digitalis is a cardiac glycoside with a positive inotropic effect on the heart and an associated decrease in systemic vascular resistance. The preparation of digitalis used in clinical practice is digoxin. Large studies in adult patients with HF have not demonstrated decreased mortality of HF

with digoxin use, but treatment is associated with reduced hospitalization rates for HF exacerbations. There are no controlled studies in children.

A. Digitalis toxicity—Any dysrhythmia that occurs during digoxin therapy should be attributed to the drug until proven otherwise. Ventricular bigeminy and first-, second-, or third-degree AV block are characteristic of digoxin toxicity. A trough level should be obtained if digoxin toxicity is suspected.

B. Digitalis poisoning—This acute emergency must be treated without delay. Digoxin poisoning most commonly occurs in toddlers who have taken their parents' or grandparents' medications. The child's stomach should be emptied immediately by gastric lavage even if several hours have passed since ingestion. Patients who have ingested massive amounts of digoxin should receive large doses of activated charcoal. In advanced heart block, atropine or temporary ventricular pacing may be needed. Digoxin immune Fab can be used to reverse potentially life-threatening intoxication. Antiarrhythmic agents may be useful.

5. Fluid restriction—Fluid restriction is rarely necessary in children with HF due to the effectiveness of diuretics and the tendency of infants and children with HF to self-regulate intake. Ensuring adequate caloric intake to promote growth is a more important goal in children with HF.

Morales DL, Zafar F, Rossano JW et al: Use of ventricular assist devices in children across the United States: analysis of 7.5 million pediatric hospitalizations. Ann Thorac Surg 2010 Oct;90(4):1313–1318, discussion 1318–1319 [PMID: 20868835].

Rosenthal D et al: International society for heart and lung transplantation: practice guidelines for management of heart failure in children. J Heart Lung Transplant 2004;23:1313 [PMID: 15607659].

GENETIC BASIS OF CONGENITAL HEART DISEASE

Environmental factors such as maternal diabetes, alcohol consumption, progesterone use, viral infection, and other maternal teratogen exposure are associated with an increased incidence of cardiac malformations. However, the importance of genetics as a cause of congenital heart disease is becoming more evident as advances in the field occur. Microdeletion in the long arm of chromosome 22 (22q11) is associated with DiGeorge syndrome. These children often have conotruncal abnormalities such as truncus arteriosus, tetralogy of Fallot, double-outlet RV, or interrupted aortic arch. Alagille, Noonan, Holt-Oram, and Williams syndromes and the Trisomies 13, 18, and 21 are all commonly associated with congenital heart lesions. Understanding these

associations as well as further targeted study investigating the genetic basis of other cardiac lesions will offer opportunities for early diagnosis, gene therapy, and recurrence risk counseling for families.

Pierpont ME et al: Genetic basis for congenital heart defects: current knowledge: a scientific statement from the American Heart Association Congenital Cardiac Defects Committee, Council on Cardiovascular Disease in the Young: endorsed by the American Academy of Pediatrics. Circulation 2007;115: 3015–3038 [PMID: 17519398].

ACYANOTIC CONGENITAL HEART DISEASE

DEFECTS IN SEPTATION

▶ 1. Atrial Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fixed, widely split S_2, RV heave.
- ▶ Grade I–III/VI systolic ejection murmur at the pulmonary area.
- ▶ Large shunts cause a diastolic flow murmur at the lower left sternal border (increased flow across the tricuspid valve).
- ▶ ECG shows rsR' in lead V_1.
- ▶ Frequently asymptomatic.

▶ General Considerations

Atrial septal defect (ASD) is an opening in the atrial septum permitting the shunting of blood between the atria. There are three major types: ostium secundum, ostium primum, and sinus venosus. Ostium secundum is the most common type and represents an embryologic deficiency in the septum secundum or too large of a central hole in the septum primum. Ostium primum defect is associated with atrioventricular septal defects. The sinus venosus defect is frequently associated with abnormal pulmonary venous return, as the location of the sinus venosus is intimately related to the right upper pulmonary vein.

Ostium secundum ASD occurs in 10% of patients with congenital heart disease and is two times more common in females than in males. The defect is most often sporadic but may be familial or have a genetic basis (Holt-Oram syndrome). After the third decade, atrial arrhythmias or pulmonary vascular disease may develop. Irreversible pulmonary hypertension resulting in cyanosis as atrial level shunting becomes right-to-left and ultimately right

heart failure can occur and is a life-limiting process (Eisenmenger syndrome).

► Clinical Findings

A. Symptoms and Signs

Most infants and children with an ASD have no cardiovascular symptoms. Older children and adults can present with exercise intolerance, easy fatigability, or, rarely, heart failure. The direction of flow across the ASD is determined by the compliance of the ventricles. Because the right ventricle is normally more compliant, shunting across the ASD is left-to-right as blood follows the path of least resistance. Therefore, cyanosis does not occur unless RV dysfunction occurs, usually as a result of pulmonary hypertension, leading to reversal of the shunt across the defect.

Peripheral pulses are normal and equal. The heart is usually hyperactive, with an RV heave felt best at the mid to lower left sternal border. S_2 at the pulmonary area is widely split and often fixed. In the absence of associated pulmonary hypertension, the pulmonary component is normal in intensity. A grade I–III/VI ejection-type systolic murmur is heard best at the left sternal border in the second intercostal space. This murmur is caused by increased flow across the pulmonic valve, not flow across the ASD. A mid-diastolic murmur is often heard in the fourth intercostal space at the left sternal border. This murmur is caused by increased flow across the tricuspid valve during diastole. The presence of this murmur suggests high flow with a pulmonary-to-systemic blood flow ratio greater than 2:1.

B. Imaging

Radiographs may show cardiac enlargement. The main pulmonary artery may be dilated and pulmonary vascular markings increased in large defects owing to the increased pulmonary blood flow.

C. Electrocardiography

The usual ECG shows right axis deviation. In the right precordial leads, an rsR′ pattern is usually present. A mutation in the cardiac homeobox gene (*NKX2-5*) is associated with an ASD, and AV block would be seen on the ECG.

D. Echocardiography

Echocardiography shows a dilated right atrium and RV. Direct visualization of the exact anatomic location of the ASD by two-dimensional echocardiography, and demonstration of a left-to-right shunt through the defect by color-flow Doppler, confirms the diagnosis and has eliminated the need for cardiac catheterization prior to surgical or catheter closure of the defect. Assessment of all pulmonary veins should be made to rule out associated anomalous pulmonary venous return.

E. Cardiac Catheterization

Although cardiac catheterization is rarely needed for diagnostic purposes, transcatheter closure of an ostium secundum ASD is now the preferred method of treatment.

If a catheterization is performed, oximetry shows a significant step-up in oxygen saturation from the superior vena cava to the right atrium. The pulmonary artery pressure and pulmonary vascular resistance are usually normal. The Qp:Qs may vary from 1.5:1 to 4:1.

► Treatment

Surgical or catheterization closure is generally recommended for symptomatic children with a large atrial level defect and associated right heart dilation. In the asymptomatic child with a large hemodynamically significant defect, closure is performed electively at age 1–3 years. Most defects are amenable to non-operative device closure during cardiac catheterization, but the defect must have adequate tissue rims on all sides on which to anchor the device. The mortality for surgical closure is less than 1%. When closure is performed by age 3 years, late complications of RV dysfunction and dysrhythmias are avoided.

► Course & Prognosis

Patients usually tolerate an ASD well in the first two decades of life, and the defect often goes unnoticed until middle or late adulthood. Pulmonary hypertension and reversal of the shunt are rare late complications. Infective endocarditis (IE) is uncommon. Spontaneous closure occurs, most frequently in children with a defect less than 4 mm in diameter, therefore outpatient follow-up is recommended. Exercise tolerance and oxygen consumption in surgically corrected children are generally normal, and restriction of physical activity is unnecessary.

Arrington CB et al: An assessment of the electrocardiogram as a screening test for large atrial septal defects in children. J Electrocardiol 2007;40:484–488 [PMID: 17673249].

Butera G et al: Treatment of isolated secundum atrial septal defects: impact of age and defect morphology in 1,013 consecutive patients. Am Heart J 2008;156:706–712 [PMID: 18926151].

2. Ventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Holosystolic murmur at lower left sternal border with RV heave.
► Presentation and course depend on size of defect and the pulmonary vascular resistance.

▶ Clinical features are failure to thrive, tachypnea, and diaphoresis with feeds.

▶ Left-to-right shunt with normal pulmonary vascular resistance.

▶ Large defects may cause Eisenmenger syndrome if not repaired early.

▶ General Considerations

Ventricular septal defect (VSD) is the most common congenital heart malformation, accounting for about 30% of all congenital heart disease. Defects in the ventricular septum occur both in the membranous portion of the septum (most common) and the muscular portion. VSDs follow one of four courses:

A. Small, Hemodynamically Insignificant Ventricular Septal Defects

Between 80% and 85% of VSDs are small (< 3 mm in diameter) at birth and will close spontaneously. In general, small defects in the muscular interventricular septum will close sooner than those in the membranous septum. In most cases, a small VSD never requires surgical closure. Fifty percent of small VSDs will close by age 2 years, and 90% by age 6 years, with most of the remaining closing during the school years.

B. Moderate-Sized Ventricular Septal Defects

Asymptomatic patients with moderate-sized VSDs (3–5 mm in diameter) account for 3%–5% of children with VSDs. In general, these children do not have clear indicators for surgical closure. Historically, in those who had cardiac catheterization, the ratio of pulmonary to systemic blood flow is usually less than 2:1, and serial cardiac catheterizations demonstrate that the shunts get progressively smaller. If the patient is asymptomatic and without evidence of pulmonary hypertension, these defects can be followed serially as some close spontaneously over time.

C. Large Ventricular Septal Defects with Normal Pulmonary Vascular Resistance

These defects are usually 6–10 mm in diameter. Unless they become markedly smaller within a few months after birth, they often require surgery. The timing of surgery depends on the clinical situation. Many infants with large VSDs and normal pulmonary vascular resistance develop symptoms of failure to thrive, tachypnea, diaphoresis with feeds by age 3–6 months, and require correction at that time. Surgery before age 2 years in patients with large VSDs essentially eliminates the risk of pulmonary vascular disease.

D. Large Ventricular Septal Defects with Pulmonary Vascular Obstructive Disease

The direction of flow across a VSD is determined by the resistance in the systemic and pulmonary vasculature, explaining why flow is usually left-to-right. In large VSDs, ventricular pressures are equalized, resulting in increased pulmonary artery pressure. In addition, shear stress caused by increased volume in the pulmonary circuit causes increased resistance over time. The vast majority of patients with inoperable pulmonary hypertension develop the condition progressively. The combined data of the multicenter National History Study indicate that almost all cases of irreversible pulmonary hypertension can be prevented by surgical repair of a large VSD before age 2 years.

▶ Clinical Findings

A. Symptoms and Signs

Patients with small or moderate left-to-right shunts usually have no cardiovascular symptoms. Patients with large left-to-right shunts are usually ill early in infancy. These infants have frequent respiratory infections and gain weight slowly. Dyspnea, diaphoresis, and fatigue are common. These symptoms can develop as early as 1–6 months of age. Older children may experience exercise intolerance. Over time, in children and adolescents with persistent large left-to-right shunt, the pulmonary vascular bed undergoes structural changes, leading to increased pulmonary vascular resistance and reversal of the shunt from left-to-right to right-to-left (Eisenmenger syndrome). Cyanosis will then be present.

1. Small left-to-right shunt—No lifts, heaves, or thrills are present. The first sound at the apex is normal, and the second sound at the pulmonary area is split physiologically. A grade II–IV/VI, medium- to high-pitched, harsh pansystolic murmur is heard best at the left sternal border in the third and fourth intercostal spaces. The murmur radiates over the entire precordium. No diastolic murmurs are heard.

2. Moderate left-to-right shunt—Slight prominence of the precordium with moderate LV heave is evident. A systolic thrill may be palpable at the lower left sternal border between the third and fourth intercostal spaces. The second sound at the pulmonary area is most often split but may be single. A grade III–IV/VI, harsh pansystolic murmur is heard best at the lower left sternal border in the fourth intercostal space. A mitral diastolic flow murmur indicates that pulmonary blood flow and subsequently the pulmonary venous return are significantly increased by the large shunt.

3. Large ventricular septal defects with pulmonary hypertension—The precordium is prominent, and the sternum bulges. Both LV and RV heaves are palpable. S_2 is palpable in the pulmonary area. A thrill may be present at

the lower left sternal border. S_2 is usually single or narrowly split, with accentuation of the pulmonary component. The murmur ranges from grade I to IV/VI and is usually harsh and pansystolic. Occasionally, when the defect is large or ventricular pressures approach equivalency, a murmur is difficult to hear. A diastolic flow murmur may be heard, depending on the size of the shunt.

B. Imaging

In patients with small shunts, the chest radiograph may be normal. Patients with large shunts have significant cardiac enlargement involving both the left and right ventricles and the left atrium. The main pulmonary artery segment may be dilated. The pulmonary vascular markings are increased.

C. Electrocardiography

The ECG is normal in small left-to-right shunts. Left ventricular hypertrophy (LVH) usually occurs in patients with large left-to-right shunts and normal pulmonary vascular resistance. Combined ventricular enlargement occurs in patients with pulmonary hypertension caused by increased flow, increased resistance, or both. Pure RV hypertrophy occurs in patients with pulmonary hypertension secondary to pulmonary vascular obstruction induced by long-standing left-to-right shunt (Eisenmenger syndrome).

D. Echocardiography

Two-dimensional echocardiography can reveal the size of a VSD and identify its anatomic location. Multiple defects can be detected by combining two-dimensional and color-flow imaging. Doppler can further evaluate the VSD by estimating the pressure difference between the left and right ventricles. A pressure difference greater than 50 mm Hg in the left ventricle compared to the right ventricle confirms the absence of severe pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

The ability to describe the VSD anatomy and estimate the pulmonary artery pressures on the basis of the gradient across the VSD allows for the vast majority of isolated defects to be repaired without cardiac catheterization and angiocardiography. Catheterization is indicated in those patients with increased pulmonary vascular resistance. Angiocardiographic examination defines the number, size, and location of the defects.

▶ Treatment

A. Medical Management

Patients who develop symptoms can be managed with anticongestive treatment (see section on Heart Failure, earlier),

particularly diuretics and systemic afterload reduction, prior to surgery or if it is expected that the defect will close over time.

B. Surgical Treatment

Patients with cardiomegaly, poor growth, poor exercise tolerance, or other clinical abnormalities who have a significant shunt (> 2:1) typically undergo surgical repair at age 3–6 months. A synthetic or pericardial patch is used for primary closure. In most centers, these children have surgery before age 1 year. As a result, Eisenmenger syndrome has been virtually eliminated. The surgical mortality rate for VSD closure is below 2%.

Transcatheter closure of muscular VSDs is also a possibility. Perimembranous VSDs have also been closed in children during catheterization, but a high incidence of complete heart block after placement of the occluding device has slowed the acceptance of this approach.

▶ Course & Prognosis

Significant late dysrhythmias are uncommon. Functional exercise capacity and oxygen consumption are usually normal, and physical restrictions are unnecessary. Adults with corrected defects have normal quality of life.

Butera G et al: Transcatheter closure of perimembranous ventricular septal defects: early and long-term results. J Am Coll Cardiol 2007;50:1189–1195 [PMID: 17868812].

Sondheimer HM, Rahimi-Alangi K: Current management of ventricular septal defect. Cardiol Young 2006;16(Suppl 3):131–135 [PMID: 17378052].

▶ 3. Atrioventricular Septal Defect

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Murmur often inaudible in neonates.

▶ Loud pulmonary component of S_2.

▶ Common in infants with Down syndrome.

▶ ECG with extreme left axis deviation.

▶ General Considerations

Atrioventricular septal defect (AVSD) results from incomplete fusion of the embryonic endocardial cushions. The endocardial cushions help to form the "crux" of the heart, which includes the lower portion of the atrial septum, the membranous portion of the ventricular septum, and the septal leaflets of the tricuspid and mitral valves. AVSD accounts for about 4% of all congenital heart disease.

Sixty percent of children with Down syndrome have congenital heart disease, and of these, 35%–40% have an AVSD.

AVSDs are defined as partial or complete. The physiology of the defect is determined by the location of the AV valves. If the valves are located in the midportion of the defect (complete AVSD), both atrial and ventricular components of the septal defect are present and the left- and right-sided AV valves share a common ring or orifice. In the partial form, there is a low insertion of the AV valves, resulting in a primum ASD without a ventricular defect component. In partial AVSD, there are two separate AV valve orifices and usually a cleft in the left-sided valve.

Partial AVSD behaves like an isolated ASD with variable amounts of regurgitation through the cleft in the left AV valve. The complete form causes large left-to-right shunts at both the ventricular and atrial levels with variable degrees of AV valve regurgitation. If there is increased pulmonary vascular resistance, the shunts may be bidirectional. Bidirectional shunting is more common in Down syndrome or in older children who have not undergone repair.

▶ Clinical Findings

A. Symptoms and Signs

The partial form may produce symptoms similar to ostium secundum ASD. Patients with complete AVSD usually have symptoms such as failure to thrive, tachypnea, diaphoresis with feeding, or recurrent bouts of pneumonia.

In the neonate with the complete form, the murmur may be inaudible due to relatively equal systemic and pulmonary vascular resistance (PVR). After 4–6 weeks, as PVR drops, a nonspecific systolic murmur develops. The murmur is usually not as harsh as that of an isolated VSD. There is both right- and left-sided cardiac enlargement. S_2 is loud, and a pronounced diastolic flow murmur may be heard at the apex and the lower left sternal border.

If severe pulmonary vascular obstructive disease is present, there is usually dominant RV enlargement. S_2 is palpable at the pulmonary area and no thrill is felt. A nonspecific short systolic murmur is heard at the lower left sternal border. No diastolic flow murmurs are heard. If a right-to-left shunt is present, cyanosis will be evident.

B. Imaging

Cardiac enlargement is always present in the complete form and pulmonary vascular markings are increased. Often, only the right heart size may be increased in the partial form, although a severe mitral valve cleft can rarely lead to left heart enlargement as well.

C. Electrocardiography

In all forms of AVSD, there is extreme left axis deviation with a counterclockwise loop in the frontal plane. The ECG is an important diagnostic tool. Only 5% of isolated VSDs have this ECG abnormality. First-degree heart block occurs in over 50% of patients. Right, left, or combined ventricular hypertrophy is present depending on the particular defect and the presence or absence of pulmonary hypertension.

D. Echocardiography

Echocardiography is the diagnostic test of choice. The anatomy can be well visualized by two-dimensional echocardiography. Both AV valves are at the same level, compared with the normal heart in which the tricuspid valve is more apically positioned. The size of the atrial and ventricular components of the defect can be measured. AV valve regurgitation can be detected. The LV outflow tract is elongated (gooseneck appearance), which produces systemic outflow obstruction in some patients.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is not routinely used to evaluate AVSD but may be used to assess pulmonary artery pressures and resistance in the older infant with Down syndrome, as this patient group is predisposed to early-onset pulmonary hypertension. Increased oxygen saturation in the RV or the right atrium identifies the level of the shunt. Angiocardiography reveals the characteristic gooseneck deformity of the LV outflow tract in the complete form.

▶ Treatment

Spontaneous closure of this type of defect does not occur and therefore surgery is required. In the partial form, surgery carries a low mortality rate (1%–2%), but patients require follow-up because of late-occurring LV outflow tract obstruction and mitral valve dysfunction. The complete form carries a higher mortality rate. Complete correction in the first year of life, prior to the onset of irreversible pulmonary hypertension, is obligatory.

PATENT (PERSISTENT) DUCTUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Continuous machinery type murmur.

▶ Bounding peripheral pulses if large ductus present.

▶ Presentation and course depends on size of the ductus and the pulmonary vascular resistance.

- ▶ Clinical features of a large ductus are failure to thrive, tachypnea, and diaphoresis with feeds.
- ▶ Left-to-right shunt with normal pulmonary vascular resistance.

▶ General Considerations

PDA is the persistence of the normal fetal vessel joining the pulmonary artery to the aorta. It closes spontaneously in normal-term infants at 1–5 days of age. PDA accounts for 10% of all congenital heart disease. The incidence of PDA is higher in infants born at altitudes over 10,000 ft. It is twice as common in females as in males. The frequency of PDA in preterm infants weighing less than 1500 g ranges from 20% to 60%. The defect may occur as an isolated abnormality or with associated lesions, commonly coarctation of the aorta and VSD. Patency of the ductus arteriosus may be necessary in some patients with complex forms of congenital heart disease (eg, hypoplastic left heart syndrome [HLHS], pulmonary atresia). Prostaglandin E_2 (PGE_2) is a product of arachidonic acid metabolism and continuous intravenous infusion maintains ductal patency.

▶ Clinical Findings

A. Symptoms and Signs

The clinical findings and course depend on the size of the shunt and the degree of pulmonary hypertension.

1. Moderate to large patent ductus arteriosus—Pulses are bounding, and pulse pressure is widened due to diastolic runoff through the ductus. S_1 is normal and S_2 is usually narrowly split. In large shunts, S_2 may have a paradoxical split (eg, S_2 narrows on inspiration and widens on expiration). Paradoxical splitting is caused by volume overload of the LV and prolonged ejection of blood from this chamber.

The murmur is characteristic. It is a rough machinery murmur maximal at the second left intercostal space. It begins shortly after S_1, rises to a peak at S_2, and passes through the S_2 into diastole, where it becomes a decrescendo murmur and fades before the S_1. The murmur tends to radiate well to the anterior lung fields but relatively poorly to the posterior lung fields. A diastolic flow murmur is often heard at the apex.

2. Patent ductus arteriosus with increased pulmonary vascular resistance—Flow across the ductus is diminished. S_2 is single and accentuated, and no significant heart murmur is present. The pulses are normal rather than bounding.

B. Imaging

In an isolated PDA, the appearance of the chest radiograph depends on the size of the shunt. If the shunt is small, the heart is not enlarged. If the shunt is large, both left atrial and LV enlargement may be seen. The aorta and the main pulmonary artery segment may also be prominent.

C. Electrocardiography

The ECG may be normal or may show LVH, depending on the size of the shunt. In patients with pulmonary hypertension caused by increased blood flow, biventricular hypertrophy usually occurs. In pulmonary vascular obstructive disease, pure right ventricular hypertrophy (RVH) occurs.

D. Echocardiography

Echocardiography provides direct visualization of the ductus and confirms the direction and degree of shunting. High-velocity left-to-right flow argues against abnormally elevated pulmonary vascular resistance, and as pulmonary vascular resistance drops during the neonatal period, higher velocity left-to-right shunting is usually seen. If suprasystemic pulmonary vascular resistance is present, flow across the ductus will be seen from right to left. Associated cardiac lesions and ductal-dependent pulmonary or systemic blood flow must be recognized by echocardiography, as closure of a PDA in this setting would be contraindicated.

E. Cardiac Catheterization and Angiocardiography

PDA closure in the catheterization laboratory with a vascular plug or coils is now routine in all but the smallest of neonates and infants.

▶ Treatment

Surgical closure is indicated when the PDA is large and the patient is small. Caution must be given to closing a PDA in patients with pulmonary vascular obstructive disease and right-to-left shunting across the ductus as this could result in RV failure. Patients with large left-to-right shunts require repair by age 1 year to prevent the development of progressive pulmonary vascular obstructive disease. Symptomatic PDA with normal pulmonary artery pressure can be safely coil or device-occluded in the catheterization laboratory, ideally after the child has reached 5 kg.

Patients with nonreactive pulmonary vascular obstruction, pulmonary vascular resistance greater than 10 Wood units (normal, < 3), and a ratio of pulmonary to systemic resistance greater than 0.7 (normal, < 0.3) despite vasodilator therapy (eg, nitric oxide) should not undergo PDA closure. These patients are made worse by PDA closure because the flow through the ductus allows preserved RV function and maintains cardiac output to the systemic circulation. These patients can be managed with pulmonary vasodilator therapy, but eventually may require heart-lung transplant in severe cases.

Presence of a symptomatic PDA is common in preterm infants. Indomethacin, a prostaglandin synthesis inhibitor, is often used to close the PDA in premature infants.

Indomethacin does not close the PDA of full-term infants or children. The success of indomethacin therapy is as high as 80%–90% in premature infants with a birth weight greater than 1200 g, but it is less successful in smaller infants. Indomethacin (0.1–0.3 mg/kg orally every 8–24 hours or 0.1–0.3 mg/kg parenterally every 12 hours) can be used if there is adequate renal, hematologic, and hepatic function. Because indomethacin may impair renal function, urine output, BUN, and creatinine should be monitored during therapy. If indomethacin is not effective and the ductus remains hemodynamically significant, surgical ligation should be performed. If the ductus partially closes so that the shunt is no longer hemodynamically significant, a second course of indomethacin may be tried.

Course & Prognosis

Patients with an isolated PDA and small-to-moderate shunts usually do well without surgery. However, in the third or fourth decade of life, symptoms of easy fatigability, dyspnea on exertion, and exercise intolerance appear in those patients who develop pulmonary hypertension and/or HF. Percutaneous closure can be done later in life if there has not been development of severe pulmonary vascular disease. For those with severe and irreversible pulmonary hypertension prognosis is not good and heart-lung transplant may be needed.

Spontaneous closure of a PDA may occur up to age 1 year, especially in preterm infants. After age 1 year, spontaneous closure is rare. Because endocarditis is a potential complication, some cardiologists recommend closure if the defect persists beyond age 1 year, even if it is small. Most of these patients undergo percutaneous occlusion as opposed to surgical ligation.

RIGHT-SIDED OBSTRUCTIVE LESIONS

1. Pulmonary Valve Stenosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ No symptoms in mild or moderate stenosis.

▶ Cyanosis and a high incidence of right-sided HF in ductal-dependent lesions.

▶ RV lift with systolic ejection click heard at the third left intercostal space.

▶ S_2 widely split with soft to inaudible P_2; grade I–VI/VI systolic ejection murmur, maximal at the pulmonary area.

▶ Dilated pulmonary artery on chest radiograph.

General Considerations

Pulmonic valve stenosis accounts for 10% of all congenital heart disease. The pulmonary valve annulus is usually small with moderate to marked poststenotic dilation of the main pulmonary artery. Obstruction to blood flow across the pulmonary valve causes an increase in RV pressure. Pressures greater than systemic are potentially life-threatening and are associated with critical obstruction. Because of the increased RV strain, severe right ventricular hypertrophy (RVH) and eventual RV failure can occur.

When obstruction is severe and the ventricular septum is intact, a right-to-left shunt will often occur at the atrial level through a patent foramen ovale (PFO). In neonates with severe obstruction and minimal antegrade pulmonary blood flow (critical PS), left-to-right flow through the ductus is essential, making prostaglandin a necessary intervention at the time of birth. These infants are cyanotic at presentation.

Clinical Findings

A. Symptoms and Signs

Patients with mild or even moderate valvular pulmonary stenosis are acyanotic and asymptomatic. Patients with severe valvular obstruction may develop cyanosis early. Patients with mild to moderate obstruction are usually well developed and well nourished. They are not prone to pulmonary infections. The pulses are normal. The precordium may be prominent, often with palpable RV heave. A systolic thrill is often present in the pulmonary area. In patients with mild to moderate stenosis, a prominent ejection click of pulmonary origin is heard at the third left intercostal space. The click varies with respiration, being more prominent during expiration than inspiration. In severe stenosis, the click tends to merge with S_1. S_2 varies with the degree of stenosis. In mild pulmonic stenosis, S_2 is normal. In moderate pulmonic stenosis, S_2 is more widely split and the pulmonary component is softer. In severe pulmonary stenosis, S_2 is single because the pulmonary component cannot be heard. A rough systolic ejection murmur is best heard at the second left interspace. It radiates well to the back. With severe pulmonary valve obstruction, the murmur is usually short. No diastolic murmurs are audible.

B. Imaging

The heart size is normal. Poststenotic dilation of the main pulmonary artery and the left pulmonary artery often occurs.

C. Electrocardiography

The ECG is usually normal with mild obstruction. In severe obstruction, RV hypertrophy with an RV strain pattern (deep inversion of the T wave) occurs in the right precordial leads (V_{3R}, V_1, V_2). Right atrial enlargement may be present. Right axis deviation occurs in moderate to severe stenosis.

D. Echocardiography

The diagnosis often is made by physical examination, but the echocardiogram confirms the diagnosis, defines the anatomy, and can identify any associated lesions. The pulmonary valve has thickened leaflets with reduced valve leaflet excursion. The transvalvular pressure gradient can be estimated accurately by Doppler, which provides an estimate of RV pressure and can assist in determining the appropriate time to intervene.

E. Cardiac Catheterization and Angiocardiography

Catheterization is reserved for therapeutic balloon valvuloplasty. In severe cases with associated RV dysfunction, a right-to-left shunt at the atrial level is indicated by a lower left atrial saturation than pulmonary vein saturation. Pulmonary artery pressure is normal. The gradient across the pulmonary valve varies from 10 to 200 mm Hg. In severe cases, the right atrial pressure is elevated, with a predominant "a" wave. Angiocardiography in the RV shows a thick pulmonary valve with a narrow opening producing a jet of contrast into the pulmonary artery. Infundibular (RV outflow tract) hypertrophy may be present and may contribute to obstruction to pulmonary blood flow.

▶ Treatment

Treatment of pulmonic stenosis is recommended for children with RV systolic pressure greater than two-thirds of systemic pressure. Immediate correction is indicated for patients with systemic or suprasystemic RV pressure. Percutaneous balloon valvuloplasty is the procedure of choice. It is as effective as surgery in relieving obstruction and causes less valve insufficiency. Surgery is needed to treat pulmonic valve stenosis when balloon pulmonic valvuloplasty is unsuccessful.

▶ Course & Prognosis

Patients with mild pulmonary stenosis live normal lives. Even those with moderate stenosis are rarely symptomatic. Those with severe valvular obstruction may develop cyanosis in infancy as described above.

After balloon pulmonary valvuloplasty or surgery, most patients have good maximum exercise capacity unless they have significant pulmonary insufficiency (PI). Limitation of physical activity is unwarranted. The quality of life of adults with successfully treated pulmonary stenosis and minimal PI is normal. Patients with PI, a frequent side effect of intervention, may be significantly limited in exercise performance. Severe PI leads to progressive RV dilation and dysfunction, which may precipitate ventricular arrhythmias or right heart failure in adulthood. Patients with severe PI may benefit from replacement of the pulmonic valve.

Drossner DM, Mahle WT: A management strategy for mild valvar pulmonary stenosis. Pediatr Cardiol 2008;29:649–652 [PMID: 18193316].

Harrild DM, Powell AJ, Tran TX et al: Long-term pulmonary regurgitation following balloon valvuloplasty for pulmonary stenosis risk factors and relationship to exercise capacity and ventricular volume and function. J Am Coll Cardiol 2010 Mar 9;55(10):1041–1047 [PMID: 20202522].

2. Subvalvular Pulmonary Stenosis

Isolated infundibular (subvalvular) pulmonary stenosis is rare. More commonly it is found in combination with other lesions, such as in tetralogy of Fallot. Infundibular hypertrophy that is associated with a small perimembranous VSD may lead to a "double-chambered RV" characterized by obstruction between the inflow and outflow portion of the RV. One should suspect such an abnormality if there is a prominent precordial thrill, no audible pulmonary ejection click, and a murmur maximal in the third and fourth intercostal spaces rather than in the second intercostal space. The clinical picture is otherwise identical to that of pulmonic valve stenosis. Intervention, if indicated, is always surgical because this condition does not improve with balloon catheter dilation.

3. Supravalvular Pulmonary Stenosis

Supravalvular pulmonary stenosis is a relatively rare condition defined by narrowing of the main pulmonary artery. The clinical picture may be identical to valvular pulmonary stenosis, although the murmur is maximal in the first intercostal space at the left sternal border and in the suprasternal notch. No ejection click is audible, as the valve itself is not involved. The murmur radiates toward the neck and over the lung fields. Children with William syndrome can have supravalvular and peripheral pulmonary stenosis as well as supravalvular aortic stenosis.

4. Peripheral (Branch) Pulmonary Artery Stenosis

In peripheral pulmonary stenosis, there are multiple narrowings of the branches of the pulmonary arteries, sometimes extending into the vessels in the periphery of the lungs. Systolic murmurs may be heard over both lung fields,

anteriorly and posteriorly, radiating to the axilla. Mild, nonpathologic pulmonary branch stenosis produces a murmur in infancy that resolves by 6 months of age. William syndrome, Alagille syndrome, and congenital rubella are commonly associated with severe forms of peripheral pulmonary artery stenosis. Surgery is often unsuccessful, as areas of stenoses near and beyond the hilum of the lungs are not accessible to the surgeons. Transcatheter balloon angioplasty and even stent placement are used to treat this condition, with moderate success. In some instances, the stenoses improve spontaneously with age.

5. Ebstein Malformation of the Tricuspid Valve

In Ebstein malformation of the tricuspid valve, the septal leaflet of the tricuspid valve is displaced toward the apex of the heart and is attached to the endocardium of the RV rather than at the tricuspid annulus. As a result, a large portion of the RV functions physiologically as part of the right atrium. This "atrialized" portion of the RV is thin-walled and does not contribute to RV output. The portion of the ventricle below the displaced tricuspid valve is diminished in volume and represents the functioning RV.

▶ Clinical Findings

A. Symptoms and Signs

The clinical picture of Ebstein malformation varies with the degree of displacement of the tricuspid valve. In the most extreme form, the septal leaflet is markedly displaced into the RV outflow tract, causing obstruction of antegrade flow into the pulmonary artery and there is very little functioning RV as the majority of the ventricle is "atrialized." The degree of tricuspid insufficiency may be so severe that forward (antegrade) flow out the RV outflow tract is further diminished leading to a right-to-left atrial level shunt and cyanosis. At the opposite extreme when antegrade pulmonary blood flow is adequate, symptoms may not develop until adulthood when tachyarrhythmias associated with right atrial dilation or reentrant electrical pathways occur. These older patients typically have less displacement of the septal leaflet of the tricuspid valve and therefore more functional RV tissue.

B. Imaging

The chest radiograph shows cardiomegaly with prominence of the right heart border. The extent of cardiomegaly depends on the degree of tricuspid valve insufficiency and the presence and size of the atrial level shunt. Massive cardiomegaly with a "wall-to-wall heart" (the heart shadow extends across the entire chest cavity from right-to-left) occurs with severe tricuspid valve displacement and/or a restrictive atrial level defect.

C. Electrocardiography

ECG may be normal but usually shows right atrial enlargement and right bundle-branch block (RBBB). There is an association between Ebstein anomaly and Wolff-Parkinson-White (WPW) syndrome, in which case a delta wave is present (short PR with a slurred upstroke of the QRS).

D. Echocardiography

Echocardiography is necessary to confirm the diagnosis and may aid in predicting outcome. Degree of tricuspid valve displacement, size of the right atrium, and presence of associated atrial level shunt all affect outcome.

▶ Course & Prognosis

In cyanotic neonates, PGE_2 is used to maintain pulmonary blood flow via the ductus arteriosus until pulmonary vascular resistance decreases, facilitating antegrade pulmonary artery flow. If the neonate remains significantly cyanotic, surgical intervention is required.

The type of surgical repair varies and depends on the severity of the disease. For example, in order to decrease the amount of tricuspid regurgitation surgery may involve atrial plication and tricuspid valve repair. The success of the procedure is highly variable. Late arrhythmias are common due to the preexisting atrial dilation. If a significant Ebstein malformation is not treated, atrial tachyarrhythmias frequently begin during adolescence and the enlarged atrialized RV could impede LV function. Postoperative exercise tolerance improves but remains lower than age-related norms.

6. Other Rare Right-Sided Malformations

A. Absence of a Pulmonary Artery

Absence of a pulmonary artery (left or right) may be an isolated malformation or may occur in association with other congenital heart lesions. It occurs occasionally in patients with tetralogy of Fallot.

B. Absence of the Pulmonary Valve

Absence of the pulmonary valve is rare and usually associated with a VSD. In about 50% of cases, infundibular pulmonary stenosis is also present (ToF with absent pulmonary valve).

Alsoufi B et al: Surgical outcomes in the treatment of patients with tetralogy of Fallot and absent pulmonary valve. Eur J Cardiothorac Surg 2007;31:354–359; discussion 359 [PMID: 17215132].

Knott-Craig CJ et al: Repair of neonates and young infants with Ebstein's anomaly and related disorders. Ann Thorac Surg 2007;84:587–592; discussion 592–593 [PMID: 17643640].

LEFT-SIDED LESIONS

1. Coarctation of the Aorta

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Absent or diminished femoral pulses.
> ▶ Upper to lower extremity systolic blood pressure gradient of > 20 mm Hg.
> ▶ Blowing systolic murmur in the back or left axilla.

▶ General Considerations

Coarctation of the aorta is a narrowing in the aortic arch that usually occurs in the proximal descending aorta near the takeoff of the left subclavian artery near the ductus arteriosus. The abdominal aorta is rarely involved. Coarctation accounts for about 6% of all congenital heart disease. Three times as many males as females are affected. Many affected females have Turner syndrome (45, XO). The incidence of associated bicuspid aortic valve with coarctation is 80%–85%.

▶ Clinical Findings

A. Symptoms and Signs

The cardinal physical finding is decreased or absent femoral pulses. Infants with severe coarctation have equal upper and lower extremity pulses from birth until the ductus arteriosus closes (ductal patency ensures flow to the descending aorta distal to the level of obstruction). Approximately 40% of children with coarctation will present as young infants. Coarctation alone, or in combination with VSD, ASD, or other congenital cardiac anomalies, is the leading cause of HF in the first month of life.

Coarctation presents insidiously in the 60% of children with no symptoms in infancy. Coarctation is usually diagnosed by a pulse and blood pressure (> 15 mm Hg) discrepancy between the arms and legs on physical examination. The pulses in the legs are diminished or absent. The left subclavian artery is occasionally involved in the coarctation, in which case the left brachial pulse is also weak. The pathognomonic murmur of coarctation is heard in the left axilla and the left back. The murmur is usually systolic but may spill into diastole, as forward flow continues across the narrow coarctation site throughout the cardiac cycle. A systolic ejection murmur is often heard at the aortic area and the lower left sternal border along with an apical ejection click if there is an associated bicuspid aortic valve.

B. Imaging

In the older child, radiographs may show a normal-sized heart, or more often some degree of LV enlargement. The aorta proximal to the coarctation is prominent. The aortic outline may indent at the level of the coarctation. The poststenotic segment is often dilated. This combination of abnormalities results in the "figure 3" sign on chest radiograph. Notching of the ribs caused by marked enlargement of the intercostal collaterals can be seen. In patients with severe coarctation and associated HF, marked cardiac enlargement and pulmonary venous congestion occur.

C. Electrocardiography

ECGs in older children may be normal or may show LVH. ECG usually shows RVH in infants with severe coarctation because the RV serves as the systemic ventricle during fetal life.

D. Echocardiography

Two-dimensional echocardiography and color-flow Doppler are used to visualize the coarctation directly, and continuous-wave Doppler estimates the degree of obstruction. Diastolic runoff flow is detected by continuous-wave Doppler if the obstruction is significant. In neonates with a PDA, a coarctation cannot be ruled out, as stenosis of the arch may evolve as the PDA closes. Identification of lesions such as a bicuspid aortic valve or mitral abnormalities may suggest the presence of a coarctation. In the face of poor LV systolic function, the gradient across the coarctation will be low, as the failing LV is unable to generate very much pressure proximal to the narrowing.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization and angiocardiography are rarely performed for diagnosis in infants or children with coarctation, but are used if transcatheter intervention is planned.

▶ Treatment

Infants with coarctation of the aorta and HF may present in extremis secondary to LV dysfunction and low cardiac output. Resuscitative measures include PGE_2 infusion (0.05–0.1 mcg/kg/min) to reopen the ductus arteriosus. End-organ damage distal to the coarctation is not uncommon, and inotropic support is frequently needed. Once stabilized, the infant should undergo corrective repair. In patients with poor LV function, balloon angioplasty of the coarctation is sometimes performed as a palliative measure. Recent data suggest that balloon angioplasty of the aorta can be the definitive procedure in many patients with good LV function. Surgery also has a high success rate.

The main complication of both surgery and balloon angioplasty is recurrent coarctation. Fortunately, this complication is treatable in the catheterization laboratory. In older patients, particularly those of adult size, transcatheter stent placement is effective for recurrent coarctation.

▶ Course & Prognosis

Children who survive the neonatal period without developing HF do well through childhood and adolescence. Fatal complications (eg, hypertensive encephalopathy or intracranial bleeding) are uncommon in childhood. Infective endarteritis is rare before adolescence, but can occur in both repaired and unrepaired coarctation. Children with coarctation corrected after age 5 years are at increased risk for systemic hypertension and myocardial dysfunction even with successful surgery. Exercise testing is mandatory for these children prior to their participation in athletic activities.

Rodes-Cabau J et al: Comparison of surgical and transcatheter treatment for native coarctation of the aorta in patients > or = 1 year old. The Quebec Native Coarctation of the Aorta study. Am Heart J 2007;154:186–192 [PMID: 17584575].

2. Aortic Stenosis

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ► Harsh systolic ejection murmur at the upper right sternal border with radiation to the neck.
> ► Thrill in the carotid arteries.
> ► Systolic click at the apex.
> ► Dilation of the ascending aorta on chest radiograph.

▶ General Considerations

Aortic stenosis is defined as obstruction to outflow from the LV at or near the aortic valve producing a systolic pressure gradient of more than 10 mm Hg between the LV and the aorta. Aortic stenosis accounts for approximately 7% of congenital heart disease. There are three anatomic types of congenital aortic stenosis.

A. Valvular Aortic Stenosis (75%)

In critical aortic stenosis presenting in infancy, the aortic valve is usually a unicuspid diaphragm-like structure without well-defined commissures. A bicuspid aortic valve or a trileaflet valve with partially fused leaflets is another anatomic possibility that can be associated with aortic stenosis. Aortic stenosis is more common in males than in females.

B. Subvalvular Aortic Stenosis (23%)

In this type, a membranous or fibrous ring occurs just below the aortic valve that causes obstruction to LV outflow. The aortic valve itself and the anterior leaflet of the mitral valve are often malformed.

C. Supravalvular Aortic Stenosis (2%)

In this type, constriction of the ascending aorta occurs just above the coronary arteries. The condition is often familial, and two different genetic patterns are found, one with abnormal facies and mental retardation (William syndrome) and one with normal facies and no developmental delay.

▶ Clinical Findings

A. Symptoms and Signs

Although isolated valvular aortic stenosis seldom causes symptoms in infancy, severe HF occasionally occurs when critical obstruction is present at birth. Response to medical therapy is poor; therefore, an aggressive approach using interventional catheterization or surgery is required. The physical findings vary depending on the anatomic type of lesion:

1. Valvular aortic stenosis—If the stenosis is severe with a gradient greater than 80 mm Hg, pulses are diminished with a slow upstroke; otherwise, pulses are usually normal. Cardiac examination reveals an LV thrust at the apex. A systolic thrill at the right base, the suprasternal notch, and over both carotid arteries may accompany moderate disease.

A prominent aortic ejection click is best heard at the apex. The click corresponds to the opening of the aortic valve. It is separated from S_1 by a short but appreciable interval. It does not vary with respiration. S_2 at the pulmonary area is normal. A loud, rough, medium- to high-pitched ejection-type systolic murmur is evident. It is loudest at the first and second intercostal spaces, radiating well into the suprasternal notch and along the carotids. The grade of the murmur correlates well with the severity of the stenosis.

2. Discrete membranous subvalvular aortic stenosis—The findings are the same as those of valvular aortic stenosis except for the absence of a click. The murmur and thrill are usually somewhat more intense at the left sternal border in the third and fourth intercostal spaces. In the setting of aortic insufficiency, a diastolic murmur is commonly heard.

3. Supravalvular aortic stenosis—The thrill and murmur are best heard in the suprasternal notch and along the

carotids but are well transmitted over the aortic area and near the mid left sternal border. There may be a difference in pulses and blood pressure between the right and left arms if the narrowing is just distal to the takeoff of the innominate artery, with more prominent pulse and pressure in the right arm (the Coanda effect).

Of those not presenting in infancy, most patients with aortic stenosis have no cardiovascular symptoms. Except in the most severe cases, patients do well until the third to fifth decades of life. Some patients have mild exercise intolerance and fatigability. In a small percentage of patients, significant symptoms (eg, chest pain with exercise, dizziness, and syncope) manifest in the first decade. Sudden death is uncommon but may occur in all forms of aortic stenosis with the greatest risk in patients with subvalvular obstruction.

B. Imaging

In most cases the heart is not enlarged. The LV, however, may be slightly prominent. In valvular aortic stenosis, dilation of the ascending aorta is frequently seen.

C. Electrocardiography

Patients with mild aortic stenosis have normal ECGs. Some patients with severe obstruction have LVH and LV strain but even in severe cases, 25% of ECGs are normal. Progressive LVH on serial ECGs indicates a significant obstruction. LV strain is one indication for surgery.

D. Echocardiography

This is a reliable noninvasive technique for the evaluation of all forms of aortic stenosis. Doppler accurately estimates the transvalvular gradient, and the level of obstruction can be confirmed by both two-dimensional echocardiographic images and by the level of flow disturbance revealed by color Doppler.

E. Cardiac Catheterization and Angiocardiography

Left heart catheterization demonstrates the pressure differential between the LV and the aorta and the anatomic level at which the gradient exists. Catheterization is reserved for patients whose resting gradient has reached 60–80 mm Hg and in whom intervention is planned. For those with valvular aortic stenosis, balloon valvuloplasty is usually the first option. In subvalvular or supravalvular aortic stenosis, interventional catheterization is not effective and surgery is required.

▶ Treatment

Percutaneous balloon valvuloplasty is now standard initial treatment for patients with valvular aortic stenosis. Surgery should be considered in symptomatic patients with a high resting gradient (60–80 mm Hg) despite balloon angioplasty,

or coexisting aortic insufficiency. In many cases, the gradient cannot be significantly diminished by valvuloplasty without producing aortic insufficiency. Patients who develop significant aortic insufficiency require surgical intervention to repair or replace the valve. The Ross procedure is an alternative to mechanical valve placement in infants and children. In this procedure, the patient's own pulmonic valve is moved to the aortic position, and an RV-to-pulmonary artery conduit is used to replace the pulmonic valve. Discrete subvalvular aortic stenosis is usually surgically repaired at a lesser gradient because continued trauma to the aortic valve by the subvalvular jet may damage the valve and produce aortic insufficiency. Unfortunately, simple resection is followed by recurrence in more than 25% of patients with subvalvular aortic stenosis. Supravalvar aortic stenosis may also require surgical repair and is commonly associated with William syndrome.

▶ Course & Prognosis

All forms of LV outflow tract obstruction tend to be progressive. Pediatric patients with LV outflow tract obstruction—with the exception of those with critical aortic stenosis of infancy—are usually asymptomatic. Symptoms accompanying severe unoperated obstruction (angina, syncope, or HF) are rare but imply serious disease. Children whose obstruction is mild to moderate have normal oxygen consumption and maximum voluntary working capacity. Children in this category with normal resting and exercising (stress) ECGs may safely participate in vigorous physical activity, including nonisometric competitive sports. Children with severe aortic stenosis are predisposed to ventricular dysrhythmias and should refrain from vigorous activity and avoid all isometric exercise.

3. Mitral Valve Prolapse

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Midsystolic click.

▶ Late systolic "whooping" or "honking" murmur.

▶ Typical symptoms include chest pain, palpitations, and dizziness.

▶ Often overdiagnosed on routine cardiac ultrasound.

General Considerations

In this condition as the mitral valve closes during systole, it moves posteriorly or superiorly (prolapses) into the left atrium. Mitral valve prolapse (MVP) occurs in about 2% of thin female adolescents, a minority of whom have concomitant mitral insufficiency. Although MVP is usually an isolated lesion, it can occur in association with connective tissue disorders such as Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes.

Clinical Findings

A. Symptoms and Signs

Most patients with MVP are asymptomatic. Chest pain, palpitations, and dizziness may be reported, but it is unclear whether these symptoms are more common in affected patients than in the normal population. Chest pain on exertion is rare and should be assessed with cardiopulmonary stress testing. Significant dysrhythmias have been reported, including increased ventricular ectopy and nonsustained ventricular tachycardia. If significant mitral regurgitation is present, atrial arrhythmias may also occur. Standard auscultation technique must be modified to diagnose MVP. A midsystolic click (with or without a systolic murmur) is elicited best in the standing position and is the hallmark of this entity. Conversely, maneuvers that increase LV volume, such as squatting or handgrip exercise, will cause delay or obliteration of the click-murmur complex. The systolic click usually is heard at the apex but may be audible at the left sternal border. A late, short systolic murmur after the click implies mitral insufficiency and is much less common than isolated prolapse. The murmur is not holosystolic, in contrast to rheumatic mitral insufficiency.

B. Imaging

Most chest radiographs are normal and are not usually indicated in this condition. In the rare case of significant mitral valve insufficiency, the left atrium may be enlarged.

C. Electrocardiography

The ECG is usually normal. Diffuse flattening or inversion of T waves may occur in the precordial leads. U waves are sometimes prominent.

D. Echocardiography

Significant posterior systolic movement of the mitral valve leaflets to the atrial side of the mitral annulus is diagnostic. Echocardiography assesses the degree of myxomatous change of the mitral valve and the degree of mitral insufficiency.

E. Other Testing

Invasive procedures are rarely indicated. Holter monitoring or event recorders may be useful in establishing the presence of ventricular dysrhythmias in patients with palpitations.

Treatment & Prognosis

Propranolol may be effective in treatment of coexisting arrhythmias. Prophylaxis for infectious endocarditis is no longer indicated, based on 2007 AHA guidelines. The natural course of this condition is not well defined. Twenty years of observation indicate that isolated MVP in childhood is usually a benign entity. Surgery for mitral insufficiency is rarely needed.

Mechleb BK et al: Mitral valve prolapse: relationship of echocardiography characteristics to natural history. Echocardiography 2006;23:434–437 [PMID: 16686634].

4. Other Congenital Left Heart Valvular Lesions

A. Congenital Mitral Stenosis

Congenital mitral stenosis is a rare disorder in which the valve leaflets are thickened and/or fused, producing a diaphragm- or funnel-like structure with a central opening. In many cases, the subvalve apparatus (papillary muscles and chordae) is also abnormal. When mitral stenosis occurs with other left-sided obstructive lesions, such as subaortic stenosis and coarctation of the aorta, the complex is called Shone syndrome. Most patients develop symptoms early in life with tachypnea, dyspnea, and failure to thrive. Physical examination reveals an accentuated S_1 and a loud pulmonary closure sound. No opening snap is heard. In most cases, a presystolic crescendo murmur is heard at the apex. Occasionally, only a mid-diastolic murmur can be heard. ECG shows right axis deviation, biatrial enlargement, and RVH. Chest radiograph reveals left atrial enlargement and frequent pulmonary venous congestion. Echocardiography shows abnormal mitral valve structures with reduced leaflet excursion and left atrial enlargement. Cardiac catheterization reveals an elevated pulmonary capillary wedge pressure and pulmonary hypertension, owing to the elevated left atrial pressure.

Mitral valve repair or mitral valve replacement with a prosthetic mitral valve may be performed, even in young infants, but it is a technically difficult procedure. Mitral valve repair is the preferred surgical option, as valve replacement can have a poor outcome in infants.

B. Cor Triatriatum

Cor triatriatum is a rare abnormality in which the pulmonary veins join in a confluence that is not completely incorporated into the left atrium. The pulmonary vein confluence communicates with the left atrium through an opening of variable size, and may be obstructed. Patients may present in a similar way as those with mitral stenosis. Clinical findings depend on the degree of obstruction of pulmonary venous flow into the left atrium. If the communication between the confluence and the left atrium is small and restrictive to flow, symptoms develop early in life. Echocardiography reveals a linear density in the left atrium with a pressure gradient present between the pulmonary venous chamber and the true left atrium. Cardiac catheterization may be needed if the diagnosis is in doubt. High pulmonary wedge pressure and low left atrial pressure (with the catheter passed through the foramen ovale into the true left atrium) support the diagnosis. Angiocardiography identifies the pulmonary vein confluence and the anatomic left atria. Surgical repair is always required in the presence of an obstructive membrane, and long-term results are good. Coexisting mitral valve abnormalities may be noted, including a supravalvular mitral ring or a dysplastic mitral valve.

C. Congenital Mitral Regurgitation

Congenital mitral regurgitation is a rare abnormality usually associated with other congenital heart lesions, such as congenitally corrected transposition of the great arteries (ccTGA), AV septal defect, and coronary artery anomalies (anomalous left coronary artery from the pulmonary artery). Isolated congenital mitral regurgitation is very rare. It is sometimes present in patients with connective tissue disorders (Marfan or Loeys-Dietz syndrome), usually related to a myxomatous prolapsing mitral valve.

D. Congenital Aortic Regurgitation

Congenital aortic regurgitation is rare. The most common associations are bicuspid aortic valve, with or without coarctation of the aorta; VSD with aortic cusp prolapse; and fenestration of the aortic valve cusp (one or more holes in the cusp).

Beierlein W et al: Long-term follow-up after mitral valve replacement in childhood: poor event-free survival in the young child. Eur J Cardiothorac Surg 2007;31:860–865 [PMID: 17383889].

DISEASES OF THE AORTA

Patients at risk for progressive aortic dilation and dissection include those with isolated bicuspid aortic valve, Marfan syndrome, Loeys-Dietz syndrome, Turner syndrome, and type IV Ehlers-Danlos syndrome.

1. Bicuspid Aortic Valve

Patients with bicuspid aortic valves have an increased incidence of aortic dilation and dissection, regardless of the presence of aortic stenosis. Histologic examination demonstrates cystic medial degeneration of the aortic wall, similar to that seen in patients with Marfan syndrome. Patients with an isolated bicuspid aortic valve require regular follow-up even in the absence of aortic insufficiency or aortic stenosis. Significant aortic root dilation requiring surgical intervention typically does not occur until adulthood.

2. Marfan and Loeys-Dietz Syndromes

Marfan syndrome is an autosomal dominant disorder of connective tissue caused by a mutation in the fibrillin-1 gene. Spontaneous mutations account for 25%–30% of cases, and thus family history is not always helpful. Patients are diagnosed by the Ghent criteria and must have at a minimum, major involvement of two body systems plus involvement of a third body system or a positive family history. Body systems involved include cardiovascular, ocular, musculoskeletal, pulmonary, and integumentary. Cardiac manifestations include aortic root dilation and MVP, which may be present at birth. Patients are at risk for aortic dilation and dissection and are restricted from competitive athletics, contact sports, and isometric activities. β-Blockers or ACE inhibitors are used to lower blood pressure and slow the rate of aortic dilation. More recently, studies are ongoing to evaluate the effectiveness of angiotensin receptor blockers (losartan). Elective surgical intervention is performed in patients of adult size when the aortic root dimension reaches 50 mm or if there is an increase of greater than 1 cm in root dimension in 1 year. The ratio of actual to expected aortic root dimension is used to determine the need for surgery in the young child. Surgical options include replacement of the dilated aortic root with a composite valve graft (Bentall technique) or a David procedure in which the patient's own aortic valve is spared and a Dacron tube graft is used to replace the dilated ascending aorta. Young age at diagnosis was previously thought to confer a poor prognosis; however, early diagnosis with close follow-up and early medical therapy has more recently been associated with more favorable outcome. Ventricular dysrhythmias may contribute to the mortality in Marfan syndrome.

Loeys-Dietz syndrome is a connective tissue disorder first described in 2005. Many patients with Loeys-Dietz were thought to have Marfan syndrome in the past. Loeys-Dietz is a result of a mutation in the transforming growth factor β (TGFβ) receptor and is associated with musculoskeletal, skin, and cardiovascular abnormalities. Cardiovascular involvement includes mitral and tricuspid valve prolapse, aneurysms of the PDA, and aortic and pulmonary artery dilation. Dissection and aneurysm formation of arteries

throughout the body can occur including in the head and neck vessels.

3. Turner Syndrome

Cardiovascular abnormalities are common in Turner syndrome. Patients are at risk for aortic dissection, typically during adulthood. Risk factors include hypertension regardless of cause, aortic dilation, bicuspid aortic valve, and coarctation of the aorta. There are rare reports of aortic dissection in adult Turner syndrome patients in the absence of any risk factors suggesting that there is a vasculopathic component to this syndrome. Patients with Turner syndrome require routine follow-up from adolescence onward to monitor for this potentially lethal complication.

CORONARY ARTERY ABNORMALITIES

Several anomalies involve the origin, course, and distribution of the coronary arteries. Abnormal origin or course of the coronary arteries are often asymptomatic and can go undetected. However, in some instances these children are at risk for sudden death. The most common congenital coronary artery abnormality in infants is anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) and is discussed in more detail here.

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery

In this condition, the left coronary artery arises from the pulmonary artery rather than the aorta. In neonates, whose pulmonary artery pressure is high, perfusion of the left coronary artery may be adequate and the infant may be asymptomatic. By age 2 months the pulmonary arterial pressure falls, causing a progressive decrease in myocardial perfusion provided by the anomalous left coronary artery. Ischemia and infarction of the LV is the result. Immediate surgery is indicated to reimplant the left coronary artery and restore myocardial perfusion.

▶ Clinical Findings

A. Symptoms and Signs

Neonates appear healthy and growth and development are relatively normal until pulmonary artery pressure decreases. Detailed questioning may disclose a history of intermittent abdominal pain (fussiness or irritability), pallor, wheezing, and sweating, especially during or after feeding. Presentation may be subtle, with nonspecific complaints of "fussiness" or intermittent "colic." The colic and fussiness are probably attacks of true angina. Presentation may be fulminant at age 2–4 months with sudden, severe HF due to LV dysfunction and mitral insufficiency. On physical examination, the infants are usually well developed and well nourished. The pulses are typically weak but equal. A prominent left precordial bulge is present. A gallop and/or holosystolic murmur of mitral regurgitation is sometimes present, though frequently auscultation alone reveals no obvious abnormalities.

B. Imaging

Chest radiographs show cardiac enlargement, left atrial enlargement, and may show pulmonary venous congestion if left ventricular function has been compromised.

C. Electrocardiography

On the ECG, there is T-wave inversion in leads I and aVL. The precordial leads also show T-wave inversion from V_4–V_7. Deep and wide Q waves are present in leads I, aVL, and sometimes in V_4–V_6. These findings of myocardial infarction are similar to those in adults.

D. Echocardiography

The diagnosis can be made with two-dimensional echo techniques by visualizing a single large right coronary artery arising from the aorta and visualization of the anomalous left coronary artery arising from the main pulmonary artery. Flow reversal in the left coronary (heading *toward* the pulmonary artery, rather than away from the aorta) confirms the diagnosis. LV dysfunction, echo-bright (ischemic) papillary muscles, and mitral regurgitation are commonly seen.

E. Cardiac Catheterization and Angiocardiography

Angiogram of the aorta fails to show the origin of the left coronary artery. A large right coronary artery fills directly from the aorta, and contrast flows from the right coronary system via collaterals into the left coronary artery and finally into the pulmonary artery. Angiogram of the RV or main pulmonary artery may show the origin of the anomalous vessel. Rarely, a left-to-right shunt may be detected as oxygenated blood passes through the collateral system without

delivering oxygen to the myocardium, and passes into the pulmonary artery.

▶ Treatment & Prognosis

The prognosis of ALCAPA depends in part on the clinical appearance of the patient at presentation. Medical management with diuretics and afterload reduction can help stabilize a critically ill patient, but surgical intervention should not be delayed. Surgery involves reimplantation of the anomalous coronary button onto the aorta. The mitral valve may have to be replaced, depending on the degree of injury to the papillary muscles and associated mitral insufficiency. Although a life-threatening problem, cardiac function nearly always recovers if the infant survives the surgery and post-operative period.

▼ CYANOTIC CONGENITAL HEART DISEASE

TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Hypoxemic spells during infancy.

▶ Right-sided aortic arch in 25% of patients.

▶ Systolic ejection murmur at the upper left sternal border.

▶ General Considerations

In tetralogy of Fallot (ToF), anterior deviation of the infundibular (pulmonary outflow) septum causes narrowing of the right ventricular outflow tract. This deviation also results in a VSD and the aorta then overrides the crest of the ventricular septum. The RV hypertrophies, not because of pulmonary stenosis, but because it is pumping against systemic resistance across a (usually) large VSD. ToF is the most common cyanotic cardiac lesion and accounts for 10% of all congenital heart disease. A right-sided aortic arch is present in 25% of cases, and ASD occurs in 15%.

Obstruction to RV outflow with a large VSD causes a right-to-left shunt at the ventricular level with arterial desaturation. The greater the obstruction and the lower the systemic vascular resistance, the greater is the right-to-left shunt. ToF is associated with deletions in the long arm of chromosome 22 (22q11, DiGeorge syndrome) in as many as 15% of affected children. This is especially common in those with an associated right aortic arch.

▶ Clinical Findings

A. Symptoms and Signs

Clinical findings vary with the degree of RV outflow obstruction. Patients with mild obstruction are minimally cyanotic or acyanotic. Those with severe obstruction are deeply cyanotic from birth. Few children are asymptomatic. In those with significant RV outflow obstruction, many have cyanosis at birth, and nearly all have cyanosis by age 4 months. The cyanosis usually is progressive, as subvalvular obstruction increases. Growth and development are not typically delayed, but easy fatigability and dyspnea on exertion are common. The fingers and toes show variable clubbing depending on age and severity of cyanosis. Historically, older children with ToF would frequently squat to increase systemic vascular resistance. This decreased the amount of right-to-left shunt, forcing blood through the pulmonary circuit, and would help ward off cyanotic spells. Squatting is rarely seen as the diagnosis is now made in infancy.

Hypoxemic spells, also called cyanotic or "Tet spells," are one of the hallmarks of severe ToF. These spells can occur spontaneously and at any time, but in infants occur most commonly with crying or feeding, while in older children they can occur with exercise. They are characterized by (1) sudden onset of cyanosis or deepening of cyanosis; (2) dyspnea; (3) alterations in consciousness, from irritability to syncope; and (4) decrease or disappearance of the systolic murmur (as RV the outflow tract becomes completely obstructed). These episodes most commonly start at age 4–6 months. Cyanotic spells are treated acutely by administration of oxygen and placing the patient in the knee-chest position (to increase systemic vascular resistance). Intravenous morphine should be administered cautiously, but is helpful for its sedative effect. Propranolol produces β-blockade and may reduce the obstruction across the RV outflow tract through its negative inotropic action. Acidosis, if present, should be corrected with intravenous sodium bicarbonate. Chronic oral prophylaxis of cyanotic spells with propranolol may be useful to delay surgery, but the onset of Tet spells usually prompts surgical intervention. In fact, in the current era, elective surgical repair generally occurs around the age of 3 months so as to avoid the development of Tet spells.

On examination, an RV lift is palpable. S_2 is predominantly aortic and single. A grade II–IV/VI, rough, systolic

ejection murmur is present at the left sternal border in the third intercostal space and radiates well to the back.

B. Laboratory Findings

Hemoglobin, hematocrit, and red blood cell count are usually elevated in older infants or children secondary to chronic arterial desaturation.

C. Imaging

Chest radiographs show a normal-size heart. The RV is hypertrophied, often shown by an upturning of the apex (boot-shaped heart). The main pulmonary artery segment is usually concave and, if there is a right aortic arch, the aortic knob is to the right of the trachea. The pulmonary vascular markings are usually decreased.

D. Electrocardiography

The QRS axis is rightward, ranging from +90 to +180 degrees. The P waves are usually normal. RVH is always present, but RV strain patterns are rare.

E. Echocardiography

Two-dimensional imaging is diagnostic, revealing thickening of the RV wall, overriding of the aorta, and a large subaortic VSD. Obstruction at the level of the infundibulum and pulmonary valve can be identified, and the size of the proximal pulmonary arteries measured. The anatomy of the coronary arteries should be visualized, as abnormal branches crossing the RV outflow tract are at risk for transection during surgical enlargement of the area.

F. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is generally done mainly in those patients with hypoplastic pulmonary arteries. If a catheterization is done, it reveals a right-to-left shunt at the ventricular level in most cases. Arterial desaturation of varying degrees is present. The RV pressure is at systemic levels and the pressure tracing in the RV is identical to that in the LV if the VSD is large. The pulmonary artery pressure is invariably low. Pressure gradients may be noted at the pulmonary valvular level, the infundibular level, or both. RV angiography reveals RV outflow obstruction and a right-to-left shunt at the ventricular level. The major indications for cardiac catheterization are to establish coronary artery and distal pulmonary artery anatomy if not able to be clearly defined by echocardiography.

▶ Treatment

A. Palliative Treatment

Most centers currently advocate complete repair of ToF during the neonatal or infant period regardless of patient size.

However, some centers prefer palliative treatment for small neonates in whom complete correction is deemed risky. Surgical palliation consists of the insertion of a GoreTex shunt from the subclavian artery to the ipsilateral pulmonary artery [modified Blalock-Taussig (BT) shunt] to replace the ductus arteriosus (which is ligated and divided) or stenting of the ductus. This secures a source of pulmonary blood flow regardless of the level of infundibular or valvular obstruction, and some believe, allows for growth of the patient's pulmonary arteries (which are usually small) prior to complete surgical correction.

B. Total Correction

Open-heart surgery for repair of ToF is performed at ages ranging from birth to 2 years, depending on the patient's anatomy and the experience of the surgical center. The current surgical trend is toward earlier repair for symptomatic infants. The major limiting anatomic feature of total correction is the size of the pulmonary arteries. During surgery, the VSD is closed and the obstruction to RV outflow removed. Although a valve sparing procedure is preferred, in many cases a transannular patch is placed across the RV outflow tract as the pulmonary valve is contributing to the obstruction. When a transannular patch repair is done, the patient has pulmonary insufficiency that is usually well tolerated for years. However, pulmonary valve replacement is eventually necessary once symptoms (usually exercise intolerance) and right ventricular dilation occur. Surgical mortality is low.

▶ Course & Prognosis

Infants with severe ToF are usually deeply cyanotic at birth. These children require early surgery. Complete repair before age 2 years usually produces a good result, and patients are currently living well into adulthood. Depending on the extent of the repair required, patients frequently require additional surgery 10–15 years after their initial repair for replacement of the pulmonary valve. Transcatheter pulmonary valves are now performed in some adolescents and young adults with a history of ToF, avoiding the need for open heart surgery. Patients with ToF are at risk for sudden death due to ventricular dysrhythmias. A competent pulmonary valve without a dilated RV appears to diminish arrhythmias and enhance exercise performance.

Harrild DM et al: Pulmonary valve replacement in tetralogy of Fallot: impact on survival and ventricular tachycardia. Circulation 2009;119:445–451 [PMID: 19139389].

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Symptoms depend on degree of pulmonary blood flow.
- ▶ Pulmonary blood flow via PDA and/or aortopulmonary collaterals.

Complete atresia of the pulmonary valve in association with a VSD is essentially an extreme form of ToF. Because there is no antegrade flow from the RV to the pulmonary artery, pulmonary blood flow must be derived from a PDA or from multiple aortopulmonary collateral arteries (MAPCAs). Symptoms depend on the amount of pulmonary blood flow. If flow is adequate, patients may be stable. If pulmonary flow is inadequate, severe hypoxemia occurs and immediate palliation is required. Newborns are stabilized with intravenous prostaglandin E_1 (PGE_1) to maintain the PDA while being prepared for surgery. Rarely, if the ductus does not contribute significantly to pulmonary blood flow (eg, the MAPCAs alone are sufficient), PGE_1 may be discontinued. Once stabilized, a BT shunt, stenting of the ductus or complete repair is undertaken. The decision to perform palliation or complete repair in a newborn is dependent on surgical expertise and preference in combination with pulmonary artery anatomy. In many centers, a palliative shunt is performed in newborns with severely hypoplastic pulmonary arteries or in those with only MAPCAs as a source of pulmonary blood flow. The goal of the shunt is to augment pulmonary blood flow and encourage vascular growth, and open-heart surgical correction is planned several months later. In children with MAPCAs, relocation of the MAPCAs is performed so that they are connected to the pulmonary artery (unifocalization) to complete the repair.

Echocardiography is usually diagnostic. Cardiac catheterization and angiocardiography or cardiac MRI can confirm the source(s) of pulmonary blood flow and document size of the distal pulmonary arteries.

Pulmonary vascular disease is common in pulmonary atresia with VSD, due both to intrinsic abnormalities of the pulmonary vasculature and to abnormal amounts of pulmonary blood flow. Even patients who have undergone surgical correction as infants are at risk. Pulmonary vascular disease is a common cause of death as early as the third decade of life.

Mainwaring RD: Hemodynamic assessment after complete repair of pulmonary atresia with major aortopulmonary collaterals. Ann Thorac Surg 2013 Apr;95(4):1397-1402 [PMID: 23453744].

Ten Cate FA: Stenting the arterial duct in neonates and infants with congenital heart disease and duct-dependent pulmonary blood flow: a multicenter experience of an evolving therapy over 18 years. Catheter Cardiovasc Interv 2013 Sep 1;82(3):E233-43 [PMID: 23420699].

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Completely different lesion from pulmonary atresia with VSD.
- ▶ Cyanosis at birth.
- ▶ Pulmonary blood flow is always ductal dependent with rare aortopulmonary collateral arteries being present.
- ▶ RV-dependent coronary arteries sometimes are present.

▶ General Considerations

Although pulmonary atresia with intact ventricular septum (PA/IVS) sounds as if it might be related to pulmonary atresia with VSD, it is a distinct cardiac condition. As the name suggests, the pulmonary valve is atretic. The pulmonic annulus usually has a small diaphragm consisting of the fused valve cusps. The ventricular septum is intact. The main pulmonary artery segment is usually present and closely approximated to the atretic valve, but is somewhat hypoplastic. Although the RV is always reduced in size, the degree of reduction is variable. The size of the RV is critical to the success of surgical repair. In some children with PA/IVS, the RV is adequate for an ultimate two-ventricular repair. A normal RV has three component parts (inlet, trabecular or body, and outlet). The absence of any one of the components makes adequate RV function unlikely and a single ventricle palliative approach is necessary. Even with all three components, some RVs are inadequate.

After birth, the pulmonary flow is provided by the ductus arteriosus. MAPCAs are usually *not* present in this disease, in contrast to pulmonary atresia with VSD. A continuous infusion of PGE_1 must be started as soon as possible after birth to maintain ductal patency.

▶ Clinical Findings

A. Symptoms and Signs

Neonates are usually cyanotic and become more so as the ductus arteriosus closes. A blowing systolic murmur resulting from the associated PDA may be heard at the pulmonary area. A holosystolic murmur is often heard at the lower left sternal

border, as many children develop tricuspid insufficiency if the RV is of good size and egress from that ventricle is only through the tricuspid valve. A PFO or ASD is essential for decompression of the right side of the heart.

B. Imaging

The heart size varies depending on the degree of tricuspid insufficiency. With severe tricuspid insufficiency, right atrial enlargement may be massive and the cardiac silhouette may fill the chest on radiograph. In patients with an associated hypoplastic tricuspid valve and or RV, most of the systemic venous return travels right-to-left across the ASD and so the heart size can be normal.

C. Electrocardiography

ECG reveals a left axis for age (45–90 degrees) in the frontal plane. Left ventricular forces dominate the ECG, and there is a paucity of RV forces, particularly with a hypoplastic RV. Findings of right atrial enlargement are usually striking.

D. Echocardiography

Echocardiography shows atresia of the pulmonary valve with varying degrees of RV cavity and tricuspid annulus hypoplasia. Patency of an intra-atrial communication and ductus are verified by echocardiography.

E. Cardiac Catheterization and Angiocardiography

RV pressure is often suprasystemic. Angiogram of the RV reveals no filling of the pulmonary artery. Unrestricted flow through the ASD is a necessity, since egress of blood from the right heart can only occur across the atrial defect and into the left atrium. A Rashkind balloon atrial septostomy may be required to open any inadequate existing communication across the atrial septum. Some children with pulmonary atresia and an intact ventricular septum have sinusoids between the RV and the coronary arteries. In some patients, the coronary circulation may depend on high right ventricular pressure. Any attempt to decompress the RV in patients with RV-dependent coronary circulation causes myocardial infarction and death because of the precipitous decrease in coronary perfusion, so precise coronary angiography is required to evaluate the anatomy. If the RV is tripartite, coronary circulation is not RV-dependent and an eventual two-chamber repair is planned. The pulmonary valve plate may be perforated and dilated during cardiac catheterization in the newborn to allow antegrade flow from the RV to the pulmonary artery and thus encourage RV cavity growth.

▶ Treatment & Prognosis

As in all ductal-dependent lesions, PGE_1 is used to stabilize the patient and maintain patency of the ductus until surgery can be performed. Surgery is usually undertaken in the first week of life. If the RV is hypoplastic, significant sinusoids are present, there is RV-dependent coronary circulation (lack of antegrade filling of the coronaries from the aorta), or the pulmonic valve cannot be opened successfully during cardiac catheterization, a BT shunt or ductal stenting is performed to establish pulmonary blood flow. Later in infancy, a communication between the RV and pulmonary artery can be created to stimulate RV cavity growth. If either RV dimension or function is inadequate for two-ventricular repair, an approach similar to that taken for a single ventricle pathway best serves these children (see section on Hypoplastic Left Heart Syndrome). Children with significant sinusoids or coronary artery abnormalities are considered for cardiac transplantation because they are at risk for coronary insufficiency and sudden death.

The prognosis in this condition is guarded.

TRICUSPID ATRESIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Marked cyanosis present from birth.

▶ ECG with left axis deviation, right atrial enlargement, and LVH.

▶ General Considerations

In tricuspid atresia, there is complete atresia of the tricuspid valve with no direct communication between the right atrium and the RV. There are two types of tricuspid atresia based on the relationship of the great arteries (normally related or transposed great arteries). The entire systemic venous return must flow through the atrial septum (either ASD or PFO) to reach the left atrium. The left atrium thus receives both the systemic venous return and the pulmonary venous return. Complete mixing occurs in the left atrium, resulting in variable degrees of arterial desaturation.

Because there is no flow to the RV, development of the RV depends on the presence of a ventricular left-to-right shunt. Severe hypoplasia of the RV occurs when there is no VSD or when the VSD is small.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms usually develop in early infancy with cyanosis present at birth in most infants. Growth and development are poor, and the infant usually exhibits exhaustion during feedings, tachypnea, and dyspnea. Patients with increased pulmonary blood flow may develop HF with less prominent cyanosis. The degree of pulmonary blood flow is most dependent on pulmonary vascular resistance. Those patients with low pulmonary vascular resistance will have increased pulmonary blood flow. A murmur from the VSD is usually present and heard best at the lower left sternal border. Digital clubbing is present in older children with long-standing cyanosis.

B. Imaging

The heart is slightly to markedly enlarged. The main pulmonary artery segment is usually small or absent. The size of the right atrium is moderately to massively enlarged, depending on the size of the communication at the atrial level. The pulmonary vascular markings are usually decreased. Pulmonary vascular markings may be increased if pulmonary blood flow is not restricted by the VSD or pulmonary stenosis.

C. Electrocardiography

The ECG shows marked left axis deviation. The P waves are tall and peaked, indicative of right atrial hypertrophy. LVH or LV dominance is found in almost all cases. RV forces on the ECG are usually low or absent.

D. Echocardiography

Two-dimensional methods are diagnostic and show absence of the tricuspid valve, the relationship between the great arteries, the anatomy of the VSD, presence of an ASD or PFO, and the size of the pulmonary arteries. Color-flow Doppler imaging can help identify atrial level shunting and levels of restriction of pulmonary blood flow, either at the VSD or in the RV outflow tract.

E. Cardiac Catheterization and Angiocardiography

Catheterization reveals a right-to-left shunt at the atrial level. Because of mixing in the left atrium, oxygen saturations in the LV, RV, pulmonary artery, and aorta are identical to those in the left atrium. Right atrial pressure is increased if the ASD is restrictive. LV and systemic pressures are normal. The catheter cannot be passed through the tricuspid valve from the right atrium to the RV. A balloon atrial septostomy is performed if a restrictive PFO or ASD is present.

▶ Treatment & Prognosis

In infants with unrestricted pulmonary blood flow, conventional anticongestive therapy with diuretics and afterload reduction should be given until the infant begins to outgrow the VSD. Sometimes, a pulmonary artery band is needed to protect the pulmonary bed from excessive flow and development of pulmonary vascular disease.

Staged palliation of tricuspid atresia is the usual surgical approach. In infants with diminished pulmonary blood flow, PGE_1 is given until an aortopulmonary shunt (BT shunt or ductal stent) can be performed. A Glenn procedure (superior vena cava to pulmonary artery anastomosis) is done with takedown of the aortopulmonary/BT shunt at 4–6 months when saturations begin to fall, and completion of the Fontan procedure (redirection of inferior vena cava and superior vena cava to pulmonary artery) is performed when the child reaches around 15 kg.

The long-term prognosis for children treated by the Fontan procedure is unknown, although patients now are living into their late 20s and early 30s. In the short term, the best results for the Fontan procedure occur in children with low pulmonary artery pressures prior to open-heart surgery.

Wald RM et al: Outcome after prenatal diagnosis of tricuspid atresia: a multicenter experience. Am Heart J 2007;153:772–778 [PMID: 17452152].

HYPOPLASTIC LEFT HEART SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Mild cyanosis at birth.
- ▶ Minimal auscultatory findings.
- ▶ Rapid onset of shock with ductal closure.

▶ General Considerations

Hypoplastic left heart syndrome (HLHS) includes several conditions in which obstructive lesions of the left heart are associated with hypoplasia of the LV. The syndrome occurs in 1.4%–3.8% of infants with congenital heart disease.

Stenosis or atresia of the mitral and aortic valves is the rule. In the neonate, survival depends on a PDA because ante-grade flow into the systemic circulation is inadequate or nonexistent. The PDA provides the only flow to the aorta and coronary arteries. Children with HLHS are usually stable at birth, but they deteriorate rapidly as the ductus closes in the first week of life. Untreated, the average age at death is the first week of life. Rarely, the ductus remains patent and infants may survive for weeks to months without PGE_1 therapy.

The diagnosis is often made prepartum by fetal echocardiography. Prepartum diagnosis aids in counseling for the expectant parents and planning for the delivery of the infant at or near a center with experience in treating HLHS.

▶ ### Clinical Findings

A. Symptoms and Signs

Neonates with HLHS appear stable at birth because the ductus is patent. They deteriorate rapidly as the ductus closes, with shock and acidosis secondary to inadequate systemic perfusion. Oxygen saturation may actually increase for a period of time as the ductus closes due to increased blood flowing to the lungs.

B. Imaging

Chest radiograph in the first day of life may be relatively unremarkable, with the exception of a small cardiac silhouette. Later, chest radiographs demonstrate cardiac enlargement with severe pulmonary venous congestion if the PDA has begun closing or if the baby has been placed on supplemental oxygen increasing pulmonary blood flow.

C. Electrocardiography

The ECG shows right axis deviation, right atrial enlargement, and RVH with a relative paucity of LV forces. The small Q wave in lead V_6 may be absent, and a qR pattern is often seen in lead V_1.

D. Echocardiography

Echocardiography is diagnostic. A hypoplastic aorta and LV with atretic or severely stenotic mitral and aortic valves are diagnostic. The systemic circulation is dependent on the PDA. Color-flow Doppler imaging shows retrograde flow in the ascending aorta, as the coronary arteries are supplied by the ductus via the small native aorta.

▶ ### Treatment & Prognosis

Initiation of PGE_1 is essential and lifesaving, as systemic circulation depends on a patent ductus arteriosus. Later management depends on balancing pulmonary and systemic blood flow both of which depend on the RV. At a few days of age the pulmonary resistance falls, favoring pulmonary over-circulation and systemic underperfusion. Therapy is then directed at encouraging systemic blood flow. Despite hypoxia and cyanosis, supplemental oxygen is avoided as this will decrease pulmonary resistance and lead to further increases in pulmonary blood flow. In some centers, nitrogen is used to decrease inspired oxygen to as low as 17%. This therapy must be carefully monitored, but results in increased pulmonary arterial resistance, which encourages systemic blood flow and improves systemic perfusion. Systemic afterload reduction will also increase systemic perfusion. Adequate perfusion can usually be obtained by keeping systemic O_2 saturation between 65% and 80%, or more accurately a Po_2 of 40 mm Hg.

Staged surgical palliation is the most common management approach. In the Norwood procedure, the relatively normal main pulmonary artery is transected and connected to the small ascending aorta. The entire aortic arch must be reconstructed due to its small size. Then, either a BT shunt (from the subclavian artery to the pulmonary artery) or a Sano shunt (from the RV to the pulmonary artery) must be created to restore pulmonary blood flow. Children who have a Norwood procedure will later require a Glenn anastomosis (superior vena cava to pulmonary artery with takedown of the systemic-pulmonary shunt) and then a Fontan (inferior vena cava to pulmonary artery, completing the systemic venous bypass of the heart) at ages 6 months and 2–3 years, respectively. Despite advances in surgical technique and postoperative care, HLHS remains one of the most challenging lesions in pediatric cardiology, with one-year survival as low as 70%.

Orthotopic heart transplantation is also a treatment option for newborns with HLHS, but in the current era is typically only performed in infants who are considered poor Norwood candidates. Heart transplantation is more commonly utilized in the event of a failed surgical palliation or if the systemic RV fails (often in adolescence or young adulthood).

Recently, some centers offer a "hybrid" approach to HLHS as a result of collaboration between surgeons and interventional cardiologists. In the hybrid procedure, the chest is opened surgically and the branch pulmonary arteries are banded, to limit pulmonary blood flow. Then, also through the open chest, a PDA stent is placed by the interventionalist to maintain systemic output. The second stage is considered a "comprehensive Glenn," in which the pulmonary artery bands and ductal stent are taken down, the aortic arch is reconstructed and the superior vena cava is surgically connected to the pulmonary arteries. Short term (30 day) survival after the first-stage "hybrid" is greater than 90% at the most experienced centers, but second stage risks and complications mitigate some of that initial survival advantage. Long-term follow-up data are not yet available.

Ohye RG et al: Comparison of shunt types in the Norwood procedure for single-ventricle lesions. N Engl J Med 2010;362(21):1980–1992 [PMID: 20505177].

TRANSPOSITION OF THE GREAT ARTERIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Cyanotic newborn without respiratory distress.
▶ More common in males.

▶ General Considerations

Transposition of the great arteries (TGA) is the second most common cyanotic congenital heart disease, accounting for 5% of all cases of congenital heart disease. The male-to-female ratio is 3:1. It is caused by an embryologic abnormality in the spiral division of the truncus arteriosus in which the aorta arises from the RV and the pulmonary artery from the LV. This is referred to as "ventriculoarterial discordance." Patients may have a VSD, or the ventricular septum may be intact. Left unrepaired, transposition is associated with a high incidence of early pulmonary vascular obstructive disease. Because pulmonary and systemic circulations are in parallel, survival is impossible without mixing between the two circuits. Specifically an interatrial communication (PFO or ASD) is critically important. The majority of mixing occurs at the atrial level (some mixing can occur at the level of the ductus as well), so even in the presence of a VSD an adequate interatrial communication is needed. If the atrial communication is inadequate at birth, the patient is severely cyanotic.

▶ Clinical Findings

A. Symptoms and Signs

Many neonates are large (up to 4 kg) and profoundly cyanotic without respiratory distress or a significant murmur. Infants with a large VSD may be less cyanotic and they usually have a prominent murmur. The findings on cardiovascular examination depend on the intracardiac defects. Obstruction to outflow from either ventricle is possible, and coarctation must be ruled out.

B. Imaging

The chest radiograph in transposition is usually nondiagnostic. Sometimes there is an "egg on a string" appearance because the aorta is directly anterior to the main pulmonary artery, giving the image of a narrow mediastinum.

C. Electrocardiography

Because the newborn ECG normally has RV predominance, the ECG in transposition is of little help, as it will frequently look normal.

D. Echocardiography

Two-dimensional imaging and Doppler evaluation demonstrate the anatomy and physiology well. The aorta arises from the RV and the pulmonary artery arises from the LV. Associated defects, such as a VSD, RV, or LV outflow tract obstruction, or coarctation, must be evaluated. The atrial septum should be closely examined, as any restriction could prove detrimental as the child awaits repair. The coronary anatomy is variable and must be defined prior to surgery.

E. Cardiac Catheterization and Angiocardiography

A Rashkind balloon atrial septostomy is frequently performed in complete transposition if the interatrial communication is restrictive. This procedure can be done at the bedside with echocardiographic guidance in most cases. The coronary anatomy can be delineated by ascending aortography if not well seen by echocardiography.

▶ Treatment

Early corrective surgery is recommended. The arterial switch operation (ASO) has replaced the previously performed atrial switch procedures (Mustard and Senning operations). The ASO is performed at age 4–7 days. The arteries are transected above the level of the valves and switched, while the coronaries are separately reimplanted. Small associated VSDs may be left to close on their own, but large VSDs are repaired. The ASD is also closed. Early surgical repair (< 14 days of age) is vital for patients with TGA and an intact ventricular septum to avoid potential deconditioning of the LV as it pumps to the low-resistance pulmonary circulation. If a large, unrestrictive VSD is present, LV pressure is maintained at systemic levels, the LV does not become deconditioned, and corrective surgery can be delayed for a few months. Surgery should be performed by age 3–4 months in those with TGA and a VSD because of the high risk of early pulmonary vascular disease associated with this defect.

Operative survival after the ASO is greater than 95% in major centers. The main advantage of the *arterial* switch procedure in comparison to the *atrial* switch procedures (Mustard and Senning operations) is that the systemic ventricle is the LV. Patients who have undergone an *atrial* switch undergo surgical patch placement to baffle the venous return through the atria to the opposite ventricle. They then have an RV as their systemic ventricle, leaving them with significant late risk of RV failure and need for heart transplantation and are at risk for atrial baffle obstruction.

Lalezari S, Bruggemans EF, Blom NA, Hazekamp MG: Thirty-year experience with the arterial switch operation. Ann Thorac Surg 2011 Sep;92(3):973–979 [PMID: 21871285].

Warnes CA: Transposition of the great arteries. Circulation 2006;114:2699–2709 [PMID: 17159076].

1. Congenitally Corrected Transposition of the Great Arteries

Congenitally corrected transposition of the great arteries (ccTGA) is a relatively uncommon congenital heart disease. Patients may present with cyanosis, heart failure, or be asymptomatic, depending on the associated lesions. In ccTGA, both atrioventricular and ventriculoarterial discordance occurs so

that the right atrium connects to a morphologic LV, which supports the pulmonary artery. Conversely, the left atrium empties via a tricuspid valve into a morphologic RV, which supports the aorta. Common associated lesions are VSD and pulmonary stenosis. A dysplastic left-sided tricuspid valve is almost always present. In the absence of associated lesions, patients with ccTGA are often undiagnosed until adulthood when they present with left-sided AV valve insufficiency or arrhythmias.

Previously, surgical repair was directed at VSD closure and relief of pulmonary outflow tract obstruction—a technique that maintained the RV as the systemic ventricle with outflow to the aorta. It is now recognized that these patients have a reduced life span due to systemic RV failure; thus other surgical techniques have been advocated. The double-switch procedure is one such technique. An atrial level switch (Mustard or Senning technique) is performed, in which pulmonary and systemic venous blood are baffled such that they drain into the contralateral ventricle (systemic venous return drains into the RV and pulmonary venous return drains into the LV). An ASO then restores the morphologic LV to its position as systemic ventricle.

Patients with ccTGA have an increased incidence of complete heart block with an estimated risk of 1% per year and an overall frequency of 50%.

Malhotra SP et al: The hemi-Mustard/bidirectional Glenn atrial switch procedure in the double-switch operation for congenitally corrected transposition of the great arteries: rationale and midterm results. J Thorac Cardiovasc Surg 2011;141(1):162–170 [PMID: 21055773].

2. Double-Outlet Right Ventricle

In this uncommon malformation, both great arteries arise from the RV. There is always a VSD that allows blood to exit the LV. Presenting symptoms depend on the relationship of the VSD to the semilunar valves. The VSD can be in variable positions, and the great arteries could be normally related or malposed. In the absence of outflow obstruction, a large left-to-right shunt exists and the clinical picture resembles that of a large VSD. Pulmonary stenosis may be present, particularly if the VSD is remote from the pulmonary artery. This physiology is similar to ToF. Alternatively, if the VSD is nearer the pulmonary artery, aortic outflow may be obstructed (called the Taussig-Bing malformation). Early primary correction is the goal. LV flow is directed to the aorta across the VSD (closing the VSD), and an RV to pulmonary artery conduit is placed to maintain unobstructed flow through the pulmonary circulation. If the aorta is far from the VSD, an arterial switch may be necessary. Echocardiography is usually sufficient to make the diagnosis and determine the orientation of the great vessels and their relationship to the VSD.

Mahle WT et al: Anatomy, echocardiography, and surgical approach to double outlet right ventricle. Cardiol Young 2008;18(Suppl 3):39–51 [PMID: 19094378].

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Abnormal pulmonary venous connection *leading to* cyanosis.

▶ Occurs with or without a murmur and may have accentuated P_2.

▶ Right atrial enlargement and RVH.

▶ General Considerations

This malformation accounts for 2% of all congenital heart lesions. Instead of the pulmonary veins draining into the left atrium, the veins empty into a confluence that usually is located behind the left atrium. However, the confluence is not connected to the left atrium and instead the pulmonary venous blood drains into the systemic venous system. Therefore, there is complete mixing of the systemic and pulmonary venous blood at the level of the right atrium. The presentation of a patient with total anomalous pulmonary venous return (TAPVR) depends on the route of drainage into the systemic circulation and whether or not this drainage route is obstructed.

The malformation is classified as either intra-, supra-, or infracardiac. Intracardiac TAPVR occurs when the pulmonary venous confluence drains directly into the heart, usually via the coronary sinus into the right atrium (rarely direct drainage into the right atrium). Supracardiac (or supradiaphragmatic) return is defined as a confluence that drains into the right superior vena cava, innominate vein, or persistent left superior vena cava. In infracardiac (or infradiaphragmatic) return, the confluence drains below the diaphragm usually into the portal venous system which empties into the inferior vena cava. Infracardiac pulmonary venous return is very frequently obstructed. This obstruction to pulmonary venous drainage makes this lesion a potential surgical emergency. Supracardiac veins may also be obstructed, though less commonly. Rarely, the pulmonary venous confluence drains to more than one location, called mixed TAPVR.

Because the entire venous drainage from the body returns to the right atrium, a right-to-left shunt must be present at the atrial level, either as an ASD or a PFO. Occasionally, the

atrial septum is restrictive and balloon septostomy is needed at birth to allow filling of the left heart.

▶ Clinical Findings

A. Unobstructed Pulmonary Venous Return

Patients with unobstructed TAPVR and a large atrial communication tend to have high pulmonary blood flow and typically present with cardiomegaly and HF rather than cyanosis. Oxygen saturations in the high 80s or low 90s are common. Most patients in this group have mild to moderate elevation of pulmonary artery pressure owing to elevated pulmonary blood flow. In most instances, pulmonary artery pressure does not reach systemic levels.

1. Symptoms and signs—Patients may have mild cyanosis and tachypnea in the neonatal period and early infancy. Examination discloses dusky nail beds and mucous membranes, but overt cyanosis and digital clubbing are usually absent. An RV heave is palpable, and P_2 is increased. A systolic and diastolic murmur may be heard as a result of increased flow across the pulmonary and tricuspid valves, respectively.

2. Imaging—Chest radiography reveals cardiomegaly involving the right heart and pulmonary artery. Pulmonary vascular markings are increased.

3. Electrocardiography—ECG shows right axis deviation and varying degrees of right atrial enlargement and right ventricular hypertrophy. A qR pattern is often seen over the right precordial leads.

4. Echocardiography—Demonstration by echocardiography of a discrete chamber posterior to the left atrium and a right-to-left atrial level shunt is strongly suggestive of the diagnosis. The availability of two-dimensional echocardiography plus color-flow Doppler has increased diagnostic accuracy such that diagnostic cardiac catheterization is rarely required.

B. With Obstructed Pulmonary Venous Return

This group includes many patients with infracardiac TAPVR and a few of the patients in whom venous drainage is into a systemic vein above the diaphragm. The pulmonary venous return is usually obstructed at the level of the ascending or descending vein that connects the confluence to the systemic veins to which it is draining. Obstruction can be caused from extravascular structures (such as the diaphragm), or by inherent stenosis within the ascending or descending vein.

1. Symptoms and signs—Infants usually present shortly after birth with severe cyanosis and respiratory distress and require early corrective surgery. Cardiac examination discloses a striking RV impulse. S_2 is markedly accentuated

and single. Although there is often no murmur, sometimes, a systolic murmur is heard over the pulmonary area with radiation over the lung fields. Diastolic murmurs are uncommon.

2. Imaging—The heart is usually small and pulmonary venous congestion severe with associated air bronchograms. The chest radiographic appearance may lead to an erroneous diagnosis of severe lung disease. In less severe cases, the heart size may be normal or slightly enlarged with mild pulmonary venous congestion.

3. Electrocardiography—The ECG shows right axis deviation, right atrial enlargement, and RVH.

4. Echocardiography—Echocardiography shows a small left atrium and LV, a dilated right heart with high RV pressure. For infracardiac TAPVR, appearance of a vessel lying parallel and anterior to the descending aorta and to the left of the inferior vena cava may represent the vein draining the confluence caudally toward the diaphragm. Color-flow Doppler echocardiography will demonstrate a right-to-left atrial level shunt and may reveal flow disturbance, commonly near the confluence or in the liver, where flow is obstructed.

5. Cardiac catheterization and angiocardiography—If echocardiography does not confirm the anatomy, cardiac catheterization and angiography demonstrate the site of entry of the anomalous veins, determine the degree of pulmonary hypertension, and calculate pulmonary vascular resistance.

▶ Treatment

Surgery is always required for TAPVR. If pulmonary venous return is obstructed, surgery must be performed immediately (obstructed TAPVR represents one of the few surgical emergencies in congenital heart disease). If early surgery is not required and the atrial septum is restrictive, a balloon atrial septostomy can be performed in newborns, to be followed shortly by less emergent surgical repair.

▶ Course & Prognosis

Most children with TAPVR do well after surgery. However, some surgical survivors develop late stenosis of the pulmonary veins. Pulmonary vein stenosis is an intractable condition that is difficult to treat either with interventional catheterization or surgery and has a poor prognosis. A heart-lung transplant may be the only remaining option available to those with severe pulmonary vein stenosis. By avoiding direct suturing at the pulmonary venous ostia, the chance of recurrent stenosis at the anastomotic site is lessened. Unfortunately, any manipulation of the pulmonary veins increases the risk of stenosis.

Seale AN et al: Total anomalous pulmonary venous connection: morphology and outcome from an international population-based study. Circulation 2010 Dec 21;122(25):2718–2726 [Epub 2010 Dec 6] [PMID: 21135364].

TRUNCUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Early HF with or without cyanosis.
▶ Systolic ejection click.

▶ General Considerations

Truncus arteriosus accounts for less than 1% of congenital heart malformations. A single great artery arises from the heart, giving rise to the systemic, pulmonary, and coronary circulations. Truncus develops embryologically as a result of failure of the division of the common truncus arteriosus into the aorta and the pulmonary artery. A VSD is always present. The number of truncal valve leaflets varies from two to six, and the valve may be insufficient or stenotic.

Truncus arteriosus is divided into subtypes by the anatomy of the pulmonary circulation. A single main pulmonary artery may arise from the base of the trunk and gives rise to branch pulmonary arteries (type 1). Alternatively, the pulmonary arteries may arise separately from the common trunk, either in close association with one another (type 2) or widely separated (type 3). This lesion can occur in association with an interrupted aortic arch.

In patients with truncus, blood from both ventricles leaves the heart through a single exit. Thus, oxygen saturation in the pulmonary artery is equal to that in the systemic arteries. The degree of systemic arterial oxygen saturation depends on the ratio of pulmonary to systemic blood flow. If pulmonary vascular resistance is normal, the pulmonary blood flow is greater than the systemic blood flow and the saturation is relatively high. If pulmonary vascular resistance is elevated because of pulmonary vascular obstructive disease or small pulmonary arteries, pulmonary blood flow is reduced and oxygen saturation is low. The systolic pressures are systemic in both ventricles.

▶ Clinical Findings

A. Symptoms and Signs

High pulmonary blood flow characterizes most patients with truncus arteriosus. These patients are usually minimally cyanotic and present in HF. Examination of the heart reveals a hyperactive precordium. A systolic thrill is common at the lower left sternal border. A loud early systolic ejection click is commonly heard. S_2 is single and accentuated. A loud holosystolic murmur is audible at the left lower sternal border. A diastolic flow murmur can often be heard at the apex due to increased pulmonary venous return crossing the mitral valve. An additional diastolic murmur of truncal insufficiency may be present.

Patients with decreased pulmonary blood flow are more profoundly cyanotic early. The most common manifestations are growth retardation, easy fatigability, and HF. The heart is not hyperactive. S_1 and S_2 are single and loud. A systolic murmur is heard at the lower left sternal border. No mitral flow murmur is heard, as pulmonary venous return is decreased. A loud systolic ejection click is commonly heard. In the current era, this lesion is often diagnosed by prenatal screening echocardiography.

B. Imaging

The common radiographic findings are a boot-shaped heart, absence of the main pulmonary artery segment, and a large aorta that has a right arch 30% of the time. The pulmonary vascular markings vary with the degree of pulmonary blood flow.

C. Electrocardiography

The axis is usually normal. RVH or combined ventricular hypertrophy is commonly present.

D. Echocardiography

Images generally show override of a single great artery (similar to ToF, but no second great artery arises directly from the heart). The origin of the pulmonary arteries and the degree of truncal valve abnormality can be defined. Color-flow Doppler can aid in the description of pulmonary flow and the function of the truncal valve, both of which are critical to management. Echocardiography is critical in identifying associated lesions which will impact surgical planning, such as the presence of an interrupted aortic arch.

E. Angiocardiography

Cardiac catheterization is not routinely performed but may be of value in older infants in whom pulmonary vascular disease must be ruled out. The single most important angiogram would be from the truncal root, as both the origin of the pulmonary arteries and the amount of truncal insufficiency would be seen from one injection.

▶ Treatment

Anticongestive measures are needed for patients with high pulmonary blood flow and congestive failure. Surgery is always required in this condition. Because of HF and the risk of development of pulmonary vascular disease, surgery is usually performed in the neonatal period or early infancy. The VSD is closed to allow LV egress to the truncal valve. The pulmonary artery (type 1) or arteries (types 2–3) are separated from the truncus as a block, and a valved conduit is fashioned from the RV to the pulmonary circulation.

Course & Prognosis

Children with a good surgical result generally do well. Outcome is also dependent to some degree on anatomy and integrity of the truncal valve, which becomes the "neoaortic" valve. Patients with a dysplastic valve may eventually require surgical repair or replacement of this valve. In addition, similar to patients with ToF, they eventually outgrow the RV-to-pulmonary artery conduit placed in infancy and require revision of the conduit in later childhood. The risk of early pulmonary vascular obstructive disease is high in the unrepaired patient and a decision to delay open-heart surgery beyond age 4–6 months is not wise even in stable patients.

Henaine R et al: Fate of the truncal valve in truncus arteriosus. Ann Thorac Surg 2008 Jan;85(1):172–178 [PMID: 18154803].

Konstantinov IE et al: Truncus arteriosus associated with interrupted aortic arch in 50 neonates: a Congenital Heart Surgeons Society study. Ann Thorac Surg 2006 Jan;81(1):214–222 [PMID: 16368368].

QUALITY IMPROVEMENT IN CONGENITAL HEART DISEASE

The National Pediatric Cardiology Quality Improvement Collaborative (NPC-QIC) was formed in response to the Joint Council on Congenital Heart Disease (JCCHD) initiative to improve outcomes of children with heart disease. The mission of the NPC-QIC is to build a collaborative network of pediatric cardiologists and an associated database to serve as the foundation for improvement projects. The inaugural project of the NPC-QIC was an improvement project aimed at improving survival and quality of life of infants with HLHS between stages 1 (Norwood) and 2 (bidirectional Glenn) of their palliative surgery.

As outcomes improve and even those with complex congenital heart disease are surviving into adulthood, the care of adults with congenital heart disease is an expanding area of need within pediatric cardiology. Subspecialty clinics addressing the needs of adults with repaired or palliated congenital heart disease are needed to assess and advise patients regarding such adult issues as the impact of pregnancy, the risks of anticoagulation during pregnancy, and appropriate adult career choices.

Baker-Smith CM et al: Variation in postoperative care following stage I palliation for single-ventricle patients: a report from the Joint Council on Congenital Heart Disease National Quality Improvement Collaborative. Congenit Heart Dis 2011 Mar–Apr;6(2):116–127 [PMID: 21426525].

ACQUIRED HEART DISEASE

RHEUMATIC FEVER

Rheumatic fever remains a major cause of morbidity and mortality in developing countries that suffer from poverty, overcrowding, and poor access to health care. Even in developed countries, rheumatic fever has not been entirely eradicated. The overall incidence in the United States is less than 1 per 100,000. Group A β-hemolytic streptococcal infection of the upper respiratory tract is the essential trigger in predisposed individuals. Only certain serotypes of group A *Streptococcus* cause rheumatic fever. The latest attempts to define host susceptibility implicate immune response genes that are present in approximately 15% of the population. The immune response triggered by infection of the pharynx with group A streptococci consists of (1) sensitization of B lymphocytes by streptococcal antigens, (2) formation of anti-streptococcal antibody, (3) formation of immune complexes that cross-react with cardiac sarcolemma antigens, and (4) myocardial and valvular inflammatory response.

The peak age of risk in the United States is 5–15 years. The disease is slightly more common in girls and in African Americans. The annual death rate from rheumatic heart disease in school-aged children (whites and non-whites) recorded in the 1980s was less than 1 per 100,000.

Clinical Findings

Two major or one major and two minor manifestations (plus supporting evidence of streptococcal infection) based on the modified Jones criteria are needed for the diagnosis of acute rheumatic fever (Table 20–13). Except in cases of rheumatic fever manifesting solely as Sydenham chorea or long-standing carditis, there should be clear evidence of a streptococcal infection such as scarlet fever, a positive throat culture for group A β-hemolytic *Streptococcus*, and increased antistreptolysin O or other streptococcal antibody titers. The antistreptolysin O titer is significantly higher in rheumatic fever than in uncomplicated streptococcal infections.

A. Carditis

Carditis is the most serious consequence of rheumatic fever and varies from minimal to life-threatening HF. The term *carditis* implies pancardiac inflammation, but it may be limited to valves, myocardium, or pericardium. Valvulitis is frequently seen, with the mitral valve most commonly affected. Mitral insufficiency is the most common valvular residua of acute rheumatic carditis. Mitral stenosis after acute rheumatic fever is rarely encountered until 5–10 years after the first episode. Thus, mitral stenosis is much more commonly seen in adults than in children.

An early decrescendo diastolic murmur consistent with aortic insufficiency is occasionally encountered as the sole

Table 20–13. Jones criteria (modified) for diagnosis of rheumatic fever.

Supporting evidence of preceding streptococcal infection, ie, increased titers of antistreptolysin O or other streptococcal antibodies, positive throat culture for group A Streptococcus

valvular manifestation of rheumatic carditis. The aortic valve is the second most common valve affected in polyvalvular as well as in single-valve disease. The aortic valve is involved more often in males and in African Americans. Dominant aortic stenosis of rheumatic origin does not occur in pediatric patients. In one large study, the shortest length of time observed for a patient to develop dominant aortic stenosis secondary to rheumatic heart disease was 20 years.

B. Polyarthritis

The large joints (knees, hips, wrists, elbows, and shoulders) are most commonly involved and the arthritis is typically migratory. Joint swelling and associated limitation of movement should be present. This is one of the more common major criteria, occurring in 80% of patients. Arthralgia alone is not a major criterion.

C. Sydenham Chorea

Sydenham chorea is characterized by involuntary and purposeless movements and is often associated with emotional lability. These symptoms become progressively worse and may be accompanied by ataxia and slurring of speech. Muscular weakness becomes apparent following the onset of the involuntary movements. Chorea is self-limiting, although it may last up to 3 months. Chorea may not be apparent for months to years after the acute episode of rheumatic fever.

D. Erythema Marginatum

A macular, serpiginous, erythematous rash with a sharply demarcated border appears primarily on the trunk and the extremities. The face is usually spared.

E. Subcutaneous Nodules

These usually occur only in severe cases, and then most commonly over the joints, scalp, and spinal column. The nodules vary from a few millimeters to 2 cm in diameter and are nontender and freely movable under the skin.

▶ Treatment & Prophylaxis

A. Treatment of the Acute Episode

1. Anti-infective therapy—Eradication of the streptococcal infection is essential. Long-acting benzathine penicillin is the drug of choice. Depending on the age and weight of the patient, a single intramuscular injection of 0.6–1.2 million units is effective; alternatively, give penicillin V, 250–500 mg orally 2–3 times a day for 10 days, or amoxicillin, 50 mg/kg (maximum 1 g) once daily for 10 days. Narrow-spectrum cephalosporins, clindamycin, azithromycin, or clarithromycin are used in those allergic to penicillin.

2. Anti-inflammatory agents

A. ASPIRIN—Aspirin, 30–60 mg/kg/d, is given in four divided doses. This dose is usually sufficient to effect dramatic relief of arthritis and fever. Higher dosages carry a greater risk of side effects and there are no proven short- or long-term benefits of high doses that produce salicylate blood levels of 20–30 mg/dL. The duration of therapy is tailored to meet the needs of the patient, but 2–6 weeks of therapy with reduction in dose toward the end of the course is usually sufficient. Other nonsteroidal anti-inflammatory agents used because of concerns about Reye syndrome are less effective than aspirin.

B. CORTICOSTEROIDS—There is no clear evidence to support the use of corticosteroids, but they are occasionally used for those with severe carditis.

3. Therapy in heart failure—Treatment for HF is based on symptoms and severity of valve involvement and cardiac dysfunction (see section on Heart Failure, earlier).

4. Bed rest and ambulation—Bed rest is not required in most cases. Activity level should be commensurate with symptoms and children should be allowed to self-limit their activity level while affected. Most acute episodes of rheumatic fever are managed on an outpatient basis.

B. Treatment After the Acute Episode

1. Prevention—Prevention is critical, as patients who have had rheumatic fever are at greater risk of recurrence if future group A β-hemolytic streptococcal infections are inadequately treated. Follow-up visits are essential to reinforce the necessity for prophylaxis, with regular intramuscular long-acting benzathine penicillin injections preferred to oral medication due to better adherence. Long-term (possibly lifelong) prophylaxis is recommended for patients with

residual rheumatic heart disease. More commonly, with no or transient cardiac involvement, 5–10 years of therapy or discontinuance in early adulthood (age 21) (whichever is longer) is an effective approach.

The following preventive regimens are in current use:

A. Penicillin g benzathine—600,000 units for less than 27 kg, 1.2 million units for more than 27 kg intramuscularly every 4 weeks is the drug of choice.

B. Penicillin V—250 mg orally twice daily is much less effective than intramuscular penicillin benzathine G (5.5 vs 0.4 streptococcal infections per 100 patient-years).

C. Sulfadiazine—500 mg for less than 27 kg and 1 g for more than 27 kg, once daily. Blood dyscrasias and lesser effectiveness in reducing streptococcal infections make this drug less satisfactory than penicillin benzathine G. This is the recommended regimen for penicillin-allergic patients.

D. Erythromycin—250 mg orally twice a day may be given to patients who are allergic to both penicillin and sulfonamides. Azithromycin or clarithromycin may also be used.

2. Residual valvular damage—As described above, the mitral and aortic valves are most commonly affected by rheumatic fever and the severity of carditis is quite variable. In the most severe cases, cardiac failure or the need for a valve replacement can occur in the acute setting. In less severe cases, valve abnormalities can persist, requiring lifelong medical management and eventual valve replacement. Other patients fully recover without residual cardiac sequelae.

Although antibiotic prophylaxis to protect against endocarditis used to be recommended for those with residual valvular abnormalities, the criteria for prevention of IE were revised in 2007 and routine prophylaxis is recommended only if a prosthetic valve is in place.

Circulation 2009;119:1541–1551 [PMID: 19246689].

KAWASAKI DISEASE

Kawasaki disease was first described in Japan in 1967 and was initially called mucocutaneous lymph node syndrome. The cause is unclear and there is no specific diagnostic test. Kawasaki disease is the leading cause of acquired heart disease in children in the United States. Eighty percent of patients are younger than 5 years old (median age at diagnosis is 2 years), and the male-to-female ratio is 1.5:1. Diagnostic criteria are fever for more than 5 days and at least four of the following features: (1) bilateral, painless, nonexudative conjunctivitis; (2) lip or oral cavity changes (eg, lip cracking and fissuring, strawberry tongue, and inflammation of the oral mucosa); (3) cervical lymphadenopathy greater than or equal to 1.5 cm in diameter and usually unilateral; (4) polymorphous exanthema; and (5) extremity changes (redness and swelling of the hands and feet with subsequent desquamation). Clinical features not part of the diagnostic criteria, but frequently associated with Kawasaki disease, are shown in Table 20–14.

The potential for cardiovascular complications is the most serious aspect of Kawasaki disease. Complications during the acute illness include myocarditis, pericarditis, valvular heart disease (usually mitral or aortic regurgitation), and coronary arteritis. Patients with fever for at least 5 days but fewer than four of the diagnostic features can be diagnosed with incomplete Kawasaki disease, especially if they have coronary artery abnormalities detected by echocardiography. Comprehensive recommendations regarding the evaluation for children with suspected incomplete Kawasaki disease were outlined in a 2004 Statement by the American Heart Association (see references at the end of this section).

Coronary artery lesions range from mild transient dilation of a coronary artery to large aneurysms. Aneurysms rarely form before day 10 of illness. Untreated patients have a 15%–25% risk of developing coronary aneurysms. Those at greatest risk for aneurysm formation are males, young infants (< 6 months), and those not treated with intravenous immunoglobulin (IVIG). Most coronary artery aneurysms

Table 20–14. Noncardiac manifestations of Kawasaki disease.

System	Associated Signs and Symptoms
Gastrointestinal	Vomiting, diarrhea, gallbladder hydrops, elevated transaminases
Blood	Elevated ESR or CRP, leukocytosis, hypoalbuminemia, mild anemia in acute phase and thrombocytosis in subacute phase (usually second to third week of illness)
Renal	Sterile pyuria, proteinuria
Respiratory	Cough, hoarseness, infiltrate on chest radiograph
Joint	Arthralgia and arthritis
Neurologic	Mononuclear pleocytosis of cerebrospinal fluid, irritability, facial palsy

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

resolve within 5 years of diagnosis; however, as aneurysms resolve, associated obstruction or stenosis (19% of all aneurysms) may develop, which may result in coronary ischemia. Giant aneurysms (> 8 mm) are less likely to resolve, and nearly 50% eventually become stenotic. Of additional concern, acute thrombosis of an aneurysm can occur, resulting in myocardial infarction that is fatal in approximately 20% of cases.

▶ **Treatment**

Immediate management of Kawasaki disease includes IVIG and high-dose aspirin. This therapy is effective in decreasing the incidence of coronary artery dilation and aneurysm formation. The currently recommended regimen is 2 g/kg of IVIG administered over 10–12 hours and 80–100 mg/kg/d of aspirin in four divided doses. The duration of high-dose aspirin is institution-dependent: many centers reduce the dose once the patient is afebrile for 48–72 hours; others continue through 5 afebrile days or day 14 of the illness. Once high-dose aspirin is discontinued, low-dose aspirin (3–5 mg/kg/d) is given through the subacute phase of the illness (6–8 weeks) or until coronary artery abnormalities resolve. If fever recurs within 48–72 hours of the initial treatment course and no other source of the fever is detected, a second dose of IVIG is often recommended; however, the effectiveness of this approach has not been clearly demonstrated. A multicenter, randomized, double-blind, placebo-controlled study demonstrated no beneficial effect of pulsed corticosteroids on the development of coronary abnormalities in patients responsive to IVIG. However, corticosteroids or other anti-inflammatory therapy (eg, infliximab) should be considered for patients with persistent fever despite one or two infusions of IVIG.

Follow-up of patients with treated Kawasaki disease depends on the degree of coronary involvement. In those with no or minimal coronary disease at the time of diagnosis, an echocardiogram 2 weeks and again 6–8 weeks after diagnosis is sufficient. Repeat echocardiography more than 8 weeks after diagnosis in those with no coronary abnormalities is optional. The risk stratification and recommended follow-up is reviewed in Table 20–15.

Table 20–15. Long-term management in Kawasaki disease.

Risk Level	Definition	Management Guidelines
I	No coronary artery changes at any stage of the illness	No ASA is needed beyond the subacute phase (6–8 wk). No follow-up beyond the first year.
II	Transient ectasia of coronary arteries during the acute phase	Same as above, or clinical follow-up ± ECG every 3–5 y.
III	Single small to medium coronary aneurysm	ASA until abnormality resolves. Annual follow-up with ECG and echo if < 10 y and every other-year stress testing if > 10 y.
IV	Giant aneurysm or multiple small to medium aneurysms without obstruction	Long-term ASA ± warfarin. Annual follow-up with ECG, echo, and stress testing.
V	Coronary artery obstruction	Long-term ASA ± warfarin ± calcium channel blocker to reduce myocardial oxygen consumption. Echo and ECG every 6 mo. Stress testing and Holter examination annually.

ASA, acetyl salicylic acid; ECG, electrocardiogram; echo, echocardiogram.

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Positive blood culture.
▶ Intracardiac oscillating mass, abscess, or new valve regurgitation on echocardiogram.
▶ Fever.
▶ Elevated erythrocyte sedimentation rate or C-reactive protein.

▶ **General Considerations**

Bacterial or fungal infection of the endocardium of the heart is rare and usually occurs in the setting of a preexisting abnormality of the heart or great arteries. It may occur in a normal heart during septicemia or as a consequence of infected indwelling central catheters.

The frequency of infective endocarditis (IE) appears to be increasing for several reasons: (1) increased survival in children with congenital heart disease, (2) greater use of central venous catheters, and (3) increased use of prosthetic material and valves. Pediatric patients without preexisting heart disease are also at increased risk for IE because of (1) increased survival rates for children with immune deficiencies, (2) long-term use of indwelling lines in ill newborns and patients with chronic diseases, and (3) increased intravenous drug abuse.

Patients at greatest risk are children with unrepaired or palliated cyanotic heart disease (especially in the presence of an aorta to pulmonary shunt), those with implanted prosthetic material, and patients who have had a prior episode of IE. Common organisms causing IE are viridans streptococci (30%–40% of cases), *Staphylococcus aureus* (25%–30%), and fungal agents (about 5%).

▶ Clinical Findings

A. History

The majority of patients with IE have a history of heart disease. There may or may not be an antecedent infection or surgical procedure (cardiac surgery, tooth extraction, tonsillectomy). Transient bacteremia occurs frequently during normal daily activities such as flossing or brushing teeth, using a toothpick and even when chewing food. Although dental and nonsterile surgical procedures also can result in transient bacteremias, these episodes are much less frequent for a given individual. This may be why a clear inciting event is often not identified in association with IE and also underlies the recent changes in guidelines for antibiotic prophylaxis to prevent IE (for details, see Wilson et al reference).

B. Symptoms, Signs, and Laboratory Findings

Although IE can present in a fulminant fashion with cardiovascular collapse, often it presents in an indolent manner with fever, malaise, and weight loss. Joint pain and vomiting are less common. On physical examination, there may be a new or changing murmur, splenomegaly, and hepatomegaly. Classic findings of Osler nodes (tender nodules, usually on the pulp of the fingers), Janeway lesions (nontender hemorrhagic macules on palms and soles), splinter hemorrhages, and Roth spots (retinal hemorrhage) are uncommonly noted in children. Laboratory findings include multiple positive blood cultures, elevated erythrocyte sedimentation rate or C-reactive protein, and hematuria. Transthoracic echocardiography can identify large vegetations in some patients, but transesophageal imaging has better sensitivity and may be necessary if the diagnosis remains in question.

▶ Prevention

In 2007, the AHA revised criteria for patients requiring prophylaxis for IE (Table 20–16). Only the high-risk patients

Table 20–16. Conditions requiring antibiotic prophylaxis for the prevention of infective endocarditis (IE).

Prosthetic cardiac valves
Prior episode of IE
Congenital heart disease (CHD)
Palliated cyanotic CHD
For 6 months postprocedure if CHD repair involves implanted prosthetic material
Repair of CHD with residual defect bordered by prosthetic material
Cardiac transplant with valvulopathy

listed require antibiotics before dental work (tooth extraction or cleaning) and procedures involving the respiratory tract or infected skin or musculoskeletal structures. IE prophylaxis is *not* recommended for gastrointestinal or genitourinary procedures, body piercing, or tattooing.

Recommended propylaxis is under 40 kg, 50 mg/kg of oral amoxicillin for patients < 40 kg and 2000 mg for those > 40 kg. This dose is to be given 1 hour prior to procedure. If the patient is allergic to amoxicillin, alternative prophylactic antibiotics are recommended in the AHA guidelines.

▶ Treatment

In general, appropriate antibiotic therapy should be initiated as soon as IE is suspected and several large volume blood cultures have been obtained via separate venipunctures. Therapy can be tailored once the pathogen and sensitivities are defined. Vancomycin or a β-lactam antibiotic, with or without gentamicin, for a 6-week course is the most common regimen. If HF occurs and progresses in the face of adequate antibiotic therapy, surgical excision of the infected area and prosthetic valve replacement must be considered.

▶ Course & Prognosis

Factors associated with a poor outcome are delayed diagnosis, presence of prosthetic material, perioperative associated IE, and *S aureus* infection. Mortality for bacterial endocarditis in children ranges from 10% to 25%, with fungal infections having a much greater mortality (50% or more).

Wilson W et al: Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation 2007;116:1736–1754 [PMID: 17446442].

PERICARDITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Chest pain made worse by deep inspiration and decreased by leaning forward.
▶ Fever and tachycardia.
▶ Shortness of breath.
▶ Pericardial friction rub.
▶ ECG with elevated ST segments.

▶ General Considerations

Pericarditis is an inflammation of the pericardium and is commonly related to an infectious process. The most common cause of pericarditis in children is viral infection (eg, coxsackievirus, mumps, Epstein-Barr, adenovirus, influenza, and human immunodeficiency virus [HIV]). Purulent pericarditis results from bacterial infection (eg, pneumococci, streptococci, staphylococci, and *Haemophilus influenzae*) and is less common but potentially life-threatening.

In some cases, pericardial disease occurs in association with a generalized process. Associations include rheumatic fever, rheumatoid arthritis, uremia, systemic lupus erythematosus, malignancy, and tuberculosis. Pericarditis after cardiac surgery (postpericardiotomy syndrome) is most commonly seen after surgical closure of an ASD. Postpericardiotomy syndrome appears to be autoimmune in nature with high titers of antiheart antibody and evidence of acute or reactivated viral illness. The syndrome is often self-limited and responds well to short courses of aspirin or corticosteroids.

▶ Clinical Findings

A. Symptoms and Signs

Childhood pericarditis usually presents with sharp stabbing mid chest, shoulder, and neck pain made worse by deep inspiration or coughing, and decreased by sitting up and leaning forward. Shortness of breath and grunting respirations are common. Physical findings depend on the presence of fluid accumulation in the pericardial space (effusion). In the absence of significant accumulation, a characteristic scratchy, high-pitched friction rub may be heard. If the effusion is large, heart sounds are distant and muffled and a friction rub may not be present. In the absence of cardiac tamponade, the peripheral, venous, and arterial pulses are normal.

Cardiac tamponade occurs in association with a large effusion, or one that has rapidly accumulated. Tamponade is characterized by jugular venous distention, tachycardia, hepatomegaly, peripheral edema, and pulsus paradoxus, in which systolic blood pressure drops more than 10 mm Hg during inspiration. Decreased cardiac filling and subsequent decrease in cardiac output result in signs of right heart failure and the potential for cardiovascular collapse.

B. Imaging

In pericarditis with a significant pericardial effusion, the cardiac silhouette is enlarged. The cardiac silhouette can appear normal if the effusion has developed over an extremely short period of time.

C. Electrocardiography

The ST segments are commonly elevated in acute pericarditis and PR segment depression may be present. Low voltages or electrical alternans (alteration in QRS amplitude between beats) can be seen with large pericardial effusions.

D. Echocardiography

Serial echocardiography allows a direct, noninvasive estimate of the volume of pericardial fluid and its change over time. Cardiac tamponade is associated with compression of the atria or respiratory alteration of ventricular inflow demonstrated by Doppler imaging.

▶ Treatment

Treatment depends on the cause of pericarditis and the size of the associated effusion. Viral pericarditis is usually self-limited and symptoms can be improved with nonsteroidal anti-inflammatory therapy. Purulent pericarditis requires immediate evacuation of the fluid and appropriate antibiotic therapy. Cardiac tamponade from any cause must be treated by immediate removal of the fluid, usually via pericardiocentesis. Pericardiocentesis should also be considered if the underlying cause is unclear or identification of the pathogen is necessary for targeted therapy. In the setting of recurrent or persistent effusions, a surgical pericardiectomy or pericardial window may be necessary. Diuretics should be avoided in the patient with cardiac tamponade because they reduce ventricular preload and can exacerbate the degree of cardiac decompensation.

▶ Prognosis

Prognosis depends to a great extent on the cause of pericardial disease. Constrictive pericarditis can develop following infectious pericarditis (especially if bacterial or tuberculous) and can be a difficult problem to manage. Cardiac tamponade will result in death unless the fluid is evacuated.

Ratnapalan S, Brown K, Benson L: Children presenting with acute pericarditis to the emergency department. Pediatr Emerg Care 2011 Jul;27(7):581–585 [PMID: 21712753].

CARDIOMYOPATHY

There are five classified forms of cardiomyopathy in children: (1) dilated, (2) hypertrophic, (3) restrictive, (4) arrhythmogenic right ventricular dysplasia (ARVD), and (5) left ventricular noncompaction. Discussion will be limited to the first three forms, which are the most common.

1. Dilated Cardiomyopathy

This most frequent of the childhood cardiomyopathies occurs with an annual incidence of 4–8 cases per 100,000 population in the United States and Europe. Although usually idiopathic, identifiable causes of dilated cardiomyopathy (DCM) include viral myocarditis, untreated tachyarrhythmias, left heart obstructive lesions, congenital abnormalities of the coronary arteries, medication toxicity (eg, anthracycline), and genetic (eg, dystrophin gene defects, sarcomeric mutations) and metabolic diseases (inborn errors of fatty acid oxidation and mitochondrial oxidative phosphorylation defects). Genetic causes are being discovered at an increasing rate with commercial testing now available for some of the more common genes.

▶ Clinical Findings

A. Signs and Symptoms

As myocardial function fails and the heart dilates, cardiac output falls, and affected children develop decreased exercise tolerance, failure to thrive, diaphoresis, and tachypnea. As the heart continues to deteriorate, congestive signs such as hepatomegaly and rales develop, and a prominent gallop can be appreciated on examination. The initial diagnosis in a previously healthy child can be difficult, as presenting symptoms can resemble a viral respiratory infection, pneumonia, or asthma.

B. Imaging

Chest radiograph shows generalized cardiomegaly with or without pulmonary venous congestion.

C. Electrocardiography

Sinus tachycardia with ST-T segment changes is commonly seen on ECG. The criteria for right and left ventricular hypertrophy may also be met and the QT interval may be prolonged. Evaluation for the presence of supraventricular arrhythmias on ECG is critical, as this is one of the few treatable and reversible causes of DCM in children.

D. Echocardiography

The echocardiogram shows LV and left atrial enlargement with decreased LV-shortening fraction and ejection fraction. The calculated end-diastolic and end-systolic dimensions are increased and mitral insufficiency is commonly seen. A careful evaluation for evidence of structural abnormalities (especially coronary artery anomalies or left heart obstructive lesions) must be performed, especially in infant patients.

E. Other Testing

Cardiac catheterization is useful to evaluate hemodynamic status and coronary artery anatomy. Endomyocardial biopsies can aid in diagnosis. Biopsy specimens may show inflammation consistent with acute myocarditis, abnormal myocyte architecture, and myocardial fibrosis. Electron micrographs may reveal evidence of mitochondrial or other metabolic disorders. Polymerase chain reaction (PCR) testing may be performed on biopsied specimens to detect viral genome products in infectious myocarditis. Skeletal muscle biopsy may be helpful in patients with evidence of skeletal muscle involvement. Cardiopulmonary stress testing is useful for measuring response to medical therapy and as an objective assessment of the cardiac limitations on exercise. Cardiac MRI is increasingly used for the diagnosis of myocarditis and can detect the presence of fibrosis by delayed gadolinium enhancement.

▶ Treatment & Prognosis

Outpatient management of pediatric DCM usually entails combinations of afterload-reducing agents and diuretics (see section on Heart Failure, earlier). In 2007, Shaddy et al published the results of a multicenter, placebo-controlled, doubleblind trial of carvedilol in children with HF. Children did not receive the same beneficial effects of β-blocker therapy as adults with HF, possibly due to the heterogenous nature of HF in children, but perhaps there are inherent differences in pediatric and adult HF. Aspirin or warfarin may be used to prevent thrombus formation in the dilated and poorly contractile cardiac chambers. Arrhythmias are more common in dilated hearts. Antiarrhythmic agents that do not suppress myocardial contractility, such as amiodarone, are used when necessary. Despite widespread use of internal defibrillators in the adult population, the technical difficulty of implanting internal defibrillators and the risk of adverse events (eg, high frequency of inappropriate discharge, vascular obstruction) in children limit their use.

Therapy of the underlying cause of cardiomyopathy is always indicated if possible. Unfortunately despite complete evaluation, a diagnosis is discovered in less than 30% of patients with DCM. If medical management is unsuccessful, cardiac transplantation is considered.

2. Hypertrophic Cardiomyopathy

The most common cause of hypertrophic cardiomyopathy (HCM) is familial hypertrophic cardiomyopathy, which is found in 1 in 500 individuals. HCM is the leading cause

of sudden cardiac death in young persons. The most common presentation is in an older child, adolescent, or adult, although it may occur in neonates. Causes of nonfamilial HCM in neonates and young children include glycogen storage disease, Noonan syndrome (including related syndromes such as LEOPARD and Costello syndrome), Friedreich ataxia, maternal gestational diabetes, mitochondrial disorders, and other metabolic disorders.

A. Familial Hypertrophic Cardiomyopathy

In the familial form, HCM is most commonly caused by a mutation in one of the several genes that encode proteins of the cardiac sarcomere (β-myosin heavy chain, cardiac troponin T or I, α-tropomyosin, and myosin-binding protein C).

1. Clinical findings—Patients may be asymptomatic despite having significant hypertrophy, or may present with symptoms of inadequate coronary perfusion or HF such as angina, syncope, palpitations, or exercise intolerance. Patients may experience sudden cardiac death as their initial presentation, often precipitated by sporting activities. Although the cardiac examination may be normal on presentation, some patients develop a left precordial bulge with a diffuse point of maximal impulse. An LV heave or an S_4 gallop may be present. If outflow tract obstruction exists, a systolic ejection murmur will be audible. A murmur may not be audible at rest but may be provoked with exercise or positional maneuvers that decrease left ventricular volume (standing), thereby increasing the outflow tract obstruction.

A. Echocardiography—The diagnosis of HCM is usually made by echocardiography and in most familial cases demonstrates asymmetrical septal hypertrophy. Young patients with metabolic or other nonfamilial causes are more likely to have concentric hypertrophy. Systolic anterior motion of the mitral valve leaflet may occur and contribute to LV outflow tract obstruction. The mitral valve leaflet may become distorted and result in mitral insufficiency. LV outflow tract obstruction may be present at rest or provoked with either amyl nitrate or monitored exercise. Systolic function is most often hypercontractile in young children but may deteriorate over time, resulting in poor contractility and LV dilation. Diastolic function is almost always abnormal.

B. Electrocardiography—The ECG may be normal, but more typically demonstrates deep Q waves in the inferolateral leads (II, III, aVF, V_5, and V_6) secondary to the increased mass of the hypertrophied septum. ST-segment abnormalities may be seen in the same leads. Age-dependent criteria for LVH are often present as are criteria for left atrial enlargement.

C. Other testing—Cardiopulmonary stress testing is valuable to evaluate for provocable LV outflow tract obstruction, ischemia, and arrhythmias, and to determine prognosis.

Extreme LVH and a blunted blood pressure response to exercise have both been associated with increased mortality in children. Cardiac MRI is useful for defining areas of myocardial fibrosis or scarring. Patients are at risk for myocardial ischemia, possibly as a result of systolic compression of the intramyocardial septal perforators, myocardial bridging of epicardial coronary arteries, or an imbalance of coronary artery supply and demand due to the presence of massive myocardial hypertrophy.

D. Cardiac catheterization—Cardiac catheterization is performed in patients with HCM who have angina, syncope, resuscitated sudden death, or a worrisome stress test. Hemodynamic findings include elevated left atrial pressure secondary to impaired diastolic filling. If midcavitary LV outflow tract obstruction is present, an associated pressure gradient will be evident. Provocation of LV outflow tract obstruction with either rapid atrial pacing or isoproterenol may be sought, but this is not commonly done in children. Angiography demonstrates a "ballerina slipper" configuration of the LV secondary to the midcavitary LV obliteration during systole. The myocardial biopsy specimen demonstrates myofiber disarray.

2. Treatment and prognosis—Treatment varies depending on symptoms and phenotype. Affected patients are restricted from competitive athletics and isometric exercise due to associated risk of sudden cardiac death. Patients with resting or latent LV outflow tract obstruction may be treated with β-blockers, verapamil, or disopyramide with variable success in alleviating obstruction. Patients with severe symptoms despite medical therapy and an LV outflow tract gradient may require additional intervention. Surgical myectomy with resection of part of the hypertrophied septum has been used in symptomatic patients with good results. At the time of myectomy, the mitral valve may require repair or replacement in patients with a long history of systolic anterior motion of the mitral valve. Ethanol ablation is used in adults with HCM and LV outflow tract obstruction. This procedure involves selective infiltration of ethanol in a coronary septal artery branch to induce a small targeted myocardial infarction. This leads to a reduction in septal size and improvement of obstruction. The long-term effects of this procedure are unknown and it is not commonly employed in children. Although dual-chamber pacing has been used in children with good relief of obstruction, larger series demonstrate no significant improvement in obstruction. Risk stratification with respect to sudden death is important in HCM. Consideration for placement of internal defibrillators in adult patients are based on the known risk factors for sudden cardiac death: severe hypertrophy (> 3 cm septal thickness in adults), documented ventricular arrhythmias, syncope, abnormal blood pressure response to exercise, resuscitated sudden death, or a strong family history of HCM with associated sudden death. The criteria for defibrillator placement in children are not as well defined.

B. Glycogen Storage Disease of the Heart

There are at least 10 types of glycogen storage disease. The type that primarily involves the heart is Pompe disease (GSD IIa) in which acid maltase, necessary for hydrolysis of the outer branches of glycogen, is absent. There is marked deposition of glycogen within the myocardium. Affected infants are well at birth, but symptoms of growth and developmental delay, feeding problems, and cardiac failure occur by the sixth month of life. Physical examination reveals generalized muscular weakness, a large tongue, and cardiomegaly without significant heart murmurs. Chest radiographs reveal cardiomegaly with or without pulmonary venous congestion. The ECG shows a short PR interval and LVH with ST depression and T-wave inversion over the left precordial leads. Echocardiography shows severe concentric LVH. Although historically children with Pompe disease usually died before age 1 year, recent enzyme replacement clinical trials have shown some promise in reversing hypertrophy and preserving cardiac function. Death may be sudden or result from progressive HF.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare entity in the pediatric population, accounting for less than 5% of all cases of cardiomyopathy. The cause is usually idiopathic but can be familial or secondary to an infiltrative process (eg, amyloidosis).

▶ Clinical Findings

Patients present with signs of congestive HF as a consequence of diastolic dysfunction in the setting of preserved systolic function. The left ventricle is more severely affected than the right ventricle in restrictive cardiomyopathy, but the right ventricle is also affected in most cases resulting in signs and symptoms consistent with biventricular congestion. Patients often present with exercise intolerance, fatigue, chest pain and orthopnea. Physical examination is remarkable for a prominent S_4 and jugular venous distention.

A. Electrocardiography

ECG demonstrates marked right and left atrial enlargement with normal ventricular voltages. ST-T–wave abnormalities including a prolonged QTc interval may be present.

B. Echocardiography

The diagnosis is confirmed echocardiographically by the presence of normal-sized ventricles with normal systolic function and massively dilated atria. Cardiac MRI is useful in ruling out pericardial abnormalities (restrictive or constrictive pericarditis) and infiltrative disorders.

▶ Treatment & Prognosis

Anticongestive therapy is used for symptomatic relief. The high risk of sudden death in restrictive cardiomyopathy

and the propensity for rapid progression of irreversible pulmonary hypertension warrant close follow-up with early consideration of cardiac transplantation.

Towbin JA et al: Incidence, causes, and outcomes of dilated cardiomyopathy in children. JAMA 2006 Oct 18;296(15): 1867–1876 [PMID: 17047217].

MYOCARDITIS

The most common causes of viral myocarditis are adenoviruses, coxsackie A and B viruses, echoviruses, parvovirus, cytomegalovirus, and influenza A virus. HIV can also cause myocarditis. The ability to identify the pathogen has been enhanced by PCR technology, which replicates identifiable segments of the viral genome from the myocardium of affected children.

▶ Clinical Findings

A. Symptoms and Signs

There are two major clinical patterns. In the first, sudden-onset HF occurs in an infant or child who was relatively healthy in the hours to days previously. This malignant form of the disease is usually secondary to overwhelming viremia with tissue invasion in multiple organ systems including the heart. In the second pattern, the onset of cardiac symptoms is gradual and there may be a history of upper respiratory tract infection or gastroenteritis in the previous month. This more insidious form may have a late postinfectious or autoimmune component. Acute and chronic presentations occur at any age and with all types of myocarditis.

The signs of HF are variable, but in a decompensated patient with fulminant myocarditis include pale gray skin; rapid, weak, and thready pulses; and breathlessness. In those with a more subacute presentation signs include increased work of breathing such as orthopnea, difficulty with feeding in infants, exercise intolerance and edema of the face and extremities. The patient is usually tachycardic and heart sounds may be muffled and distant; an S_3 or S_4 gallop (or both) are common. Murmurs are usually absent, although a murmur of tricuspid or mitral insufficiency may be heard.

Moist rales are usually present at both lung bases. The liver is enlarged and frequently tender.

B. Imaging

Generalized cardiomegaly is seen on radiographs along with moderate to marked pulmonary venous congestion.

C. Electrocardiography

The ECG is variable. Classically, there is low-voltage QRS in all frontal and precordial leads with ST-segment depression and inversion of T waves in leads I, III, and aVF (and in the left precordial leads during the acute stage). Dysrhythmias are common, and AV and intraventricular conduction disturbances may be present.

D. Echocardiography

Echocardiography demonstrates four-chamber dilation with poor ventricular function and AV valve regurgitation. A pericardial effusion may be present. Patients with a more acute presentation may have less ventricular dilation than those with a longer history of HF-related symptoms.

E. Myocardial Biopsy

An endomyocardial biopsy may be helpful in the diagnosis of viral myocarditis. An inflammatory infiltrate with myocyte damage can be seen by hematoxylin and eosin staining. Viral PCR testing of the biopsy specimen may yield a positive result in 30%–40% of patients suspected to have myocarditis. However, myocarditis is thought to be a "patchy" process, so it is possible that biopsy results are falsely negative if the area of active myocarditis was missed.

F. Cardiac MRI

Cardiac MRI is increasing in use as a potential diagnostic modality for myocarditis. Abnormalities in T2-weighted imaging (consistent with myocardial edema, inflammation) and global relative enhancement (evidence of capillary leak) are evident in patients with acute myocarditis. This imaging method requires general anesthesia in infants and young children, which is associated with significant risk in those with HF and must be a consideration when ordering this test.

▶ Treatment

The inpatient cardiac support measures outlined previously in the section on heart failure are used in the treatment of these patients. The use of digitalis in a rapidly deteriorating child with myocarditis is dangerous and should be undertaken with great caution, as it may cause ventricular dysrhythmias.

Administration of immunomodulating medications such as corticosteroids for myocarditis is controversial. If the patient's condition deteriorates despite anticongestive measures, corticosteroids are commonly used, although conclusive data supporting their effectiveness are lacking. Subsequent to the successful use of IVIG in children with Kawasaki disease, there have been several trials of IVIG in presumed viral myocarditis. The therapeutic value of IVIG remains unconfirmed. Initiation of mechanical circulatory support in those with fulminant or severe myocarditis is another therapeutic option as a bridge to transplantation or recovery.

▶ Prognosis

The prognosis of myocarditis is determined by the age at onset and the response to therapy. Children presenting with fulminant myocarditis and severe hemodynamic compromise have a 75% early mortality. Those at highest risk for a poor outcome are those presenting in the first year of life. Complete recovery is possible, although some patients recover clinically but have persistent LV dysfunction and require ongoing medical therapy for HF. It is possible that subclinical myocarditis in childhood is the pathophysiologic basis for some of the "idiopathic" DCMs later in life. Children with myocarditis whose ventricular function fails to return to normal may be candidates for cardiac transplantation if they remain symptomatic or suffer growth failure despite maximal medical management.

May LJ, Patton DJ, Fruitman DS: The evolving approach to paediatric myocarditis: A review of the current literature. Cardiol Young 2011 Jun;21(3):241–251 [Epub 2011 Jan 28] [PMID: 21272427].

▼ PREVENTIVE CARDIOLOGY

HYPERTENSION

Blood pressure should be determined at every pediatric visit beginning at 3 years. Because blood pressure is being more carefully monitored, systemic hypertension has become more widely recognized as a pediatric problem. Pediatric standards for blood pressure have been published. Blood pressures in children must be obtained when the child is relaxed and an appropriate-size cuff must always be used. The widest cuff that fits between the axilla and the antecubital fossa should be used (covers 60%–75% of the upper arm). Most children aged 10–11 years need a standard adult cuff (bladder width of 12 cm), and many high school students need a large adult cuff (width of 16 cm) or leg cuff (width of 18 cm). The pressure coinciding with the onset (K_1) and the loss (K_5) of the Korotkoff sounds determines the systolic and diastolic blood pressure, respectively. If a properly measured blood pressure exceeds the 95th percentile (Table 20-17), the measurement should be repeated several times over a 2- to 4-week interval. If it is elevated persistently, a search for the

cause should be undertaken. Although most hypertension in children is essential, the incidence of treatable causes is higher in children than in adults; these include conditions such as coarctation of the aorta, renal artery stenosis, chronic renal disease, and pheochromocytoma, as well as medication side effects (eg, steroids). If no cause is identified, and hypertension is deemed essential, antihypertensive therapy should be initiated and nutritional and exercise counseling given. β-Blockers or ACE inhibitors are the usual first-line medical therapies for essential hypertension in children.

Falkner B: Hypertension in children and adolescents: epidemiology and natural history. Pediatr Nephrol 2010 Jul;25(7):1219-1224 [PMID: 19421783].

ATHEROSCLEROSIS & DYSLIPIDEMIAS

Awareness of coronary artery risk factors in general, and atherosclerosis in particular, has risen dramatically in the general population since the mid-1970s. Although coronary artery disease is still the leading cause of death in the United States, the age-adjusted incidence of death from ischemic heart disease has been decreasing as a result of improved diet, decreased smoking, awareness and treatment of hypertension, and an increase in physical activity. The level of serum lipids in childhood usually remains constant through adolescence. Biochemical abnormalities in the lipid profile appearing early in childhood correlate with higher risk for coronary artery disease in adulthood. Low-density lipoprotein (LDL) is atherogenic, while its counterpart, high-density lipoprotein (HDL) has been identified as an anti-atherogenic factor.

Routine lipid screening of children at age 3 years remains controversial. The National Cholesterol Education Program recommends selective screening in children with high-risk family members, defined as a parent with total cholesterol greater than 240 mg/dL or a parent or grandparent with early-onset cardiovascular disease. When children have LDL levels greater than 130 mg/dL on two successive tests, dietary lifestyle counseling is appropriate. Dietary modification may decrease cholesterol levels by 5%–20%. If the patient is unresponsive to diet change and at extreme risk (eg, LDL > 160 mg/dL, HDL < 35 mg/dL, and a history of cardiovascular disease in a first-degree relative at an age < 40 years), drug therapy may be indicated. Cholestyramine, a bile acid–binding resin, is rarely used today due to poor adherence. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are more commonly used in the pediatric population. Niacin is useful for treatment of hypertriglyceridemia.

CHEST PAIN

Overview

Chest pain is a common pediatric complaint, accounting for 6 in 1000 visits to urban emergency departments and urgent care clinics. Although children with chest pain are commonly referred for cardiac evaluation, chest pain in children is rarely cardiac in origin. Other more likely causes of chest pain in children include reactive airways disease, musculoskeletal pain, esophagitis, gastritis, and functional pain.

Detailed history and physical examination should guide the pediatrician to the appropriate workup of chest pain. Rarely is there a need for laboratory tests or evaluation by a specialist. The duration, location, intensity, frequency, and

radiation of the pain should be documented, and possible triggering events preceding the pain should be explored. For instance, chest pain following exertion may lead to a more elaborate evaluation for a cardiac disorder. The timing of the pain in relation to meals may suggest a gastrointestinal cause. The patient should also be asked about how pain relief is achieved. A social history to reveal psychosocial stressors and cigarette smoke exposure may be revealing. On physical examination, attention must be placed on the vital signs; general appearance of the child; the chest wall musculature; cardiac, pulmonary, and abdominal examination findings; and quality of peripheral pulses. If the pain can be reproduced through direct palpation of the chest wall, it is almost always musculoskeletal in origin.

Etiology

Cardiac disease is a rare cause of chest pain, but, if misdiagnosed, it may be life-threatening. Although myocardial infarction rarely occurs in healthy children, patients with diabetes mellitus, chronic anemia, abnormal coronary artery anatomy, or HCM may be at increased risk for ischemia. A history of Kawasaki disease with coronary involvement is a risk for myocardial infarction secondary to thrombosis of coronary aneurysms. More than 50% of children and adolescents who exhibit sequelae from Kawasaki disease arrive at the emergency department with chest pain.

Young children may mistake palpitations for chest pain. Supraventricular tachycardia (SVT), atrial flutter, premature ventricular contractions (PVCs), or ventricular tachycardia may be described as chest pain in children. Structural lesions that can cause chest pain include aortic stenosis, pulmonary stenosis, and mitral valve prolapse. Other cardiac lesions causing chest pain include DCM, myocarditis, pericarditis, rheumatic carditis, and aortic dissection.

Noncardiac chest pain may be due to a respiratory illness, reactive airway disease, pneumonia, pneumothorax, or pulmonary embolism. Gastrointestinal causes of chest pain include reflux, esophagitis, and foreign body ingestion. The most common cause of chest pain (30% of children) is inflammation of musculoskeletal structures of the chest wall. Costochondritis is caused by inflammation of the costochondral joints and is usually unilateral and reproducible on examination.

In most cases, sophisticated testing is not required. However, if a cardiac origin is suspected, a pediatric cardiologist should be consulted. Evaluation in these instances may include an ECG, chest radiograph, echocardiogram, Holter monitor, or serum troponin levels if there are known risk factors for ischemia.

Hanson CL, Hokanson JS: Etiology of chest pain in children and adolescents referred to cardiology clinic. WMJ 2011 Apr;110(2):58–62 [PMID: 21560558].

CARDIAC TRANSPLANTATION

Cardiac transplantation is an effective therapeutic modality for infants and children with end-stage cardiac disease. Indications for transplantation include (1) progressive HF despite maximal medical therapy, (2) complex congenital heart diseases that are not amenable to surgical repair or palliation, or in instances in which the surgical palliative approach has an equal or higher risk of mortality compared with transplantation, and (3) malignant arrhythmias unresponsive to medical therapy, catheter ablation, or automatic implantable cardiodefibrillator. Approximately 300–400 pediatric cardiac transplant procedures are performed annually in the United States. Infant (< 1 year of age) transplants account for 30% of pediatric cardiac transplants. The current estimated graft half-life for children undergoing cardiac transplantation in infancy is over 19 years, while overall pediatric heart transplant graft half-life is approximately 14 years.

Careful evaluation of the recipient and the donor is performed prior to cardiac transplantation. Assessment of the recipient's pulmonary vascular resistance is critical, as irreversible and severe pulmonary hypertension is a risk factor for post-transplant right heart failure and early death. End-organ function of the recipient may also influence post-transplant outcome and should be evaluated closely. Donor-related factors that can have an impact on outcome include cardiac function, amount of inotropic support needed, active infection (HIV and hepatitis B and C are contraindications to donation), donor size, and ischemic time to transplantation.

Immunosuppression

The ideal post-transplant immunosuppressive regimen allows the immune system to continue to recognize and respond to foreign antigens in a productive manner while avoiding graft rejection. Although there are many different regimens, calcineurin inhibitors (eg, cyclosporine and tacrolimus) remain the mainstay of maintenance immunosuppression in pediatric heart transplantation. Calcineurin inhibitors may be used in isolation in children considered to be at low risk for graft rejection. Double-drug therapy includes the addition of antimetabolite or antiproliferative medications such as azathioprine, mycophenolate mofetil, or sirolimus. Because of the significant adverse side effects of corticosteroids in children, many centers attempt to avoid chronic steroid use. Growth retardation, susceptibility to infection, impaired wound healing, hypertension, diabetes, osteoporosis, and a cushingoid appearance are some of the consequences of long-term steroid use.

Graft Rejection

Despite advances in immunosuppression, graft rejection remains the leading cause of death in the first 3 years after transplantation. The pathophysiologic mechanisms of rejection

are not entirely known. T cells are required for rejection, but multiple cell lines and mechanisms are likely involved. Because graft rejection can present in the absence of clinical symptomatology, monitoring for and diagnosing rejection in a timely fashion can be difficult. Screening regimens include serial physical examinations, electrocardiography, echocardiography, and cardiac catheterization with endomyocardial biopsy.

▶ Rejection Surveillance

A. Symptoms and Signs

Acute graft rejection may not cause symptoms in the early stages. With progression, patients may develop tachycardia, tachypnea, rales, a gallop rhythm, or hepatosplenomegaly. Infants and young children may present with irritability, poor feeding, vomiting, or lethargy. There is 50% mortality within 1 year for those suffering an episode of rejection associated with hemodynamic compromise, so early detection is critical.

B. Imaging

In an actively rejecting patient, chest radiographs may show cardiomegaly, pulmonary edema, or pleural effusions.

C. Electrocardiography

Abnormalities in conduction can be present, although the most typical finding is reduced QRS voltages. Both atrial and ventricular arrhythmias can occur in rejection.

D. Echocardiography

Echocardiography is a noninvasive rejection surveillance tool that is especially useful in infant recipients, but helpful in all ages. Changes in ventricular compliance and function may initially be subtle, but are progressive with increasing duration of the rejection episode. A new pericardial effusion or worsening valvular insufficiency may also indicate rejection.

E. Cardiac Catheterization and Endomyocardial Biopsy

Hemodynamic assessment including ventricular filling pressures, cardiac output, and oxygen consumption can be obtained via cardiac catheterization. The endomyocardial biopsy is useful in diagnosing acute graft rejection. However, because not all episodes of symptomatic rejection result in a positive biopsy result, this tool is not universally reliable. The appearance of infiltrating lymphocytes with myocellular damage on the biopsy is the hallmark of cell-mediated graft rejection and is helpful if present.

▶ Treatment of Graft Rejection

The goal of graft rejection treatment is to reverse the immunologic inflammatory cascade. High-dose corticosteroids are the first line of treatment. Frequently additional therapy with antithymocyte biologic preparations such as antithymocyte globulin (a rabbit-based polyclonal antibody) is needed to reverse rejection. Most rejection episodes can be treated effectively if diagnosed promptly. Usually graft function returns to its baseline state, although severe rejection episodes can result in chronic graft failure, graft loss, and patient death even with optimal therapy. Antibody mediated rejection is another form of acute rejection that is treated in a similar fashion as T-cell mediated rejection, but the addition of plasmapheresis and IVIG to the treatment regimen may improve outcomes. The diagnosis of antibody mediated rejection varies across centers, but can be a combination of clinical findings consistent with rejection in the absence of evidence of cell-mediated rejection, evidence of complement deposition on endomyocardial biopsy and new or increasing antibody production (typically anti-human lymphocyte antigen [HLA] antibodies) in the circulation.

▶ Course & Prognosis

The quality of life of pediatric heart transplant recipients is usually quite good. The risk of infection is low after the immediate post-transplant period in spite of chronic immunosuppression. Cytomegalovirus is the most common pathogen responsible for infection-related morbidity and mortality in heart transplant recipients. Most children tolerate environmental pathogens well. Nonadherence with lifetime immunosuppression is of great concern especially in adolescent patients. Several recent studies have identified nonadherence as the leading cause of late death. Post-transplant lymphoproliferative disorder, a syndrome related to Epstein-Barr virus infection, can result in a Burkitt-like lymphoma that usually responds to a reduction in immunosuppression, but occasionally must be treated with chemotherapy and can be fatal. The overwhelming majority of children are not physically limited and do not require restrictions related to the cardiovascular system.

The greatest long-term concern after heart transplantation is related to cardiac allograft vasculopathy (transplant coronary artery disease). Cardiac allograft vasculopathy results from intimal proliferation within the lumen of the coronary arteries that can ultimately result in complete luminal occlusion. These lesions are diffuse and often involve distal vessels and thus are usually not amenable to bypass grafting, angioplasty, or stent placement. The etiology of these lesions has an immune basis, but the specifics are not known making targeted therapy challenging. Overall, despite the concerns of immunosuppression, the risk of late rejection, and coronary disease, the majority of pediatric patients enjoy a good quality of life with survival rates that are improving. Currently, 10-year survival is around 60% overall for pediatric recipients. Newer, more specific, and more effective immunosuppressive agents are currently

being tried in clinical studies or are being evaluated in pre-clinical studies, making the future promising for children after cardiac transplantation.

QUALITY IMPROVEMENT FOR PEDIATRIC HEART TRANSPLANTATION

The Pediatric Heart Transplant Study (PHTS) group is a consortium of over 40 pediatric heart transplant centers in North America and Europe that maintains an event-driven database that is used to support research aimed at improving treatment options and outcomes for children in need of a heart transplant or who have had a transplant. This group was established in 1993 and has published over 56 manuscripts in peer-reviewed journals. Each participating center receives an annual report that details center-specific outcomes compared to the collaborative group as a whole. This report is utilized for internal quality assurance purposes and as a performance benchmark.

PRIMARY PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Often subtle with symptoms of dyspnea, fatigue, chest pain, and syncope.

▶ Loud pulmonary component of S_2; ECG with RVH.

▶ Implies exclusion of secondary causes of pulmonary hypertension.

▶ Rare, progressive, and often fatal disease without treatment.

General Considerations

Unexplained or primary pulmonary hypertension (PPH) in children is a rare disease with an estimated overall incidence of 1–2 persons per million worldwide. Pulmonary hypertension is defined as a mean pulmonary pressure greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise. PPH is a diagnosis made after exclusion of all other causes of pulmonary hypertension. Secondary pulmonary hypertension is most commonly associated with congenital heart disease, pulmonary parenchymal disease, causes of chronic hypoxia (upper airway obstruction), thrombosis, liver disease, hemoglobinopathies, and collagen vascular disease. PPH is difficult to diagnose in the early stages because of its subtle manifestations. Most patients with PPH are young adult women, although the gender incidence is equal in children. Although the outcome for pediatric PPH is improving due to the advent of new therapies, prognosis remains guarded with only 72% survival at 5 years. Familial PPH occurs in 6%–12% of affected individuals. When a clear familial association is known, the disease shows evidence of genetic anticipation, presenting at younger ages in subsequent generations.

Clinical Findings

A. Symptoms and Signs

The clinical picture varies with the severity of pulmonary hypertension, and usually early symptoms are subtle, delaying the diagnosis. Initial symptoms may be dyspnea, palpitations, or chest pain, often brought on by strenuous exercise or competitive sports. Syncope may be the first symptom, which usually implies severe disease. As the disease progresses, patients have signs of low cardiac output and right heart failure. Right heart failure may be manifested by hepatomegaly, peripheral edema, and an S_3 gallop on examination. Murmurs of pulmonary regurgitation and tricuspid regurgitation may be present, and the pulmonary component of S_2 is usually pronounced.

B. Imaging

The chest radiograph most often reveals a prominent main pulmonary artery, and the RV may be enlarged. The peripheral pulmonary vascular markings may be normal or diminished. However, in 6% of patients with confirmed PPH, the chest radiograph is normal.

C. Electrocardiography

The ECG usually shows RVH with an upright T wave in V_1 (when it should be negative in young children) or a qR complex in lead V_1 or V_{3R}. Also present may be evidence of right axis deviation and right atrial enlargement.

D. Echocardiography

The echocardiogram is an essential tool for excluding congenital heart disease as a cause of pulmonary hypertension.

It frequently shows RVH and dilation. In the absence of other structural disease, any tricuspid and PI jets can be used to estimate pulmonary artery systolic and diastolic pressures, respectively. Other echocardiographic modalities such as myocardial performance index and input vascular impedance are in the early stages of use in evaluation of pulmonary hypertension.

E. Cardiac Catheterization and Angiocardiography

Cardiac catheterization is the best method for determining the severity of disease. As an invasive test, it carries with it associated risks and should be performed with caution. The procedure is performed to rule out cardiac (eg, restrictive cardiomyopathy) or vascular (eg, pulmonary vein stenosis) causes of pulmonary hypertension, determine the severity of disease, and define treatment strategies. The reactivity of the pulmonary vascular bed to short-acting vasodilator agents (oxygen, nitric oxide, or prostacyclin) can be assessed and used to determine treatment options. Angiography may show a decrease in the number of small pulmonary arteries with tortuous vessels.

F. Other Evaluation Modalities

Cardiac MRI is used in some patients to evaluate right ventricular function, pulmonary artery anatomy, and hemodynamics, as well as thromboembolic phenomena. Cardiopulmonary exercise testing using cycle ergometry correlates with disease severity. More simply, a 6-minute walk test, in which distance walked and perceived level of exertion are measured, has a strong independent association with mortality in late disease.

▶ Treatment

The goal of therapy is to reduce pulmonary artery pressure, increase cardiac output, and improve quality of life. Cardiac catheterization data are used to determine the proper treatment. Patients responsive to pulmonary vasodilators are given calcium channel blockers such as nifedipine or diltiazem. Patients unresponsive to vasodilators initially receive one of three classes of drugs: prostanoids (such as epoprostenol), endothelin receptor antagonists (such as bosentan), or phosphodiesterase-5 inhibitors (such as tadalafil). All of these agents have distinct mechanisms of action that can reduce pulmonary vascular resistance. Warfarin is commonly used for anticoagulation to prevent thromboembolic events, usually with a goal to maintain the INR between 1.5 and 2.0.

Atrial septostomy is indicated in some patients with refractory pulmonary hypertension and symptoms. Cardiac output falls as pulmonary vascular resistance rises, so an interatrial shunt can preserve left heart output, albeit with deoxygenated blood. Lung transplantation should be considered in patients with intractable pulmonary hypertension and in those with associated anatomic lesions that contribute to high pulmonary arterial pressure, like pulmonary vein stenosis. Heart-lung transplant procedures appear to have survival benefits over isolated lung transplantation in patients with pulmonary hypertension. Recurrence of pulmonary hypertension is rare after heart-lung transplant.

DISORDERS OF RATE & RHYTHM

Cardiac rhythm abnormalities can occur in two different patient populations: (1) healthy children with structurally normal hearts who have an intrinsic abnormality of the electrical conduction system; and (2) children with congenital heart disease who are at risk for a cardiac rhythm abnormalities based on the underlying heart defect itself. In the latter population, changes in cardiac muscle cells associated with a chronic state of altered cardiac hemodynamics and any operative procedures with surgical suture lines/scars place the patients at higher risk for certain types of arrhythmias.

The evaluation and treatment of cardiac rhythm disorders have advanced significantly over the last several decades. Arguably, the most significant advancements in the last few years have continued in the area of the genetic basis of rhythm disorders such as long QT syndrome which will be discussed at the end of the chapter. Treatment for cardiac rhythm abnormalities includes clinical monitoring with no intervention, antiarrhythmic medications, invasive electrophysiology study and ablation procedures, pacemakers, and internal cardioverter/defibrillators.

Deal BJ et al: Arrhythmic complications associated with the treatment of patients with congenital cardiac disease: consensus definitions from the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease. Cardiol Young 2008 Dec;18(Suppl 2):202–205.

▼ DISORDERS OF THE SINUS NODE

SINUS ARRHYTHMIA

Phasic variation in the heart rate (sinus arrhythmia) is normal. Typically, the sinus rate varies with the respiratory cycle (heart rate increases with inspiration and decreases with expiration), whereas P-QRS-T intervals remain stable. Sinus arrhythmia may occur in association with respiratory distress or increased intracranial pressure, or it may be present in normal children. In isolation, it never requires treatment; however, it may be associated with sinus node dysfunction or autonomic nervous system dysfunction.

SINUS BRADYCARDIA

Sinus bradycardia is defined as a heart rate below the normal limit for age (neonates to 6 years, 60 beats/min; 7–11 years, 45 beats/min; > 12 years, 40 beats/min). Sinus bradycardia is often seen in athletic children. Causes of sinus bradycardia include hypoxia, central nervous system damage, eating disorders, and medication side effects. Symptomatic bradycardia (syncope, low cardiac output, or exercise intolerance) requires treatment (atropine, isoproterenol, or cardiac pacing).

SINUS TACHYCARDIA

The heart rate normally accelerates in response to stress such as exercise, anxiety, fever, hypovolemia, anemia, or HF. Although sinus tachycardia in the normal heart is well tolerated, symptomatic tachycardia with decreased cardiac output warrants evaluation for structural heart disease, cardiomyopathy or true tachyarrhythmias. The first evaluation should be made with a 12-lead ECG (not a one lead rhythm strip) to determine the precise mechanism of the rapid rate. Treatment may be indicated for correction of the underlying cause of sinus tachycardia (eg, transfusion for anemia or correction of hypovolemia or fever).

SINUS NODE DYSFUNCTION

Sinus node dysfunction is a clinical syndrome of inappropriate sinus nodal function and rate. The abnormality may be a true anatomic defect of the sinus node or its surrounding tissue, or it may be an abnormality of autonomic input. It is defined as one or more of the following: severe sinus bradycardia, marked sinus arrhythmia, sinus pause or arrest, chronotropic incompetence (inability of the heart rate to increase with activity or other demands), or combined bradyarrhythmias and tachyarrhythmias. It is usually associated with postoperative repair of congenital heart disease (most commonly the Mustard or Senning repair for complete TGA or the Fontan procedure), but it is also seen in normal hearts, in unoperated congenital heart disease, and in acquired heart diseases. Symptoms usually manifest between ages 2 and 17 years and consist of episodes of presyncope, syncope, palpitations, pallor, or exercise intolerance.

The evaluation of sinus node dysfunction may involve the following: baseline ECG, 24-hour ambulatory ECG monitoring, exercise stress test, and transient event monitoring. Treatment for sinus node dysfunction is indicated only in symptomatic patients. Bradyarrhythmias are treated with vagolytic (atropine) or adrenergic (aminophylline) agents or permanent cardiac pacemakers.

PREMATURE BEATS

Atrial Premature Beats

Atrial premature beats are triggered by an ectopic focus in the atrium. They are one of the most common premature beats occurring in pediatric patients, particularly during the fetal and newborn periods. The premature beat may be conducted to the ventricle and therefore followed by a QRS complex or it may be nonconducted, as the beat has occurred so early that the AV node is still refractory (Figure 20–4). A brief pause usually occurs until the next normal sinus beat occurs. As an isolated finding, atrial premature beats are benign and require no treatment.

Junctional Premature Beats

Junctional premature beats arise in the atrioventricular node or the bundle of His. They induce a normal QRS complex with no preceding P wave. Junctional premature beats are usually benign and require no specific therapy.

Ventricular Premature Beats

Ventricular premature beats are sometimes referred to as premature ventricular contractions (PVC) or as ventricular ectopy. They are relatively common, occurring in 1%–2% of patients with normal hearts. They are characterized by an early beat with a wide QRS complex, without a preceding P wave, and with a full compensatory pause following this early beat (Figure 20–5).

Ventricular premature beats originating from a single ectopic focus all have the same configuration; those of multifocal origin show varying configurations. The consecutive occurrence of two ventricular premature beats is referred to as a ventricular couplet and of three or more as ventricular tachycardia. Most ventricular premature beats in otherwise normal patients are usually benign. However, patients with frequent PVCs are usually evaluated further with tests such as a 24-hour ambulatory ECG or with exercise testing to rule out concerning arrhythmias. An echocardiogram may be performed to evaluate ventricular function. The significance of ventricular premature beats can be confirmed by having the patient exercise. As the heart rate increases, benign ventricular premature beats usually disappear. If exercise results in an increase or coupling of contractions, underlying disease may be present. Multifocal ventricular premature beats are always abnormal and may be more dangerous. They may be associated with drug overdose (tricyclic antidepressants or digoxin toxicity), electrolyte imbalance, myocarditis, or hypoxia. Treatment is directed at correcting the underlying disorder.

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT) is a term used to describe any rapid rhythm originating from the atrium, the atrioventricular node, or an accessory pathway. These tachycardias are rapid, narrow complex tachycardias. The mode of presentation depends on the heart rate, the presence of underlying cardiac structural or functional abnormalities, coexisting illness, and patient age. An otherwise healthy
▲ **Figure 20–4.** Lead II rhythm strip with premature atrial contractions. Beats 1, 3, 7, and 8 are conducted to the ventricles, whereas beats 2, 4, 5, and 6 are not.

child with SVT may complain of intermittent periods of rapid heartbeat. An infant with SVT may have poor feeding and increased fatigue (manifesting as less awake time). Incessant tachycardia, even if fairly slow (120–150 beats/min), may cause myocardial dysfunction and HF if left untreated. In children with preexisting HF or an underlying systemic disease such as anemia or sepsis, SVT may result in decreased heart function and further signs of hemodynamic instability much more rapidly than in a healthy child.

The mechanisms of tachycardia are generally divided into reentrant and automatic mechanisms and can be described by the location of tachycardia origination (Table 20–18).

Reentrant tachycardias represent approximately 80% of pediatric arrhythmias. Reentrant tachycardias have the following characteristics: they initiate abruptly, they have a fixed rate, they have little variation with fever or internal catecholamines, and they terminate abruptly. They can be terminated to sinus rhythm with maneuvers such as vagal maneuvers, administration of adenosine, pacing maneuvers, or DC cardioversion. (For vagal maneuvers or adenosine, the atrioventricular node must be part of the reentrant circuit.)

Reentrant tachycardia mechanisms involve two connections where electrical conduction travels down one of the pathways and then backs up the other, creating a sustained repetitive circular loop. The circuit can be confined to the atrium (*atrial flutter* in a normal heart or *intra-atrial reentrant tachycardia* in a patient with congenital heart disease) (Figure 20–6). It may be confined within the AV node (*AV nodal reentrant tachycardia*), or it may encompass an accessory connection between atria and ventricle (*accessory pathway–mediated tachycardia*). If, during tachycardia, the electrical impulse travels antegrade (from atria to ventricles) through the AV node and retrograde (from ventricle to atria) back up the accessory pathway, orthodromic reciprocating tachycardia is present. If, instead, the impulse travels antegrade through the accessory pathway and retrograde up through the AV node, antidromic reciprocating tachycardia is present. This latter tachycardia would present as a wide complex tachycardia. *Wolff-Parkinson-White* (WPW) *syndrome* is a subclass of reentrant tachycardia in which, during sinus rhythm, the impulse travels antegrade down the accessory connection, bypassing the AV node and
▲ **Figure 20–5.** Lead V$_5$ rhythm strip with unifocal premature ventricular contractions in a bigeminy pattern. The arrow shows a ventricular couplet.

creating ventricular preexcitation (early eccentric activation of the ventricle with a short PR interval and slurred upstroke of the QRS, a delta wave) (Figure 20–7). Most patients with WPW have otherwise structurally normal hearts. However, WPW has been noted to occur with increased frequency in association with the following congenital cardiac lesions: tricuspid atresia, Ebstein anomaly of the tricuspid valve, HCM, and ccTGA. Different than other causes of tachycardias described above where the arrhythmia is not life-threatening, there have been rare cases of sudden collapse from WPW syndrome. The mechanism of this sudden event is the development of atrial fibrillation, conducting down a rapid accessory pathway to the ventricle leading to ventricular fibrillation and sudden death. For this reason, most centers recommend that even asymptomatic patients undergo an invasive procedure to assess the conduction properties of the WPW accessory pathway (described under treatment for tachyarrhythmias).

Improved surgical survival for patients with congenital heart disease has created a new, increasingly prevalent, chronic arrhythmia which is similar to atrial flutter in a normal heart structure. These arrhythmias have been referred to by many names: intra-atrial reentrant tachycardia, incisional tachycardia, macroreentry, or postoperative atrial flutter. In this tachycardia, electrically isolated corridors of atrial myocardium (eg, the tricuspid valve–inferior vena cava isthmus, or the region between an atrial incision and the crista terminalis) act as pathways for sustained reentrant circuits of electrical activity. These tachycardias are chronic, medically refractory, and clinically incapacitating.

The *automatic tachycardias* represent approximately 20% of childhood arrhythmias. The characteristics of these types of arrhythmias include gradual onset, rate variability, variations in rate with fever or increasing internal catecholamines, and gradual offset. Maneuvers such as vagal maneuvers, adenosine, and attempt pacing can alter the rhythm temporarily but they do not result in termination of the rhythm to sinus rhythm as would be seen in the reentrant tachycardias. Automatic tachycardias can be episodic or incessant. They are usually under autonomic influence.

Table 20–18. Mechanism of supraventricular tachycardia.

Site of Origination	Automatic Mechanisms	Reentrant Mechanisms
Sinus node	Sinus tachycardia	Sinoatrial node reentry
Atrium	Ectopic atrial tachycardia Multifocal atrial tachycardia	Atrial flutter Intra-atrial reentrant tachycardia Atrial fibrillation
Atrioventricular node	Junctional ectopic tachycardia	Atrioventricular nodal reentrant tachycardia (AVNRT)
Accessory pathways		Concealed accessory pathways Wolff-Parkinson-White (WPW) syndrome
		Permanent form of junctional reciprocating tachycardia (PJRT) Mahaim fiber tachycardia
▲ **Figure 20–6.** Leads aVF (F) and V$_1$, showing atrial flutter with "sawtooth" atrial flutter waves.
▲ **Figure 20–7.** Leads I and II with spontaneous intermittent ventricular preexcitation (Wolff-Parkinson-White syndrome).

When they are incessant, they are usually associated with HF and a clinical picture of DCM. Automatic tachycardias are created when a focus of cardiac tissue develops an abnormally fast spontaneous rate of depolarization. For ectopic atrial tachycardia, the ECG demonstrates a normal QRS complex preceded by an abnormal P wave (Figure 20–8). Junctional ectopic tachycardia does not have a P wave preceding the QRS waves and may be associated with AV dissociation or 1:1 retrograde conduction.

Cohen MI et al: PACES/HRS expert consensus statement on the management of the asymptomatic young patient with a Wolff-Parkinson-White (WPW, ventricular preexcitation) electrocardiographic pattern: developed in partnership between the Pediatric and Congenital Electrophysiology Society (PACES) and the Heart Rhythm Society (HRS). Heart Rhythm 2012;9(6):1006–1024 [PMID: 22579340].

▶ Clinical Findings

A. Symptoms and Signs

Presentation varies with age. Infants tend to turn pale and mottled with onset of tachycardia and may become irritable. With long duration of tachycardia, symptoms of HF develop. Older children complain of dizziness, palpitations, fatigue, and chest pain. Heart rates range from 240–300 beats/min in the younger child to 150–180 beats/min in the teenager. HF is less common in children than in infants. Tachycardia may be associated with either congenital heart defects or acquired conditions such as cardiomyopathies and myocarditis.

B. Imaging

Chest radiographs are normal during the early course of tachycardia and therefore are usually not obtained. If HF is present, the heart is enlarged and pulmonary venous congestion is evident.

C. Electrocardiography

ECG is the most important tool in the diagnosis of SVT and to define the precise tachycardia mechanism. Findings include a heart rate that is rapid and out of proportion to the patient's physical status (eg, a rate of 140 beats/min with an abnormal P wave while quiet and asleep). For reentrant mechanisms, the rhythm would be extremely regular with little variability. For automatic mechanisms, the rhythm would be irregular with a gradual increasing and decreasing of

▲ **Figure 20–8.** Lead II rhythm strip of ectopic atrial tachycardia. The tracing demonstrates a variable rate with a maximum of 260 beats/min, an abnormal P wave, and a gradual termination.

the rate. The QRS complex is usually the same as during normal sinus rhythm. However, the QRS complex is occasionally widened (SVT with aberrant ventricular conduction), in which case the condition may be difficult to differentiate from ventricular tachycardia. The presence of P waves and their association with the QRS are important in determining tachycardia mechanism. With automatic tachycardias, there is often a 1:1 or 2:1 A:V relationship with P waves preceding the QRS. With reentrant tachycardias, such as accessory pathway–mediated tachycardias, a small retrograde P wave can often be seen just after the QRS. With atrioventricular nodal reentrant tachycardia, P waves cannot be identified as they are occurring at the same time as the QRS.

▶ **Treatment**

A. Acute Treatment

During the initial episodes of SVT, patients require close monitoring. Correction of acidosis and electrolyte abnormalities is also indicated. The following acute treatments are effective in terminating tachycardia only for patients with reentrant SVT. Acute treatment for automatic SVT is aimed at rate control, usually with a β-blocker.

1. Vagal maneuvers—The "diving reflex" produced by placing an ice bag on the nasal bridge for 20 seconds (for infants) or by immersing the face in ice water (for children or adolescents) will increase parasympathetic tone and terminate some tachycardias. The Valsalva maneuver, which

can be performed by older compliant children, may also terminate reentrant tachycardias.

2. Adenosine—Adenosine transiently blocks AV conduction and terminates tachycardias that incorporate the AV node or may aid in the diagnosis of arrhythmias confined to the atrium by causing a pause in ventricular conduction, so one can identify the presence of multiple P waves. The dose is 100–250 mcg/kg by rapid intravenous bolus. It is antagonized by aminophylline and should be used with caution in patients with sinus node dysfunction or asthma.

3. Transesophageal atrial pacing—Atrial overdrive pacing and termination can be performed from a bipolar electrode-tipped catheter positioned in the esophagus adjacent to the left atrium. Overdrive pacing at rates approximately 30% faster than the tachycardia rate will interrupt a reentrant tachycardia circuit and restore sinus rhythm.

4. Direct current cardioversion—Direct current cardioversion (0.5–2 synchronized J/kg) should be used immediately when a patient presents in cardiovascular collapse. This will convert a reentrant mechanism to sinus. Automatic tachycardia will not respond to cardioversion.

B. Chronic Treatment

Once the patient has been diagnosed with SVT and the mechanism has been evaluated, then long-term treatment options can be considered. Options include monitoring clinically for tachycardia recurrences, medical management

with antiarrhythmic medications, or an invasive electrophysiology study and ablation procedure. In infancy and early childhood, antiarrhythmic medications are the mainstay of therapy. Medications such as digoxin and β-blockers are the first-line therapies. Other antiarrhythmic medications (eg, verapamil, flecainide, propafenone, sotalol, and amiodarone) have increased pharmacologic actions and are extremely effective. However, these medications also have serious side effects, including induction of arrhythmias and sudden death, and should be used only under the direction of a pediatric cardiologist.

Tachycardias, both automatic and reentrant, can be more definitively addressed with an invasive electrophysiology study and ablation procedure. This is a nonsurgical transvascular catheter technique that desiccates an arrhythmia focus or accessory pathway and permanently cures an arrhythmia. The ablation catheters can utilize either a heat source (radiofrequency) or a cool source (cryoablation). The latter has been reported to be safer around the normal conduction pathway and thus decreases the risk of inadvertent atrioventricular block. The success rate from an ablation procedure in a patient with a normal heart structure is > 90%, with a recurrence risk of < 10%. The procedure can be performed in infants or adults. In children younger than age 4 years, the risks of procedural complications or failed ablation are potentially higher, and the procedure should be reserved for those whose arrhythmias are refractory to medical management. The high success rate, low complication and low recurrence rates, in addition to the elimination of the need for chronic antiarrhythmic medications have made ablation procedures the primary treatment option in most pediatric cardiovascular centers. In patients with congenital heart disease, electrophysiology study and ablation procedures are also utilized to address arrhythmia substrates. The success rate of these procedures is lower than in patients with a normal heart structure, often reported in the 75%–80% range.

▶ **Prognosis**

SVT in infants and children generally carries an excellent prognosis. It can be treated with medical management or with the potentially curative ablation procedures. There are, however, rare cases of incessant SVT leading to HF and there is reported sudden collapse from atrial fibrillation in the presence of WPW. All patients with complaints of rapid heartbeats or other symptoms where there is a concern for tachyarrhythmia should be referred for evaluation.

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is uncommon in childhood (Figure 20–9). It is usually associated with underlying abnormalities of the myocardium (myocarditis, cardiomyopathy, myocardial tumors, or postoperative congenital heart disease) or toxicity (hypoxia, electrolyte imbalance, or drug toxicity). On occasion, it can be secondary to a primary electrical abnormality in an otherwise normal heart. Sustained ventricular tachycardia can be an unstable situation,
▲ **Figure 20–9.** Twelve-lead ECG from a child with imipramine toxicity and ventricular tachycardia.

and, if left untreated, it could degenerate into ventricular fibrillation and sudden collapse.

Ventricular tachycardia must be differentiated from accelerated idioventricular rhythm. The latter is a sustained ventricular tachycardia occurring in neonates with normal hearts, with a ventricular tachycardia rate within 10% of the preceding sinus rate. This is a self-limiting arrhythmia that requires no treatment. Because of the consequences of sustained ventricular tachycardia, however, a symptomatic patient with a wide complex tachycardia should be considered to have ventricular tachycardia (not an accelerated idioventricular rhythm) until proven otherwise.

Acute termination of ventricular tachycardia involves restoration of the normal myocardium when possible (correction of electrolyte imbalance, drug toxicity, etc) and direct current cardioversion (1–4 J/kg), cardioversion with lidocaine (1 mg/kg), or with amiodarone (5 mg/kg load). Chronic suppression of ventricular arrhythmias with antiarrhythmic drugs has many side effects (including proarrhythmia and death), and it must be initiated in the hospital under the direction of a pediatric cardiologist. If the etiology of the tachycardia is a primary electrical abnormality, then catheter ablation procedures can be offered in select patients as a potentially curative treatment option. Ablation for ventricular tachycardia in the pediatric population is much less commonly performed compared to ablation for SVT.

LONG QT SYNDROME

Long QT syndrome is a malignant disorder of cardiac conduction where cardiac repolarization is prolonged (QTc measurement on ECG) and this predisposes the patient to sudden episodes of syncope, seizures, or sudden death (5% per year if untreated). The mechanism is a pause-dependent initiation of torsades de pointes, a multifocal ventricular tachycardia. It can be congenital or acquired. Congenital long QT syndrome is inherited in an autosomal dominant (more common) or recessive pattern or it may occur spontaneously (less likely). The recessive inheritance pattern is associated with congenital deafness and the Jervell and Lange-Nielsen syndrome. Congenital long QT syndrome is caused by a defect in one of several genes that code for ion channels in cardiac myocytes. As many as 10 genes have been identified and these defects explain 75% of the patient population with symptoms and signs consistent with long QT. The diagnosis of long QT syndrome is suspected in a patient or a family with a history of sudden syncope, seizures, documented

dysrrhythmia, or cardiac arrest. Evaluation includes an ECG which shows a long QTc measurement, 24-hour ambulatory ECG, and possibly an exercise test. There is a commercially available genetic test for the primary genes which cause long QT syndrome. This test is most helpful in determining who in a family has long QT syndrome. Unfortunately, this test cannot completely rule it out as there continues to be a 25% false negative rate.

The mainstay of treatment for long QT syndrome has been exercise restriction, treatment with β-blockade, and possibly the placement of an internal cardioverter/defibrillator. Within the next several years, more gene-specific therapies are anticipated to be developed.

Long QT syndrome can also be acquired, resulting from altered ventricular repolarization secondary to myocardial toxins, ischemia, or inflammation. This condition also predisposes a patient to ventricular arrhythmias. Numerous medications can also cause QT prolongation.

SUDDEN DEATH

Everyone in a family, school, and community are affected when an otherwise healthy child dies suddenly and unexpectedly. There are several cardiac causes of sudden death. Long QT syndrome and HCM are two of the most common cause of sudden death in young athletes. Other causes include dilated or restrictive cardiomyopathies, arrhythmogenic RV dysplasia, congenital structural anomalies of the coronary arteries, and primary arrhythmias such as catecholamine sensitive ventricular tachycardia or Brugada syndrome. Many of these causes are genetic and thus family members of the patient may also be unknowingly affected. Arrhythmias in patients with postoperative congenital heart disease are important causes of morbidity and mortality and may present as sudden death events.

Because of the genetic nature of some of the causes of sudden death, it is necessary to conduct a detailed family history looking for seizures, syncope, or early sudden death. Family members should be examined with an arrhythmia screen consisting of a physical examination, ECG, and echocardiography to detect arrhythmias or cardiomyopathies.

▼ DISORDERS OF ATRIOVENTRICULAR CONDUCTION

▶ General Considerations

The atrioventricular node is the electrical connection between the atrium and the ventricles. Atrioventricular blocks involve a slowing or disruption of this connection and are described according to the degree of this slowing or disruption. The term "heart block" has been utilized, although "atrioventricular block" is more precise.

First-Degree Atrioventricular Block

First-degree atrioventricular block is an ECG diagnosis of prolongation of the PR interval. The block does not, in itself, cause problems. It may be associated with structural congenital heart defects, namely AV septal defects and ccTGA, and with diseases such as rheumatic carditis. The PR interval is prolonged in patients receiving digoxin therapy.

Second-Degree Atrioventricular Block

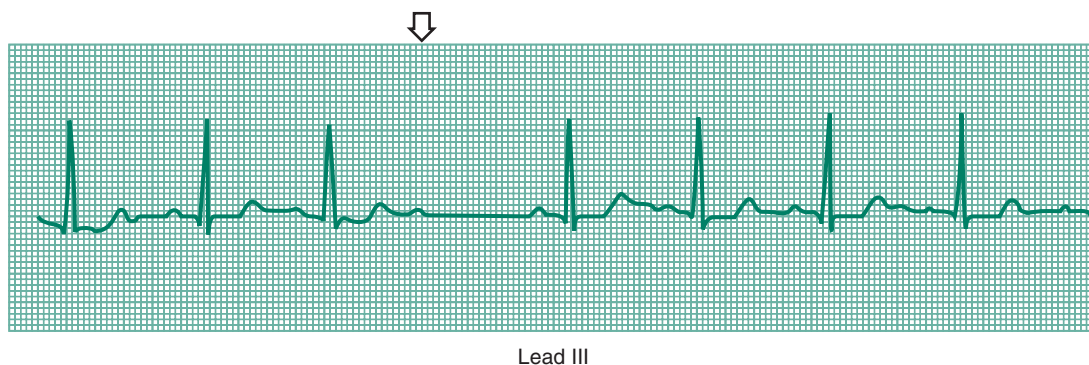
Mobitz type I (Wenckebach) atrioventricular block is recognized by progressive prolongation of the PR interval until there is no QRS following a P wave (Figure 20–10). Mobitz type I block occurs in normal hearts at rest and is usually benign. In Mobitz type II block, there is no progressive lengthening of the PR interval before the dropped beat (Figure 20–11). Mobitz type II block is frequently associated with organic heart disease, and a complete evaluation is necessary.

Complete Atrioventricular Block

In complete atrioventricular block, the atria and ventricles beat independently. Ventricular rates can range from 40 to 80 beats/min, whereas atrial rates are faster (Figure 20–12). The most common form of complete atrioventricular block is congenital complete atrioventricular block which occurs in a fetus or infant with an otherwise normal heart. There is a very high association with maternal systemic lupus erythematosus antibodies and therefore it is recommended to screen the mother of an affected infant even if the mother has no symptoms of collagen vascular disease. Congenital complete atrioventricular block is also associated with some forms of congenital heart disease (congenitally corrected transposition of the great vessels and AV septal defect). Acquired complete atrioventricular block may be secondary to acute myocarditis, drug toxicity, electrolyte imbalance, hypoxia, and cardiac surgery.

▶ Clinical Findings

The primary finding in infants and children with complete atrioventricular block is a significantly low heart rate for age. The diagnosis is often made prenatally when fetal bradycardia is documented. An ultrasound is then conducted as well as a fetal echocardiogram of the heart. With the fetal echocardiogram, atrial and ventricular contractions can be distinguished and the atrial rate is documented as being higher than the ventricular rate with no relationship to each other. If the heart rates are sufficiently low, then there will be low cardiac output, decreased cardiac function, and the
Lead I

▲ **Figure 20–10.** Lead I rhythm strip with Mobitz type I (Wenckebach) second-degree heart block. There is progressive lengthening of the PR interval prior to the nonconducted P wave (*arrows*).


Lead III

▲ **Figure 20–11.** Lead III rhythm strip with Mobitz type II second-degree heart block. There is a consistent PR interval with occasional loss of AV conduction (*arrow*).
▲ **Figure 20–12.** Twelve-lead ECG and lead II rhythm strip of complete heart block. The atrial rate is 150 beats/min, and the ventricular rate is 60 beats/min.

development of hydrops fetalis. Postnatal adaptation largely depends on the heart rate; infants with heart rates less than 55 beats/min are at significantly greater risk for low cardiac output, HF, and death. Wide QRS complexes and a rapid atrial rate are also poor prognostic signs. Most patients have an innocent flow murmur from increased stroke volume. In symptomatic patients, the heart can be quite enlarged, and pulmonary edema may be present.

Complete atrioventricular block can also occur in older patients. Patients may be asymptomatic or may present with presyncope, syncope, or fatigue. Complete cardiac

evaluation, including ECG, echocardiography, and Holter monitoring, is necessary to assess the patient for ventricular dysfunction and to relate any symptoms to concurrent arrhythmias.

▶ **Treatment**

When diagnosis of complete atrioventricular block is made in a fetus, the treatment depends on gestational age, ventricular rate, and the presence or absence of hydrops. Some centers have advocated the administration of steroids, intravenous immune globulin (IVIG), and/or β-adrenergic stimulation

treatment of the mother in some instances (fetuses that have associated heart failure). Emergent delivery is sometimes warranted. Postnatal treatment for neonates or older patients who present with significant symptoms and require immediate intervention includes temporary support by the infusions of isoproterenol, temporary transvenous pacing wires, or by temporary transcutaneous pacemakers if needed. The relationship of complete congenital atrioventricular block to auto-antibody production and cardiomyopathy is the basis for the consideration of immune modulation with steroids and IVIG in neonates in addition to their mothers. Long-term treatment involves the placement of a permanent pacemaker.

SYNCOPE (FAINTING)

Syncope is a sudden transient loss of consciousness that resolves spontaneously. The common form of syncope (simple fainting) occurs in 15% of children and is a disorder of control of heart rate and blood pressure by the autonomic nervous system that causes hypotension or bradycardia. It is often associated with rapid rising and postural hypotension, prolonged standing, or hypovolemia. Patients exhibit vagal symptoms such as pallor, nausea, or diaphoresis. Syncope, also known as autonomic dysfunction, can be evaluated with head-up tilt table testing. The patient is placed supine on a tilt table, and then—under constant heart rate and blood pressure monitoring—is tilted to the upright position. If symptoms develop, they can be classified as vasodepressor (hypotension), cardioinhibitory (bradycardia), or mixed.

Syncope is usually self-limited (can recur over approximately 6 months to 2 years) and can be controlled with dietary salt and volume loading to prevent hypovolemia. In refractory cases, medications to manipulate the autonomic nervous system have been useful. Fludrocortisone (0.1 mg/kg/d) is a mineralocorticoid that causes renal salt resorption and thus increases intravascular volume. Although β-blockers have been used for treatment of syncope, there is a paucity of data regarding their effectiveness. Vagolytic agents (disopyramide, 2.5 mg/kg four times daily) help control hypervagotonia, and the selective serotonin reuptake inhibitors have also been effective in alleviating symptoms. Syncope that occurs during exercise or stress or is associated with a positive family history is a warning sign that a serious underlying dysrhythmia may be present, calling for further investigation.

▼ DISORDERS OF THE ESOPHAGUS

GASTROESOPHAGEAL REFLUX & GERD

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Uncomplicated gastroesophageal reflux (GER) refers to recurrent postprandial spitting and vomiting in healthy infants that resolves spontaneously.

▶ Gastroesophageal reflux disease (GERD) is present when reflux causes secondary symptoms or complications.

▶ Esophageal manifestations of GERD include symptoms (heartburn, regurgitation) and mucosal complications (esophagitis, stricture, Barrett esophagus).

▶ GERD has been implicated in pathogenesis of many extraesophageal symptoms, including upper and lower airway findings. In most settings, objective confirmation of extraesophageal reflux complications is challenging.

▶ Upper gastrointestinal (GI) radiograph is useful to rule out other anatomical GI diseases, but it should not be considered an evaluation for reflux or reflux disease.

▶ Clinical Findings

A. Infants With Gastroesophageal Reflux

Gastroesophageal (GE) reflux is common in young infants and is a physiological event. Frequent postprandial regurgitation, ranging from effortless to forceful, is the most common infant symptom. Infant GER is usually benign, and it is expected to resolve by 12–18 months of life.

Reflux of gastric contents into the esophagus occurs during spontaneous relaxations of the lower esophageal sphincter that are unaccompanied by swallowing. Low pressures in the lower esophageal sphincter or developmental immaturity of the sphincter are not causes of GER in infants. Factors promoting reflux in infants include small stomach capacity, frequent large-volume feedings, short esophageal length, supine positioning, and slow swallowing response to the flow of refluxed material up the esophagus. Infants' individual responses to the stimulus of reflux, particularly the maturity of their self-settling skills, are important factors determining the severity of reflux-related symptoms.

An important point in evaluating infants with GER is to determine whether the vomited material contains bile. Bile-stained emesis in an infant requires immediate evaluation as it may be a symptom of intestinal obstruction (malrotation with volvulus, intussusception).

Other symptoms may be associated with GERD in infants, although these situations are far less common than benign, physiologic GER. These clinical presentations include failure to thrive, food refusal, pain behavior, GI bleeding, upper or lower airway-associated respiratory symptoms, or Sandifer syndrome.

B. Older Children With Reflux

GERD is diagnosed when reflux causes persistent symptoms with or without inflammation of the esophagus. Older children with GERD complain of adult-type symptoms of regurgitation into the mouth, heartburn, and dysphagia. Esophagitis can occur as a complication of GERD and requires endoscopy with biopsy for diagnostic confirmation. Children with asthma, cystic fibrosis, developmental handicaps, hiatal hernia, and repaired tracheoesophageal fistula are at increased risk of GERD and esophagitis.

C. Extraesophageal Manifestations of Reflux Disease

GERD is implicated in the pathogenesis of several disorders unrelated to inherent esophageal mucosal injury. In infants, GERD has been linked to the occurrence of apnea or apparent

life-threatening events (ALTEs), although the majority of pathologic cases are not reflux associated. Upper airway symptoms (hoarseness, sinusitis, laryngeal erythema, and edema), lower airway symptoms (asthma, recurrent pneumonia, recurrent cough), dental erosions, and Sandifer syndrome have all been linked to GERD, although proof of cause-and-effect relationship in many clinical circumstances can be challenging.

D. Diagnostic Studies

History and physical examination alone should help differentiate infants with benign, recurrent vomiting (physiologic GER) from those who have red flags for GERD or other underlying primary conditions that may present with recurrent emesis at this age. Warning signs that warrant further investigation in the infant with recurrent vomiting include bilious emesis, GI bleeding, onset of vomiting after 6 months, failure to thrive, diarrhea, fever, hepatosplenomegaly, abdominal tenderness or distension, or neurologic changes. Infants with suspected physiologic GER do not require further evaluations unless there is clinical concern for complicated GERD or nonreflux diagnoses.

An upper GI series should be considered when anatomic etiologies of recurrent vomiting are considered, but should not be considered to be a test for GERD.

In older children with heartburn or frequent regurgitation, a trial of acid-suppressant therapy may be both diagnostic and therapeutic. If a child has symptoms requiring ongoing acid suppressant therapy, or if symptoms fail to improve with empiric therapy, consider referral to a pediatric gastroenterologist to assist in evaluation for complicated GERD, or nonreflux diagnoses including eosinophilic esophagitis (EoE).

Esophagoscopy and mucosal biopsies are useful to evaluate for mucosal injury secondary to GERD (Barrett esophagus, stricture, erosive esophagitis), or to evaluate for nonreflux diagnoses that present with reflux-like symptoms, including EoE. Endoscopic evaluation is not requisite for the evaluation of all infants and children with suspected GERD.

Intraluminal esophageal pH monitoring (pH probe) and combined multiple intraluminal impedance and pH monitoring (pH impedance probe) are indicated to quantify reflux, and to evaluate for objective evidence of symptom associations with regards to atypical reflux presentations. pH probe studies quantify esophageal acid exposure, and pH impedance studies also add detection of bolus fluid transit, including both acidic and nonacidic reflux. pH impedance studies in particular may have higher diagnostic yield in evaluating for respiratory or atypical complications of reflux disease, or in evaluating for breakthrough reflux symptoms while a patient is on acid-suppressant therapy.

▶ Treatment & Prognosis

Reflux resolves spontaneously in 85% of affected infants by 12 months of age, coincident with assumption of erect posture and initiation of solid feedings. Until then, regurgitation volume may be reduced by offering small feedings at frequent intervals and by thickening feedings with rice cereal (2–3 tsp/oz of formula). Prethickened "antireflux" formulas are available. In infants with unexplained crying/fussy behavior, there is no evidence to support empiric use of acid suppression.

Acid suppression may be used to treat suspected esophageal or extraesophageal complications of acid reflux in infants and older children. Therapeutic options include histamine-2 (H_2)–receptor antagonists or proton pump inhibitors (PPIs). PPI therapy has been shown to significantly heal both esophageal mucosal injury and symptoms from GERD within an 8- to 12-week period. There is no sufficient evidence to support the routine use of prokinetic agents for treatment of pediatric GERD.

Spontaneous resolution is less likely in older children with GERD. In addition, children with underlying neurodevelopmental disorders are at risk for persistent GERD. Episodic symptoms may be controlled with intermittent use of acid blockers. Patients with persistent symptoms may require chronic acid suppression. Complications of reflux esophagitis or chronic GERD include feeding dysfunction, esophageal stricture, and anemia (see Figure 21-1). Barrett esophagus, a precancerous condition, is uncommon in children, but it may occur in patients with an underlying primary diagnosis that offers high risk for GERD.

Antireflux surgery (Nissen fundoplication) may be considered in a child with GERD who (1) fails medical therapy (2) is dependent on persistent, aggressive medical therapy, (3) is nonadherent to medical therapy, and (4) has persistent, severe respiratory complications of GERD or
▲ **Figure 21–1.** Esophagitis associated with gastroesophageal reflux disease. Mucosa is erythematous with loss of vascular pattern.

other life-threatening complications of GERD. Potential complications after antireflux surgery include dumping syndrome, gas bloat syndrome, persistent retching/gagging, or wrap failure.

EOSINOPHILIC ESOPHAGITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Feeding dysfunction, dysphagia, esophageal food impaction, and heartburn.

► Must rule out other causes for esophageal eosinophilia before assigning diagnosis of eosinophilic esophagitis (EoE).

► Esophagoscopy may reveal white eosinophilic exudates, ringlike esophageal folds, and esophageal stricture. Esophageal mucosal biopsy shows dense eosinophilic infiltrate of the epithelium.

► Elimination of food allergens or swallowed topical steroids are effective treatments for EoE.

► Clinical Findings

A. Symptoms and Signs

This recently recognized entity occurs in all ages and most frequently affects boys. Common initial presentations in young children include feeding dysfunction and vague nonspecific symptoms of GERD such as abdominal pain, vomiting, and regurgitation. If a history of careful and lengthy chewing, long mealtimes, washing food down with liquid or avoiding highly textured foods is encountered, one may suspect EoE. In adolescent's symptoms of solid food dysphagia, heartburn and acute and recurrent food impactions predominate. If a child's symptoms are unresponsive to medical and/or surgical management of GERD, EoE should be strongly considered as a diagnostic possibility. A family or personal history of atopy, asthma, dysphagia, or food impaction is not uncommon.
▲ **Figure 21–2.** Esophagitis associated with eosinophilic esophagitis. Mucosa contains linear folds, white exudate, and has loss of vascular pattern.

B. Laboratory Findings

Peripheral eosinophilia may or may not be present. The esophageal mucosa usually appears abnormal with features of thickening, longitudinal mucosal fissures, and circumferential mucosal rings. The esophagus is often sprinkled with pinpoint white exudates that superficially resemble *Candida* infection. On microscopic examination the white spots are composed of eosinophils (Figure 21–2). Basal cell layers of the esophageal mucosa are hypertrophied and infiltrated by eosinophils (usually > 15/40 × light microscopic field). A lengthy stricture may be seen, which can split merely with the passage of an endoscope. Serum IgE may be elevated, but this is not a diagnostic finding. Specific allergens can often be identified by skin testing, and patient can sometimes identify foods that precipitate pain and dysphagia.

► Differential Diagnosis

The most common differential conditions are peptic esophagitis, congenital esophageal stricture, and Candidal esophagitis. EoE may be part of a generalized eosinophilic gastroenteropathy, a very rare, steroid-responsive entity. Patients with eosinophilic gastroenteropathy can also present with gastric outlet obstruction or intestinal caused by large local infiltrates of eosinophils in the antrum, duodenum, and cecum.

► Diagnosis

The diagnosis of EoE is based on clinical and histopathological features. Symptoms referable to esophageal dysfunction must be seen in association with esophageal eosinophilia

and a normal gastric and duodenal mucosa. Other causes for esophageal eosinophilia, in particular, GERD, must be ruled out.

▶ Treatment

Dietary exclusion of offending allergens (elemental diet, removal of allergenic foods) is effective treatment. Such diets are useful in young children, but adherence in older children can be difficult. Topical corticosteroids also offer an effective treatment choice. Steroids are puffed in the mouth and swallowed from a metered dose pulmonary inhaler; this method of administration is completely opposite of how topical steroids are administered for the treatment of asthma. Two puffs of fluticasone from an inhaler twice daily using an age-appropriate metered dose is a common recommendation. Patients should not rinse their mouth or eat for 30 minutes to maximize the effectiveness. Systemic corticosteroids benefit most patients with more acute or severe symptoms. Esophageal dilation may be required to treat strictures. The association of EoE and esophageal malignancy has not been identified. Parent and family support is available at American Partnership for Eosinophilic Disorders APFED.org.

ACHALASIA OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Gradual onset of distal esophageal obstruction.
- ▶ Dysphagia, esophageal food impaction, chronic pulmonary aspiration.
- ▶ Failure of lower esophageal relaxation during swallowing with abnormalities of esophageal peristalsis.
- ▶ High resting pressure of the lower esophageal sphincter.

▶ Clinical Findings

A. Symptoms and Signs

Achalasia most commonly occurs in children who are older than 5 years, but cases during infancy have been reported.

Common symptoms in one recent study were emesis (84.6%), dysphagia (69.2%), weight loss (46.0%), and chronic cough (46.1%). Patients may eat slowly and often require large amounts of fluid when ingesting solid food. Dysphagia is relieved by repeated forceful swallowing or vomiting. Familial cases occur in Allgrove syndrome (alacrima, adrenal insufficiency, and achalasia, associated with a defect in the AAAS gene on 12q13, encoding the ALADIN protein) and familial dysautonomia. Though no genetic or pathophysiologic basis has been identified, there have been recent case reports of achalasia in pediatric autism patients. Chronic cough, wheezing, recurrent aspiration pneumonitis, anemia, and poor weight gain are common.

B. Imaging and Manometry

Barium esophagram shows a dilated esophagus with a tapered "beak" at the GE junction. Esophageal dilation may not be present in infants because of the short duration of distal obstruction. Fluoroscopy shows irregular tertiary contractions of the esophageal wall, indicative of disordered esophageal peristalsis. Achalasia has also been identified incidentally in patients undergoing GE scintigraphy. Esophageal manometry classically shows high resting pressure of the lower esophageal sphincter, failure of sphincter relaxation after swallowing, and abnormal esophageal peristalsis, though these findings may be sporadic, with some partial or normal relaxations present in some swallows. High-resolution manometry testing in adult patients suggests varying subtypes of achalasia, which may predict likelihood of response to different therapies.

C. Differential Diagnosis

Congenital or peptic esophageal stricture, esophageal webs, and esophageal masses may mimic achalasia. EoE commonly presents with symptoms of dysphagia and food impaction, similar to achalasia. Cricopharyngeal achalasia or spasm is a rare cause of dysphagia in children, but it shares some clinical features of primary achalasia involving the lower esophageal sphincter. Intestinal pseudo-obstruction, multiple endocrine neoplasia type 2b, systemic amyloidosis, and postvagotomy syndrome cause esophageal dysmotility and symptoms similar to achalasia. Teenage girls may be suspected of having an eating disorder. In Chagas disease, caused by the parasite *Trypanosoma cruzi*, nNOS and ganglion cells are diminished or absent in the muscular layers of the lower esophageal sphincter causing an acquired achalasia.

▶ Treatment & Prognosis

Endoscopic injection of botulinum toxin paralyzes the lower esophageal sphincter and temporarily relieves obstruction

but has relapse rates of greater than 50%. Pneumatic dilation of the lower esophageal sphincter produces temporary relief of obstruction that may last weeks to years. Pediatric trials are limited, but a recent single center experience of endoscopic dilation showed a long-term success rate of up to 87% with one to three dilations. Because of concerns that dilation may increase inflammation between the esophageal mucosal and muscular layers, however, some have advocated surgical myotomy as the best initial treatment. While, long-lasting functional relief is achieved by surgically dividing the lower esophageal sphincter (Heller myotomy), recurrence risk of obstructive symptoms following myotomy in children has been reported to be as high as 27%. Postoperative GERD is common, leading some to perform a fundoplication or place diaphragm valves at the same time as myotomy. In adult achalasia, per-oral endoscopic myotomy (POEM) has been increasingly utilized as a less invasive alternative to surgical treatment, with isolated case reports in children. In a large retrospective pediatric study, general response rates of pneumatic dilation compared to Heller myotomy were not significantly different, though recent studies suggest that children over 6 may have better outcomes with pneumatic dilation. Self-expanding metal stents have been used with success in adults with achalasia but have not been studied in children.

Because of the shorter duration of esophageal obstruction in children, there is less secondary dilation of the esophagus. Thus, the prognosis for return or retention of some normal esophageal motor function after surgery is better than in adults.

CAUSTIC BURNS OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Reported history of ingestion, with or without evidence of oropharyngeal injury.

▶ Odynophagia, drooling, and food refusal typical of esophageal injury.

▶ Endoscopic evaluation of severity and extent of injury at 24–48 hours postingestion.

▶ Significant risk for development of esophageal strictures, especially in second- and third-degree lesions.

▶ Clinical Findings

A. Symptoms and Signs

Ingestion of caustic solids or liquids (pH < 2 or pH > 12) produces esophageal lesions ranging from superficial inflammation to deep necrosis with ulceration, perforation, mediastinitis, or peritonitis. Acidic substances typically lead to limited injury because of the small volume ingested due to the sour taste. In addition, acid ingestions often lead to superficial coagulative necrosis with eschar formation. Conversely, the more benign taste of alkali ingestions may allow for larger volume ingestions, subsequent liquefactive necrosis that can lead to deeper mucosal penetration. Beyond the pH, factors that determine the severity of injury from a caustic ingestion include the amount ingested, the physical state of the agent, and the duration of mucosal exposure time. For these reasons, powdered or gel formulations of dishwashing detergent are especially dangerous, because of their innocuous taste, high pH, and tendency to stick to the mucosa. Symptoms of hoarseness, stridor, and dyspnea suggest associated airway injury, while odynophagia, drooling, and food refusal are typical with more severe esophageal injury. The lips, mouth, and airway should be examined in suspected caustic ingestion, although up to 12% of children without oral lesions can have significant esophageal injury.

B. Imaging Studies

Esophagoscopy is often a routine part of the evaluation in caustic ingestions to determine the severity and extent of the esophageal injury. Timing of endoscopy is important, however, as endoscopy may not indicate the true severity of injury if it is performed too early (< 24–48 hours) and may increase the risk of perforation if it is performed too late (> 72 hours) due to formation of granulation tissue. Grading

of esophageal lesions into first degree (superficial injury, erythema only), second degree (transmucosal with erythema, ulceration, and sloughing), and third degree (transmural with circumferential sloughing and deep mucosal ulceration) can help predict prognosis. Circumferential lesions should be particularly noted, since they carry the highest risk of stricture formation. In a recent large single-center study, 34% of over 200 ingestions in children were grade 2 or 3, with 50% of these eventually requiring one or more endoscopic dilations for stricture formation. If dilation is felt to be necessary, it should not be performed in the acute phase of injury. Elevation of white blood cell count was found in a recent pediatric study to be a sensitive, but not specific, indicator of high-grade injury. In addition, despite the lack of clinical findings, esophageal lesions have been found in up to 35% and gastric lesions in up to 14% of patients. Because of the relative lack of good prognostic indicators of significant injury, most clinical guidelines recommend endoscopic evaluation as part of standard management in pediatric caustic ingestions. Plain radiographs of the chest and abdomen may be performed if there is clinical suspicion of perforation. Contrast studies of the esophagus should be performed when endoscopic evaluation is not available, as they are unlikely to detect grades 1 and 2 lesions. Some centers have advocated conservative management with upper GI series within 3 weeks of injury, reserving endoscopic evaluation for those with evidence of stricture.

▶ Treatment & Prognosis

Clinical observation is always prudent, as it is often difficult to predict the severity of esophageal injury at presentation. Vomiting should not be induced and administration of buffering agents should be avoided to prevent an exothermic reaction in the stomach. Intravenous corticosteroids (eg, methylprednisolone, 1–2 mg/kg/d) are given immediately to reduce oral swelling and laryngeal edema. Many centers advocate continued corticosteroids for the first week to decrease the risk of stricture formation; however, meta-analysis has not been able to show a clinical benefit from this practice. Intravenous fluids are necessary if dysphagia prevents oral intake. Treatment may be stopped if there are only first-degree burns at endoscopy. Whereas speculation suggest that broad-spectrum antibiotic coverage with third-generation cephalosporins may decrease stricture formation by preventing bacterial colonization into necrotic tissue, the use of antibiotics in cases of perforation is mandatory. Acid-blockade is often used to decrease additional injury from acid reflux.

Esophageal strictures develop in areas of anatomic narrowing (thoracic inlet, GE junction, or point of compression where the left bronchus crosses the esophagus), where contact with the caustic agent is more prolonged. Strictures occur only with full-thickness esophageal necrosis and prevalence of stricture formation varies from 10% to 50%. Shortening

of the esophagus is a late complication that may cause hiatal hernia. Repeated esophageal dilations may be necessary as a stricture develops, with one review showing 35% requiring more than seven dilations. In that series of 175 patients, there was long-term success in only 16% of patients, with 4.5% having complications of perforation and a 2.8% mortality rate. In complicated cases esophageal stenting may be beneficial during early management. Newer, fully covered, self-expanding, removable esophageal stents, now available in pediatric sizes, may offer additional options for recurrent caustic strictures. Alternatively, in a multicenter analysis, endoscopic administration of topical mitomycin-C was effective in treatment of refractory caustic strictures of the esophagus. Animal models utilizing 5-fluorouricil in the early management of caustic esophageal injuries have also shown promise in preventing fibrosis and stricture formation. Surgical replacement of the esophagus by colonic interposition or gastric tube may be needed for long strictures resistant to dilation.

FOREIGN BODIES IN THE ALIMENTARY TRACT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Dysphagia, odynophagia, drooling, regurgitation, and chest/abdominal pain are typical symptoms of esophageal foreign body.

- ▶ Esophageal foreign bodies should be removed within 24 hours of ingestion.

- ▶ Esophageal button batteries must be removed emergently because of their ability to cause lethal injury.

- ▶ Most foreign bodies in the stomach will pass spontaneously.

Older infants and toddlers engage their environment, in part, by placing items in their mouth. As a result, foreign body ingestions are a common occurrence in pediatrics. Fortunately, 80%–90% of foreign bodies pass spontaneously with only 10%–20% requiring endoscopic or surgical management. At presentation the most common symptoms of an ingested foreign body are dysphagia, odynophagia, drooling, regurgitation, and chest or abdominal pain. Respiratory symptoms, such as cough, become prominent for foreign bodies retained in the esophagus for more than 1 week. A high index of suspicion should be maintained for toddlers presenting with these symptoms, even without a witnessed ingestion. If the ingestion is witnessed, the timing of the event is important to note as it will have implications for the timing of any necessary endoscopic procedures for removal.

The most common foreign body ingested by children is the coin (Figure 21–3). Ingested foreign bodies tend to lodge in narrowed areas—valleculae, thoracic inlet, GE junction, pylorus, ligament of Treitz, and ileocecal junction, or at the site of congenital or acquired intestinal stenoses. The evaluation of a swallowed foreign body starts with plain radiography. Radio-opaque objects will be easily visualized. Non–radio-opaque objects, such as plastic toys, may not appear on standard radiograph. If there is particular concern, based on patient symptoms, for a retained esophageal foreign body that is non–radio-opaque, a contrast esophagram is a useful test. Use of contrast, however, may delay or increase the risk of anesthesia due to aspiration concerns.
▲ **Figure 21–3.** Foreign body in esophagus. Coin is lodged in the esophageal lumen.

Esophageal foreign bodies should be removed within 24 hours to avoid ulceration, which can lead to serious complications such as erosion into a vessel or stricture formation. Disk-shaped button batteries lodged in the esophagus are especially concerning and should be removed immediately. Button batteries may cause an electrical thermal injury in as little as 2 hours and have resulted in death from subsequent aortoenteric fistula formation, even weeks after battery removal. Button batteries in the stomach will generally pass uneventfully, but they should be monitored closely to ensure prompt passage. With larger batteries (> 20 mm) and in younger children (< 5 years of age) endoscopic evaluation with gastric batteries may still be considered in order to evaluate the esophagus for signs of injury and risk of aortoesophageal fistula. Rates of significant injury and death due to swallowed button batteries have increased in recent years with the transition toward production of higher-voltage lithium batteries.

Esophageal food impaction should always raise the question of underlying esophagitis. In particular, EoE has been shown to be present in up to 75% of pediatric patients presenting initially with esophageal food impaction.

Smooth foreign bodies in the stomach, such as buttons or coins, may be monitored without attempting removal for up to several months if the child is free of symptoms. Straight pins, screws, and nails are examples of objects with a blunt end that is heavier than the sharp end. These asymmetrically weighted objects will generally pass without incident and so need for endoscopic removal must be considered on a case-by-case basis. In contrast, double-sided sharp objects that are weighted equally on each end, such as fishbones and wooden toothpicks, should be removed as they can migrate through the wall of the GI tract into the pericardium, liver, and inferior vena cava. Large, open safety pins should be removed from the stomach because they may not pass the pyloric sphincter and may cause perforation. Objects longer than 5 cm may be unable to pass the ligament of Treitz and should be removed. Magnets require consideration for removal only if there has been more than one ingested, or if a single magnet was ingested along with a metallic object, because of the risk of fistula or erosion of mucosal tissue trapped between two adherent foreign bodies. Rare earth metal magnets, or neodymium magnets, are very powerful small magnets that are sold in bulk and have caused multiple cases of bowel perforation necessitating surgical intervention. Ingestion of multiple magnets should lead to immediate endoscopic removal if technically feasible. If not, their migration through the GI tract should be followed radiographically until they are passed.

The use of balanced electrolyte lavage solutions containing polyethylene glycol may help the passage of small, smooth foreign bodies lodged in the intestine. Lavage is especially useful in hastening the passage of foreign bodies that may contain an absorbable toxic material such as a heavy metal. Failure of a small, smooth foreign body to exit the stomach after several days suggests the possibility of gastric outlet obstruction.

Most foreign bodies can be removed from the esophagus or stomach by a skilled endoscopist. In some circumstances an alternative technique can be used. An experienced radiologist using fluoroscopy can utilize a Foley catheter with balloon inflated below the foreign body to extract esophageal coins in the upper esophagus while the awake patient is placed in the Trendelenburg position. Contraindications include precarious airway, history that foreign body has been present for several days, and previous esophageal surgery.

DISORDERS OF THE STOMACH & DUODENUM

HIATAL HERNIA

In paraesophageal hiatal hernias, the esophagus and GE junction are in their normal anatomic position, but the gastric cardia is herniated through the diaphragmatic hiatus alongside the GE junction. In sliding hiatal hernias, the GE junction and a portion of the proximal stomach are displaced above the diaphragmatic hiatus. Sliding hiatal hernias are common. Congenital paraesophageal hernias are rare in childhood; patients may present with recurrent pulmonary infections, vomiting, anemia, failure to thrive, or dysphagia. The most common cause of paraesophageal hernia is previous fundoplication surgery. Radiographic studies typically reveal a cystic mass in the posterior mediastinum or a dilated esophagus. The diagnosis is typically made with an upper GI series or a CT scan of the chest and abdomen. Presence of a Schatzki ring on upper GI has been found to be associated with hiatal hernia in 96% of children and should increase the index of suspicion. Recently, use of pH Impedance probe testing has been proposed as an effective method to identify hiatal hernia in children, where inversion of the usual acid:nonacid reflux ratio to more than 1.0 was reported to have a sensitivity of 93.8% and specificity of 79.6%. Treatment in symptomatic cases is generally surgical, with laparoscopic approach being used more commonly. Controversy exists about using biosynthetic mesh in the repair of these hernias, as its use definitely decreases the risk of recurrent hernia but has also been associated with esophageal erosion in children. GE reflux may accompany sliding hiatal hernias, although most produce no symptoms. Fundoplication is indicated if paraesophageal or sliding hiatal hernias produce persistent symptoms, though the presence of a preoperative hiatal hernia has been found to triple the risk of recurrent GERD following fundoplication.

PYLORIC STENOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Postnatal muscular hypertrophy of the pylorus.

▶ Progressive gastric outlet obstruction, nonbilious vomiting, dehydration, and alkalosis in infants younger than 12 weeks.

▶ Upper GI contrast radiographs or abdominal ultrasound are diagnostic.

The cause of postnatal pyloric muscular hypertrophy with gastric outlet obstruction is unknown. The incidence is 1–8 per 1000 births, with a 4:1 male predominance. A positive family history is present in 13% of patients. Recent studies suggest that erythromycin in the neonatal period is associated with a higher incidence of pyloric stenosis in infants younger than 30 days, though the mean age at diagnosis in a large population-based study was 43.1 days. Epidemiological studies identify no increased risk of pyloric stenosis with macrolide antibiotic exposure via breast milk.

▶ Clinical Findings

A. Symptoms and Signs

Projectile postprandial vomiting usually begins between 2 and 4 weeks of age but may start as late as 12 weeks. Vomiting starts at birth in about 10% of cases and onset of symptoms may be delayed in preterm infants. Vomitus is

rarely bilious but may be blood-streaked. Infants are usually hungry and nurse avidly. Constipation, weight loss, fretfulness, dehydration, and finally apathy occur. The upper abdomen may be distended after feeding, and prominent gastric peristaltic waves from left to right may be seen. An oval mass, 5–15 mm in longest dimension can be felt on deep palpation in the right upper abdomen, especially after vomiting. This palpable "olive," however, was only present in 13.6% of patients studied.

B. Laboratory Findings

Hypochloremic alkalosis with potassium depletion is the classic metabolic findings, though low chloride may be seen in as few as 23% and alkalosis in 14.4%. These findings may not be as common in younger infants and their absence should not dissuade from the diagnosis in the appropriate clinical setting. Dehydration causes elevated hemoglobin and hematocrit. Mild unconjugated bilirubinemia occurs in 2%–5% of cases.

C. Imaging

Ultrasonography shows a hypoechoic muscle ring greater than 4-mm thick with a hyperdense center and a pyloric channel length greater than 15 mm. A barium upper GI series reveals retention of contrast in the stomach and a long narrow pyloric channel with a double track of barium. The hypertrophied muscle mass produces typical semilunar filling defects in the antrum. Isolated pylorospasm is common in young infants and by itself is insufficient to make a diagnosis of pyloric stenosis. Infants presenting younger than 21 days may not fulfill these classic ultrasonographic criteria and may require clinical judgment to interpret "borderline" measures of pyloric muscle thickness.

▶ Treatment & Prognosis

Ramstedt pyloromyotomy is the treatment of choice and consists of incision down to the mucosa along the pyloric length. The procedure can be performed laparoscopically, with similar efficacy and improved cosmetic results compared to open procedures. An alternative, double Y, form of pyloromyotomy may promote more rapid resolution of vomiting and increased weight gain in the first postoperative week compared to the traditional Ramstedt procedure. Treatment of dehydration and electrolyte imbalance is mandatory before surgical treatment, even if it takes 24–48 hours. Use of IV cimetidine and other acid-blocking agents has been shown in small studies to rapidly correct metabolic alkalosis, allowing more rapid progression to surgery and resolution of symptoms. Patients often vomit postoperatively as a consequence of gastritis, esophagitis, or associated GE reflux. The outlook after surgery is excellent, though patients may show as much as a four times greater risk for development

of chronic abdominal pain of childhood The postoperative barium radiograph remains abnormal for many months despite relief of symptoms.

GASTRIC & DUODENAL ULCER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Localized erosions of gastric or duodenal mucosa.

▶ Pain and bleeding are the most common symptoms.

▶ Underlying severe illness, *Helicobacter pylori* infection, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes.

▶ Diagnosis by endoscopy.

▶ General Considerations

Gastric and duodenal ulcers occur at any age. Boys are affected more frequently than girls. In the United States, most childhood gastric and duodenal ulcers are associated with underlying illness, toxins, or drugs that cause breakdown in mucosal defenses.

Worldwide, the most common cause of gastric and duodenal ulcer is mucosal infection with the bacterium *H pylori*. Between 10% and 20% of North American children have antibodies against *H pylori*. Antibody prevalence increases with age, poor sanitation, crowded living conditions, and family exposure. In some developing countries, over 90% of schoolchildren have serologic evidence of past or present infection. Infection is thought to be acquired in childhood, but only in a small percentage of infected persons will infection lead to nodular gastritis, peptic ulcer, or in the case of long-standing infection, gastric lymphoid tumors, and adenocarcinoma of the stomach. Some bacterial virulence factors have been identified, but the host and bacterial characteristics that contribute to disease progression are still largely unknown. In contrast to ulcers secondary to *H pylori*, non–*H pylori* ulcers tend to occur as frequently in girls as boys,

present at a younger age, and are more likely to recur. In a large study of over 1000 children undergoing endoscopy, 5.4% had ulcers, with 47% of these due to *H pylori*, 16.5% related to NSAIDs, and 35.8% unrelated to either HP or NASIDs. Recent evidence suggests that the prevalence of non–*H pylori* peptic ulcers is increasing.

Illnesses predisposing to secondary ulcers include central nervous system (CNS) disease, burns, sepsis, multiorgan system failure, chronic lung disease, Crohn disease (CrD), cirrhosis, and rheumatoid arthritis. The most common drugs causing secondary ulcers are aspirin, alcohol, and NSAIDs. NSAID use may lead to ulcers throughout the upper GI tract but most often in the stomach and duodenum. Severe ulcerative lesions in full-term neonates have been found to be associated with maternal antacid use in the last month of pregnancy.

▶ Clinical Findings

A. Symptoms and Signs

In children younger than 6 years, vomiting and upper GI bleeding are the most common symptoms of gastric and duodenal ulcer. Older children are more likely to complain of epigastric abdominal pain. The first attack of acute *H pylori* gastritis may be accompanied by vomiting and hematemesis. Ulcers in the pyloric channel may cause gastric outlet obstruction. Chronic blood loss may cause iron-deficiency anemia. Deep penetration of the ulcer may erode into a mucosal arteriole and cause acute hemorrhage. Penetrating duodenal ulcers (especially common during cancer chemotherapy, immunosuppression, and in the intensive care setting) may perforate the duodenal wall, resulting in peritonitis or abscess.

B. Diagnostic Studies

Upper GI endoscopy is the most accurate diagnostic examination. The typical endoscopic appearance of an ulcer is a white exudative base with erythematous margins (Figure 21–4). Endoscopy also provides the mechanism for testing of other causes of peptic symptoms such as esophagitis, eosinophilic GI disease, and celiac disease (CD). Endoscopic diagnosis of active *H pylori* infection may be achieved by histologic examination of gastric biopsies or measurement of urease activity on gastric tissue specimens. Additional noninvasive methods of diagnosis of active *H pylori* infection include evaluation of breath for radiolabeled carbon dioxide after administration of radiolabeled urea by mouth and detection of *H pylori* antigen in the stool. False-negative results for the latter two tests have been described when the patient is taking a PPI. Serum antibodies against *H pylori* have poor sensitivity and specificity, and do not prove that there is active infection or that treatment is needed. For severe or recurrent ulcerations not caused by *H pylori*, stress, or medications,

▲ **Figure 21–4.** Gastric ulcer. White exudate coats the ulcer bed of antral ulcer that is surrounded by an erythematous margin.

a serum gastrin level may be considered to evaluate for a gastrin-secreting tumor (Zollinger-Ellison syndrome), though mild to moderate elevation in gastrin levels can be seen with use of PPI drugs. Upper GI barium radiographs may show an ulcer crater. Radiologic signs suggestive of peptic disease in adults (duodenal spasticity and thick irregular folds) are not reliable indicators in children.

▶ Treatment

Acid suppression or neutralization is the mainstay of non-infectious ulcer therapy. Liquid antacids in the volumes needed to neutralize gastric acid are usually unacceptable to children. H_2-receptor antagonists and PPIs are more effective and usually produce endoscopic healing in 4–8 weeks.

As an adjunct therapy, 7- to 14-day courses of sucralfate may be helpful as a mucosal protective agent to speed healing and decrease symptoms. Bland "ulcer diets" do not speed healing, but foods causing pain should be avoided. Caffeine should be avoided because it increases gastric acid secretion. Aspirin, alcohol, NSAIDs, and other gastric irritants should be avoided as well.

Treatment of symptomatic *H pylori* infection requires eradication of the organism, a goal that remains elusive in children. The optimal medical regimen is still undetermined. The most common regimen is a triple combination of amoxicillin, clarithromycin, and PPI. Quadruple combinations, involving an additional antibiotic, may yield higher

eradication rates. Alternative antibiotics include metronidazole, imidazole, tetracycline, and levofloxacin. Bismuth subsalicylate is commonly used as a substitute for the PPI. Regimens are typically continued for a minimum of 10 days. Sequential therapy, which involves induction with amoxicillin plus PPI for 5 days followed by clarithromycin/metronidazole/PPI for 5 days, may also yield higher eradication rates than standard triple combination therapy. Resistance to antibiotics is common and varies by region of the world. Regional antibiotic resistance patterns for *H pylori* should be a guide in selecting a treatment regimen for symptomatic infection. Test of cure can be achieved by either the urease breath test or fecal *H pylori* antigen test.

Endoscopic therapy of bleeding ulcers may be considered for severe or refractory lesions posing a risk for significant morbidity or mortality. Therapeutic options include injection therapy, application of monopolar or bipolar electrocoagulation, placement of clipping devices, or use of argon plasma coagulation.

CONGENITAL DIAPHRAGMATIC HERNIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Congenital diaphragmatic hernia (CDH) typically is diagnosed prenatally by screening ultrasound.

▶ Pulmonary hypoplasia and cardiovascular dysfunction are clinical challenges in the postnatal period.

▶ After surgical repair, chronic pulmonary disease and GER can be lifelong morbidities.

Herniation of abdominal contents through the diaphragm usually occurs through a posterolateral defect involving the left side of the diaphragm (foramen of Bochdalek). In about 5% of cases, the diaphragmatic defect is retrosternal (foramen of Morgagni). In eventration of the diaphragm, a subtype of CDH, a leaf of the diaphragm with hypoplastic muscular elements balloons into the chest and leads to similar but milder symptoms. Hernias result from failure of the embryologic diaphragmatic anlagen to fuse and divide the thoracic and abdominal cavities at 8–10 weeks'

gestation. The herniation of abdominal contents into the thoracic cavity can lead to pulmonary hypoplasia and significant cardiovascular dysfunction after birth, in particular severe persistent pulmonary hypertension.

Diagnosis of CDH is typically made prenatally by ultrasound. Associated congenital malformations, most commonly cardiovascular, are commonly seen. With the advent of improved care of cardiopulmonary disease in the newborn period, including the use of inhaled nitric oxide, high-frequency oscillatory ventilation and extracorporeal membrane oxygenation, survival has improved for infants with CDH and is as high as 70%–90% in some centers. Fetal surgery with tracheal occlusion has been attempted to improve fetal pulmonary development. Operative repair of the diaphragmatic defect is usually performed in the newborn period once cardiopulmonary stabilization is achieved, with increasing utilization of laparoscopic and thoracoscopic minimally invasive approaches. Occasionally, diaphragmatic hernia is first identified in an older infant or child during incidental radiograph or routine physical examination. These children usually have a much more favorable prognosis than neonates. CDH survivors are often found to have significant chronic pulmonary disease as well as GER, the latter possibly resulting from abnormal intrinsic innervation of the lower esophagus.

CONGENITAL DUODENAL OBSTRUCTION

▶ General Considerations

Obstruction is generally classified into intrinsic and extrinsic causes, although rare cases of simultaneous intrinsic and extrinsic anomalies have been reported. Extrinsic duodenal obstruction is usually due to congenital peritoneal bands associated with intestinal malrotation, annular pancreas, or duodenal duplication. In rare cases, a preduodenal portal vein has been associated with extrinsic obstruction as well. Intrinsic obstruction is caused by stenosis, mucosal diaphragm (so-called wind sock deformity), or duodenal atresia. In atresia, the duodenal lumen may be obliterated by a membrane or completely interrupted with a fibrous cord between the two segments. Atresia is more often distal to the ampulla of Vater than proximal. In about two-thirds of patients with congenital duodenal obstruction, there are other associated anomalies.

▶ Imaging Studies

Diagnosis of congenital duodenal obstructions is often made prenatally by ultrasound. Prenatal diagnosis predicts complete

obstruction in 77% of cases and is associated with polyhydramnios, prematurity, and higher risk of maternal-fetal complications. Presence of a "double bubble" on ultrasound, in association with an echogenic band in the second portion of the duodenum was found to be 100% sensitive and specific for an annular pancreas. Postnatal abdominal plain radiographs show gaseous distention of the stomach and proximal duodenum (the "double-bubble" radiologic sign). With protracted vomiting, there is less air in the stomach and less abdominal distention. Absence of distal intestinal gas suggests atresia or severe extrinsic obstruction, whereas a pattern of intestinal air scattered over the lower abdomen may indicate partial duodenal obstruction. Barium enema may be helpful in determining the presence of malrotation or atresia in the lower GI tract, as well as evaluating for radiographic evidence of Hirschsprung disease, which may also present with abdominal distension and vomiting.

▶ Clinical Findings

A. Duodenal Atresia

Maternal polyhydramnios is common and often leads to prenatal diagnosis by ultrasonography. Vomiting (usually bile-stained) and epigastric distention begin within a few hours of birth. Meconium may be passed normally. Duodenal atresia is often associated with other congenital anomalies (30%), including esophageal atresia, intestinal atresias, and cardiac and renal anomalies. Prematurity (25%–50%) and Down syndrome (20%–30%) are also associated with duodenal atresia.

B. Duodenal Stenosis

In this condition, duodenal obstruction is not complete. Onset of obvious obstructive symptoms may be delayed for weeks or years. Although the stenotic area is usually distal to the ampulla of Vater, the vomitus does not always contain bile. Duodenal stenosis or atresia is the most common GI tract malformation in children with Down syndrome, occurring in 3.9%.

C. Annular Pancreas

Annular pancreas is a rotational defect in which normal fusion of the dorsal and ventral pancreatic anlagen does not occur, and a ring of pancreatic tissue encircles the duodenum. The presenting symptom is duodenal obstruction. Down syndrome and congenital anomalies of the GI tract occur frequently. Polyhydramnios is common. Symptoms may develop late in childhood or even in adulthood if the obstruction is not complete in infancy. Treatment consists of duodenoduodenostomy or duodenojejunostomy without operative dissection or division of the pancreatic annulus. Pancreatic function is normal.

▶ Treatment & Prognosis

In almost all settings, surgical intervention (either laparoscopic or open) is required for congenital duodenal obstructive lesions. Typically, duodenoduodenostomy is performed to bypass the area of stenosis or atresia. For duodenal stenoses, however, there have been isolated reports of successful endoscopic treatment with balloon dilation. Thorough surgical exploration is typically done to ensure that no lower GI tract anomalies are present. More recent reports document the safety and utility of a laparoscopic approach. The mortality rate is increased in infants with prematurity, Down syndrome, and associated congenital anomalies. Duodenal dilation and hypomotility from antenatal obstruction may cause duodenal dysmotility with obstructive symptoms even after surgical treatment. Placement of transanastomotic feeding tubes at the time of the initial repair has been found to result in more rapid progression to full enteral feeds and decreased need for parenteral nutrition (PN). The overall prognosis for these patients is good, with the majority of their mortality risk due to associated anomalies other than duodenal obstruction.

▼ DISORDERS OF THE SMALL INTESTINE

INTESTINAL ATRESIA & STENOSIS

Excluding anal anomalies, intestinal atresia or stenosis accounts for one-third of all cases of neonatal intestinal obstruction (see Chapter 1). Antenatal ultrasound can identify intestinal atresia in utero; polyhydramnios occurs in most affected pregnancies. Sensitivity of antenatal ultrasound is greater in more proximal atresias. Other congenital anomalies may be present in up to 54% of cases and 52% are delivered preterm. In apparently isolated atresia cases, occult congenital cardiac anomalies have been reported in as many as 30%. In one large population-based study, the prevalence was 2.9 per 10,000 births, although there is some

evidence that the prevalence may be increasing. The localization and relative incidence of atresias and stenoses are listed in Table 21–1. Although jejunal and ileal atresias are often grouped together, there are data to suggest that jejunal atresias are associated with increased morbidity and mortality compared to ileal atresia. These differences may be related to increased compliance of the jejunal wall, resulting in more proximal dilation and subsequent loss in peristaltic activity.

Bile-stained vomiting and abdominal distention begin in the first 48 hours of life. Multiple sites in the intestine may be affected and the overall length of the small intestine may be significantly shortened. Radiographic features include dilated loops of small bowel and absence of colonic gas. Barium enema reveals narrow-caliber microcolon because of lack of intestinal flow distal to the atresia. In over 10% of patients with intestinal atresia, the mesentery is absent, and the SMA cannot be identified beyond the origin of the right colic and ileocolic arteries. The ileum coils around one of these two arteries, giving rise to the so-called Christmas tree deformity on contrast radiographs. The tenuous blood supply often compromises surgical anastomoses. The differential diagnosis of intestinal atresia includes Hirschsprung disease, paralytic ileus secondary to sepsis, midgut volvulus, and meconium ileus. Surgery is mandatory. Postoperative complications include short bowel syndrome (SBS) in 15% and small bowel hypomotility secondary to antenatal obstruction. Overall mortality has been reported at 8%, with increased risk in low-birth-weight and premature infants.

INTESTINAL MALROTATION

▶ General Considerations

The midgut extends from the duodenojejunal junction to the mid-transverse colon. It is supplied by the superior mesenteric artery (SMA), which runs in the root of the mesentery. During gestation, the midgut elongates into the umbilical sac, returning to an intra-abdominal position during the 10th week of gestation. The root of the mesentery rotates in a counterclockwise direction during retraction causing the colon to cross the abdominal cavity ventrally. The cecum moves from the left to the right lower quadrant, and the duodenum crosses dorsally becoming partly retroperitoneal. When rotation is incomplete, the dorsal fixation of the mesentery is defective and shortened, so that the bowel from the ligament of Treitz to the mid-transverse colon may rotate around its narrow mesenteric root and occlude the SMA (volvulus). From autopsy studies it is estimated that up to 1% of the general population may have intestinal malrotation, which is diagnosed in the first year of life in 70%–90% of patients.

▶ Clinical Findings

A. Symptoms and Signs

Malrotation with volvulus accounts for 10% of neonatal intestinal obstructions. Most infants present in the first 3 weeks of life with bile-stained vomiting or with overt small bowel obstruction. Intrauterine volvulus may cause intestinal obstruction or perforation at birth. The neonate may present with ascites or meconium peritonitis. Later presenting signs include intermittent intestinal obstruction, malabsorption, protein-losing enteropathy, or diarrhea. Associated congenital anomalies, especially cardiac, occur in over 25% of symptomatic patients. Many of these may be found in a subgroup of malrotation patients with heterotaxy syndromes, with

Table 21–1. Localization and relative frequency of congenital gastrointestinal atresias and stenoses.

	Area Involved	Type of Lesion	Relative Frequency (%)
Pylorus		Atresia; web or diaphragm	1
Duodenum	80% are distal to the ampulla of Vater	Atresia, stenosis; web or diaphragm	45
Jejunoileal	Proximal jejunum and distal ileum	Atresia (multiple in 6%–29%); stenosis	50
Colon	Left colon and rectum	Atresia (usually associated with atresias of the small bowel)	5–9

associated asplenia or polysplenia. Older children and adults with undiagnosed malrotation typically present with chronic GI symptoms of nausea, vomiting, diarrhea, abdominal pain, dyspepsia, bloating, and early satiety.

B. Imaging

An upper GI series is considered the gold standard for diagnosis, with a reported sensitivity of 96%, and classically shows the duodenojejunal junction and the jejunum on the right side of the spine. The diagnosis of malrotation can be further confirmed by barium enema, which may demonstrate a mobile cecum located in the midline, right upper quadrant, or left abdomen. Plain films of the abdomen in the newborn period may show a "double-bubble" sign, resulting in a misdiagnosis of duodenal atresia. CT scan and ultrasound of the abdomen may be used to make the diagnosis as well and are characterized by the "whirlpool sign" denoting midgut volvulus. Reversal of the normal position of the SMA and superior mesenteric vein (SMV) may be seen in malrotation, though normal position may be found in up to 29% of patients. Identification of the third portion of the duodenum within the retroperitoneum makes malrotation very unlikely.

► Treatment & Prognosis

Surgical treatment of malrotation is the Ladd procedure. In young infants the Ladd procedure should be performed even if volvulus has not occurred. The duodenum is mobilized, the short mesenteric root is extended, and the bowel is then fixed in a more normal distribution. Treatment of malrotation discovered in children older than 12 months is uncertain. Because volvulus can occur at any age, surgical repair is usually recommended, even in asymptomatic children. Laparoscopic repair of malrotation is possible but is technically difficult and is never performed in the presence of volvulus.

Midgut volvulus is a surgical emergency. Bowel necrosis results from occlusion of the SMA. When necrosis is extensive, it is recommended that a first operation include only reduction of the volvulus with lysis of mesenteric bands. Resection of necrotic bowel should be delayed if possible until a second-look operation 24–48 hours later can be undertaken in the hope that more bowel can be salvaged. The prognosis is guarded if perforation, peritonitis, or extensive intestinal necrosis is present. Mid-gut volvulus is one of the most common indications for small bowel transplant in children, responsible for 10% of cases in a recent series.

SHORT BOWEL SYNDROME

► General Considerations

Short bowel syndrome (SBS) is defined as a condition resulting from reduced intestinal absorptive surface that leads to alteration in intestinal function that compromises normal growth, fluid/electrolyte balance, or hydration status. The vast majority of pediatric patients with SBS have undergone neonatal surgical resection of intestine. The most common etiologies in children are necrotizing enterocolitis (45%); intestinal atresias (23%); gastroschisis (15%); volvulus (15%); and, less commonly, congenital short bowel, long-segment Hirschsprung disease, and ischemic bowel. In many instances, infants with SBS require PN in order to provide adequate caloric, fluid, and electrolyte delivery in the setting of insufficient intestinal absorptive function. The requirement of supplemental PN for more than 2–3 months in the setting of SBS or any other underlying disorder qualifies the diagnosis of intestinal failure (IF).

The goal in management of the patient with SBS is to promote growth and adaptation of the intestine such that adequate nutrition can be delivered and absorbed enterally. Many factors, including patient's gestational age, postsurgical anatomic (including residual small bowel length and presence of ileocecal valve and/or colon), presence of small bowel bacterial overgrowth, and underlying surgical disease, influence the process and likelihood of bowel adaptation and achievement of enteral autonomy. Although no specific anatomic bowel length measurements offer 100% certainty in predicting clinical outcomes in SBS, residual small intestine less than 30 cm offers at least some prediction that a patient may require long-term, if not indefinite, PN. Serum citrulline level may serve as a reliable biomarker in order to help predict functional intestinal mass.

► Symptoms & Signs

Typical symptoms for the patient with SBS are related to their underlying malabsorptive state, including diarrhea, dehydration, electrolyte or micronutrient deficiency states, and growth failure. Patients with SBS are also at risk for small bowel obstruction, bowel dilation and dysmotility (with secondary small bowel bacterial overgrowth), hepatobiliary disorders including cholelithiasis, nephrolithiasis due to calcium oxalate stones, oral feeding challenges, and

GI mucosal inflammatory problems including noninfectious colitis and anastomotic ulcerations. For patients with IF, complications related to underlying PN therapy are common and can be life threatening. PN-associated liver disease (PNALD) is a progressive cholestatic liver injury that occurs in pediatric patients on PN and may progress to end-stage liver disease in 10% of affected patients. Recurrent catheter-related bloodstream infections are relatively common in pediatric patients with SBS and IF. Other complication-related central venous catheters including occlusions may require intervention.

▶ Treatment & Prognosis

Goal in management of SBS is to promote growth and adaptation while minimizing and/or treating complications of the underlying intestinal disorder or PN therapy. Intestinal rehabilitation for the child with SBS and IF refers to the multidisciplinary team approach to individual patient care, involving gastroenterology, nutrition, and surgery, and has been shown to improve outcomes. Enteral nutrition should be catered to favor absorption, commonly requiring continuous delivery of an elemental formula through a gastrostomy tube. Commonly prescribed pharmacologic adjuncts include acid suppressive therapy, antimotility and antidiarrheal agents, and antibiotics for the treatment of small bowel bacterial overgrowth. Emerging therapies targeted to promote bowel adaptation include glucagon-like peptide 2 analogues, which show promise in potentially increasing absorption and bowel adaptation in early trials.

Management for the patient with SBS and IF should include strategies to manage or prevent complications related to PN therapy, including infection and liver disease. Antimicrobial lock solutions using either ethanol or antibiotics may have a role in reducing rate of infection. Compelling evidence over the past several years suggests that modification of parenteral lipid solution, either through reduction in dose of soy-based intralipid or replacement with a fish-oil based lipid solution (Omegaven), improves outcomes associated with PNALD in pediatric patients.

Autologous bowel reconstructive surgery (bowel lengthening) should be considered in a patient who is failing to advance enterally and has anatomy amendable to surgical intervention, typically with regards to adequate bowel dilation. Both the serial transverse enteroplasty (STEP) procedure and longitudinal intestinal lengthening and tailoring (Bianchi) procedure have been successful in allowing weaning from TPN in up to 50% of patients in reported series. In recent years, the STEP procedure has gained favor as being potentially less technically demanding and repeatable, if the bowel dilates sufficiently after the initial procedure.

When medical, nutritional, and surgical managements fail, intestinal transplantation may be considered for a child with refractory and life-threatening complications of IF. Current outcome data after pediatric intestinal transplantation suggest 1- and 3-year survival rates of 83% and 60%, respectively.

INTUSSUSCEPTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Intussusception is the most common cause of bowel obstruction in the first 2 years of life.

▶ The most common location for intussusception is ileocolic and 85% of cases are idiopathic.

▶ Ultrasound is the most sensitive and specific diagnostic modality for intussusception.

▶ Air enema is the best therapeutic approach in the stable patient, with successful reduction in 75% of cases.

Intussusception is the invagination of one segment of intestine into another segment. Although intussusception can occur anywhere along the small and large bowel, most commonly the intussusception starts just proximal to the ileocecal valve and extends for varying distances into the colon. The terminal ileum telescopes into the colon. Swelling, hemorrhage, incarceration, vascular compromise, and necrosis of the intussuscepted ileum may occur, as well as intestinal perforation and peritonitis. Intussusception is the most frequent cause of intestinal obstruction in the first 2 years of life. It is three times more common in males than in females. In 85% of cases the cause is idiopathic but the likelihood of identifying a cause of intussusception increases with the age of the patient. Implicated primary causes of intussusception include small bowel polyp, Meckel diverticulum, omphalomesenteric remnant, duplication, Henoch-Schönlein purpura, lymphoma, lipoma, parasites, foreign bodies, and viral enteritis with hypertrophy of Peyer patches. Intussusception of the small bowel can occur in patients with CD and cystic fibrosis related to the bulk of stool in the terminal ileum. In children older than 6 years, lymphoma is the most common cause of intussusception.

Clinical Findings

Characteristically, a previously healthy infant 3–12 months of age develops recurring paroxysms of abdominal pain with screaming and drawing up of the knees. Vomiting and diarrhea occur soon afterward (90% of cases), and bloody bowel movements with mucus appear within the next 12 hours (50%). The child is characteristically lethargic between paroxysms and may be febrile. The abdomen is tender and often distended. A sausage-shaped mass may be palpated, usually in the upper mid abdomen. The likelihood of bowel compromise increases with the duration of symptoms. In older children, sudden attacks of abdominal pain may be related to chronic recurrent intussusception with spontaneous reduction.

Diagnosis & Treatment

The constellation of abdominal pain, lethargy, vomiting, with a suspicious abdominal radiograph was found to have a sensitivity of 95% in identifying intussusceptions in children. Abdominal radiographs alone, however, are poorly sensitive for the diagnosis of intussusception. Abdominal ultrasound carries sensitivity for diagnosis of intussusception of 98%–100%. Barium enema and air enema are both diagnostic and therapeutic. Reduction of the intussusception by barium enema should not be attempted if signs of strangulated bowel, perforation, or toxicity are present. Air insufflation of the colon under fluoroscopic guidance is a safe alternative to barium enema that has excellent diagnostic sensitivity and specificity without the risk of contaminating the abdominal cavity with barium. Rates of successful reduction by air enema approach 75%. The rate of perforation with either liquid or air enema is approximately 1%. Care is required in patient selection for either air or barium enema because if ischemic damage to the intestine is suspected based on symptom severity (shock or sepsis), the risk of perforation increases and surgical reduction is preferred. Surgery is thus required for extremely ill patients, in patients with evidence of bowel perforation, or in those in whom hydrostatic or pneumatic reduction has been unsuccessful (25%). Surgery has the advantage of identifying a lead point such as Meckel diverticulum, lymphoma, or small bowel polyp. Surgical reduction of intussusception is associated with a lower recurrence rate than pneumatic reduction.

Prognosis

The likelihood of successful reduction by enema decreases if symptom duration is greater than 24 hours. Similarly, of those requiring surgical reduction, the risk of subsequent bowel resection increased from 17% to 39% in patients with symptoms greater than 24 hours. The mortality rate with treatment is 1%–2%. The patient should be observed carefully after hydrostatic or pneumatic reduction because intussusception recurs within 24 hours in 10% of patients. Intussusception in patients older than 5 years confers a greater risk of persistent symptoms, having an underlying lead point and recurrence of intussusception.

Applegate KE: Intussusception in children: evidence-based diagnosis and treatment. Pediatr Radiol 2009 Apr;39(Suppl 2):S140–S143 [PMID: 19308373].

INGUINAL HERNIA

A peritoneal sac precedes the testicle as it descends from the genital ridge to the scrotum. The lower portion of this sac envelops the testis as the tunica vaginalis, and the remainder normally atrophies by the time of birth forming a cord (processus vaginalis). In some cases, peritoneal fluid may become trapped in the tunica vaginalis (noncommunicating hydrocele). If the processus vaginalis remains open, peritoneal fluid or an abdominal structure may be forced into it (indirect inguinal hernia).

Inguinal hernias are most often indirect and occur more frequently (9:1) in boys than in girls. Hernias may present at any age. The incidence in preterm male infants is close to 5% and is reported in 30% of male infants weighing 1000 g or less.

Clinical Findings

No symptoms are associated with an empty processus vaginalis. In most cases, a hernia is a painless inguinal swelling. Parents may be the only one to see the mass, as it may retract when the infant is active, cold, frightened, or agitated. A history of inguinal fullness associated with coughing or long periods of standing, or presence of a firm, globular, and tender swelling, sometimes associated with vomiting and abdominal distention are clinical clues. In some instances, a herniated loop of intestine may become partially obstructed leading to severe pain. Rarely, bowel becomes trapped in the hernia sac, and complete intestinal obstruction occurs. Gangrene of the hernia contents or testis may occur. In girls, the ovary may prolapse into the hernia sac presenting as a mass below the inguinal ligament. Suggestive histories are often the only criterion for diagnosis, along with the "silk glove" feel of the rubbing together of the two walls of the empty hernia sac.

Differential Diagnosis

Inguinal lymph nodes may be mistaken for a hernia. Nodes are usually multiple with more discrete borders. A hydrocele of the cord should transilluminate. An undescended testis is usually mobile in the canal and is associated with absence of the gonad in the scrotum.

▶ Treatment

Incarceration of an inguinal hernia is more likely to occur in boys and in children younger than 10 months. Manual reduction of incarcerated inguinal hernias can be attempted after the sedated infant is placed in the Trendelenburg position with an ice bag on the affected side. Manual reduction is contraindicated if incarceration has been present for more than 12 hours or if bloody stools are noted. Surgery is indicated if a hernia has ever incarcerated. Hydroceles frequently resolve by age 2 years. Controversy remains about whether the side opposite a unilateral hernia should be surgically explored. Exploration of the unaffected groin can document an open processus vaginalis, but patency does not always guarantee that herniation will occur, especially in patients older than 1 year, in whom the risk of contralateral hernia is about 10%.

Antonoff MB, Kreykes NS, Saltzman DA, Acton RD: American Academy of Pediatrics Section on Surgery hernia survey revisited. J Pediatr Surg 2005 Jun;40(6):1009–1014 [PMID: 15991187].

Zendejas B et al: Incidence of inguinal hernia repairs in Olmsted County, MN: a population-based study. Ann Surg 2013 Mar; 257(3):520–526 [PMID: 23388353].

UMBILICAL HERNIA

Umbilical hernias are more common in full-term, African American infants. Small bowel may incarcerate in small-diameter umbilical hernias. Most umbilical hernias regress spontaneously if the fascial defect has a diameter of less than 1 cm. Hernias persisting after age 4 years should be treated surgically. Reducing the hernia and strapping the skin over the abdominal wall defect does not accelerate healing.

PATENT OMPHALOMESENTERIC DUCT

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Persistent umbilical discharge in an infant may represent a patent omphalomesenteric duct.
- ▶ Ultrasound is the preferred diagnostic method for patent omphalomesenteric duct.
- ▶ Surgical excision of the omphalomesenteric remnant is required.

The omphalomesenteric duct connects the fetal yolk sac to the developing gut. This duct is usually obliterated early in embryologic development, but failure of this process can lead to a variety of structures that originate from the embryonic duct remnant connecting the ileum to the undersurface of the umbilicus. If the remnant is patent, it can lead to herniation of intestinal contents into the umbilical cord or lead to fecal discharge from the umbilicus. A fibrous cord may become the focal point for an intestinal obstruction. Mucoid umbilical discharge may indicate a mucocele in the omphalomesenteric remnant with an opening at the umbilicus. A closed mucocele may protrude through the umbilicus and appear as a polypoid mass that may be mistaken for an umbilical granuloma because it is firm and bright red. Cauterization of a mucocele is not recommended. Surgical excision of omphalomesenteric remnants is indicated. Ultrasound examination or abdominal computed tomography (CT) can help confirm the diagnosis of omphalomesenteric duct remnants.

Durakbasa CU et al: Symptomatic omphalomesenteric duct remnants in children. Pediatr Int 2010 Jun;52(3):480–484 [PMID: 19863751].

MECKEL DIVERTICULUM

Meckel diverticulum is the most common form of omphalomesenteric duct remnant and is usually located on the antimesenteric border of the mid to distal ileum. It occurs in 1.5% of the population and in the majority of cases causes no symptoms. Familial cases have been reported. If complications occur, they are three times more common in males than in females. More than 50% of complications occur in the first 2 years of life.

▶ Clinical Findings

A. Symptoms and Signs

Forty to 60% of symptomatic patients have painless episodes of maroon or melanotic rectal bleeding. Bleeding is due to deep ileal ulcers adjacent to the diverticulum caused by acid secreted by heterotopic gastric tissue and may be voluminous enough to cause shock and anemia. Occult bleeding is less common. Intestinal obstruction occurs in 25% of symptomatic patients as a result of ileocolonic intussusception. Intestinal volvulus may occur around a fibrous remnant of the vitelline duct extending from the tip of the diverticulum to the abdominal wall. In some patients, entrapment of bowel under a band running between the diverticulum and the base of the mesentery occurs. Meckel diverticula may be trapped in an inguinal hernia. Diverticulitis occurs in 10%–20% of symptomatic patients and is clinically indistinguishable from acute appendicitis. Perforation and peritonitis may occur.

B. Imaging

Diagnosis of Meckel diverticulum is made with a Meckel scan. Technetium-99 (^{99m}Tc)-pertechnetate is taken up by the heterotopic gastric mucosa in the diverticulum and

outlines the diverticulum on a nuclear scan. Giving penta-gastrin or cimetidine before administering the radionuclide increases ^{99m}Tc-pertechnetate uptake and retention by the heterotopic gastric mucosa, and can increase the sensitivity of the test.

▶ Treatment & Prognosis

Treatment is surgical. At laparoscopy or laparotomy, the ileum proximal and distal to the diverticulum may reveal ulcerations and heterotopic gastric tissue adjacent to the neck of the diverticulum. The prognosis for Meckel diverticulum is good.

ACUTE APPENDICITIS

▶ General Considerations

Acute appendicitis is the most common indication for emergency abdominal surgery in childhood. The frequency increases with age and peaks between 15 and 30 years. Obstruction of the appendix by fecalith (25%) is a common predisposing factor. Parasites may rarely cause obstruction (especially ascarids) and most of the remaining cases are idiopathic.

The incidence of perforation is high in childhood (40%), especially in children younger than 2 years, in whom pain is often poorly localized and symptoms nonspecific. To avoid delay in diagnosis, it is important to maintain close communication with parents and perform a thorough initial physical examination with sequential examinations at frequent intervals over several hours to correctly interpret the evolving symptoms and signs.

▶ Clinical Findings

A. Symptoms and Signs

The typical patient has fever and periumbilical abdominal pain, which then localizes to the right lower quadrant with signs of peritoneal irritation. Anorexia, vomiting, constipation, and diarrhea also occur. Contrary to the vomiting of acute gastroenteritis which usually precedes abdominal pain, vomiting in appendicitis usually follows the onset of pain and is often bilious. The clinical picture is frequently atypical, especially in young children and infants. A rectal examination may clarify the site of tenderness or reveal a localized appendiceal mass. Serial examinations are critical in differentiating appendicitis from the many other conditions that transiently mimic its symptoms.

B. Laboratory Findings

The white blood cell count is seldom higher than $15,000/\mu L$. Pyuria, fecal leukocytes, and guaiac-positive stool are sometimes present. The combination of elevated C-reactive protein (CRP) and leukocytosis has been reported to have positive predictive value of 92% for acute appendicitis, although having normal values for both measures does not exclude the diagnosis. Levels of interleukin 6 (IL-6) show promise as a potential biomarker for acute appendicitis, usually peaking within 24 hours of onset of pain.

C. Imaging

A radio-opaque fecalith reportedly is present in two-thirds of cases of ruptured appendix. In experienced hands, ultrasonography of the appendix shows a noncompressible, thickened appendix in 93% of cases. A localized fluid collection adjacent to or surrounding the appendix may also be seen. Abdominal CT after rectal instillation of contrast with thin cuts in the area of the appendix may be diagnostic. An otherwise normal abdominal CT scan with a nonvisualized appendix has still been reported to have a negative predictive value of 99%. Analysis of diagnostic strategies for pediatric patients with suspected appendicitis has shown abdominal ultrasound, followed by CT scan for negative studies, to be the most cost-effective compared to CT or ultrasound alone. Indium-labeled white blood cell scan may localize to an inflamed appendix. Enlarged mesenteric lymph nodes are a nondiagnostic finding.

▶ Differential Diagnosis

The presence of pneumonia, pleural effusion, urinary tract infection, right-sided kidney stone, cholecystitis, perihepatitis, and pelvic inflammatory disease may mimic appendicitis. Acute gastroenteritis with *Yersinia enterocolitica* may present as pseudoappendicitis in 17% of cases. Other medical and surgical conditions causing acute abdomen should also be considered (see Table 21–7).

▶ Treatment & Prognosis

Exploratory laparotomy or laparoscopy is indicated when the diagnosis of acute appendicitis cannot be ruled out after a period of close observation. Postoperative antibiotic therapy is reserved for patients with gangrenous or perforated appendix. A single intraoperative dose of cefoxitin or cefotetan is recommended for all patients to prevent postoperative infection. Nonoperative management of perforated appendicitis with antibiotic therapy and image-guided drainage of abdominal abscesses has become more commonplace. Failure of nonoperative management may occur in up to 38% of patients and is more commonly associated with bandemia on admission and persistent fever after the initial 24 hours of antibiotics. The mortality rate is less than 1% during childhood, despite the high incidence of perforation. In uncomplicated nonruptured appendicitis, a laparoscopic approach is associated with a shortened hospital stay.

DUPLICATIONS OF THE GASTROINTESTINAL TRACT

Enteric duplications are congenital spherical or tubular structures found most commonly in the ileum. Other common locations of duplication are the duodenum, rectum, and esophagus. Duplications usually contain fluid and sometimes blood if necrosis has taken place. Most duplications are attached to the mesenteric side of the gut and generally do not communicate with the intestinal lumen. The epithelial lining of the duplication is usually of the same type as the bowel from which it originates. Some duplications (neuroenteric cysts) are attached to the spinal cord and are associated with hemivertebrae and anterior or posterior spina bifida.

Symptoms of vomiting, abdominal distention, colicky pain, rectal bleeding, partial or total intestinal obstruction, or an abdominal mass may start in infancy. Diarrhea and malabsorption may result from bacterial overgrowth in communicating duplications. Physical examination may reveal a rounded, smooth, movable mass, and barium radiograph or CT of the abdomen may show a noncalcified cystic mass displacing other organs. ^{99m}Tc-pertechnetate scan may help identify duplications containing gastric mucosa. Duplications of the ileum can give rise to an intussusception. Prompt surgical treatment is indicated.

▼ DISORDERS OF THE COLON

CONGENITAL AGANGLIONIC MEGACOLON (HIRSCHSPRUNG DISEASE)

▶ General Considerations

Hirschsprung disease results from an absence of ganglion cells in the mucosal and muscular layers of the colon. Neural crest cells fail to migrate into the mesodermal layers of the gut during gestation, possibly secondary to abnormal end-organ cell surface receptors or local deficiency of nitric oxide synthesis. The absence of ganglion cells results

in failure of the colonic muscles to relax in front of an advancing bolus. In 80% of individuals, aganglionosis is restricted to the rectosigmoid colon (short-segment disease); in 15%–20%, aganglionosis extends proximal to the sigmoid colon (long-segment disease); in about 5%, aganglionosis affects the entire large intestine (total colonic aganglionosis). Segmental aganglionosis is possible but rare.

The aganglionic segment has normal or slightly narrowed caliber with dilation of the normal colon proximal to the obstructing aganglionic segment. The mucosa of the dilated colonic segment may become thin and inflamed, causing diarrhea, bleeding, and protein loss (enterocolitis).

A familial pattern has been described, particularly in total colonic aganglionosis. The incidence of Hirschsprung disease is 1 in 5000 live births; it is four times more common in boys than girls. A chromosomal abnormality is present in approximately 12% of individuals with Hirschsprung disease. Mutations in the ret proto-oncogene have been identified in about 15% of nonsyndromic cases. The most common chromosomal abnormality is associated Down syndrome, which occurs in 2%–10% of all individuals.

▶ Clinical Findings

A. Symptoms and Signs

Failure of the newborn to pass meconium, followed by vomiting, abdominal distention, and reluctance to feed, suggests the diagnosis of Hirschsprung disease. Most children with Hirschsprung disease do not pass stool in the first 24 hours of their life. Enterocolitis manifested by fever, explosive diarrhea, and prostration is reported in approximately 50% of affected newborns. Enterocolitis may lead to inflammatory and ischemic changes in the colon, with perforation and sepsis. In some patients, especially those with short segments involved, symptoms are not obvious at birth. In later infancy, alternating obstipation and diarrhea predominate. The older child is more likely to have constipation alone. The stools can be foul-smelling and ribbon-like. The abdomen is distended with prominent veins. Peristaltic waves are visible and fecal masses palpable. Intermittent bouts of intestinal obstruction, hypochromic anemia, hypoproteinemia, and failure to thrive are common. Encopresis is rare.

On digital rectal examination, the anal canal and rectum are devoid of fecal material despite obvious retained stool on abdominal examination or radiographs. If the aganglionic segment is short, there may be a gush of flatus and stool as the finger is withdrawn.

Infants of diabetic mothers may have similar symptoms, and in this setting small left colon syndrome should be suspected. Meglumine diatrizoate (Gastrografin) enema is both diagnostic and therapeutic in small left colon syndrome as it reveals a meconium plug in the left colon, which is often

passed during the diagnostic radiograph. The left colon is narrow but usually functional.

B. Laboratory Findings

Ganglion cells are absent in both the submucosal and muscular layers of involved bowel. Special stains may show nerve trunk hypertrophy and increased acetylcholinesterase activity. Ganglionated bowel above the aganglionic segment is sometimes found to contain more than normal numbers of ganglion cells in abnormal locations (neuronal dysplasia).

C. Imaging

Plain abdominal radiographs may reveal dilated proximal colon and absence of gas in the pelvic colon. Barium enema using a catheter without a balloon and with the tip inserted barely beyond the anal sphincter usually demonstrates a narrow distal segment with a sharp transition to the proximal dilated (normal) colon. Transition zones may not be seen in neonates since the normal proximal bowel has not had time to become dilated. Retention of barium for 24–48 hours is not diagnostic of Hirschsprung disease in older children as it typically occurs in retentive constipation as well.

D. Special Examinations

Rectal manometric testing reveals failure of reflex relaxation of the internal anal sphincter after distention of the rectum in all patients with Hirschsprung disease, regardless of the length of the aganglionic segment. In occasional patients, a nonrelaxing internal anal sphincter is the only abnormality. This condition is often called "ultrashort segment Hirschsprung disease."

▶ Differential Diagnosis

Hirschsprung disease accounts for 15%–20% of cases of neonatal intestinal obstruction. It must be differentiated from the small left colon syndrome by biopsy. In childhood, Hirschsprung disease must be differentiated from retentive constipation, hypothyroidism, intestinal pseudo-obstruction, and other motility disorders. In older infants and children, it can also be confused with CD because of the striking abdominal distention and failure to thrive.

▶ Treatment & Prognosis

Treatment is surgical. Depending on the child's size and state of health, a diverting colostomy (or ileostomy) may be performed or the surgeon may undertake a primary repair. In unstable infants, resection of the aganglionic segment may be postponed. At the time of definitive surgery, the transition zone between ganglionated and nonganglionated bowel is identified. Aganglionic bowel is resected, and a pull-through of ganglionated bowel to the preanal rectal remnant is made. The three most commonly performed repairs are

the Swenson, Duhamel, and Soave procedures. Several surgical techniques, including laparoscopic pull-through, are in use. In children with ultrashort segment disease, an internal anal sphincter myotomy, or botulinum toxin injection of the internal anal sphincter may control symptoms.

Complications after surgery include fecal retention, fecal incontinence, anastomotic breakdown, or anastomotic stricture. Postoperative obstruction may result from inadvertent retention of a distal aganglionic colon segment or postoperative destruction of ganglion cells secondary to vascular impairment. Neuronal dysplasia of the remaining bowel may produce a pseudo-obstruction syndrome. Enterocolitis occurs postoperatively in 15% of patients.

CONSTIPATION

Chronic constipation in childhood is defined as two or more of the following characteristics for 2 months: (1) fewer than three bowel movements per week; (2) more than one episode of encopresis per week; (3) impaction of the rectum with stool; (4) passage of stool so large it obstructs the toilet; (5) retentive posturing and fecal withholding; and (6) pain with defecation. Retention of feces in the rectum results in encopresis (involuntary fecal leakage) in 60% of children with constipation. Most constipation in childhood is a result of voluntary or involuntary retentive behavior (chronic retentive constipation). About 2% of healthy primary school children have chronic retentive constipation. The ratio of males to females may be as high as 4:1.

▶ Clinical Findings

Infants younger than 3 months often grunt, strain, and turn red in the face while passing normal stools. Failure to appreciate this normal developmental pattern may lead to the unwise use of laxatives or enemas. Many infants who strain are displaying symptoms of infant dyschezia. The diagnostic criteria for infant dyschezia are at least 10 minutes of straining and crying before successful passage of soft stools in an otherwise healthy infant younger than 6 months. Infants and children may, however, develop the ability to ignore the sensation of rectal fullness and retain stool. Many factors reinforce this behavior, which results in impaction of the rectum and overflow incontinence or encopresis. Among

these are painful defecation; skeletal muscle weakness; psychological issues, especially those relating to abuse, control and authority; modesty and distaste for school bathrooms; medications; and other factors listed in Table 21–2. The dilated rectum gradually becomes less sensitive to fullness, thus perpetuating the problem.

▶ Differential Diagnosis

One must distinguish between chronic retentive constipation from Hirschsprung disease as summarized in Table 21–3.

▶ Treatment

A careful diet history is important to ensure that the child is consuming adequate dietary fiber and maintaining an adequate fluid intake. If diet change alone is ineffective, medications may be required. Treatment is usually begun with osmotic stool softeners such as milk of magnesia, lactulose, or polyethylene glycol solution (MiraLax). Stimulant laxatives such as standardized extract of senna fruit (Senokot syrup, ExLax) can be used for those with chronic difficulties in which there are concerns about a dilated colon resulting in inefficient empting. If encopresis is present, treatment should start with relieving fecal impaction. Disimpaction can be achieved in several ways, including medications

such as hypertonic phosphate or saline enemas, mineral oil (2–3 mL/kg/d), and nonabsorbable osmotic agents such as polyethylene glycol (MiraLax, 1 g/kg/d) and milk of magnesia (1–2 mL/kg/d). Effective stool softeners should thereafter be given regularly in doses sufficient to induce two or three loose bowel movements per day. After several weeks to months of regular loose stools, stool softeners can be tapered and stopped. For many children with retentive constipation behavioral modification is an integral part of management. Regular toilet sittings, ensuring proper foot placement while sitting on the toilet and addressing any underlying fears about toileting by the child. Mineral oil should not be given to nonambulatory infants, physically handicapped or bedbound children, or any child with GE reflux. Aspiration of mineral oil may cause lipid pneumonia. A multiple vitamin supplement is recommended while mineral oil is given. Recurrence of encopresis is common and should be treated promptly to eliminate the fecal impaction and avoid the cycle of impaction, soiling, and retentive behaviors.

Table 21–2. Causes of constipation.

Functional or retentive causes	**Abnormalities of myenteric ganglion cells**
Dietary causes	Hirschsprung disease
Undernutrition, dehydration	Waardenburg syndrome
Excessive milk intake	Multiple endocrine neoplasia 2a
Lack of bulk	**Hypo- and hyperganglionosis**
Cathartic abuse	von Recklinghausen disease
Drugs	Multiple endocrine neoplasia 2b
Narcotics	Intestinal neuronal dysplasia
Antihistamines	Chronic intestinal pseudo-obstruction
Some antidepressants	**Spinal cord defects**
Vincristine	**Metabolic and endocrine disorders**
Structural defects of gastrointestinal tract	Hypothyroidism
Anus and rectum	Hyperparathyroidism
Fissure, hemorrhoids, abscess	Renal tubular acidosis
Anterior ectopic anus	Diabetes insipidus (dehydration)
Anal and rectal stenosis	Vitamin D intoxication (hypercalcemia)
Presacral teratoma	Idiopathic hypercalcemia
Small bowel and colon	**Skeletal muscle weakness or incoordination**
Tumor, stricture	Cerebral palsy
Chronic volvulus	Muscular dystrophy/myotonia
Intussusception	
Smooth muscle diseases	
Scleroderma and dermatomyositis	
Systemic lupus erythematosus	
Chronic intestinal pseudo-obstruction

ANAL FISSURE

Anal fissure is a slit-like tear in the squamous epithelial mucosa of the anal canal between the anocutaneous junction and the dentate line that usually occurs secondary to the passage of large, hard fecal masses. Anal stenosis, anal crypt abscess, and trauma can be contributory factors. Most anal fissures are single in number and occur at the posterior midline. Multiple fissures of the anal canal, lateral fissures, or those that extend proximal to the dentate line should raise the suspicion of a more serious underlying disease process including sexual abuse. Anal fissures may be the presenting sign of CrD disease in older children.

The infant or child with anal fissure typically cries with defecation and will try to hold back stools. Sparse, bright red bleeding is seen on the outside of the stool or on the toilet tissue following defecation. The fissure can often be seen if the patient is examined in a knee-chest position with the buttocks spread apart. When a fissure cannot be identified, it is essential to rule out other causes of rectal bleeding such as juvenile polyp, perianal inflammation due to group A β-hemolytic streptococcus, or inflammatory bowel disease

(IBD). Anal fissures should be treated promptly to break the constipation, fissure, pain, retention, and constipation cycle. A stool softener should be given. Anal dilation relieves sphincter spasm. Warm sitz baths after defecation may be helpful. Rarely, silver nitrate cauterization or surgery is indicated. Anal surgery should be avoided in patients with Crohn disease because of the high risk of recurrence and progression after surgery.

CONGENITAL ANORECTAL ANOMALIES

1. Anterior Displacement of the Anus

Anterior displacement of the anus is a common anomaly of infant girls. Its usual presentation in infants is constipation and straining with stool. On physical examination, the anus looks normal but is ventrally displaced, located close to the vaginal fourchette (in females) or to the base of the scrotum (in males). The diagnosis is made in girls if the distance from the vaginal fourchette to the center of the anal opening is less than 34% of the total distance from fourchette to coccyx. In boys, the diagnosis is made if the distance from the base of the scrotum to the anal aperture is less than 46% of the total distance from scrotum to coccyx. Often on internal digital examination a posterior "rectal shelf" will be appreciated. In severe anterior displacement, when the anal opening is located less than 10% of the distance from the vaginal fourchette to the coccyx, the anal sphincter muscle may not completely encircle the anal opening and severe obstipation similar to that seen in imperforate anus may occur. Indeed, extreme anterior displacement of the anus may be a form of imperforate anus. Surgery is not needed in most cases. Stool softeners or occasional glycerin suppositories usually relieve straining. This problem improves significantly by age 3–4 years as normal toddler lordosis disappears.

2. Anal Stenosis

Anal stenosis usually presents in the newborn period. The anal aperture may be very small and filled with a dot of meconium. Defecation is difficult, with ribbonlike stools, blood and mucus per rectum, fecal impaction, and abdominal distention. Anal stenosis occurs in about 3 of 10,000 live births, with slightly more males affected. Anal stenosis may not be apparent at birth because the anus looks normal. Rectal bleeding in a straining infant often leads to a rectal examination which reveals a tight ring in the anal canal. Dilation of the anal ring is usually curative but may have to be repeated daily for several weeks.

3. Imperforate Anus

Imperforate anus typically develops during the fifth to seventh week of pregnancy and occurs in 1 of 5000 live births, slightly more common males. Almost 50% of babies with

imperforate anus have additional defects, often in association with a particular syndrome.

Defects are generally classified as low (rectoperineal malformation); the rectum may not connect to the anus, a membrane may be present over the anal opening, the anal opening may be narrow or misplaced, or a high lesion where the rectum may connect to part of the urinary tract or the reproductive system through a fistula. Infants with low imperforate anus fail to pass meconium. There may be a greenish bulging membrane obstructing the anal aperture. Perforation of the anal membrane is a relatively simple surgical procedure. A skin tag shaped like a "bucket handle" is seen on the perineum of some males below which a stenotic aperture can be seen. The aperture is sometimes surrounded by normal anal musculature, but in many cases the aperture is a rectoperineal fistula and the anal musculature is displaced posteriorly or is absent. Eighty to 90% of patients with low imperforate anus are continent after surgery.

In high imperforate anus, physical examination usually shows no anal musculature. There may be a rectoperineal, rectovesicular, rectourethral, or rectovaginal fistula; hypoplastic buttocks; cloacal anomalies; and sometimes evidence of distal neurologic deficit. It is critical in these cases to fully evaluate the complex anatomy and neurologic function before attempting corrective surgery. A diverting colostomy is usually performed to protect the urinary tract and relieve obstruction. After reparative surgery, only 30% of patients with high imperforate anus achieve fecal continence.

CLOSTRIDIUM DIFFICILE INFECTION IN CHILDREN

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ *Clostridium difficile* in children leads to a spectrum of clinical disease, from asymptomatic colonization to severe pseudomembranous colitis with fever, severe abdominal pain, and bloody diarrhea.

▶ Risk factors for *C difficile* disease include previous antibiotic use and a variety of chronic diseases, including immunodeficiency, cystic fibrosis, Hirschsprung disease, IBD, oncology patients, and solid-organ transplant recipients.

▶ Community-acquired *C difficile* disease in healthy hosts is increasing in incidence.

▶ Pathogenesis

C difficile is a spore-forming gram-positive bacillus that causes human disease via the secretion of enterotoxins that cause necrotizing inflammation of the colon. Interestingly, asymptomatic *C difficile* colonization of the human GI tract occurs commonly in infants and can occur in older children and adults as well. To some extent, *C difficile* may reside in balance with the constituent intestinal microbiome in a health host. Disruption of normal commensal intestinal bacteria or interruption of host immune defense, via intestinal injury or host immune suppression, then appears to give *C difficile* a potential foothold in the human gut where it can lead to disease. Hospitalization is a critical risk factor for *C difficile* disease. Additional risk factors in children include previous antibiotic use and a variety of chronic diseases including IBD, cystic fibrosis, Hirschsprung disease, solid-organ transplant recipients, oncology patients, and immunodeficient hosts. For reasons that are incompletely understood, community-acquired symptomatic *C difficile* infection in healthy children is increasing in incidence.

In recent years there has been an alarming increase in the incidence, morbidity, and mortality of *C difficile* reported in Europe, Canada, and the United States. At least a portion of this increase seems to be due to the expansion of a new strain of *C difficile*, identified as the North American Pulsed Field type 1 (NAP1) *C difficile*, which has been found to have increased toxin production, sporulation, and antibiotic resistance. Surveillance from children's hospitals seems to mirror the increase in incidence of *C difficile* in adults but not necessarily the increase in morbidity and mortality. Pediatric hospitalizations in the United States due to *C difficile* have almost doubled between 1997 and 2006. The NAP1 strain was identified in 19% of *C difficile* isolates in a recent pediatric study.

▶ Clinical Findings

C difficile disease in children represents a spectrum of clinical symptoms, ranging from asymptomatic colonization to persistent, watery diarrhea to pseudomembranous colitis. Recognizing that antibiotic exposure remains a critical risk factor, the onset of colitis ranges from 1 to 14 days after initiation of antibiotic therapy to as many as 30 days after antibiotics have been discontinued. Clindamycin was one of the first antibiotics associated with pseudomembranous colitis, but now all antibiotics are now recognized to be potential causes, although erythromycin seems less likely than most. In pediatric patients, amoxicillin and cephalosporins are commonly associated with pseudomembranous enterocolitis, probably because of their widespread use.

The patient with pseudomembranous colitis characteristically has fever, abdominal distention, tenesmus, diarrhea, and generalized abdominal tenderness. Chronic presentations with low-grade fever, diarrhea, and abdominal pain have

been described. Diarrheal stools contain sheets of neutrophils and sometimes gross blood. Plain abdominal radiographs show a thickened colon wall and ileus. Endoscopically, the colon appears to be covered by small, raised white plaques (pseudomembranes) with areas of apparently normal bowel in between (Figure 21–5). Biopsy specimens show "exploding crypts or volcano lesion"—an eruption of white cells that appears to be shooting out of affected crypts. Stool cultures often show overgrowth of *Staphylococcus aureus*, which is probably an opportunistic organism growing in the necrotic tissue. *C difficile* can be cultured in specialized laboratories. Identification of stool toxins is the usual method of diagnosis. Use of real-time polymerase chain reaction (PCR) for toxin identification has been replacing more traditional enzyme immunoassay (EIA) methods of stool toxin detection, because of improved sensitivity. Interpretation of *C difficile* diagnostic testing in infants remains controversial because asymptomatic colonization is well recognized in the first year of life.

▶ Treatment

Standard treatment of pseudomembranous colitis consists of stopping antibiotics and instituting therapy with oral metronidazole (30 mg/kg/d) or vancomycin (30–50 mg/kg/d). Vancomycin is many times more expensive than metronidazole and no more efficacious. Metronidazole can be given intravenously in patients with vomiting or ileus. With
increasing virulence and antibiotic resistance being reported, alternative therapies, such as rifaximin and nitazoxanide, are being used and show similar response rates as oral vancomycin. Relapse occurs after treatment in 10%–50% of patients because of exsporulation of residual spores in the colon. Spores are very hardy and may remain viable on inanimate surfaces for up to 12 months. Retreatment with the same antibiotic regimen is usually effective, but multiple relapses are possible and may be a significant management problem. Adjunctive strategies, such as *Saccharomyces boulardii* probiotic therapy, cholestyramine as a toxin-binder and pulsed courses of antibiotics have been used for refractory disease. Fecal bacteriotherapy, known popularly as *fecal transplantation*, is now a widely accepted and nearly 100% effective treatment for the treatment of recurrent *C difficile* infection in adults but experience remains limited in children.

▼ DISORDERS OF THE PERITONEAL CAVITY

PERITONITIS

Primary bacterial peritonitis accounts for less than 2% of childhood peritonitis. The most common causative organisms are *Escherichia coli*, other enteric organisms, hemolytic streptococci, and pneumococci. Primary peritonitis occurs in patients with splenectomy, splenic dysfunction, or ascites (nephrotic syndrome, advanced liver disease, kwashiorkor). It also occurs in infants with pyelonephritis or pneumonia.

Secondary peritonitis is much more common. It is associated with peritoneal dialysis, penetrating abdominal trauma, or ruptured viscus. The organisms associated with secondary peritonitis vary with the cause. Organisms not commonly pathogenic such as *Staphylococcus epidermidis* and *Candida* may cause secondary peritonitis in patients receiving peritoneal dialysis. Multiple enteric organisms may be isolated after penetrating abdominal injury, bowel perforation, or ruptured appendicitis. Intra-abdominal abscesses may form in pelvic, subhepatic, or subphrenic areas, but discrete localization of infection is less common in young infants than in adults.

▲ **Figure 21–5.** *Clostridium difficile*–associated pseudomembranes. Colonic mucosa is covered with plaques coated with white exudates.

Symptoms of peritonitis include abdominal pain, fever, nausea, vomiting, acidosis, and shock. Respirations are shallow. The abdomen is tender, rigid, and distended, with involuntary guarding. Bowel sounds may be absent. Diarrhea is fairly common in primary peritonitis and less so in secondary peritonitis. Most peritonitis is an acute medical emergency. In patients receiving peritoneal dialysis, peritonitis can be a chronic infection causing milder symptoms.

Leukocyte count is high initially (> 20,000/μL) with a predominance of immature forms, and later it may fall to neutropenic levels, especially in primary peritonitis. Abdominal imaging can confirm the presence of ascites. Bacterial peritonitis should be suspected if paracentesis fluid contains more than 500 leukocytes/μL or more than 32 mg/dL of lactate; if it has a pH less than 7.34; or if the pH is over 0.1 pH unit less than arterial blood pH. Diagnosis is made by Gram stain and culture, preferably of 5–10 mL of fluid for optimal yield. The blood culture is often positive in primary peritonitis.

Antibiotic treatment and supportive therapy for dehydration, shock, and acidosis are indicated. Surgical treatment of the underlying cause of secondary peritonitis is critical. Removal of infected peritoneal dialysis catheters in patients with secondary peritonitis is sometimes necessary and almost always required if *Candida* infection is present.

CHYLOUS ASCITES

Neonatal chylous ascites may be due to congenital infection or developmental abnormality of the lymphatic system (intestinal lymphangiectasia). If the thoracic duct is involved, chylothorax may be present. Later in life, chylous ascites may result from congenital lymphangiectasia, retroperitoneal or lymphatic tumors, peritoneal bands, abdominal trauma, or infection, or it may occur after cardiac or abdominal surgery. It may be associated with intestinal malrotation.

▶ Clinical Findings

A. Symptoms and Signs

Both congenital and acquired lymphatic obstructions cause chylous ascites, diarrhea, and failure to thrive. The abdomen is distended, with a fluid wave and shifting dullness. Unilateral or generalized peripheral edema may be present.

B. Laboratory Findings

Laboratory findings include hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. Ascitic fluid contains lymphocytes and has the biochemical composition of chyle if the patient has just been fed; otherwise, it is indistinguishable from ascites secondary to cirrhosis.

▶ Differential Diagnosis

Chylous ascites must be differentiated from ascites due to liver disease and in the older child, from constrictive pericarditis, chronically elevated right heart pressure, malignancy, infection, or inflammatory diseases causing lymphatic obstruction. In the newborn, urinary ascites from anatomic abnormalities of the kidney or collecting system must be considered. A simple test to diagnose urinary ascites is a urea nitrogen or creatinine concentration of abdominal fluid. Neither of these is present in chylous or hepatic ascites.

▶ Complications & Sequelae

Chylous ascites caused by intestinal lymphatic obstruction is associated with fat malabsorption and protein loss. Intestinal loss of albumin and γ-globulin may lead to edema and increase the risk of infection. Rapidly accumulating chylous ascites may cause respiratory complications. The primary infections and malignancies causing chylous ascites may be life threatening.

▶ Treatment & Prognosis

Little can be done to correct congenital abnormalities due to hypoplasia, aplasia, or ectasia of the lymphatics unless they are surgically resectable. More recently, somatostatin and fibrin glue have been tried with varying success. Treatment is supportive, consisting mainly of a very high-protein diet and careful attention to infections. Shunting of peritoneal fluid into the venous system is sometimes effective. A fat-free diet supplemented with medium-chain triglycerides decreases the formation of chylous ascites. Total PN (TPN) may rarely be necessary. Infusions of albumin generally provide only temporary relief and are rarely used for chronic management. In the neonate, congenital chylous ascites may spontaneously disappear following one or more paracenteses and a medium-chain triglyceride diet.

GASTROINTESTINAL TUMORS & MALIGNANCIES

JUVENILE POLYPS

Juvenile polyps belong to the hamartomatous category of polyps are usually pedunculated and solitary (Figure 21–6). The head of the polyp is composed of hyperplastic glandular and vascular elements, often with cystic transformation. Juvenile polyps are benign, and 80% occur in the rectosigmoid. These are the most common type of intestinal polyps in children. Their incidence is highest between ages 3 and 5 years. They are rare before age 1 year and usually occur before age 10. The painless passage of small amounts of bright red blood with mucus on a normal or constipated stool is the most frequent manifestation. Abdominal pain is rare, but low-lying polyps may prolapse during defecation. Colonoscopy is diagnostic and therapeutic when polyps are suspected. After removal of the polyp by electrocautery, nothing further should be done if histologic findings confirm the diagnosis. There is a slight risk of developing further juvenile polyps. Other polyposis syndromes are summarized in Table 21–4.

Rarely, many juvenile polyps may be present in the colon, causing anemia, diarrhea with mucus, and protein loss. An individual may be diagnosed with juvenile polyposis syndrome if there are more than five juvenile polyps in the colon, multiple juvenile polyps elsewhere in the GI tract, or any number of juvenile polyps with a family history of juvenile polyposis syndrome. Other types of hamartomatous polyp syndromes include Peutz–Jeghers syndrome and the PTEN hamartoma tumor syndrome. Peutz-Jaghers syndrome is associated with polyps commonly in the small intestine and colon but can also been seen in the stomach and in other organs. There is a distinctive mucocutaneous pigmentation (freckling) that appears early on but can disappear by age 5, along the vermillion border of the lips, buccal mucosa, and hands and feet. Besides of the higher risk of both GI and non-GI malignancies, routine cancer surveillance is necessary. In addition, 50% will develop intussusception at some point in their lifetime. PTEN hamartoma syndrome involves a spectrum of hamartomatous conditions that are associated with mutations in the PTEN gene. This includes nearly all Cowden syndrome and some Bannayan-Riley Ruvalcaba syndrome and Proteus syndrome. Besides hamartomas and other benign tumors throughout the body, there is an increased risk of intestinal and extraintestinal cancers.

Zbuk KM, Eng C: Hamartomatous polyposis syndromes: Nat Clin Pract Gastroenterol Hepatol 2007 Sep;4(9):492–502.

CANCERS OF THE ESOPHAGUS, SMALL BOWEL, & COLON

Esophageal cancer is rare in childhood. Cysts, leiomyomas, and hamartomas predominate. Caustic injury of the esophagus increases the very long-term risk of squamous cell carcinoma. Chronic peptic esophagitis is associated with Barrett esophagus, a precancerous lesion. Simple GE reflux in infancy without esophagitis is not a risk for cancer of the esophagus.

The most common gastric or small bowel cancer in children is lymphoma or lymphosarcoma. Intermittent abdominal pain, abdominal mass, intussusception, or a celiac-like picture may be present. Carcinoid tumors are usually benign and most often an incidental finding in the appendix. Metastasis is rare. The carcinoid syndrome (flushing, sweating, hypertension, diarrhea, and vomiting), associated with serotonin secretion, only occurs with metastatic carcinoid tumors.

Adenocarcinoma of the colon is rare in childhood. The transverse colon and rectosigmoid are the two most commonly affected sites. The low 5-year survival rate relates to the nonspecificity of presenting complaints and the large

▲ **Figure 21–6.** Juvenile polyp. Solitary, smooth polyp coated with exudate and erythematous pattern that lies on the surface of a normal colonic mucosa.

Table 21–4. Gastrointestinal polyposis syndromes.

	Location	Number	Histology	Extraintestinal Findings	Malignant Potential	Recommended Therapy
Juvenile polyps	Colon	Single (70%) Several (30%)	Hyperplastic, hamartomatous	None	None	Remove polyp for continuous bleeding or prolapse.
Juvenile polyposis syndrome[a]	Colon, stomach, small bowel	≥ 5	Hyperplastic, hamartomatous, can have focal adenomatous change	None	Up to 50%	Remove all polyps. Consider colectomy if very numerous or adenomatous.
PTEN hamartoma tumor syndrome[a]	Colon, stomach, small bowel	Multiple	Hyperplastic, hamartomatous	Skin, eyes, GU, CNS. Cancers especially for breast, thyroid, and endometrium	16% colorectal cancer risk	Surveillance colonoscopies
Peutz-Jeghers syndrome[a]	Small bowel, stomach, colon	Multiple	Hamartomatous	Pigmented cutaneous and oral macules; ovarian cysts and tumors; bony exostoses	2%–3%	Remove accessible polyps or those causing obstruction or bleeding.
Cronkhite-Canada syndrome	Stomach, colon; less commonly, esophagus and small bowel	Multiple	Hamartomatous	Alopecia; onychodystrophy; hyperpigmentation	Rare	None.
Familial adenomatous polyposis[a]	Colon; less commonly, stomach and small bowel	Multiple	Adenomatous	None	95%–100%	Colectomy by age 18 years.

[a]Autosomal dominant.
[b]Autosomal recessive.

percentage of undifferentiated types. Children with a family history of colon cancer, chronic ulcerative colitis (UC), or familial polyposis syndromes are at greater risk.

MESENTERIC CYSTS

Mesenteric and omental cysts are rare intra-abdominal masses in children. These cysts may be small or large, single or multiloculated. They are thin-walled and contain serous, chylous, or hemorrhagic fluid. They are commonly located in the small bowel mesentery but are also found in the mesocolon. Most mesenteric cysts cause no symptoms and are found incidentally. Traction on the mesentery may lead to colicky abdominal pain, which can be mild and recurrent but may appear acutely with vomiting. Volvulus may occur around a cyst, and hemorrhage into a cyst may be mild or hemodynamically significant. A rounded mass can occasionally be palpated or seen on radiograph displacing adjacent intestine. Abdominal ultrasonography is usually diagnostic. Surgical removal is indicated.

Tan JJ, Tan KK, Chew SP: Mesenteric cysts: an institution experience over 14 years and review of the literature. Worl J Surg 2009 Sep;33(9):1961–1965 [PMID: 19609826].

INTESTINAL HEMANGIOMAS AND VASCULAR MALFORMATIONS

Hemangiomas and vascular malformations of the GI tract are uncommon causes of GI bleeding in children and adults. Like their skin counterparts, intestinal hemangiomas are typically not present at birth and then appear in the first 2 months of life, undergoing a rapidly proliferating growth phase during the first year, during which they are most likely to cause symptomatic bleeding, before involution thereafter. Vascular malformations include capillary, arterial, venous, and mixed lesions, and are present from birth with risk of bleeding throughout life. The physically largest subtype of vascular lesion is the cavernous malformation, which may protrude into the lumen as a polypoid lesion or may invade the intestine from mucosa to serosa.

▶ Clinical Presentation

These vascular lesions are most often found in the small intestine and may cause acute or occult blood loss. They may also cause intussusception, local stricture, or intramural hematoma. Thrombocytopenia and consumptive coagulopathy are occasional complications of rapidly growing hemangiomas during their rapid proliferation phase. Typically intestinal vascular lesions are found in isolation, but associated syndromes include the blue rubber bleb nevus syndrome, the Osler-Rendu-Weber syndrome, and the Klippel-Trenaunay-Weber syndrome. The diagnosis of GI bleeding can be challenging, particularly when bleeding is occult. The physical examination is typically not helpful unless there are other skin hemangiomas present in the young child that may point to an intestinal hemangioma. Vascular protocols with CT or magnetic resonance imaging (MRI) may identify larger vascular lesions. Endoscopic techniques remain crucial to the diagnosis of intestinal vascular lesions. Video capsule endoscopy and small bowel enteroscopy have allowed for diagnosis and potential therapy of small bowel vascular lesions that were previously inaccessible endoscopically.

▶ Treatment

Rapidly proliferating hemangiomas of the skin and liver have been treated medically with corticosteroids, propranolol, interferon, and vincristine. There is relatively little experience with using these medical techniques for intestinal hemangiomas. Endoscopic techniques for treatment of vascular lesions include banding, submucosal injections of sclerosants, and electrocautery methods. Surgical resection of the vascular lesion and surrounding bowel may be required for lesions in the mid-small bowel that are not accessible by endoscopy or for large lesions that are not amenable to endoscopic therapies.

Yoo S: GI-associated hemangiomas and vascular malformations. Clin Colon Rectal Surg 2011 Sep;24(3):193–200 [PMID: 22942801].

▼ MAJOR GASTROINTESTINAL SYMPTOMS & SIGNS

ACUTE DIARRHEA

Viruses are the most common cause of acute gastroenteritis in developing and developed countries. Bacterial and parasitic enteric infections are discussed in Chapters 42 and 43. Of the viral agents causing enteric infection, rotavirus, a 67-nm double-stranded RNA virus with at least eight serotypes, is the most common. As with most viral pathogens, rotavirus affects the small intestine, causing voluminous watery diarrhea without leukocytes or blood. In the United States, rotavirus primarily affects infants between 3 and 15 months of age. The peak incidence in the United States is in the winter with sporadic cases occurring at other times. The virus is transmitted via the fecal-oral route and survives for hours on hands and for days on environmental surfaces.

1. Rotavirus Infection

The incubation period for rotavirus is 1–3 days. Symptoms caused by rotavirus are similar to other viral pathogens. Vomiting is the first symptom in 80%–90% of patients, followed within 24 hours by low-grade fever and watery diarrhea. Diarrhea usually lasts 4–8 days but may last longer in young infants or immunocompromised patients. Rotavirus cannot be definitively diagnosed on clinical grounds alone. Rotavirus antigens can be identified in stool or virus can be seen by scanning electron microscopy. The specific identification of rotavirus is not required in every case, however, as treatment is nonspecific. Additionally laboratory testing is also generally unnecessary, but, when obtained, it will usually show a normal white blood cell count. Hyper- or hyponatremia may occur with dehydration. Metabolic acidosis can occur from bicarbonate loss in the stool, ketosis from poor intake, and in severe cases lactic acidemia occurs from hypotension and hypoperfusion. Stools do not contain blood or white blood cells.

Treatment is nonspecific and supportive, aimed at replacement of fluid and electrolyte deficits, along with ongoing losses, especially in small infants. (Oral and intravenous therapy are discussed in Chapter 45.) The use of oral rehydration solutions is appropriate in most cases. The use of clear liquids or hypocaloric (dilute formula) diets for more than 48 hours is not advisable. Early initiation of refeeding is recommended. Intestinal lactase levels may be reduced during rotavirus infection. Therefore, the brief use of a lactose-free diet may be associated with a shorter period of diarrhea but is not critical to successful recovery in healthy infants. Reduced fat intake during recovery may decrease nausea and vomiting.

Antidiarrheal medications are ineffective (kaolin-pectin combinations) and in some circumstances can be dangerous (loperamide, tincture of opium, diphenoxylate with atropine). Bismuth subsalicylate preparations may reduce stool volume but are not critical to recovery. Oral immunoglobulin or specific antiviral agents have occasionally been useful in limiting duration of disease in immunocompromised patients.

Most children are infected with rotavirus more than once, with the first infection being the most severe. Some protective immunity is imparted by the first infection. Prevention of infection occurs primarily by good hygiene and prevention of fecal-oral contamination. As treatment for rotavirus is nonspecific, prevention of illness is critical.

The American Academy of Pediatrics issued guidelines in January 2007 recommending the routine use of bovine-based pentavalent rotavirus vaccine to be given orally to infants at 2, 4, and 6 months of age.

2. Other Viral Infections Causing Acute Diarrhea

Other viral pathogens causing diarrhea in children can be identified in stool by electron microscopy, viral culture, or enzyme-linked immunoassay. Depending on the geographic location, enteric adenoviruses (serotypes 40 and 41) or caliciviruses are the next most common viral pathogens in infants. The symptoms of enteric adenovirus infection are similar to those of rotavirus, but infection is not seasonal and the duration of illness may be longer. The Norwalk agent (now called norovirus), a calicivirus, is a small RNA virus that mainly causes vomiting but can also cause diarrhea in older children and adults, usually in common source outbreaks. The duration of symptoms is short, usually 24–48 hours. Other potentially pathogenic viruses include astroviruses, corona-like viruses, and other small round viruses.

Cytomegalovirus rarely causes diarrhea in immunocompetent children but may cause erosive colitis or enteritis in immunocompromised hosts. Cytomegalovirus enteritis is particularly common after solid-organ and bone marrow transplant and in the late stages of human immunodeficiency virus (HIV) infection. Probiotics are moderately effective in treating acute viral gastroenteritis in healthy children. Probiotics should be used with extreme caution, however, in immunocompromised, chronically debilitated, or seriously ill children.

CHRONIC DIARRHEA

Bowel habits are variable, making the specific diagnosis of chronic diarrhea difficult. Some healthy infants may have five to eight stools daily. A gradual or sudden increase in the number and volume of stools to more than 15 g/kg/d combined with an increase in fluidity should raise a suspicion that an organic cause of chronic diarrhea is present. Diarrhea may result from (1) interruption of normal cell transport processes for water, electrolytes, or nutrients; (2) decrease in surface area available for absorption secondary to shortened bowel or mucosal disease; (3) increase in intestinal motility; (4) increase in unabsorbable osmotically active molecules in the intestinal lumen; (5) increase in intestinal permeability, leading to increased loss of water and electrolytes; and (6) stimulation of enterocyte secretion by toxins or cytokines. The most common entities causing chronic diarrhea are listed as follows. Malabsorption syndromes, which also cause chronic or recurrent diarrhea, are considered separately.

1. Causes of Chronic Diarrhea

A. Antibiotic Therapy

Acute and chronic diarrhea is reported in up to 60% of children receiving antibiotics. Only a small fraction of these patients have *C difficile*–related pseudomembranous enterocolitis. Eradication of normal gut flora and overgrowth of other organisms may cause antibiotic-associated diarrhea. Most antibiotic-associated diarrhea is watery, is not associated with systemic symptoms, and decreases when antibiotic therapy is stopped. Recent data suggest that the use of probiotics may decrease the incidence and severity of this diarrhea by helping to restore intestinal microbial balance.

B. Extraintestinal Infections

Infections of the urinary tract and upper respiratory tract (especially otitis media) are at times associated with diarrhea, though the mechanism is incompletely understood. Antibiotic treatment of the primary infection, toxins released by infecting organisms, and local irritation of the rectum (in patients with bladder infection) may play a role.

C. Malnutrition

Malnutrition is associated with an increased frequency of enteral infections. Decreased bile acid synthesis, decreased pancreatic enzyme output, decreased disaccharidase activity, altered motility, and changes in the intestinal flora all may contribute to diarrhea. In addition, severely malnourished children are at higher risk of enteric infections because of depressed immune functions, both cellular and humoral.

D. Diet and Medications

Relative deficiency of pancreatic amylase in young infants causes osmotic diarrhea after starchy foods. Fruit juices, especially those high in fructose or sorbitol, produce diarrhea because these osmotically active sugars are poorly absorbed. Intestinal irritants (spices and foods high in fiber)

and histamine-containing or histamine-releasing foods (eg, citrus fruits, tomatoes, fermented cheeses, red wines, and scombroid fish) may also cause diarrhea.

Laxative abuse in association with eating disorders or münchausen syndrome by proxy can cause unpredictable diarrhea. A high concentration of magnesium in the stool may indicate overuse of milk of magnesia or other magnesium-containing laxatives. Detection of other laxative preparations in the stool or circulation requires sophisticated analysis not available in most laboratories. A high index of suspicion and careful observation may be required to make this diagnosis.

E. Allergic Diarrhea

Diarrhea resulting from allergy to dietary proteins is a frequently entertained but rarely proven diagnosis. GI symptoms from cow's milk protein allergy are more common in infants younger than 12 months.

In contrast to the self-limited cow's milk protein hypersensitivity of infancy, infants, and older children may develop more severe diarrhea caused by a systemic allergic reaction. For instance, food protein–induced enterocolitis syndrome (FPIES) is a life-threatening condition occurring during infancy manifested by large volume diarrhea, acidosis, and shock as a result of an allergic reaction to common food proteins such as milk and soy. Patients require hospitalization for volume resuscitation and strict avoidance of allergens. Reintroduction of allergens should be performed in a controlled setting by an experienced allergist.

Infants and children may develop an enteropathy secondary to milk protein, resulting in flattening of small bowel villi, steatorrhea, hypoproteinemia, occult blood loss, and chronic diarrhea. Skin testing is not reliable since it detects circulating antibodies, not the T-cell–mediated responses that are probably responsible for food sensitivity reactions. Double-blind oral challenge with the suspected food under careful observation is often necessary to confirm this intestinal protein allergy. Small bowel biopsy findings are nonspecific. The diagnosis is often confirmed by either double-blind oral challenge with the suspected food or dietary elimination of the food followed by disappearance of occult blood in the stool and improvement in other symptoms. Consultation with an allergist is recommended for long-term management of patients with this disease.

Anaphylactic, immunoglobulin E (IgE)–mediated reactions to foods can occur in both young and older children. After ingestion, the patient quickly develops vomiting, then diarrhea, pallor, and hypotension. In these cases, radioallergosorbent test (RAST) and skin testing are positive. Food challenges should be undertaken in a setting in which resuscitation can be performed as there is often a progressively more severe reaction with subsequent ingestions. The close association between ingestion and symptoms usually leaves little doubt about the diagnosis.

F. Chronic Nonspecific Diarrhea

Chronic nonspecific diarrhea, also called *toddler's diarrhea*, is the most common cause of loose stools in otherwise thriving children. The typical patient is a healthy, thriving child aged 6–20 months who has three to six loose stools per day during the waking hours. They do not have blood in their stools. They grow normally and may have a family history of functional bowel disease. No organic etiology is found for their diarrhea, with stool tests for blood, white blood cells, fat, parasites, and bacterial pathogens being negative. Diarrhea may worsen with a low-residue, low-fat, or high-carbohydrate diet and during periods of stress and infection. Excessive fruit juice ingestion seems to worsen symptoms. This syndrome resolves spontaneously usually by age 3½ years or after potty training. Possible causes of this diarrhea include abnormalities of bile acid absorption in the terminal ileum, excess intake of osmotically active carbohydrates, and abnormal motor function. A change in dietary fiber (either increasing fiber if deficient or decreasing fiber if excessive), a slight increase in dietary fat, and restriction of osmotically active carbohydrates like fruit juices will usually help control symptoms. If these measures fail, loperamide (0.1–0.2 mg/kg/d in two or three divided doses) can be used as needed for symptomatic relief.

G. Immunologic Causes of Chronic Diarrhea

Chronic diarrhea is common in immune deficiency states, especially immunoglobulin A (IgA) deficiency and T-cell abnormalities. It can be due to an autoimmune enteropathy associated with the immune deficient state or could be due to chronic infection. The infectious causes of the diarrhea include common bacterial, viral, fungal, or parasitic organisms usually considered nonpathogenic (rotavirus, *Blastocystis hominis*, *Candida*), or unusual organisms (cytomegalovirus, *Cryptosporidium*, *Isospora belli*, *Mycobacterium* spp, microsporidia).

Between 50% and 60% of patients with common variable immune deficiency have enteropathy characterized by intestinal villous atrophy. Lymphonodular hyperplasia of the small intestine is also prominent. Patients with congenital or Bruton-type agammaglobulinemia usually have diarrhea and abnormal intestinal morphology. Patients with isolated IgA deficiency can have chronic diarrhea, a celiac disease-like picture, lymphoid nodular hyperplasia, and are prone to giardiasis. Patients with isolated defects of cellular immunity, combined cellular and humoral immune incompetence, and HIV infection may have severe chronic diarrhea leading to malnutrition but often the cause cannot be identified. Chronic granulomatous disease may be associated with intestinal symptoms suggestive of chronic IBD. Specific treatments are available for many of the unusual pathogens causing diarrhea in the immunocompromised host. Thus, a vigorous diagnostic search for specific pathogens is warranted in these

individuals. In addition, treatment must be directed toward correcting the immunologic defect.

H. Other Causes of Chronic Diarrhea

Most infections of the GI tract are acute and resolve spontaneously or with specific antibiotic therapy. Organisms most prone to cause chronic or recurrent diarrhea in immunocompetent children are *Giardia lamblia*, *Entamoeba histolytica*, *Salmonella* species, and *Yersinia*. Infection with these organisms requires a small inoculum. Some patients may develop a postinfectious diarrhea, with persistent diarrhea present despite the eradication of the offending organism, either viral or bacterial. Bacterial overgrowth of the small bowel in patients with SBS, those undergoing chemotherapy, or with anatomic abnormalities may experience chronic diarrhea.

Pancreatic insufficiency due to cystic fibrosis or Shwachman–Diamond Syndrome may result in chronic diarrhea, typically in conjunction with failure to thrive. Certain tumors of childhood (neuroblastoma, ganglioneuroma, metastatic carcinoid, pancreatic VIPoma, or gastrinoma) may secrete substances such as gastrin and vasoactive intestinal polypeptide (VIP) that promote small intestinal secretion of water and electrolytes. Conditions that result in increased or disordered intestinal motility such as hyperthyroidism or irritable bowel syndrome may also present with diarrhea. Children may present with large volume, chronic and intermittent watery diarrhea that does not cease when they discontinue oral feedings.

GASTROINTESTINAL BLEEDING

Vomiting blood and passing blood per rectum are alarming symptoms. The history, physical examination, and initial evaluation are key to identifying the bleeding source. In large-volume, acute GI bleeding the primary focus, however, should first center on stabilizing the patient to ensure adequate hemodynamic support.

▶ History

The first goal of the history is to determine if GI bleeding is truly blood and if the source is the GI tract. A number of substances simulate hematochezia or melena (Table 21–5). The presence of blood should be confirmed chemically with guaiac testing. Coughing, tonsillitis, lost teeth, menarche, or epistaxis may cause what appears to be occult or overt GI

Table 21–5. Identification of sites of gastrointestinal bleeding.

Symptom or Sign	Location of Bleeding Lesion
Effortless bright red blood from the mouth	Nasopharyngeal or oral lesions; tonsillitis; esophageal varices; lacerations of esophageal or gastric mucosa (Mallory-Weiss syndrome)
Vomiting of bright red blood or of "coffee grounds"	Lesion proximal to ligament of Treitz
Melanotic stool	Lesion proximal to ligament of Treitz, upper small bowel. Blood loss in excess of 50–100 mL/24 h
Bright red or dark red blood in stools	Lesion in the ileum or colon. (Massive upper gastrointestinal bleeding may also be associated with bright red blood in stool.)
Streak of blood on outside of a stool	Lesion in the rectal ampulla or anal canal

bleeding. A careful history of the specifics surrounding the bleeding is critical. Is the blood in emesis, stool, or both? How much blood is there and what is its color and character? History of NSAID use and other medications should be ascertained. Inquiry about associated dysphagia, epigastric pain, or retrosternal pain should be made and, if present, suggest GER or a peptic cause of bleeding. Table 21–6 gives further cues in the presentation to help identify the source of bleeding.

Other important aspects of the history include foreign-body/caustic ingestion, history of chronic illnesses (especially liver/biliary disease), personal or family history of food allergy/atopy, current and recent medications, associated symptoms (pain, vomiting, diarrhea, fever, weight loss), and family history of GI disorders (IBD, CD, liver disease, bleeding/coagulation disorder). In addition to these historical features, the age of the patient offers additional clues to determine the likely etiology. In the presence of massive upper GI bleeding in the toddler, a high index of suspicion for button battery ingestion must be maintained despite the lack of any known history of ingestion. Table 21–7 lists causes of GI bleeding by age and presentation.

▶ Physical Examination

The most important aspect of the examination and initial assessment is to determine if the child acutely or chronically ill and initiate supportive measures as rapidly as necessary. The physical examination should be thorough. Physical signs of portal hypertension, intestinal obstruction, or coagulopathy are particularly important. The nasal passages should be inspected for signs of recent epistaxis, the vagina for menstrual blood, and the anus for fissures and hemorrhoids.

Table 21–6. Differential diagnosis of gastrointestinal bleeding in children by symptoms and age at presentation.

	Infant	Child (2–12 y)	Adolescent (> 12 y)
Hematemesis	Swallowed maternal blood Peptic esophagitis Mallory-Weiss tear Gastritis Gastric ulcer Duodenal ulcer	Epistaxis Peptic esophagitis Caustic ingestion Mallory-Weiss tear Esophageal varices Gastritis Gastric ulcer Duodenal ulcer Hereditary hemorrhagic telangiectasia Hemobilia Henoch-Schönlein purpura	Esophageal ulcer Peptic esophagitis Mallory-Weiss tear Esophageal varices Gastric ulcer Gastritis Duodenal ulcer Hereditary hemorrhagic telangiectasia Hemobilia Henoch-Schönlein purpura

[c]Often accompanied by vomiting and right upper quadrant pain.
Reproduced, with permission, from Treem WR: Gastrointestinal bleeding in children. Gastrointest Endosc Clin N Am 1994;4:75.

Skin examination should assess for hemangiomas, eczema, petechiae, or purpura.

A systolic blood pressure below 100 mm Hg and a pulse rate above 100 beats/min in an older child suggest at least a 20% reduction of blood volume. A pulse rate increase of 20 beats/min or a drop in systolic blood pressure greater than 10 mm Hg when the patient sits up is also a sensitive index of volume depletion. Tachycardia may be the initial indication of persistent bleeding.

▶ Laboratory Findings

Initial laboratory tests should include a complete blood cell count (CBC), prothrombin time (PT), and partial thromboplastin time (PTT), at minimum. In specific cases it may be prudent to add a liver profile (with suspected variceal bleeding), erythrocyte sedimentation rate (ESR)/CRP (with possible IBD), blood urea nitrogen (BUN)/creatinine (for possible hemolytic uremic syndrome), and stool culture/*C difficile* toxin assay (for acute bloody diarrhea suggestive of infectious colitis). Low mean corpuscular volume (MCV) in association with anemia suggests chronic GI losses and may warrant addition of iron studies as well. Serial determination of vital signs and hematocrit are essential to assess ongoing bleeding. Detection of blood in the gastric aspirate confirms a bleeding site proximal to the ligament of Treitz. However, its absence does not rule out the duodenum as the source. Testing the stool for occult blood will help monitor ongoing loss of blood. In a large

Pelvic inflammatory disease

study of over 600 cases of pediatric upper GI bleeding, only 4% who were found to have significant drop in hemoglobin levels required transfusion or emergent endoscopic or surgical intervention. In this series having one or more risk factors, including melena, hematochezia, unwell appearance, and/or large amount of fresh blood in the emesis, had a sensitivity of 100% in identifying the significant bleeds.

▶ Imaging Studies

In infants with acute onset of bloody stools, multiple-view plain x-rays of the abdomen are helpful in assessing for pneumatosis intestinalis or signs of obstruction. Children younger than 2, with a history and examination suggestive of intussusception, should undergo air or water-soluble contrast enema. Painless, large-volume bleeding may prompt performance of a ^{99}Tc-pertectnetate nuclear scan to assess for a Meckel diverticulum. Pretreatment with an H_2-receptor antagonist may be helpful in increasing the sensitivity of this study; however, a negative scan does not preclude the diagnosis. CT scan of the abdomen with oral and IV contrast may be indicated to look for structural and inflammatory causes of bleeding. More recently, CT enterography has been proposed as a useful tool in cases of lower GI bleeding in children. Persistent bleeding without a clear source may prompt consideration of a radioisotope-tagged red blood cell (RBC) scan with ^{99m}Tc-sulfur colloid, though the bleeding must be active at the time of the study, with a rate of at least 0.1 mL/min. Angiography is generally less sensitive, requiring 1–2 mL/min.

▶ Treatment

In severe bleeding, the ABCs of resuscitation should be performed. Adequate IV access is critical in these cases to ensure that fluid boluses and blood products are able to be delivered. If a hemorrhagic diathesis is detected, vitamin K should be given intravenously and additional blood products should be administered as needed to correct any underlying coagulopathy. In severe bleeding, the need for volume replacement is monitored by measurement of central venous pressure. In less severe cases, vital signs, serial hematocrits, and gastric aspirates are sufficient.

In suspected upper GI bleeding, gastric lavage with saline should be performed, but there is no value of lavage in controlling bleeding. After stabilization, upper intestinal endoscopy may be considered to identify the bleeding site. Endoscopy is superior to barium contrast study for lesions such as esophageal varices, stress ulcers, and gastritis. A large retrospective study of endoscopy performed for upper GI bleeding in children found that a definitive source for bleeding was identified in 57%, with a suspected source in another 30%. Risk factors for a nondiagnostic endoscopy in this series were a history of bleeding of less than 1 month and a delay of greater than 48 hours between presentation and endoscopy. Acid suppression with intravenous H_2-antagonists or, preferably PPIs, may be helpful in suspected peptic causes of bleeding. Colonoscopy may identify the source of bright red rectal bleeding, but it should be performed as an emergency procedure only if the extent of bleeding warrants immediate investigation and if plain abdominal radiographs show no signs of intestinal obstruction. Colonoscopy on an unprepped colon is often inadequate for making a diagnosis. Capsule endoscopy may help identify the site of bleeding if colonoscopy and upper endoscopy findings are negative. Push or balloon enteroscopy may be helpful to perform therapeutic interventions, obtain biopsies, or mark small bowel lesions (prior to laparotomy/laparoscopy) identified on capsule endoscopy.

Persistent vascular bleeding (varices [Figure 21–7], vascular anomalies) may be relieved temporarily using intravenous octreotide, 1–4 mcg/kg/h. Sustained infusion of octreotide may be used for up to 48 hours if needed with careful monitoring of glucose homeostasis. A single-center review of cases of massive variceal bleeding in children found a significant decrease in transfusion requirements with the use of octreotide. Bleeding from esophageal varices may be stopped by compression with a Sengstaken-Blakemore tube. Endoscopic sclerosis or banding of bleeding varices is effective treatment.

If gastric decompression, acid suppressive therapy, and transfusion are ineffective in stopping ulcer bleeding, endoscopic therapy with argon plasma coagulation, local injection of epinephrine, electrocautery, or application of hemostatic clips may be employed. If bleeding remains refractory to therapy, emergency surgery may be necessary. In some cases, angiography and selective embolization have been used successfully in unidentified and refractory bleeding.

VOMITING

Vomiting is an extremely complex activity and is triggered by stimulation of chemoreceptors and mechanoreceptors in the wall of the GI tract, activated by contraction, distension, and physical damage. The vomiting center, paraventricular nuclei, in the brain controls the emetic response. These nuclei receive afferent input from many sources, abdominal splanchnic nerves, the vagus nerve, vestibulolabyrinthine receptors, the cerebral cortex, and chemoreceptor trigger zone (CTZ). Vagal afferents from the gut to brain are stimulated by ingested drugs and toxins, mechanical stretch, inflammation, and local neurotransmitters. Additionally, local feedback loops in the gut also appear capable of initiating vomiting. Once the vomiting response is triggered, a pattern of somatic muscle action occurs with abdominal, thoracic, and diaphragm muscles contracting against a closed glottis. The resulting increased intra-abdominal pressure reverses the negative pressure of the esophagus and forces gastric contents upward. The vomiting response also alters intestinal motility by generating a retroperistaltic contractile complex that moves intestinal contents toward the esophagus.

Vomiting is the presenting symptom of many pediatric conditions. It is the pediatrician's difficult job to find the underlying cause. The most common cause of vomiting in childhood is probably acute viral gastroenteritis. However, obstruction and acute or chronic inflammation of the GI tract and associated structures are also major causes. CNS inflammation, pressure, or tumor may cause vomiting. Metabolic derangements associated with inborn errors of metabolism, sepsis, and drug intoxication can stimulate either the CTZ or the brain directly to promote vomiting. Regurgitation associated with GE reflux of infants should be distinguished from vomiting. Occasionally, regurgitated fluid stimulates the pharyngeal afferents and provokes gagging or even a complete vomiting complex.

Control of vomiting with medication is rarely necessary in acute gastroenteritis, but it may relieve nausea and vomiting and decrease the need for intravenous fluids and/or hospitalization. Antihistamines and anticholinergics are appropriate for motion sickness because of their labyrinthine effects. $5-HT_3$–receptor antagonists (ondansetron, granisetron) are useful for vomiting associated with surgery and chemotherapy. Benzodiazepines, corticosteroids, and substituted benzamides are also used in chemotherapy-induced vomiting. Butyrophenones (droperidol, haloperidol) are powerful drugs that block the D_2 receptor in the CTZ and are used for intractable vomiting in acute gastritis, chemotherapy, and after surgery. Phenothiazines are helpful in chemotherapy, cyclic vomiting, and acute GI infection but are not recommended for outpatient use because of extrapyramidal side effects.

1. Cyclic Vomiting Syndrome

▶ **Clinical Findings**

Cyclic vomiting syndrome (CVS) is defined as three or more recurrent episodes of stereotypical vomiting in children usually older than 1 year. The emesis is forceful and frequent,

occurring up to six times per hour for up to 72 hours or more. Episode frequency ranges from two to three per month to less than one per year. Nausea, retching, and small-volume bilious emesis continue even after the stomach is emptied. Hematemesis secondary to forceful vomiting and a Mallory-Weiss tear may occur. Patients experience abdominal pain, anorexia, and, occasionally, diarrhea. Autonomic symptoms, such as pallor, sweating, temperature instability, and lethargy are common and give the patient a very ill appearance. The episodes end suddenly, often after a period of sleep. In some children, dehydration, electrolyte imbalance, and shock may occur. Between episodes, the child is completely healthy.

The cause of CVS is unknown; however, a relationship to migraine headaches has long been recognized. Family history is positive for migraine in 50%–70% of cases and many patients develop migraine headaches as adults. Research suggests that abnormalities of neurotransmitters and hormones provoke CVS. About one-quarter of patients have typical migraine symptoms during episodes: premonitory sensation, headache, photophobia, and phonophobia. Identifiable triggers are similar to migraines and include infection, positive or negative emotional stress, diet (chocolate, cheese, monosodium glutamate), menses, sleep deprivation, or motion sickness.

▶ Differential Diagnosis

Conditions that mimic CVS include drug toxicity, increased intracranial pressure, seizures, brain tumor, Chiari malformation, recurrent sinusitis, choledochal cyst, gallstones, recurrent small bowel obstruction, IBD, familial pancreatitis, obstructive uropathy, recurrent urinary infection, diabetes, mitochondrial diseases, disorders of fatty and organic acid metabolism, adrenal insufficiency, and münchausen syndrome by proxy. Although tests for GE reflux are often positive in these patients, it is unlikely that GE reflux and CVS are related.

▶ Treatment

Avoidance of triggers prevents episodes in some patients. Sleep can also end an episode although some children awaken and resume vomiting. Diphenhydramine or lorazepam is used at the onset of spells in some children to reduce nausea and induce sleep. Early use of antimigraine medications (sumatriptan), antiemetics (ondansetron), or antihistamines can abort spells in some patients. Once a spell is well established, intravenous fluids are often required to end it. With careful supervision, some children with predictable spells can receive intravenous fluids at home. Several approaches usually are tried before an effective therapy is found. Preventing spells with prophylactic propranolol, amitriptyline, or antihistamines such as cyproheptadine is often effective in some patients with frequent or disabling spells. Some patients have been successfully treated with anticonvulsants.

Sudel B, Li BU: Treatment options for cyclic vomiting syndrome. Curr Treat Options Gastroenterol 2005;8:387 [PMID: 16162304].

RECURRENT ABDOMINAL PAIN

Approximately 2%–4% of all pediatric office visits occur because of unexplained, recurrent abdominal pain. In addition, up to 17% of adolescents have been reported to have recurrent abdominal pain. Based on the Rome III criteria, the descriptive term "recurrent abdominal pain" has been discarded for the more meaningful terms that fall into the categories of "functional GI disorders," which encompasses four entities: functional dyspepsia, irritable bowel syndrome, abdominal migraines, and childhood functional abdominal pain not otherwise specified.

▶ Clinical Findings

A. Symptoms and Signs

Children with functional abdominal pain experience recurrent attacks of abdominal pain or discomfort at least once per week for at least 2 months. Attacks of pain are of variable duration and intensity. Parents or patients commonly report that the pain is constant, all day, every day. The pain is usually localized to the periumbilical area but may also be more generalized. The pain occurs primarily during the day but may prevent children from falling asleep at night. It may be associated with pallor, nausea, or vomiting, and also with dramatic reactions such as frantic crying, clutching the abdomen, and doubling over. Parents may become alarmed and take their children into the emergency departments, where the evaluation is negative for an acute abdomen. School attendance may suffer, and enjoyable family events may be disrupted.

Alarm symptoms that would suggest a more severe organic etiology are absent. These include dysphagia, persistent vomiting, GI blood loss, pain leading to night awakening, rashes, or joint aches. In addition, these children do not have a history of unintentional weight loss or fevers.

Functional abdominal pain usually bears little relationship to bowel habits and physical activity. However, some patients have a symptom constellation suggestive of irritable bowel syndrome, including bloating, postprandial pain, lower abdominal discomfort, and erratic stool habits with a sensation of obstipation or incomplete evacuation of stool. A precipitating or stressful situation in the child's life at the time the pains began can sometimes be elicited. School phobia may be a precipitant. A history of functional GI complaints is often found in family members. A family history, however, of IBD, peptic ulcer disease, and CD is absent.

A thorough physical examination that includes a rectal examination is essential and usually normal. Complaints of

abdominal tenderness elicited during palpation may be out of proportion to visible signs of distress.

B. Laboratory Findings

Complete blood count, sedimentation rate, and stool test for occult blood are usually a sufficient evaluation. Extraintestinal sources such as kidney, spleen, and genitourinary tract may require assessment. In the adolescent female patient, ultrasound of the abdomen and pelvis may be helpful to detect gallbladder or ovarian pathology. If the pain is atypical, further testing suggested by symptoms and family history should be done. This may include additional imaging studies or endoscopic analysis.

▶ Differential Diagnosis

Abdominal pain secondary to disorders causing acute abdomen are listed in Table 21–7. Pinworms, mesenteric lymphadenitis, and chronic appendicitis are improbable causes of recurrent abdominal pain. *H pylori* infection does not cause recurrent abdominal pain. Lactose intolerance usually causes abdominal distention, gas, and diarrhea with milk ingestion. At times, however, abdominal discomfort may be the only symptom. Abdominal migraine and cyclic vomiting are less common conditions with an episodic character often associated with vomiting. The incidence of peptic gastritis, esophagitis, duodenitis, and ulcer disease is probably underappreciated.

▶ Treatment & Prognosis

Treatment consists of reassurance based on a thorough history and physical examination and a sympathetic, age-appropriate explanation of the nature of functional pain. It is important to acknowledge that the child is experiencing pain. The concept of "visceral hyperalgesia" or increased pain signaling from physiologic stimuli such as gas, acid secretion, or stool is one that parents can understand and helps them respond appropriately to the child's complaints. Another analogy might be to compare a child's abdominal pain to usual headaches that another person may experience, in that the workup can be normal even though there is pain. Reassurance without education is rarely helpful. Regular activity should be resumed, especially school attendance. Therapy for psychosocial stressors, including biofeedback therapy, may be necessary. In older patients, and in those with what appears to be visceral hyperalgesia, amitriptyline in low doses may occasionally be helpful. Antispasmodic medications are rarely helpful and should be reserved for patients with more typical irritable bowel complaints.

ACUTE ABDOMEN

An acute abdomen is a constellation of findings indicating an intra-abdominal process that may require surgery. A degree of urgency is implied when this diagnosis is suspected. The pain of an acute abdomen intensifies over time and is rarely relieved without definitive treatment. Pain is often accompanied by nausea, vomiting, diarrhea, fever, and anorexia. Pain may be localized or generalized. The abdomen may be distended and tense, and bowel sounds reduced or obstructive. Patients appear ill and are reluctant to be examined or moved. The acute abdomen is usually a result of infection of the intra-abdominal or pelvic organs, but it also occurs with intestinal obstruction, intestinal perforation, inflammatory conditions, trauma, and some metabolic disorders. Some of the conditions causing acute abdomen are listed in Table 21–8. Reaching a timely and accurate diagnosis is critical and requires skill in physical diagnosis,

Table 21–8. Malabsorption syndromes.

Intraluminal abnormalities	Graft-vs-host disease
Acid hypersecretion (eg, Zollinger-Ellison syndrome)	Mucosal injury
	Celiac disease
Exocrine pancreatic insufficiency	Allergic enteropathy
	IBD
Cystic fibrosis	Radiation enteritis
Shwachman syndrome	Enzyme deficiency
Malnutrition	Lactase deficiency
Enzyme deficiency	Sucrase-isomaltase deficiency
Enterokinase deficiency	Short bowel syndrome
Trypsinogen deficiency	**Vascular abnormalities**
Co-lipase deficiency	Ischemic bowel
Decreased intraluminal bile acids	Vasculitis: lupus, mixed connective tissue disorder
Chronic parenchymal liver disease	Congestive heart failure
Biliary obstruction	Intestinal lymphangiectasia
Bile acid loss (short gut, ileal disease)	**Metabolic genetic disease**
	Abetalipoproteinemia
Bile acid deconjugation by bacterial overgrowth	Congenital secretory diarrheas
Mucosal abnormalities	Lysinuric protein intolerance
Infection (eg, *Giardia, Cryptosporidium*)	Cystinosis

recognition of the symptoms of a large number of conditions, and a judicious selection of laboratory and radiologic tests. (Acute appendicitis is discussed earlier in the section Disorders of the Small Intestine.)

MALABSORPTION SYNDROMES

Malabsorption of ingested food has many causes (see Table 21–8). Shortened length (usually via surgical resection) and mucosal damage (CD) both reduce surface area. Impaired motility interferes with normal propulsive movements, which affects mixing of food with pancreatic and biliary secretions and permits anaerobic bacterial overgrowth. Bacterial overgrowth may lead to increased carbohydrate fermentation with resultant acidic diarrhea. A second mechanism is bacterial bile acid deconjugation leading to fat malabsorption as seen in intestinal pseudo-obstruction or postoperative blind loop syndrome. Impaired intestinal lymphatic (congenital lymphangiectasia) or venous drainage also causes malabsorption. Diseases reducing pancreatic exocrine function (cystic fibrosis, Shwachman syndrome) or the production and flow of biliary secretions cause nutrient malabsorption. Malabsorption of specific nutrients may also be genetically determined (disaccharidase deficiency, glucose-galactose malabsorption, and abetalipoproteinemia).

▶ Clinical Findings

Diarrhea, vomiting, anorexia, abdominal pain, failure to thrive, and abdominal distention are common. Stools associated with fat malabsorption are characterized as bulky, foul, greasy, and pale; in contrast, those seen with osmotic diarrhea are loose, watery, and acidic. Stool microscopic examination for neutral fat (pancreatic insufficiency as in cystic fibrosis) and fatty acids (as in mucosal injury, liver disease) may be useful.

Quantifying fat malabsorption by timed stool collection compares amount of ingested to excreted fat. Stool loss of 10%–15% of ingested fat is normal in infancy, while loss of 5% of ingested fat is normal for 1- to 10-year-olds. Fat-soluble vitamin deficiency occurs with long-standing fat malabsorption and is manifested by prolonged PT (vitamin K) and low levels of serum carotene (vitamin A), vitamin E, and vitamin D. Loss of serum proteins across the intestinal mucosa is suggested by elevated fecal α_1-antitrypsin levels. Disaccharide or monosaccharide malabsorption manifests by stool pH less than 5.5 due to lactic acid and reducing substances in the stool. Specific enzyme deficiencies may be evaluated by breath hydrogen test, or small intestinal biopsy showing normal histology and measurement of specific disaccharidase activity. Other screening tests suggesting a specific diagnosis include sweat chloride concentration (cystic fibrosis), intestinal mucosal biopsy (CD, lymphangiectasia, IBD), liver and gallbladder function tests, and pancreatic

secretion after stimulation with secretin and cholecystokinin. Some of the most common disorders associated with malabsorption in pediatric patients are detailed as follows.

1. Protein-Losing Enteropathy

Loss of plasma proteins into the GI tract occurs in association with intestinal inflammation, intestinal graft-versus-host disease, acute and chronic intestinal infections, venous and lymphatic obstruction or malformations, and infiltration of the intestine or its lymphatics and vasculature by malignant cells. Chronic elevation of venous pressure in children with the Fontan procedure and elevated right-sided heart pressures may produce protein-losing enteropathy.

▶ Clinical Findings

Signs and symptoms are mainly those caused by hypoproteinemia and in some instances by fat malabsorption: edema, ascites, poor weight gain, anemia, and specific vitamin (fat-soluble vitamins A, D, E, K) and mineral deficiencies. Serum albumin and globulins may be decreased. Fecal α_1-antitrypsin is elevated (> 3 mg/g dry weight stool; slightly higher in breast-fed infants). Disorders associated with protein-losing enteropathy are listed in Table 21–9. In the presence of intestinal bleeding, fecal α_1-antitrypsin measurements are falsely high.

Table 21–9. Disorders associated with protein-losing enteropathy.

Cardiac disease
Congestive heart failure
Constrictive pericarditis
Cardiomyopathy
Post-Fontan procedure with elevated right atrial pressure
Lymphatic disease
Primary congenital lymphangiectasia
Secondary lymphangiectasia
Malrotation
Malignancy: lymphoma, retroperitoneal tumor
Other: sarcoid, arsenic poisoning
Inflammation
Giant hypertrophic gastritis (Ménétrier disease), often secondary to cytomegalovirus infection or *Helicobacter pylori*
Infection: TB, *Clostridium difficile*, parasite (eg, *Giardia*), bacteria (eg, *Salmonella*)
Allergic enteropathy
Celiac disease
Radiation enteritis
Graft-vs-host disease
Inflammatory bowel disease
Hirschsprung disease
Necrotizing enterocolitis
Vascular disorders
Systemic lupus erythematosus and mixed connective tissue disorder

► Differential Diagnosis

Hypoalbuminemia may be due to increased catabolism, poor protein intake, impaired hepatic protein synthesis, or congenital malformations of lymphatics outside the GI tract. Protein losses in the urine from nephritis and nephrotic syndrome may also cause hypoalbuminemia.

► Treatment

Albumin infusion, diuretics, and a high-protein, low-fat diet may control symptoms. Nutritional deficiencies should be addressed. Treatment must be directed toward identifying and treating the underlying cause.

2. Celiac Disease (Gluten Enteropathy)

Celiac disease (CD) is an immune-mediated enteropathy triggered by gluten, a protein in wheat, rye, and barley. CD presents anytime after gluten is introduced in the diet, with symptoms of abdominal pain, diarrhea, vomiting, distention, and sometimes constipation. Other manifestations include oral ulcers, a pruritic rash (dermatitis herpetiformis), growth and pubertal delay, iron-deficiency anemia, decreased bone mineralization, and arthritis. Disease frequency in Western populations approaches 1 in 100. Associated conditions include type 1 diabetes (4%–10%), Down syndrome (5%–12%), Turner syndrome (4%–8%), IgA deficiency (2%–8%), autoimmune thyroiditis (8%), and family history of CD (5%–10%). Almost all CD patients express HLA-DQ2 or DQ8 tissue antigens.

► Clinical Findings

A. Symptoms and Signs

1. Gastrointestinal manifestations—The classic form of CD consists of GI symptoms with onset soon after gluten-containing foods are introduced in the diet, usually between 6 and 24 months of age. Chronic diarrhea, abdominal distention, irritability, anorexia, vomiting, and poor weight gain are typical. Celiac crisis, with dehydration, hypotension, hypokalemia, and explosive diarrhea, is rare. Older children may have chronic abdominal pain, chronic constipation, bloating, and diarrhea that mimic symptoms of lactose intolerance, functional abdominal pain, or irritable bowel syndrome.

2. Nongastrointestinal manifestations—Adolescents may present with delayed puberty or short stature, and in females, delayed menarche. CD should be considered in children with unexplained iron-deficiency anemia, decreased bone mineral density, elevated liver function enzymes, arthritis, or epilepsy with cerebral calcifications. Asymptomatic individuals are identified on screening, such as those with type 1 diabetes. The need for early screening and treatment in asymptomatic individuals is unclear.

B. Laboratory Findings

1. Serologic and genetic testing—Screening tests exist with excellent sensitivity and specificity. In IgA-sufficient patients these are the IgA antitissue transglutaminase, IgA antiendomysial and IgA/IgG antideamidated gliadin peptide antibodies. In the presence of IgA deficiency, IgG-based antitissue transglutaminase and antiendomysium antibodies are available. Genetic testing for HLA-DQ2 and DQ8 has a high negative predictive value, and is useful in assessing risk for CD in family members, but not for screening for the presence of CD.

2. Stools—Stools may have increased levels of partially digested fat and may be acidic from secondary lactose intolerance.

3. Hypoalbuminemia—Hypoalbuminemia can be severe enough to lead to edema.

4. Anemia—Anemia with low MCV and evidence of iron deficiency is common.

C. Biopsy Findings

Patients should remain on a diet containing gluten until biopsy. Characteristic duodenal biopsy findings on light microscopy are villous atrophy with increased numbers of intraepithelial lymphocytes. Findings may be patchy.

► Differential Diagnosis

The differential diagnosis includes food allergies, Crohn disease, postinfectious diarrhea, immunodeficiencies, graft-versus-host disease, and hypergastrinemia (Zollinger-Ellison syndrome).

► Treatment

A. Diet

Treatment is dietary gluten restriction for life. All sources of wheat, rye, and barley are eliminated. Most, but not all, patients tolerate oats. The intestinal mucosa should normalize by 6–12 months while lactose intolerance resolves often within a few weeks. Supplemental calories, vitamins, and minerals are indicated only in the acute phase. CD-related antibody titers decrease on a gluten-free diet.

B. Corticosteroids

Corticosteroids are indicated only in patients with celiac crisis with profound anorexia, malnutrition, diarrhea, edema, abdominal distention, and hypokalemia.

► Prognosis

Enteropathy-associated T-cell lymphoma of the small bowel occurs with increased frequency in adults with long-standing

untreated disease. Individuals with poor adherence to gluten-free diet may be at increased risk for fractures, iron-deficiency anemia, and infertility.

American Celiac Disease Alliance: www.americanceliac.org.

Catassi C, Fasano A: Celiac disease diagnosis: Simple rules are better than complicated algorithms. Am J Med 2010 Aug;123(8):691–693 [PMID: 20670718].

Husby S et al: European Society for Pediatric Gastroenterology, Hepatology, and Nutrition guidelines for the diagnosis of celiac disease. J Pediatr Gastroenterol Nutr 2012;54:136–160 [PMID: 22197856].

3. Disaccharidase Deficiency

Starches and the disaccharides sucrose and lactose are the most important dietary carbohydrates. Dietary disaccharides and the oligosaccharide products of pancreatic amylase action on starch require hydrolysis by intestinal brush border disaccharidases for absorption. Disaccharidase levels are higher in the jejunum and proximal ileum than in the distal ileum and duodenum. Characteristics of primary disaccharidase deficiency include permanent disaccharide intolerance, absence of intestinal injury, and frequent positive family history. Because disaccharidases are located on the luminal surface of intestinal enterocytes, mucosal damage, such as from acute viral enteritis, causes transient secondary disaccharidase deficiency.

A. Lactase Deficiency

Congenital lactase deficiency is extremely rare. All human ethnic groups are lactase-sufficient at birth. Genetic or familial lactase deficiency appears after 5 years of age. In Asians, Alaskan natives, and Native Americans, genetic lactase deficiency develops in virtually 100%. In Africans, the incidence in most tribes is over 80%. In African Americans, the incidence is about 70%, and among Caucasian Americans, between 30% and 60%. Acquired or secondary lactase deficiency caused by intestinal injury due to viral infection, inflammatory disease, radiation, and drugs is common, but transient, resolving within a few weeks.

Lactose ingestion in deficient individuals causes variable degrees of diarrhea, abdominal distention, flatus, and abdominal pain depending on the residual enzyme activity and the dose of lactose. Stools are liquid or frothy with a pH less than 5.5 owing to the presence of organic acids. Reducing substances are present in fresh stools. Diagnostic tests include genetic testing, lactose breath test with a rise in breath hydrogen content due to fermentation of undigested lactose by normal colonic flora, and a lactose load test in which blood glucose fails to rise more than 10 mg/dL after ingestion of 1 g/kg of lactose. Symptoms resolve when dietary lactose is restricted or lactase supplementation

is added to milk products or taken with meals to enhance lactose hydrolysis.

B. Sucrase-Isomaltase Deficiency

This condition is inherited in an autosomal recessive fashion and is most common in Greenland, Iceland, and among Alaskan natives. The condition is rare in other groups. Abdominal distention, failure to thrive, and watery diarrhea are the presenting symptoms. Stools are usually watery and acidic. Because sucrose is not a reducing sugar, stool may test negative for reducing substances unless the sucrose is hydrolyzed by colon bacteria. Diagnosis is made by oral sucrose tolerance testing (1 g/kg) with elevated breath hydrogen content, or by testing a snap frozen intestinal biopsy for enzyme activity. There are partial enzyme deficiencies. Treatment is avoidance of sucrose and starches rich in amylopectin, or the use of sacrosidase enzyme supplement.

Treem WR: Clinical aspects and treatment of congenital sucrose-isomaltase deficiency. J Pediatr Gastroenterol Nutr 2012;55(Suppl 2):S7–S13 [PMID: 23103658].

CSID parent support group: www.csidinfo.com.

QOL Medical, LLC: www.sucraid.net.

4. Glucose-Galactose Malabsorption

Glucose-galactose malabsorption is a rare disorder in which the sodium-glucose transport protein is defective. Transport of glucose in the intestinal epithelium and renal tubule is impaired. Diarrhea begins with the first feedings, accompanied by reducing sugar in the stool and acidosis. Small bowel histologic findings are normal. Glycosuria and aminoaciduria may occur. The glucose tolerance test is abnormally flat. Fructose is well tolerated. Diarrhea subsides promptly on withdrawal of glucose and galactose from the diet. The acquired, transient form of glucose-galactose malabsorption occurs mainly in infants younger than 6 months, usually following acute viral or bacterial enteritis.

In the congenital disease, exclusion of glucose and galactose from the diet is mandatory. A carbohydrate-free base formula is used with added fructose. The prognosis is good if diagnosed early. Tolerance for glucose and galactose improves with age. In the secondary (acquired) form, prolonged PN may be required until healing.

Wright EM et al: Active sugar transport in health and disease. J Intern Med 2007;26:32–43 [PMID: 17222166].

5. Dietary Fructose Intolerance

Fructose malabsorption occurs when fructose is in excess of glucose, often with consumption of high-fructose corn syrup. Malabsorbed fructose is fermented by colonic bacteria, and excess hydrogen and other gases are produced.

Symptoms include abdominal pain, bloating, flatulence, and diarrhea. These symptoms may mimic irritable bowel syndrome. The capacity for human fructose absorption has a wide range and may be inducible by dietary consumption. Diagnosis is made with a fructose breath hydrogen test and is bolstered by the occurrence of symptoms during the test.

Kyaw MH, Mayberry JF: Fructose malabsorption: true condition or a variance from normality. J Clin Gastroenterol 2011 Jan;45(1):16–21 [PMID: 20818234].

6. Intestinal Lymphangiectasia

This form of protein-losing enteropathy results from a congenital ectasia of the bowel lymphatic system often associated with abnormalities of the lymphatics in the extremities. Obstruction of lymphatic drainage of the intestine leads to rupture of the intestinal lacteals with leakage of lymph into the lumen of the bowel. Fat loss in the stool may be significant. Chronic loss of lymphocytes and immunoglobulins increases the susceptibility to infections.

▶ Clinical Findings

Peripheral edema, diarrhea, abdominal distention, chylous effusions, and repeated infections are common. Laboratory findings include reduced serum albumin, decreased immunoglobulin levels, lymphocytopenia, and anemia. Serum calcium and magnesium are frequently depressed as these cations are lost in complex with unabsorbed fatty acids. Lymphocytes may be seen on a stool smear. Fecal α_1-antitrypsin is elevated. Radiographic studies reveal an edematous small bowel wall, and biopsy findings reveal dilated lacteals in the villi and lamina propria. If only the lymphatics of the deeper layers of bowel or intestinal mesenteries are involved, laparotomy may be necessary to establish the diagnosis. Capsule (camera) endoscopy shows diagnostic brightness secondary to the fat-filled lacteals.

▶ Differential Diagnosis

Other causes of protein-losing enteropathy must be considered, although an associated lymphedematous extremity strongly favors this diagnosis.

▶ Treatment & Prognosis

A high-protein diet (6–7 g/kg/d may be needed) enriched with medium-chain triglycerides as a fat source usually allows for adequate nutrition and growth in patients with intestinal mucosal lymphangiectasia. The serum albumin may not normalize. Vitamin and calcium supplements should be given. Parenteral nutritional supplementation may be needed temporarily. Surgery may be curative if the lesion is localized to a small area of the bowel or in cases of constrictive pericarditis or obstructing tumors. IV albumin

and immune globulin may also be used to control symptoms but are usually not needed chronically. The prognosis is not favorable, although remission may occur with age. Malignant degeneration of the abnormal lymphatics may occur, and intestinal lymphoma of the B-cell type may be a long-term complication.

7. Cow's Milk Protein Intolerance

Milk protein intolerance refers to nonallergic food sensitivity and is more common in males than females and in young infants with a family history of atopy. The estimated prevalence is 0.5%–1.0%. Symptoms may occur while the infant is still exclusively breast-fed. The most common form is a healthy infant with flecks of blood in the stool. Infants may present with loose mucoid stools that are blood streaked but otherwise appear well. These symptoms typically occur as a result of cow's milk protein that is either present in formula or breast milk. A family history of atopy is common in these infants. Skin testing is not reliable and not indicated. Treatment consists of eliminating the source of the protein; in the breast-fed infant, maternal avoidance of milk protein will usually reduce signs of colitis. Substituting a protein hydrolysate formula for cow's milk-based formula may reduce symptoms. A more severe form of FPIES may require steroids. Allergic colitis in young infants is self-limited, usually disappearing by 8–12 months of age. Since no long-term consequences of this problem have been identified, some suggest that if the symptoms are mild and the infant is thriving, no treatment may be indicated. Colonoscopy is not required for diagnosis, but rectal biopsies, if performed, show mild lymphonodular hyperplasia, mucosal edema, and eosinophilia.

In older children, milk protein sensitivity may induce eosinophilic gastroenteritis with protein-losing enteropathy, iron deficiency, hypoalbuminemia, and hypogammaglobulinemia. A celiac-like syndrome with villous atrophy, malabsorption, hypoalbuminemia, occult blood in the stool, and anemia can occur.

De Greef E et al: Diagnosis and management of cow's milk protein allergy in infants. World J Pediatr 2012 Feb;8(1):19–24 [PMID: 22282379].
Leonard SA, Nowak-Wegrzyn A: Food protein-induced enterocolitis syndrome: an update on natural history and review of management. Ann Allergy Asthma Immunol 2011 Aug;107(2):95–101 [PMID: 21802016].

8. Pancreatic Insufficiency

The most common cause of pancreatic exocrine insufficiency in childhood is cystic fibrosis. Decreased secretion of pancreatic digestive enzymes is caused by obstruction of the exocrine ducts by thick secretions, which destroys

pancreatic acinar cells. Destruction of acinar cells may occur before birth. Some genotypes of cystic fibrosis have partially or completely preserved pancreatic exocrine function. Other conditions associated with exocrine pancreatic insufficiency are discussed in Chapter 22.

9. Other Genetic Disorders Causing Malabsorption

A. Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive condition in which the secretion of triglyceride-rich lipoproteins from the small intestine (chylomicrons) and liver (very low-density lipoproteins) is abnormal. Profound steatosis of the intestinal enterocytes (and hepatocytes) and severe fat malabsorption occur. Deficiencies of fat-soluble vitamins develop with neurologic complications of vitamin E deficiency and atypical retinitis pigmentosa. Serum cholesterol level is very low, and red cell membrane lipids are abnormal, causing acanthosis of red blood cells, which may be the key to diagnosis.

B. Acrodermatitis Enteropathica

Acrodermatitis enteropathica is an autosomal recessive condition in which the intestine has a selective inability to absorb zinc. The condition usually becomes obvious at the time of weaning from breast-feeding and is characterized by rash on the extremities, rashes around the body orifices, eczema, profound failure to thrive, steatorrhea, diarrhea, and immune deficiency. Zinc supplementation by mouth results in rapid improvement.

INFLAMMATORY BOWEL DISEASE

▶ General Considerations

Inflammatory bowel disease (IBD), a chronic relapsing inflammatory disease, is most commonly differentiated into Crohn disease (CrD) and ulcerative colitis (UC). The etiology is multifactorial, involving a complex interaction of environmental and genetic factors leading to maladaptive immune responses to flora in the GI tract. The genetic association is clear, with 5%–30% of patients identifying a family member with IBD, and a 10–20 relative risk of a sibling developing IBD. The 15%–36% concordance rate for monozygotic twins indicates that genetics is important but not sufficient for development of IBD.

▶ Clinical Findings

A. Symptoms and Signs

Most commonly, inflammation causes abdominal pain, diarrhea, bloody stools, fever, anorexia, fatigue, and weight loss. CrD may also cause a stricturing process with abdominal pain and intestinal obstruction, or as a penetrating/fistulizing process with abscess, perianal disease, or symptoms similar to acute appendicitis. UC usually presents with crampy abdominal pain, diarrhea, and blood in the stool.

CrD can affect any part of the GI tract from the lips to the anus. In pediatrics, CrD most often affects the terminal ileum and colon although it may have a patchy distribution with skip areas of uninvolved bowel. UC is limited to the colon, and in children it usually involves the entire colon (pancolitis) without skip areas. The younger the age of onset, the more likely the course will be severe.

Extraintestinal manifestations are common in both forms of IBD and may precede the intestinal complaints. These include uveitis, recurrent oral aphthous ulcers, arthritis, growth and pubertal delay, liver involvement (typically primary sclerosing cholangitis), rash (erythema nodosa and pyoderma gangrenosum), and iron-deficiency anemia.

B. Diagnostic Testing

Diagnosis is based on typical presentation, course, radiographic, endoscopic, and histologic findings, and exclusion of other disorders. No single test is diagnostic. Patients with IBD often have low hemoglobin, iron, and serum albumin levels, and elevated ESR and CRP and fecal calprotectin. IBD-related serum antibodies are present in most, with antibodies to *Saccharomyces cerevisiae* (ASCA) in 60% of patients with CrD, while serum perinuclear antineutrophil cytoplasmic antibodies (pANCAs) are present in approximately 70% of UC patients. These, and other IBD-related antibodies, may be helpful in differentiating CrD from UC, but they are neither sensitive nor specific enough to be diagnostic. Barium upper GI radiographs with small bowel follow-through may reveal small bowel disease, especially terminal ileal thickening with separation of bowel loops, and enteric fistulas. Abdominal imaging with US, CT, or magnetic resonance may show mucosal and mural edema and exclude other etiologies.

Upper endoscopy and ileocolonoscopy are the most useful diagnostic modalities, revealing severity and extent of upper intestinal, ileal, and colonic involvement. Video capsule provides images of the entire small bowel. Granulomas are found in only 25%–50% of CrD cases. Deep linear ulcers, white exudate (Figure 21–8), aphthous lesions (Figure 21–9), patchy involvement, and perianal disease suggest CrD. Superficial and continuous involvement of the colon sparing the upper GI tract are most consistent with UC. Both forms of IBD may have mild gastritis and/or duodenitis.

▶ Differential Diagnosis

When extraintestinal symptoms predominate, CrD can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, CD, or hypopituitarism. The acute onset of ileocolitis may be mistaken for intestinal obstruction, appendicitis,
▲ **Figure 21–8.** Ulcerative colitis. White exudate is present overlying an abnormal colonic mucosa that has lost its typical vascular pattern.

▲ **Figure 21–9.** Crohn colitis. Discrete aphthous lesions are scattered across a thickened mucosa with some areas with normal vascular pattern.

lymphoma, amebiasis, or tuberculosis. Malabsorption symptoms suggest CD, peptic ulcer, Giardia infection, food protein allergy, anorexia nervosa, or growth failure from endocrine causes. Perianal disease may suggest child abuse. Crampy diarrhea and blood in the stool can also occur with infection such as *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *E histolytica*, enteroinvasive *E coli* (*E coli* O157), *Aeromonas hydrophila*, *Giardia*, and *C difficile*, and, if immunocompromised, CMV. Mild IBD mimics irritable bowel syndrome, or lactose intolerance. Eosinophilic gastroenteropathy and vasculitic lesions should also be considered. Behçet disease should be considered if there are deep intestinal ulcers, and is characterized by oral aphthous ulcerations along with at least two of the following: genital ulcers, synovitis, posterior uveitis, meningoencephalitis, and pustular vasculitis. Chronic granulomatous disease and sarcoidosis also cause granulomas.

▶ Complications

A. Crohn Disease

Nutritional complications from chronic active disease, malabsorption, anorexia, protein-losing enteropathy, bile salt malabsorption, or secondary lactose intolerance include failure to thrive, short stature, decreased bone mineralization, and specific nutrient deficiencies, including iron, calcium, zinc, vitamin B$_{12}$, and vitamin D. In addition, corticosteroid therapy may impact growth and bone mineral density. Most patients achieve reasonable final adult height. Intestinal obstruction, fistulae, abdominal abscess, perianal disease, pyoderma gangrenosum, arthritis, and amyloidosis occur. Crohn colitis carries a risk for adenocarcinoma of the colon.

B. Ulcerative Colitis

Even with the typical features and course of UC, up to 3%–5% of patients may have an ultimate diagnosis of CrD. Arthritis, uveitis, pyoderma gangrenosum, and malnutrition all occur. Growth failure and delayed puberty are less common than in CrD while liver disease (chronic active hepatitis, sclerosing cholangitis) is more common. Adenocarcinoma of the colon occurs with an incidence of 1%–2% per year after the first 7–8 years of disease in patients with pancolitis and is significantly higher in patients with both UC and sclerosing cholangitis.

▶ Treatment

A. Medical Treatment

Therapy for pediatric IBD involves induction of remission, maintenance of remission, and addressing nutritional deficiencies to promote normal growth and development. Treatment includes anti-inflammatory, immunomodulatory, antidiarrheal, antibiotic, and biological options. No

medical therapy is uniformly effective in all patients. In severe CrD, growth hormone may be needed to attain full height potential.

1. Diet—Ensuring adequate nutrition for normal growth as well as for puberty can be challenging. In addition to total calories, micronutrient, calcium, and vitamin deficiencies should be replenished. Restrictive or bland diets are counterproductive because they usually result in poor intake. A high-protein, high-carbohydrate diet with normal amounts of fat is recommended. A diet with decreased fiber may reduce symptoms during active colitis or partial intestinal obstruction; however, once the colitis is controlled, increased fiber may benefit mucosal health via bacterial production of fatty acids. Low-lactose diet or lactase replacement may be needed temporarily for small bowel CrD. Ileal disease may require antibiotics to treat bacterial overgrowth and extra fat-soluble vitamins due to increased losses. Supplemental calories in the form of liquid diets or enteral (nasogastric [NG] tube supplements) are well tolerated and promote catch-up growth in severe CrD. Bowel rest with liquid or elemental diet or PN is a therapy for CrD, and it promotes linear growth and sexual development. Diet therapies are less effective in UC.

2. Aminosalicylates (ASA)—Multiple preparations of 5-ASA derivatives are available and are used to induce and maintain remission in mild CrD and UC. Common preparations including 5-ASA products such as sulfasalazine (50 mg/kg/d), or balsalazide (0.75–2.5 g PO tid) or mesalamine products, are available in tablets, granules, and delayed release formulations targeting specific locations in the GI tract (adult dose range 2.4–4.8 g/d). Side effects include skin rash; nausea; headache and abdominal pain; hair loss; diarrhea; and rarely nephritis, pericarditis, serum sickness, hemolytic anemia, aplastic anemia, and pancreatitis. Sulfasalazine, in which sulfa delivers the 5-ASA, may cause sulfa-related side effects including photosensitivity and rash.

3. Corticosteroids—Patients with moderate to severe CrD and UC generally respond quickly to corticosteroids. Methylprednisolone (1 mg/kg/d) may be given intravenously when disease is severe. For moderate disease, prednisone (1 mg/kg/d, orally in one to two divided doses) is given until symptomatic response, followed by gradual tapering over 4–8 weeks. A flare is common during the taper, requiring reinduction and a slower taper course. Steroid dependence is an indication for use of an immunomodulator. Ileocecal CrD is effectively treated with budesonide (9 mg QAM), with less side effects than systemic steroids, due to "single-pass" clearance by the liver. Corticosteroid enemas and foams are useful topical agents for distal proctitis or left-sided colitis. While on systemic corticosteroids, consideration should be given to calcium and vitamin D supplementation as well as acid suppression to prevent gastritis.

4. Immunomodulators: azathioprine (AZA), 6-mercaptopurine (6MP), and methotrexate (MTX)—If IBD is moderate to severe, or the patient is steroid-dependent, immunomodulators are effective in maintaining remission and reducing the need for corticosteroids. AZA (2–3 mg/kg/d PO) or 6MP (1–2 mg/kg/d PO) provides effective maintenance therapy for moderate to severe CrD. The optimal dose of AZA or 6MP depends on the enzyme thiopurine methylene transferase (TPMT), which should be assessed before starting therapy to determine dosing. For individuals deficient in TPMT, MTX should be used; for intermediate enzyme activity, dose is reduced by 50%. In cases where adherence may be an issue, or where dose adjustments may be necessary, AZA or 6MP metabolites may be measured in red blood cells by specialized testing. Maximum therapeutic efficacy may not be seen for 2–3 months after beginning treatment. Side effects include pancreatitis, hepatotoxicity, and bone marrow suppression.

MTX, effective in CrD but not UC, has a more rapid onset of action, usually 2–3 weeks, and is given in weekly doses, orally or intramuscularly. Most common side effect is nausea, while serious adverse events include bone marrow, liver, lung, and kidney toxicities. MTX is well known to cause fetal death and deformities.

5. Antibiotics—Metronidazole (15–30 mg/kg/d in three divided doses) and ciprofloxacin have been used to treat perianal CrD and bacterial overgrowth. Peripheral neuropathy may occur with prolonged use of metronidazole.

6. Biologicals—Infliximab, a chimeric monoclonal antibody against tumor necrosis factor-α (TNFα) is used for moderate to severe CrD and UC, and for fistulizing disease. Adalimumab and certolizumab are similar injectable agents. Recurrence of disease often occurs within 12 months of stopping therapy. Use of biologics is associated with risk for infusion reactions, injection site reactions, and increased risk for opportunistic infections and for malignancy. Rarely, hepatosplenic T-cell lymphoma is associated with use of biological with AZA/6MP.

7. Other agents—Cyclosporine or tacrolimus may be used as a "bridge" to more definitive therapy (such as colectomy for UC). Thalidomide has been used, especially in patients with oral and vaginal ulcers secondary to CrD, but is a known teratogen. Probiotics and prebiotics are frequently used but with very limited data on efficacy.

8. Surveillance—After 7–8 years of colitis, cancer screening with routine colonoscopy and multiple biopsies is recommended. Persistent metaplasia, aneuploidy, or dysplasia indicates need for colectomy.

B. Surgical Treatment

1. Crohn disease—Ileocecal resection is the most common surgery but is not curative. Indications for surgery in CrD include stricture, obstruction, uncontrollable bleeding,

perforation, abscess, fistula, and failure of medical management. Up to 50% of patients with CrD eventually require a surgical procedure, and repeated surgery is common.

2. Ulcerative colitis—Total colectomy is curative and is recommended for patients with steroid dependence or steroid resistance, uncontrolled hemorrhage, toxic megacolon, high-grade dysplasia, or malignant tumors. Colectomy may also be performed for prevention of colorectal cancer after 7–8 years of disease. Colectomy usually requires a temporary ileostomy with J-pouch formation. After ileostomy takedown, pouchitis develops in up to 25% of patients, manifested by diarrhea and cramping, but it usually responds to metronidazole or ciprofloxacin. Liver disease associated with UC (sclerosing cholangitis) is not improved by colectomy.

▶ **Quality Improvement**

The ImproveCareNow network develops collaborative, data-driven improvements in the health of children with IBD. Remission rates have increased to greater than 75%.

▼ LIVER DISORDERS

PROLONGED NEONATAL CHOLESTATIC JAUNDICE

Key clinical features of disorders causing prolonged neonatal cholestasis are (1) jaundice with elevated serum conjugated (or direct) bilirubin fraction (> 2 mg/dL or > 20% of total bilirubin), (2) variably acholic stools, (3) dark urine, and (4) hepatomegaly.

Prolonged neonatal cholestasis (conditions with decreased bile flow) is caused by both intrahepatic and extrahepatic diseases. Specific clinical clues (Table 22–1) distinguish these two major categories of jaundice in 85% of cases. Histologic examination of percutaneous liver biopsy specimens increases the accuracy of differentiation to 95% (Table 22–2).

INTRAHEPATIC CHOLESTASIS

✦ ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Elevated total and conjugated bilirubin.
▶ Hepatomegaly and dark urine.
▶ Patency of extrahepatic biliary tree.

▶ General Considerations

Intrahepatic cholestasis is characterized by impaired hepatocyte secretion of bile and patency of the extrahepatic biliary system. A specific cause can be identified in about 60% of cases. Patency of the extrahepatic biliary tract is suggested by pigmented stools and lack of bile duct proliferation and portal tract bile plugs on liver biopsy. It can be confirmed least invasively by hepatobiliary scintigraphy using technetium-99m (^{99m}Tc)-dimethyliminodiacetic acid (diethyl-IDA [DIDA]). Radioactivity in the bowel within 4–24 hours is evidence of bile duct patency, as is finding bilirubin in duodenal aspirates. However, these tests are rarely needed in the clinical setting. Patency can also be determined, when clinically indicated, by cholangiography carried out either intraoperatively, percutaneously by transhepatic cholecystography, or by endoscopic retrograde cholangiopancreatography (ERCP) using a pediatric-size side-viewing endoscope. Magnetic resonance cholangiopancreatography in infants is of limited use and highly dependent on the operator and equipment.

1. Perinatal or Neonatal Hepatitis Resulting from Infection

This diagnosis is considered in infants with jaundice, hepatomegaly, vomiting, lethargy, fever, and petechiae. It is important to identify perinatally acquired viral, bacterial, or protozoal infections (Table 22–3). Infection may occur transplacentally, by ascent through the cervix into amniotic fluid, from swallowed contaminated fluids (maternal blood, urine, vaginal secretions) during delivery, from blood transfusions administered in the early neonatal period, or from breast milk or environmental exposure. Infectious agents associated with neonatal intrahepatic cholestasis include herpes simplex virus, varicella virus, enteroviruses (coxsackievirus and echovirus), cytomegalovirus (CMV), rubella virus, adenovirus, parvovirus, human herpesvirus type 6 (HHV-6), hepatitis B virus (HBV), human immunodeficiency virus (HIV), *Treponema pallidum,* and *Toxoplasma gondii.* Although hepatitis C may be transmitted vertically, it rarely causes neonatal cholestasis. The degree of liver cell injury caused by these agents is variable, ranging from massive hepatic necrosis (herpes simplex, enteroviruses) to

Table 22–1. Characteristic clinical features of intrahepatic and extrahepatic neonatal cholestasis.

Intrahepatic	Extrahepatic
Preterm infant, small for gestational age, appears ill	Full-term infant, seems well
Hepatosplenomegaly, other organ or system involvement	Hepatomegaly (firm to hard)
Stools with some pigment	Acholic stools
Associated cause identified (infections, metabolic, familial, etc)	Polysplenia or asplenia syndromes, midline liver

focal necrosis and mild inflammation (CMV, HBV). Serum bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and bile acids are typically elevated. The infant is jaundiced, may have petechiae or rash, and generally appears ill.

▶ Clinical Findings

A. Symptoms and Signs

Clinical symptoms typically present in the first 2 weeks of life, but may appear as late as age 2–3 months. Jaundice may be noted as early as the first 24 hours of life. Poor oral intake, poor sucking reflex, lethargy, hypotonia, and vomiting are frequent. Stools may be normal to pale in color, but are seldom acholic. Dark urine stains the diaper. Firm hepatomegaly is present and splenomegaly is variably present. Macular, papular, vesicular, or petechial rashes may occur. In less severe cases, failure to thrive may be the primary problem. Unusual presentations include neonatal liver failure, hypoproteinemia, anasarca (nonhemolytic hydrops), and hemorrhagic disease of the newborn.

Table 22–2. Characteristic histologic features of intrahepatic and extrahepatic neonatal cholestasis.

	Intrahepatic	Extrahepatic
Giant cells	+++	+
Lobules	Disarray	Normal
Portal reaction	Inflammation, minimal fibrosis	Fibrosis, lymphocytic infiltrate
Neoductular proliferation	Rare	Marked
Other	Steatosis, extramedullary hematopoiesis	Portal bile duct plugging, bile lakes

B. Diagnostic Studies

Neutropenia, thrombocytopenia, and signs of mild hemolysis are common. Mixed hyperbilirubinemia, elevated aminotransferases with near-normal alkaline phosphatase, prolongation of clotting studies, mild acidosis, and elevated cord serum IgM suggest congenital infection. Nasopharyngeal washings, urine, stool, serum, and cerebrospinal fluid (CSF) should be cultured for virus and tested for pathogen-specific nucleic acid. Specific IgM antibody may be useful, as are long-bone radiographs to determine the presence of "celery stalking" in the metaphyseal regions of the humeri, femurs, and tibias. When indicated, computed tomography (CT) scans can identify intracranial calcifications (especially with CMV and toxoplasmosis). Hepatobiliary scintigraphy shows decreased hepatic clearance of the circulating isotope with intact excretion into the gut. Careful ophthalmologic examination may be useful for diagnosis of herpes simplex virus, CMV, toxoplasmosis, and rubella.

A percutaneous liver biopsy is useful in distinguishing intrahepatic from extrahepatic cholestasis, but may not identify a specific infectious agent (see Table 22–2). Exceptions are the typical inclusions of CMV in hepatocytes or bile duct epithelial cells, the presence of intranuclear acidophilic inclusions of herpes simplex or varicella-zoster virus, the presence of adenovirus basophilic intranuclear inclusions, or positive immunohistochemical stains for several viruses. Variable degrees of lobular disarray characterized by focal necrosis, multinucleated giant-cell transformation, and ballooned pale hepatocytes with loss of cordlike arrangement of liver cells are usual. Intrahepatocytic and canalicular cholestasis may be prominent. Portal changes are not striking, but modest neoductular proliferation and mild fibrosis may occur. Viral cultures, immunohistochemical stains, or polymerase chain reaction (PCR) testing of biopsy material may be helpful.

▶ Differential Diagnosis

Great care must be taken to distinguish infectious causes of intrahepatic cholestasis from genetic or metabolic disorders because the clinical presentations are similar and may overlap. Galactosemia, hereditary fructose intolerance, and tyrosinemia must be investigated promptly, because specific dietary or drug therapy is available. These infants may also have concomitant bacteremia. α_1-antitrypsin deficiency, cystic fibrosis, bile acid synthesis defects, progressive familial intrahepatic cholestasis, mitochondrial respiratory chain disorders, and neonatal iron storage disease must also be considered. Specific physical features may suggest Alagille, arthrogryposis/renal dysfunction/cholestasis (ARC) syndrome or Zellweger syndrome. Idiopathic neonatal hepatitis can be indistinguishable from infectious causes.

Table 22–3. Infectious causes of neonatal hepatitis.

Infectious Agent	Diagnostic Tests	Specimens	Treatment
Cytomegalovirus	Culture and PCR, liver histology, IgM/[a]IgG	Urine, blood, liver	Ganciclovir (Foscarnet)[b]
Herpes simplex	PCR and culture, liver histology, Ag (skin)	Liver, blood, eye, throat, rectal, CSF, skin	Acyclovir
Rubella	Culture, IgM/[a]IgG	Liver, blood, urine	Supportive
Varicella	Culture, PCR, Ag (skin)	Skin, blood, CSF, liver	Acyclovir (Foscarnet)[b]
Parvovirus	Serum IgM/[a]IgG, PCR	Blood	Supportive, IVIG
Enteroviruses	Culture and PCR	Blood, urine, CSF, throat, rectal, liver	IVIG
Adenovirus	Culture and PCR	Nasal/throat, rectal, blood, liver, urine	No established therapy, Cidofovir or IVIG may have value
Hepatitis B virus (HBV)	HBsAg, HBcAg IgM, HBV DNA	Serum	Supportive for acute infection
Hepatitis C virus (HCV)	HCV PCR, HCV IgG	Serum	Supportive for acute infection
Treponema pallidum	Serology; darkfield exam (skin)	Serum, CSF	Penicillin
Toxoplasma gondii	IgM/[a]IgG, PCR, culture	Serum, CSF, liver	Pyrimethamine and sulfadiazine with folinic acid for 6 mo
Mycobacterium tuberculosis	Chest radiograph, liver tissue histologic stains, culture or PCR, gastric aspirate stain, culture or PCR	Serum, liver, gastric aspirate	INH, pyrazinamide, rifampin (If multiple-drug resistant TB is present, consult a specialist)
Bacterial infection	Cultures or PCR testing	Blood, urine, other cultures	Appropriate antibiotics

Ag, viral antigen testing; CSF, cerebrospinal fluid; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; INH, isoniazid; IVIG, intravenous gamma globulin; PCR, polymerase chain reaction test for viral DNA or RNA; PPD, purified protein derivative.

[a]IgG = positive indicates maternal infection and transfer of antibody transplacentally; negative indicates unlikelihood of infection in mother and infant.
[b]Use foscarnet for resistant viruses. Treat only if symptomatic.
[c]Discontinue streptomycin as soon as possible.

Patients with intrahepatic cholestasis frequently appear ill, whereas infants with extrahepatic cholestasis do not typically appear ill, have stools that are usually completely acholic, and have an enlarged, firm liver. Histologic findings are described in Table 22–2.

▶ **Treatment**

Most forms of viral neonatal hepatitis are treated symptomatically. However, infections with herpes simplex virus, varicella, CMV, parvovirus, and toxoplasmosis have specific treatments (see Table 22–3). Penicillin for suspected syphilis, specific antiviral therapy, or antibiotics for bacterial hepatitis need to be administered promptly. Fluids and adequate nutritional intake are encouraged. Intravenous dextrose is needed if feedings are not well tolerated. The consequences of cholestasis are treated as indicated (Table 22–4). Vitamin K orally or by injection and vitamins D and E orally should be provided. Choleretics (ursodeoxycholic acid [UDCA] or cholestyramine) are used if cholestasis persists. Corticosteroids are contraindicated.

▶ **Prognosis**

Multiple organ involvement is commonly associated with neonatal infectious hepatitis and has a poor outcome. Hepatic or cardiac failure, intractable acidosis, or intracranial hemorrhage may be fatal in herpesvirus, adenovirus, or enterovirus infections, and occasionally in CMV or rubella infection. HBV rarely causes fulminant neonatal hepatitis; most infected infants are immunotolerant to hepatitis B. Although persistent liver disease with any virus can result in mild chronic hepatitis, portal fibrosis, or cirrhosis, the neonatal liver usually recovers without fibrosis after acute infections. Chronic cholestasis, although rare following infections, may lead to dental enamel hypoplasia, failure to thrive, biliary rickets, severe pruritus, and xanthoma.

Table 22–4. Treatment of complications of chronic cholestatic liver disease.

Indication	Treatment	Dose	Toxicity
Intrahepatic cholestasis	Phenobarbital Cholestyramine or colestipol hydrochloride Ursodeoxycholic acid	3–10 mg/kg/d 250–500 mg/kg/d 15–20 mg/kg/d	Drowsiness, irritability, interference with vitamin D metabolism Constipation, acidosis, binding of drugs, increased steatorrhea Transient increase in pruritus
Pruritus	Phenobarbital Cholestyramine or colestipol Antihistamines: diphenhydramine hydrochloride Hydroxyzine Ultraviolet light B Rifampin Ursodeoxycholic acid Naltrexone	3–10 mg/kg/d 250–500 mg/kg/d 5–10 mg/kg/d 2–5 mg/kg/d Exposure as needed 10 mg/kg/d 15–20 mg/kg/d 1 mg/kg/day	Drowsiness, irritability, interference with vitamin D metabolism Constipation, acidosis, binding of drugs, increased steatorrhea Drowsiness Drowsiness Skin burn Hepatotoxicity, marrow suppression Transient increase in pruritus Irritability, vomiting
Steatorrhea	Formula containing medium-chain triglycerides (eg, Pregestimil or Alimentum) Oil supplement containing medium-chain triglycerides	120–150 kcal/kg/d for infants 1–2 mL/kg/d	Expensive Diarrhea, aspiration
Malabsorption of fat-soluble vitamins	Vitamin A Vitamin D 25-hydroxy-cholecalciferol (25-OH vitamin D) 1,25-dihydroxy-cholecalciferol (1,25 OH$_2$ vitamin D) Vitamin E (oral) Vitamin E (oral, TPGS[a]) Vitamin E (intramuscular) Vitamin K (oral) Vitamin K (intramuscular)	10,000–25,000 U/d 800–5000 U/d (up to 1000 U//kg/d for infants) 3–5 mcg/kg/d 0.05–0.2 mcg/kg/d 25–200 IU/kg/d 15–25 IU/kg/d 1–2 mg/kg/d 2.5 mg twice per week to 5 mg/d 2–5 mg each 4 wk	Hepatitis, pseudotumor cerebri, bone lesions Hypercalcemia, hypercalciuria Hypercalcemia, hypercalciuria Hypercalcemia, hypercalciuria Potentiation of vitamin K deficiency Potentiation of vitamin K deficiency Muscle calcifications
Malabsorption of other nutrients	Multiple vitamin Calcium Phosphorus Zinc	One to two times the standard dose 25–100 mg/kg/d 25–50 mg/kg/d 1 mg/kg/d	 Hypercalcemia, hypercalciuria Gastrointestinal intolerance Interference with copper and iron absorption

[a]D-α-Tocopheryl polyethylene glycol-1000 succinate.

2. Specific Infectious Agents

A. Neonatal Hepatitis B Virus Disease

Vertical transmission of HBV may occur at any time during perinatal life. Most cases of neonatal disease are acquired from mothers who are asymptomatic carriers of HBV. Although HBV has been found in most body fluids, including breast milk, neonatal transmission occurs primarily from exposure to maternal blood at delivery and only occasionally transplacentally (<5%–10% of cases). In chronic hepatitis B surface antigen (HBsAg)–carrier mothers, neonatal acquisition risk is greatest if the mother (1) is also hepatitis B "e" antigen (HBeAg)–positive and hepatitis B "e" antibody (HBeAb)–negative, (2) has high serum levels of hepatitis B

core antibody (HBcAb), or (3) has high blood levels of HBV DNA, indicating circulating infectious virus.

Neonatal HBV liver disease is extremely variable. The infant has a 70%–90% chance of acquiring HBV at birth from an HBsAg/HBeAg-positive mother if the infant does not receive prophylaxis. Most infected infants develop a prolonged asymptomatic immunotolerant stage of HBV infection. Fulminant hepatic necrosis and liver failure rarely occur in infants. Other patients develop chronic hepatitis with focal hepatocyte necrosis and a mild portal inflammatory response. Cholestasis is intracellular and canalicular. Chronic hepatitis may persist for many years, with serologic evidence of persisting antigenemia (HBsAg) and mildly elevated or normal serum aminotransferases. Chronic hepatitis may rarely progress to cirrhosis within 1–2 years. Most infected infants have only mild biochemical evidence, if any, of liver injury and do not appear ill. Most infants remain asymptomatic in an immune-tolerant state of HBV infection for a variable period of time and become an inactive carrier, develop chronic hepatitis or remain immune tolerant through childhood (see section on Hepatitis B).

To prevent perinatal transmission, all infants of mothers who are HBsAg-positive (regardless of HBeAg status) should receive hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine within the first 24 hours after birth and vaccine again at ages 1 and 6 months (see Chapter 10). This prevents HBV infection in 85%–95% of infants. HBIG can provide some protection when given as late as 72 hours after birth. If not given at birth it can be administered as late as 7 days postpartum as long as the infant has received the vaccine. Universal HBV immunization at birth, with two follow-up doses, is recommended for all infants regardless of maternal HBV status. Universal screening of pregnant women for HbsAg is conducted to determine which infants will need HBIG.

B. Neonatal Bacterial Hepatitis

Most bacterial liver infections in newborns are acquired by transplacental invasion from amnionitis with ascending spread from maternal vaginal or cervical infection. Onset is abrupt, usually within 48–72 hours after delivery, with signs of sepsis and often shock. Jaundice appears early with direct hyperbilirubinemia. The liver enlarges rapidly, and the histologic picture is that of diffuse hepatitis with or without microabscesses. The most common organisms involved are *Escherichia coli, Listeria monocytogenes*, and group B streptococci. Neonatal liver abscesses caused by *E coli* or *Staphylococcus aureus* may result from omphalitis or umbilical vein catheterization. Bacterial hepatitis and neonatal liver abscesses require specific antibiotics in optimal doses and combinations and, rarely, surgical or radiologic interventional drainage. Deaths are common, but survivors show no long-term consequences of liver disease.

C. Neonatal Jaundice with Urinary Tract Infection

Urinary tract infections typically present with cholestasis between the second and fourth weeks of life. Lethargy, fever, poor appetite, jaundice, and hepatomegaly may be present. Except for mixed hyperbilirubinemia, other liver function tests (LFTs) are mildly abnormal. Leukocytosis is present, and infection is confirmed by urine culture. The liver impairment is caused by the action of endotoxin and cytokines on bile secretion.

Treatment of the infection leads to resolution of the cholestasis without hepatic sequelae. Metabolic liver diseases, such as galactosemia and tyrosinemia, may present with gram-negative bacterial urinary tract infection and must be excluded.

3. Intrahepatic Cholestasis Resulting from Inborn Errors of Metabolism, Familial, & "Toxic" Causes

These cholestatic syndromes caused by specific enzyme deficiencies, other genetic disorders, or certain toxins share findings of intrahepatic cholestasis (ie, jaundice, hepatomegaly, and normal to completely acholic stools). Specific clinical conditions have characteristic clinical signs.

A. Enzyme Deficiencies and Other Inherited Disorders

Establishing the specific diagnosis as early as possible is important because dietary or pharmacologic treatment may be available (Table 22–5). Reversal of liver disease and clinical symptoms may be prompt and maintained in several disorders as long as the diet is maintained. As with other genetic disorders, parents of the affected infant should be offered genetic counseling. For some disorders, prenatal genetic diagnosis is available.

Cholestasis caused by metabolic diseases (eg, galactosemia, hereditary fructose intolerance, and tyrosinemia) is frequently accompanied by vomiting, lethargy, poor feeding, hypoglycemia, or irritability. The infants often appear septic; gram-negative bacteria can be cultured from blood in 25%–50% of symptomatic cases, especially in patients with galactosemia and cholestasis. Neonatal screening programs for galactosemia usually detect the disorder before cholestasis develops. Other metabolic and genetic causes of

Table 22–5. Metabolic and genetic causes of neonatal cholestasis.

Disease	Inborn Error	Hepatic Pathology	Diagnostic Studies
Galactosemia	Galactose-1-phosphate uridyltransferase	Cholestasis, steatosis, necrosis, pseudoacini, fibrosis	Galactose-1-phosphate uridyltransferase assay of red blood cells or genotyping[a]
Fructose intolerance	Fructose-1-phosphate aldolase	Steatosis, necrosis, pseudoacini, fibrosis	Liver fructose-1-phosphate aldolase assay or genotyping[a]
Tyrosinemia	Fumarylacetoacetase	Necrosis, steatosis, pseudoacini, portal fibrosis	Urinary succinylacetone, fumarylacetoacetase assay of red blood cells
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator gene	Cholestasis, neoductular proliferation, excess bile duct mucus, portal fibrosis	Sweat test and genotyping[a]
Hypopituitarism	Deficient production of pituitary hormones	Cholestasis, giant cells	Thyroxin, TSH, cortisol levels
α_1-Antitrypsin deficiency	Abnormal α_1-antitrypsin molecule (PiZZ or PiSZ phenotype)	Giant cells, cholestasis, steatosis, neoductular proliferation, fibrosis, PAS-diastase–resistant cytoplasmic globules	Serum α_1-antitrypsin phenotype or genotype
Gaucher disease	β-Glucosidase	Cholestasis, cytoplasmic inclusions in Kupffer cells (foam cells)	β-Glucosidase assay in leukocytes or genotyping[a]
Niemann-Pick type C disease	Lysosomal sphingomyelinase	Cholestasis, cytoplasmic inclusions in Kupffer cells	Sphingomyelinase assay of leukocytes or liver or fibroblasts (type C); genotyping[a]
Glycogen storage disease type IV	Branching enzyme	Fibrosis, cirrhosis, PAS-diastase–resistant cytoplasmic inclusions	Branching enzyme analysis of leukocytes or liver, genotyping[a]
Neonatal hemochromatosis	Transplacental alloimmunization	Giant cells, portal fibrosis, hemosiderosis, cirrhosis	Histology, iron stains, lip biopsy, chest and abdominal MRI
Peroxisomal disorders (eg, Zellweger syndrome)	Deficient peroxisomal enzymes or assembly	Cholestasis, necrosis, fibrosis, cirrhosis, hemosiderosis	Plasma very-long-chain fatty acids, qualitative bile acids, plasmalogen, pipecolic acid, liver electron microscopy, genotyping[a]
Abnormalities in bile acid metabolism	Several enzyme deficiencies defined	Cholestasis, necrosis, giant cells	Urine, serum, duodenal fluid analyzed for bile acids by fast atom bombardment–mass spectroscopy
Byler disease and syndrome (PFIC types I and II)	FIC-1 (*ATP8B1*) and BSEP (*ABCB11*) genes	Cholestasis, necrosis, giant cells, fibrosis	Histology, family history, normal cholesterol, low or normal γ-glutamyl transpeptidase, genotyping[a]
Arthrogryposis/renal dysfunction/cholestasis syndrome	*VPS33B* and *VIPAR* genes	Cholestasis, fibrosis	Genotyping[a]
MDR3 deficiency (PFIC type III)	MDR3 (*ABCB4*) gene	Cholestasis, bile duct proliferation, portal fibrosis	Bile phospholipid level, genotyping[a]
Alagille syndrome (syndromic paucity of interlobular bile ducts)	*JAGGED1* gene and *NOTCH2* mutations	Cholestasis, paucity of interlobular bile ducts, increased copper levels	Three or more clinical features, liver histology, genotyping[a]
Mitochondrial hepatopathies (respiratory chain diseases and mtDNA depletion syndrome)	*POLG, BCS1l, SCO1, DGUOK,* and *MPV17* and other gene mutations	Cholestasis, steatosis, portal fibrosis, abnormal mitochondria on electron microscopy	mtDNA depletion studies, respiratory chain studies on liver or muscle, genotyping[a]

[a]Performed on leukocyte DNA.
IV, intravenous; MDR3, multiple-drug resistance protein type 3; MRI, magnetic resonance imaging; mtDNA, mitochondrial DNA; PAS, periodic acid–Schiff; PFIC, progressive familial intrahepatic cholestasis; TSH, thyroid-stimulating hormone.

neonatal intrahepatic cholestasis are outlined in Table 22–5. Treatment of these disorders is discussed in Chapter 36.

B. "Toxic" Causes of Neonatal Cholestasis

1. Neonatal ischemic-hypoxic conditions—Perinatal events that result in hypoperfusion of the gastrointestinal system are sometimes followed within 1–2 weeks by cholestasis. This occurs in preterm infants with respiratory distress, severe hypoxia, hypoglycemia, shock, and acidosis. When these perinatal conditions develop in association with gastrointestinal lesions, such as ruptured omphalocele, gastroschisis, or necrotizing enterocolitis, a subsequent cholestatic picture is common (25%–50% of cases). Liver function studies reveal mixed hyperbilirubinemia, elevated alkaline phosphatase and γ-glutamyl transpeptidase (GGT) values, and variable elevation of the aminotransferases. Stools are seldom persistently acholic.

The mainstays of treatment are choleretics (UDCA), introduction of enteral feedings using special formulas as soon as possible, and nutrient supplementation until the cholestasis resolves (see Table 22–4). As long as no severe intestinal problem is present (eg, short gut syndrome or intestinal failure), resolution of the hepatic abnormalities is the rule, although this may take many weeks.

2. Prolonged parenteral nutrition—Cholestasis may develop after 1–2 weeks in premature newborns receiving parenteral nutrition. Even full-term infants with significant intestinal atresia, resections, or dysmotility may develop parenteral nutrition–associated cholestasis. Contributing factors include toxicity of intravenous lipid emulsions, diminished stimulation of bile flow from prolonged absence of feedings, frequent episodes of sepsis, small intestinal bacterial overgrowth with translocation of intestinal bacteria and their cell wall products, missing nutrients or antioxidants, photooxidation of amino acids, infusion of lipid hydroperoxides or plant sterols, and the "physiologic cholestatic" propensity of the premature infant. Activation of innate immune pathways in the liver appears to be involved. Histology of the liver may be identical to that of biliary atresia. Early introduction of feedings has reduced the frequency of this disorder. The prognosis is generally good; however, in infants with intestinal failure occasional cases progress to cirrhosis, liver failure, and hepatoma. These infants may require liver and intestinal, or multivisceral, transplantation. Oral erythromycin as a pro-motility agent may reduce the incidence of cholestasis in very-low-birth-weight infants. Intravenous fish oil–based lipid emulsions or reduction in soy-oil-based lipid emulsions may reverse features of cholestasis.

3. Inspissated bile syndrome—This syndrome is the result of accumulation of bile in canaliculi and in the small- and medium-sized bile ducts in hemolytic disease of the newborn (Rh, ABO) and in some infants receiving parenteral nutrition. The same mechanisms may cause intrinsic obstruction of the common bile duct. An ischemia-reperfusion injury may also contribute to cholestasis in Rh incompatibility. Stools may become acholic and levels of bilirubin, primarily conjugated, may reach 40 mg/dL. If inspissation of bile occurs within the extrahepatic biliary tree, differentiation from biliary atresia may be difficult. Although most cases improve slowly over 2–6 months, persistence of complete cholestasis for more than 1–2 weeks requires further studies (ultrasonography, hepatobiliary iminodiacetic acid [HIDA] scanning, liver biopsy) with possible cholangiography. Irrigation of the common bile duct is sometimes necessary to dislodge the obstructing inspissated biliary material.

4. Idiopathic Neonatal Hepatitis (Giant-Cell Hepatitis)

This idiopathic type of cholestatic jaundice, which has a typical liver biopsy appearance, accounts for 20%–30% of cases of neonatal intrahepatic cholestasis but is decreasing in frequency as new causes of cholestasis are discovered. The degree of cholestasis is variable, and the disorder may be indistinguishable from extrahepatic causes in 10% of cases. Many cases of this disorder have been shown in recent years to have specific etiologies. Viral infections, α_1-antitrypsin deficiency, Alagille syndrome, Niemann-Pick type C disease (NPC), progressive familial intrahepatic cholestasis (PFIC), citrin deficiency, neonatal hemochromatosis, and bile acid synthesis defects may present with similar clinical and histologic features. In idiopathic neonatal hepatitis, PFIC types I and II and ARC syndrome, and disease due to bile acid synthesis defects, the GGT levels are normal or low. Electron microscopy of the liver biopsy and genotyping will help distinguish NPC and PFIC.

Intrauterine growth retardation, prematurity, poor feeding, emesis, poor growth, and partially or intermittently acholic stools are characteristic of intrahepatic cholestasis. Serious hemorrhage from vitamin K deficiency may also be present. Patients with neonatal lupus erythematosus may present with giant-cell hepatitis; however, thrombocytopenia, rash, or congenital heart block is usually also present.

In cases of suspected idiopathic neonatal hepatitis (diagnosed in the absence of infectious, known genetic, metabolic, and toxic causes), patency of the biliary tree may need to be verified to exclude extrahepatic surgical disorders. HIDA scanning and ultrasonography may be helpful in this regard if stools are acholic. Liver biopsy findings are usually diagnostic after age 6–8 weeks (see Table 22–2), but may be misleading before age 6 weeks. Failure to detect patency of the biliary tree, nondiagnostic liver biopsy findings, or persisting complete cholestasis (acholic stools) are indications for minilaparotomy and intraoperative cholangiography performed by an experienced surgeon, ERCP, percutaneous cholecystography, or magnetic resonance cholangiopancreatography (MRCP). Occasionally, a small but patent (hypoplastic) extrahepatic biliary tree is demonstrated (as in Alagille syndrome); it is probably the result, rather than the cause, of diminished bile flow. Surgical reconstruction of hypoplastic biliary trees in Alagille syndrome should not be attempted.

Therapy should include choleretics, a special formula with medium-chain triglycerides (eg, Pregestimil, Alimentum) or breast milk (if growth is adequate), and supplemental fat-soluble vitamins in water-soluble form (see Table 22–4). This therapy is continued as long as significant cholestasis remains (conjugated bilirubin > 1 mg/dL). Fat-soluble vitamin serum levels and INR should be monitored at regular intervals while supplements are given and repeated at least once after their discontinuation.

Eighty percent of patients recover without significant hepatic fibrosis. However, failure to resolve the cholestatic picture by age 6–12 months is associated with progressive liver disease and evolving cirrhosis, most likely caused by a yet to be defined underlying genetic/metabolic disorder. This may occur with either normal or diminished numbers of interlobular bile ducts (paucity of interlobular ducts). Liver transplantation has been successful when signs of hepatic decompensation are noted (rising bilirubin, coagulopathy, intractable ascites).

5. Paucity of Interlobular Bile Ducts

Forms of intrahepatic cholestasis caused by decreased numbers of interlobular bile ducts (< 0.5 bile ducts per portal tract) may be classified according to whether they are associated with other malformations. Alagille syndrome (syndromic paucity or arteriohepatic dysplasia) is caused by mutations in the gene *JAGGED1*, located on chromosome 20p, which codes for a ligand of the notch receptor, or more rarely in the gene *NOTCH2*. Alagille syndrome is recognized by the characteristic facies, which becomes more obvious with age. The forehead is prominent. The eyes are set deep and sometimes widely apart (hypertelorism). The chin is small and slightly pointed and projects forward. The ears are prominent. The stool color varies with the severity of cholestasis. Pruritus begins by age 3–6 months. Firm, smooth hepatomegaly may be present or the liver may be of normal size. Cardiac murmurs are present in 95% of patients, and butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) are present in 50%. Xanthomas develop as hypercholesterolemia becomes a problem. Occasionally, early cholestasis is mild and not recognized or the patient presents with complex congenital heart disease (eg, tetralogy of Fallot).

Conjugated hyperbilirubinemia may be mild to severe (2–15 mg/dL). Serum alkaline phosphatase, GGT, and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated, aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

Cardiac involvement includes peripheral pulmonary artery, branch pulmonary artery, or pulmonary valvular stenoses, atrial septal defect, coarctation of the aorta, and tetralogy of Fallot. Up to 10%–15% of patients have intracranial vascular or cystic abnormalities or may develop intracranial hemorrhage or stroke early in childhood.

Eye findings (posterior embryotoxon or a prominent Schwalbe line in 90%) and renal abnormalities (dysplastic kidneys, renal tubular ectasia, single kidney, RTA, hematuria) are also characteristic and occur in about 40% of patients. Growth retardation with normal to increased levels of growth hormone (growth hormone resistance) is common. Some patients may rarely have pancreatic insufficiency that may contribute to the fat malabsorption. Although variable, the intelligence quotient is frequently low. Hypogonadism with micropenis may be present. A weak, high-pitched voice may develop. Neurologic disorders resulting from vitamin E deficiency (areflexia, ataxia, ophthalmoplegia) eventually develop in many unsupplemented children and may be profound.

In the nonsyndromic form, paucity of interlobular bile ducts occurs in the absence of the extrahepatic malformations may also occur in conditions such as α_1-antitrypsin deficiency, Zellweger syndrome, in association with lymphedema (Aagenaes syndrome), PFIC, cystic fibrosis, CMV or rubella infection, and inborn errors of bile acid metabolism.

High doses (250 mg/kg/d) of cholestyramine may control pruritus, lower cholesterol, and clear xanthomas. UDCA (15–20 mg/kg/d) appears to be more effective and causes fewer side effects than cholestyramine. Rifampicin may also reduce pruritus. Naltrexone (1 mg/kg/d) is occasionally required.

Partial biliary diversion or ileal exclusion surgery may reduce pruritus in about half of severe cases. Nutritional therapy to prevent wasting and deficiencies of fat-soluble vitamins is of particular importance because of the severity of cholestasis (see Table 22–4).

Prognosis is more favorable in the syndromic than in the nonsyndromic varieties. In the former, only 30%–40% of patients have severe complications of disease, whereas over 70% of patients with nonsyndromic varieties progress to cirrhosis. Many of this latter group may have forms of PFIC. In Alagille syndrome, cholestasis may improve by age 2–4 years, with minimal residual hepatic fibrosis. Survival into adulthood despite raised serum bile acids, aminotransferases, and alkaline phosphatase occurs in about 50% of cases. Several patients have developed hepatocellular carcinoma. Hypogonadism has been noted; however, fertility is not obviously affected in most cases. Cardiovascular anomalies and intracranial vascular lesions may shorten life expectancy. Some patients have persistent, severe cholestasis, rendering their quality of life poor. Recurrent bone fractures may result from metabolic bone disease. Liver transplantation has been successfully performed under these circumstances. Intracranial hemorrhage, moya moya disease, or stroke may occur in up to 10%–12% of affected children.

6. Progressive Familial Intrahepatic Cholestasis (PFIC; Byler Disease and Byler Syndrome)

PFIC is a group of disorders presenting as pruritus, diarrhea, jaundice, fat-soluble vitamin deficiencies, and failure to thrive in the first 6–12 months of life. PFIC type I (Byler disease), caused by mutations in the gene coding FIC1, an aminophospholipid floppase, is associated with low to normal serum levels of GGT and cholesterol and elevated levels of bilirubin, aminotransferases, and bile acids. Pancreatitis and hearing loss may develop. Liver biopsy demonstrates cellular cholestasis, sometimes with a paucity of interlobular bile ducts and centrilobular fibrosis that progresses to cirrhosis. Giant cells are absent. Electron microscopy shows diagnostic granular "Byler bile" in canaliculi. Treatment includes administration of UDCA, partial biliary diversion or ileal exclusion if the condition is unresponsive to UDCA, and liver transplantation if unresponsive to these therapies.

With partial biliary diversion or ileal exclusion surgery, many patients show improved growth and liver histology, reduction in symptoms and, thus, avoid liver transplantation. Following liver transplantation, chronic diarrhea and fatty liver may complicate recovery.

PFIC type II is caused by mutations in the bile salt export pump (BSEP) gene, which codes for the adenosine triphosphate–dependent canalicular bile salt transport protein. These patients are clinically and biochemically similar to PFIC type I patients, but liver histology includes numerous "giant cells." There is an increased incidence of hepatocellular carcinoma in these patients with severe gene mutations. Treatment is similar to PFIC type I although close monitoring for hepatocellular carcinoma is essential. Following liver transplantation, recurrent disease has been described in patients who developed immune-mediated BSEP dysfunction.

PFIC type III is caused by mutations in the multiple drug resistance protein type 3 (MDR3) gene, which encodes a canalicular protein that pumps phospholipid into bile. Serum GGT and bile acid levels are both elevated, bile duct proliferation and portal tract fibrosis are seen in liver biopsies (resembling biliary atresia), and bile phospholipid levels are low. Treatment is similar to that for other forms of PFIC except that partial biliary diversion is not recommended.

Bile acid synthesis defects are clinically similar to PFIC types I and II, with low serum levels of GGT and cholesterol; however, the serum level of total bile acids is inappropriately normal or low and urine bile acid analysis may identify a synthesis defect. Treatment of bile acid synthesis defects is with oral cholic acid and UDCA. About 1/3 of PFIC patients have negative genotyping for the above genes and most likely have yet-to-be discovered genetic etiologies.

Best Pract Res Clin Gastroenterol 2010;24:541 [PMID: 20955958].

EXTRAHEPATIC NEONATAL CHOLESTASIS

Extrahepatic neonatal cholestasis is characterized by complete and persistent cholestasis (acholic stools) in the first 3 months of life; lack of patency of the extrahepatic biliary tree proved by intraoperative, percutaneous, or endoscopic cholangiography; firm to hard hepatomegaly; and typical features on histologic examination of liver biopsy tissue (see Table 22–2). Causes include biliary atresia, choledochal cyst,

spontaneous perforation of the extrahepatic ducts, and intrinsic or extrinsic obstruction of the common duct.

1. Biliary Atresia

▶ General Considerations

Biliary atresia is the progressive fibroinflammatory obliteration of the lumen of all, or part of, the extrahepatic biliary tree presenting within the first 3 months of life. Biliary atresia occurs in 1:6600 (Taiwan)–1:18,000 (Europe) births, and in the United States the incidence is approximately 1:12,000. The incidence is highest in Asians, African Americans, and pre-term infants, and there is a slight female predominance. There are at least two types of biliary atresia: the perinatal form (80% of cases), in which a perinatal insult, such as a virus infection, is believed to initiate inflammatory obstruction and fibrosis of the biliary tree, and the fetal-embryonic form (20% of cases), in which the extrahepatic biliary system did not develop normally. In the perinatal form, meconium and initial stools are usually normal in color, suggesting early patency of the ducts. Evidence obtained from surgically removed remnants of the extrahepatic biliary tree suggests an inflammatory sclerosing cholangiopathy. Recent research supports an autoimmune reaction that is responsible for progressive intrahepatic bile duct injury and fibrosis. In the fetal-embryonic type, the bile duct presumably did not develop normally and is associated with other nonhepatic congenital anomalies. The association of biliary atresia with the polysplenia syndrome (heterotaxia, preduodenal portal vein, interruption of the inferior vena cava, polysplenia, and midline liver) and asplenia syndrome supports an embryonic origin of biliary atresia in these cases.

▶ Clinical Findings

A. Symptoms and Signs

Jaundice may be noted in the newborn period or develops about age 2–3 weeks. Urine stains the diaper; and stools are often pale yellow, buff-colored, gray, or acholic. Seepage of bilirubin products across the intestinal mucosa may give some yellow coloration to the stools. Hepatomegaly is common, and the liver may feel firm to hard. By age 2–6 months, the growth curve reveals poor weight gain. Symptoms of portal hypertension (splenomegaly, ascites, variceal bleeding) may develop in the first year of life. Pruritus, digital clubbing, failure to thrive, bone fractures, and bleeding complications may also occur later in childhood.

B. Laboratory Findings and Imaging

No single laboratory test will consistently differentiate biliary atresia from other causes of complete obstructive jaundice. Although biliary atresia is suggested by persistent elevation of serum GGT or alkaline phosphatase levels, these findings have also been reported in severe neonatal hepatitis, α_1-antitrypsin deficiency, and bile duct paucity. Furthermore, these tests will not differentiate the location of the obstruction within the extrahepatic system. Generally, the aminotransferases are only modestly elevated in biliary atresia. Serum proteins and blood clotting factors are not affected early in the disease. Ultrasonography of the biliary system should be performed to exclude the presence of choledochal cyst and intra-abdominal anomalies; a triangular cord sign in the hepatic porta suggests biliary atresia. A HIDA scan showing lack of intestinal excretion is always present in biliary atresia, but may be seen with multiple other causes of intrahepatic cholestasis. Liver biopsy specimens (particularly if obtained after age 6–8 weeks) can differentiate intrahepatic causes of cholestasis from biliary atresia in over 90% of cases (see Table 22–2).

▶ Differential Diagnosis

The major diagnostic dilemma is distinguishing between this entity and bile duct paucity, metabolic liver disease (particularly α_1-antitrypsin deficiency), choledochal cyst, or intrinsic bile duct obstruction (stones, bile plugs). Although spontaneous perforation of extrahepatic bile ducts leads to jaundice and acholic stools, the infants in such cases are usually quite ill with chemical peritonitis from biliary ascites, and hepatomegaly is not found.

If the diagnosis of biliary atresia cannot be excluded by the diagnostic evaluation and percutaneous liver biopsy, surgical exploration should be performed as soon as possible. Laparotomy or laparoscopy must include liver biopsy and an operative cholangiogram if a gallbladder is present. The presence of yellow bile in the gallbladder implies patency of the proximal extrahepatic duct system. Radiographic visualization of cholangiographic contrast in the duodenum excludes obstruction to the distal extrahepatic ducts.

▶ Treatment

In the absence of surgical correction or transplantation, biliary cirrhosis, hepatic failure, and death occur uniformly by age 18–24 months.

The standard procedure at the time of diagnosis of biliary atresia is the hepatoportoenterostomy (Kasai procedure). Occasionally, portocholecystostomy (gallbladder Kasai procedure) may be performed if the gallbladder is present and the passage from it to the duodenum is patent. These procedures are best done in specialized centers where experienced surgical, pediatric, and nursing personnel are available. Surgery should be performed as early as possible (ideally before 45 days of life); the Kasai procedure should generally not be undertaken in infants older than age 4 months, because the likelihood of bile drainage at this age is very low. Orthotopic liver transplantation is now indicated for patients who do not undergo the Kasai procedure, who fail

to drain bile after the Kasai procedure, or who progress to end-stage biliary cirrhosis despite surgical treatment. The 3- to 5-year survival rate following liver transplantation for biliary atresia is at least 80%–90%. Biliary atresia is the leading indication for pediatric liver transplantation.

Whether or not the Kasai procedure is performed, supportive medical treatment consists of vitamin and caloric support (vitamins A, D, E, and K and formulas containing medium-chain triglycerides [Pregestimil or Alimentum]) (see Table 22–4). Monitoring of fat-soluble vitamin levels is essential to ensure adequate supplementation. Suspected bacterial infections (eg, ascending cholangitis) should be treated promptly with broad-spectrum antibiotics, and any bleeding tendency should be corrected with intramuscular vitamin K. Ascites can be managed initially with reduced sodium intake and spironolactone. Choleretics and bile acid–binding products (cholestyramine, aluminum hydroxide gel) are of little use. The value of UDCA remains to be determined. Antibiotic prophylaxis reduces the recurrence rate of cholangitis. The role of post-Kasai corticosteroids is controversial.

▶ **Prognosis**

When bile flow is sustained following portoenterostomy (serum total bilirubin < 2 mg/dL by 3 months of age), the 10-year survival rate without liver transplantation is up to 35%. Death is usually caused by liver failure, sepsis, intractable variceal bleeding or respiratory failure secondary to intractable ascites. Esophageal variceal hemorrhage develops in 40% of patients, yet terminal hemorrhage is unusual. Occasional long-term survivors develop hepatopulmonary syndrome (intrapulmonary right to left shunting of blood resulting in hypoxia) or portopulmonary hypertension (pulmonary arterial hypertension in patients with portal hypertension). Liver transplantation has dramatically changed the outlook for these patients.

2. Choledochal Cyst

ESSENTIALS OF DIAGNOSIS

▶ Abnormal abdominal ultrasound with cyst of the biliary tree.

▶ **Clinical Features**

A. Symptoms and Signs

Choledochal cysts are cystic lesions of all or part of the extrahepatic biliary system and in rare cases the cystic malformation can include the intrahepatic bile duct branches. In most cases, the clinical manifestations, basic laboratory findings, and histopathologic features on liver biopsy are indistinguishable from those associated with biliary atresia. In older children, choledochal cyst presents as recurrent episodes of right upper quadrant abdominal pain, fevers, vomiting, obstructive jaundice, pancreatitis, or as a right abdominal mass. Infants and children with choledochal cysts are at increased risk for developing bacterial cholangitis. Choledochal cysts cause only 2%–5% of cases of extrahepatic neonatal cholestasis; the incidence is higher in girls and patients of Asian descent. Neonatal symptomatic cysts may be associated with atresia of the distal common duct—accounting for the diagnostic dilemma—and may simply be part of the spectrum of biliary atresia.

B. Imaging Studies

Ultrasonography or magnetic resonance imaging (MRI) reveals the presence of a cyst.

▶ **Treatment**

Timely surgery is indicated for neonates once abnormalities in clotting factors have been corrected and bacterial cholangitis, if present, has been treated with intravenous antibiotics. Excision of the cyst and choledocho–Roux-en-Y jejunal anastomosis are recommended. In some cases, because of technical problems, only the mucosa of the cyst can be removed with jejunal anastomosis to the proximal bile duct. Anastomosis of cyst to jejunum or duodenum is not recommended due to the continued risks of cholangitis and bile duct carcinoma (cholangiocarcinoma).

▶ **Prognosis**

The prognosis depends on the presence or absence of associated evidence of atresia and the appearance of the intrahepatic ducts. If atresia is found, the prognosis is similar to that described in the preceding section. If an isolated extrahepatic cyst is encountered, the outcome is generally excellent, with resolution of the jaundice and return to normal liver architecture. However, bouts of ascending cholangitis may occur, particularly if intrahepatic cysts are present or stricture of the anastomotic site develops. The risk of cholangiocarcinoma developing within the cyst is about 5%–15% in adulthood; therefore, cystectomy or excision of cyst mucosa should be undertaken whenever possible.

Hung MH et al: Choledochal cysts in infants and children: experiences over a 20-year period at a single institution. Eur J Pediatr 2011;170:1179 [PMID: 21350805].

Tsai MS et al: Clinicopathological feature and surgical outcome of choledochal cyst in different age groups: the implication of surgical timing. J Gastrointest Surg 2008;12:2191 [PMID: 18677540].

3. Spontaneous Perforation of the Extrahepatic Bile Ducts

The sudden appearance of obstructive jaundice, acholic stools, and abdominal enlargement with ascites in a sick newborn is suggestive of this condition. The liver is usually normal in size, and a yellow-green discoloration can often be discerned under the umbilicus or in the scrotum. In 24% of cases, stones or sludge obstructs the common bile duct. HIDA scan or ERCP shows leakage from the biliary tree, and ultrasonography confirms ascites or fluid around the bile duct.

Treatment is surgical. Simple drainage, without attempts at oversewing the perforation, is sufficient in primary perforations. A diversion anastomosis is constructed in cases associated with choledochal cyst or stenosis. The prognosis is generally good.

Pereira E et al: Conservative management of spontaneous bile duct perforation in infancy: case report and literature review. J Pediatr Surg 2012;47:1757 [PMID: 22974619].

OTHER NEONATAL HYPERBILIRUBINEMIC CONDITIONS (NONCHOLESTATIC NONHEMOLYTIC)

Two other groups of disorders are associated with hyperbilirubinemia: (1) unconjugated hyperbilirubinemia, present in breast milk jaundice, Lucey-Driscoll syndrome, congenital hypothyroidism, upper intestinal obstruction, Gilbert disease, Crigler-Najjar syndrome, and drug-induced hyperbilirubinemia; and (2) conjugated noncholestatic hyperbilirubinemia, present in the Dubin-Johnson syndrome and Rotor syndrome.

1. Unconjugated Hyperbilirubinemia

A. Breast Milk Jaundice

Persistent elevation of the indirect bilirubin fraction (> 80% of total bilirubin) may occur in up to 36% of breast-fed infants. Enhanced β-glucuronidase activity in breast milk is one factor that increases absorption of unconjugated bilirubin. Substances (eg, L-aspartic acid) in casein hydrolysate formulas inhibit this enzyme. The increased enterohepatic shunting of unconjugated bilirubin exceeds the normal conjugating capacity in the liver of these infants. The mutation for Gilbert syndrome (UDP-glucuronyltransferase 1A1 [*UGT1A1*]) predisposes to breast milk jaundice and to more prolonged jaundice. Neonates who carry the 211 and 388 variants in the *UGT1A1* and *OATP 2* genes, respectively, and feed with breast milk, are at high risk to develop severe hyperbilirubinemia. Low volumes of ingested breast milk may also contribute to jaundice in the first week of life. Finally, breast milk may suppress UGT1A1 expression in the infant's intestines which may also lead to unconjugated hyperbilirubinemia.

Hyperbilirubinemia does not usually exceed 20 mg/dL, with most cases in the range of 10–15 mg/dL. Jaundice is noticeable by the fifth to seventh day of breast feeding. It may accentuate the underlying physiologic jaundice—especially early, when total fluid intake may be less than optimal. Except for jaundice, the physical examination is normal; urine does not stain the diaper, and the stools are golden yellow.

The jaundice peaks before the third week of life and clears before age 3 months in almost all infants, even when breast feeding is continued. All infants who remain jaundiced past age 2–3 weeks should have measurement of conjugated bilirubin to exclude cholestasis and hepatobiliary disease.

Kernicterus has rarely been reported in association with this condition. In special situations, breast feeding may be discontinued temporarily and replaced by formula feedings for 2–3 days until serum bilirubin decreases by 2–8 mg/dL. Cow's milk formulas inhibit the intestinal reabsorption of unconjugated bilirubin. When breast feeding is reinstituted, the serum bilirubin may increase slightly, but not to the previous level. Phototherapy is not indicated in the healthy full-term infant with this condition unless bilirubin levels meet high-risk levels as defined by the American Academy of Pediatrics.

Bhutani VK et al: Expert Committee for Severe Neonatal Hyperbilirubinemia; European Society for Pediatric Research; American Academy of Pediatrics: management of jaundice and prevention of severe neonatal hyperbilirubinemia in infants ≥ 35 weeks gestation. Neonatology 2008;94:63 [PMID: 18204221].

Fujiwara R et al: Reduced expression of UGT1A1 in intestines of humanized UGT1 mice via inactivation of NF-κB leads to hyperbilirubinemia. Gastroenterology 2012;142:109 [PMID: 21983082].

Preer GL, Philipp BL: Understanding and managing breast milk jaundice. Arch Dis Child Fetal Neonatal Ed 2011;96:F461 [PMID: 20688866].

B. Congenital Hypothyroidism

Although the differential diagnosis of indirect hyperbilirubinemia should always include congenital hypothyroidism, the diagnosis is usually suggested by clinical and physical clues or, more commonly, from the newborn screening results. The jaundice clears quickly with replacement thyroid hormone therapy, although the mechanism is unclear.

Tiker F: Congenital hypothyroidism and early severe hyperbilirubinemia. Clin Pediatr (Phila) 2003;42:365 [PMID: 12800733].

C. Upper Intestinal Obstruction

The association of indirect hyperbilirubinemia with high intestinal obstruction (eg, duodenal atresia, annular pancreas, pyloric stenosis) in the newborn has been observed repeatedly; the mechanism is unknown. Diminished levels of hepatic glucuronyl transferase are found on liver biopsy in pyloric stenosis, and genetic studies suggest that this indirect hyperbilirubinemia may be an early sign of Gilbert syndrome.

Treatment is that of the underlying obstructive condition (usually surgical). Jaundice disappears once adequate nutrition is achieved.

Hua L et al: The role of UGT1A1∗28 mutation in jaundiced infants with hypertrophic pyloric stenosis. Pediatr Res 2005;58:881 [PMID: 16257926].

D. Gilbert Syndrome

Gilbert syndrome is a common form of familial hyperbilirubinemia present in 3%–7% of the population. It is associated with a partial reduction of hepatic bilirubin uridine diphosphate-glucuronyl transferase activity. Affected infants may have more rapid increase in jaundice in the newborn period, accentuated breast milk jaundice, and jaundice with intestinal obstruction. During puberty and beyond, mild fluctuating jaundice, especially with illness and vague constitutional symptoms, is common. Shortened red blood cell survival in some patients is thought to be caused by reduced activity of enzymes involved in heme biosynthesis (protoporphyrinogen oxidase). Reduction of hyperbilirubinemia has been achieved in patients by administration of phenobarbital (5–8 mg/kg/d), although this therapy is not justified.

The disease is inherited as an abnormality of the promoter region of uridine diphosphate-glucuronyl transferase-1 (*UDGT1*); however, another factor appears to be necessary for disease expression. The homozygous (16%) and heterozygous states (40%) are common. Males are affected more often than females (4:1) for reasons that are not clear. Serum unconjugated bilirubin is generally less than 3–6 mg/dL, although unusual cases may exceed 8 mg/dL. The findings on liver biopsy and most LFTs are normal. An increase of 1.4 mg/dL or more in the level of unconjugated bilirubin after a 2-day fast (300 kcal/d) is consistent with the diagnosis of Gilbert syndrome. Gilbert syndrome, conferred by the donor liver, can occur following liver transplantation. Genetic testing is available but rarely needed. No treatment is necessary.

Kathemann S et al: Gilbert's syndrome—a frequent cause of unconjugated hyperbilirubinemia in children after orthotopic liver transplantation. Pediatr Transplant 2012;16:20 [PMID: 22360405].

E. Crigler-Najjar Syndrome

Infants with type 1 Crigler-Najjar syndrome usually develop rapid severe unconjugated hyperbilirubinemia (> 30–40 mg/dL) with neurologic consequences (kernicterus). Consanguinity is often present. Prompt recognition of this entity and treatment with exchange transfusions are required, followed by phototherapy. Some patients have no neurologic signs until adolescence or early adulthood, at which time deterioration may occur suddenly. For diagnosis of this condition, it may be useful to obtain a duodenal bile specimen, which characteristically will be colorless and contain a predominance of unconjugated bilirubin, small amounts of monoconjugates, and only traces of unconjugated bilirubin. Phenobarbital administration does not significantly alter these findings, nor does it lower serum bilirubin levels. UGT genetic testing is available. The deficiency in UGT1A1 is inherited in an autosomal recessive pattern. A combination of aggressive phototherapy and cholestyramine may keep bilirubin levels below 25 mg/dL. The use of tin protoporphyrin or tin mesoporphyrin remains experimental. Orlistat therapy may decrease bilirubin in a subset of patients. Liver transplantation is curative and may prevent kernicterus if performed early. Auxiliary orthotopic transplantation also relieves the jaundice while the patient retains native liver. Hepatocyte transplantation is experimental and future gene therapy may be possible

A milder form (type 2) with both autosomal dominant and recessive inheritance is rarely associated with neurologic complications. Hyperbilirubinemia is less severe, and the bile is pigmented and contains small amounts of bilirubin monoglucuronide and diglucuronide. Patients with this form respond to phenobarbital (4 mg/kg/d in infants) with lowering of serum bilirubin levels. An increased proportion of monoconjugated and diconjugated bilirubin in the bile follows phenobarbital treatment. Liver biopsy findings and LFTs are consistently normal in both types.

Kohli S et al: Novel human pathological mutations. Gene symbol: UGT1A1 Disease: Crigler-Najjar syndrome 1. Hum Genet 2010;127:485 [PMID: 21488310].

F. Drug-Induced Hyperbilirubinemia

Vitamin K_3 (menadiol) may elevate indirect bilirubin levels by causing hemolysis. Vitamin K_1 (phytonadione)

can be used safely in neonates. Carbamazepine can cause conjugated hyperbilirubinemia in infancy. Rifampin and antiretroviral protease inhibitors may cause unconjugated hyperbilirubinemia. Pancuronium bromide and chloral hydrate have been implicated in causing neonatal jaundice. Other drugs (eg, ceftriaxone, sulfonamides) may displace bilirubin from albumin, potentially increasing the risk of kernicterus—especially in the sick premature infant.

2. Conjugated Noncholestatic Hyperbilirubinemia (Dubin-Johnson Syndrome & Rotor Syndrome)

These diagnoses are suspected when persistent or recurrent conjugated hyperbilirubinemia and jaundice occur and liver function tests are normal. The basic defect in Dubin-Johnson syndrome is in the multiple organic anion transport protein 2 (*MRP2*) of the bile canaliculus, causing impaired hepatocyte excretion of conjugated bilirubin into bile. A variable degree of impairment in uptake and conjugation complicates the clinical picture. Transmission is autosomal recessive, so a positive family history is occasionally obtained. In Rotor syndrome, the defect lies in hepatic uptake and storage of bilirubin. OATP1B1 and OATP1B3 are the two transporters that are deficient. Bile acids are metabolized normally, so that cholestasis does not occur. Bilirubin values range from 2 to 5 mg/dL, and other LFTs are normal.

In Rotor syndrome, the liver is normal; in Dubin-Johnson syndrome, it is darkly pigmented on gross inspection and may be enlarged. Microscopic examination reveals numerous dark-brown pigment granules consisting of polymers of epinephrine metabolites, especially in the centrilobular regions. However, the amount of pigment varies within families, and some jaundiced family members may have no demonstrable pigmentation in the liver. Otherwise, the liver is histologically normal. Oral cholecystography fails to visualize the gall-bladder in Dubin-Johnson syndrome, but is normal in Rotor syndrome. Differences in the excretion patterns of bromosulfophthalein, in results of HIDA cholescintigraphy, in urinary coproporphyrin I and III levels, and in the serum pattern of monoglucuronide and diglucuronide conjugates of bilirubin can help distinguish between these two conditions. Genotyping of *MRP2* is available but for the Rotor syndrome this is only available on a research basis.

Choleretic agents (eg, UDCA) may help reduce the cholestasis in infants with Dubin-Johnson syndrome.

HEPATITIS A

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Gastrointestinal upset (anorexia, vomiting, diarrhea).
▶ Jaundice.
▶ Liver tenderness and enlargement.
▶ Abnormal LFTs.
▶ Local epidemic of hepatitis A infection.
▶ Positive anti–hepatitis A virus (HAV) IgM antibody.

▶ Pathogenesis

Hepatitis A virus (HAV) infection occurs in both epidemic and sporadic fashion (Table 22–6). Fecal-oral route is the mode of transmission in epidemic outbreaks from contaminated food or water supplies, including by food handlers. HAV viral particles are found in stools during the acute phase of hepatitis A infection. Sporadic cases usually result from contact with an infected individual. Transmission through blood products obtained during the viremic phase is a rare event, although it has occurred in a newborn nursery.

▶ Prevention

Isolation of the patient during initial phases of illness is indicated, although most patients with hepatitis A are noninfectious by the time the disease becomes overt. Stool, diapers, and other fecally stained clothing should be handled with care for 1 week after the appearance of jaundice.

Passive-active immunization of exposed susceptible persons < 12 months old; over 40 years of age: anyone who is immunocompromised or who has chronic liver disease is recommended with immune globulin, 0.02 mL/kg intramuscularly. Illness is prevented in > 85% of individuals if immune globulin is given within 2 weeks of exposure. For individuals 12 months to 40 years old HAV vaccine is recommended following exposure. Infants < 12 months old traveling to endemic disease areas should receive HAV vaccine or 0.02 or 0.06 mL/kg (for trip > 3 months) of immune globulin as prophylaxis. Older individuals should receive the HAV vaccine. All children older than 12 months with chronic liver disease should receive two doses of HAV vaccine 6 months apart. It is currently recommended that all children 12–18 months of age receive HAV vaccination in the United States. If an emigrant child from an endemic area is adopted, the immediate family members should be immunized. Lifelong immunity to HAV follows infection.

Table 22–6. Hepatitis viruses.

	HAV	HBV	HCV	HDV	HEV
Type of virus	Enterovirus (RNA)	Hepadnavirus (DNA)	Flavivirus (RNA)	Deltavirus (RNA)	Hepevirus (RNA)
Transmission routes	Fecal-oral	Parenteral, sexual, vertical	Parenteral, sexual, vertical	Parenteral, sexual	Fecal-oral
Incubation period (days)	15–40	45–160	30–150	20–90	14–65
Diagnostic test	Anti-HAV IgM	HBsAg, anti-HBc IgM, DNA PCR	Anti-HCV, RNA PCR	Anti-HDV antibody	Anti-HEV IgM HEV PCR
Mortality rate (acute)	0.1%–0.2%	0.5%–2%	1%–2%	2%–20%	1%–2% (10%–20% in pregnant women)
Carrier state	No	Yes	Yes	Yes	No

Treatment	None	Interferon-α (pegylated interferon in adults), nucleoside analogues (lamivudine > 2 y old, tenofovir > 12 y, adefovir > 12; entecavir or telbivudine > 16)	Pegylated interferon plus ribavirin	Treatment for HBV	None

HAV, hepatitis A virus; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HDV, hepatitis D (delta) virus; HEV, hepatitis E virus; PCR, polymerase chain reaction.

HEPATITIS VIRUS ABBREVIATIONS	
HAV	Hepatitis A virus
Anti-HAV IgM	IgM antibody to HAV
HBV	Hepatitis B virus
HBsAg	HBV surface antigen
HBcAg	HBV core antigen
HBeAg	HBV e antigen
Anti-HBs	Antibody to HBsAg
Anti-HBc	Antibody to HBcAg
Anti-HBc IgM	IgM antibody to HBcAg
Anti-HBe	Antibody to HBeAg
HCV	Hepatitis C virus
Anti-HCV	Antibody to HCV
HDV	Hepatitis D (delta) virus
Anti-HDV	Antibody to HDV
HEV	Hepatitis E virus
Anti-HEV	Antibody to HEV

Antibody to HAV appears within 1–4 weeks of clinical symptoms. Although the great majority of children with infectious hepatitis are asymptomatic or have mild disease and recover completely, some will develop fulminant hepatitis leading to death or requiring liver transplantation.

▶ **Clinical Findings**

A. History

Historical risk factors may include direct exposure to a previously jaundiced individual or recently arrived individual from a high prevalence country, consumption of seafood, contaminated water or imported fruits or vegetables, attendance in a day care center, or recent travel to an area of endemic infection. Following an incubation period of 15–40 days, nonspecific symptoms usually precede the development of jaundice by 5–10 days. In developing countries, hepatitis A is common and most children are exposed to HAV by age 10 years, while only 20% are exposed by age 20 years in developed countries.

B. Symptoms and Signs

The overt form of the disease is easily recognized by the clinical manifestations. However, two-thirds of children are asymptomatic, and two-thirds of symptomatic children are anicteric. Therefore, the presenting symptoms in children with HAV resemble gastroenteritis. Fever, anorexia, vomiting, headache, and abdominal pain are typical and dark urine precedes jaundice, which peaks in 1–2 weeks and then begins to subside. The stools may become light- or clay-colored. Clinical improvement can occur as jaundice develops.

Tender hepatomegaly and jaundice are typically present; splenomegaly is variable.

C. Laboratory Findings

Serum aminotransferases and conjugated and unconjugated bilirubin levels are elevated. Although unusual, hypoalbuminemia, hypoglycemia, and marked prolongation of PT (international normalized ratio [INR] > 2.0) are serious prognostic findings. Diagnosis is made by a positive anti-HAV IgM, whereas anti-HAV IgG persists after recovery.

Percutaneous liver biopsy is rarely indicated. "Balloon cells" and acidophilic bodies are characteristic histologic findings. Liver cell necrosis may be diffuse or focal, with accompanying infiltration of inflammatory cells containing polymorphonuclear leukocytes, lymphocytes, macrophages, and plasma cells, particularly in portal areas. Some bile duct proliferation may be seen in the perilobular portal areas alongside areas of bile stasis. Regenerative liver cells and proliferation of reticuloendothelial cells are present. Occasionally massive hepatocyte necrosis portends a poor prognosis.

▶ Differential Diagnosis

Before jaundice appears, the symptoms are those of nonspecific viral enteritis. Other diseases with somewhat similar onset include pancreatitis, infectious mononucleosis, leptospirosis, drug-induced hepatitis, Wilson disease, autoimmune hepatitis (AIH), and infection with other hepatitis viruses. Acquired CMV disease may also mimic HAV, although lymphadenopathy is usually present in the former.

▶ Treatment

No specific treatment measures are required although bed rest is reasonable for the child who appears ill. Sedatives and corticosteroids should be avoided. During the icteric phase, lower-fat foods may diminish gastrointestinal symptoms, but do not affect overall outcome. Drugs and elective surgery should be avoided. Hospitalization is recommended for children with coagulopathy, encephalopathy, or severe vomiting.

▶ Prognosis

Ninety-nine percent of children recover without sequelae. Persons with underlying chronic liver disease have an increased risk of death. In rare cases of acute liver failure due to HAV hepatitis, the patient may die within days to weeks and requires evaluation for liver transplantation. The prognosis is poor if hepatic coma or ascites develop; liver transplantation is indicated under these circumstances and is life-saving. Incomplete resolution can cause a prolonged hepatitis; however, resolution invariably occurs without long-term hepatic sequelae. Rare cases of aplastic anemia following acute infectious hepatitis have been reported. A benign relapse of symptoms may occur in 10%–15% of cases after 6–10 weeks of apparent resolution.

HEPATITIS B

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Gastrointestinal upset, anorexia, vomiting, diarrhea.

▶ Jaundice, tender hepatomegaly, abnormal LFTs.

▶ Serologic evidence of hepatitis B disease: HBsAg, HBeAg, anti-HBc IgM.

▶ History of parenteral, sexual, or household exposure or maternal HBsAg carriage.

▶ General Considerations

In contrast to HAV, hepatitis B virus (HBV) infection has a longer incubation period of 45–160 days (see Table 22–6). HBV is a DNA virus that is either acquired perinatally from a carrier mother, or later in life from exposure to contaminated blood through shared needles, needle sticks, skin piercing, tattoos, or sexual transmission. Transmission via blood products has been almost eliminated by donor-screening and donor blood testing protocols.

▶ Pathophysiology

The HBV particle is composed of a core that is found in the nucleus of infected liver cells and a double outer shell (surface antigen). The surface antigen in blood is termed HBsAg, which elicits an antibody (anti-HBs). The core antigen is termed HBcAg and its antibody is anti-HBc. Anti-HBc IgM antibody indicates recent viral infection. Another important antigen-antibody system associated with HBV disease is the "e" (envelope) antigen system. HBeAg, a truncated soluble form of HBcAg, correlates with active virus replication. Persistence of HBeAg is a marker of infectivity, whereas the

appearance of anti-HBe generally implies a lower level of viral replication. However, HBV mutant viruses (precore mutant) may replicate with negative HBeAg tests and positive tests for anti-HBe antibody (HBeAg-negative chronic hepatitis) and are associated with a more virulent form of hepatitis. Circulating HBV DNA (measured by PCR) also indicates viral replication.

▶ Prevention

HBV vaccination is the preferred method for prevention. Universal immunization of all infants born in the United States and of adolescents is now recommended, as it is in most other countries. Other control methods include screening of blood donors and pregnant women, use of properly sterilized needles and surgical equipment, avoidance of sexual contact with carriers, general adoption of safe sex practices, and vaccination of household contacts, sexual partners, medical personnel, and those at high risk. For postexposure prophylaxis, HBV vaccine alone (see Chapter 10) or together with administration of hepatitis B immune globulin (HBIG) (0.06 mL/kg intramuscularly, given as soon as possible after exposure, up to 7 days). The risk of vertical transmission is dramatically reduced with the combination of newborn vaccination and HBIG administration.

▶ Clinical Findings

A. Symptoms and Signs

Most infants and young children are completely asymptomatic, especially if the infection is acquired vertically. Symptoms of acute HBV infection include slight fever (which may be absent), malaise, and mild gastrointestinal upset. Visible jaundice is usually the first significant finding and is accompanied by darkening of the urine and pale or clay-colored stools. Hepatomegaly is frequently present. Occasionally an antigen-antibody complex presentation antedates the appearance of icterus, and is characterized by macular rash, urticaria, and arthritis. HBV infection more rarely presents as a glomerulonephritis or nephrotic syndrome from immune complexes.

B. Laboratory Findings

The diagnosis of acute HBV infection is confirmed by the presence of HBsAg and anti-HBc IgM. Recovery from acute infection is accompanied by HBsAg clearance and appearance of anti-HBs and anti-HBc IgG. Individuals who are immune by vaccination are positive for anti-HBs, but negative for anti-HBc IgG. Chronic infection is defined as the presence of HBsAg for at least 6 months. Vertical transmission to newborns is documented by positive HBsAg. LFT results are similar to those discussed earlier for hepatitis A. Liver biopsy is most useful in chronic infection to determine the degree of fibrosis and inflammation. Renal involvement may be suspected on the basis of urinary findings suggesting glomerulonephritis or nephrotic syndrome. The various phases of chronic HBV infection are shown in Table 22–7.

▶ Differential Diagnosis

The differentiation between HAV and HBV disease is aided by a history of parenteral exposure, an HBsAg-positive parent, or an unusually long period of incubation. HBV and hepatitis C virus (HCV) infection or Epstein-Barr virus (EBV) infection are differentiated serologically. The history may suggest a drug-induced hepatitis, especially if a serum sickness prodrome is reported. Autoimmune hepatitis Wilson disease, hemochromatosis, nonalcoholic fatty liver disease (NAFLD), α_1-antitrypsin deficiency, and drug-induced hepatitis should also be considered.

▶ Treatment

Supportive measures such as bed rest and a nutritious diet are used during the active symptomatic stage of acute HBV infection. Corticosteroids are contraindicated. No other treatment is needed for acute HBV infection. For acute infection complicated by acute liver failure, nucleos(t)ide therapy may be

Table 22–7. Phases of chronic hepatitis B infection.

Phase	HBeAg/Anti-HBeAB	HBsAg/Anti-HBsAB	ALT	HBV DNA
Immune tolerant	Positive/negative	Positive/negative	Normal	> 20,000 IU/mL
Immune active	Positive/negative	Positive/negative	Elevated	High
Chronic HBsAg carrier	Negative/positive	Positive/negative	Normal	< 2000 IU/mL
HBeAg negative hepatitis/ reactivation	Negative/positive	Positive/negative	Elevated	> 2000 IU/mL
HBsAg clearance	Negative/positive	Negative/positive	Normal	Undetectable

helpful. For patients with chronic infection who persist in the immunoactive phase for more than 6 months or with HBeAg-negative chronic hepatitis, there are currently two approved treatment options. Treatment with α-interferon (5–6 million U/m² of body surface area injected subcutaneously three times a week for 4–6 months) inhibits viral replication in 30%–40% of patients, normalizes the ALT level, and leads to the disappearance of HBeAg and the appearance of anti-HBe. Side effects are common. Younger children may respond better than older children. Orally administered nucleoside analog therapy (lamivudine 3 mg/kg/d up to 100 mg/d for children > 2 years old or adefovir 10 mg/d or tenofovir 300 mg/d for children > 12 years old and entecavir [0.5 mg once daily] or telbivudine [600 mg once daily] for children > 16 years old) leads to a successful response in 25% of treated children, with minimal side effects, but may require long-term treatment. However, resistant organisms can emerge, more frequently with lamivudine. Pegylated interferon, several oral antiviral agents (with much lower rates of resistance), and combination therapy are promising options being tested in children. Immunotolerant children and chronic carriers do not respond to therapy. Liver transplantation is successful in acute liver failure due to hepatitis B; however, reinfection is common following liver transplantation for chronic hepatitis B unless long-term HBIG or antivirals are used.

▶ Prognosis

The prognosis for acute HBV infection is good in older children, although acute liver failure (< 0.1%) or chronic hepatitis and cirrhosis (up to 10%) may supervene. The course of the acute disease is variable, but jaundice seldom persists for more than 2 weeks. HBsAg disappears in 95% of cases at the time of clinical recovery. Chronic infection is particularly common in children with vertical transmission, Down syndrome, or leukemia, and in those undergoing chronic hemodialysis. Persistence of neonatally acquired HBsAg occurs in 70%–90% of infants without immunoprophylaxis or vaccination. The presence of HBeAg in the HBsAg carrier indicates ongoing viral replication. However, 1%–2% of children infected at birth will show spontaneous seroconversion of HBeAg each year. If HBV infection is acquired later in childhood, HBV is cleared and recovery occurs in 90%–95% of patients. Chronic HBV disease predisposes the patient to development of hepatocellular carcinoma. Once chronic HBV infection is established, surveillance for development of hepatocellular carcinoma with serum α-fetoprotein is performed biannually and ultrasonography yearly. Routine HBV vaccination of newborns in endemic countries has reduced the incidence of acute liver failure, chronic hepatitis, and hepatocellular carcinoma in children.

HEPATITIS C

▶ General Considerations

Hepatitis C virus (HCV) is the most common cause of non-B chronic hepatitis (see Table 22–6). Risk factors in adults and adolescents include illicit use of intravenous drugs, occupational or sexual exposure and a history of transfusion of blood products prior to 1992. The risk from transfused blood products has diminished greatly (from 1–2:100 to < 1:100,000 units of blood) since the advent of blood testing for ALT and anti-HCV. In the past, children with hemophilia or on chronic hemodialysis were also at significant risk. Most cases in children are now associated with transmission from an infected mother (vertical transmission) or rarely from other household contacts. Vertical transmission from HCV-infected mothers occurs more commonly with mothers who are HIV-positive (15%–20%) compared with those who are HIV-negative (5%–6%). Approximately 0.2% of children, 0.4% of adolescents and 1.5% of adults in the United States have serologic evidence of infection. Transmission of the virus from breast milk is very rare. HCV rarely causes fulminant hepatitis in children or adults in Western countries, but different serotypes do so in Asia.

HCV is a single-stranded RNA flavivirus. At least seven genotypes of HCV exist. Several well-defined HCV antigens are the basis for serologic antibody tests. The third-generation enzyme-linked immunosorbent assay (ELISA) test for anti-HCV is highly accurate. Anti-HCV is generally present when symptoms occur; however, test results may be negative in the first few months of infection. The presence of HCV RNA in serum indicates active infection.

▶ Prevention

At present, the only effective means of prevention is avoidance of exposure through elimination of risk-taking behaviors such as illicit use of intravenous drugs. There is no effective prevention for vertical transmission, but avoidance of fetal scalp monitoring in infant of mothers with HCV has been suggested. Elective Caesarean section is not recommended for HCV-monoinfected women, as it confers no reduction in the rate of mother-to-infant HCV transmission. Breastfeeding does not promote HCV transmission from mother to infant. It is advised to avoid breastfeeding if the nipples are bleeding, if mastitis is present or if the mother is experiencing a flare of hepatitis with jaundice postpartum. There is no vaccine, and no benefit from using immune globulin in infants born to infected mothers.

▶ Clinical Findings

A. Symptoms and Signs

Most childhood cases, especially those acquired vertically, are asymptomatic despite development of chronic hepatitis. The incubation period is 1–5 months, with insidious onset of symptoms. Flu-like prodromal symptoms and jaundice occur in less than 25% of cases. Hepatosplenomegaly may or may not be evident in chronic hepatitis. Ascites, clubbing, palmar erythema, or spider angiomas are rare and indicate progression to cirrhosis.

B. Laboratory Findings

Since anti-HCV IgG crosses the placenta, testing anti-HCV IgG is not informative until the infant is 18 months old, at which time antibody testing should be performed. Patients > 18 months of age with positive anti-HCV IgG should have subsequent testing for serum HCV RNA in order to determine active infection. Serum HCV RNA can be tested prior to 18 months of age, but should not be tested before 2 months old. If serum HCV RNA is positive in infancy, it should be rechecked when the infant is 12 months of age in order to determine presence of chronic hepatitis. Fluctuating mild to moderate elevations of aminotransferases over long periods are characteristic of chronic HCV infection; however, normal aminotransferases are common in children.

Percutaneous liver biopsy should be considered in chronic cases. Histologic examination shows portal triaditis with chronic inflammatory cells, occasional lymphocyte nodules in portal tracts, mild macrovesicular steatosis, and variable bridging necrosis, fibrosis, and cirrhosis; most children have mild to moderate fibrosis on liver biopsy. Cirrhosis in adults generally requires 20–30 years of chronic HCV infection, but it has occasionally developed sooner in children.

▶ Differential Diagnosis

HCV disease should be distinguished from HAV and HBV disease by serologic testing. Other causes of cirrhosis in children should be considered in cases of chronic illness, such as Wilson disease, α_1-antitrypsin deficiency, autoimmune hepatitis, drug-induced hepatitis, or steatohepatitis.

▶ Treatment

In 2012, triple therapy was implemented for adults with chronic HCV. Triple therapy includes pegylated interferon-α, ribavirin and a protease inhibitor (boceprevir or telaprevir). Triple therapy has been associated with successful eradication of virus in up to 80% of treatment-naïve genotype 1 cases. Indications for treatment of chronic infection in children are unclear, but generally include chronic hepatitis and fibrosis. The current approved therapy for treatment of children consists of pegylated interferon-α 2a or 2b (104 mcg/m^2

BSA weekly for 2a and 60 mcg/m^2 BSA weekly for 2b) and ribavirin (15 mg/kg/d). The sustained virological response rates of this double therapy are approximately 40% in genotype 1 (most common in United States) and approximately 80% for genotypes 2 and 3. Clinical trials of triple therapy for children with genotype 1 HCV are under investigation. End-stage liver disease secondary to HCV responds well to liver transplantation, although re-infection of the transplanted liver is very common and occasionally rapidly progressive. Pre- and post-transplant antiviral therapy may reduce the risk of reinfection.

▶ Prognosis

Following an acute infection with HCV, 70%–80% of adults and older children develop a chronic infection. Twenty percent of adults with chronic HCV develop cirrhosis by 30 years. Infants infected by vertical transmission have a high rate of spontaneous resolution approaching 25%–40%. Most have spontaneous resolution by 24 months of age, but some may have spontaneous resolution as late as 7 years after vertical infection. The majority of children with chronic HCV have mild inflammation and fibrosis on liver biopsy, although cirrhosis may develop rapidly in rare cases or after decades. The longer-term outcome in children is less well defined. Limited 30-year follow-up of infants exposed to HCV by transfusion suggests a lower rate of progression to cirrhosis compared to adults. The prognosis for infants infected at birth with concomitant HIV infection is unknown, but the course appears benign for the first 10 years of life. In adults, chronic HCV infection has been associated with mixed cryoglobulinemia, polyarteritis nodosa, a sicca-like syndrome, and membranoproliferative glomerulonephritis, as well as hepatocellular carcinoma.

HEPATITIS D (DELTA AGENT)

The hepatitis D virus (HDV) is a 36-nm defective virus that requires the presence of HBsAg to be infectious (see Table 22–6). Thus, HDV infection can occur only in the presence of HBV infection. Transmission is by

parenteral exposure or intimate contact. HDV is rare in North America. HDV can infect simultaneously with HBV, causing acute hepatitis, or can superinfect a patient with chronic HBV infection, predisposing the individual to chronic hepatitis or fulminant hepatitis. In children, the association between chronic HDV coinfection with HBV and chronic hepatitis and cirrhosis is strong. Vertical HDV transmission is rare. HDV can be detected by anti-HDV IgG, which indicates active or previous infection; active infection is confirmed by detecting HDV RNA by PCR or by detecting HDV IgM antibody. Treatment is directed at therapy for HBV infection.

Hughes SA et al: Hepatitis delta virus. Lancet 2011;378:73 [PMID: 21511329].

HEPATITIS E

Hepatitis E virus (HEV) infection is a cause of enterically transmitted, epidemic hepatitis (see Table 22–6). It is rare in the United States. HEV is a hepevirus that is transmitted via the fecal-oral route. It occurs predominantly in developing countries in association with waterborne epidemics, and has only a 3% secondary attack rate in household contacts. Areas reporting epidemics include Southeast Asia, China, the Indian subcontinent, the Middle East, northern and western Africa, Mexico, and Central America, with sporadic cases in the United States and Europe. Recent reports suggest zoonotic transmission occurs in low endemic regions. Its clinical manifestations resemble HAV infection except that symptomatic disease is rare in children, more common in adolescents and adults, and is associated with a high mortality (10%–20%) in pregnant women, particularly in the third trimester. HEV infection in individuals with chronic liver disease can cause acute deterioration. Zoonotic transmission from pigs, boars, and deer can lead to chronic infection and cirrhosis in immunocompromised individuals. Outside of these settings chronic disease is not reported. Diagnosis is established by detecting anti-HEV IgM antibody or by HEV PCR. A recombinant vaccine is being tested. There is no effective treatment.

Kamar N et al: Hepatitis E. Lancet 2012;379:2477 [PMID: 22549046].

OTHER HEPATITIS VIRUSES

Other undiscovered viruses may cause cases of acute liver failure (ALF)/severe hepatitis in children, in some cases in association with aplastic anemia. Aplastic anemia occurs in a small proportion of patients recovering from hepatitis and in 10%–20% of those undergoing liver transplantation for ALF

of unknown etiology. Parvovirus has been associated with severe hepatitis; the prognosis is relatively good in children. Infectious mononucleosis (EBV) is commonly associated with acute hepatitis and rare cases of EBV-associated ALF have been reported. CMV, adenovirus, herpes simplex virus, HHV-6, HIV, brucella, Q-fever, and leptospirosis are other infectious causes of acute hepatitis.

ACUTE LIVER FAILURE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Acute hepatitis with deepening jaundice.
► Extreme elevation of AST and ALT.
► Prolonged PT and INR.
► Encephalopathy and cerebral edema.
► Asterixis and fetor hepaticus.

► General Considerations

Acute Liver Failure (ALF) is defined as acute liver dysfunction associated with significant hepatic synthetic dysfunction evidenced by a vitamin K–resistant coagulopathy (INR > 2.0) within 8 weeks after the onset of liver injury. This is often associated with encephalopathy, but in young children, encephalopathy may be difficult to detect or absent. Without liver transplantation, mortality is approximately 50% in children. In many cases, an identifiable cause is not found, but is postulated to be an unusually virulent infectious agent or aggressive host immune response. Common identifiable causes of ALF are shown in Table 22–8. Patients with immunologic deficiency diseases and those receiving immunosuppressive drugs are vulnerable to herpes viruses. In children with HIV infection, nucleoside reverse transcriptase inhibitors have triggered lactic acidosis and liver failure. In patients with underlying respiratory chain defects, valproic acid may trigger ALF.

Table 22–8. Common identifiable causes[a] of ALF by age.

Neonates	Infections: herpesviruses and enteroviruses. Metabolic: neonatal iron storage disease, galactosemia, fructosemia, tyrosinemia, FAO, mitochondrial disorders. Ischemia: congenital heart disease.
Infants 1–24 mo	Infections: HAV, HBV. Metabolic: FAO, mitochondrial disorders, tyrosinemia. Drug: acetaminophen, valproate. Immune: AIH, HLH.
Children	Infections: EBV, HAV. Metabolic: FAO, Wilson disease. Drug: acetaminophen, valproate, others. Immune: AIH.
Adolescents	Infections: EBV, HAV. Metabolic: FAO, Wilson disease, acute fatty liver of pregnancy. Drug: acetaminophen, valproate, herbs, "ecstasy," others. Immune: AIH.

AIH, autoimmune hepatitis; ALF, acute liver failure; EBV, Epstein-Barr virus; FAO, fatty acid oxidation defects; HAV, hepatitis A; HBV, hepatitis B; HLH, hemophagocytic lymphohistiocytosis.
[a]Unknown cause of ALF remains the most common etiology.

► Clinical Findings

A. History

In some patients, ALF presents with the rapid development of deepening jaundice, bleeding, confusion, and progressive coma, while others are asymptomatic at the onset and then suddenly become severely ill during the second week of the disease. Jaundice, fever, anorexia, vomiting, and abdominal pain are the most common symptoms. A careful history of drug and toxin exposure may identify a drug-induced cause.

B. Symptoms and Signs

Children may present with flu-like symptoms, including malaise, myalgias, jaundice, nausea, and vomiting. Tender hepatomegaly is common, which may be followed by progressive shrinking of the liver, often with worsening hepatic function. Signs of chronic liver disease (splenomegaly, spider hemangiomata) should suggest an underlying chronic liver disease. Hyper-reflexia and positive extensor plantar responses are seen before the onset of encephalopathy. Impairment of renal function, manifested by either oliguria or anuria, is an ominous sign.

C. Laboratory Findings

Characteristic findings include elevated serum bilirubin levels (usually > 15–20 mg/dL), sustained elevations of AST and ALT (> 3000 U/L), low serum albumin, hypoglycemia, and prolonged PT and INR. Blood ammonia levels become elevated, whereas blood urea nitrogen is often very low. Prolonged PT from disseminated intravascular coagulation (DIC) can be differentiated by determination of factor V (low in ALF and DIC) and VIII (normal to high in ALF and low in DIC). Rapid decreases in AST and ALT, together with shrinking hepatomegaly, due to massive necrosis and collapse, combined with worsening coagulopathy portend a poor prognosis. A high AST and ALT with normal bilirubin suggests acetaminophen toxicity or metabolic causes.

► Differential Diagnosis

Severe hepatitis, with or without coagulopathy, due to infections, metabolic disease, autoimmune hepatitis or drug toxicity can initially mimic ALF. Acute leukemia, cardiomyopathy, and Budd-Chiari syndrome can mimic severe hepatitis. Patients with Reye syndrome or urea cycle defects are typically anicteric.

► Complications

The development of renal failure and depth of hepatic coma are major prognostic factors. Patients in stage 4 coma (unresponsiveness to verbal stimuli, decorticate or decerebrate posturing) rarely survive without liver transplantation and may have residual central nervous system deficits even after transplant. Cerebral edema, which usually accompanies coma, is frequently the cause of death. Extreme prolongation of PT or INR greater than 3.5 predicts poor recovery except with acetaminophen overdose. Sepsis, hemorrhage, renal failure, and cardiorespiratory arrest are common terminal events.

► Treatment

Excellent critical care is paramount, including careful management of hypoglycemia, bleeding and coagulopathy, hyperammonemia, cerebral edema, and fluid balance, while systematically investigating for potentially treatable causes. Several therapies have failed to affect outcome, including exchange transfusion, plasmapheresis with plasma exchange, total body washout, charcoal hemoperfusion, and hemodialysis using a special high-permeability membrane. Spontaneous survival may occur in up to 50% of patients. Liver transplant may be lifesaving in patients without signs of spontaneous recovery, with 60%–80% 1- to 3-year survival. Therefore, early transfer of patients in ALF to centers where liver transplantation can be performed is recommended. Criteria for deciding when to perform transplantation are not firmly established; however, serum bilirubin over 20 mg/dL, INR greater than 4, and factor V levels less than 20% indicate a poor prognosis. Living related donors may be required for transplantation in a timely fashion. The prognosis is better for acetaminophen ingestion, particularly

when *N*-acetylcysteine treatment is given. Corticosteroids may be harmful, except in autoimmune hepatitis for which steroids may reverse ALF. Acyclovir is essential in herpes simplex or varicella-zoster virus infection. For hyperammonemia, oral antibiotics such as neomycin or rifaximin, and lactulose (1–2 mL/kg three or four times daily) are used to reduce blood ammonia levels and trap ammonia in the colon.

Close monitoring of fluid and electrolytes is mandatory and requires a central venous line. Adequate dextrose should be infused (6–8 mg/kg/min) to maintain normal blood glucose and cellular metabolism. Diuretics, sedatives, and tranquilizers should be used sparingly. Early signs of cerebral edema are treated with infusions of mannitol (0.5–1.0 g/kg). Comatose patients should be intubated, given mechanical ventilatory support, and monitored for signs of infection. Coagulopathy is treated with fresh-frozen plasma, recombinant factor VIIa, other clotting factor concentrates, platelet infusions, or exchange transfusion for bleeding or procedures. Hemodialysis may help stabilize a patient while awaiting liver transplantation. Monitoring for increased intracranial pressure (hepatic coma stages 3 and 4) in patients awaiting liver transplantation is advocated by some. Continuous venous-venous dialysis may be helpful to maintain fluid balance.

▶ Prognosis

The prognosis is primarily dependent on the etiology and depth of coma. Only 20%–30% of children with stage 3 or 4 hepatic encephalopathy will have a spontaneous recovery. Children with acute acetaminophen toxicity have a high rate of spontaneous survival, while 40% of children with indeterminate ALF (of unknown etiology) will have a spontaneous recovery. Data from a recent large study suggest that the spontaneous recovery rate is about 40%–50% when all causes of ALF are combined; 30% of patients will receive a liver transplant; and 20% will die without a transplant. Exchange transfusions or other modes of heroic therapy do not improve survival figures. Indeterminate ALF, non-acetaminophen drug-induced ALF, and ALF in infants are associated with a poorer prognosis. Acetaminophen and autoimmune hepatitis etiologies of ALF and rising levels of factors V and VII, coupled with rising levels of serum α-fetoprotein, may signify a more favorable prognosis. The 1-year survival rate in patients who undergo liver transplantation for ALF is 60%–85%.

AUTOIMMUNE HEPATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Acute or chronic hepatitis.

▶ Hypergammaglobulinemia.

▶ Positive antinuclear antibodies (ANA), anti–smooth muscle antibodies (ASMA), anti–liver-kidney microsomal (LKM) antibodies, or anti–soluble liver antigen antibodies (SLA).

▶ Clinical Findings

A. History

Autoimmune hepatitis (AIH) is a progressive inflammatory disorder of unknown etiology. It is characterized histologically by portal tract inflammation that extends into the parenchyma; serologically by the presence of non-organ specific autoantibodies; biochemically by elevated aminotransferases and serum IgG; and clinically by response to immunosuppressive treatment in the absence of other known causes of liver disease. Pediatric patients may complain of a gradual onset of jaundice that may be asymptomatic or associated with fever, malaise, and abdominal pain or distension. Other complaints at the time of presentation may include a recurrent rash, arthritis, chronic diarrhea or amenorrhea. A family history of autoimmune disease is often present and a high prevalence of seroimmunologic abnormalities has also been noted in relatives.

B. Symptoms and Signs

Asymptomatic hepatomegaly and/or splenomegaly may be found on examination, in association with elevated liver tests. In more advanced cases, jaundice and ascites may develop. Cutaneous signs of chronic liver disease may be noted (eg, spider angiomas, palmar erythema, and digital clubbing). Occasionally patients present with acute liver failure (ALF).

C. Laboratory Findings

LFTs reveal moderate elevations of serum AST, ALT, and alkaline phosphatase. Serum bilirubin may be mildly elevated and albumin may be low. Serum IgG levels are generally elevated in the range of 2–6 g/dL. Two subtypes of disease have been described based on the autoantibodies present: type 1—ANA &/or ASMA (anti-actin); type 2—anti-LKM (anti–cytochrome P-450). Type 1 AIH is the most common form of AIH in the United States. Type 2 AIH presents at a younger age and is more likely to present with ALF compared to type 1. A genetic susceptibility to AIH is suggested by the increased incidence of the histocompatibility alleles HLA DR∗0301 (type 1) or HLA DR∗0701 (type 2). Liver biopsy reveals the typical histological picture of interface hepatitis: a dense infiltration of the portal tracts consisting mainly of lymphocytes and plasma cells that extends into the liver lobules with destruction of the hepatocytes at the periphery of the lobule and erosion of the limiting plate. There may be bridging fibrosis or cirrhosis evident as well.

▶ Differential Diagnosis

Laboratory and histologic findings differentiate other types of chronic hepatitis (eg, HBV, HCV; steatohepatitis; Wilson disease; α_1-antitrypsin deficiency; primary sclerosing cholangitis [PSC]). PSC occasionally presents in a manner similar to AIH, including the presence of autoantibodies. Ten to fifteen percent of pediatric patients have an "overlap syndrome" of AIH and PSC. Anti-HCV antibodies can be falsely positive and should be confirmed by HCV PCR. Drug-induced (minocycline, isoniazid, methyldopa, pemoline) chronic hepatitis should be ruled out. In addition, minocycline has been reported as a potential "trigger" of type 1 AIH.

▶ Complications

Untreated disease that continues for months to years eventually results in cirrhosis, with complications of portal hypertension and liver synthetic dysfunction. Persistent malaise, fatigue, amenorrhea, and anorexia parallel disease activity. Bleeding from esophageal varices and development of ascites usually signal impending hepatic failure.

▶ Treatment

Corticosteroids (prednisone, 2 mg/kg/d maximum 60 mg) decrease the mortality rate during the early active phase of the disease. Recent data in adults suggests budesonide may be as efficacious as prednisone with less steroid side effects. Azathioprine or 6-mercaptopurine (6-MP), 1–2 mg/kg/d, is of value in decreasing the side effects of long-term corticosteroid therapy, but should not be used alone during the induction phase of treatment. Steroids are reduced over a 3- to 12-month period, and azathioprine is continued for at least 1–2 years if AST and ALT remain consistently normal.

Whether a patient should be weaned completely off steroids is controversial. Liver biopsy is performed before stopping azathioprine or 6-MP therapy; if inflammation persists, then azathioprine or 6-MP is continued. Thiopurine methyltransferase activity in red blood cells should be assessed prior to starting azathioprine or 6-MP, to prevent extremely high blood levels and severe bone marrow toxicity. Relapses are treated with a course of steroids. Many patients require chronic azathioprine or 6-MP therapy. Cyclosporine, tacrolimus, or methotrexate may be helpful in poorly responsive cases. Mycophenolate mofetil can be substituted for azathioprine or 6-MP. Liver transplantation is indicated when disease progresses to decompensated cirrhosis despite therapy or in cases presenting in ALF that do not respond to steroid therapy.

▶ Prognosis

The overall prognosis for AIH is improved significantly with early therapy. Some studies report cures (normal histologic findings) in 15%–20% of patients. Relapses (seen clinically and histologically) occur in 40%–50% of patients after cessation of therapy; remissions follow repeat treatment. Survival for 10 years is common despite residual cirrhosis. Of children with AIH, 20%–50% eventually require liver transplantation. Complications of portal hypertension (bleeding varices, ascites, spontaneous bacterial peritonitis, and hepatopulmonary syndrome) require specific therapy. Liver transplantation is successful 70%–90% of the time. Disease recurs after transplantation 10%–50% of the time and is treated similarly to pretransplant disease.

Chai PF et al: Childhood autoimmune liver disease: indications and outcome of liver transplantation. J Pediatr Gastroenterol Nutr 2010;50:295 [PMID: 20118802].

Mieli-Vergani G, Vergani D: Autoimmune hepatitis. Nat Rev 2011;8:320 [PMID: 21537351].

NONALCOHOLIC FATTY LIVER DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Hepatomegaly in patient with BMI > 95th percentile.
- ▶ Elevated ALT > AST.
- ▶ Detection of fatty infiltration of the liver on ultrasound.
- ▶ Histologic evidence of fat in the liver.
- ▶ Insulin resistance.

Nonalcoholic fatty liver disease (NAFLD), a clinicopathologic condition of abnormal heptic fat deposition in the

absence of alcohol, is the most common cause of abnormal liver function tests in the United States. NAFLD ranges from bland steatosis, to fat and inflammation, with or without scarring (also referred to as nonalcoholic steatohepatitis, NASH) to cirrhosis. Trends in NAFLD parallel trends in obesity, with up to 10% of all children, and 38% of obese children affected in the United States. Many children with NAFLD are also affected by type 2 diabetes mellitus, hypertension, hyperlipidemia and the metabolic syndrome. Most children are 11-13 years of age at diagnosis, with males (ratio of 2:1) and Hispanics at highest risk.

▶ Prevention

The most effective therapy is prevention of the overweight or obese state.

▶ Clinical Findings

A. History

Most patients with NAFLD are asymptomatic and discovered upon routine screening. Some may complain of fatigue or right upper quadrant pain. Obesity and insulin resistance are known risk factors.

B. Symptoms and Signs

Patients with NAFLD may present with asymptomatic soft hepatomegaly, though abdominal adiposity may make this difficult to assess. Physical findings of insulin resistance (acanthosis nigricans and a buffalo hump) are frequently present.

C. Laboratory Findings

Serum aminotransferases will not identify bland steatosis, so NAFLD patient may have completely normal AST and ALT. If elevated, the AST and ALT are typically elevated less than 1.5 times the upper limit of normal, with an ALT:AST ratio of > 1. Alkaline phosphatase and GGT may be mildly elevated, but bilirubin is normal. Hyperglycemia and hyperlipidemia are also common. If performed, the liver biopsy may show micro- or macrovesicular steatosis, hepatocyte ballooning, Mallory bodies, and lobular or portal inflammation. In addition, varying degrees of fibrosis from portal focused to cirrhosis may be present. There are no established reliable biochemical predictors of the degree of hepatic fibrosis, but new biomarkers, like patatin-like phospholipase domain-containing 3 polymorphisms and cytokeratin-18, show promise in research laboratories.

D. Imaging

Ultrasonography or CT scan can be used to confirm fatty infiltration of the liver. Ultrasound is the preferred methodology due to lower cost and lack of radiation exposure, though it may be insensitive in severe central adiposity or if less than 30% steatosis is present. Currently, radiologic imaging cannot distinguish bland steatosis from the more severe NASH, nor reliably identify fibrosis. Transient elastography is a research tool that shows promise in estimating hepatic fibrosis.

▶ Differential Diagnosis

Steatohepatitis is also associated with Wilson disease, hereditary fructose intolerance, tyrosinemia, HCV hepatitis, cystic fibrosis, fatty acid oxidation defects, kwashiorkor, Reye syndrome, respiratory chain defects, total parenteral nutrition associated liver disease and toxic hepatopathy (ethanol and others).

▶ Complications

Untreated, NAFLD with hepatic inflammation can progress to cirrhosis with complications that include portal hypertension. Dyslipidemia, hypertension, and insulin resistance are more common in children and adolescents with NAFLD.

▶ Treatment

Multiple potential therapies, including metformin, UDCA, and lipid lowering agents have been tested without therapeutic success. Therefore, treatment is focused on lifestyle modifications, through both dietary changes and exercise, to induce slow weight loss. A 10% decrease in body weight can significantly improve NAFLD. Vitamin E, an antioxidant, has shown promise in clinical trials in improving histologically confirmed NASH.

▶ Prognosis

Although untreated, NAFLD can progress to cirrhosis and liver failure; there is a very high response rate to weight reduction. However, success in achieving long-term weight reduction is low in children and adults.

α₁-ANTITRYPSIN DEFICIENCY LIVER DISEASE

> ## ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

> ▶ Serum α_1-antitrypsin level < 50–80 mg/dL.
> ▶ Identification of a specific protease inhibitor (PI) phenotype (PIZZ, PISZ) or genotype.
> ▶ Detection of diastase-resistant glycoprotein deposits in periportal hepatocytes.
> ▶ Histologic evidence of liver disease.
> ▶ Family history of early-onset pulmonary disease or liver disease.

▶ General Considerations

The disease is caused by a deficiency in α_1-antitrypsin, a protease inhibitor (Pi) system, predisposing patients to chronic liver disease, and an early onset of pulmonary emphysema. It is most often associated with the Pi phenotypes ZZ and SZ. The accumulation of misfolded aggregates of α_1-antitrypsin protein in the liver causes the liver injury by unclear mechanisms.

▶ Clinical Findings

A. Symptoms and Signs

α_1-Antitrypsin deficiency should be considered in all infants with neonatal cholestasis. About 10%–20% of affected individuals present with neonatal cholestasis. Serum GGT is usually elevated. Jaundice, acholic stools, and malabsorption may also be present. Infants are often small for gestational age, and hepatosplenomegaly may be present. The family history may be positive for emphysema or cirrhosis.

The disease can also present in older children, where hepatomegaly or physical findings suggestive of cirrhosis and portal hypertension should lead to consideration of α_1-antitrypsin deficiency. Recurrent pulmonary disease (bronchitis, pneumonia) may be present in some older children. Very few children have significant pulmonary involvement. Most affected children are completely asymptomatic, with no laboratory or clinical evidence of liver or lung disease.

B. Laboratory Findings

Levels of the α_1-globulin fraction may be less than 0.2 g/dL. α_1-Antitrypsin level is low (< 50–80 mg/dL) in homozygotes (ZZ). Specific Pi phenotyping should be done to confirm the diagnosis. Genotyping is also available. LFTs often reflect underlying hepatic pathologic changes. Hyperbilirubinemia (mixed) and elevated aminotransferases, alkaline phosphatase, and GGT are present early. Hyperbilirubinemia generally resolves, while aminotransferase and GGT elevation may persist. Signs of cirrhosis and hypersplenism may develop even when LFTs are normal.

Liver biopsy findings after age 6 months show diastase-resistant, periodic acid–Schiff staining intracellular globules, particularly in periportal zones. These may be absent prior to age 6 months, but when present are characteristic of α_1-antitrypsin deficiency.

▶ Differential Diagnosis

In newborns, other specific causes of neonatal cholestasis need to be considered, including biliary atresia. In older children, other causes of insidious cirrhosis (eg, HBV or HCV infection, AIH, Wilson disease, cystic fibrosis, and glycogen storage disease) should be considered.

▶ Complications

Of all infants with PiZZ α_1-antitrypsin deficiency, only 15%–20% develop liver disease in childhood, and many have clinical recovery. Thus, other genetic or environmental modifiers must be involved. An associated abnormality in the microsomal disposal of accumulated aggregates may contribute to the liver disease phenotype. The complications of portal hypertension, cirrhosis, and chronic cholestasis predominate in affected children. Occasionally, children develop paucity of interlobular bile ducts.

Early-onset pulmonary emphysema occurs in young adults (age 30–40 years), particularly in smokers. An increased susceptibility to hepatocellular carcinoma has been noted in cirrhosis associated with α_1-antitrypsin deficiency.

▶ Treatment

There is no specific treatment for the liver disease of this disorder. Replacement of the protein by transfusion therapy is used to prevent or treat pulmonary disease in affected adults. The neonatal cholestatic condition is treated with choleretics, medium-chain triglyceride–containing formula, and water-soluble preparations of fat-soluble vitamins (see Table 22–4). UCDA may reduce AST, ALT, and GGT, but its effect on outcome is unknown. Portal hypertension, esophageal bleeding, ascites, and other complications are treated as described elsewhere. Hepatitis A and B vaccines should be given to children with α_1-antitrypsin deficiency. Genetic counseling is indicated when the diagnosis is made. Diagnosis by prenatal screening is possible. Liver transplantation, performed for development of end-stage liver disease, cures the deficiency and prevents the development of pulmonary disease. Passive and active cigarette smoke exposure should be eliminated to help prevent pulmonary manifestations, and obesity should be avoided.

▶ Prognosis

Of those patients presenting with neonatal cholestasis, approximately 10%–25% will need liver transplantation in the first 5 years of life, 15%–25% during childhood or adolescence, and 50%–75% will survive into adulthood with variable degrees of liver fibrosis. A correlation between histologic patterns and clinical course has been documented in the infantile form of the disease. Liver failure can be expected 5–15 years after development of cirrhosis. Recurrence or persistence of hyperbilirubinemia along with worsening coagulation studies indicates the need for evaluation for liver transplantation. Decompensated cirrhosis caused by this disease is an indication for liver transplantation. Pulmonary involvement is prevented by liver transplantation. Heterozygotes may have a slightly higher incidence of liver disease. The exact relationship between low levels of serum α_1-antitrypsin and the development of liver disease is unclear. Emphysema develops because of a lack of inhibition of neutrophil elastase, which destroys pulmonary connective tissue.

WILSON DISEASE (HEPATOLENTICULAR DEGENERATION)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Acute or chronic liver disease.
- ▶ Deteriorating neurologic status.
- ▶ Kayser-Fleischer rings.
- ▶ Elevated liver copper.
- ▶ Abnormalities in levels of ceruloplasmin and serum and urine copper.

▶ General Considerations

Wilson disease is caused by mutations in the gene *ATP7B* on chromosome 13 coding for a specific P-type adenosine triphosphatase involved in copper transport. This results in impaired bile excretion of copper and incorporation of copper into ceruloplasmin by the liver. The accumulated hepatic copper causes oxidant (free-radical) damage to the liver. Subsequently, copper accumulates in the basal ganglia and other tissues. The disease should be considered in all children older than age 2 years with evidence of liver disease (especially with hemolysis) or with suggestive neurologic signs. A family history is often present, and 25% of patients are identified by screening asymptomatic homozygous family members. The disease is autosomal recessive and occurs in 1:30,000 live births in all populations.

▶ Clinical Findings

A. Symptoms and Signs

Hepatic involvement may present as acute liver failure, acute hepatitis, chronic liver disease, cholelithiasis, fatty liver disease, or as cirrhosis with portal hypertension. Findings may include jaundice, hepatomegaly early in childhood, splenomegaly, and Kayser-Fleischer rings. The disease is considered after 3–4 years of age. The later onset of neurologic or psychiatric manifestations after age 10 years may include tremor, dysarthria, and drooling. Deterioration in school performance can be the earliest neurologic expression of disease. The Kayser-Fleischer ring is a brown band at the junction of the iris and cornea, generally requiring slit-lamp examination for detection. Absence of Kayser-Fleischer rings does not exclude this diagnosis.

B. Laboratory Findings

The laboratory diagnosis can be challenging. Plasma ceruloplasmin levels (measured by the oxidase method) are usually less than 20 mg/dL. (Normal values are 23–43 mg/dL.) Low values, however, occur normally in infants younger than 3 months, and in at least 10%–20% of homozygotes the levels may be within the lower end of the normal range (20–30 mg/dL), particularly if immunoassays are used to measure ceruloplasmin. Rare patients with higher ceruloplasmin levels have been reported. Serum copper levels are low, but the overlap with normal is too great for satisfactory discrimination. In acute fulminant Wilson disease, serum copper levels are elevated markedly, owing to hepatic necrosis and release of copper. The presence of anemia, hemolysis, very high serum bilirubin levels (> 20–30 mg/dL), low alkaline phosphatase, and low uric acid are characteristic of acute Wilson disease. Urine copper excretion in children older than 3 years is normally less than 30 mcg/d; in Wilson disease, it is generally greater than 100 mcg/d although it can be as low as > 40 mcg/d. Finally, the tissue content of copper from a liver biopsy, normally less than 40–50 mcg/g dry tissue, is greater than 250 mcg/g in most Wilson disease patients, but may be as low as > 75 mcg/d when characteristic liver histology is present.

Glycosuria and aminoaciduria have been reported. Hemolysis and gallstones may be present; bone lesions simulating those of osteochondritis dissecans have also been found.

The coarse nodular cirrhosis, macrovesicular steatosis, and glycogenated nuclei in hepatocytes seen on liver biopsy may distinguish Wilson disease from other types of cirrhosis. Early in the disease, vacuolation of liver cells, steatosis, and lipofuscin granules can be seen, as well as Mallory bodies. The presence of Mallory bodies in a child is strongly suggestive of Wilson disease. Stains for copper may sometimes be negative despite high copper content in the liver. Therefore, quantitative liver copper levels must be determined biochemically on biopsy specimens. Electron microscopy findings of abnormal mitochondria may be helpful.

▶ Differential Diagnosis

During the icteric phase, acute or chronic viral hepatitis, α_1-antitrypsin deficiency, AIH, and drug-induced hepatitis are the usual diagnostic possibilities. NASH may have similar histology and be confused with Wilson disease in overweight patients. Later, other causes of cirrhosis and portal hypertension require consideration. Laboratory testing for plasma ceruloplasmin, 24-hour urine copper excretion, liver quantitative copper concentration, and a slit-lamp examination of the cornea will differentiate Wilson disease from the others. Urinary copper excretion during penicillamine challenge (500 mg twice a day in the older child or adult) may also be helpful. Genetic testing of *ATP7B* is available and may be helpful if two disease causing mutations are present. Other copper storage diseases that occur in early childhood include Indian childhood cirrhosis, Tyrolean childhood cirrhosis, and idiopathic copper toxicosis. However, ceruloplasmin concentrations are normal to elevated in these conditions.

▶ Complications

Cirrhosis, hepatic coma, progressive neurologic degeneration, and death are the rule in the untreated patient. The complications of portal hypertension (variceal hemorrhage, ascites) may be present at diagnosis. Progressive central nervous system disease and terminal aspiration pneumonia were common in untreated older people. Acute hemolytic disease may result in acute renal failure and profound jaundice as part of the presentation of fulminant hepatitis.

▶ Treatment

Copper chelation with D-penicillamine or trientine hydrochloride, 750–1500 mg/d orally, is the treatment of choice, whether or not the patient is symptomatic. The target dose for children is 20 mg/kg/d; begin with 250 mg/d and increase the dose weekly by 250 mg increments. Strict dietary restriction of copper intake is not practical. Supplementation with zinc acetate (25–50 mg orally, three times daily) may reduce copper absorption but must not be given at same time as copper chelators. Copper chelation or zinc therapy is continued for life, although doses of chelators may be reduced transiently at the time of surgery or early in pregnancy. Vitamin B_6 (25 mg) is given daily during therapy with penicillamine to prevent optic neuritis. In some countries, after a clinical response to penicillamine or trientine, zinc therapy is substituted and continued for life. Tetrathiomolybdate is being tested as an alternative therapy. Noncompliance with any of the drug regimens (including zinc therapy) can lead to sudden fulminant liver failure and death.

Liver transplantation is indicated for all cases of acute fulminant disease with hemolysis and renal failure, for progressive hepatic decompensation despite several months of therapy, and severe progressive hepatic insufficiency in patients who inadvisedly discontinue penicillamine, triene, or zinc therapy.

▶ Prognosis

The prognosis of untreated Wilson disease is poor. The fulminant presentation is fatal without liver transplantation. Copper chelation reduces hepatic copper content, reverses many of the liver lesions, and can stabilize the clinical course of established cirrhosis. Neurologic symptoms generally respond to therapy. All siblings should be immediately screened and homozygotes given treatment with copper chelation or zinc acetate therapy, even if asymptomatic. Recent data suggest that zinc monotherapy may not be as effective for hepatic Wilson disease as copper chelation. Genetic testing (haplotype analysis or *ATP7B* genotyping) is available clinically if there is any doubt about the diagnosis and for family members.

DRUG-INDUCED LIVER DISEASE

▶ General Considerations

Drug-induced liver injury (DILI) may be predictable or and unpredictable. Predictable hepatotoxins cause liver injury in

a dose dependent manner. Unpredictable hepatotoxins cause liver injury in an idiosyncratic manner, which may be influenced by the genetic and environmental characteristics of particular individuals. DILI has been described in a wide variety of medications including antihypertensives, acetaminophen, anabolic steroids, antibiotics, anticonvulsants, antidepressants, antituberculosis medications, antipsychotics, antivirals, herbals, dietary supplements, and weight loss agents.

▶ Symptoms

Many people with DILI are asymptomatic and detected because aminotransferases are performed for other reasons. If symptomatic, indicating more severe DILI, patients may have malaise, anorexia, nausea and vomiting, right upper quadrant pain, jaundice, acholic stools, and dark urine. Some may have severe pruritus. If the DILI is a hypersensitivity reaction, fever and rash may also occur.

▶ Diagnosis

No specific testing for DILI is available, with diagnosis requiring a causality assessment. This assessment should determine if the patient was exposed to the drug during a logical time period; if the drug has previously been reported to cause DILI; and if the symptom complex is consistent with DILI. In addition, other explanations for liver injury should be sought, including viral hepatitis, autoimmune hepatitis, and alcohol abuse.

▶ Treatment

Primary therapy is discontinuation of the offending drug, and avoiding re-exposure. This typically results in rapid and complete resolution of symptoms. However, DILI severe enough to cause acute liver failure has a poor prognosis without urgent liver transplant. Specific therapies for some DILI exist, such as N-acetylcysteine for acetaminophen poisoning. The use of ursodeoxycholic acid may speed resolution of jaundice. The use of corticosteroids for DILI remains controversial.

Liver Tox: Clinical and research information on drug-induced liver injury, http://www.livertox.nih.gov/.

CIRRHOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Underlying liver disease.
- ▶ Nodular hard liver and splenomegaly.
- ▶ Nodular liver on abdominal imaging.
- ▶ Liver biopsy demonstrating cirrhosis.

▶ General Considerations

Cirrhosis is a histologically defined condition of the liver characterized by diffuse hepatocyte injury and regeneration, an increase in connective tissue (bridging fibrosis), and disorganization of the lobular and vascular architecture (regenerative nodules). It may be micronodular or macronodular in appearance. It is the vasculature distortion that leads to increased resistance to blood flow, producing portal hypertension and its consequences.

Many liver diseases may progress to cirrhosis. In children, the two most common forms of cirrhosis are postnecrotic and biliary, each of which has different causes, symptoms, and treatments. Both forms can eventually lead to liver failure and death.

▶ Clinical Findings

A. History

Many children with cirrhosis may be asymptomatic early in the course. Malaise, loss of appetite, failure to thrive, and nausea are frequent complaints, especially in anicteric varieties. Easy bruising may be reported. Jaundice may or may not be present.

B. Symptoms and Signs

The first indication of underlying liver disease may be splenomegaly, ascites, gastrointestinal hemorrhage, or hepatic encephalopathy. Variable hepatomegaly, spider angiomas, warm skin, palmar erythema, or digital clubbing may be present. A small, shrunken liver may present. Most often, the liver is enlarged slightly, especially in the subxiphoid region, where it has a firm to hard quality and an irregular edge. Splenomegaly generally precedes other complications of portal hypertension. Ascites may be detected as shifting dullness or a fluid wave. Gynecomastia may be noted in males. Digital clubbing occurs in 10%–15% of cases. Pretibial edema often occurs, reflecting underlying hypoproteinemia. In adolescent girls, irregularities of menstruation or/and amenorrhea may be early complaints.

In biliary cirrhosis, patients often have jaundice, dark urine, pruritus, hepatomegaly, and sometimes xanthomas, in addition to the previously mentioned clinical findings. Malnutrition and failure to thrive due to steatorrhea may be more apparent in this form of cirrhosis.

C. Laboratory Findings

Mild abnormalities of AST and ALT are often present, with a decreased level of albumin and a variable increase in the level of γ-globulins. PT is prolonged and may be unresponsive to vitamin K administration. Burr and target red cells may be noted on the peripheral blood smear. Anemia, thrombocytopenia, and leukopenia are present if hypersplenism exists.

However, blood tests may be normal in patients with cirrhosis.

In biliary cirrhosis, elevated conjugated bilirubin, bile acids, GGT, alkaline phosphatase, and cholesterol are common.

D. Imaging

Hepatic ultrasound, CT, or MRI examination may demonstrate abnormal hepatic texture and nodules. In biliary cirrhosis, abnormalities of the biliary tree may be apparent.

E. Pathologic Findings

Liver biopsy findings of regenerating nodules and surrounding fibrosis are hallmarks of cirrhosis. Pathologic features of biliary cirrhosis also include canalicular and hepatocyte cholestasis, as well as plugging of bile ducts. The interlobular bile ducts may be increased or decreased, depending on the cause and the stage of the disease process.

▶ Differential Diagnosis

In the pediatric population, postnecrotic cirrhosis is often a result of acute or chronic liver disease (eg, viral hepatitis [HBV, HCV], autoimmune or drug-induced hepatitis, idiopathic neonatal giant-cell hepatitis); more recently, NAFLD; or certain inborn errors of metabolism (see Table 22–5). The evolution to cirrhosis may be insidious, with no recognized icteric phase, as in some cases of HBV or HCV infection, autoimmune hepatitis, Wilson disease, or α_1-antitrypsin deficiency. At the time of diagnosis of cirrhosis, the underlying liver disease may be active, with abnormal LFTs; or it may be quiescent, with normal LFTs. Most cases of biliary cirrhosis result from congenital abnormalities of the bile ducts (biliary atresia, choledochal cyst), tumors of the bile duct, Caroli disease, PFIC, PSC, paucity of the intrahepatic bile ducts, and cystic fibrosis. Occasionally, cirrhosis may follow a hypersensitivity reaction to certain drugs such as phenytoin. Parasites (*Opisthorchis sinensis, Fasciola*, and *Ascaris*) may be causative in children living in endemic areas.

▶ Complications

Major complications of cirrhosis in childhood include progressive nutritional disturbances, hormonal disturbances, and the evolution of portal hypertension and its complications. Hepatocellular carcinoma occurs with increased frequency in the cirrhotic liver, especially in patients with the chronic form of hereditary tyrosinemia or after longstanding HBV or HCV disease.

▶ Treatment

At present, there is no proven medical treatment for cirrhosis, but whenever a treatable condition is identified (eg, Wilson disease, galactosemia, AIH) or an offending agent eliminated (HBV, HCV, drugs, toxins), disease progression can be altered; occasionally regression of fibrosis has been noted. Recent evidence suggests that cirrhosis from HCV may be reversed by successful antiviral therapy. Children with cirrhosis should receive the hepatitis A and B vaccines, and they should be monitored for the development of hepatocellular carcinoma with serial serum α-fetoprotein determinations annually and abdominal ultrasound for hepatic nodules at least annually. Liver transplantation may be appropriate in patients with: cirrhosis caused by a progressive disease; evidence of worsening hepatic synthetic function; or complications of cirrhosis that are no longer manageable.

▶ Prognosis

Postnecrotic cirrhosis has an unpredictable course. Without transplantation, affected patients may die from liver failure within 10–15 years. Patients with a rising bilirubin, a vitamin K–resistant coagulopathy, or diuretic refractory ascites usually survive less than 1–2 years. The terminal event in some patients may be generalized hemorrhage, sepsis, or cardiorespiratory arrest. For patients with biliary cirrhosis, the prognosis is similar, except for those with surgically corrected lesions that result in regression or stabilization of the underlying liver condition. With liver transplantation, the long-term survival rate is 70%–90%.

PORTAL HYPERTENSION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Splenomegaly.
- ▶ Recurrent ascites.
- ▶ Variceal hemorrhage.
- ▶ Hypersplenism.

▶ General Considerations

Portal hypertension is defined as an increase in the portal venous pressure to more than 5 mm Hg greater than the inferior vena caval pressure. Portal hypertension is most

commonly a result of cirrhosis. Portal hypertension without cirrhosis may be divided into prehepatic, suprahepatic, and intrahepatic causes. Although the specific lesions vary somewhat in their clinical signs and symptoms, the consequences of portal hypertension are common to all.

A. Prehepatic Portal Hypertension

Prehepatic portal hypertension from acquired abnormalities of the portal and splenic veins accounts for 30%–50% of cases of variceal hemorrhage in children. A history of neonatal omphalitis, sepsis, dehydration, or umbilical vein catheterization may be present. Causes in older children include local trauma, peritonitis (pyelophlebitis), hypercoagulable states, and pancreatitis. Symptoms may occur before age 1 year, but in most cases the diagnosis is not made until age 3–5 years. Patients with a positive neonatal history tend to be symptomatic earlier.

A variety of portal or splenic vein malformations, some of which may be congenital, have been described, including defects in valves and atretic segments. Cavernous transformation is probably the result of attempted collateralization around the thrombosed portal vein rather than a congenital malformation. The site of the venous obstruction may be anywhere from the hilum of the liver to the hilum of the spleen.

B. Suprahepatic Vein Occlusion or Thrombosis (Budd-Chiari Syndrome)

No cause can be demonstrated in most instances in children, while tumor, medications, and hypercoagulable states are common causes in adults. The occasional association of hepatic vein thrombosis in inflammatory bowel disease favors the presence of endogenous toxins traversing the liver. Vasculitis leading to endophlebitis of the hepatic veins has been described. In addition, hepatic vein obstruction may be secondary to tumor, abdominal trauma, hyperthermia, or sepsis, or it may occur following the repair of an omphalocele or gastroschisis. Congenital vena caval bands, webs, a membrane, or stricture above the hepatic veins are sometimes causative. Hepatic vein thrombosis may be a complication of oral contraceptive medications. Underlying thrombotic conditions (deficiency of antithrombin III, protein C or S, or factor V Leiden; antiphospholipid antibodies; or mutations of the prothrombin gene) are common in adults.

C. Intrahepatic Portal Hypertension

1. Cirrhosis—See previous section.

2. Veno-occlusive disease (acute stage)—This entity occurs most frequently in bone marrow or stem cell transplant recipients. Additional causes include the high-dose thiopurines, ingestion of pyrrolizidine alkaloids ("bush tea") or other herbal teas, and a familial form of the disease occurring in congenital immunodeficiency states. The acute form of the disease generally occurs in the first month after

bone marrow transplantation and is heralded by the triad of weight gain (ascites), tender hepatomegaly, and jaundice.

3. Congenital hepatic fibrosis—This is a rare autosomal recessive cause of intrahepatic presinusoidal portal hypertension (see Table 22–10). Liver biopsy is generally diagnostic, demonstrating Von Meyenburg complexes (abnormal clusters of ectatic bile ducts). On angiography, the intrahepatic branches of the portal vein may be duplicated. Autosomal recessive polycystic kidney disease is frequently associated with this disorder.

4. Other rare causes—Hepatoportal sclerosis (idiopathic portal hypertension, noncirrhotic portal fibrosis), focal nodular regeneration of the liver, and schistosomal hepatic fibrosis are also rare causes of intrahepatic presinusoidal portal hypertension.

▶ Clinical Findings

A. Symptoms and Signs

For prehepatic portal hypertension, splenomegaly in an otherwise well child is the most constant physical sign. Recurrent episodes of abdominal distention resulting from ascites may be noted. The usual presenting symptoms are hematemesis and melena.

The presence of prehepatic portal hypertension is suggested by the following: (1) an episode of severe infection in the newborn period or early infancy—especially omphalitis, sepsis, gastroenteritis, severe dehydration, or prolonged or difficult umbilical vein catheterizations; (2) no previous evidence of liver disease; (3) a history of well-being prior to onset or recognition of symptoms; and (4) normal liver size and tests with splenomegaly.

Most patients with suprahepatic portal hypertension present with abdominal pain, tender hepatomegaly of acute onset, and abdominal enlargement caused by ascites. Jaundice is present in only 25% of patients. Vomiting, hematemesis, and diarrhea are less common. Cutaneous signs of chronic liver disease are often absent, as the obstruction is usually acute. Distended superficial veins on the back and the anterior abdomen, along with dependent edema, are seen when inferior vena cava obstruction affects hepatic vein outflow. Absence of hepatojugular reflux (jugular distention when pressure is applied to the liver) is a helpful clinical sign.

The symptoms and signs of intrahepatic portal hypertension are generally those of cirrhosis (see earlier section on Cirrhosis).

B. Laboratory Findings and Imaging

Most other common causes of splenomegaly or hepatosplenomegaly may be excluded by appropriate laboratory tests. Cultures, EBV and hepatitis serologies, blood smear examination, bone marrow studies, and LFTs may be necessary. In prehepatic portal hypertension, LFTs are generally normal.

In Budd-Chiari syndrome and veno-occlusive disease, mild to moderate hyperbilirubinemia with modest elevations of aminotransferases and PT are often present. Significant early increases in fibrinolytic parameters (especially plasminogen activator inhibitor 1) have been reported in veno-occlusive disease. Hypersplenism with mild leucopenia and thrombocytopenia is often present. Upper endoscopy may reveal varices in symptomatic patients.

Doppler-assisted ultrasound scanning of the liver, portal vein, splenic vein, inferior vena cava, and hepatic veins may assist in defining the vascular anatomy. In prehepatic portal hypertension, abnormalities of the portal or splenic vein may be apparent, whereas the hepatic veins are normal. When noncirrhotic portal hypertension is suspected, angiography often is diagnostic. Selective arteriography of the superior mesenteric artery or MRI is recommended prior to surgical shunting to determine the patency of the superior mesenteric vein.

For suprahepatic portal hypertension, an inferior vena cavogram using catheters from above or below the suspected obstruction may reveal an intrinsic filling defect, an infiltrating tumor, or extrinsic compression of the inferior vena cava by an adjacent lesion. A large caudate lobe of the liver suggests Budd-Chiari syndrome. Care must be taken in interpreting extrinsic pressure defects of the subdiaphragmatic inferior vena cava if ascites is significant.

Simultaneous wedged hepatic vein pressure and hepatic venography are useful to demonstrate obstruction to major hepatic vein ostia and smaller vessels. In the absence of obstruction, reflux across the sinusoids into the portal vein branches can be accomplished. Pressures should also be taken from the right heart and supradiaphragmatic portion of the inferior vena cava to eliminate constrictive pericarditis and pulmonary hypertension from the differential diagnosis.

▶ Differential Diagnosis

All causes of splenomegaly must be included in the differential diagnosis. The most common ones are infections, immune thrombocytopenic purpura, blood dyscrasias, lipidosis, reticuloendotheliosis, cirrhosis of the liver, and cysts or hemangiomas of the spleen. When hematemesis or melena occurs, other causes of gastrointestinal bleeding are possible, such as gastric or duodenal ulcers, tumors, duplications, and inflammatory bowel disease.

Because ascites is almost always present in suprahepatic portal hypertension, cirrhosis resulting from any cause must be excluded. Other suprahepatic (cardiac, pulmonary) causes of portal hypertension must also be ruled out. Although ascites may occur in prehepatic portal hypertension, it is uncommon.

▶ Complications

The major manifestation and complication of portal hypertension is bleeding from esophageal varices. Fatal exsanguination is uncommon, but hypovolemic shock or resulting anemia may require prompt treatment. Hypersplenism with leukopenia and thrombocytopenia occurs, but seldom causes major symptoms.

Without treatment, complete and persistent hepatic vein obstruction in suprahepatic portal hypertension leads to liver failure, coma, and death. A nonportal type of cirrhosis may develop in the chronic form of hepatic veno-occlusive disease in which small- and medium-sized hepatic veins are affected. Death from renal failure may occur in rare cases of congenital hepatic fibrosis.

▶ Treatment

Definitive treatment of noncirrhotic portal hypertension is generally lacking. Aggressive medical treatment of the complications of prehepatic portal hypertension is generally quite effective. Excellent results with either portosystemic shunt or the mesorex (mesenterico–left portal bypass) shunt. When possible, the mesorex shunt is the preferred technique. Veno-occlusive disease may be prevented somewhat by the prophylactic use of UCDA or defibrotide prior to conditioning for bone marrow transplantation. Treatment with defibrotide and withdrawal of the suspected offending agent, if possible, may increase the chance of recovery. Transjugular intrahepatic portosystemic shunts have been successful in bridging to recovery in veno-occlusive disease. For suprahepatic portal hypertension, efforts should be directed at correcting the underlying cause, if possible. Either surgical or angiographic relief of obstruction should be attempted if a defined obstruction of the vessels is apparent. Liver transplantation, if not contraindicated, should be considered early if direct correction is not possible. In most cases, management of portal hypertension is directed at management of the complications (Table 22–9).

▶ Prognosis

For prehepatic portal hypertension, the prognosis depends on the site of the block, the effectiveness of variceal eradication, the availability of suitable vessels for shunting procedures, and the experience of the surgeon. In patients treated by medical means, bleeding episodes seem to diminish with adolescence.

The prognosis in patients treated by medical and supportive therapy may be better than in the surgically treated group, especially when surgery is performed at an early age, although no comparative study has been done. Portacaval encephalopathy is unusual after shunting except when protein intake is excessive, but neurologic outcome may be better in patients who receive a mesorex shunt when compared with medical management alone.

The mortality rate of hepatic vein obstruction is very high (95%). In veno-occlusive disease, the prognosis is better, with complete recovery possible in 50% of acute forms and 5%–10% of subacute forms.

Table 22–9. Treatment of complications of portal hypertension.

Complication	Diagnosis	Treatment
Bleeding esophageal varices	Endoscopic verification of variceal bleeding.	Endosclerosis or variceal band ligation. Octreotide, 30 mcg/m^2 BSA/h intravenous. Pediatric Sengstaken-Blakemore tube. Surgical portosystemic shunt, TIPS, surgical variceal ligation, selective venous embolization, OLT. Propranolol may be useful to prevent recurrent bleeding.
Ascites	Clinical examination (fluid wave, shifting dullness), abdominal ultrasonography.	Sodium restriction (1–2 mEq/kg/d), spironolactone (3–5 mg/kg/d), furosemide (1–2 mg/kg/d), intravenous albumin (0.5–1 g/kg per dose), paracentesis, peritoneovenous (LeVeen) shunt, TIPS, surgical portosystemic shunt, OLT.[a]
Hepatic encephalopathy	Abnormal neurologic examination, elevated plasma ammonia.	Protein restriction (0.5–1 g/kg/d), intravenous glucose (6–8 mg/kg/min), neomycin (2–4 g/m^2 BSA PO in four doses), rifaximin (200 mg three times a day in children > 12 y), lactulose (1 mL/kg per dose [up to 30 mL] every 4–6 h PO), plasmapheresis, hemodialysis, OLT.[a]
Hypersplenism	Low WBC count, platelets, and/or hemoglobin. Splenomegaly.	No intervention, partial splenic embolization, surgical portosystemic shunt, TIPS, OLT. Splenectomy may worsen variceal bleeding.

BSA, body surface area; OLT, orthotopic liver transplantation; TIPS, transjugular intrahepatic portosystemic shunt; WBC, white blood cell.

BILIARY TRACT DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Episodic right upper quadrant abdominal pain.

▶ Elevated bilirubin, alkaline phosphatase, and GGT.

▶ Stones or sludge seen on abdominal ultrasound.

1. Cholelithiasis

▶ General Considerations

Gallstones may develop at all ages in the pediatric population and in utero. Gallstones may be divided into cholesterol stones (> 50% cholesterol) and pigment (black [sterile bile] and brown [infected bile]) stones. Pigment stones predominate in the first decade of life, while cholesterol stones account for up to 90% of gallstones in adolescence. For some patients, gallbladder dysfunction is associated with biliary sludge formation, which may evolve into "sludge balls" or tumefaction bile and then into gallstones. The process is reversible in many patients.

▶ Clinical Findings

A. History

Most symptomatic gallstones are associated with acute or recurrent episodes of moderate to severe, sharp right upper quadrant or epigastric pain. The pain may radiate substernally or to the right shoulder. On rare occasions, the presentation may include a history of jaundice, back pain, or generalized abdominal discomfort, when it is associated with pancreatitis, suggesting stone impaction in the common duct or ampulla hepatopancreatica. Nausea and vomiting may occur during attacks. Pain episodes often occur postprandially, especially after ingestion of fatty foods. The groups at risk for gallstones include patients with known or suspected hemolytic disease; females; teenagers with prior pregnancy; obese individuals; individuals with rapid weight loss; children with portal vein thrombosis; certain racial or ethnic groups, particularly Native Americans (Pima Indians) and Hispanics; infants and children with ileal disease (Crohn disease) or prior ileal resection; patients with cystic fibrosis or Wilson disease; infants on prolonged parenteral hyperalimentation and those with bile acid transporter defects. Other, less certain risk factors include a positive family history, use of birth control pills, and diabetes mellitus.

B. Symptoms and Signs

During acute episodes of pain, tenderness is present in the right upper quadrant or epigastrium, with a positive inspiratory arrest (Murphy sign), usually without peritoneal signs. While rarely present, scleral icterus is helpful. Evidence of underlying hemolytic disease in addition to icterus may include pallor (anemia), splenomegaly, tachycardia, and high-output cardiac murmur. Fever is unusual in uncomplicated cases.

C. Laboratory Findings

Laboratory tests are usually normal unless calculi have lodged in the extrahepatic biliary system, in which case the serum bilirubin and GGT (or alkaline phosphatase) may be elevated. Amylase and lipase levels may be increased if stone obstruction occurs at the ampulla hepatopancreatica.

D. Imaging

Ultrasound evaluation is the best imaging technique, showing abnormal intraluminal contents (stones, sludge) as well as anatomic alterations of the gallbladder or dilation of the biliary ductal system. The presence of an anechoic acoustic shadow differentiates calculi from intraluminal sludge or sludge balls. Plain abdominal radiographs will show calculi with a high calcium content in the region of the gallbladder in up to 15% of patients. Lack of visualization of the gallbladder with hepatobiliary scintigraphy suggests chronic cholecystitis. In selected cases, ERCP, MRCP, or endoscopic ultrasound may be helpful in defining subtle abnormalities of the bile ducts and locating intraductal stones.

▶ Differential Diagnosis

Other abnormal conditions of the biliary system with similar presentation are summarized in Table 22–10. Liver disease (hepatitis, abscess, or tumor) can cause similar symptoms or signs. Peptic disease, reflux esophagitis, paraesophageal hiatal hernia, cardiac disease, and pneumomediastinum must be considered when the pain is epigastric or substernal in location. Renal or pancreatic disease is a possible explanation if the pain is localized to the right flank or mid back. Subcapsular or supracapsular lesions of the liver (abscess, tumor, or hematoma) or right lower lobe infiltrate may also be a cause of nontraumatic right shoulder pain.

▶ Complications

Major problems are related to stone impaction in either the cystic or common duct, which may lead to stricture formation or perforation. Acute distention and subsequent perforation of the gallbladder may occur when gallstones cause obstruction of the cystic duct. Stones impacted at the level of the ampulla hepatopancreatica often cause gallstone pancreatitis.

▶ Treatment

Symptomatic cholelithiasis is treated by laparoscopic cholecystectomy or open cholecystectomy in selected cases. Intraoperative cholangiography via the cystic duct is recommended so that the physician can be certain the biliary system is free of retained stones. Calculi in the extrahepatic bile ducts may be removed at ERCP.

Gallstones developing in premature infants on parenteral nutrition can be followed by ultrasound examination. Most of the infants are asymptomatic, and the stones will resolve in 3–36 months. Gallstone dissolution using cholelitholytics (UCDA) or mechanical means (lithotripsy) has not been approved for children. Asymptomatic gallstones do not usually require treatment, as less than 20% will eventually cause problems.

▶ Prognosis

The prognosis is excellent in uncomplicated cases that come to standard cholecystectomy.

Svensson J et al: Gallstone disease in children. Semin Pediatr Surg 2012;21:255 [PMID: 22800978].

2. Primary Sclerosing Cholangitis

> ### ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES
>
> ▶ Pruritus and jaundice.
> ▶ Elevated GGT.
> ▶ Associated with inflammatory bowel disease.
> ▶ Abnormal ERCP or MRCP.

▶ General Considerations

Primary sclerosing cholangitis (PSC) is a progressive liver disease characterized by chronic inflammation and fibrosis of the intrahepatic and/or extrahepatic bile ducts, leading to fibrotic strictures and saccular dilations of all or parts of the biliary tree. The etiology of PSC is likely multifactorial, including genetic predispositions, with alteration in innate and autoimmunity. PSC is more common in males, and has a strong relationship to inflammatory bowel disease, particularly ulcerative colitis. A PSC like condition can also be seen with histiocytosis X, autoimmune hepatitis, IgG4

Table 22–10. Biliary tract diseases of childhood.

	Acute Hydrops Transient Dilation of Gallbladder[a,b]	Choledochal Cyst[c] (see Figure 22–1)	Acalculous Cholecystitis[d]	Caroli Disease[e] (Idiopathic Intrahepatic Bile Duct Dilation)	Congenital Hepatic Fibrosis[f]	Biliary Dyskinesia[g]
Predisposing or associated conditions	Premature infants with prolonged fasting or systemic illness. Hepatitis. Abnormalities of cystic duct. Kawasaki disease. Bacterial sepsis, EBV.	Congenital lesion. Female sex. Asians. Rarely with Caroli disease or congenital hepatic fibrosis.	Systemic illness, sepsis (*Streptococcus, Salmonella, Klebsiella,* etc), HIV infection. Gallbladder stasis, obstruction of cystic duct (stones, nodes, tumor).	Congenital lesion. Also found in congenital hepatic fibrosis or with choledochal cyst. Female sex. Autosomal recessive polycystic kidney disease.	Familial (autosomal recessive) 25% with autosomal recessive polycystic kidney disease (PKHD1 mutation). Choledochal cyst. Caroli disease. Meckel-Gruber, Ivemark, or Jeune syndrome.	Adolescents.
Symptoms	Absent in premature infants. Vomiting, abdominal pain in older children.	Abdominal pain, vomiting, jaundice.	Acute severe abdominal pain, vomiting, fever.	Recurrent abdominal pain, vomiting. Fever, jaundice when cholangitis occurs.	Hematemesis, melena from bleeding esophageal varices.	Intermittent RUQ pain.
Signs	RUQ abdominal mass. Tenderness in some.	Icterus, acholic stools, dark urine in neonatal period. RUQ abdominal mass or tenderness in older children.	Tenderness in mid and right upper abdomen. Occasional palpable mass in RUQ.	Icterus, hepatomegaly.	Hepatosplenomegaly.	Usually normal exam.
Laboratory abnormalities	Most are normal. Increased WBC count during sepsis (may be decreased in premature infants). Abnormal LFTs in hepatitis.	Conjugated hyperbilirubinemia, elevated GGT, slightly increased AST. Elevated pancreatic serum amylase common.	Elevated WBC count, normal or slight abnormality of LFTs.	Abnormal LFTs. Increased WBC count with cholangitis. Urine abnormalities if associated with congenital hepatic fibrosis.	Low platelet and WBC count (hypersplenism), slight elevation of AST, GGT. Inability to concentrate urine.	Usually normal.
Diagnostic studies most useful	Gallbladder US.	Gallbladder US, hepatobiliary scintigraphy, MRCP, or ERCP.	Scintigraphy to confirm nonfunction of gallbladder. US or abdominal CT scan to rule out other neighboring disease.	Transhepatic cholangiography, MRCP, ERCP, scintigraphy, US, intravenous pyelography.	Liver biopsy. US of liver and kidneys. Upper endoscopy.	Normal US, CCK stimulated hepatobiliary scintigraphy demonstrating a very reduced ejection fraction.
Treatment	Treatment of associated condition. Needle or tube cystostomy rarely required. Cholecystectomy seldom indicated.	Surgical resection and choledochojejunostomy.	Broad-spectrum antibiotic coverage, then cholecystectomy.	Antibiotics and surgical or endoscopic drainage for cholangitis. Liver transplantation for some. Lobectomy for localized disease.	Treatment of portal hypertension. Liver and kidney transplantation for some.	Cholecystectomy in well selected cases. Biliary sphincterotomy in rare cases.

Complications	Perforation with bile peritonitis rare.	Progressive biliary cirrhosis. Increased incidence of cholangiocarcinoma. Cholangitis in some.	Perforation and bile peritonitis, sepsis, abscess or fistula formation. Pancreatitis.	Sepsis with episodes of cholangitis, biliary cirrhosis, portal hypertension. Intraductal stones. Cholangiocarcinoma.	Bleeding from varices. Splenic rupture, severe thrombocytopenia. Progressive renal failure.	Continued pain after surgery.
Prognosis	Excellent with resolution of underlying condition. Consider cystic duct obstruction if disorder fails to resolve.	Depends on anatomic type of cyst, associated condition, and success of surgery. Liver transplantation required in some.	Good with early diagnosis and treatment.	Poor, with gradual deterioration of liver function. Multiple surgical drainage procedures expected. Liver transplantation should improve long-term prognosis.	Good in absence of serious renal involvement and with control of portal hypertension. Slightly increased risk of cholangiocarcinoma.	Good short-term outcome in well-selected patients.

AST, aspartate aminotransferase; CCK, cholecystokinin; CT, computed tomography; EBV, Epstein-Barr virus; ERCP, endoscopic retrograde cholangiopancreatography; GGTx, Y-glutamyl transpeptidase; HIV, human immunodeficiency virus; LFT, liver function test; MRCP, magnetic resonance cholangiopancreatography; RUQ, right upper quadrant; US, ultrasound; WBC, white blood cell.

autoimmune pancreatitis, sicca syndromes, congenital and acquired immunodeficiency syndromes, and cystic fibrosis.

▶ Clinical Findings

A. Symptoms and Signs

PSC often has an insidious onset and may be asymptomatic. Clinical symptoms may include abdominal pain, fatigue, pruritus, jaundice, and weight loss. Acholic stools and steatorrhea can occur. Physical findings include hepatomegaly, splenomegaly, and jaundice.

B. Laboratory Findings

The earliest finding may be asymptomatic elevation of the GGT. Subsequent laboratory abnormalities include elevated levels of alkaline phosphatase and bile acids. Later, cholestatic jaundice and elevated AST and ALT may occur. Patients with associated inflammatory bowel disease often test positive for perinuclear antineutrophil cytoplasmic antibodies. Other markers of autoimmune liver disease (ANA and ASMA) are often found, but are not specific for PSC. Sclerosing cholangitis due to cryptosporidia is common in immunodeficiency syndromes.

C. Imaging

Ultrasound may show saccular dilation of normal intrahepatic bile ducts with segmental strictures, described as "beads on a string." MRCP is the diagnostic study of choice, demonstrating irregularities of the biliary tree. ERCP may be more sensitive for the diagnosis of irregularities of the intrahepatic biliary tree and allow for therapeutic interventions.

▶ Differential Diagnosis

The differential diagnosis includes infectious hepatitis, secondary cholangitis, AIH, metabolic liver disease, cystic fibrosis, choledochal cyst, or other anomalies of the biliary tree, including Caroli disease, choledochal cyst, and congenital hepatic fibrosis (see Table 22–10).

▶ Complications

Complications include secondary bacterial cholangitis, pancreatitis, biliary fibrosis, and cirrhosis. Slow progression to end-stage liver disease with liver failure is common, and patients are at increased risk of cholangiocarcinoma.

▶ Treatment

Treatment of PSC focuses on supportive care. Ursodeoxycholic acid is often used in pediatrics, though high doses may worsen disease in adults. Oral vancomycin has been used, though very little data support its use. Patients with autoimmune sclerosing cholangitis or IgG4

cholangitis may benefit from treatment with corticosteroids and azathioprine. Antibiotic treatment of cholangitis and dilation and stenting of dominant bile duct strictures can reduce symptoms. Liver transplantation is effective for patients with end-stage complications, but the disease may recur in up to 10% after transplant.

▶ Prognosis

The majority of patients will eventually require liver transplantation, and PSC is the fifth leading indication for liver transplantation in the United States. The median duration from the time of diagnosis to end-stage liver disease is 12–15 years.

3. Other Biliary Tract Disorders

For a schematic representation of the various types of choledochal cysts, see Figure 22–1. For summary information on acute hydrops, choledochal cyst, acalculous cholecystitis, Caroli disease, biliary dyskinesia, and congenital hepatic fibrosis, see Table 22–10.

PYOGENIC & AMEBIC LIVER ABSCESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Fever and painful enlarged liver.
- ▶ Ultrasound of liver demonstrating an abscess.
- ▶ Positive serum ameba antibody or positive bacterial culture of abscess fluid.

▶ General Considerations

Pyogenic liver abscesses are rare in developed countries, but remain a significant issue in developing countries. The most common cause is *S aureus*, with enteric bacteria less common; fungal abscesses also occur. The resulting lesion tends to be solitary and located in the right hepatic lobe. Unusual causes

TYPE		FINDINGS

I — Spherical dilation of the common duct (GB, CBD)

II — Congenital diverticulum of the common bile duct

III — Intraduodenal diverticulum of the common bile duct (choledochocele)

IVa — Multiple intrahepatic communicating cysts (Caroli disease)

IVb — Mixed extrahepatic and intrahepatic fusiform or cystic dilation (possibly variants of Caroli disease, congenital hepatic fibrosis)

▲ **Figure 22–1.** Classification of cystic dilation of the bile ducts. Types I, II, and III are extrahepatic choledochal cysts. Type IVa is solely intrahepatic, and type IVb is both intrahepatic and extrahepatic.

include omphalitis, subacute infective endocarditis, pyelonephritis, Crohn disease, and perinephric abscess. In immunocompromised patients, *S aureus*, gram-negative organisms, and fungi may seed the liver from the arterial system. Multiple pyogenic liver abscesses are associated with severe sepsis. Children receiving anti-inflammatory and immunosuppressive agents and children with defects in white blood cell function (chronic granulomatous disease) are prone to pyogenic hepatic abscesses, especially those caused by *S aureus*.

Amebic liver abscess can occur when *Entamoeba histolytica* invasion occurs via the large bowel, although a history of diarrhea (colitis-like picture) is not always obtained.

▶ **Clinical Findings**

A. History

With any liver abscess, nonspecific complaints of fever, chills, malaise, and abdominal pain are frequent. Amebic liver abscess is rare in children. An increased risk is associated with travel in areas of endemic infection (Mexico, Southeast Asia) within 5 months of presentation.

B. Symptoms and Signs

Weight loss is very common, especially when diagnosis is delayed. A few patients have shaking chills and jaundice. The dominant complaint is a constant dull pain over an enlarged liver that is tender to palpation. An elevated hemidiaphragm with reduced or absent respiratory excursion may be demonstrated on physical examination and confirmed by fluoroscopy.

Fever and abdominal pain are the two most common symptoms of amebic liver abscess. Abdominal tenderness and hepatomegaly are present in over 50%. An occasional prodrome may include cough, dyspnea, and shoulder pain when rupture of the abscess into the right chest occurs.

C. Laboratory Findings

Laboratory studies show leukocytosis and, at times, anemia. LFTs may be normal or reveal mild elevation of transaminases and alkaline phosphatase. Early in the course, LFTs may suggest mild hepatitis. Blood cultures may be positive. The distinction between pyogenic and amebic abscesses is best made by indirect hemagglutination test for specific antibody (which is positive in more than 95% of patients with amebic liver disease) and the prompt clinical response of the latter to antiamebic therapy (metronidazole). Examination of material obtained by needle aspiration of the abscess using ultrasound guidance is often diagnostic.

D. Imaging

Ultrasound liver scan is the most useful diagnostic aid in evaluating pyogenic and amebic abscesses, detecting lesions as small as 1–2 cm. MRI, CT, or nuclear scanning with gallium or technetium sulfur colloid may be useful in differentiating tumor or hydatid cyst. Consolidation of the right lower lobe is common (10%–30% of patients) in amebic abscess.

▶ **Differential Diagnosis**

Hepatitis, hepatoma, hydatid cyst, gallbladder disease, or biliary tract infections can mimic liver abscess. Subphrenic abscesses, empyema, and pneumonia may give a similar picture. Inflammatory disease of the intestines or of the biliary system may be complicated by liver abscess.

▶ **Complications**

Spontaneous rupture of the abscess may occur with extension of infection into the subphrenic space, thorax, peritoneal cavity, and, occasionally, the pericardium. Bronchopleural fistula with large sputum production and hemoptysis can develop in severe cases. Simultaneously, the amebic liver abscess may be secondarily infected with bacteria (in 10%–20% of patients). Metastatic hematogenous spread to the lungs and the brain has been reported.

▶ Treatment

Ultrasound- or CT-guided percutaneous needle aspiration for aerobic and anaerobic culture with simultaneous placement of a catheter for drainage, combined with appropriate antibiotic therapy, is the treatment of choice for solitary pyogenic liver abscess. Multiple liver abscesses may also be treated successfully by this method. Surgical intervention may be indicated if rupture occurs outside the capsule of the liver or if enterohepatic fistulae are suspected.

Amebic abscesses in uncomplicated cases should be treated promptly with oral metronidazole, 35–50 mg/kg/d, in three divided doses for 10 days. Intravenous metronidazole can be used for patients unable to take oral medication. Failure to improve after 72 hours of drug therapy suggests superimposed bacterial infection or an incorrect diagnosis. At this point, needle aspiration or surgical drainage is indicated. Once oral feedings can be tolerated, a luminal amebicide such as iodoquinol should be initiated. Resolution of the abscess cavity occurs over 3–6 months.

▶ Prognosis

With drainage and antibiotics, the cure rate is about 90%. Mortality rates have improved, but remain at 15% for pyogenic liver abscess, especially with extrahepatic complications, and less than 1% for amebic abscess.

Mishra K et al: Liver abscess in children: an overview. World J Pediatr 2010;6:210 [PMID: 20706820].

Singh O et al: Comparative study of catheter drainage and needle aspiration in management of large liver abscesses. Indian J Gastroenterol 2009;28:88 [PMID: 19907956].

LIVER TUMORS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ Abdominal enlargement and pain, weight loss, anemia.
- ▶ Hepatomegaly with or without a definable mass.
- ▶ Mass lesion on imaging studies.
- ▶ Laparotomy and tissue biopsy.

▶ General Considerations

Primary neoplasms of the liver represent 0.3%–5% of all solid tumors in children. Of these, two-thirds are malignant, with hepatoblastoma being most common (79% of all pediatric liver cancers). Hepatoblastoma typically occurs in children ages 6 months to 3 years, with a male predominance. Most children present with a symptomatic abdominal mass, though with more advanced disease, weight loss, anorexia, abdominal pain and emesis may occur. Children with Beckwith-Wiedemann Syndrome and familial adenomatosis polyposis coli are at increased risk of hepatoblastoma, and should undergo routine screening with α-fetoprotein determinations and abdominal ultrasound until the age of 5 years. In addition, low-birth-weight infants (< 1000 grams) have a 15 times increased risk of hepatoblastoma, as compared to infants > 2500 grams. Pathologic differentiation from hepatocellular carcinoma, the other major malignant tumor of the liver, may be difficult.

Hepatocellular carcinoma most commonly occurs between the ages of 10–12 years and is more common in males. Children are more likely to be symptomatic, with abdominal distension, pain, and advanced disease, including anorexia and weight loss, at presentation. Patients with chronic HBV or HCV infection, cirrhosis, glycogen storage disease type I, tyrosinemia, and α_1-antitrypsin deficiency are at increased risk for developing hepatocellular carcinoma. The late development of hepatocellular carcinoma in patients receiving androgens for treatment of Fanconi syndrome and aplastic anemia must also be kept in mind. The use of anabolic steroids by body-conscious adolescents poses a risk of hepatic neoplasia. In addition, Wilms tumors, neuroblastoma and lymphoma may all metastasize to the liver.

▶ Clinical Findings

A. History

Noticeable abdominal distension, with or without pain, is the most constant feature. A parent may note a bulge in the upper abdomen or report feeling a hard mass. Constitutional symptoms (eg, anorexia, weight loss, fatigue, fever, and chills) may be present. Jaundice or pruritus may be present if obstruction of the biliary tree occurs. Virilization has been reported as a consequence of gonadotropin activity of tumors. Feminization with bilateral gynecomastia may occur in association with high estradiol levels in the blood, the latter a consequence of increased aromatization of circulating androgens by the liver. Leydig cell hyperplasia without spermatogenesis has also been reported.

B. Symptoms and Signs

Weight loss, pallor, and abdominal pain associated with a large abdomen are common. Physical examination reveals hepatomegaly with or without a definite tumor mass, usually to the right of the midline. In the absence of cirrhosis, signs of chronic liver disease are usually absent. However, evidence of virilization or feminization in prepubertal children may be noted.

C. Laboratory Findings

Normal LFTs are the rule. Anemia frequently occurs, especially in cases of hepatoblastoma. Cystathioninuria has been reported.

α-Fetoprotein levels are typically elevated, especially in hepatoblastoma. Estradiol levels are sometimes elevated. Tissue diagnosis is best obtained at laparotomy, although ultrasound- or CT-guided needle biopsy of the liver mass can be used.

D. Imaging

Ultrasonography, CT, and MRI are useful for diagnosis, staging, and following tumor response to therapy. A scintigraphic study of bone and chest CT are generally part of the pre-operative workup to evaluate metastatic disease.

▶ Differential Diagnosis

In the absence of a palpable mass, the differential diagnosis is that of hepatomegaly with or without anemia or jaundice. Hematologic and nutritional conditions should be ruled out, as well as HBV and HCV infection, α_1-antitrypsin deficiency disease, lipid storage diseases, histiocytosis X, glycogen storage disease, tyrosinemia, congenital hepatic fibrosis, cysts, adenoma, focal nodular hyperplasia, and hemangiomas. If fever is present, hepatic abscess (pyogenic or amebic) must be considered. Veno-occlusive disease and hepatic vein thrombosis are rare possibilities. Tumors in the left lobe may be mistaken for pancreatic pseudocysts.

▶ Complications

Progressive enlargement of the tumor, abdominal discomfort, ascites, respiratory difficulty, and widespread metastases (especially to the lungs and the abdominal lymph nodes) are the rule. Rupture of the neoplastic liver and intraperitoneal hemorrhage has been reported. Progressive anemia and emaciation predispose the patient to an early septic death.

▶ Treatment

For tumors that are resectable, an aggressive surgical approach with complete resection of the lesion offers the only chance for cure. Individual lung metastases should also be surgically resected. Radiotherapy and chemotherapy have been disappointing in the treatment of hepatocellular carcinoma, although hepatoblastomas are generally more responsive. Chemotherapy may be used for initial cytoreduction of tumors (especially hepatoblastoma) found to be unresectable at the time of primary surgery (see Chapter 31 for additional discussion). Second-look celiotomy has, in some cases, allowed resection of the tumor, resulting in a reduced mortality rate. Liver transplantation can be an option in hepatoblastoma with unresectable disease limited to the liver, with an 85% 10-year survival. For hepatocellular carcinoma, the survival rate is poor due to the typically advanced stage at diagnosis. The survival rate may be better for those patients in whom the tumor is incidental to another disorder (tyrosinemia, biliary atresia, cirrhosis) or is less than a total of 7 cm diameter without vascular invasion. In HBV-endemic areas, childhood HBV vaccination has reduced the incidence of hepatocellular carcinoma.

▶ Prognosis

If the tumor is completely removed, the survival rate is 90% for hepatoblastoma and 33% for hepatocellular carcinoma. If metastases that cannot be surgically resected are present, survival is reduced to 40% for hepatoblastoma. In well-selected candidates with unresectable hepatoblastoma, survival after liver transplantation approaches 65%.

LIVER TRANSPLANTATION

Orthotopic liver transplantation is indicated in children with end-stage liver disease, acute fulminant hepatic failure, or complications from metabolic liver disorders. Approximately 600 pediatric liver transplants are performed annually, with excellent 1 year (83%–91%) and 5 year (82%–84%) survival rates. The multitude of immunosuppression options, ability to individualize immunosuppression, improved candidate selection, refinements in surgical techniques, anticipatory monitoring for complications (eg, CMV and EBV infections, hypertension, renal dysfunction, and dyslipidemias) and experience in postoperative management have all contributed to improved outcomes over time. The major indications for childhood transplantation are shown in Table 22–11.

Children who are potential candidates for liver transplantation should be referred to a pediatric transplant center early for evaluation. In addition to full-sized cadaveric organs, children may also receive reduced segment or split cadaveric livers and live donor donation, all of which have expanded the potential donor pool. Lifetime immunosuppression therapy, using combinations of tacrolimus, cyclosporine, prednisone, azathioprine, mycophenolate mofetil, or sirolimus, with its incumbent risks, is generally necessary to prevent rejection. Small studies have examined the potential for complete immunosuppression withdrawal, with a more definitive multicenter study currently underway. Currently, the minimal amount of immunosuppression that will prevent allograft rejection should be chosen. The overall quality of life for children with a transplanted liver appears to be excellent. There is an increased risk (up to 25%) of renal dysfunction and low intelligence scores. The lifelong

Table 22–11. Indications for pediatric liver transplantation.

Indication	Percent of Pediatric Transplants
Biliary atresia (failed Kasai or decompensated cirrhosis)	39.6

PFIC, progressive familial intrahepatic cholestasis.

risk of EBV-induced lymphoproliferative disease, which is approximately 5%, is related to age and EBV exposure status at time of transplantation, and intensity of immunosuppression. Various protocols are being tested for prevention and treatment of lymphoproliferative disease.

▼ PANCREATIC DISORDERS ACUTE PANCREATITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Epigastric abdominal pain radiating to the back.
► Nausea and vomiting.
► Elevated serum amylase and lipase.
► Evidence of pancreatic inflammation by CT or ultrasound.

▶ General Considerations

The rate of hospitalization for acute pancreatitis in children is 0.02–0.09/1000 US population. The incidence of pediatric acute pancreatitis seems to be increasing. Most cases of acute pancreatitis are the result of drugs, viral infections, systemic diseases, abdominal trauma, or obstruction of pancreatic flow. More than 20% are idiopathic. Causes of pancreatic obstruction include stones, choledochal cyst, tumors of the duodenum, pancreas divisum, and ascariasis. Acute pancreatitis has been seen following treatment with sulfasalazine, thiazides, valproic acid, azathioprine, mercaptopurine, asparaginase, antiretroviral drugs (especially didanosine), high-dose corticosteroids, and other drugs. It may also occur in cystic fibrosis, systemic lupus erythematosus, α_1-antitrypsin deficiency, diabetes mellitus, Crohn disease, glycogen storage disease type I, hyperlipidemia types I and V, hyperparathyroidism, Henoch-Schönlein purpura, Reye syndrome, organic acidopathies, Kawasaki disease, or chronic renal failure; during rapid refeeding in cases of malnutrition; following spinal fusion surgery; and in families. Alcohol-induced pancreatitis should be considered in the teenage patient.

▶ Clinical Findings

A. History

An acute onset of persistent (hours to days), moderate to severe upper abdominal and midabdominal pain occasionally referred to the back, frequently associated with vomiting, or nausea is the common presenting picture.

B. Symptoms and Signs

The abdomen is tender, but not rigid, and bowel sounds are diminished, suggesting peritoneal irritation. Abdominal distention is common in infants and younger children and classic symptoms of abdominal pain, tenderness and nausea are less common in this age group. Jaundice is unusual. Ascites may be noted, and a left-sided pleural effusion is present in some patients. Periumbilical and flank bruising indicate hemorrhagic pancreatitis.

C. Laboratory Findings

An elevated serum amylase or lipase (more than three times normal) is the key laboratory finding. The elevated serum lipase persists longer than serum amylase. Infants younger than 6 months may not have an elevated amylase or lipase. In this setting, an elevated immunoreactive trypsinogen may be more sensitive. Pancreatic lipase can help differentiate nonpancreatic causes (eg, salivary, intestinal, or tuboovarian) of serum amylase elevation. Leukocytosis, hyperglycemia (serum glucose > 300 mg/dL), hypocalcemia, falling hematocrit, rising blood urea nitrogen, hypoxemia,

and acidosis may all occur in severe cases and imply a poor prognosis.

D. Imaging

Plain radiographic films of the abdomen may show a localized ileus (sentinel loop). Ultrasonography is primarily used to assess for biliary tract disease leading to pancreatitis, but can show decreased echodensity of the pancreas in comparison with the left lobe of the liver. The pancreas is often difficult to image with ultrasound due to overlying gas. CT scanning images the pancreas more consistently and is better for detecting pancreatic phlegmon, pseudocyst, necrosis, or abscess formation. The computed tomography severity index (CTSI) is useful in identifying patients at increased risk for serious complications. ERCP or MRCP may be useful in confirming patency of the main pancreatic duct in cases of abdominal trauma; in recurrent acute pancreatitis; or in revealing stones, ductal strictures, and pancreas divisum.

▶ Differential Diagnosis

Other causes of acute upper abdominal pain include gastritis; peptic ulcer disease; duodenal ulcer; hepatitis; liver abscess; cholelithiasis; cholecystitis; choledocholithiasis; acute gastroenteritis or atypical appendicitis; pneumonia; volvulus; intussusception; and nonaccidental trauma.

▶ Complications

Early complications include shock, fluid and electrolyte disturbances, ileus, acute respiratory distress syndrome, and hypocalcemia. Hypervolemia due to renal insufficiency related to renal tubular necrosis may occur. The gastrointestinal, neurologic, musculoskeletal, hepatobiliary, dermatologic, and hematologic systems may also be involved. Early predictors of a more aggressive course include renal dysfunction, significant fluid requirements, and multisystem organ dysfunction and a high CTSI. Five to 20% of patients can develop a pseudocyst 1–4 weeks later that may be asymptomatic or present with recurrence of abdominal pain and rise in the serum amylase. Up to 60%–70% of pseudocysts resolve spontaneously. Infection, hemorrhage, rupture, or fistulization may occur. Phlegmon formation is rare in children, but when present may extend from the gland into the retroperitoneum or into the lesser sac. Most regress, but some require drainage. Infection may occur in this inflammatory mass. Pancreatic abscess formation, which is rare (3%–5%), develops 2–3 weeks after the initial insult. Fever, leukocytosis, and pain suggest this complication; diagnosis is made by ultrasound or CT scanning. Chronic pancreatitis, exocrine or endocrine pancreatic insufficiency, and pancreatic lithiasis are rare sequelae of acute pancreatitis.

▶ Treatment

Medical management includes careful attention to fluid, electrolytes, and respiratory status. Gastric decompression may be helpful if there is significant vomiting. Pain should be controlled with opioids. Acid suppression may be helpful. Nutrition is provided by the parenteral or enteral (jejunal or gastric) route. Broad-spectrum antibiotic coverage is useful only in necrotizing pancreatitis. Drugs known to produce acute pancreatitis should be discontinued. Surgical treatment is reserved for traumatic disruption of the gland, intraductal stone, other anatomic obstructive lesions, and unresolved or infected pseudocysts or abscesses. Early endoscopic decompression of the biliary system reduces the morbidity associated with pancreatitis caused by obstruction of the common bile duct.

▶ Prognosis

In the pediatric age group, the prognosis is surprisingly good with conservative management.

Morinville VD et al: Increasing incidence of acute pancreatitis at an American pediatric tertiary care center: is greater awareness among physicians responsible? Pancreas 2010;39:5 [PMID: 19752770].

CHRONIC PANCREATITIS

Chronic pancreatitis is differentiated from acute pancreatitis in that the pancreas remains structurally or functionally abnormal after an attack.

The causes are multiple and can be divided into toxic-metabolic (eg, alcohol, chronic renal failure, hypercalcemia), idiopathic, genetic (increasingly recognized in children and adolescents), autoimmune, recurrent and severe acute pancreatitis, and obstructive pancreatitis (eg, pancreas divisum, choledochal cyst).

▶ Clinical Findings

A. History

The diagnosis often is delayed by the nonspecificity of symptoms and the lack of persistent laboratory abnormalities. There is usually a prolonged history of recurrent upper abdominal pain of variable severity. Radiation of the pain into the back is a frequent complaint.

B. Symptoms and Signs

Fever and vomiting are rare. Diarrhea, due to steatorrhea, and symptoms of diabetes may develop later in the course. Malnutrition due to acquired exocrine pancreatic insufficiency may also occur.

C. Laboratory Findings

Serum amylase and lipase levels are usually elevated during early acute attacks, but are often normal in the chronic phase. Pancreatic insufficiency may be diagnosed by demonstration of a low fecal pancreatic elastase 1. Mutations of the cationic trypsinogen gene, the pancreatic secretory trypsin inhibitor, the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) and chymotrypsin C are associated with recurrent acute and chronic pancreatitis. Elevated blood glucose and glycohemoglobin levels and glycosuria frequently occur in protracted disease. Sweat chloride should be checked for cystic fibrosis, α_1-antitrypsin level or phenotype, and serum calcium for hyperparathyroidism.

D. Imaging

Radiographs of the abdomen may show pancreatic calcifications in up to 30% of patients. Ultrasound or CT examination demonstrates an abnormal gland (enlargement or atrophy), ductal dilation, and calculi in up to 80%. CT is the initial imaging procedure of choice. MRCP or ERCP can show ductal dilation, stones, strictures, or stenotic segments. Endoscopic ultrasound in the diagnosis and staging of chronic pancreatitis is being evaluated.

▶ Differential Diagnosis

Other causes of recurrent abdominal pain must be considered. Specific causes of pancreatitis such as autoimmune pancreatitis, hyperparathyroidism; systemic lupus erythematosus; infectious disease; α_1-antitrypsin deficiency; and ductal obstruction by tumors, stones, or helminths must be excluded by appropriate tests.

▶ Complications

Disabling abdominal pain, steatorrhea, malnutrition, pancreatic pseudocysts, and diabetes are the most frequent long-term complications. Pancreatic carcinoma occurs more frequently in patients with chronic pancreatitis, and in up to 40% of patients with hereditary pancreatitis by age 70.

▶ Treatment

Medical management of acute attacks is indicated (see section on Acute Pancreatitis, earlier). If ductal obstruction is strongly suspected, endoscopic therapy (balloon dilation, stenting, stone removal, or sphincterotomy) should be pursued. Relapses occur in most patients. Pancreatic enzyme therapy should be used in patients with pancreatic insufficiency. Antioxidant therapy is being investigated. Pseudocysts may be marsupialized to the surface or drained into the stomach or into a loop of jejunum if they fail to regress spontaneously. Lateral pancreaticojejunostomy or the Frey procedure can reduce pain in pediatric patients with a dilated pancreatic duct and may prevent or delay progression of functional pancreatic impairment. Pancreatectomy and islet cell autotransplantation has been used in selected cases of chronic pancreatitis.

▶ Prognosis

In the absence of a correctable lesion, the prognosis is not good. Disabling episodes of pain, pancreatic insufficiency, diabetes, and pancreatic cancer may ensue. Narcotic addiction and suicide are risks in teenagers with disabling disease.

GASTROINTESTINAL & HEPATOBILIARY MANIFESTATIONS OF CYSTIC FIBROSIS

Cystic fibrosis is a disease with protean manifestations. Although pulmonary and pancreatic involvement dominate the clinical picture for most patients (see Chapter 19), various other organs can be involved. Table 22–12 lists the important gastrointestinal, pancreatic, and hepatobiliary conditions that may affect patients with cystic fibrosis along with their clinical findings, incidence, most useful diagnostic studies, and preferred treatment.

Table 22–12. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis.

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
Esophagus	Gastroesophageal reflux, esophagitis	Pyrosis, dysphagia, epigastric pain, hematemesis.	All ages.	10–20	Endoscopy and biopsy, overnight pH study.	H$_2$ blockers, PPIs, surgical antireflux procedure.
	Varices	Hematemesis, melena.	Childhood and adolescents.	3–5	Endoscopy.	Endosclerosis, band ligation, drugs (see text), TIPS, surgical shunt, liver transplantation (see Table 22–9).
Stomach	Gastritis	Upper abdominal pain, vomiting, hematemesis.	School age and older.	10–25	Endoscopy and biopsy.	H$_2$ blockers, PPIs.
	Hiatal hernia	Reflux symptoms (see above), epigastric pain.	School age and older.	3–5	UGI; endoscopy.	As above. Surgery in some.
Intestine	Meconium ileus	Abdominal distention, bilious emesis.	Neonate.	10–15	Radiologic studies, plain abdominal films; contrast enema shows microcolon.	Dislodgement of obstruction with Gastrografin enema. Surgery if unsuccessful or if case complicated by atresia, perforation, or volvulus.
	Distal intestinal obstruction syndrome	Abdominal pain, acute and recurrent; distention; occasional vomiting.	Any age, usually school age through adolescence.	5–10	Palpable mass in right lower quadrant, radiologic studies.	Gastrografin enema, intestinal lavage solution, diet, bulk laxatives, adjustment of pancreatic enzyme intake.
	Intussusception	Acute, intermittent abdominal pain; distention; emesis.	Infants through adolescence.	1–3	Radiographic studies, barium enema.	Reduction by barium or air enema or surgery if needed. Diet. Bulk laxatives. Adjustment of pancreatic enzyme intake.
	Rectal prolapse	Anal discomfort, rectal bleeding.	Infants and children to age 4–5 y.	15–25	Visual mass protruding from anus.	Manual reduction, adjustment of pancreatic enzyme dosage, reassurance as problem resolves by age 3–5 y.
	Carbohydrate intolerance	Abdominal pain, flatulence, continued diarrhea with adequate enzyme replacement therapy.	Any age.	10–25	Intestinal mucosal biopsy and disaccharidase analysis. Lactose breathe hydrogen test.	Reduce lactose intake; lactase; reduction of gastric hyperacidity if mucosa shows partial villous atrophy. Beware concurrent celiac disease or *Giardia* infection.
	Small bowel bacterial overgrowth	Abdominal pain, flatulence, continued diarrhea with adequate enzyme replacement therapy.	Any age: Higher risk with previous intestinal surgery.	Unknown	Culture of duodenal fluid, glucose breath hydrogen test.	Probiotic therapy, oral antibiotics (metronidazole, trimethoprim-sulfamethoxazole).

(*Continued*)

Table 22–12. Gastrointestinal and hepatobiliary manifestations of cystic fibrosis. (*Continued*)

Organ	Condition	Symptoms	Age at Presentation	Incidence (%)	Diagnostic Evaluation	Management
Pancreas	Total exocrine insufficiency	Diarrhea, steatorrhea, malnutrition, failure to thrive. Fat-soluble vitamin deficiency.	Neonate through infancy.	85–90	72-h fecal fat evaluation, fecal pancreatic elastase, direct pancreatic function tests.	Pancreatic enzyme replacement, may need elemental formula, fat-soluble vitamin supplements.
	Pancreatic sufficiency (partial exocrine insufficiency)	Occasional diarrhea, mild growth delay.	Any age.	10–15	72-h fecal fat evaluation, direct pancreatic function tests, fecal pancreatic elastase.	Pancreatic enzyme replacement in selected patients. Fat-soluble vitamin supplements as indicated by biochemical evaluation.
	Pancreatitis	Recurrent abdominal pain, vomiting.	Older children through adolescence. Primarily in patients with partial pancreatic sufficiency.	0.1	Increased serum lipase and amylase, CT, MRCP, ERCP.	Endoscopic removal of sludge or stones if present, endoscopic papillotomy.
	Diabetes	Weight loss, polyuria, polydipsia.	Older children through adolescence.	5–7	Glucose tolerance test and insulin levels.	Diet, insulin.
Liver	Steatosis	Hepatomegaly, often in setting of malnutrition, elevated ALT.	Neonates and infants, but can be seen at all ages.	20–60	US showing homogeneous increased echogenicity. Liver biopsy.	Improved nutrition, replacement of pancreatic enzymes, vitamins, and essential fatty acids.
	Hepatic fibrosis	Hepatomegaly, firm liver. May have abnormal AST, ALT.	Infants and older patients. Prevalence uncertain.	10–70	US showing heterogeneous echogenicity. Liver biopsy.	As above. Ursodeoxycholic acid.
	Cirrhosis	Hepatosplenomegaly, hematemesis from esophageal varices; hypersplenism, jaundice, ascites late in course.	Infants through adolescence.	5–10	US showing nodular liver, signs of portal hypertension. Liver biopsy, endoscopy.	Improved nutrition, ursodeoxycholic acid, endosclerosis or band ligation of varices, or partial splenic embolization, liver transplantation.
	Neonatal jaundice	Cholestatic jaundice hepatomegaly; often seen with meconium ileus.	Neonates.	0.1–1	Sweat chloride test, liver biopsy	Nutritional support, special formula with medium-chain triglyceride–containing oil, pancreatic enzyme replacement, vitamin supplements.

Gallbladder	Microgallbladder	None.	Congenital—present at any age.	30	US or hepatobiliary scintigraphy.	None needed.
	Cholelithiasis	Recurrent right upper quadrant abdominal pain, rarely jaundice.	School age through adolescence.	1–10	US.	Surgery if symptomatic and low-risk, trial of cholelitholytics in others.
Extrahepatic bile ducts	Intraluminal obstruction (sludge, stones, tumor)	Jaundice, hepatomegaly, abdominal pain.	Neonates, then older children through adolescence.	Rare in neonates (< 0.1)	US and hepatobiliary scintigraphy, MRCP.	Surgery in neonates; ERCP in older patients or surgery.
	Extraluminal obstruction (intrapancreatic compression, tumor)	As above.	Older children to adults.	Rare (< 1)	As above.	Surgical biliary drainage procedure or ERCP.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; PPI, proton pump inhibitor; TIPS, transjugular intrahepatic portosystemic shunt; UGI, upper gastrointestinal; US; abdominal ultrasound.

SYNDROMES WITH PANCREATIC EXOCRINE INSUFFICIENCY

Several syndromes are associated with exocrine pancreatic insufficiency. Patients present with a history of failure to thrive, diarrhea, fatty stools, and an absence of respiratory symptoms. Laboratory findings include a normal sweat chloride; low fecal pancreatic elastase 1; and low to absent pancreatic lipase, amylase, and trypsin levels on duodenal intubation. Each disorder has several associated clinical features that aid in the differential diagnosis. In Shwachman-Diamond syndrome, pancreatic exocrine hypoplasia with widespread fatty replacement of the glandular acinar tissue is associated with neutropenia because of maturational arrest of the granulocyte series. Bone marrow failure is seen in one third. Metaphyseal dysostosis and an elevated fetal hemoglobin level are common; immunoglobulin deficiency and hepatic dysfunction are also reported. CT examination of the pancreas demonstrates the widespread fatty replacement. Genotyping of the *SBDS* gene is available. Serum immunoreactive trypsinogen levels are extremely low.

Other associations of exocrine pancreatic insufficiency include (1) aplastic alae, aplasia cutis, deafness (Johanson-Blizzard syndrome); (2) sideroblastic anemia, developmental delay, seizures, and liver dysfunction (Pearson bone marrow pancreas syndrome); (3) duodenal atresia or stenosis; (4) malnutrition; and (5) pancreatic hypoplasia or agenesis.

The complications and sequelae of exocrine pancreatic insufficiency are malnutrition, diarrhea, and growth failure. The degree of steatorrhea may lessen with age. Intragastric lipolysis by lingual lipase may compensate in patients with low or absent pancreatic function. In Shwachman-Diamond syndrome, short stature and bony dysplasias are problematic. Increased numbers of infections may result from chronic neutropenia and the reduced neutrophil mobility that is present in many patients. An increased incidence of leukemia has been noted in these patients; thus patients with myelodysplasia syndrome should be considered for hematopoietic stem cell transplantation.

Pancreatic enzyme and fat-soluble vitamin replacement are required therapy in most patients. The prognosis appears to be good for those able to survive the increased number of bacterial infections early in life and lack severe associated defects.

ISOLATED EXOCRINE PANCREATIC ENZYME DEFECT

Normal premature infants and most newborns produce little, if any, pancreatic amylase following meals or exogenous hormonal stimulation. This temporary physiologic insufficiency may persist for the first 3–6 months of life and be responsible for diarrhea when complex carbohydrates (cereals) are introduced into the diet.

Congenital pancreatic lipase deficiency and congenital colipase deficiency are extremely rare disorders, causing diarrhea and variable malnutrition with malabsorption of dietary fat and fat-soluble vitamins. The sweat chloride level is normal and neutropenia is absent. Treatment is oral replacement of pancreatic enzymes and a low-fat diet or formula containing medium-chain triglycerides.

Exocrine pancreatic insufficiency of proteolytic enzymes (eg, trypsinogen, trypsin, chymotrypsin) is caused by enterokinase deficiency, a duodenal mucosal enzyme required for activation of the pancreatic proenzymes. These patients present with malnutrition associated with hypoproteinemia and edema, but do not have respiratory symptoms and have a normal sweat test. They respond to pancreatic enzyme replacement therapy and feeding formulas that contain a casein hydrolysate (eg, Nutramigen, Pregestimil).

PANCREATIC TUMORS

Pancreatic tumors, whether benign or malignant, are rare. In the setting of malignancy, the majority of patients present with abdominal pain. Pancreatic tumors most often arise from ductal or acinar epithelium (malignant adenocarcinoma) or from islet (endocrine) components within the gland, such as the benign insulinoma (adenoma) derived from β cells. Other pancreatic tumors originate from these pluripotential endocrine cells (eg, gastrinoma, VIPoma, glucagonoma), and produce diverse symptoms, because they release biologically active polypeptides from this ectopic location. The clinical features of these tumors are summarized in Table 22–13. The differential diagnosis of pancreatic tumors includes Wilms tumor, neuroblastoma,

Table 22–13. Pancreatic tumors.

	Age	Major Findings	Diagnosis	Treatment	Associated Conditions
Insulinoma	Any age	Hypoglycemia, seizures; high serum insulin; weight gain; abdominal pain and mass infrequent	CT scan, MRI, PET, EUS, SRS	Surgery, diazoxide, SSTA	MEN1
Adenocarcinoma	Any age	Epigastric pain, mass, weight loss, anemia, biliary obstruction	Ultrasound, CT scan, MRI, EUS	Surgery	Chronic pancreatitis
Gastrinoma	Older than age 5–8 y	Male sex, gastric hypersecretion, peptic symptoms, multiple ulcers, gastrointestinal bleeding, anemia, diarrhea	Elevated fasting gastrin and postsecretin suppression test (> 300 pg/mL), CT scan, MRI, EUS, SRS, laparotomy	PPI, surgical resection, total gastrectomy, SSTA	Zollinger-Ellison syndrome, MEN1, neurofibromatosis
VIPoma	Any age (more common 2–4 y old)	Secretory diarrhea, hypokalemia, hypochlorhydria, weight loss, flushing	Elevated VIP levels (> 75 pg/mL); sometimes, elevated serum gastrin and pancreatic polypeptide; CT, EUS, SRS	Surgery, SSTA, IV fluids	
Glucagonoma	Older patients	Diabetes, necrolytic migratory erythema, diarrhea, anemia, thrombotic events, depression	Elevated glucagon, hyperglycemia, gastrin, VIP, CT, MRI, EUS, SRS	Surgery, SSTA	

CT, computed tomography; EUS, endoscopic ultrasound; IV, intravenous; MEN1, multiple endocrine neoplasia syndrome type I; MRI, magnetic resonance imaging; PPI, proton pump inhibitor; PET, Positron emission tomography; SRS, somatostatin-receptor scintigraphy; SSTA, somatostatin analogue; VIP, vasoactive intestinal polypeptide.

and malignant lymphoma. In older children, endoscopic ultrasonography can aid in localizing these tumors.

Fluid, Electrolyte, & Acid-Base Disorders & Therapy

Douglas M. Ford, MD

REGULATION OF BODY FLUIDS, ELECTROLYTES, & TONICITY

Total body water (TBW) constitutes 50%–75% of the total body mass, depending on age, sex, and fat content. After an initial postnatal diuresis, the TBW slowly decreases to the adult range near puberty (Figure 23–1). TBW is divided into the intracellular and extracellular spaces. Intracellular fluid (ICF) accounts for two-thirds of the TBW and extracellular fluid (ECF) for one-third. The ECF is further compartmentalized into plasma (intravascular) volume and interstitial fluid (ISF).

The principal constituents of plasma are sodium, chloride, bicarbonate, and protein (primarily albumin). The ISF is similar to plasma but lacks significant amounts of protein (Figure 23–2). Conversely, the ICF is rich in potassium, magnesium, phosphates, sulfates, and protein.

An understanding of osmotic shifts between the ECF and ICF is fundamental to understanding disorders of fluid balance. Iso-osmolality is generally maintained between fluid compartments. Because the cell membrane is water-permeable, abnormal fluid shifts occur if the concentration of solutes that cannot permeate the cell membrane in the ECF does not equal the concentration of such solutes in the ICF. Thus, NaCl, mannitol, and glucose (in the setting of hyperglycemia) remain restricted to the ECF space and contribute effective osmoles by obligating water to remain in the ECF compartment. In contrast, a freely permeable solute such as urea does not contribute effective osmoles because it is not restricted to the ECF and readily crosses cell membranes. Tonicity, or effective osmolality, differs from measured osmolality in that it accounts only for osmotically active impermeable solutes rather than all osmotically active solutes, including those that are permeable to cell membranes. Osmolality may be estimated by the following formula:

$$\text{mOsm/kg} = 2(\text{Na}^+, \text{mEq/L}) + \frac{\text{Glucose, mg/dL}}{18} + \frac{\text{BUN, mg/dL}}{2.8}$$

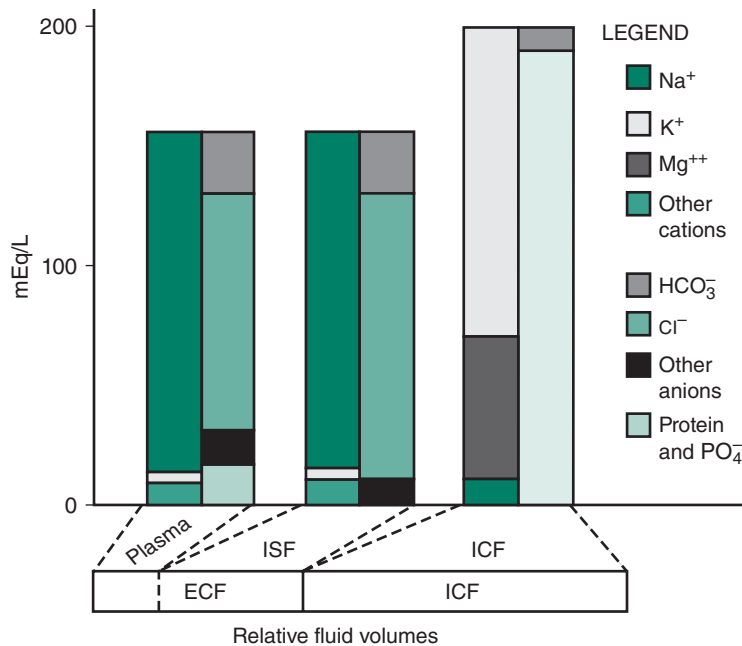
Although osmolality and osmolarity differ, the former being an expression of osmotic activity per weight (kg) and the latter per volume (L) of solution, for clinical purposes they are similar and occasionally used interchangeably. Oncotic pressure, or colloid osmotic pressure, represents the osmotic activity of macromolecular constituents such as albumin in the plasma and body fluids. The importance of albumin in maintaining intravascular volume status is reflected in the setting of the nephrotic syndrome, protein losing enteropathy, and other low serum albumin states wherein fluids accumulate in the interstitial compartment leading to pitting edema.

The principal mechanisms that regulate ECF volume and tonicity are thirst, vasopressin or antidiuretic hormone (ADH), aldosterone, and atrial natriuretic factor (ANF), the latter three exerting their influence by their effects on renal water and sodium handling.

Thirst

Water intake is commonly determined by cultural factors rather than by thirst. Thirst is not physiologically stimulated until plasma osmolality reaches 290 mOsm/kg, a level at which ADH levels are sufficient to induce maximal antidiuresis. Thirst provides control over a wide range of fluid volumes and can even be a response to an absence of or lack of responsiveness to ADH, which results in the production of copious, dilute urine, as in central or nephrogenic diabetes insipidus, or other ADH unresponsive states such as obstructive uropathy. One who cannot perceive thirst develops profound problems with fluid balance.

Antidiuretic Hormone

In the kidney, ADH increases water reabsorption in the cortical and medullary collecting ducts, leading to formation of concentrated urine. In the absence of ADH, dilute urine is produced. Under normal conditions, ADH secretion is regulated by the tonicity of body fluids rather than the fluid
▲ **Figure 23–1.** Body water compartments related to age. (Modified, with permission, from Friis-Hansen B: Body water compartments in children: changes during growth and related changes in body composition. Pediatrics 1961;28:169.)


▲ **Figure 23–2.** Composition of body fluids. ECF, extracellular fluid; ICF, intracellular fluid; ISF, interstitial fluid.

volume and becomes detectable at a plasma osmolality of 280 mOsm/kg or greater. However, tonicity may be sacrificed to preserve ECF volume, as in the case of hyponatremic dehydration, wherein ADH secretion and renal water retention are maximal.

Aldosterone

Aldosterone is released from the adrenal cortex in response to decreased effective circulating volume and stimulation of the renin-angiotensin-aldosterone axis or in response to increasing plasma K^+. Aldosterone enhances renal tubular reabsorption of Na^+ in exchange for K^+, and to a lesser degree H^+. At a constant osmolality, retention of Na^+ leads to expansion of ECF volume and suppression of aldosterone release.

Atrial Natriuretic Factor

ANF, a polypeptide hormone secreted principally by the cardiac atria in response to atrial dilation, plays an important role in regulation of blood volume and blood pressure. ANF inhibits renin secretion and aldosterone synthesis and causes an increase in glomerular filtration rate and renal sodium excretion. ANF also guards against excessive plasma volume expansion in the face of increased ECF volume by shifting fluid from the vascular to the interstitial compartment. ANF inhibits angiotensin II– and norepinephrine-induced vasoconstriction and acts in the brain to decrease the desire for salt and inhibit the release of ADH. Thus, the net effect of ANF is a decrease in blood volume and blood pressure associated with natriuresis and diuresis.

ACID-BASE BALANCE

The pH of arterial blood is maintained between 7.38 and 7.42 to ensure that pH-sensitive enzyme systems function normally. Acid-base balance is maintained by interaction of the lungs, kidneys, and systemic buffering systems. Over 50% of the blood's buffering capacity is provided by the carbonic acid–bicarbonate system, roughly 30% by hemoglobin, and the remainder by phosphates and ammonium. The carbonic acid–bicarbonate system, depicted chemically as

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$
interacts via the lungs and kidneys, and in conjunction with the nonbicarbonate systems, to stabilize systemic pH. The concentration of dissolved CO_2 in blood is established by the respiratory system and that of HCO_3^- by the kidneys.

Disturbances in acid-base balance are initially stabilized by chemical buffering, compensated for by pulmonary or renal regulation of CO_2 or, respectively, and ultimately corrected when the primary cause of the acid-base disturbance is eliminated.

Renal regulation of acid-base balance is accomplished by the reabsorption of filtered, primarily in the proximal tubule, and the excretion of H^+ or HCO_3^- in the distal nephron to match the net input of acid or base. When urine is alkalinized, HCO_3^- enters the kidney and is ultimately lost in the urine. Alkalinization of the urine may occur when an absolute or relative excess of bicarbonate exists. However, urinary alkalinization will not occur if there is a deficiency of Na^+ or K^+, because HCO_3^- must also be retained to maintain electroneutrality. In contrast, the urine may be acidified if an absolute or relative decrease occurs in systemic HCO_3^-. In this setting, proximal tubular HCO_3^- reabsorption and distal tubular H^+ excretion are maximal. A "paradoxical aciduria" with low urinary pH may be seen in the setting of hypokalemic metabolic alkalosis and systemic K^+ depletion wherein H^+ is exchanged and excreted in preference to K^+ in response to mineralocorticoid. Some of the processes involved in acid-base regulation are shown in Figure 23–3.

▼ FLUID & ELECTROLYTE MANAGEMENT

Therapy of fluid and electrolyte disorders is directed toward providing maintenance fluid and electrolyte requirements, replenishing prior losses, and replacing persistent abnormal losses. Therapy should be phased to (1) rapidly expand the ECF volume and restore tissue perfusion, (2) replenish fluid and electrolyte deficits while correcting attendant acid-base abnormalities, (3) meet the patient's nutritional needs, and (4) replace ongoing losses.

The cornerstone of therapy involves an understanding of maintenance fluid and electrolyte requirements. Maintenance requirements call for provision of enough water, glucose, and electrolytes to prevent deterioration of body stores for a euvolemic patient. During short-term parenteral therapy, sufficient glucose is provided to prevent ketosis and limit protein catabolism, although this usually provides little more than 20% of the patient's true caloric needs. Prior to the administration of maintenance fluids, it is important to consider the patient's volume status and to determine whether intravenous fluids are truly needed.

Various models have been devised to facilitate calculation of maintenance requirements based on body surface area, weight, and caloric expenditure. A system based on caloric expenditure is most helpful, because 1 mL of water is needed for each kilocalorie expended. The system presented in Table 23–1 is based on caloric needs and is applicable to children weighing more than 3 kg.

As depicted in Table 23–1, a child weighing 30 kg would need 1700 kcal or 1700 mL of water daily. If the child received parenteral fluids for 2 days, the fluid would usually contain 5% glucose, which would provide 340 kcal/d, or 20% of the maintenance caloric needs. Maintenance fluid requirements take into account normal insensible water losses and water lost in sweat, urine, and stool, and assume the patient to be afebrile, at their true dry weight, and relatively inactive. Thus, if excessive losses occur, standard "maintenance

Table 23–2. Alterations of maintenance fluid requirements.

Factor	Altered Requirement
Fever	12%/°C[a]
Hyperventilation	10–60 mL/100 kcal
Sweating	10–25 mL/100 kcal
Hyperthyroidism	Variable: 25%–50%
Gastrointestinal loss and renal disease	Monitor and analyze output. Adjust therapy accordingly.

[a]Do not correct for 38°C; correct 24% for 39°C.

fluids" will be inadequate. In contrast, if losses are reduced for any reason, standard "maintenance fluid" administration would be excessive. Maintenance requirements are greater for low-birth-weight and preterm infants. Table 23–2 lists other factors that commonly alter fluid and caloric needs.

Electrolyte losses occur primarily through the urinary tract and to a lesser degree via the skin and stool. Although maintenance sodium and potassium electrolyte needs have historically been approximated to be in the 3 mEq Na/100 kcal and 2 mEq K/100 kcal range, respectively, leading to the common use of intravenous fluids with 30–40 mEq/L of sodium (1/4 normal saline) and 20 mEq/L of potassium, over the past 10 years Moritz and Ayus have drawn attention to the very serious problem of hospital-acquired hyponatremia in children with the use of hypotonic IV solutions. It is notable, that hyponatremia is the most common electrolyte abnormality in children and affects ~ 25% of hospitalized pediatric patients. It is also important to emphasize that the astute clinician will bear in mind the dynamic nature of clinical context in treating patients. A child with profound water loss stools and hypernatremia who is placed on hypotonic IV fluids and whose diarrhea ceases, but is continued on hypotonic solution without close monitoring of serum electrolytes is at grave risk for the devastating clinical consequences that may develop in the setting of hyponatremia, such as seizures and neurologic impairment. Although stress-induced nonosmotic release of vasopressin and associated increased free water retention is certainly a factor in the development of hospital-acquired hyponatremia in children, 3 mEq Na/100 kcal underestimates daily sodium needs by about half. True needs more closely approximate 5–6 mEq/100 kcal in these clinical situations. In recent years, there also has been a trend for total parenteral nutrition solution sodium, and other electrolytes to be calculated and ordered on a milliequivalents-per-kilogram basis rather than the more classic milliequivalents-per-liter basis (eg, 0.2 or 0.45 normal). It is extremely important to understand

Table 23–1. Caloric and water needs per unit of body weight.

Body Weight (kg)	kcal/kg	mL of Water/kg
3–10	100	100
11–20	1000 kcal + 50 kcal/kg for each kg > 10 kg	1000 mL + 50 mL/kg for each kg > 10 kg
> 20	1500 kcal + 20 kcal/kg for each kg > 20 kg	1500 mL + 20 mL/kg for each kg > 20 kg

Data from Holliday MA, Segar WE: The maintenance need for water in parenteral fluid therapy. Pediatrics 1957;19:823.

that if the administered fluid volume is decreased in this setting, as the child is weaned from supplemental IV fluids to enteral intake, the sodium and other electrolytes will need to be reduced accordingly to avoid progressively increasing IV fluid tonicity that can result in hypernatremia or other electrolyte derangements.

It is helpful to monitor the patient's daily weight, urinary output, fluid input, and urine specific gravity. However, if stress-induced nonosmotic release of ADH is operative in a given patient, serial monitoring of the urine specific gravity may give the false impression that the child is still dehydrated when they are fluid replete, but still generating a concentrated urine. If fluid or electrolyte balance is abnormal, serial determination of serum electrolyte concentrations, blood urea nitrogen, and creatinine are necessary. In patients with significant burns, anuria, oliguria, or persistent abnormal stool or urine losses (eg, from a stoma, or polyuria secondary to a renal concentrating defect), it is important to measure output, and if needed its electrolyte components, so appropriate replacement can be provided.

DEHYDRATION

Depletion of body fluids is one of the most commonly encountered problems in clinical pediatrics. Children have a high incidence of gastrointestinal diseases, including gastroenteritis, and may demonstrate gastrointestinal symptoms in nongastrointestinal conditions, such as pneumonia or meningitis. Infants and young children often decrease their oral intake when ill, and their high ratio of surface area to weight promotes significant evaporative losses. Renal concentrating mechanisms do not maximally conserve water in early life, and fever may significantly increase fluid needs. Dehydration decreases ECF volume, leading to decreased tissue perfusion, progressive uremia and abnormal renal function studies, compensatory tachycardia, and lactic acidosis. The clinical effects of dehydration relate to the degree of dehydration and to the relative amounts of salt and water lost. Caregivers must be particularly aware of dehydration occurring in breast-fed newborn infants who go home soon after birth and whose mothers fail to produce enough milk. This problem is more common in the hot summer months and has been associated with severe dehydration, brain damage, and death.

The clinical evaluation of a child with dehydration should focus on the composition and volume of fluid intake; the frequency and amount of vomiting, diarrhea, and urine output; the degree and duration of fever; the nature of any administered medications; and the existence of underlying medical conditions. A recently recorded weight, if known, can be very helpful in calculating the magnitude of dehydration. Important clinical features in estimating the degree of dehydration include the capillary refill time, postural blood pressure, and heart rate changes; dryness of the lips and mucous membranes; lack of tears; lack of external jugular venous filling when supine; a sunken fontanelle in an infant; oliguria; and altered mental status (Table 23–3). Children generally respond to a decrease in circulating volume with a compensatory increase in pulse rate and may maintain

Table 23–3. Clinical manifestations of dehydration.

Clinical Signs	Degree of Dehydration		
	Mild	**Moderate**	**Severe**
Decrease in body weight	3%–5%	6%–10%	11%–15%
Skin			
Turgor	Normal ±	Decreased	Markedly decreased
Color	Normal	Pale	Markedly decreased
Mucous membranes	Dry ⟶		Mottled or gray; parched
Hemodynamic Signs			
Pulse	Normal	Slight increase	Tachycardia
Capillary refill	2–3 s	3–4 s	> 4 s
Blood pressure	Normal ⟶		Low
Perfusion	Normal ⟶		Circulatory collapse
Fluid Loss			
Urinary output	Mild oliguria	Oliguria	Anuria
Tears	Decreased		Absent
Urinary Indices			
Specific gravity	> 1.020 ⟶		Anuria
Urine [Na^+]	< 20 mEq/L ⟶		Anuria

their blood pressure in the face of severe dehydration. A low or falling blood pressure is, therefore, a late sign of shock in children, and when present should prompt emergent treatment. Salient laboratory parameters include a high urine specific gravity (in the absence of an underlying renal concentrating defect as seen in diabetes insipidus or chronic obstructive or reflux nephropathy), a relatively greater elevation in blood urea nitrogen than in serum creatinine, a low urinary [Na^+] excretion (< 20 mEq/L), and an elevated hematocrit or serum albumin level secondary to hemoconcentration.

Emergent intravenous therapy is indicated when there is evidence of compromised perfusion (inadequate capillary refill, tachycardia, poor color, oliguria, or hypotension). The initial goal is to rapidly expand the plasma volume and to prevent circulatory collapse. A 20-mL/kg bolus of isotonic fluid should be given intravenously as rapidly as possible. Either colloid (5% albumin) or crystalloid (normal saline or Ringer lactate) may be used. Colloid is particularly useful in hypernatremic patients in shock, in malnourished infants, and in neonates. If no intravenous site is available, fluid may be administered intraosseously through the marrow space of the tibia. If there is no response to the first fluid bolus, a second bolus may be given. When adequate tissue perfusion is demonstrated by improved capillary refill, decreased pulse rate and urine output, and improved mental status, deficit replacement may be instituted. If adequate perfusion is not restored after 40 mL/kg of isotonic fluids, other pathologic processes must be considered such as sepsis, occult hemorrhage, or cardiogenic shock. Isotonic dehydration may be treated by providing half of the remaining fluid deficit over 8 hours and the second half over the ensuing 16 hours in the form of 5% dextrose with 0.45% saline containing 20 mEq/L of KCl. In the presence of metabolic acidosis, potassium acetate may be considered. Maintenance fluids and replacement of ongoing losses should also be provided. Typical electrolyte compositions of various body fluids are depicted in Table 23–4, although it may be necessary to measure the specific constituents of a patient's fluid losses to guide therapy. If the patient is unable to eat for a prolonged period, nutritional needs must be met through hyperalimentation or enteral tube feedings.

Oral rehydration may be provided to children with mild to moderate dehydration. Clear liquid beverages found in the home, such as broth, soda, juice, and tea are inappropriate for the treatment of dehydration. Commercially available solutions provide 45–75 mEq/L of Na^+, 20–25 mEq/L of K^+, 30–34 mEq/L of citrate or bicarbonate, and 2%–2.5% of glucose. Frequent small aliquots (5–15 mL) should be given to provide approximately 50 mL/kg over 4 hours for mild dehydration and up to 100 mL/kg over 6 hours for moderate dehydration. Oral rehydration is contraindicated in children with altered levels of consciousness or respiratory distress who cannot drink freely; in children suspected of having an acute surgical abdomen; in infants with greater than 10% volume depletion; in children with hemodynamic instability; and in the setting of severe hyponatremia ([Na^+] < 120 mEq/L) or hypernatremia ([Na^+] > 160 mEq/L). Failure of oral rehydration due to persistent vomiting or inability to keep up with losses mandates intravenous therapy. Successful oral rehydration requires explicit instructions to caregivers and close clinical follow-up of the child.

The type of dehydration is characterized by the serum [Na^+]. If relatively more solute is lost than water, the [Na^+] falls, and hyponatremic dehydration ([Na^+] < 130 mEq/L) ensues. This is important clinically because hypotonicity of the plasma contributes to further volume loss from the ECF into the intracellular space. Thus, tissue perfusion is more significantly impaired for a given degree of hyponatremic dehydration than for a comparable degree of isotonic or hypertonic dehydration. It is important to note, however, that significant solute losses also occur in hypernatremic dehydration. Furthermore, because plasma volume is somewhat protected in hypernatremic dehydration, it poses the risk of the clinician underestimating the severity of dehydration. Typical fluid and electrolyte losses associated with each form of dehydration are shown in Table 23–5.

Table 23–4. Typical electrolyte compositions of various body fluids.

	Na^+ (mEq/L)	K^+ (mEq/L)	(mEq/L)
Diarrhea	10–90	10–80	40
Gastric	20–80	5–20	0
Small intestine	100–140	5–15	40
Ileostomy	45–135	3–15	40

HYPONATREMIA

Hyponatremia may be factitious in the presence of high plasma lipids or proteins, which decrease the percentage of plasma volume that is water. Hyponatremia in the absence of hypotonicity also occurs when an osmotically active solute, such as glucose or mannitol, is added to the ECF. Water drawn from the ICF dilutes the serum [Na$^+$] despite isotonicity or hypertonicity.

Patients with hyponatremic dehydration generally demonstrate typical signs and symptoms of dehydration (see Table 23–3), because the vascular space is compromised as water leaves the ECF to maintain osmotic neutrality. The treatment of hyponatremic dehydration is fairly straightforward. The magnitude of the sodium deficit may be calculated by the following formula:

$$\text{Na}^+ \text{ deficit} = (\text{Na}^+ \text{ desired} - \text{Na}^+ \text{ observed}) \times \text{Bodyweight (kg)} \times 0.6$$

Half of the deficit is replenished in the first 8 hours of therapy, and the remainder is given over the following 16 hours. Maintenance and replacement fluids should also be provided. The deficit plus maintenance calculations often approximate 5% dextrose with 0.45% or higher saline. The rise in serum [Na$^+$] should not exceed 0.5–1.0 mEq/L/h or 20 mEq/L/24 h unless the patient demonstrates central nervous system (CNS) symptoms that warrant more rapid initial correction. The dangers of too rapid correction of hyponatremia include cerebral dehydration and injury due to fluid shifts from the ICF compartment.

Hypovolemic hyponatremia also occurs in cerebral salt-wasting associated with CNS insults, a condition characterized by high urine output and elevated urinary [Na$^+$] (> 80 mEq/L) due to an increase in ANF, and is a diagnosis of exclusion requiring a natriuresis in a patient with a contracted effective circulatory blood volume in the absence of other causes for Na$^+$ excretion. This must be distinguished from the syndrome of inappropriate secretion of ADH (SIADH), which may also manifest in CNS conditions and pulmonary disorders. In contrast to cerebral salt-wasting, SIADH is characterized by euvolemia or mild volume expansion and relatively low urine output due to ADH-induced water retention. Urinary [Na$^+$] is high in both conditions, though generally not as high as in SIADH. It is important to distinguish between these two conditions, because the treatment of the former involves replacement of urinary salt and water losses, whereas the treatment of SIADH involves water restriction. It is also important to remember that in SIADH patients are not necessarily oliguric, and that their urine does not need to be maximally concentrated but merely inappropriately concentrated for their degree of serum tonicity.

In cases of severe hyponatremia (serum [Na$^+$] < 120 mEq/L) with CNS symptoms, intravenous 3% NaCl may be given over 1 hour to raise the [Na$^+$] to 120 mEq/L to alleviate CNS manifestations and sequelae. In general, 6 mL/kg of 3% NaCl will raise the serum [Na$^+$] by about 5 mEq/L. If 3% NaCl is administered, estimated Na$^+$ and fluid deficits should be adjusted accordingly. Further correction should proceed slowly, as outlined earlier.

Hypervolemic hyponatremia may occur in edematous disorders such as nephrotic syndrome, congestive heart failure, and cirrhosis, wherein water is retained in excess of salt. Treatment involves restriction of Na$^+$ and water and correction of the underlying disorder. Hypervolemic hyponatremia due to water intoxication is characterized by a maximally dilute urine (specific gravity < 1.003) and is also treated with water restriction.

HYPERNATREMIA

Although diarrhea is commonly associated with hyponatremic or isonatremic dehydration, hypernatremia may develop in the presence of persistent fever or decreased fluid intake or in response to improperly mixed rehydration solutions. Extreme care is required to treat hypernatremic dehydration appropriately. If the serum [Na$^+$] falls precipitously, the osmolality of the ECF drops more rapidly than that of the CNS. Water shifts from the ECF compartment into the CNS to maintain osmotic neutrality. If hypertonicity is corrected too rapidly (a drop in [Na$^+$] of > 0.5–1 mEq/L/h), cerebral edema, seizures, and CNS injury may occur. Thus, following the initial restoration of adequate tissue perfusion using isotonic fluids, a gradual decrease in serum [Na$^+$] is desired (10–15 mEq/L/d). This is commonly achieved using 5% dextrose with 0.2% saline to replace the calculated fluid deficit over 48 hours. Maintenance and replacement fluids should also be provided. If the serum [Na$^+$] is not correcting appropriately, the free water deficit may be estimated as 4 mL/kg of free water for each milliequivalent of serum [Na$^+$] above 145 mEq/L and provided as 5% dextrose over 48 hours. If metabolic acidosis is also present, it must be corrected slowly to avoid CNS irritability. Potassium is provided as indicated—as the acetate salt if necessary. Electrolyte concentrations should be assessed every 2 hours in order to control the decline in serum [Na$^+$]. Elevations of blood glucose and blood urea nitrogen may worsen the hyperosmolar state in hypernatremic dehydration and should also be monitored closely. Hyperglycemia is often associated with hypernatremic dehydration and may necessitate lower intravenous glucose concentrations (eg, 2.5%).

Patients with diabetes insipidus, whether nephrogenic or central in origin, are prone to develop profound hypernatremic dehydration as a result of unremitting urinary-free water losses (urine specific gravity < 1.010), particularly during superimposed gastrointestinal illnesses associated with vomiting or diarrhea. Treatment involves restoration of fluid and electrolyte deficits as described earlier as well as replacement

of excessive water losses. Formal water deprivation testing to distinguish responsiveness to ADH should only be done during daylight hours after restoration of normal fluid volume status.

However, if a child presents with marked dehydration and a serum Na^+ greater than 150 mEq/L, it may prove helpful and timely to obtain a plasma vasopressin level at the time of their initial presentation. The evaluation and treatment of nephrogenic and central diabetes insipidus are discussed in detail in Chapters 24 and 34, respectively.

Hypervolemic hypernatremia (salt poisoning), associated with excess total body salt and water, may occur as a consequence of providing improperly mixed formula, excessive NaCl or $NaHCO_3$ administration, or as a feature of primary hyperaldosteronism. Treatment includes the use of diuretics, and potentially, concomitant water replacement or even dialysis.

POTASSIUM DISORDERS

The predominantly intracellular distribution of potassium is maintained by the actions of Na^+-K^+-ATPase in the cell membranes. Potassium is shifted into the ECF and plasma by acidemia and into the ICF in the setting of alkalosis, hypochloremia, or in conjunction with insulin-induced cellular glucose uptake. The ratio of intracellular to extracellular K^+ is the major determinant of the cellular resting membrane potential and contributes to the action potential in neural and muscular tissue. Abnormalities of K^+ balance are potentially life-threatening. In the kidney, K^+ is filtered at the glomerulus, reabsorbed in the proximal tubule, and excreted in the distal tubule. Distal tubular K^+ excretion is regulated primarily by the mineralocorticoid aldosterone. Renal K^+ excretion is primarily dependent on the urinary flow rate, and continues for significant periods even after the intake of K^+ is decreased. Thus, by the time urinary $[K^+]$ decreases, the systemic K^+ pool has been depleted significantly. In general, the greater the urine flow the greater the urinary K^+ excretion.

The causes of net K^+ loss are primarily renal in origin. Gastrointestinal losses through nasogastric suction or vomiting reduce total body K^+ to some degree. However, the resultant volume depletion results in an increase in plasma aldosterone, promoting renal excretion of K^+ in exchange for Na^+ reclamation to preserve circulatory volume. Diuretics (especially thiazides), mineralocorticoids, and intrinsic renal tubular diseases (eg, Bartter syndrome) enhance the renal excretion of K^+. Systemic K^+ depletion in hypokalemic metabolic acidosis may lead to "paradoxic aciduria" and low urine pH wherein H^+ is preferentially exchanged for Na^+ in response to aldosterone. Clinically, hypokalemia is associated with neuromuscular excitability, decreased peristalsis or ileus, hyporeflexia, paralysis, rhabdomyolysis, and arrhythmias. Electrocardiographic changes include flattened T waves, a shortened PR interval, and the appearance of U waves. Arrhythmias associated with hypokalemia include premature ventricular contractions; atrial, nodal, or ventricular tachycardia; and ventricular fibrillation. Hypokalemia increases responsiveness to digitalis and may precipitate overt digitalis toxicity. In the presence of arrhythmias, extreme muscle weakness, or respiratory compromise, intravenous K^+ should be given. If the patient is hypophosphatemic ($[PO_4^{3-}]< 2$ mg/dL), a phosphate salt may be used. The first priority in the treatment of hypokalemia is the restoration of an adequate serum $[K^+]$. Providing maintenance amounts of K^+ is usually sufficient; however, when the serum $[K^+]$ is dangerously low and K^+ must be administered intravenously, it is imperative that the patient have a cardiac monitor. Intravenous K^+ should generally not be given faster than at a rate of 0.3 mEq/kg/h. Oral K^+ supplements may be needed for weeks to replenish depleted body stores.

Hyperkalemia—due to decreased renal K^+ excretion, mineralocorticoid deficiency or unresponsiveness, or K^+ release from the ICF compartment—is characterized by muscle weakness, paresthesias, and tetany; ascending paralysis; and arrhythmias. Electrocardiographic changes associated with hyperkalemia include peaked T waves, widening of the QRS complex, and arrhythmias such as sinus bradycardia or sinus arrest, atrioventricular block, nodal or idioventricular rhythms, and ventricular tachycardia or fibrillation. The severity of hyperkalemia depends on the electrocardiographic changes, the status of the other electrolytes, and the stability of the underlying disorder. A rhythm strip should be obtained when significant hyperkalemia is suspected. If the serum $[K^+]$ is less than 6.5 mEq/L, discontinuing K^+ supplementation may be sufficient if there is no ongoing K^+ source, such as cell lysis, and if urine output continues. If the serum $[K^+]$ is greater than 7 mEq/L or if potentiating factors such as hyponatremia, digitalis toxicity, and renal failure are present, more aggressive therapy is needed. If electrocardiographic changes or arrhythmias are present, treatment must be initiated promptly. Intravenous 10% calcium gluconate (0.2–0.5 mL/kg over 2–10 minutes) will rapidly ameliorate depolarization and may be repeated after 5 minutes if electrocardiographic changes persist. Calcium should be given only with a cardiac monitor in place and should be discontinued if bradycardia develops. The intravenous administration of a diuretic that acts in the loop of Henle, such as furosemide (1–2 mg/kg), will augment renal K^+ excretion and can be very helpful in lowering serum and total body $[K^+]$. Administering Na^+ and increasing systemic pH with bicarbonate therapy (1–2 mEq/kg) will shift K^+ from the ECF to the ICF compartment, as will therapy with a β-agonist such as albuterol. In nondiabetic patients, 0.5 g/kg of glucose over 1–2 hours will enhance endogenous insulin secretion, lowering serum $[K^+]$ 1–2 mEq/L. Administration of intravenous glucose and insulin may be needed as a

simultaneous drip (0.5–1 g/kg glucose and 0.3 units of regular insulin per gram of glucose) given over 2 hours with monitoring of the serum glucose level every 15 minutes.

The therapies outlined above provide transient benefits. Ultimately, K^+ must be reduced to normal levels by reestablishing adequate renal excretion using diuretics or optimizing urinary flow, using ion exchange resins such as sodium polystyrene sulfonate orally or as a retention enema (0.2–0.5 g/kg orally or 1 g/kg as an enema), or by dialysis.

▼ ACID-BASE DISTURBANCES

When evaluating a disturbance in acid-base balance, the systemic pH, partial carbon dioxide pressure (P_{CO_2}), serum HCO_3^-, and anion gap must be considered. The anion gap, $Na^+ - (Cl^- + HCO_3^-)$, is an expression of the unmeasured anions in the plasma and is normally 12 ± 4 mEq/L. An increase above normal suggests the presence of an unmeasured anion, such as occurs in diabetic ketoacidosis, lactic acidosis, salicylate intoxication, and so on. Although the base excess (or deficit) is also used clinically, it is important to recall that this expression of acid-base balance is influenced by the renal response to respiratory disorders and cannot be interpreted independently (as in a compensated respiratory acidosis, wherein the base excess may be quite large). Recently, there has been greater interest in the Stewart approach to acid-base disturbances and the calculation of the "strong ion difference," which is beyond the scope of the present discussion. The interested reader is referred to the review by Gunnerson and Kellum listed in the references at the end of this chapter.

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by a primary decrease in serum $[HCO_3^-]$ and systemic pH due to the loss of HCO_3^- from the kidneys or gastrointestinal tract, the addition of an acid (from external sources or via altered metabolic processes), or the rapid dilution of the ECF with nonbicarbonate–containing solution (usually normal saline). When HCO_3^- is lost through the kidneys or gastrointestinal tract, Cl^- must be reabsorbed with Na^+ disproportionately, resulting in a hyperchloremic acidosis with a normal anion gap. Thus, a normal anion gap acidosis in the absence of diarrhea or other bicarbonate-rich gastrointestinal losses suggests the possibility of renal tubular acidosis and should be evaluated appropriately. (See Chapter 24.) In contrast, acidosis that results from addition of an unmeasured acid is associated with a widened anion gap. Examples are diabetic ketoacidosis, lactic acidosis, starvation, uremia, toxin ingestion (salicylates, ethylene glycol, or methanol), and certain inborn errors of organic or amino acid metabolism. Dehydration may also result in a widened anion gap acidosis as a result of inadequate tissue perfusion, decreased O_2 delivery, and subsequent lactic and keto acid production. Respiratory compensation is accomplished through an increase in minute ventilation and a decrease in P_{CO_2}. The patient's history, physical findings, and laboratory features should lead to the appropriate diagnosis.

The ingestion of unknown toxins or the possibility of an inborn error of metabolism (see Chapter 36) must be considered in children without an obvious cause for a widened anion gap acidosis. Unfortunately, some hospital laboratories fail to include ethylene glycol or methanol in their standard toxicology screens, so assay of these toxins must be requested specifically. This is of critical importance when therapy with fomepizole (4-methylpyrazole) must be considered for either ingestion—and instituted promptly to obviate profound toxicity. Ethylene glycol (eg, antifreeze) is particularly worrisome because of its sweet taste and accounts for a significant number of toxin ingestions. Screening by fluorescence of urine under a Wood lamp is relatively simple but does not replace specific laboratory assessment. Salicylate intoxication has a stimulatory effect on the respiratory center of the CNS; thus, patients may initially present with respiratory alkalosis or mixed respiratory alkalosis and widened anion gap acidosis.

Most types of metabolic acidosis will resolve with correction of the underlying disorder, improved renal perfusion, and acid excretion. Intravenous $NaHCO_3$ administration may be considered in the setting of metabolic acidosis when the pH is less than 7.0 or the $[HCO_3^-]$ is less than 5 mEq/L,

but only if adequate ventilation is ensured. The dose (in milliequivalents) of $NaHCO_3$ may be calculated as

$$\text{Weight (kg)} \times \text{Base deficit} \times 0.3$$

and given as a continuous infusion over 1 hour. The effect of $NaHCO_3$ in lowering serum potassium and ionized calcium concentrations must also be considered and monitored.

METABOLIC ALKALOSIS

Metabolic alkalosis is characterized by a primary increase in $[HCO_3^-]$ and pH resulting from a loss of strong acid or gain of buffer base. The most common cause for a metabolic alkalosis is the loss of gastric juice via nasogastric suction or vomiting. This results in a Cl^--responsive alkalosis, characterized by a low urinary $[Cl^-]$ (< 20 mEq/L) indicative of a volume-contracted state that will be responsive to the provision of adequate Cl^- salt (usually in the form of normal saline). Cystic fibrosis may also be associated with a Cl^--responsive alkalosis due to the high losses of NaCl through the sweat, whereas congenital Cl^--losing diarrhea is a rare cause of Cl^--responsive metabolic alkalosis. Chloride-resistant alkaloses are characterized by a urinary $[Cl^-]$ greater than 20 mEq/L and include Bartter syndrome, Cushing syndrome, and primary hyperaldosteronism, conditions associated with primary increases in urinary $[Cl^-]$, or volume-expanded states lacking stimuli for renal Cl^- reabsorption. Thus, the urinary $[Cl^-]$ is helpful in distinguishing the nature of a metabolic alkalosis, but must be specifically requested in many laboratories because it is not routinely included in urine electrolyte panels. The serum $[K^+]$ is also low in these settings (hypokalemic metabolic alkalosis) owing to a combination of increased mineralocorticoid activity associated with volume contraction, the shift of K^+ to the ICF compartment, and preferential reabsorption of Na^+ rather than K^+ to preserve intravascular volume. A hypokalemic alkalosis seen in the setting of primary mineralocorticoid excess would be expected to be associated with systemic hypertension clinically, as observed in an adrenal adenoma.

RESPIRATORY ACIDOSIS

Respiratory acidosis develops when alveolar ventilation is decreased, increasing PCO_2 and lowering systemic pH. The kidneys compensate for respiratory acidosis by increasing HCO_3^- reabsorption, a process that takes several days to fully manifest. Patients with acute respiratory acidosis frequently demonstrate air hunger with retractions and the use of accessory respiratory muscles. Respiratory acidosis occurs in upper or lower airway obstruction, ventilation-perfusion disturbances, CNS depression, and neuromuscular defects. Hypercapnia is not as detrimental as the hypoxia that usually accompanies these disorders. The goal of therapy is to correct or compensate for the underlying pathologic process to improve alveolar ventilation. Bicarbonate therapy is not indicated in a pure respiratory acidosis, because it will worsen the acidosis by shifting the equilibrium of the carbonic acid–bicarbonate buffer system to increase PCO_2.

RESPIRATORY ALKALOSIS

Respiratory alkalosis occurs when hyperventilation results in a decrease in PCO_2 and an increase in systemic pH. Depending on the acuity of the respiratory alkalosis, there may be an associated compensatory loss of bicarbonate by the kidneys manifested as a low serum bicarbonate level and a normal anion gap that may be misinterpreted as a normal anion gap acidosis if all acid-base parameters are not considered. Patients may experience tingling, paresthesias, dizziness, palpitations, syncope, or even tetany and seizures due to the associated decrease in ionized calcium. Causes of respiratory alkalosis include psychobehavioral disturbances, CNS irritation from meningitis or encephalitis, salicylate intoxication, and iatrogenic over ventilation in patients who are mechanically ventilated. Therapy is directed toward the causal process. Rebreathing into a paper bag will decrease the severity of symptoms in acute hyperventilation.

Kidney & Urinary Tract

Gary M. Lum, MD

▼ EVALUATION OF THE KIDNEY & URINARY TRACT

HISTORY

When renal disease is suspected, the history should include

1. Family history of cystic disease, hereditary nephritis, deafness, dialysis, or renal transplantation
2. Preceding acute or chronic illnesses (eg, urinary tract infection [UTI], pharyngitis, impetigo, or endocarditis)
3. Rashes or joint pains
4. Growth delay or failure to thrive
5. Polyuria, polydipsia, enuresis, urinary frequency, or dysuria
6. Documentation of hematuria, proteinuria, or discolored urine
7. Pain (abdominal, costovertebral angle, or flank) or trauma
8. Sudden weight gain or edema
9. Drug or toxin exposure
10. Data pertaining to the newborn with suspected urinary tract disease: prenatal ultrasonographic studies, birth asphyxia, Apgar scores, oligohydramnios, dysmorphic features, abdominal masses, voiding patterns, anomalous development, and umbilical artery catheterization

PHYSICAL EXAMINATION

Important aspects of the physical examination include the height, weight, skin lesions (café au lait or ash leaf spots), pallor, edema, or skeletal deformities. Anomalies of the ears, eyes, or external genitalia may be associated with renal anomalies or disease. The blood pressure should be measured in a quiet setting. The cuff should cover two-thirds of the child's upper arm, and peripheral pulses should be noted. The abdomen should be palpated, with attention to the kidneys, abdominal masses, musculature, and the presence of ascites. An ultrasonic device is useful for measurements in infants.

LABORATORY EVALUATION OF RENAL FUNCTION

Serum Analysis

The standard indicators of renal function are serum levels of urea nitrogen and creatinine; their ratio is normally about 10:1. This ratio may increase when renal perfusion or urine flow is decreased, as in urinary tract obstruction or dehydration. Because serum urea nitrogen levels are more affected by these and other factors (eg, nitrogen intake, catabolism, use of corticosteroids) than are creatinine levels, the most reliable single indicator of glomerular function is the serum level of creatinine. For example, an increase in serum creatinine from 0.5 to 1.0 mg/dL represents a 50% decrease in glomerular filtration rate. The serum creatinine level of small children should be well under 0.8 mg/dL. Only larger adolescents should have levels exceeding 1 mg/dL. Less precise but nonetheless important indicators of possible renal disease are abnormalities of serum electrolytes, pH, calcium, phosphorus, magnesium, albumin, or complement.

Glomerular Filtration Rate

The endogenous creatinine clearance (C_{cr}) in milliliters per minute estimates the glomerular filtration rate (GFR). A 24-hour urine collection is the "classic" approach for determining creatinine clearance; however, it is often difficult to obtain in the pediatric population. The procedure for collecting a timed urine specimen should be explained carefully so that the parent or patient understands fully the rationale of (1) first emptying the bladder (discarding that urine) and noting the time; and (2) putting all urine subsequently voided into the

collection receptacle, including the last void, 24 hours later. Reliability of the 24-hour collection can be checked by measuring the total 24-hour creatinine excretion in the specimen. Total daily creatinine excretion (creatinine index) should be 14–20 mg/kg. Creatinine indices on either side of this range suggest collections that were either inadequate or excessive. Calculation by the following formula requires measurements of plasma creatinine (P_{cr}) in mg/mL, urine creatinine (U_{cr}) in mg/mL, and urine volume (V) expressed as mL/min:

$$C_{cr} = \frac{U_{cr}V}{P_{cr}}$$

Creatinine is a reflection of body muscle mass. Because accepted ranges of normal C_{cr} are based on adult parameters, correction for size is needed to determine normal ranges in children. Clearance is corrected to a standard body surface area of 1.73 m^2 in the formula:

$$\text{"Corrected" C} = \frac{\text{Patient's } C_{cr} \times 1.73 \text{ m}^2}{\text{Patient's body surface area}}$$

Although 80–125 mL/min/1.73 m^2 is the normal range for C_{cr}, estimates at the lower end of this range may indicate problems.

The Schwartz formula is a reliable formula for quick approximation of C_{cr} based on plasma creatinine level and length in centimeters:

$$C_{cr} \text{ (mL/min/1.73 m}^2\text{)} = k \times \text{height (cm)}/P_{cr} \text{ (mg/dL)}$$

where k is a constant: 0.45 for infants 1–52 weeks old, 0.55 for children 1–13 years old, 0.55 for females 1–18 years old, and 0.7 for males 13–18 years old.

Urine Concentrating Ability

Inability to concentrate urine causes polyuria, polydipsia, or enuresis and is often the first sign of chronic renal failure, and, in some cases, raises the possibility of diabetes insipidus. The first morning void should be concentrated (specific gravity 1.020 or higher), presuming cessation of drinking anything through the night. Thus, determination of the specific gravity of a first morning void is an easy and helpful test of the kidney's concentrating ability.

Urinalysis

Commercially available dipsticks can be used to screen the urine for blood leukocytes, nitrites, protein, and specific gravity and to approximate the urine pH. Positive results for blood should always be confirmed by microscopy, which is also the only way to determine if there is significant crystalluria. Significant proteinuria (> 150 mg/dL) detected by dipstick should be confirmed by quantitation, either with a 24-hour urine collection or by the protein/creatinine ratio of a random specimen.

In children with asymptomatic hematuria or proteinuria, the search for renal origins will yield the most results. Isolated proteinuria may also reflect urologic abnormalities, benign excretion, or glomerular alterations. RBC casts suggest glomerulonephritis (GN), but the absence of casts does not rule out this disease. Anatomic abnormalities such as cystic disease may also cause hematuria.

Benign hematuria, including benign familial hematuria, is diagnosed by exclusion. In this group are children whose hematuria is caused by asymptomatic hypercalciuria. Figure 24–1 suggests an approach to the renal workup of hematuria. GN is discussed in more detail later in this chapter.

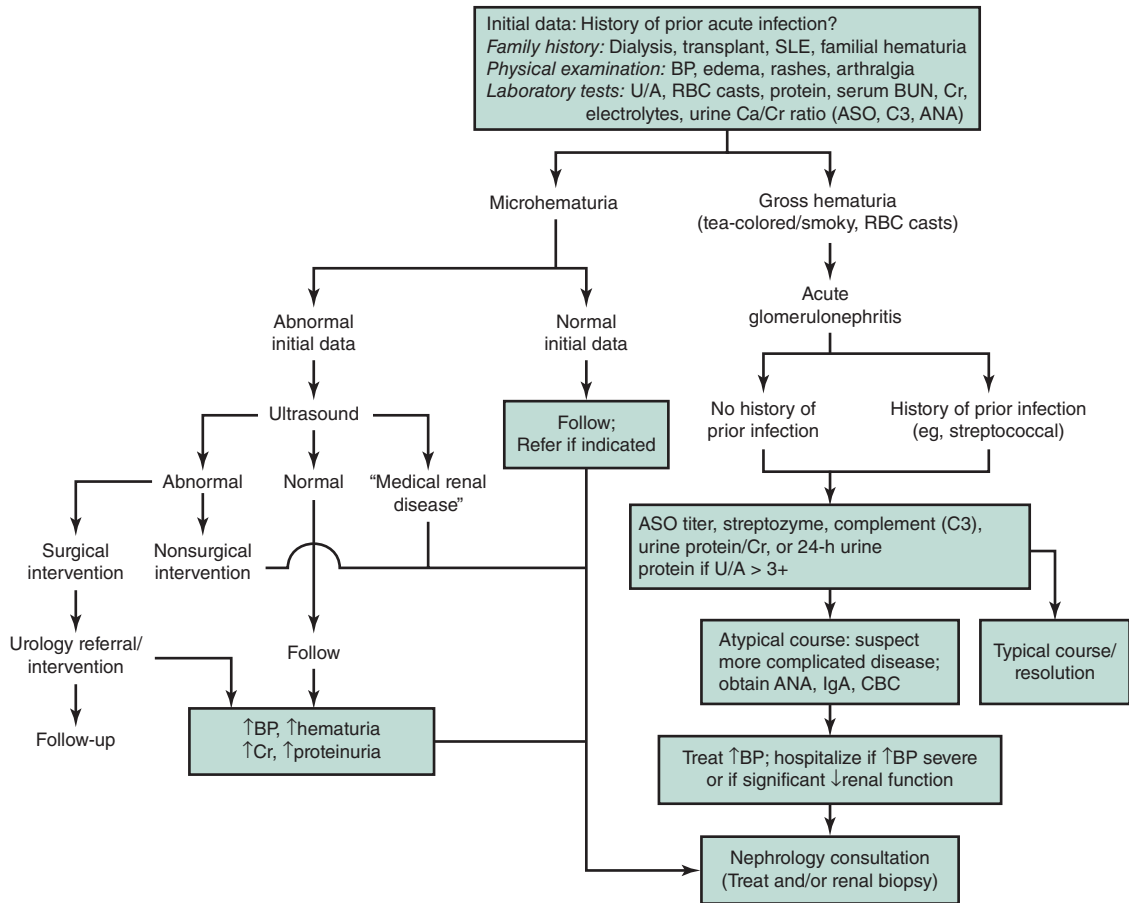
Combined proteinuria and hematuria is characteristic of more significant glomerular disease. Quantitation of proteinuria is customarily accomplished by a timed collection (eg, over a 24-hour period). However, given the frequency of errors in collection in the pediatric population, the degree of proteinuria may be estimated by the ratio of protein mg/dL/creatinine mg/dL in a random urine sample. A protein/creatinine ratio above 0.2 is abnormal. If the laboratory reports this as mg protein/gram of creatinine, normal is 200 or less.

In the evaluation of asymptomatic proteinuria, orthostatic or postural proteinuria should be ruled out. This can be accomplished simply by comparing the protein/creatinine ratio of urine formed in the supine position (the first morning void accumulated in the bladder while sleeping) to a sample obtained during daily ambulation. If the "supine" sample is normal and proteinuria is occurring only during upright posture, this demonstrates postural (benign) proteinuria. If both samples are abnormal, proteinuria would be considered "persistent."

An approach to the workup of isolated proteinuria, including nephrotic syndrome, is shown in Figure 24–2. Note that corticosteroid therapy is included in the algorithm because this may be initiated for nephrotic syndrome prior to referral. Other renal lesions with proteinuric manifestations are discussed later in this chapter.

Special Tests of Renal Function

Measurements of urinary sodium, creatinine, and osmolality are useful in differentiating prerenal from renal causes of renal insufficiency, such as acute tubular necrosis. Prolonged underperfusion causes varying increases in serum creatinine and blood urea nitrogen (BUN) concentrations, prompting the need to differentiate between this state and acute tubular necrosis (see section Acute Renal Failure). The physiologic response to decreased renal perfusion is decreased urinary output, increased urine osmolality, increased urinary solutes (eg, creatinine), and decreased urinary sodium (usually < 20 mEq/L).

The presence of certain substances in urine may suggest tubular dysfunction. For example, urine glucose should be less than 5 mg/dL. Hyperphosphaturia occurs with significant tubular abnormalities (eg, Fanconi syndrome). Measurement of the phosphate concentration of a 24-hour urine specimen


▲ **Figure 24–1.** Approach to the renal workup of hematuria. (Exclude UTI, lithiasis, trauma, bleeding disorders, sickle cell disease.) Complement is depressed in acute poststreptococcal type of glomerulonephritis (about 30 days), chronic glomerulonephritis (persistent), and lupus. ANA, antinuclear antibody; ASO, antistreptolysin antibody; BP, blood pressure; BUN, blood urea nitrogen; C3, complement; Ca, calcium; CBC, complete blood count; Cr, creatinine; IgA, immunoglobulin A; RBC, red blood cell; SLE, systemic lupus erythematosus; U/A, urinalysis.

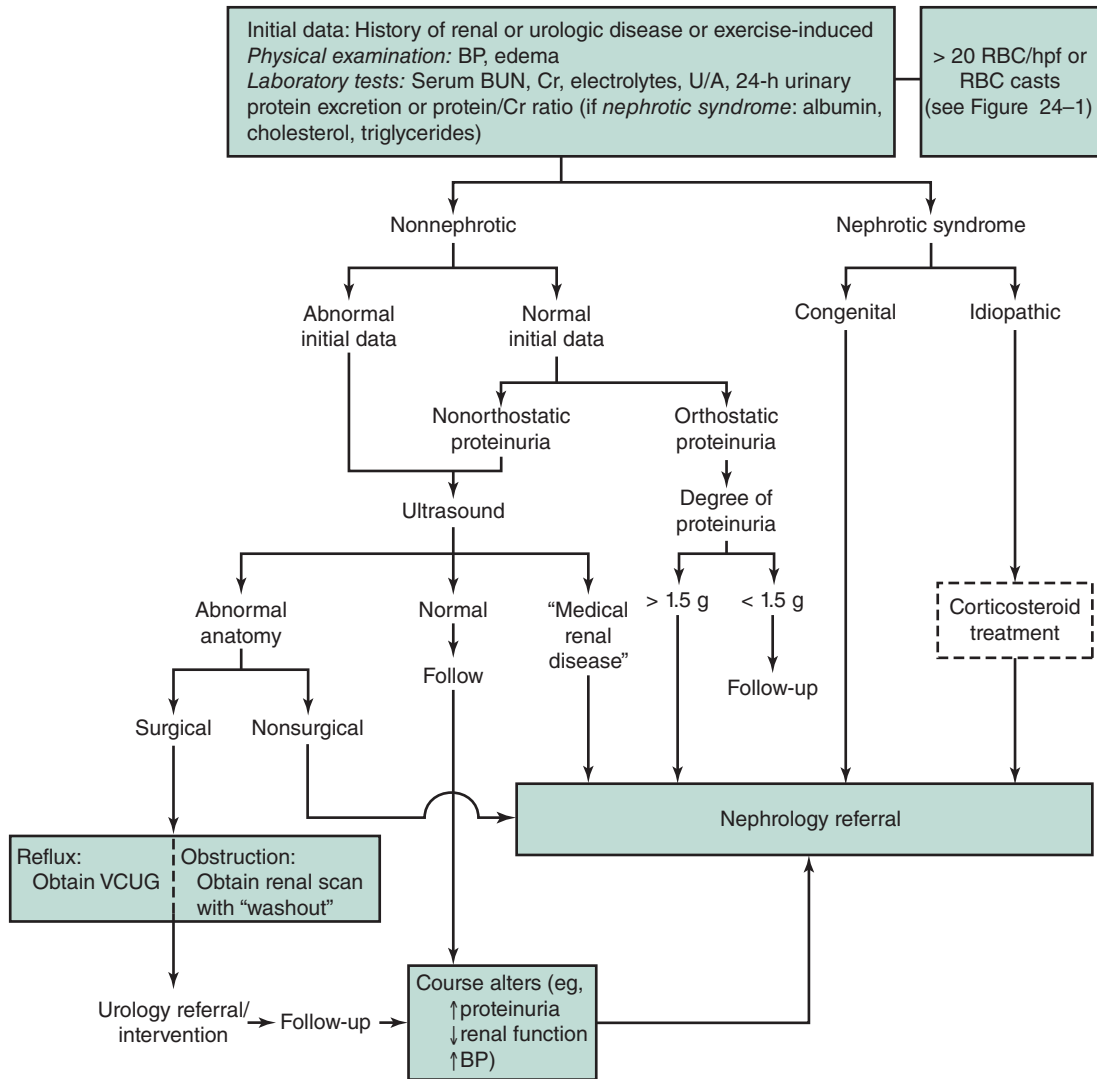
and evaluation of tubular reabsorption of phosphorus (TRP) will help document renal tubular diseases as well as hyperparathyroid states. TRP (expressed as percentage of reabsorption) is calculated as follows:

$$TRP = 100 \left[1 - \frac{S_{cr} \times U_{PO_4}}{S_{PO_4} \times U_{cr}} \right]$$

where S_{cr} = serum creatinine; U_{cr} = urine creatinine; S_{PO_4} = serum phosphate; and U_{PO_4} = urine phosphate. All values for creatinine and phosphate are expressed in milligrams per deciliter for purposes of calculation. A TRP value of 80% or more is considered normal, although it depends somewhat on the value of S_{PO_4}.

The urinary excretion of amino acids in generalized tubular disease reflects a quantitative increase rather than a qualitative change. Diseases affecting proximal tubular reabsorption of bicarbonate—including isolated renal tubular acidosis (RTA), Fanconi syndrome (which occurs in diseases such as cystinosis), and chronic renal failure—are discussed later in the chapter.

LABORATORY EVALUATION OF IMMUNOLOGIC FUNCTION

Many parenchymal renal diseases are thought to have immune causation, although the mechanisms are largely unknown. Examples include (1) deposition of circulating antigen-antibody complexes that are directly injurious or incite injurious responses and (2) formation of antibody


▲ **Figure 24–2.** Approach to the workup of isolated proteinuria. BP, blood pressure; Cr, creatinine; hpf, high-power field; RBC, red blood cell; U/A, urinalysis; VCUG, voiding cystourethrogram. Rules out benign postural proteinuria with urine protein/creatine ratio of first morning void (recumbent urine) versus day void (upright). Will normalize within a month in poststreptococcal glomerulonephritis.

directed against the glomerular basement membrane (rare in children).

C3 and C4 complement components should be measured when immune-mediated renal injury or chronic GN is suspected. Where clinically indicated, antinuclear antibodies, hepatitis B surface antigen, and rheumatoid factor should be obtained. In rare cases, cold-precipitable proteins (cryoglobulins), C3 "nephritic" factor, or antiglomerular basement membrane (anti-GBM) antibody measurements may help

confirm a specific diagnosis. At some point in the workup, the diagnosis may be supported or confirmed by histologic examination of renal tissue.

RADIOGRAPHIC EVALUATION

Renal ultrasonography is a useful noninvasive tool for evaluating renal parenchymal disease, urinary tract abnormalities, or renal blood flow. Excretory urography is used to assess the

anatomy and function of the kidneys, collecting system, and bladder. Radioisotope studies provide information about renal anatomy, blood flow, and integrity and function of the glomerular, tubular, and collecting systems. Renal stones are best seen by computed tomography.

Voiding cystourethrography or cystoscopy is indicated when vesicoureteral reflux (VUR) or bladder outlet obstruction is suspected. Cystoscopy is rarely useful in the evaluation of asymptomatic hematuria or proteinuria in children.

Renal arteriography or venography is indicated to define vascular abnormalities (eg, renal artery stenosis) prior to surgical intervention or transluminal angiography. Less invasive measures such as ultrasonography and Doppler studies can demonstrate renal blood flow or thromboses. More specific identification of stenoses of the renal artery is accomplished by magnetic resonance arteriography.

RENAL BIOPSY

Histologic information is valuable for diagnosis, to guide treatment, and to inform prognosis. Satisfactory evaluation of renal tissue requires examination by light, immuno-fluorescence, and electron microscopy. The need for a renal biopsy should be determined by a pediatric nephrologist.

▼ CONGENITAL ANOMALIES OF THE URINARY TRACT

RENAL PARENCHYMAL ANOMALIES

About 10% of children have congenital anomalies of the genitourinary tract, which range in severity from asymptomatic to lethal. Some asymptomatic abnormalities may have significant complications. For example, patients with "horseshoe" kidney (kidneys fused in their lower poles), although not representing renal parenchymal disease or reduction in kidney function, have a higher incidence of renal calculi. Unilateral agenesis or multicystic dysplasia is usually accompanied by compensatory hypertrophy of the contralateral kidney and thus should be compatible with normal renal function, requiring no specific nephrology referral or follow-up. Supernumerary and ectopic kidneys are usually of no significance. Abnormal genitourinary tract development is associated with varying degrees of renal dysgenesis and dysfunction ranging from mild to severe; an example of the latter is in utero bilateral renal agenesis, which is associated with severe oligohydramnios, pulmonary hypoplasia, abnormal (Potter) facies, and perinatal death.

1. Renal Dysgenesis

Renal dysgenesis is a spectrum of anomalies. In simple hypoplasia, which may be unilateral or bilateral, the affected kidneys are smaller than normal. In some forms of dysgenesis, immature, undifferentiated renal tissue persists. In some situations, the number of normal nephrons is insufficient to sustain life once the child reaches a critical body size. The lack of adequate renal tissue may not be readily discernible in the newborn period in the presence of normal urine production. Often, discovery of renal insufficiency in an infant is coincident with blood work drawn for other purposes showing an elevated serum creatinine.

Other forms of renal dysgenesis include oligomeganephronia (characterized by the presence of only a few large glomeruli) and the cystic dysplasias (characterized by the presence of renal cysts). This group includes microcystic disease (congenital nephrosis). A simple cyst within a kidney, different from either autosomal recessive or dominant polycystic kidney disease, is clinically unimportant. An entire kidney lost to multicystic development with concomitant hypertrophy and normal function of the contralateral side should also be of no clinical consequence.

2. Polycystic Kidney Disease

Both forms of polycystic kidney disease (autosomal dominant [ADPKD] or recessive [ARPKD]) are increasingly diagnosed by prenatal ultrasound. In its most severe form (ARPKD), the cystic kidneys are nonfunctional in utero, and, therefore, newborns can have Potter facies and other complications of oligohydramnios. In infancy and childhood, kidney enlargement by cysts may initially be recognized by abdominal palpation of renal masses. Hypertension is an early problem in ARPKD. The rate of the progression of renal insufficiency varies, as does growth failure, other complications of chronic renal failure, and early development of end-stage renal disease. In ADPKD, two genes, *ADPKD1* and *ADPKD2*, account for 80% and 10% of cases, respectively. Susceptibility of family members is detected by gene linkage studies. Renal ultrasound identifies cysts in about 80% of affected children by age 5 years. Children with this diagnosis need monitoring for the development and treatment of hypertension, which usually develops in the teenage years. These patients would not be expected to develop renal insufficiency, if any, until later in adult years.

3. Medullary Cystic Disease (Juvenile Nephronophthisis)

Medullary cystic disease is characterized by cysts of varying sizes in the renal medulla with tubular and interstitial nephritis. Children present with renal failure and signs of tubular dysfunction (decreased concentrating ability, Fanconi syndrome). This lesion should not be confused with medullary sponge kidney (renal tubular ectasia), a frequently asymptomatic disease occurring in adults.

DISTAL URINARY TRACT ANOMALIES

1. Obstructive Uropathy

Obstruction at the ureteropelvic junction may be the result of intrinsic muscle abnormalities, aberrant vessels, or fibrous bands. The lesion can cause hydronephrosis and usually presents as an abdominal mass in the newborn. Obstruction can occur in other parts of the ureter, especially at its entrance into the bladder, causing proximal hydroureter and hydronephrosis. Renal radionuclide scan with furosemide "wash-out" will reveal or rule out obstruction as the cause of the hydronephrosis. Whether intrinsic or extrinsic, urinary tract obstruction should be relieved surgically as soon as possible to minimize damage to the kidneys.

Severe bladder malformations such as exstrophy are clinically obvious and a surgical challenge. More subtle—but urgent in terms of diagnosis—is obstruction of urine flow from vestigial posterior urethral valves. This anomaly, which occurs almost exclusively in males, usually presents in newborns with anuria or a poor voiding stream secondary to severe obstruction of urine flow. The kidneys and bladder may be easily palpable. Leakage (ureteric perforation, although rare) proximal to the obstruction may produce urinary ascites. Surgical drainage of urine is urgently required to prevent irreversible damage.

Prune belly syndrome is an association of urinary tract anomalies with cryptorchidism and absent abdominal musculature. Although complex anomalies, especially renal dysplasia, usually cause early death or the need for dialysis or transplantation, some patients have lived into the third decade with varying degrees of renal insufficiency. Timely urinary diversion is essential to sustain renal function.

Other complex malformations and external genital anomalies such as hypospadias are beyond the scope of this text. The challenge presented by urologic abnormalities resulting in severe compromise and destruction of renal tissue is to preserve all remaining renal function and treat the complications of progressive chronic renal failure. Involvement of a specialist in pediatric urology in early management is essential.

2. Reflux Nephropathy

The retrograde flow of urine from the bladder into the ureter (vesicoureteral reflux) may cause renal scarring and subsequent renal insufficiency or hypertension, or both, especially in the presence of UTI. A finding of hydronephrosis on renal ultrasound is suggestive of vesicoureteral reflux. Its presence can be confirmed or eliminated by a voiding cystourethrogram, which would also be obtained to rule out reflux in the evaluation of UTI. Low-grade reflux may resolve in the absence of infection, in which case antibiotic prophylaxis (advised with any degree of reflux) is undertaken while awaiting signs of spontaneous resolution. Surgery may be required for chronic severe reflux.

▼ HEMATURIA & GLOMERULAR DISEASE

MICROHEMATURIA

Children with painful hematuria should be investigated for UTI or direct injury to the urinary tract. Dysuria is common in cystitis or urethritis; associated back pain suggests the possibility of pyelonephritis; colicky flank pain may indicate the passage of a stone. Bright red blood or clots in the urine are associated with bleeding disorders, trauma, and arteriovenous malformations. Abdominal masses suggest the presence of urinary tract obstruction, cystic disease, or tumors of the renal or perirenal structures.

Asymptomatic hematuria is a challenge because clinical and diagnostic data are required to decide whether to refer the child to a nephrologist. The diagnosis of hematuria should not rely solely on a urine "dipstick" evaluation, but should be verified by a microscopic RBC count. Ruling out hypercalciuria as a cause of hematuria by a random urine calcium/creatinine ratio is one of the initial steps in the evaluation of hematuria. A value above 0.2 requires verification with a 24-hour collection. Hypercalciuria is excretion of calcium in excess of 4 mg/kg/d. Figure 24–1 delineates the outpatient approach to renal hematuria. The concern regarding the differential diagnosis is the possible presence of glomerular disease.

GLOMERULONEPHRITIS

The various types of glomerulonephritis (GN) have similar manifestations. Table 24–1 lists the most commonly encountered disorders in the differential diagnosis of childhood GN, including their clinical and histopathologic abnormalities. Severe glomerular histopathologic and clinical entities, such as anti-GBM antibody disease (Goodpasture syndrome), Wegener granulomatosis, and idiopathic, rapidly progressive GN, may be considered in the differential diagnosis of acute GN, but these disorders are exceedingly rare in children.

1. Acute Poststreptococcal Glomerulonephritis

The diagnosis of acute poststreptoccocal glomerulonephritis is supported by a recent history (7–14 days previously) of group A β-hemolytic streptococcal infection, typically involving the pharynx or skin. If a positive culture is not available, recent infection may be supported by an elevated antistreptolysin O titer or by high titers of other antistreptococcal antibodies. Other infections can cause similar glomerular injury; thus, "postinfection" glomerulonephritis

Table 24–1. Glomerular diseases encountered in childhood.

Entity	Clinical Course	Prognosis
Postinfection glomerulonephritis (GN). Onset occurs 10–14 d after acute illness, commonly streptococcal. Characteristics include acute onset, tea-colored urine, mild to severe renal insufficiency, and edema.	Acute phase is usually over in 2 wk. Complete resolution occurs in 95% of cases. Severity of renal failure and hypertension varies. Microhematuria may persist to 18 mo. Hypocomplementemia resolves in 1–30 d.	Excellent. Chronic disease is rare. Severe proteinuria, atypical presentation or course, or persistent hypocomplementemia suggest another entity.
Membranoproliferative GN. Presentation ranges from mild microhematuria to acute GN syndrome. Diagnosis is made by renal biopsy. Etiology is unknown. Types I and II are most common. Lesion is chronic.	Course can be mild to severe (rapid deterioration in renal function); may mimic postinfection GN. Proteinuria can be severe. Complement depression is intermittent to persistent. Hypertension is usually significant.	Type I may respond to corticosteroids. Type II (dense deposit disease) is less responsive to treatment; function decrease varies from immediate to as long as 15 y in 30%–50% of untreated cases.
IgA nephropathy. Classic presentation is asymptomatic gross hematuria during acute unrelated illness, with microhematuria between episodes. Occasional instances of acute GN syndrome occur. Etiology is unknown. Diagnosis is made by biopsy.	90% of cases resolve in 1–5 y. Gross hematuric episodes resolve with recovery from acute illness. Severity of renal insufficiency and hypertension varies. Proteinuria occurs in more severe, atypical cases.	Generally good; a small percentage develops chronic renal failure. Proteinuria in the nephrotic range is a poor sign. There is no universally accepted medication. (Corticosteroids may be useful in severe cases.)
Henoch-Schönlein purpura GN. Degree of renal involvement varies. Asymptomatic microhematuria is most common, but GN syndrome can occur. Renal biopsy is recommended in severe cases; it can provide prognostic information.	Presentation varies with severity of renal lesion. In rare cases, may progress rapidly to serious renal failure. Hypertension varies. Proteinuria in the nephrotic range and severe decline in function can occur.	Overall, prognosis is good. Patients presenting with > 50% reduction in function or proteinuria exceeding 1 g/24 h may develop chronic renal failure. Severity of renal biopsy picture can best guide approach in such cases. There is no universally accepted medication therapy.
GN of systemic lupus erythematosus (SLE). Microhematuria and proteinuria are rarely first signs of this systemic disease. Renal involvement varies, but severe GN may ensue with remissions and exacerbations throughout the course.	Renal involvement is mild to severe. Clinical complexity depends on degree of renal insufficiency and other systems involved. Serum complement is depressed. Hypertension is significant. Manifestations of the severity of the renal lesion guide therapeutic intervention.	Renal involvement accounts for most significant morbidity in SLE. Control of hypertension affects renal prognosis. Medication is guided by symptoms, serology, and renal lesion. End-stage renal failure can occur.
Hereditary GN (eg, Alport syndrome). Transmission is autosomal-dominant/X-linked, with family history marked by end-stage renal failure, especially in young males. Deafness and eye abnormalities are associated.	There is no acute syndrome. Females are generally less affected but are carriers. Hypertension and increasing proteinuria occur with advancing renal failure. There is no known treatment.	Progressive proteinuria and hypertension occur early, with gradual decline in renal function in those most severely affected. Disease progresses to end-stage renal failure in most males.

(GN) may be a better term for this type of acute glomerulonephritis (AGN). In most cases, recovery is expected and usually complete within weeks. If the diagnosis is in question, or if the renal function of a patient with postinfection GN progressively deteriorates, a renal biopsy should be performed and treatment with corticosteroids initiated.

The clinical presentation of GN is gross hematuria generally accompanied by varying degrees of increase in serum creatinine, edema, and hypertension. Urine may be coffee-colored or tea-colored. Microscopic examination of urine reveals RBCs too numerous to count. Microscopy may reveal RBC casts. If present, these are diagnostic of GN, but their absence does not exclude the diagnosis. Edema is often seen (periorbital, facial, extremities), caused by sodium and water retention resulting from alteration in glomerular function. Symptoms are usually nonspecific. In cases accompanied by hypertension (a common finding), headache may be present. Fever is uncommon. Severe glomerular injury (which usually occurs in severe, acute presentations of the more chronic or destructive forms of GN) may be accompanied by massive proteinuria (nephrotic syndrome), anasarca, ascites, and severe compromise of renal function.

Typical poststreptococcal GN has no specific treatment. Antibiotic therapy is indicated if an infection is still present. Disturbances in renal function and resulting hypertension may require close monitoring, reduction in salt intake, diuretics, or other antihypertensive drugs. In severe cases of renal failure, hemodialysis or peritoneal dialysis may be necessary. Corticosteroids may also be administered in an attempt to influence the course of the GN.

The acute abnormalities generally resolve in 2–3 weeks. Low levels of serum complement (C3) may normalize as early as 24 hours or as late as 30 days after onset. Other complement-consuming glomerulonephritides include membranoproliferative GN (chronic GN with persistent complement depression) and lupus GN. In poststreptococcal GN, although microscopic hematuria may persist for as long as a year, 85% of children recover completely. Persistent deterioration in renal function, urinary abnormalities beyond 18 months, persistent hypocomplementemia, and nephrotic syndrome are ominous signs. If any of these is present, a renal biopsy is indicated.

2. IgA Nephropathy

When asymptomatic gross hematuria appears to accompany a minor acute febrile illness or other stressful occurrence, the diagnosis of IgA nephropathy may be entertained. In contrast to postinfection GN, IgA nephropathy is not associated with prior streptococcal infection, complement is not depressed, and in 50% of cases, serum immunoglobin A is elevated. Often there are no associated symptoms or signs. Gross hematuria resolves within days, and there are no serious sequelae in 85% of cases. Treatment is not indicated, and the prognosis is good in most cases. Prognosis is guarded, however, if severe proteinuria, hypertension, or renal insufficiency is present or develops. In such instances, although no treatment is universally accepted, corticosteroids and other immunosuppressive drugs are used. Omega-3 fatty acids from fish oils are thought to be helpful.

3. Henoch-Schönlein Purpura

The diagnosis of Henoch-Schönlein purpura rests on the presence of a typical maculopapular and purpuric rash found primarily, but not exclusively, on the dorsal surfaces of the lower extremities and buttocks. Most children have abdominal pain, and bloody diarrhea may be present. Joint pain is common, and, depending on the extent of renal involvement, hypertension may be present. Joint and abdominal pain responds to treatment with corticosteroids. Renal involvement ranges from mild GN with microhematuria to severe GN and varying degrees of renal insufficiency. GN with massive proteinuria and renal insufficiency carries a poor prognosis. Twenty percent of such cases result

in end-stage renal failure. There is no universally accepted treatment, but corticosteroids are often administered (see Chapter 30).

4. Membranoproliferative Glomerulonephritis

The most common "chronic" form of GN in childhood is membranoproliferative GN. The diagnosis is established from the histologic appearance of the glomeruli on biopsy tissue. There are two major histologic types of membranoproliferative GN. Clinically, type II carries the worse prognosis, as end-stage renal failure develops in most cases. Type I more often responds to treatment with corticosteroids. C3 is depressed (in both types) and may be useful as a marker of response to treatment.

5. Lupus Glomerulonephritis

The diagnosis of systemic lupus erythematosus (SLE) is based on its numerous clinical features and abnormal laboratory findings that include a positive antinuclear antibody test, depressed serum complement, and increased serum double-stranded DNA. Renal involvement is indicated by varying degrees of hematuria and proteinuria. More severe cases are accompanied by renal insufficiency and hypertension. Significant renal involvement requires treatment with various combinations of immunosuppressive drugs including prednisone (as a primary drug), azathioprine, cyclophosphamide, mycophenalate, tacrolimus, and rituximab, a monoclonal antibody against the B-cell surface antigen CD20. End-stage renal failure develops in 10%–15% of patients with childhood SLE.

6. Hereditary Glomerulonephritis

The most commonly encountered hereditary GN is Alport syndrome, characterized by hearing loss and GN, occurring predominantly in males. It is a chronic form of GN and thus does not present with the clinical features typically seen in patients with acute processes. A family history is generally present, but there is a spontaneous mutation rate of about 18%. In individuals with the progressive form of GN, end-stage renal failure occurs, usually in the second to third decade of life. Although currently there is no treatment for this disorder, careful management of associated hypertension may slow the process.

Sanders JT, Wyatt RJ: IgA nephropathy and Henoch-Schönlein purpura nephritis. Curr Opin Pediatr 2008;20:163–170 [PMID: 18332712].

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis is characterized by diffuse or focal inflammation and edema of the renal interstitium and secondary involvement of the tubules. The condition is most commonly drug related (eg, β-lactam–containing antibiotics, such as methicillin).

Fever, rigor, abdominal or flank pain, and rashes may occur in drug-associated cases. Urinalysis usually reveals leukocyturia and hematuria. Hansel staining of the urinary sediment often demonstrates eosinophils. The inflammation can cause significant deterioration of renal function. If the diagnosis is unclear because of the absence of a history of drug or toxin exposure or the absence of eosinophils in the urine, a renal biopsy may be performed to demonstrate the characteristic tubular and interstitial inflammation. Immediate identification and removal of the causative agent is imperative and may be all that is necessary. Treatment with corticosteroids is helpful in patients with progressive renal insufficiency or nephrotic syndrome. Severe renal failure requires supportive dialysis.

Gonzalez E et al: Early steroid treatment improves the recovery of renal function in patients with drug-induced acute interstitial nephritis. Kidney Int 2008;73:940–946 [PMID: 18185501].

▼ PROTEINURIA & RENAL DISEASE

Urine is rarely completely protein-free, but the average excretion is well below 150 mg/24 h. Small increases in urinary protein can accompany febrile illnesses or exertion and in some cases occur while in the upright posture.

An algorithm for investigation of isolated proteinuria is presented in Figure 24–2. In idiopathic nephrotic syndrome without associated features of GN, treatment with corticosteroids may be initiated. Nephrologic advice or follow-up should be sought, especially in patients with difficult or frequently relapsing unexplained proteinuria.

CONGENITAL NEPHROSIS

Congenital nephrosis is a rare autosomal recessive disorder. The kidneys are pale and large and may show microcystic dilations (microcystic disease) of the proximal tubules and glomerular abnormalities, including proliferation, crescent formation, and thickening of capillary walls. The pathogenesis is not well understood.

Infants with congenital nephrosis commonly have low birth weight, a large placenta, wide cranial sutures, and delayed ossification. Mild edema may be seen after the first few weeks of life. Anasarca follows, and the abdomen can become greatly distended by ascites. Massive proteinuria associated with typical-appearing nephrotic syndrome and hyperlipidemia is the rule. Hematuria is common. If the patient lives long enough, progressive renal failure occurs. Most affected infants succumb to infections by a few months of life.

Treatment prior to dialysis and transplantation has little to offer other than nutritional support and management of the chronic renal failure.

IDIOPATHIC NEPHROTIC SYNDROME OF CHILDHOOD (MINIMAL CHANGE DISEASE)

Nephrotic syndrome is characterized by proteinuria, hypoproteinemia, edema, and hyperlipidemia. It may occur as a result of any form of glomerular disease and may rarely be associated with a several extrarenal conditions. In young children, the disease usually takes the form of idiopathic nephrotic syndrome of childhood (nil disease, lipoid nephrosis, minimal change disease), which has characteristic clinical and laboratory findings, but no well-understood cause.

▶ Clinical Findings

Affected patients are generally younger than age 6 years at onset. Typically, periorbital swelling and oliguria are noted, often following an influenza-like syndrome. Within a few days, increasing edema—even anasarca—becomes evident. Most children have few complaints other than vague malaise or abdominal pain. With significant "third spacing" of plasma volume, however, some children may present with hypotension. With marked edema, dyspnea due to pleural effusions may also occur.

Despite heavy proteinuria, the urine sediment is usually normal, although microscopic hematuria may be present. Plasma albumin concentration is low, and lipid levels increased. When azotemia occurs, it is usually secondary to intravascular volume depletion.

Glomerular morphology is unremarkable except for fusion of foot processes of the glomerular basement membrane. This nonspecific finding is associated with many proteinuric states.

▶ Complications

Infections (eg, peritonitis) sometimes occur, and *Streptococcus pneumoniae* is frequently the cause. Hypercoagulability may be present, and thromboembolic phenomena are commonly reported. Hypertension can be noted, and renal insufficiency can result from decreased renal perfusion.

▶ Treatment & Prognosis

As soon as the diagnosis of idiopathic nephrotic syndrome is made, corticosteroid treatment should be started. Prednisone, 2 mg/kg/d (maximum, 60 mg/d), is given for 6 weeks as a single daily dose. The same dose is then administered on an alternate-day schedule for 6 weeks; thereafter, the dose is tapered gradually and discontinued over the ensuing 2 months. The goal of this regimen is the disappearance of proteinuria. If remission is not achieved during the initial phase of corticosteroid treatment, additional nephrologic consultation should be obtained. If remission is achieved,

only to be followed by relapse, the treatment course may be repeated. A renal biopsy is often considered when there is little or no response to treatment. One should take into account that the histologic findings may not alter the treatment plan, which is designed to eliminate the nephrotic syndrome regardless of underlying renal histology.

Unless the edema causes symptoms such as respiratory compromise due to ascites, diuretics should be used with extreme care. Patients may have decreased circulating volume and are also at risk for venous thrombosis. Careful restoration of compromised circulating volume with intravenous 25% albumin infusion and administration of a diuretic such as furosemide is helpful in mobilizing edema. Infections such as peritonitis should be treated promptly to reduce morbidity. Immunization with pneumococcal conjugate and polysaccharide vaccines is advised.

A favorable response of proteinuria to corticosteroids and subsequent favorable response during relapse suggests a good prognosis. Failure to respond or early relapse usually heralds a prolonged series of relapses. This not only may indicate the presence of more serious nephropathy, but presents a challenge in choosing future therapy for those either severely corticosteroid "dependent" and/or in danger of increasing steroid side effects. Historically, chlorambucil or cyclophosphamide drug therapy added to corticosteroid treatment have been utilized in an attempt to achieve corticosteroid discontinuance while maintaining remission. Such drugs are often used effectively, but only in children who respond well to corticosteroids in the first place. Because of potential significant side effects associated with these drugs, tacrolimus or cyclosporine is now added instead for the treatment of steroid dependent cases. Increasing reports and experience suggest that cases in which nephrotic syndrome is poorly responsive to or "dependent" upon corticosteroids, even with an added agent such as tacrolimus, may respond to rituximab. Patients who do not respond to corticosteroids or who relapse frequently should be referred to a pediatric nephrologist, if such referral was not made earlier in the course.

FOCAL GLOMERULAR SCLEROSIS

Focal glomerular sclerosis is one cause of corticosteroid-resistant or frequent relapsing nephrotic syndrome. The cause is unknown. The diagnosis is made by renal biopsy, which shows normal-appearing glomeruli as well as some partially or completely sclerosed glomeruli. The lesion has serious prognostic implications because as many as 15%–20% of cases can progress to end-stage renal failure. The response to corticosteroid treatment is variable. In difficult cases, especially when prolonged use of steroids is resulting in significant undesirable side effects, other immunosuppressive agents such as cyclosporin A or tacrolimus have been used in addition to corticosteroids to try to achieve longer remission with corticosteroid discontinuance. Recurrence of focal glomerular sclerosis resulting in nephrotic syndrome may occur after renal transplantation. The recurrence is usually treated with plasmapheresis and/or rituximab; the latter agent is also showing encouraging utility in treating the nephrotic syndrome of membranous or mesangial nephropathy as well as refractory nephrotic syndrome associated with other forms of glomerular disease or vasculitis.

MESANGIAL NEPHROPATHY (MESANGIAL GLOMERULONEPHRITIS)

Mesangial nephropathy is another form of corticosteroid-resistant nephrotic syndrome. The renal biopsy shows a distinct increase in the mesangial matrix of the glomeruli. Very often the expanded mesangium contains deposits of IgM demonstrable on immunofluorescent staining. The cause is unknown. Corticosteroid therapy may induce remission, but relapses are common. Choices for treating this type of nephrotic syndrome are the same as noted earlier.

MEMBRANOUS NEPHROPATHY (MEMBRANOUS GLOMERULONEPHRITIS)

Although largely idiopathic in nature, membranous nephropathy can be found in association with hepatitis B antigenemia, SLE, congenital and secondary syphilis, renal vein thrombosis; with immunologic disorders such as autoimmune thyroiditis; and with administration of drugs such as penicillamine. The pathogenesis is unknown, but the glomerular lesion is thought to be the result of prolonged deposition of circulating antigen-antibody complexes.

The onset of membranous nephropathy may be insidious or may resemble that of idiopathic nephrotic syndrome of childhood (see earlier section). It occurs more often in older children and adults. The proteinuria of membranous nephropathy responds poorly to corticosteroid therapy, although low-dose corticosteroid therapy may reduce or delay development of chronic renal insufficiency. The diagnosis is made by renal biopsy.

▼ DISEASES OF THE RENAL VESSELS

RENAL VEIN THROMBOSIS

In newborns, renal vein thrombosis may complicate sepsis or dehydration. It may be observed in infants of diabetic mothers, may be associated with umbilical vein catheterization, or may result from any condition that produces a hypercoagulable state (eg, clotting factor deficiency, SLE,

or thrombocytosis). Renal vein thrombosis is less common in older children and adolescents. It may develop following trauma or without any apparent predisposing factors. Spontaneous renal vein thrombosis has been associated with membranous glomerulonephropathy. Nephrotic syndrome may either cause or result from renal vein thrombosis.

▶ Clinical Findings

Renal vein thrombosis in newborns is generally characterized by the sudden development of an abdominal mass. If the thrombosis is bilateral, oliguria may be present; urine output may be normal with a unilateral thrombus. In older children, flank pain, sometimes with a palpable mass, is a common presentation.

No single laboratory test is diagnostic of renal vein thrombosis. Hematuria usually is present; proteinuria is less constant. In the newborn, thrombocytopenia may be found, but it is rare in older children. The diagnosis is made by ultrasonography and Doppler flow studies.

▶ Treatment

Anticoagulation with heparin is the treatment of choice in newborns and older children. In the newborn, a course of heparin combined with treatment of the underlying problem is usually all that is required. Management in other cases is less straightforward. The tendency for recurrence and embolization has led some to recommend long-term anticoagulation. If an underlying membranous GN is suspected, biopsy should be performed.

▶ Course & Prognosis

The mortality rate in newborns from renal vein thrombosis depends on the underlying cause. With unilateral renal venous thromboses at any age, the prognosis for adequate renal function is good. Renal vein thrombosis may rarely recur in the same kidney or occur in the other kidney years after the original episode of thrombus formation. Extension into the vena cava with pulmonary emboli is possible.

RENAL ARTERIAL DISEASE

Arterial disease (eg, fibromuscular hyperplasia, congenital stenosis) is a rare cause of hypertension in children. Although few clinical clues are specific to underlying arterial lesions, they should be suspected in children with severe hypertension, with onset at or before age 10 years, or with delayed visualization on nuclear scan of the kidneys. The diagnosis is established by renal arteriography with selective renal vein renin measurements. Some of these lesions may be approached by transluminal angioplasty or surgery (see section Hypertension), but repair may be technically impossible in small children. Although thrombosis of renal arteries is rare, it should be considered in a patient with acute onset of hypertension and hematuria in an appropriate setting (eg, in association with hyperviscosity or umbilical artery catheterization). Early diagnosis and treatment provides the best chance of reestablishing renal blood flow.

Tullus K: Renovascular hypertension in children. Lancet 2008;371: 1453–1463 [PMID: 18440428].

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome is the most common glomerular vascular cause of acute renal failure in childhood. The diarrhea-associated form is usually the result of infection with Shiga toxin–producing (also called verotoxin-producing) strains of *Shigella* or *Escherichia coli*. Ingestion of under-cooked ground beef or unpasteurized foods is a common source. There are many serotypes, but the most common pathogen in the United States is *E coli* O157:H7. Bloody diarrhea is the usual presenting complaint, followed by hemolysis and renal failure. Circulating verotoxin causes endothelial damage, which leads to platelet deposition, microvascular occlusion with subsequent hemolysis, and thrombocytopenia. Similar microvascular endothelial activation may also be triggered by drugs (eg, cyclosporin A); by viruses (human immunodeficiency virus [HIV]); and by pneumococcal infections, in which bacterial neuraminidase exposes the Thomsen-Friedenreich antigen on RBCs, platelets, and endothelial cells, thereby causing platelet aggregation, endothelial damage, and hemolysis. Rare cases are caused by genetic factors (eg, congenitally depressed C3 complement and factor H deficiency).

▶ Clinical Findings

Hemolytic-uremic syndrome due to Shigella or *E coli* begins with a prodrome of abdominal pain, diarrhea, and vomiting. Oliguria, pallor, and bleeding manifestations, principally gastrointestinal, occur next. Hypertension and seizures develop in some children—especially those who develop severe renal failure and fluid overload. There may also be significant endothelial involvement in the central nervous system (CNS).

Anemia is profound, and RBC fragments are seen on blood smears. A high reticulocyte count confirms the hemolytic nature of the anemia, but may not be noted in the presence of renal failure. Thrombocytopenia is profound, but other coagulation abnormalities are less consistent. Serum fibrin split products are often present, but fulminant disseminated intravascular coagulation is rare. Hematuria and proteinuria are often present. The serum complement level is normal except in those cases related to congenital predisposition.

▶ Complications

These usually result from renal failure. Neurologic problems, particularly seizures, may result from hyponatremia, hypertension, or CNS vascular disease. Severe bleeding,

transfusion requirements, and hospital-acquired infections must be anticipated.

Treatment

Meticulous attention to fluid and electrolyte status is crucial. The use of antimotility agents and antibiotics for hemolytic-uremic syndrome caused by gastrointestinal infection is believed to worsen the disease. Antibiotics may upregulate and cause the release of large amounts of bacterial Shiga toxin. Timely dialysis improves the prognosis. Since prostacyclin-stimulating factor, a potent inhibitor of platelet aggregation, may be absent in some cases, plasma infusion or plasmapheresis has been advocated in severe cases (generally in those cases with severe CNS involvement). Platelet inhibitors have also been tried, but the results have not been impressive, especially late in the disease. Nonetheless, using a platelet inhibitor early in the disease in an attempt to halt platelet consumption and microvascular occlusion may obviate the need for platelet transfusions and reduce the progression of renal failure. RBC and platelet transfusions may be necessary. Although the risk of volume overload is significant, this can be minimized by dialysis. Erythropoietin (epoetin alfa) treatment may reduce RBC transfusion needs. Although no therapy is universally accepted, strict control of hypertension, adequate nutrition support, and the timely use of dialysis reduce morbidity and mortality. If renal failure is "nonoliguric," and if urine output is sufficient to ensure against fluid overload and electrolyte abnormalities, management of renal failure without dialysis is possible.

Course & Prognosis

Most commonly, children recover from the acute episode within 2–3 weeks. Some residual renal disease (including hypertension) occurs in about 30%, and end-stage renal failure occurs in about 15%. Thus, follow-up of children recovering from hemolytic-uremic syndrome should include serial determinations of renal function for 1–2 years and monitoring of blood pressure for 5 years. Mortality (about 3%–5%) is most likely in the early phase, primarily resulting from CNS or cardiac complications.

▼ RENAL FAILURE

ACUTE RENAL FAILURE

Acute renal failure is the sudden inability to excrete urine of sufficient quantity or composition to maintain body fluid homeostasis. Explanations include quickly reversible

Table 24–2. Classification of renal failure.

Prerenal
Dehydration due to gastroenteritis, malnutrition, or diarrhea
Hemorrhage, aortic or renal vessel injury, trauma, cardiac disease or surgery, renal arterial thrombosis
Diabetic acidosis
Hypovolemia associated with capillary leak or nephrotic syndrome
Shock
Heart failure

Renal
Hemolytic-uremic syndrome
Acute glomerulonephritis
Prolonged renal hypoperfusion
Nephrotoxins
Acute tubular necrosis or vasomotor nephropathy
Renal (cortical) necrosis
Intravascular coagulation: septic shock, hemorrhage
Diseases of renal vessels
Iatrogenic (eg, drug toxicity)
Sepsis with shock
Drowning, especially fresh water
Crystalluria: sulfonamide or uric acid
Hypercalcemia from cancer treatment
Hepatic failure

Postrenal
Obstruction due to tumor, hematoma, posterior urethral valves, ureteropelvic junction stricture, ureterovesical junction stricture, ureterocele
Stones
Trauma to a solitary kidney or collecting system
Renal vein thrombosis

problems such as dehydration or urinary tract obstruction, as well as new-onset renal disease (eg, acute glomerulonephritis), drug-related toxic nephropathies, or renal ischemia; the latter is primarily suspected in settings of significant hemodynamic instability or other circumstances resulting in decreased renal perfusion. Table 24–2 lists prerenal, renal, and postrenal causes of acute renal failure.

Clinical Findings

The hallmark of early acute renal failure is oliguria with subsequent variable rise in serum creatinine and BUN; these observations are more likely to be the initial concern in a hospitalized patient. Although an exact etiologic diagnosis may be unclear at the onset, classifying oliguria as outlined in Table 24–2 is helpful in determining if an immediately reversible cause is present.

Entities that should be quickly addressed and corrected, for example, volume depletion, urinary tract obstruction or hypotension should be considered first. Once normal renal perfusion and lack of urinary tract obstruction is ensured,

Table 24–3. Urine studies.

	Prenatal Failure	Acute Tubular Necrosis
Urine osmolality	50 mOsm/kg > plasma osmolality	≤ plasma osmolality
Urine sodium	< 10 mEq/L	> 20 mEq/L
Ratio of urine creatinine to plasma creatinine	> 40:1	< 40:1
Specific gravity	> 1.020	1.012–1.018

if there is no clinical evidence for de novo renal disease or exposure to nephrotoxic agents, a diagnosis of acute tubular necrosis (vasomotor nephropathy, ischemic injury) may be entertained.

A. Prenatal Causes

The most common cause of acute decreased renal function in children is compromised renal perfusion. It is usually secondary to dehydration, although abnormalities of renal vasculature and poor cardiac performance may also be considered. Table 24–3 lists the urinary indices helpful in distinguishing these "prerenal" conditions from true renal parenchymal insult, such as in acute tubular necrosis.

B. Renal Causes

Causes of renal failure intrinsic to the kidneys include acute glomerulonephritides, hemolytic-uremic syndrome, acute interstitial nephritis, and nephrotoxic injury. The diagnosis of acute tubular necrosis (vasomotor nephropathy)—which is reserved for those cases in which renal ischemic insult is believed to be the likely cause—should be considered when correction of prerenal or postrenal problems does not improve renal function and there is no evidence of de novo renal disease.

C. Postrenal Causes

Postrenal failure, usually found in newborns with urologic anatomic abnormalities, is accompanied by varying degrees of renal insufficiency. One should always keep in mind the possibility of acute urinary tract obstruction in acute renal failure, especially in the setting of anuria of acute onset. Whatever the cause, ensuring urine drainage is the first step toward reversibility of oliguria.

▶ Complications

The severity of the complications of acute renal failure depends on the degree of renal functional impairment and oliguria. Common complications include (1) fluid overload (hypertension, congestive heart failure, and pulmonary edema), (2) electrolyte disturbances (hyperkalemia), (3) metabolic acidosis, (4) hyperphosphatemia, and (5) elevations in BUN and creatinine.

▶ Treatment

Prerenal and/or postrenal factors should be excluded or rectified. Normal circulating volume should be maintained and normal blood pressure and cardiac performance established with appropriate fluids. Strict measurement of input and output must be maintained, with input adjusted as reduction in output dictates. Placement of a Foley bladder catheter can aid in timely measurement of and adjustment to changes in output. However, in cases where oligo/anuric renal failure is well established (ie, insignificant urine volume), the foreign body should be removed to minimize bladder infection risk. Measurement of central venous pressure may be indicated. Administration of pressor drugs to correct hypotension may be needed. Increasing urine output with diuretics, such as furosemide (1–5 mg/kg, per dose, intravenously, maximum of 200 mg), can be attempted. The effective dose will depend on the amount of functional compromise (if < 50% function, initiate attempt at diuresis with maximum dose). If a response does not occur within 1 hour and the urine output remains low (< 0.5 mL/kg/h), the furosemide dose, if not already maximized, should be increased up to 5 mg/kg. In some cases, the addition of a long-acting thiazide diuretic, such as metolazone, may improve the response. If no diuresis occurs with maximum dosing, further administration of diuretics should cease.

If these maneuvers stimulate some urine flow but biochemical evidence of acute renal failure persists, the resulting nonoliguric acute renal failure should be more manageable. Fluid overload and dialysis may be averted. However, if the medications and nutrients required exceed the renal capacity for excretion, and there is no increase in urine output with the use of maximum doses of diuretics (loop diuretic plus a thiazide diuretic) dialysis is indicated. Institution of dialysis before more severe complications of acute renal failure develop is likely to improve clinical management and outcome. It is important to adjust medication dosage according to the degree of renal function.

A. Acute Dialysis: Indications

Immediate indications for dialysis are (1) severe hyperkalemia; (2) unrelenting metabolic acidosis (usually in a situation where fluid overload prevents sodium bicarbonate administration); (3) fluid overload with or without severe hypertension or congestive heart failure (a situation in which volume concerns would seriously compromise administration of adequate nutritional support or of necessary intravenous medications); and (4) symptoms of uremia, usually

manifested in children by CNS depression. In cases in which one is concerned about the so called "uremic" bleeding, it is important to keep in mind that despite the use of the clinical term uremia, it is not the blood urea nitrogen which contributes to platelet dysfunction in renal failure. Accumulation of metabolic end products that contribute to bleeding correlate better with the amount of renal function as reflected by the serum creatinine. This is especially true in cases in which the BUN, which is potentially affected by many things in an ill patient, appears to be disproportionately elevated with respect to the serum creatinine.

B. Methods of Dialysis

Peritoneal dialysis is generally preferred in children because of ease of performance and patient tolerance. Although peritoneal dialysis is technically less efficient than hemodialysis, hemodynamic stability and metabolic control can be better sustained because this technique can be applied on a relatively continuous basis. Hemodialysis should be considered (1) if rapid removal of toxins is desired, (2) if the size of the patient makes hemodialysis less technically cumbersome and hemodynamically well tolerated, or (3) if impediments to efficient peritoneal dialysis are present (eg, ileus, adhesions). Furthermore, if vascular access and usage of anticoagulation are not impediments, a slow, continuous hemodialytic process, continuous renal replacement therapy (CRRT), may be applied, with either heparin or citrate used for anticoagulation. CRRT is also a very useful approach in patients already being supported with extracorporeal membrane oxygenation (ECMO).

C. Complications of Dialysis

Complications of peritoneal dialysis include peritonitis, volume depletion, and technical complications such as dialysate leakage and respiratory compromise from intra-abdominal dialysate fluid. Peritonitis can be avoided by strict aseptic technique. Peritoneal fluid cultures are obtained as clinically indicated. Leakage is reduced by good catheter placement technique and appropriate intra-abdominal dialysate volumes. Adjustment of the electrolyte concentration of dialysate is important to maintain electrolyte balance. Potassium (absent from standard dialysate solutions) can be added to the dialysate as required. Phosphate is also absent because hyperphosphatemia is an expected problem in renal failure. Nonetheless, if phosphate intake is inadequate, hypophosphatemia must be addressed. Correction of fluid overload is accomplished by using high osmolar dialysis fluids. Higher dextrose concentrations (maximum 4.25%) can correct fluid overload rapidly at the risk of causing hyperglycemia. Fluid removal may also be increased with more frequent exchanges of the dialysate, but rapid osmotic transfer of water may result in hypernatremia.

Even in small infants, hemodialysis can rapidly correct major metabolic and electrolyte disturbances as well as volume overload. The process is highly efficient, but the speed of the changes can cause problems such as hemodynamic instability. Anticoagulation with heparin is required. Careful monitoring of the appropriate biochemical parameters is important. Note that during or immediately following the procedure, blood sampling will produce misleading results because equilibration between extravascular compartments and the blood will not have been achieved. Vascular access must be obtained and carefully monitored. Hemodialysis is generally intermittent and utilized as clinically indicated. If need be, CRRT may be used to maintain more minute-to-minute, continuous metabolic and fluid control especially in the very hemodynamically unstable or septic patient. With this technique, either heparin or citrate may be used for anticoagulation, with the choice based upon which is more suitable for the situation.

▶ Course & Prognosis

The course and prognosis of acute renal failure vary with the etiology. If severe oliguria occurs in acute tubular necrosis, it usually lasts about 10 days. Anuria or oliguria lasting longer than 3 weeks makes the diagnosis of acute tubular necrosis unlikely and favors alternative diagnoses such as vascular injury, severe ischemia (cortical necrosis), GN, or obstruction. The diuretic phase begins with an increase in urinary output to large volumes of isosthenuric urine containing sodium levels of 80–150 mEq/L. During the recovery phase, signs and symptoms subside rapidly, although polyuria may persist for several days or weeks. Urinary abnormalities usually disappear completely within a few months. If renal recovery does not ensue, arrangements are made for chronic dialysis and eventual renal transplantation.

Walters S et al: Dialysis and pediatric acute kidney injury: choice of renal support modality. Pediatr Nephrol 2009;24:37–48 [PMID: 18483748].

CHRONIC RENAL FAILURE

Chronic renal failure in children most commonly results from developmental abnormalities of the kidneys or urinary tract. Infants with renal agenesis are not expected to survive. Depending on the degree of dysgenesis (including multicystic development), the resulting renal function will determine outcome. Abnormal development of the urinary tract may not permit normal renal development. Obstructive uropathy or severe VUR nephropathy, without (or despite) surgical intervention, continues to cause a significant amount of progressive renal insufficiency in children. In older children, the

chronic glomerulonephritides and nephropathies, irreversible nephrotoxic injury, or hemolytic-uremic syndrome may also cause chronic renal failure. Early evaluation and close follow-up by a nephrologist in these situations is advised.

▶ Complications

Any remaining unaffected renal tissue can compensate for gradual loss of functioning nephrons in progressive chronic renal failure, but complications of renal insufficiency appear when compensatory ability is overwhelmed. In children who have developmentally reduced function and are unable to concentrate the urine, polyuria and dehydration are more likely to be problems than fluid overload. Output may be expected to gradually diminish as renal failure progresses to end stage; however, some children can continue to produce generous quantities of urine (but not of good quality) even though they require dialysis. A salt-wasting state can also occur. In contrast, children who develop chronic renal failure due to glomerular disease or renal injury will characteristically retain sodium and water and develop hypertension.

Metabolic acidosis and growth retardation occur early in chronic renal failure. Disturbances in calcium, phosphorus, and vitamin D metabolism leading to renal osteodystrophy and rickets require prompt attention. Increases in parathyroid hormone occur in response to decreased serum calcium from lack of renally activated vitamin D and/or rising serum phosphorus. The increase in parathyroid hormone, which improves renal tubular excretion of phosphorous, can maintain a normal serum calcium and serum phosphate level early in the course, but at the expense of the skeleton. The increase in parathyroid hormone will also be reflected in an increase in alkaline phosphatase. Anemia due to decreased erythropoietin production can occur relatively early on as well.

Symptoms such as anorexia, nausea, and malaise occur late in chronic renal failure (generally less than 30% renal function). These symptoms can be avoided if chronic renal failure has been detected early and associated complications treated, but may require initiation of renal replacement therapy. CNS abnormalities such as confusion and lethargy are very late symptoms, followed even later by stupor and coma. Other late complications of untreated renal failure are platelet dysfunction and bleeding tendencies. Pericarditis, congestive heart failure, pulmonary edema, and hypertension may occur.

▶ Treatment

A. Management of Complications

Treatment of chronic renal failure is primarily aimed at controlling the associated complications. Hypertension, hyperkalemia, hyperphosphatemia, acidosis, and anemia are among the early problems. Acidosis may be treated with sodium citrate solutions, as long as the added sodium will not aggravate hypertension. Sodium restriction is advisable when hypertension is present. Hyperphosphatemia is controlled by dietary restriction and dietary phosphate binders (eg, calcium carbonate). Vitamin D should be given to maintain normal serum calcium. When the BUN level exceeds approximately 50 mg/dL, or if the child is lethargic or anorexic, dietary protein should be restricted. Potassium restriction will be necessary as the GFR falls to a level where urinary output decreases sharply. Diet must be maintained to provide the child's daily requirements.

Renal function must be monitored regularly (creatinine and BUN), and serum electrolytes, calcium, phosphorus, alkaline phosphatase, and hemoglobin and hematocrit levels monitored to guide changes in fluid and dietary management as well as dosages of phosphate binder, citrate buffer, vitamin D, blood pressure medications, and epoetin alfa. Growth failure may be treated with human recombinant growth hormone. These treatments require careful monitoring to minimize symptoms while the need for chronic dialysis and transplantation continues to be assessed.

Care must be taken to avoid medications that aggravate hypertension; increase the body burden of sodium, potassium, or phosphate; or increase production of BUN. Successful management relies greatly on education of the patient and family.

Attention must also be directed toward the psychosocial needs of the patient and family as they adjust to chronic illness and the eventual need for dialysis and kidney transplantation.

B. Dialysis and Transplantation

Chronic peritoneal dialysis (home-based) and hemodialysis provide life-saving treatment for children prior to renal transplantation. The best measure of the success of chronic dialysis in children is the level of physical and psychosocial rehabilitation achieved, such as continued participation in day-to-day activities and school attendance. Although catch-up growth rarely occurs, patients can grow at an acceptable rate even though they may remain in the lower percentiles. Use of epoetin alfa, growth hormone, and better control of renal osteodystrophy contribute to improved outcome.

At present, the graft survival rate for living-related kidney transplants is 90% at 1 year, 85% at 2 years, and 75% at 5 years. With cadaveric transplantation, graft survivals are 76%, 71%, and 62%, respectively. Overall, the mortality rate is 4% for recipients of living-related donors and 6.8% for recipients of cadaver organs. These percentages are affected by the increased mortality, reported to be as high as 75%, in infants younger than age 1 year, primarily due to technical issues and complications of immunosuppression. A body weight of at least 15 kg is associated with a significantly improved survival rate. Adequate growth and well-being are directly related to acceptance of the graft, the degree of normal function, and the side effects of medications.

Shroff R, Ledermann S: Long-term outcome of chronic dialysis in children. Pediatr Nephrol 2009;24:463–474 [PMID: 18214549].

HYPERTENSION

Hypertension in children is commonly of renal origin. It is anticipated as a complication of known renal parenchymal disease, but it may be found on routine physical examination in an otherwise normal child. Increased understanding of the roles of water and salt retention and overactivity of the renin-angiotensin system has done much to guide therapy; nevertheless, not all forms of hypertension can be explained by these two mechanisms.

The causes of renal hypertension in the newborn period include (1) congenital anomalies of the kidneys or renal vasculature, (2) obstruction of the urinary tract, (3) thrombosis of renal vasculature or kidneys, and (4) volume overload. Some instances of apparent paradoxic elevations of blood pressure have been reported in clinical situations in which chronic diuretic therapy is used, such as in bronchopulmonary dysplasia. Hypertensive infants and older children should be examined for renal, vascular, or aortic abnormalities (eg, thrombosis, neurofibromatosis, coarctation) as well as some endocrine disorders, including pheochromocytoma, glucocorticoid-remedial aldosteronism, primary hyperaldosteronism, pseudoaldosteronism (Liddle syndrome), and pseudohypoaldosteroism (Gordon syndrome).

► Clinical Findings

A child is normotensive if the average recorded systolic and diastolic blood pressures are lower than the 90th percentile for age and sex. The 90th percentile in the newborn period is approximately 85–90/55–65 mm Hg for both sexes. In the first year of life, the acceptable levels are 90–100/60–67 mm Hg. Incremental increases with growth occur, gradually approaching young adult ranges of 100–120/65–75 mm Hg in the late teens. Careful measurement of blood pressure requires correct cuff size and reliable equipment. The cuff should be wide enough to cover two-thirds of the upper arm and should encircle the arm completely without an overlap in the inflatable bladder. Although an anxious child may have an elevation in blood pressure, abnormal readings must not be too hastily attributed to this cause. Repeat measurement is helpful, especially after the child has been consoled.

Routine laboratory studies include serum BUN, creatinine and electrolytes, a complete blood count, urinalysis, and urine culture. Abnormal BUN and creatinine would support underlying renal disease as the cause and serum electrolytes demonstrating hypokalemic alkalosis may represent either hyperaldosteronism or pseudoaldosteronism in which case urine sodium and chloride should be measured. Renal ultrasonography with Doppler flow is helpful in determining the possible presence of renal scarring, urinary tract obstruction or renovascular flow disturbances as a cause of hypertension. A renal biopsy (which rarely reveals the cause of hypertension unless clinical evidence of renal disease is present) should be undertaken with special care in the hypertensive patient and preferably after pressures have been controlled by therapy. Figure 24–3 presents a suggested approach to the outpatient workup of hypertension.

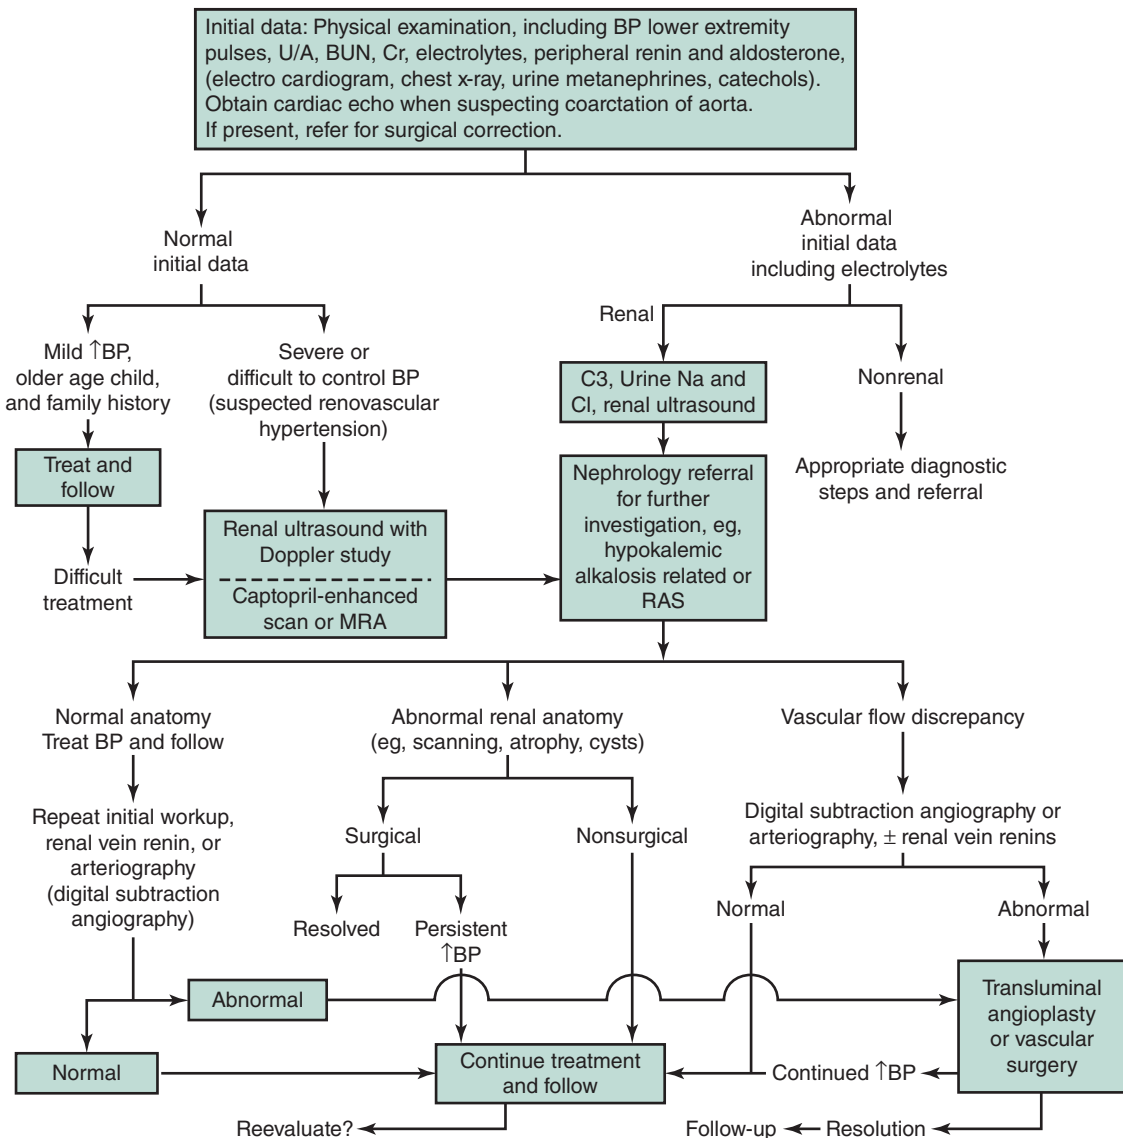
► Treatment

A. Acute Hypertensive Emergencies

A hypertensive emergency exists when CNS signs of hypertension appear, such as papilledema or encephalopathy. Retinal hemorrhages or exudates also indicate a need for prompt and effective control. In children, end-organ abnormalities secondary to hypertension commonly are not present. Treatment varies with the clinical presentation. The primary classes of useful antihypertensive drugs are (1) diuretics, (2) α- and β-adrenergic blockers, (3) angiotensin-converting enzyme inhibitors, (4) calcium channel blockers, and (5) vasodilators.

Whatever method is used to control emergent hypertension, medications for sustained control should also be initiated so that normal blood pressure will be maintained when the emergent measures are discontinued (Table 24–4). Acute elevations of blood pressure not exceeding the 95th percentile for age may be treated with oral antihypertensives, aiming for progressive improvement and control within 48 hours.

1. Sublingual nifedipine—This calcium channel blocker is rapid acting, and, in appropriate doses, should not result in hypotensive blood pressure levels. The liquid from a 10-mg capsule can be drawn into a syringe and the dosage approximated. The exact dosage for children who weigh less than 10–30 kg is difficult to ascertain by this method, but 5 mg is a safe starting point. Because the treatment is given for rising blood pressure, it is unlikely that the effects will be greater than desired. Larger children with malignant hypertension require 10 mg. In such cases, the capsule may simply be pierced and the medication squeezed under the patient's tongue. In children who are able to swallow capsules, and are large enough for a 10-mg dose, the child may bite the capsule, then swallow it for rapid onset of the drug. IV medication to achieve sustained control should be initiated as soon as possible.

2. Sodium nitroprusside—Sodium nitroprusside is considered one of the most rapidly effective IV medications to gain control of malignant hypertension but long-term usage is limited by fear of possible thiocyanate toxicity especially in


▲ **Figure 24–3.** Approach to the outpatient workup of hypertension. ANA, antinuclear antibody; BP, blood pressure; BUN, blood urea nitrogen; C3, complement; Cr, creatinine; MRA, magnetic resonance angiography; U/A, urinalysis.

renal failure. As with other vasodilators, it will result in reflex tachycardia requiring the addition of a β-blocker, and fluid retention requiring addition of a diuretic.

3. Furosemide—Administered at 1–5 mg/kg intravenously, this diuretic reduces blood volume and enhances the effectiveness of antihypertensive drugs.

4. Labetalol or Esmolol—IV forms of β-blockers can be very effective if there are no cardiac or respiratory contraindications to their use.

5. Intravenous hydralazine—This vasodilator is sometimes effective. Dosage varies according to the severity of the hypertension and should begin at about 0.15 mg/kg.

Table 24–4. Antihypertensive drugs for emergency treatment.

Drug	Oral Dose	Major Side Effects[a]
Nifedipine	0.25–0.5 mg/kg SL	Flushing, tachycardia
Labetalol	1–3 mg/kg/h IV	Secondary to β-blocking activity
Sodium nitroprusside	0.5–10 mg/kg/min IV drip	Cyanide toxicity, sodium and water retention
Furosemide	1–5 mg/kg IV	Secondary to severe volume contraction, hypokalemia
Esmolol hydrochloride	Load 500 mcg/kg/ over 1 minute followed by continuous 50–200 mcg/kg, titrate	Secondary to β-blocking
Hydralazine	0.1–0.2 mg/kg IV	Sodium and water retention, tachycardia, flushing

[a]Many more side effects than those listed have been reported. IV, intravenous; SL, sublingual.

Will cause physiologic responses requiring addition of β-blocker and diuretic.

B. Sustained Hypertension

Several choices are available for treatment (Table 24–5). A single drug such as a β-blocker (unless contraindicated, eg, in reactive airway disease) may be adequate to treat mild hypertension. Diuretics are useful to treat renal insufficiency, but the disadvantages of possible electrolyte imbalance must be considered. Single-drug therapy with an angiotensin-converting enzyme inhibitor is useful, especially because most hypertension in children is renal in origin. Calcium channel blockers are increasingly useful, and appear well tolerated in children. The use of the vasodilator type of antihypertensive drug requires concomitant administration of a diuretic to counter the effect of vasodilation on increasing renal sodium and water retention and a β-blocker to counter reflex tachycardia. Minoxidil, considered the most powerful of the orally administered vasodilators, can be extremely efficacious in the treatment of severe, sustained hypertension, but its effect is greatly offset by these other effects. Hirsutism is also a significant side effect. Hydralazine hydrochloride may still be the most common vasodilator in pediatric use—but, again, the necessity of using two additional drugs for maximum benefit relegates use to severe situations calling for management with three or four drugs. The advice of a pediatric nephrologist should be sought.

Table 24–5. Antihypertensive drugs for ambulatory treatment.

Drug	Oral Dose	Major Side Effects[a]
Hydrochlorothiazide	2–4 mg/kg/24 h as single dose or in 2 divided doses	Potassium depletion, hyperuricemia
Furosemide	1–5 mg/kg per dose, 2–3 doses per day	Potassium and volume depletion
Hydralazine	0.75 mg/kg/24 h in 4–6 divided doses	Lupus erythematosus, tachycardia, headache
Amlodipine	0.2–0.5 mg/kg/d in 2 divided doses	Fatigue, headache, facial flushing
Propranolol	0.2–5 mg/kg per dose, 2–3 doses per day	Syncope, cardiac failure, hypoglycemia
Minoxidil	0.15 mg/kg per dose, 2–3 doses per day	Tachycardia, angina, fluid retention, hirsutism
Captopril	0.3–2 mg/kg per dose, 2–3 doses per day	Rash, hyperkalemia, glomerulopathy
Lisinopril	0.5–1 mg/kg/d in 2 divided doses	Hyperkalemia, cough
Nifedipine	0.5–1 mg/kg/d, 3 doses per day	Flushing, tachycardia

[a]Many more side effects than those listed have been reported.

Hogg RJ et al: A multicenter study of the pharmacokinetics of lisinopril in pediatric patients with hypertension. Pediatr Nephrol 2007;22:695 [PMID: 17216247].

▼ INHERITED OR DEVELOPMENTAL DEFECTS OF THE KIDNEYS

There are many developmental, hereditary, or metabolic defects of the kidneys and collecting system. The clinical consequences include metabolic abnormalities, failure to thrive, nephrolithiasis, renal glomerular or tubular dysfunction, and chronic renal failure. Table 24–6 lists some of the major entities.

DISORDERS OF THE RENAL TUBULES

Three subtypes of renal tubular acidosis (RTA) are recognized: (1) the classic form, called type I or distal RTA; (2) the

Table 24–6. Inherited or developmental defects of the urinary tract.

Cystic diseases of genetic origin
Polycystic disease
  Autosomal recessive form (infantile)
  Autosomal dominant form (adult)
  Other syndromes that include either form
Cortical cysts
  Several syndromes are known to have various renal cystic
    manifestations, including "simple" cysts; may not have
    significant effect on renal functional status or be associated
    with progressive disease
Medullary cysts
  Medullary sponge kidney
  Medullary cystic disease (nephronophthisis)
Hereditary and familial cystic dysplasia
  Congenital nephrosis
  "Finnish" disease
 	
Dysplastic renal diseases
Renal aplasia (unilateral, bilateral)
Renal hypoplasia (unilateral, bilateral, total, segmental)
Multicystic renal dysplasia (unilateral, bilateral, multilocular,
  postobstructive)
Familial and hereditary renal dysplasias
Oligomeganephronia
 	
Hereditary diseases associated with nephritis
Hereditary nephritis with deafness and ocular defects
  (Alport syndrome)
Nail-patella syndrome
Familial hyperprolinemia
Hereditary nephrotic syndrome
Hereditary osteolysis with nephropathy
Hereditary nephritis with thoracic asphyxiant dystrophy syndrome
 	
Hereditary diseases associated with intrarenal deposition of
  metabolites
Angiokeratoma corporis diffusum (Fabry disease)
Heredopathia atactica polyneuritiformis (Refsum disease)
	Various storage diseases (eg, G_{M1} monosialogangliosidosis,
	  Hurler syndrome, Niemann-Pick disease, familial metachromatic
	  leukodystrophy, glycogenosis type I [von Gierke disease],
	  glycogenosis type II [Pompe disease])
	Hereditary amyloidosis (familial Mediterranean fever, heredofamilial
	  urticaria with deafness and neuropathy, primary familial
	  amyloidosis with polyneuropathy)
	
	Hereditary renal diseases associated with tubular transport defects
	Hartnup disease
	Fanconi anemia
	Oculocerebrorenal syndrome of Lowe
	Cystinosis (infantile, adolescent, adult types)
	Wilson disease
	Galactosemia
	Hereditary fructose intolerance
	Renal tubular acidosis (many types)
	Hereditary tyrosinemia
	Renal glycosuria
	Vitamin D–resistant rickets
	Pseudohypoparathyroidism
	Vasopressin-resistant diabetes insipidus
	Hypouricemia
	
	Hereditary diseases associated with lithiasis
	Hyperoxaluria
	ʟ-Glyceric aciduria
	Xanthinuria
	Lesch-Nyhan syndrome and variants, gout
	Nephropathy due to familial hyperparathyroidism
	Cystinuria (types I, II, III)
	Glycinuria
	
	Miscellaneous
	Hereditary intestinal vitamin B_{12} malabsorption
	Total and partial lipodystrophy
	Sickle cell anemia
	Bartter syndrome

bicarbonate-wasting form, called type II or proximal RTA; and (3) type IV, or hyperkalemic RTA (rare in children), which is associated with hyporeninemic hypoaldosteronism. Types I and II and their variants are encountered most frequently in children. Type III is a combination of types I and II.

Other primary tubular disorders in childhood, such as glycinuria, hypouricemia, or renal glycosuria, may result from a defect in a single tubular transport pathway (see Table 24–6).

1. Distal Renal Tubular Acidosis (Type I)

The most common form of distal RTA in childhood is the hereditary form. The clinical presentation is one of failure to thrive, anorexia, vomiting, and dehydration. Hyperchloremic metabolic acidosis, hypokalemia, and a urinary pH exceeding 6.5 are found. Acidosis is more severe in the presence of a bicarbonate "leak." This variant of distal RTA with bicarbonate wasting has been called type III but for clinical purposes need not be considered as a distinct entity. Concomitant hypercalciuria may lead to rickets, nephrocalcinosis, nephrolithiasis, and renal failure.

Other situations that may be responsible for distal RTA are found in some of the entities listed in Table 24–6.

Distal RTA results from a defect in the distal nephron, in the tubular transport of hydrogen ion, or in the maintenance of a steep enough gradient for proper excretion of hydrogen ion. This defect can be accompanied by degrees of bicarbonate wasting.

The classic test for distal RTA is an acid load from NH_4Cl. The test is cumbersome and can produce severe acidosis. A clinical trial of alkali administration should be used to rule out proximal (type II) RTA. The dose of alkali required to achieve a normal plasma bicarbonate concentration in patients with distal RTA is low (seldom exceeding 2–3 mEq/kg/24 h)—in contrast to that required in proximal RTA (> 10 mEq/kg/24 h). Higher doses are needed, however, if distal RTA is accompanied by bicarbonate wasting. Correction of acidosis can result in reduced complications and improved growth.

Distal RTA is usually permanent, although it sometimes occurs as a secondary complication. If the defect is not caused by a significant tubular disorder and renal damage is prevented, the prognosis with treatment is good.

2. Proximal Renal Tubular Acidosis (Type II)

Proximal RTA, the most common form of RTA in childhood, is characterized by an alkaline urine pH, loss of bicarbonate in the urine, and mildly reduced serum bicarbonate concentration. This occurs as a result of a lower than normal bicarbonate threshold, above which bicarbonate appears in the urine. Thus, urinary acidification can occur when the concentration of serum bicarbonate drops below that threshold, and bicarbonate disappears from the urine; this ability to eventually acidify the urine thus reflects normal distal tubular function.

Proximal RTA is often an isolated defect, and in the newborn can be considered an aspect of renal immaturity. Onset in infants is accompanied by failure to thrive, hyperchloremic acidosis, hypokalemia, and, rarely, nephrocalcinosis. Secondary forms result from reflux or obstructive uropathy or occur in association with other tubular disorders (see Table 24–6). Proximal RTA requires more than 3 mEq/kg of alkali per day to correct the acidosis. Serum bicarbonate should be monitored weekly until a level of at least 20 mEq/L is attained.

Citrate solutions (eg, Bicitra, Polycitra) are somewhat more easily tolerated than sodium bicarbonate. Bicitra contains 1 mEq/mL of Na^+ and citrate. Polycitra contains 2 mEq/mL of citrate and 1 mEq each of Na^+ and K^+. The required daily dosage is divided into three doses. Potassium supplementation may be required, because the added sodium load presented to the distal tubule may exaggerate potassium losses.

The prognosis is excellent in cases of isolated defects, especially when the problem is related to renal immaturity. Alkali therapy can usually be discontinued after several months to 2 years. Growth should be normal, and the gradual increase in the serum bicarbonate level to greater than 22 mEq/L heralds the presence of a raised bicarbonate threshold in the tubules. If the defect is part of a more complex tubular abnormality (Fanconi syndrome with attendant phosphaturia, glycosuria, and amino aciduria), the prognosis depends on the underlying disorder or syndrome.

OCULOCEREBRORENAL SYNDROME (LOWE SYNDROME)

Lowe syndrome results from various mutations in the *ORCL1* gene, which codes for a Golgi apparatus phosphatase. Affected males have anomalies involving the eyes, brain, and kidneys. The physical stigmata and degree of mental retardation vary with the location of the mutation. In addition to congenital cataracts and buphthalmos, the typical facies includes prominent epicanthal folds, frontal prominence, and a tendency to scaphocephaly. Muscle hypotonia is a prominent finding. The renal abnormalities are of tubule function and include hypophosphatemic rickets with low serum phosphorus levels, low to normal serum calcium levels, elevated serum alkaline phosphatase levels, RTA, and aminoaciduria. Treatment includes alkali therapy, phosphate replacement, and vitamin D. Antenatal diagnosis is possible.

HYPOKALEMIC ALKALOSIS (BARTTER SYNDROME, GITELMAN SYNDROME, & LIDDLE SYNDROME)

Bartter syndrome is characterized by severe hypokalemic, hypochloremic metabolic alkalosis, extremely high levels of circulating renin and aldosterone, and a paradoxic absence of hypertension. On renal biopsy, a striking juxtaglomerular hyperplasia is seen.

A neonatal form of Bartter syndrome is thought to result from mutations in two genes affecting either Na^+–K^+ or K^+ transport. These patients have life-threatening episodes of fever and dehydration with hypercalciuria and early-onset nephrocalcinosis. Classic Bartter syndrome presenting in infancy with polyuria and growth retardation (but not nephrocalcinosis) is thought to result from mutations in a chloride channel gene. Gitelman syndrome occurs in older children and features episodes of muscle weakness, tetany, hypokalemia, and hypomagnesemia. These children have hypocalciuria. In Liddle syndrome, the presenting significant clinical abnormality may at first be hypertension, although hypokalemia may also be evident. Serum renin and aldosterone are low and serum sodium is elevated.

Treatment with prostaglandin inhibitors and potassium-conserving diuretics (eg, amiloride combined with magnesium supplements) and potassium and magnesium where indicated is beneficial in Bartter syndrome and Gitelman syndrome. Although the prognosis is guarded, a few patients seem to have less severe forms of the disease that are compatible with long survival times. Treatment in Liddle syndrome is with a low sodium diet and potassium sparing diuretics, excluding spironolactone, since it acts by regulation of aldosterone.

CYSTINOSIS

There are three types of cystinosis: adult, adolescent, and infantile. The adolescent type is characterized by cystine deposition, which, if not treated with phosphocysteamine (Cystagon) which aids in the metabolic conversion of cystine (unable to exit cells) to cysteine (able to exit cells), is accompanied by the development of the renal Fanconi syndrome (renal tubular dysfunction) and varying degrees of renal failure. Growth is usually normal. The infantile type is the most common and the most severe. Characteristically, children present in the first or second year of life with Fanconi syndrome and, without the metabolic benefit of Cystagon treatment, progress to end-stage renal failure.

Cystinosis results from mutations in the *CTNS* gene, which codes for a cystine transporter. About 50% of patients share an identical deletion. Inheritance is autosomal recessive. Cystine is stored in cellular lysosomes in virtually all tissues. Eventually, cystine accumulation results in cell damage and cell death, particularly in the renal tubules. Renal failure between ages 6 and 12 years is common in the infantile form.

Whenever the diagnosis of cystinosis is suspected, slit-lamp examination of the corneas should be performed. Cystine crystal deposition causes an almost pathognomonic ground-glass "dazzle" appearance. Increased white cell cystine levels are diagnostic. Hypothyroidism is common.

Cystagon therapy is helpful in the treatment of cystinosis and can retard progression of renal failure and the accumulation of cystine in other organs. Depending on the progression of chronic renal failure, management is directed toward all side effects of renal failure, with particular attention paid to the control of renal osteodystrophy. Dialysis and transplantation may be needed.

Nesterova G, Gahl W: Nephropathic cystinosis: late complications of a multisystem disease. Pediatr Nephrol 2008;32:863–878 [PMID: 18008091].

NEPHROGENIC DIABETES INSIPIDUS

The congenital X-linked recessive form of nephrogenic (no response to vasopressin) diabetes insipidus results from mutations in the vasopressin receptor, *AVPR2*. Autosomal (recessive and dominant) forms of nephrogenic diabetes insipidus are caused by mutations of the *AQP2* gene that codes for a water channel protein, aquaporin-2. Genetic counseling and mutation testing are available.

Urine concentrating ability is impaired in a number of other conditions—sickle cell anemia, pyelonephritis, potassium depletion, hypercalcemia, cystinosis and other renal tubular disorders, and obstructive uropathy—and as a result of nephrotoxic drugs. Children receiving lithium treatment should be monitored for the development of nephrogenic diabetes insipidus.

The symptoms of nephrogenic diabetes insipidus are polyuria, polydipsia, and failure to thrive. In some children, particularly if the solute intake is unrestricted, adjustment to an elevated serum osmolality may develop. These children are particularly susceptible to episodes of dehydration, fever, vomiting, and convulsions.

The diagnosis can be suspected on the basis of a history of polydipsia and polyuria insensitive to the administration of vasopressin, desmopressin acetate, or lypressin. The diagnosis is confirmed by performing a vasopressin test. Carefully monitored water restriction does not increase the tubular reabsorption of water (TcH$_2$O) to above 3 mL/min/m^2. Urine osmolality remains lower than 450 mOsm/kg, whereas serum osmolality rises and total body weight falls. Before weight reduction of more than 5% occurs or before serum osmolality exceeds 320 mOsm/kg, vasopressin should be administered.

In infants, it is usually best to allow water as demanded and to restrict salt. Serum sodium levels should be evaluated at intervals to avoid hyperosmolality from inadvertent water restriction. In later childhood, sodium intake should continue to be restricted to 2.0–2.5 mEq/kg/24 h.

Treatment with hydrochlorothiazide is helpful, and many patients show improvement with administration of prostaglandin inhibitors such as indomethacin or tolmetin.

Linshaw MA: Back to basics: congenital nephrogenic diabetes insipidus. Pediatr Rev 2007;28:372–380 [PMID: 17908859].

NEPHROLITHIASIS

Renal calculi in children may result from inborn errors of metabolism, such as cystine in cystinuria, glycine in hyperglycinuria, urates in Lesch-Nyhan syndrome, and oxalates in oxalosis. Stones may occur secondary to hypercalciuria in distal tubular acidosis, and large stones are quite often seen in children with spina bifida who have paralyzed lower limbs or any situation where immobilization promotes calcium mobilization from bones. Treatment is limited to that of the primary condition, if possible. Most cases of nephrolithiasis have no basis in a metabolic disturbance, however, and are initially addressed with attention toward maintaining optimal hydration. Surgical removal of stones or lithotrypsy should be considered only for obstruction, intractable severe pain, and chronic infection.

Tanaka ST, Pope JC 4th: Pediatric stone disease. Curr Urol Rev 2009;10:138–143 [PMID: 19239819].

1. Cystinuria

Cystinuria, like Hartnup disease and several other disorders, is primarily an abnormality of amino acid transport across both the enteric and proximal renal tubular epithelium. There are at least three biochemical types. In the first type, the bowel transport of basic amino acids and cystine is

impaired, but transport of cysteine is not impaired. In the renal tubule, basic amino acids are again rejected by the tubule, but cystine absorption appears to be normal. The reason for cystinuria remains obscure. Heterozygous individuals have no aminoaciduria. The second type is similar to the first except that heterozygous individuals excrete excess cystine and lysine in the urine, and cystine transport in the bowel is normal. In the third type, only the nephron is involved. The only clinical manifestations are related to stone formation: ureteral colic, dysuria, hematuria, proteinuria, and secondary UTI. Urinary excretion of cystine, lysine, arginine, and ornithine is increased.

The most reliable way to prevent stone formation is to maintain a constantly high free-water clearance. This involves generous fluid intake. Alkalinization of the urine is helpful. If these measures do not prevent significant renal lithiasis, the use of tiopronin (Thiola) is recommended.

Ahmed K et al: Management of cystinuric patients: an observational, retrospective, single-centre analysis. Urol Int 2008;80P:141–144 [PMID: 18362482].

2. Primary Hyperoxaluria

Oxalate in humans is derived from the oxidative deamination of glycine to glyoxylate, from the serine-glycolate pathway, and from ascorbic acid. At least two enzymatic blocks have been described. Type I is a deficiency of liver-specific peroxisomal alanine–glyoxylate aminotransferase. Type II is glyoxylate reductase deficiency.

Excess oxalate combines with calcium to form insoluble deposits in the kidneys, lungs, and other tissues, beginning during childhood. The joints are occasionally involved, but the main effect is on the kidneys, where progressive oxalate deposition leads to fibrosis and eventual renal failure.

Pyridoxine supplementation and a low-oxalate diet have been tried as therapy, but the overall prognosis is poor, and most patients succumb to uremia by early adulthood. Renal transplantation is not very successful because of destruction of the transplant kidney. However, encouraging results have been obtained with concomitant liver transplantation, correcting the metabolic defect.

Hyperoxaluria may also be a consequence of severe ileal disease or ileal resection.

▼ URINARY TRACT INFECTIONS

It is estimated that 8% of girls and 2% of boys will acquire UTIs in childhood. Girls older than age 6 months have UTIs far more commonly than boys, whereas uncircumcised boys younger than 3 months of age have more UTIs than girls. Circumcision reduces the risk of UTI in boys. The density of distal urethral and periurethral bacterial colonization with uropathogenic bacteria correlates with the risk of UTI in children. Most UTIs are ascending infections. Specific adhesins present on the fimbria of uropathogenic bacteria allow colonization of the uroepithelium in the urethra and bladder and increase the likelihood of UTI. The organisms most commonly responsible for UTI are fecal flora, most commonly *E coli* (> 85%), *Klebsiella*, *Proteus*, other gram-negative bacteria, and, less frequently, *Enterococcus* or coagulase-negative staphylococci.

▶ Pathogenesis

Dysfunctional voiding, which is uncoordinated relaxation of the urethral sphincter during voiding, leads to incomplete emptying of the bladder, increasing the risk of bacterial colonization. Similarly, any condition that interferes with complete emptying of the bladder, such as constipation, vesicoureteral reflux, urinary tract obstruction, or neurogenic bladder, increases the risk of UTI. Poor perineal hygiene, structural abnormalities of the urinary tract, catheterization, instrumentation of the urinary tract, and sexual activity increase the risk as well.

The inflammatory response to pyelonephritis may produce renal parenchymal scars. Such scars in infancy and childhood may contribute to hypertension, renal disease, and renal failure later in life.

▶ Clinical Findings

A. Symptoms and Signs

Newborns and infants with UTI have nonspecific signs, including fever, hypothermia, jaundice, poor feeding, irritability, vomiting, failure to thrive, and sepsis. Strong, foul-smelling or cloudy urine may be noted. Preschool children may have abdominal or flank pain, vomiting, fever, urinary frequency, dysuria, urgency, or enuresis. School-aged children commonly have classic signs of cystitis (frequency, dysuria, and urgency) or pyelonephritis (fever, vomiting, and flank pain). Costovertebral tenderness is unusual in young children, but may be demonstrated by school-aged children. Physical examination should include attention to blood pressure determination, abdominal examination, and a genitourinary examination. Urethritis, poor perineal hygiene, herpes simplex virus, or other genitourinary infections may be apparent on examination.

B. Laboratory Findings

Screening urinalysis indicates pyuria (> 5 WBCs/high-power field) in most children with UTI, but some children can have sterile pyuria without UTI. White cells from the urethra or vagina may be present in urine or may be in the urine because of a renal inflammatory process. The leukocyte esterase test correlates well with pyuria, but has a similar false-positive rate. The detection of urinary nitrite by dipstick is highly correlated with enteric organisms being

cultured from urine. Most young children (70%) with UTI have negative nitrite tests, however. They empty their bladders frequently, and it requires several hours for bacteria to convert ingested nitrates to nitrite in the bladder.

The gold standard for diagnosis remains the culture of a properly collected urine specimen. Collection of urine for urinalysis and culture is difficult in children due to frequent contamination of the sample. In toilet-trained, cooperative, older children, a midstream, clean-catch method is satisfactory. Although cleaning of the perineum does not improve specimen quality, straddling of the toilet to separate the labia in girls, retraction of the foreskin in boys, and collecting midstream urine significantly reduce contamination. In infants and young children, bladder catheterization or suprapubic collection is necessary in most cases to avoid contaminated samples. Bagged urine specimens are helpful only if negative. Specimens that are not immediately cultured should be refrigerated and kept cold during transport. Any growth is considered significant from a suprapubic culture. Quantitative recovery of 10^5 cfu/mL or more is considered significant from clean-catch specimens, and 10^4–10^5 is considered significant from catheterized specimens. Usually the recovery of multiple organisms indicates contamination.

Asymptomatic bacteriuria is detected in 0.5%–1.0% of children who are screened with urine culture. Asymptomatic bacteriuria, as seen commonly in children requiring chronic bladder catheterization, is believed to represent colonization of the urinary tract with nonuropathogenic bacteria. Treatment in such cases may increase the risk of symptomatic UTI by eliminating nonpathogenic colonization. Screening urine cultures in asymptomatic children are, therefore, generally discouraged.

C. Imaging

Because congenital urologic abnormalities increase the risk of UTI, a renal ultrasound, which is a noninvasive study, is recommended for children with UTI. In cases where hydronephrosis and/or frank evidence of urinary tract obstruction is demonstrated, a voiding cystourethrogram (VCUG) is performed to demonstrate vesicoureteral reflux or a renal scan can be done to confirm obstruction and demonstrate the amount of functioning renal tissue. VUR is a congenital abnormality present in about 1% of the population beyond infancy and is graded using the international scale (I—reflux into ureter; II—reflux to the kidneys; III—reflux to kidneys with dilation of ureter only; IV—reflux with dilation of ureter and mild blunting of renal calyces; V—reflux with dilation of ureter and blunting of renal calyces). Reflux is detected in 30%–50% of children presenting with a UTI at 1 year of age and younger. The natural history of reflux is to improve, and 80% of reflux of grades I, II, or III will resolve or significantly improve within 3 years following detection provided there is prophylaxis against infection.

VCUG should be done selectively on children with a first UTI; candidates for VCUG should include those in whom a urologic abnormality is suspected due to weak stream, dribbling, or perineal abnormalities. Boys with a first UTI may have posterior urethral valves, an important congenital abnormality that requires surgery. Children older than 3 years of age who are otherwise healthy and growing well usually can be followed clinically and do not need an immediate VCUG for a first UTI, but a renal ultrasound is recommended. The yield of VCUG in sexually active teenagers is very low.

Ultrasonographic examination of kidneys should be done acutely in children presenting with pyelonephritis and repeated in those who have not improved after 3–5 days of antimicrobial treatment appropriate for the susceptibility of the organism. The examination is done to detect renal or perirenal abscesses or obstruction of the kidneys.

▶ Treatment

A. Antibiotic Therapy

Management of UTI is influenced by clinical assessment. Very young children (younger than 3 months) and children with dehydration, toxicity, or sepsis should be admitted to the hospital and treated with parenteral antimicrobials. Older infants and children who are not seriously ill can be treated as outpatients. Initial antimicrobial therapy is based on prior history of infection and antimicrobial use, as well as location of the infection in the urinary tract.

Uncomplicated cystitis can be treated with amoxicillin, trimethoprim–sulfamethoxazole, or a first-generation cephalosporin. These antimicrobials are concentrated in the lower urinary tract, and high cure rates are common. There are significant differences in the rates of antimicrobial resistance, so knowledge of the rates in the local community is important. More seriously ill children are initially treated parenterally with a third-generation cephalosporin or aminoglycoside. The initial antimicrobial choice is adjusted after culture and susceptibility results are known. The recommended duration of antimicrobial therapy for uncomplicated cystitis is 7–10 days. For sexually mature teenagers with cystitis, fluoroquinolones such as ciprofloxacin and levofloxacin for 3 days are effective and cost-effective. Short-course therapy of cystitis is not recommended in children, because differentiating upper and lower tract disease may be difficult and higher failure rates are reported in most studies of short-course therapy.

Acute pyelonephritis is usually treated for 10 days. In nontoxic children older than 3 months of age who are not vomiting, oral treatment with an agent such as cefixime can be used. In sicker children, parenteral therapy may be required initially. Most of these children can complete therapy orally once symptomatic improvement has occurred.

A repeat urine culture 24–48 hours after beginning therapy is not needed if the child is improving and doing well.

B. Follow-Up

Children with UTI should be followed with screening urinalysis 1 and 2 months after resolution of UTI. Dipstick nitrite determination can be used at home by parents on first morning voided urine in children with frequently recurring UTI.

C. Prophylactic Antimicrobials

Selected children with frequently recurring UTI may benefit from prophylactic antimicrobials. In children with high-grade VUR, prophylactic antimicrobials may be beneficial in reducing UTI, as an alternative to surgical correction, or in the interval prior to surgical therapy. Many experts recommend surgical correction of higher-grade reflux, particularly grade V. Trimethoprim-sulfamethoxazole and nitrofurantoin are approved for prophylaxis. The use of broader-spectrum antimicrobials leads to colonization and infection with resistant strains.

Children with dysfunctional voiding generally do not benefit from prophylactic antimicrobials; rather, addressing the underlying dysfunctional voiding is most important.

NEUROLOGICAL ASSESSMENT & NEURODIAGNOSTICS

HISTORY & EXAMINATION

1. History

Even in an era of increasingly sophisticated neurodiagnostic testing, the assessment of the child with a possible neurologic disorder begins with history, general physical exam as well as detailed neurologic examination. The standard pediatric history and physical examination are presented in Chapter 9. A careful history will allow the clinician to establish the nature and course of the illness. The progression of the illness, that is, acute, chronic, progressive or static, episodic or continuous, will help to determine the approach to the evaluation. When the developmental history is vague, other resources such as extended family members and baby books may provide clarification of prior development. Episodic events such as headaches or seizures warrant emphasis on precise details preceding and during these events. Often spells can be videotaped and this can provide important details that will assist in diagnosis.

2. Neurologic Examination

A general physical examination is an essential aspect of the assessment. Growth parameters and head circumference should be charted (see Chapter 3). A developmental assessment using an appropriate screening tool is part of every neurologic evaluation of the infant and young child and can be used to document a child's developmental status. Chapter 3 delineates age-appropriate developmental landmarks (see Tables 3–1 and 3–2). Multiple instruments are available for screening infants and children. Among these The Ages & Stages Questionnaires®, Third Edition (ASQ-3), a parent-completed screening tool, is widely used when assessing infants and young children. The Modified Checklist for Autism in Toddlers (M-CHAT™) is a screening tool for assessing toddlers between 16 and 30 months of age for risk of autism spectrum disorders. The specifics of the neurologic examination are determined by the age of the child and the ability to cooperate in the examination. Expected newborn-infant reflexes and automations and other examination suggestions pertinent to that age group are included in Chapter 2. The hallmark of neurologic diagnosis is *localization*, defining where in the nervous system the "lesion" is. While not all childhood neurologic disorders are easily localized, the part of the nervous system involved, for example, central versus neuromuscular, can often be defined and will act as a guide for evaluation and diagnosis.

Table 25–1 outlines components of the neurologic examination. Much of the examination of the frightened infant or toddler is by necessity observational. An organized approach to the examination is thus imperative. Playing games will engage a toddler or preschooler: throwing and catching a ball, stacking blocks, hopping, jogging, counting, and drawing (circles, lines) can reduce anxiety and allow assessment of fine and gross motor coordination, balance, and handedness. In the older child, "casual" conversation can reveal both language and cognitive competence as will drawing, writing, calculating, and spelling.

DIAGNOSTIC TESTING

1. Electroencephalography

Electroencephalography (EEG) is a noninvasive method for recording cerebral activity. The background patterns of the EEG vary by both age and clinical state of the subject, for example, infant, toddler, adolescent; awake, drowsy, or asleep. Intermittent activity often reflects disordered central nervous system (CNS) function. The EEG has its greatest clinical applicability in the evaluation of seizure disorders. An EEG may demonstrate "epileptiform activity," that is,

Table 25–1. Neurologic examination: toddler age and up.

Category	Operation	Assesses
Mental status	Level of consciousness; orientation, language, cortical function developmental screen (age specific questions); activity level; affect.	Both cortical and subcortical pathways
Cranial nerves	CN I: omit most of the time (smell). CN II: pupils (light reflex), vision (acuity), fields, fundi. CN III, IV, VI: extraocular movements, pupils, convergence, (strabismus). CN V: facial sensation (upper, middle, lower; V_1, V_2, V_3); motor—move jaw laterally, open, close against resistance. CN VII: upper—eye closure, brow; lower—grimace, show teeth. CN VIII: whispered voice from 10–20 ft each ear. Tuning fork tests. CN IX, X: sensation? Movement of palate to "ahh" or tongue blade ("gagging"—often omit). CN XI: turning head right, left; flexing against resistance. CN XII: protrude tongue, push it out cheek. Push left, right against resistance (examiner's thumb).	
Motor	Tone: trunk (infant)—hold prone, supine; manipulate relaxed limbs; hold under arms. Strength: proximal/distal—shoulder abduction/grasp; get up from floor (hips); dorsiflexion of foot. 0 = no movement; 1 = trace; 3 = against gravity; 5 = normal (0–5 grading strength)	Brain: "suprasegmental" influence. Cord: lower motor neuron-"segmental" component
Reflexes	Tendon reflexes: biceps, triceps, brachioradialis, knee, ankle. Cutaneous: abdominal (cremasteric).	Pyramidal tract Spinal cord: sensory/motor nerve arc
Station	Standing, eyes open, closed, hands out (Romberg test): truncal balance.	Cerebellum (vermis) Posterior columns
Gait	Walking (running in hall); heel-toe (tandem gait) forward, backward. Balance on each foot.	Cerebellum (vermis)
Coordination (truncal, limb)	Balance on each foot; hopping; finger-nose-finger pursuit. Stack blocks. Reach for a rattle. Rapid alternating movements.	Cerebellum: lateral lobes
Sensory	Light touch, sharp (pain), vibration (tuning fork-toe, finger, on bone), position (same). Cortical: 2 point, finger writing, object identification, position limb in space, barognosis (weight).	Peripheral nerve Posterior column Anterior/lateral column Parietal lobe

patterns that indicate risk for seizures and epilepsy, though not necessarily diagnostic of such. At times, however, the findings on an EEG are diagnostic, as in the hypsarrhythmic pattern of infantile spasms (West syndrome) or generalized three-cycle-per-second spike-wave pattern of absence epilepsy. Synchronized video recording with EEG has increased the utility of the test in assessing episodic disorders. EEG can be very useful in the evaluation of altered mental status and in some encephalopathies.

The EEG itself, in isolation, is rarely diagnostic but is one part of the child's clinical picture. Routine EEG, obtained in the outpatient setting, is usually brief (< 30 minutes). Therefore, events of interest are usually not recorded. If the child is unable to cooperate, it may be impossible to obtain a study or the study may be uninterpretable due to artifact

from movement, crying, etc. Medications used for sedation of an uncooperative child, especially barbiturates and benzodiazepines, may produce artifact in the tracing, which can confuse interpretation and may decrease the likelihood of recording abnormalities such as epileptiform discharges. Children without a history of epilepsy may have an abnormal EEG. EEG findings such as those occasionally seen in migraine, learning disabilities, or behavior disorders are often nonspecific and do not reflect structural brain damage. When questions arise regarding the clinical significance of EEG findings, consultation with a pediatric neurologist is appropriate.

Due to more prolonged recording duration, ambulatory EEG obtained over 24–48 hours can be useful in assessing events to ascertain if they are due to epileptic seizures.

Likewise, recording the EEG during nocturnal polysomnographic studies can help differentiate between nonepileptic sleep-related events from nocturnal epileptic seizures arising from sleep.

Prolonged bedside EEG recordings are useful in the assessment of patients with altered mental status, suspected nonconvulsive status epilepticus, and drug-induced coma (for the treatment of increased intracranial pressure or status epilepticus), as well as infants with hypoxic ischemic encephalopathy. The EEG is less commonly used for determining so-called brain death (electrocerebral inactivity).

Continuous video-EEG monitoring, obtained as an inpatient, allows assessment of the patient with medically intractable epilepsy. The children are admitted to a specialized unit (epilepsy monitoring unit [EMU]) for up to a week or more. When children are admitted to the hospital, medications are often reduced or discontinued, increasing the likelihood of recording an event. Localization of the seizure focus by recording during seizures can lead to resective surgery for the patient who has failed medical therapy. Correlating video with EEG has also proven useful in characterizing spells that may or may not be seizures.

2. Evoked Potentials

Visual, auditory, or somatosensory evoked potentials (evoked responses) can be obtained by repetitive stimulation of the retina by light flashes, the cochlea by sounds, or a nerve by galvanic stimuli, which results in cortical response when recorded from the scalp surface using averaging techniques. The presence or absence of evoked potential waves and their latencies from the time of the stimuli are determined and can be useful in some specific situations although they are not routinely obtained for evaluation of neurologic disorders.

However, auditory evoked responses are now the standard for screening hearing in the neonate. Intraoperative somatosensory evoked potentials are often used during spine surgery to assist the surgeon during placement of instrumentation for identification of potentially reversible spinal cord injury. Similar techniques are used in other surgeries when there is risk of nerve injury such as craniofacial surgeries.

3. Lumbar Puncture

Assessing cerebral spinal fluid is a necessity in some clinical situations. Spinal fluid is usually obtained by inserting a small-gauge needle (eg, No. 22) through the L3–L4 intervertebral space into the thecal sac while the patient is lying in a lateral recumbent position. Radiographic guidance and sedation may be necessary in some patients. After an opening pressure is measured, fluid is removed to examine for evidence of infection, inflammation, or evidence of metabolic disorders (Table 25–2). Fluid is often sent for red and white cell counts, for determination of the concentrations of protein and glucose, for viral polymerase chain reaction (PCR), and for viral and bacterial cultures. In some cases, additional information is obtained with special staining techniques for mycobacteria and fungus and by testing for specific viral agents, antibody titer determinations, cytopathologic study, lactate and pyruvate concentrations, and amino acid and neurotransmitter analysis. Lumbar puncture is imperative when bacterial meningitis is suspected. Caution must be exercised, however, when signs of increased intracranial pressure (eg, papilledema) or focal neurologic signs are present that might indicate a substantial risk of precipitating tentorial or tonsillar herniation.

4. Genetic/Metabolic Testing

The diagnostic yield of genetic and metabolic evaluation of children with global developmental delay or intellectual disability (GDD/ID) depends on the specific testing done. Microarray testing is diagnostic in almost 8% of children with GDD/ID and in appropriate clinical situations; tests for metabolic disorders have a yield of up to 5%. Thus, focused assessments for genetic disorders should be part of the evaluation of the child with GDD/ID.

5. Electromyography & Nerve Conduction Velocity Testing

Electromyography (EMG) and nerve conduction velocity testing (NCV) are used for assessment of neuromuscular disorders such as spinal muscular atrophy, the Guillain-Barre syndrome, defects in neuromuscular transmission such as myasthenia gravis and infantile botulism, myopathies, acquired and hereditary neuropathies, and leukodystrophies, disorders associated with central as well as peripheral demyelination.

NCV is performed by introducing a small current into peripheral nerves using small discs overlying the nerves. The conduction velocity of the stimulus is calculated. EMG records spontaneous and volitional electrical activity of skeletal muscle tissue. It requires placement of tiny needles into selected muscles. While uncomfortable, the tests are not painful and sedation is only rarely necessary. For more details, refer to section "Disorders of Childhood Affecting Muscles" in the chapter.

PEDIATRIC NEURORADIOLOGIC PROCEDURES

1. Computed Tomography

CT scanning is a noninvasive technique, which allows visualization of intracranial contents by obtaining a series of cross-sectional (axial) roentgenograms. Serial images are obtained, which allow computation of x-ray absorption and computation of images which appear as serial slices. Current scanning techniques allow rapid acquisition of data, often without sedation. CT scanning is of high

Table 25–2. Characteristics of cerebrospinal fluid in the normal child and in central nervous system infections and inflammatory conditions.

Condition	Initial Pressure (mm H₂0)	Appearance	Cells/µL	Protein (mg/dL)	Glucose (mg/dL)	Other Tests	Comments
Normal	< 160	Clear	0–5 lymphocytes; first 3 mo, 1–3 PMNs; neonates, up to 30 lymphocytes, rare RBCs	15–35 (lumbar), 5–15 (ventricular); up to 150 (lumbar) for short time after birth; to 6 mo up to 65	50–80 (two-thirds of blood glucose); may be increased after seizure	CSF-IgG index[a] < 0.7[a]; LDH 2–27 U/L	CSF protein in first month may be up to 170 mg/dL in small-for-date or premature infants; no increase in WBCs due to seizure
Bloody tap	Normal or low	Bloody (sometimes with clot)	One additional WBC/700 RBCs[b]; RBCs not crenated	One additional milligram per 800 RBCs[b]	Normal	RBC number should fall between first and third tubes; wait 5 min between tubes	Spin down fluid, supernatant will be clear and colorless[c]
Bacterial meningitis, acute	200–750+	Opalescent to purulent	Up to thousands, mostly PMNs; early, few cells	Up to hundreds	Decreased; may be none	Smear and culture mandatory; LDH > 24 U/L; lactate, IL-8, TNF elevated, correlate with prognosis	Very early, glucose may be normal; PCR meningococci and pneumococci in plasma, CSF may aid diagnosis
Bacterial meningitis, partially treated	Usually increased	Clear or opalescent	Usually increased; PMNs usually predominate	Elevated	Normal or decreased	LDH usually > 24 U/L; PCR may still be positive	Smear and culture may be negative if antibiotics have been in use
Tuberculous meningitis	150–750+	Opalescent; fibrin web or pellicle	250–500, mostly lymphocytes; early, more PMNs	45–500; parallels cell count; increases over time	Decreased; may be none	Smear for acid-fast organism: CSF culture and inoculation; PCR	Consider AIDS, a common comorbidity of tuberculosis
Fungal meningitis	Increased	Variable; often clear	10–500; early, more PMNs; then mostly lymphocytes	Elevated and increasing	Decreased	India ink preparations, cryptococcal antigen, PCR, culture, inoculations, immunofluorescence tests	Often superimposed in patients who are debilitated or on immunosuppressive therapy
Aseptic meningo-encephalitis (viral meningitis, or parameningeal disease); encephalitis is similar	Normal or slightly increased	Clear unless cell count > 300/µL	None to a few hundred, mostly lymphocytes; PMNs predominate early	20–125	Normal; may be low in mumps, herpes, or other viral infections	CSF, stool, blood, throat washings for viral cultures; LDH < 28 U/L; PCR for HSV, CMV, EBV, enterovirus, etc	Acute and convalescent antibody titers for some viruses; in mumps, up to 1000 lymphocytes; serum amylase often elevated; up to 1000 cells present in enteroviral infection

Table 25–2. Characteristics of cerebrospinal fluid in the normal child and in central nervous system infections and inflammatory conditions. (*Continued*)

Condition	Initial Pressure (mm H$_2$O)	Appearance	Cells/μL	Protein (mg/dL)	Glucose (mg/dL)	Other Tests	Comments
Parainfectious encephalomy-elitis (ADEM)	80–450, usually increased	Usually clear	0–50+, mostly lymphocytes; lower numbers, even 0, in MS	15–75	Normal	CSF-IgG index, oligoclonal bands variable; in MS, moderate increase	No organisms; fulminant cases resemble bacterial meningitis
Polyneuritis	Normal and occasionally increased	Early: normal; late: xanthochromic if protein high	Normal; occasionally slight increase	Early: normal; late: 45–1500	Normal	CSF-IgG index may be increased; oligoclonal bands variable	Try to find cause (viral infections, toxins, lupus, diabetes, etc)
Meningeal carci-nomatosis	Often elevated	Clear to opalescent	Cytologic identification of tumor cells	Often mildly to moderately elevated	Often depressed	Cytology	Seen with leukemia, medulloblastoma, meningeal melanosis, histiocytosis X
Brain abscess	Normal or increased	Usually clear	5–500 in 80%; mostly PMNs	Usually slightly increased	Normal; occasionally decreased	Imaging study of brain (MRI)	Cell count related to proximity to meninges; findings as in purulent meningitis if abscess ruptures

ADEM, acute disseminated encephalomyelitis; AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HSV, herpes simplex virus; IL-8, interleukin 8; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; MS, multiple sclerosis; PCR, polymerase chain reaction; PMN, polymorpho-nuclear neutrophil; RBC, red blood cell; TNF, tumor necrosis factor; WBC, white blood cell.

[a]CSF-IgG index = (CSF IgG/serum IgG)/(CSF albumin/serum albumin).

[b]Many studies document pitfalls in using these ratios due to WBC lysis. Clinical judgment and repeat lumbar punctures may be necessary to rule out meningitis in this situation.

[c]CSF WBC (predicted) = CSF RBC × (blood WBC/blood RBC). O:P ratio = (observed CSF WBC)/(predicted CSF WBC). Also, do WBC:RBC ratio. If O:P ratio ≤ 0.01, and WBC:RBC ratio ≤ 1:100, meningitis is absent.

sensitivity (88%–96% of lesions larger than 1–2 cm can be seen) but low specificity (tumor, infection, or infarct may look the same). It is particularly useful for assessment of head trauma, allowing excellent visualization of intracranial blood. It allows visualization of the ventricular system to assess hydrocephalus. It is useful in determining presence of intracranial calcifications such as those associated with intrauterine infections, with tubers in patients with tuberous sclerosis complex, etc. Intravenous injection of iodized contrast media may be helpful in some situations but is not routinely used. CT angiography (CTA) is possible using contrast and specialized techniques to visualize vascular anatomy and can replace catheter angiography in evaluation of stroke. Radiation exposure is approximately the same as that from a skull radiographic series and must be considered when obtaining a CT scan.

2. Magnetic Resonance Imaging

MRI is a noninvasive technique that provides high-resolution images of soft tissues. MRI uses the magnetic properties of certain nuclei to produce diagnostically useful signals (Table 25–3). The technique is based on detecting the response (resonance) of hydrogen proton to electromagnetic radiation. The strength of MRI signals varies with the relationship of water to protein and lipid in tissue. MRI can provide information about the histological, physiologic, and biochemical status of tissues as well as gross anatomic features. Sedation is often necessary for MRI scans in children who are unable to lie still for 45 minutes to avoid any movement artifact.

MRI is used to assess a wide variety of neurologic disorders such as tumors, edema, ischemic and hemorrhagic lesions, vascular disorders, inflammation, demyelination, CNS infection, metabolic disorders, and degenerative processes. Because bone does not produce artifact in the images,

Table 25–3. Utility of MRI protocols.

Protocol	Useful For
T1	Anatomy, myelination
T2	Pathologic changes; myelination
FLAIR	Pathologic changes
T1 with gadolinium	disruption of blood-brain barrier
Perfusion-weighted imaging	Cerebral blood flow/stroke
DWI	Acute ischemia (stroke)
ADC	Acute cerebral ischemia

ADC, apparent diffusion coefficient; DWI, diffusion-weighted imaging; FLAIR, fluid-attenuated inversion recovery.

the posterior fossa contents can be studied far better with MRI than with CT scans allowing brainstem, blood vessels, and the cranial nerves imaging.

Magnetic resonance angiography (MRA) or venography (MRV) is used to visualize large extra- and intracranial blood vessels (arterial and venous) without injection of dye, though they are not as sensitive as conventional angiography. The lack of radiation exposure is an advantage over CTA (see previous section). Perfusion-weighted imaging and diffusion-weighted imaging (DWI) (measuring random motion of water molecules) are used to evaluate brain ischemic penumbra and cytotoxic edema in acute stroke as well as toxic and metabolic brain disorders.

MR spectroscopy (MRS) assesses biochemical changes in CNS tissue, measuring signals of increased cellular activity and oxidative metabolism. For example, MRS can be used to identify brain tumors.

Newer applications of MRI allow for functional assessment of the CNS. Functional MRI (fMRI) is used to localize various brain functions such as language and motor by assessing blood oxygenation changes in an area of interest during language or motor tasks. The axonal tracts of neurologic pathways such as the optic radiations, or motor system, can be identified using diffusion tensor imaging (DTI). These techniques generally require a team involving a neuropsychologist and radiologist to derive specific paradigms for testing and evaluation of imaging, as well as a cooperative patient.

3. Positron Emission Tomography

Positron emission tomography (PET) is a nuclear medicine imaging technique that utilizes radiolabeled substrates such as intravenously administered fluorodeoxyglucose to measure the metabolic rate at given sites within the brain, producing three-dimensional reconstructions for localization of CNS function. These scans may be coregistered with a traditional CT scan or MRI allowing more precise localization of functional processes. It is proving to be very useful in preoperative evaluation for epilepsy surgery. PET is most often performed in the interictal state. The information from PET scan complements EEG, single-photon emission computerized tomography (SPECT), and MRI findings to aid in defining the epileptogenic zone ("focus"). PET coregistered with CT scans or MRI scans is used for assessing systemic tumors and is becoming increasingly available for use in evaluation of the CNS.

4. Single-Photon Emission Computerized Tomography

An application of nuclear medicine imaging, SPECT scans image cerebral blood flow using a radioactive tracer (typically technetium-99m) to produce multiple cuts similar to those obtained in CT scans. This allows virtual three-dimensional visualization of vascular blood flow. It is useful in assessment of

patients for epilepsy surgery, aiding in identification of increased blood flow in a seizure focus during a seizure. In children with brain tumors, SPECT can help in differentiating tumor recurrence from post-treatment changes, in assessing the response to treatment, in directing biopsy, and in planning therapy. Regional cerebral blood flow can be assessed in children with strokes due to vascular stenosis and moyamoya disease.

5. Ultrasonography

Ultrasonography (US) offers a pictorial display of the varying densities of tissues in a given anatomic region by recording the echoes of ultrasonic waves reflected from it. US allows assessment of brain structures quickly with easily portable equipment, without ionizing radiation, and at about one-fourth the cost of CT scanning. Sedation is usually not necessary, and the procedure can be repeated as often as needed without risk to the patient. Ultrasonography has been used for in-utero diagnosis of hydrocephalus and other anomalies. In neonates, the thin skull and the open anterior fontanel have facilitated imaging of the brain, and ultrasonography is used to screen and follow infants at risk for intracranial hemorrhage. Other uses in neonates include detection of hydrocephalus, periventricular ischemic lesions, major brain and spine malformations, and calcifications. US of the neonatal spine can be used to determine the presence of anomalies at the lumbosacral level. Once the fontanels start to close, this modality is no longer useful due to inability to penetrate bone.

6. Cerebral Angiography

Arteriography remains useful in the diagnosis of cerebrovascular disorders, particularly cerebrovascular accidents and potentially operable vascular malformations. In some brain tumors, arteriography may be used to define the nature of tumors and for surgical planning. Since cerebral angiography uses traditional x-ray to produce images, there is significant exposure to ionizing radiation.

7. Myelography

Radiographic examination of the spine may be indicated in cases of spinal cord tumors, myelitis, or various forms of spinal dysraphism and in the rare instance of herniated disks in children. MRI has largely replaced sonography, CT, and myelography for examination of the spinal cord.

▼ DISORDERS AFFECTING THE NERVOUS SYSTEM IN INFANTS & CHILDREN

ALTERED STATES OF CONSCIOUSNESS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

► Reduction or alteration in cognitive and affective mental functioning and in arousability or attentiveness

► Acute onset

▶ General Considerations

Many terms are used to describe the continuum from fully alert and aware, to complete unresponsiveness, including obtundation, lethargy, somnolence, stupor, light coma, and deep coma. Several scales have been used to grade the depth of unconsciousness (Table 25–4). The commonly used Glasgow Coma Scale is summarized in Table 12–5. Physicians should use one of these scales and provide further descriptions in case narratives (such as, "opens eyes with painful stimulus,

Table 25–4. Gradation of coma.

	Deep Coma		Light Coma		
	Grade 4	Grade 3	Grade 2	Grade 1	Stupor
Response to pain	0	+	Avoidance	Avoidance	Arousal unsustained
Tone/posture	Flaccid	Decerebrate	Variable	Variable	Normal
Tendon reflexes	0	+/−	+	+	+
Pupil response	0	+	+	+	+
Response to verbal stimuli	0	0	0	0	+
Other corneal reflex	0	+	+	+	+
Gag reflex	0	+	+	+	+

but does not respond to voice"). These descriptions help subsequent observers quantify unconsciousness and evaluate changes in the patient's condition.

The neurologic substrate for consciousness is the ascending reticular activating system in the brainstem, which extends the thalamus and paraventricular nucleus of the hypothalamus. Large lesions of the cortex, especially bilateral lesions, can also cause coma.

- *Persistent vegetative state* denotes a chronic condition in which there is preservation of the sleep-wake cycle but no awareness of self or the environment and no recovery of mental function. Sleep-wake cycles are present.
- *Minimally conscious state* denotes patients that do not meet criteria for persistent vegetative state. These patients occasionally may have purposeful movements.
- *Brain death* refers to patients in coma without brainstem reflexes or spontaneous respirations.

Conditions mistaken for coma:

- *Locked-in syndrome* describes patients who are conscious but have no access to motor or verbal expression because of massive loss of motor function of the pontine portion of the brainstem. Vertical eye movements may be preserved.
- *Akinetic-mutism:* Patient is aware, but does not initiate movement or follow commands. Caused by lesions of the frontal lobes.
- *Catatonia* refers to patients with psychiatric illness. Patients retain ability to maintain trunk and limb postures.

▶ Treatment

A. Emergency Measures

The clinician must first stabilize the child using the ABCs of resuscitation. The airway must be kept open with positioning;

endotracheal intubation is often considered. Breathing and adequate air exchange can be assessed by auscultation. Hand bag respiratory assistance with oxygen may be needed. Circulation must be ensured by assessing pulse and blood pressure. An intravenous line is always necessary. Fluids, plasma, blood, or even a dopamine drip (1–20 mcg/kg/min) may be required in cases of hypotension. Initial intravenous fluids should contain glucose until further assessment disproves hypoglycemia as a cause. An extremely hypothermic or febrile child may require vigorous warming or cooling to save life. The assessment of vital signs may signal the diagnosis. Slow, insufficient respirations suggest poisoning by hypnotic drugs; apnea may indicate diphenoxylate hydrochloride poisoning. Rapid, deep respirations suggest acidosis, possibly metabolic, as with diabetic coma; toxin exposure, such as that due to aspirin; or neurogenic causes, as in Reye syndrome. Hyperthermia may indicate infection or heat stroke; hypothermia may indicate cold exposure, ethanol poisoning, or hypoglycemia (especially in infancy).

The signs of impending brain herniation are another priority of the initial assessment. Bradycardia, high blood pressure, and irregular breathing are signs of severely increased intracranial pressure. Third nerve palsy (with the eye deviated down and out, and a "blown" pupil [unilateral pupillary dilation]) is a sign of impending temporal lobe or brainstem herniation. These signs suggest a need for hyperventilation to reduce cerebral edema, consideration of mannitol, prompt neurosurgical consultation, and head CT. If brainstem herniation or increased pressure is possible, intracranial monitoring may be necessary. Initial treatment of impending herniation includes keeping the patient's head up (15–30 degrees) and providing moderate hyperventilation. The use of mannitol, diuretics, barbiturates, hypothermia, and drainage of cerebrospinal fluid (CSF) are more heroic measures covered in detail in Chapter 14.

Table 25–5. Some causes of coma in childhood.

Mechanism of Coma	Likely Cause	
	Newborn Infant	**Older Child**
Anoxia 　Asphyxia 　Respiratory obstruction 　Severe anemia	Birth asphyxia, HIE Meconium aspiration, infection (especially respiratory syncytial virus) Hydrops fetalis	Carbon monoxide (CO) poisoning Croup, tracheitis, epiglottitis Hemolysis, blood loss
Ischemia 　Cardiac 　Shock	Shunting lesions, hypoplastic left heart Asphyxia, sepsis	Shunting lesions, aortic stenosis, myocarditis, blood loss, infection
Head trauma (structural cause)	Birth contusion, hemorrhage, nonaccidental trauma (NAT)	Falls, auto accidents, athletic injuries
Infection (most common cause in childhood)	Gram-negative meningitis, enterovirus, herpes encephalitis, sepsis	Bacterial meningitis, viral encephalitis, postinfectious encephalitis, sepsis, typhoid, malaria
Vascular (CVA or stroke, often of unknown cause)	Intraventricular hemorrhage, sinus thrombosis	Arterial or venous occlusion with congenital heart disease, head or neck trauma
Neoplasm (structural cause)	Rare this age. Choroid plexus papilloma with severe hydrocephalus	Brainstem glioma, increased pressure with posterior fossa tumors
Drugs (toxidrome)	Maternal sedatives; injected pudendal and paracervical analgesics	Overdose, salicylates, lithium, sedatives, psychotropic agents
Epilepsy	Constant minor motor seizures; electrical seizure without motor manifestations	Nonconvulsive or, absence status, postictal state; drugs given to stop seizures
Toxins (toxidrome)	Maternal sedatives or injections	Arsenic, alcohol, CO, pesticides, mushroom, lead
Hypoglycemia	Birth injury, diabetic progeny, toxemic progeny	Diabetes, "prediabetes," hypoglycemic agents
Increased intracranial pressure (metabolic or structural cause)	Anoxic brain damage, hydrocephalus, metabolic disorders (urea cycle; amino-, organic acidurias)	Toxic encephalopathy, Reye syndrome, head trauma, tumor of posterior fossa
Hepatic causes	Hepatic failure, inborn metabolic errors in bilirubin conjugation	Hepatic failure
Renal causes, hypertensive encephalopathy	Hypoplastic kidneys	Nephritis, acute (AGN) and chronic; uremia, uremic syndrome
Hypothermia, hyperthermia	Iatrogenic (head cooling)	Cold weather exposure, drowning; heat stroke
Hypercapnia	Congenital lung anomalies, bronchopulmonary dysplasia	Cystic fibrosis (hypercapnia, anoxia)
Electrolyte changes 　Hyper- or hyponatremia 　Hyper- or hypocalcemia 　Severe acidosis, lactic acidosis	Iatrogenic ($NaHCO_3$ use), salt poisoning (formula errors) SIADH, adrenogenital syndrome, dialysis (iatrogenic) Epticemia, metabolic errors, adrenogenital syndrome	Diarrhea, dehydration Lactic acidosis Infection, diabetic coma, poisoning (eg, aspirin), hyperglycemic nonketotic coma
Purpuric	Disseminated intravascular coagulation (DIC)	DIC, leukemia, thrombotic thrombocytopenic purpura

AGN, acute glomerulonephritis; SIADH, syndrome of inappropriate antidiuretic hormone secretion.
Modified and reproduced, with permission, from Lewis J, Moe PG: The unconscious child. In: Conn H, Conn R (eds): *Current Diagnosis*, 5th ed. WB Saunders; 1977.

A history obtained from parents, witnesses, or ambulance personnel is desirable. An important point is whether the child is known to have a chronic illness, such as diabetes, hemophilia, epilepsy, or cystic fibrosis. Recent acute illness raises the possibility of coma caused by viral or bacterial meningitis.

Trauma is a common cause of coma. Lack of a history of trauma, especially in infants, does not rule it out. Abusive head trauma or an unwitnessed fall may have occurred. In coma of unknown cause, poisoning is always a possibility, especially in toddlers. Absence of a history of ingestion of a

toxic substance or of medication in the home does not rule out poisoning as a cause.

Often the history is obtained concurrently with a brief pediatric and neurologic screening examination. After the assessment of vital signs, the general examination proceeds with a trauma assessment. Palpation of the head and fontanel, inspection of the ears for infection or hemorrhage, and a careful examination for neck stiffness are indicated. If circumstances suggest head or neck trauma, the head and neck must be immobilized so that any fracture or dislocation will not be aggravated. The skin must be inspected for petechiae or purpura that might suggest bacteremia, infection, bleeding disorder, or traumatic bruising. Examination of the chest, abdomen, and limbs is important to exclude enclosed hemorrhage or traumatic fractures.

Neurologic examination quantifies the stimulus response and depth of coma, such as responsiveness to verbal or painful stimuli. Are the eye movements spontaneous, or is it necessary to do the doll's eye maneuver (rotating the head rapidly to see whether the eyes follow in a patient without neck trauma)? Motor and sensory examinations assess reflex asymmetries, Babinski sign, and evidence of spontaneous posturing or posturing induced by noxious stimuli (eg, decorticate or decerebrate posturing).

If the cause of the coma is not obvious, emergency laboratory tests must be obtained. Table 25–5 lists some of the causes of coma in children. Most comas (90%) in children have a medical (vs structural) cause. Infection is a common cause (30%). An immediate blood glucose, complete blood count, urine obtained by catheterization if necessary, pH and electrolytes (including bicarbonate), serum urea nitrogen, and aspartate aminotransferase and ammonia are initial screens. Urine, blood, and even gastric contents must be saved for toxin screen if the underlying cause is not obvious. Blood culture and lumbar puncture often are necessary to rule out CNS infection. However, papilledema is a relative contraindication to lumbar puncture. Often, a blood culture is obtained, antibiotics started, and imaging study of the brain done prior to a diagnostic lumbar puncture. If meningitis is suspected and a lumbar puncture is delayed or believed to be hazardous, antibiotics should be started and the diagnostic lumbar puncture done later. Tests that are helpful in obscure cases of coma include oxygen and carbon dioxide partial pressures, serum and urine osmolality, porphyrins, lead levels, general toxicology screen, serum amino acids, and urine organic acids. Hashimoto encephalopathy is a controversial, yet potentially treatable consideration. A formal metabolic consultation is also useful in this setting.

If head trauma or increased pressure is suspected, an emergency CT scan or MRI is necessary. CT is usually helpful as an initial screening examination, but MRI is more sensitive in finding anoxic brain injury early in the course. Bone windows on the former study or skull radiographs can be done at the same sitting. The absence of skull fracture does not rule out coma caused by closed head trauma. Injury that results from shaking a child is one example. Treatment of head injury associated with coma is discussed in detail in Chapter 12.

Rarely, an emergency EEG aids in diagnosing the cause of coma. Nonconvulsive status epilepticus or a focal finding as seen with herpes encephalitis (periodic lateralized epileptiform discharges) and focal slowing as seen with stroke or cerebritis are cases in which the EEG might be helpful. The EEG also may correlate with the stage of coma and add prognostic information. An EEG should be ordered if seizures are suspected. If obvious motor seizures have occurred, treatment for status epilepticus is given with intravenous drugs (see later section on Seizure Disorders).

B. General Measures

Vital signs must be monitored and maintained. The patient's response to vocal or painful stimuli and orientation to time, place, and situation are monitored. Posture and movements of the limbs, either spontaneously or in response to pain, are serially noted. Pupillary size, equality, and reaction to light, and movement of the eyes to the doll's eye maneuver or ice water caloric tests should be recorded (in patients without spine injury). Intravenous fluids can be tailored to the situation, as for treatment of acidosis, shock, or hypovolemia. Nasogastric suction is initially important. The bladder should be catheterized for monitoring urine output and for urinalysis.

Prognosis

About 50% of children with nontraumatic causes of coma have a good outcome. In studies of adults assessed on admission or within the first days after the onset of coma, an analysis of multiple variables was most helpful in assessing prognosis. Abnormal neuro-ophthalmologic signs (eg, the absence of pupillary reaction or of eye movement in response to the doll's eye maneuver or ice water caloric testing and the absence of corneal responses) were unfavorable. Delay in the return of motor responses, tone, or eye opening was also unfavorable. In children, the assessment done on admission is about as predictive as one done in the succeeding days. Approximately two-thirds of outcomes can be successfully predicted at an early stage on the basis of coma severity, extraocular movements, pupillary reactions, motor patterns, blood pressure, temperature, and seizure type. In patients with severe head trauma, a Glasgow Coma Scale ≤ 5, hypothermia, hyperglycemia, and coagulation disorders are factors associated with an increased risk of mortality. Other characteristics, such as the need for assisted respiration, the presence of increased intracranial pressure, and the duration of coma, are not significantly predictive. Published reports suggest that an anoxic (in contrast to traumatic, metabolic, or toxic) coma, such as that caused by near drowning, has a much poorer outlook.

SEIZURE DISORDERS (EPILEPSIES)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Recurrent unprovoked seizures.

▶ Often, interictal electroencephalographic changes.

▶ General Considerations

A seizure is a sudden, transient disturbance of brain function, manifested by involuntary motor, sensory, autonomic, or psychic phenomena, alone or in any combination, often accompanied by alteration or loss of consciousness. Seizures can be caused by any factor that disturbs brain function. They may occur after a metabolic, traumatic, anoxic, or infectious insult to the brain (classified as symptomatic seizures), or spontaneously without prior known CNS insult. Genetic mutations are increasingly identified in many patients without prior known cause of seizures.

Repeated seizures without an evident acute symptomatic cause or provocation (eg, fever) are defined as epilepsy. The incidence is highest in the newborn period and higher in childhood than in later life, with another peak in the elderly. Prevalence flattens out after age 10–15 years. The chance of having a second seizure after an initial unprovoked episode in a child is about 50%. The risk of recurrence after a second unprovoked seizure is 85%. Sixty-five to seventy percent of children with epilepsy will achieve seizure remission with appropriate medication.

▶ Classification

The International League Against Epilepsy (ILAE) has established classifications of seizures and epilepsy syndromes. These were revised in 2010. Seizures are classified as either focal, previously called partial (with suspected seizure onset that can be localized to one part of the brain), or generalized (likely involving the whole brain or a network of the brain).

There are several types of generalized seizures that are recognized with the new classification: generalized tonic-clonic, absence (typical, atypical and with special features), myoclonic, myoclonic atonic, tonic, clonic, and atonic seizures. Focal seizures are no longer classified as simple and complex; this prior classification was based on loss of awareness which can be difficult to assess with some seizures, particularly if language areas are involved. With the new nomenclature, description of the seizure is most beneficial with suggested terms such as "without impairment of consciousness," "with motor involvement," or "hypomotor" seizure. This will allow better description and thus better classification of seizures.

Epilepsy syndromes are defined by the nature of the seizures typically present, age of onset, EEG findings, and other clinical factors. The prior terminology of idiopathic, symptomatic, and cryptogenic is no longer in use with the new ILAE classification system. The recommended terms are now "genetic," to indicate a known or presumed genetic etiology. "Structural/metabolic" to indicate a known structural or metabolic etiology to an epilepsy syndrome; an example would be tuberous sclerosis or underlying stroke; and lastly "unknown" for those patients for whom a cause has not yet been identified.

1. Seizures & Epilepsy in Childhood

Characterizing the seizure is necessary for accurate diagnosis, which will determine the nature of further evaluation and treatment and help in prognostication (Tables 25–6 and 25–7).

▶ Clinical Findings

A. History, Symptoms, and Signs

Seizures are stereotyped paroxysmal clinical events; the key to diagnosis is usually in the history. Not all paroxysmal events are epileptic. A detailed description of seizure onset is important in determining if an event is a seizure and if there is localized onset (partial or focal seizure). Events prior to, during, and after the seizure need to be described, although observers often recall little except generalized convulsive activity because of its dramatic appearance. An aura may

Table 25–6. Seizures by age at onset, pattern, and preferred treatment.

Seizure Type Epilepsy Syndrome	Age at Onset	Clinical Manifestations	Causative Factors	EEG Pattern	Other Diagnostic Studies	Treatment and Comments
Neonatal seizures	Birth–2 wk	Can be any seizure type, can be very subtle.	Neurologic insults (hypoxia/ischemia; intracranial hemorrhage) present more in first 3 d or after 8th day; metabolic disturbances alone between 3rd and 8th days; hypoglycemia, hypocalcemia, hyper- and hyponatremia. Drug withdrawal. Pyridoxine dependency. Other metabolic disorders. CNS infections. Structural abnormalities. Genetic causes increasing recognized.	May correlate poorly with clinical seizures. Focal spikes or slow rhythms; multifocal discharges. Electroclinical dissociation may occur: electrical seizure without clinical manifestations.	Lumbar puncture; CSF PCR for herpes, enterovirus; serum Ca^{2+}, PO_4^{3-}, serum and CSF glucose, Mg^{2+}; BUN, amino acid screen, blood ammonia, organic acid screen, TORCHS, other metabolic testing if suspected. Ultrasound or CT/MRI for suspected intracranial hemorrhage and structural abnormalities.	Benzodiazepines, phenobarbital, IV or IM; if seizures not controlled, add phenytoin IV. Recent experience with levetiracetam and topiramate. Treat underlying disorder. Seizures due to brain damage often resistant to anticonvulsants. When cause in doubt, stop protein feedings until enzyme deficiencies of urea cycle or amino acid metabolism ruled out.
Epileptic spasms	3–18 mo, usually about 6 mo	Abrupt, usually but not always symmetrical adduction or flexion of limbs with flexion of head and trunk; or abduction and extensor movements (similar to Moro reflex). Occur in clusters typically upon awakening. Associated irritability and regression in development.	Etiology identified in approximately two-thirds fitting structural/metabolic or genetic. Tuberous sclerosis in 5%–10%. TORCHS, homeobox gene mutations, *ARX*, and other genetic mutations.	Hypsarrhythmia (chaotic high-voltage slow waves or random spikes [90%]); other abnormalities in 10%. Rarely normal at onset. EEG normalization early in course usually correlates with reduction of seizures; not helpful prognostically regarding mental development.	Funduscopic and skin examination, amino and organic acid screen. Chromosomes TORCHS screen, CT, or MRI scan should be done to (1) establish definite diagnosis, (2) aid in genetic counseling. Trial of pyridoxine. Occasionally, surgical resection of cortical malformation. Consider gene panels.	ACTH. Vigabatrin, especially if tuberous sclerosis. B$_6$ (pyridoxine) trial. In resistant cases, topiramate, zonisamide, valproic acid, lamotrigine, ketogenic diet. Early treatment leads to improved outcome.
Febrile convulsions	3 mo–5 y (maximum 6–18 mo); most common childhood seizure (incidence 2%)	Usually generalized seizures, < 15 min; rarely focal in onset. May lead to status epilepticus. Recurrence risk of second febrile seizure 30% (50% if younger than 1 y of age); recurrence risk is same after status epilepticus.	Nonneurologic febrile illness (temperature rises to 39°C or higher). Risk factors: positive family history, day care, slow development, prolonged neonatal hospitalization.	Normal interictal EEG, especially when obtained 8–10 d after seizure. Therefore, not useful unless complicating features.	Lumbar puncture in infants or whenever suspicion of meningitis exists.	Treat underlying illness, fever. Diazepam orally, 0.3–0.5 mg/kg, divided 3 times daily during illness may be considered. Diastat rectally for prolonged (> 5 min) seizure. Prophylaxis with phenobarbital or valproic acid rarely needed.

(*Continued*)

Table 25–6. Seizures by age at onset, pattern, and preferred treatment. (*Continued*)

Seizure Type Epilepsy Syndrome	Age at Onset	Clinical Manifestations	Causative Factors	EEG Pattern	Other Diagnostic Studies	Treatment and Comments
Lennox-Gastaut syndrome)	Any time in childhood (usually 2–7 y)	Mixed seizures including tonic, myoclonic (shocklike violent contractions of one or more muscle groups, singly or irregularly repetitive); rare atonic ("drop attacks") and atypical absence with episodes of absence status epilepticus.	Multiple causes, usually resulting in diffuse neuronal damage. History of infantile spasms; prenatal or perinatal brain damage; viral meningoencephalitis; CNS degenerative disorders; structural cerebral abnormalities (eg, migrational abnormalities).	Atypical slow (1–2.5 Hz) spike-wave complexes and bursts of high-voltage generalized spikes, often with diffusely slow background frequencies. Electrodecremental and fast spikes during sleep.	As dictated by index of suspicion: genetic testing; inherited metabolic disorders, neuronal ceroid lipofuscinosis, others. MRI scan, WBC lysosomal enzymes. Skin or conjunctival biopsy for electron microscopy, nerve conduction studies if degenerative disease suspected.	Difficult to treat. Topiramate, ethosuximide, felbamate, levetiracetam, zonisamide, valproate, clonazepam, rufinamide, clobazam (approval pending) ketogenic diet, vagus nerve stimulation. Avoid phenytoin, carbamazepine, oxcarbazepine, gabapentin.
Doose Syndrome	Any time in childhood (usually 2–7 y)	Mixed seizures, including with atonic, myoclonic atonic, atypical absence, tonic seizures and generalized tonic-clonic seizures	Rarely is etiology found, likely genetic, < 5% with SCN1A, large percentage with family history of febrile seizures	Generalized spike wave discharges, central theta slowing	Genetic testing	Can be difficult to treat, consider topiramate, felbamate, levetiracetam, zonisamide, valproate, rufinamide, ketogenic diet, VNS, avoid phenytoin, carbamazepine, oxcarbazepine, and gabapentin
Dravet Syndrome	First to second year of life	Initially prolonged febrile seizure that may be hemiconvulsions, after 1 year of age with multiple seizure types typically sensitive to change in temperature	85% with SCN1a, others with SCN1B, GABA receptor mutations	Multifocal epileptiform discharges, generalized epileptiform discharges, mild slowing	Genetic testing also associated with abnormal gait in adolescent requiring supportive therapy	Can be difficult to treat, consider topiramate, zonisamide, valproic acid, levetiracetam, ketogenic diet, clobazam, stiripentol. Avoid Na channel blockers such as phenytoin, carbamazepine, oxcarbazepine.
Childhood absence epilepsy	3–12 y	Lapses of consciousness or vacant stares, lasting about 3–10 s, often in clusters. Automatisms of face and hands; clonic activity in 30%–45%. Often confused with complex partial seizures but no aura or postictal confusion. Some risk for developing generalized tonic clonic seizures.	Unknown. Genetic component. Abnormal thalamocortical circuitry.	3/s bilaterally synchronous, symmetrical, high-voltage spikes and waves provoked by hyperventilation. EEG always abnormal. EEG normalization correlates closely with control of seizures.	Hyperventilation often provokes attacks. Imaging studies rarely of value.	Ethosuximide most effective and best tolerated; valproic acid. Lamotrigine, in resistant cases, zonisamide, topiramate, levetiracetam, acetazolamide, ketogenic diet.
Juvenile absence epilepsy	10–15 y	Absence seizures less frequent than in childhood absence epilepsy. May have greater risk of convulsive seizures.	Unknown (idiopathic), possibly genetic.	3-Hz spike wave and atypical generalized discharges.	Not always triggered by hyperventilation.	Same as childhood absence epilepsy but may be more difficult to treat successfully.

Focal seizures	Any age	Seizure may involve any part of body; may spread in fixed pattern.	Often unknown; birth trauma, inflammatory process, vascular accidents, meningoencephalitis, malformations of cortical development (dysplasia), etc. If seizures are coupled with new or progressive neurologic deficits, a structural lesion (eg, brain tumor) is likely. If epilepsia partialis continua (simple partial status epilepticus), Rasmussen syndrome is likely.	EEG may be normal; focal spikes or slow waves in appropriate cortical region; "rolandic spikes" (centrotemporal spikes) are typical. Possibly genetic.	MRI, repeat if seizures poorly controlled or progressive.	Oxcarbazepine, carbamazepine; lamotrigine, gabapentin, topiramate, levetiracetam, zonisamide, lacosamide, and phenytoin. Valproic acid useful adjunct. If medications fail, surgery may be an option.
Benign epilepsy of childhood with centrotemporal spikes (BECTS/ rolandic epilepsy)	5–16 y	Simple partial seizures of face, tongue, hand. With or without secondary generalization. Usually nocturnal. Similar seizure patterns may be observed in patients with focal cortical lesions. Almost always remits by puberty.	Seizure history or abnormal EEG findings in relatives of 40% of affected probands and 18%–20% of parents and siblings, suggesting transmission by a single autosomal dominant gene, possibly with age-dependent penetrance.	Centrotemporal spikes or sharp waves ("rolandic discharges") appearing paroxysmally against a normal EEG background.	Seldom need CT or MRI scan.	Often no medication is necessary, especially if seizure is exclusively nocturnal and infrequent. Oxcarbazepine, carbamazepine or others. (See complex partial seizures.)
Juvenile myoclonic epilepsy (of Janz)	Late childhood and adolescence, peaking at 13 y	Mild myoclonic jerks of neck and shoulder flexor muscles after awakening. Usually generalized tonic-clonic seizures as well. Often absence seizures. Intelligence usually normal. Rarely resolves but usually remits on medications.	40% of relatives have myoclonias, especially in females; 15% have the abnormal EEG pattern with clinical attacks.	Interictal EEG shows variety of spike-and-wave sequences or 4–6-Hz multispike-and-wave complexes ("fast spikes").	If course is unfavorable, differentiate from progressive myoclonic syndromes by appropriate studies (eg, biopsies [muscles, liver, etc]). Imaging may not be necessary.	Lamotrigine, valproic acid, topiramate, levetiracetam, zonisamide.
Generalized tonic-clonic seizures (grand mal) (GTCS)	Any age	Loss of consciousness; tonic-clonic movements, often preceded by vague aura or cry. Incontinence in 15%. Postictal confusion and somnolence. Often mixed with or masking other seizure patterns.	Often unknown. Genetic component. May be seen with metabolic disturbances, trauma, infection, intoxication, degenerative disorders, brain tumors.	Bilaterally synchronous, symmetrical multiple high-voltage spikes, spikes waves (eg, 3/s). EEG often normal in those younger than age 4 y. Focal spikes may become "secondarily generalized."	Imaging; metabolic and infectious evaluation may be appropriate.	Levitiracetam; topiramate, lamotrigine, zonisamide, valproic acid, felbamate. Combinations may be necessary. Carbamazepine, oxcarbazepine or valproic acid; phenytoin may also be effective.

ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; IM, intramuscularly; IV, intravenously; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PET, positron emission tomography; SPECT, single-photon emission tomography; TORCHS, toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex, and syphilis; WBC, white blood cell.

Table 25–7. Common childhood epileptic syndromes.

Syndrome	Characteristics
Benign idiopathic neonatal convulsions (BINC)	So-called 5th day fits (97% have onset on 3rd–7th day of life); 6% of neonatal convulsions; clonic, multifocal, usually brief; occasional status epilepticus
Benign familial neonatal convulsions (BFNC)	Autosomal dominant; onset in 2–90 d; genes, **KCNQ2** or **KCNQ3**; clonic; 86% recover (KCNQ2 has also recently been associate with a more severe infantile epilepsy presentation)
Generalized tonic-clonic seizures (GTCS)	Age at onset, 3–11 y; may have family or personal history of febrile convulsions; 50% have 3/s spike-wave EEG; may have concurrent absence seizures
Childhood absence epilepsy	Incidence higher in girls than in boys; age at onset, 3–12 y (peak 6–7 y); 10–200 seizures per day; 3/s spike-wave EEG; up to 40% may develop GTCS
Juvenile absence epilepsy	Incidence higher in boys than in girls; age at onset, 10–12 y; uncommon; less frequent seizures; 3–4/s general spike-wave EEG; most have GTCS; some remit
Juvenile myoclonic epilepsy (Janz syndrome)	Age at onset, 12–18 y (average, 15 y); myoclonic jerks upper limbs, seldom fall; 4–6/s general spike-wave EEG; untreated, 90% have GTCS, mostly on waking; 20%–30% have absence seizures; 25%–40% are photosensitive; 10% remission rate (90% do not remit)
Benign epilepsy with centrotemporal spikes (BECTS); "rolandic epilepsy"	Age at onset 3–13 y (most at 4–10 y); 80% have brief, 2–5 min nocturnal (sleep) seizures only; usually simple partial seizures (face, tongue, cheek, hand) sensory or motor; occasionally have GTCS; bilateral independent spikes on EEG; may not need medication if seizures infrequent; remits at puberty
Benign epilepsy of childhood with occipital paroxysms (Panayiotopoulos syndrome)	6% of children with epilepsy; age at onset 3–6 y in 80% of patients (mean age, 5 y; range, 1–12 y); autonomic symptoms and visual aura may suggest migraine

precede the clinically apparent seizure and indicates focal onset. The patient may describe a feeling of fear, numbness or tingling in the fingers, or bright lights in one visual field. The specific symptoms may help define the location of seizure onset (eg, déjà vu suggests temporal lobe onset).

Often, the child does not recall or cannot define the aura, though the family may note alterations in behavior at the onset. Videotapes of events have been extremely useful.

Families may not immediately recall the details of the event but asking specific questions can help provide the details needed to determine the seizure type and, if partial, the site of onset. Did the patient become extremely pale before falling? Was the patient able to respond to queries during the episode? Was the patient unconscious or was there just impaired awareness? Did the patient fall stiffly or gradually slump to the floor? Was there an injury? How long did the tonic stiffening or clonic jerking last? Where in the body did the clonic activity take place? Which direction were head and eyes turned? Postictal states can be helpful in diagnosis. After complex partial and generalized convulsive seizures, postictal sleep typically occurs, but postictal changes are not seen after generalized absence seizures. Was there loss of speech after the seizure (suggesting left temporal lobe seizure) or was the patient able to respond and speak in short order? The parent may report lateralized motor activity (eg, the child's eyes may deviate to one side or the child may experience dystonic posturing of a limb). Motor activity without impaired awareness supports the diagnosis of focal seizures as do impaired awareness and automatisms previously defined as a complex partial seizure.

In contrast, generalized seizures usually manifest with acute loss of consciousness, usually with generalized motor activity. Tonic posturing, tonic-clonic activity, or myoclonus (spasms) may occur. In children with generalized absence seizures, behavioral arrest may be associated with automatisms such as blinking, chewing, or hand movements, making it difficult to differentiate between absence seizures and partial seizures.

Description of the semiology of the event may help determine if the child experienced an epileptic seizure or a nonepileptic event mimicking or misinterpreted as an epileptic seizure. Frequently, the child presenting with a presumed first seizure has experienced unrecognized seizures before the event that brings the child to medical attention. In particular, partial and absence seizures may not be recognized except in retrospect. Thus, careful questioning regarding prior events is important in the child being evaluated for new onset of seizures.

B. Diagnostic Evaluation

The extent and urgency of the diagnostic evaluation is determined, in general, by the child's age, the severity and type of seizure, whether the child is ill or injured, and the clinician's suspicion about the underlying cause. Seizures in early infancy are often symptomatic. Therefore, the younger the child, the more extensive must be the diagnostic assessment.

It is generally accepted that every child with new onset of *unprovoked* seizures should be evaluated with an EEG and MRI, although this need not be done emergently. An EEG is very unlikely to yield clinically useful information in the child with a febrile seizure. Other diagnostic studies should be used selectively.

Metabolic abnormalities are seldom found in the well child with seizures. Unless there is a high clinical suspicion of

serious medical conditions (eg, uremia, hyponatremia, hypo-calcemia, etc), "routine" laboratory tests rarely yield clinically significant information. Special studies may be necessary in circumstances that suggest an acute systemic etiology for a seizure, for example, in the presence of apparent renal failure, sepsis, or substance abuse. Emergent imaging of the brain is usually not necessary in the absence evidence of trauma or of acute abnormalities on examination.

C. Electroencephalography

Appropriate use of EEG requires awareness of its limitations as well as its utility. The limitations of EEG even with epilepsy, for which it is most useful, are considerable. A routine EEG captures electrical activity during a very short period of time, usually 20–30 minutes. Thus, it is useful primarily for defining interictal activity (except for the fortuitous recording of a clinical seizure or in situations when seizures are easily provoked such as childhood absence epilepsy). A seizure is a clinical phenomenon; an EEG showing epileptiform activity may confirm and clarify the clinical diagnosis (for instance, defining an epilepsy syndrome), but it is only occasionally diagnostic.

1. Diagnostic value—The greatest value of the EEG in convulsive disorders is to help characterize seizure types and epilepsy syndromes. This can aid in prognostication and in selecting appropriate therapy (see Table 25–6). It is sometimes difficult to distinguish between hypomotor seizures due to generalized absence epilepsy vs localization-related epilepsy. The differing EEG patterns of these seizures will then prove most helpful. The presence of a mixed seizure EEG pattern in a child with clinically generalized convulsive seizures or only focal seizures may lead to identification of specific epilepsy syndromes and help the clinician select anticonvulsants effective for the seizure types identified by the EEG. Similarly, the EEG may help in diagnosing seizures in a young infant with minimal or atypical clinical manifestations; it may show hypsarrhythmia (high-amplitude spikes and slow waves with a chaotic background) in infantile spasms or the 1–4/s slow spike-wave pattern of the Lennox-Gastaut syndrome. The EEG may show focal slowing that, if constant, particularly when there are corresponding focal seizure manifestations and abnormal neurologic findings, will alert the physician to the presence of a structural lesion. In this case, brain imaging may establish the cause and help determine further investigation and treatment.

The EEG need not be abnormal in a child with epilepsy. Normal EEGs are seen following a first generalized seizure in one-third of children younger than age 4 years. The initial EEG is normal in about 20% of older children with epilepsy and in about 10% of adults with epilepsy. These percentages are reduced when serial tracings are obtained especially if sleep-deprived. Focal spikes and generalized spike-wave discharges are seen in 30% of close nonepileptic relatives of patients with epilepsy.

2. Prognostic value—EEG following febrile seizures is almost always normal and is not clearly predictive of subsequent seizures and therefore is not useful in these situations. Hypsarrhythmia or slow spike and wave patterns support the diagnosis of infantile spasms and Lennox-Gastaut syndrome, respectively. Both are expressions of diffuse brain dysfunction (epileptic encephalopathy) and are generally of grave significance. Central-temporal (rolandic spikes) and occipital spike-wave activity (occipital paroxysms) are the EEG correlates of idiopathic focal epilepsies of childhood.

Following successful treatment, an abnormal EEG may become normal and may aid in the decision to discontinue medications but is not always present. Normalization can also be seen in infants with infantile spasms who have been successfully treated and, less commonly, in children with other epileptic encephalopathies.

EEG should be repeated when the severity and frequency of seizures increase despite adequate anticonvulsant therapy, when the clinical seizure pattern changes significantly, or when progressive neurologic deficits develop. Emergence of new focal or diffuse slowing may indicate a progressive lesion or a neurodegenerative disorder.

The EEG may be helpful in determining when to discontinue anticonvulsant therapy. The presence or absence of epileptiform activity on the EEG prior to withdrawal of anticonvulsants after a seizure-free period of 2 years on medications has been shown to correlate with the degree of risk of seizure recurrence. However, persistent focal epileptiform discharges are common in children with so-called benign epilepsies until they resolve spontaneously in adolescence and may not be considered a reason to not reduce anticonvulsants.

▶ Differential Diagnosis

It is extremely important to be accurate in the diagnosis of epilepsy and not to make the diagnosis without ample proof. To the layperson, epilepsy often has connotations of brain damage and limitation of activity. A person so diagnosed may be excluded from certain occupations in later life. It is often very difficult to change an inaccurate diagnosis of many years' standing.

Misinterpretation of behaviors in children is the most common reason for misdiagnosis. Psychogenic nonepileptic seizures are much less common in children than in adults but must be considered even in the young or cognitively impaired child. The most commonly misinterpreted behaviors are inattention in school-aged children with attention disorders, stereotypies in children with autistic spectrum disorder, sleep-related movements, habit movements such as head-banging and so-called infantile masturbation (sometimes referred to as gratification movements), and gastroesophageal reflux in very young (often impaired) infants. Some of the common nonepileptic events that mimic seizure disorder are listed in Table 25–8.

Table 25–8. Nonepileptic paroxysmal events.

Breath-holding attacks (cyanotic and pallid) (see below)
Cyanotic: Age 6 mo–3 y. Always precipitated by trauma and fright. Cyanosis; sometimes stiffening, tonic (or jerking-clonic) convulsion (anoxic seizure). Patient may sleep following attack. Family history positive in 30%. Electroencephalogram (EEG) is not useful. No medication treatment is useful but interpretation and reassurance are very important.
Pallid: Usually, there is no apparent precipitant although fright may precipitate. Pallor may be followed by seizure (anoxic-ischemic). Vagally mediated (heart-slowing), like adult syncope. EEG is not useful.

Tics (Tourette syndrome)
Simple or complex stereotyped jerks or movements, coughs, grunts, sniffs. Worse at repose or with stress. May be suppressed during physician visit. Family history often positive for tics or for obsessive compulsive disorder. Diagnosis is clinical. Magnetic resonance imaging (MRI) and EEG are negative. Medications may benefit.

Parasomnias (night terrors, sleep talking, walking, "sit-ups")
Ages 3–10 y. Usually occur in first sleep cycle (30–90 min after going to sleep), with crying, screaming, and autonomic discharge (pupils dilated, perspiring, etc). May last only a few minutes or be more prolonged. Child goes back to sleep and has no recall of event next day. Sleep studies (polysomnogram and EEG) are normal. Sleep talking and walking and short "sit-ups" in bed are fragmentary arousals. If a spell is recorded, EEG shows arousal from deep sleep, but behavior seems wakeful. Child needs to be protected from injury and gradually settled down and taken back to bed. Medications may be considered in rare instances.

Nightmares
Nightmares or vivid dreams occur in subsequent cycles of sleep, often in early morning hours, and generally are partially recalled the next day. The bizarre and frightening behavior may sometimes be confused with complex partial seizures but occurs during REM (rapid eye movement) sleep, whereas epilepsy usually does not. In extreme or difficult cases, an all-night sleep EEG may help differentiate seizures from nightmares. Frontal lobe epilepsy with sleep related "hypermotor" seizures should be considered.

Migraine
On occasion, migraine can be associated with an acute confusional state. Usual migraine prodrome of spots before the eyes, dizziness, visual field defects, followed by headache and then agitated confusion is present. History of other, more typical migraine with severe headache and vomiting but without confusion may aid in diagnosis. Severe headache with vomiting as child comes out of spell may aid in distinguishing the attack from epilepsy. However, partial seizures, while brief, may be associated with more prolonged postictal agitation and confusion. Other seizure manifestations are practically never seen (eg, tonic-clonic movements, falling, complete loss of consciousness). EEG in migraine is usually normal and seldom has epileptiform abnormalities often seen in patients with epilepsy. Migraine and epilepsy are sometimes linked: Benign occipital epilepsy may present with migraine-like visual aura and headache. There may be migraine-caused cortical ischemia which leads to later epilepsy. Postictal headache can be confused with migraine.

Benign nocturnal myoclonus
Common in infants and may last even up to school age. Focal or generalized jerks (the latter also called hypnic or sleep jerks) may persist from onset of sleep on and off all night. A video record for physician review can aid in diagnosis. EEG taken during jerks is normal, proving that these jerks are not epilepsy. Treatment is reassurance.

Shuddering
Shuddering or shivering attacks can occur in infancy and may be a forerunner of essential tremor in later life. Often, family history is positive for tremor. Shivering may be very frequent. EEG is normal. There is no clouding or loss of consciousness.

Gastroesophageal reflux (Sandifer syndrome)
Seen more commonly in children with cerebral palsy or brain damage; reflux of acid gastric contents may cause pain that cannot be described by child. Unusual posturing (dystonic or other) of head and neck or trunk may occur, an apparent attempt to stretch the esophagus or close the opening. There is no loss of consciousness, but eye rolling, apnea, and occasional vomiting may simulate a seizure. An upper gastrointestinal series, cine of swallowing, sometimes even an EEG (normal during episode) may be necessary to distinguish from seizures.

Infantile masturbation/gratification movements
Rarely in infants, repetitive rocking or rubbing motions may simulate seizures. Infant may look out of contact, be poorly responsive to environment, and have autonomic expressions (eg, perspiration, dilated pupils) that may be confused with seizures. Observation by a skilled individual, sometimes even in a hospital setting, may be necessary to distinguish from seizures. EEG is normal between and during attacks. Interpretation and reassurance are the only necessary treatment.

Conversion reaction/psychogenic nonepileptic seizures
Up to 50% of patients with nonepileptic seizures also have epilepsy. Episodes may involve writhing, pelvic thrusting, tonic movements, bizarre jerking and thrashing, or even apparently sudden unresponsiveness. Often, there is ongoing psychological trauma. Children may be developmentally delayed. Spells must often be seen or recorded with a videorecorder to distinguish from epilepsy but are sometimes so bizarre they are easily differentiated. A normal EEG during a spell is a key diagnostic feature. Sometimes, psychogenic seizures can be precipitated by suggestion with injection of normal saline in a controlled situation but this is generally felt to be ethically inappropriate since it involves lying to the patient regarding the reason for the procedure. Combativeness is common; self-injury and incontinence, rare.

Temper tantrums and rage attacks
Child often reports amnesia for events during spell. Attacks are usually precipitated by frustration or anger, often directed either verbally or physically, and subside with behavior modification and isolation. EEGs are generally normal but seldom obtained during an attack. It should be noted that directed violence is very uncommon following partial seizures but severe agitation can occur.

Benign paroxysmal vertigo
Brief attacks of vertigo in which child often appears frightened and pale and clutches parent. Attacks last 5–30 s. Sometimes, nystagmus is identified. There is no loss of consciousness. Usually, child is well and returns to play immediately afterward. Attacks may occur in clusters, and then disappear for months. Attacks are usually seen in infants and preschoolers aged 2–5 y. EEG is normal. If caloric tests can be obtained (often very difficult in this age group), abnormalities with hypofunction of one side are sometimes seen. Medications are usually not desirable or necessary.

Staring spells
Teachers often make referral for absence or "petit mal" seizures in children who stare or seem preoccupied at school. Helpful in the history is the lack of these spells at home (eg, before breakfast, a common time for absence seizures). Lack of other epilepsy in child or family history often is helpful. These children often have difficulties with school and cognitive or learning disabilities. Child can generally be brought out of spell by a firm command or touch. EEG is sometimes necessary to confirm that absence seizures are not occurring. A 24-h ambulatory EEG to record attacks during child's everyday school activities is occasionally necessary.

▶ Complications & Sequelae

A. Psychosocial Impact

Emotional disturbances, especially depression but also anxiety, anger, and feelings of guilt and inadequacy, often occur in the patient as well as the parents of a child with epilepsy. Actual or perceived stigma as well as issues regarding "disclosure" are common. There is an increased risk of suicide in people with epilepsy. Schools often limit activities of children with epilepsy inappropriately and stigmatize children by these limitations.

Epilepsy with onset in childhood has an impact on adult function. Adults with early onset of epilepsy are less likely to complete high school, have less adequate employment, and are less likely to marry. This is also true of populations with well-controlled epilepsy. Persistent epilepsy results in significant dependence; even when epilepsy is successfully treated, patients with long-standing epilepsy often do not become independent due to driving restrictions and safety concerns.

B. Cognitive Delay

Untreated seizures can have an impact on cognition and memory. Clearly, epileptic encephalopathy (ie, regression in cognitive ability and development associated with uncontrolled seizures) does occur, particularly in young children with catastrophic epilepsies such as infantile spasms (West syndrome), Dravet syndrome, and Lennox-Gastaut syndrome. The impact of persistent partial seizures on development is less clear although persistent temporal lobe seizures in adults are associated with cognitive dysfunction. It is not likely that interictal epileptiform activity contributes to cognitive impairment in older children, although increased epileptiform burden has been demonstrated to cause mild cognitive problems in some disorders previously thought to be benign, such as benign epilepsy with central temporal spikes (BECTS). Continuous epileptiform activity in sleep is associated with Landau-Kleffner syndrome (acquired epileptic aphasia) and the syndrome of Electroencephalographic Status Epilepticus in Sleep (ESES) which are associated with cognitive decline.

Pseudodementia may occur in children with poorly controlled epilepsy because their seizures interfere with their learning. Depression is a common cause of impaired cognitive function in children with epilepsy. Anticonvulsants are less likely to cause such interference at usual therapeutic doses, although phenobarbital topiramate and zonisamide may produce cognitive impairment, reversible on discontinuing the medication. Psychosis can also occur after seizures or as a side effect of medications.

C. Injury and Death

Children with epilepsy are at far greater risk of injuries than the general pediatric population. Physical injuries, especially lacerations of the forehead and chin, are frequent in astatic or akinetic seizures (so-called drop attacks), necessitating protective headgear. In all other seizure disorders in childhood, injuries as a direct result of an attack are not as common although drowning, injuries related to working in kitchens, and falls from heights remain potential risks for all children with active epilepsy. It is therefore extremely important to stress "seizure precautions," in particular, water safety. Bathrooms are a particularly dangerous room for people with uncontrolled epilepsy as the room is usually small and has many hard surfaces. Showers are recommended over bathing as they decrease the likelihood of drowning. Appropriate supervision is recommended.

The greatest fear of a parent of a child with new-onset of epilepsy is the possibility of death or brain injury. There is an increased risk of premature death in patients with symptomatic epilepsy, especially those who have not achieved seizure control. Most of the mortality in children with epilepsy is related to the underlying neurologic disorder, not the seizures. Sudden unexpected death with epilepsy (SUDEP) is a rare event in children. Although children with epilepsy have an increased risk of death, SUDEP occurs in only 1–2:10,000 patient-years. The greatest risk for SUDEP is in children with medically uncontrolled epilepsy, especially with symptomatic epilepsy (associated with identifiable CNS etiology). There is no current proven strategy to prevent SUDEP other than seizure control. The mechanism for SUDEP is unclear but is probably most commonly related to either cardiac arrhythmia induced by a seizure or sudden respiratory insufficiency. Vigorous attempts to control intractable seizure disorders remain the most important approach. Identifying life-threatening disorders (eg, identifying patients with cardiac arrhythmias, especially prolonged QT syndrome) as the cause of misdiagnosed epilepsy is clearly of utmost importance. While SUDEP is rare, increased mortality in children with epilepsy should be mentioned when counseling families.

▶ Treatment

The ideal treatment of acute seizures is the correction of specific causes. However, even when a biochemical disorder, a tumor, meningitis, or another specific cause is being treated, anticonvulsant drugs are often still required.

A. First Aid

Caregivers should be instructed to protect the patient against self-injury. Turning the child to the side is useful for preventing aspiration. Thrusting a spoon handle, tongue depressor, or finger into the clenched mouth of a convulsing patient or trying to restrain tonic-clonic movements may cause worse injuries than a bitten tongue or bruised limb and could potentially become a choking hazard. Parents are often concerned that cyanosis will occur during generalized convulsive seizures but it is rare for clinically significant hypoxia

to occur. Mouth-to-mouth resuscitation is rarely necessary and is unlikely to be effective.

For prolonged seizures (those lasting over 5 minutes), acute home treatment with benzodiazepines such as rectal diazepam gel (Diastat) or intranasal midazolam may be administered to prevent the development of status epilepticus and has proven to be safe even when administered by nonmedical professionals, including teachers and day care providers, when appropriately instructed.

B. Antiepileptic Drug (AED) Therapy

1. Drug selection—Treat with the drug appropriate to the clinical situation, as outlined in Table 25–9.

2. Treatment strategy—The child with a single seizure has a 50% chance of recurrence. Thus, it is usually not necessary to initiate AED therapy until the diagnosis of epilepsy is established, that is, there is a second seizure. The seizure type and epilepsy syndrome as well as potential side effects will determine which drug to initiate (see Table 25–9). Start with one drug in moderate dosage and increase the dosage until seizures are controlled. If seizures are not controlled on the maximal tolerated dosage of one major AED, gradually switch to another before using two-drug therapy. Polytherapy (ie, the use of more than two medications concurrently) is rarely sufficiently effective to warrant the considerable risk of adverse side effects from the synergistic impact of multiple medications.

Dosages and usual target serum levels of commonly prescribed AEDs are listed in Table 25–9. Individual variations must be expected, both in tolerance and efficacy. The therapeutic range may also vary somewhat with the method used to determine levels, and published levels are not always reflective of clinical efficacy and tolerability.

3. Long-term management and discontinuation of treatment—AEDs should be continued until the patient is free of seizures for at least 1–2 years. In about 75% of patients, seizures will not recur following discontinuation of medication after 2 years of remission. Variables such as younger age at onset, normal EEG, undetermined etiology, and ease of controlling seizures carry a favorable prognosis, whereas identified etiology, later onset, continued epileptiform EEG, difficulty in establishing initial control of the seizures, polytherapy, generalized tonic-clonic or myoclonic seizures, as well as an abnormal neurologic examination are associated with a higher risk of recurrence. Most AEDs (with the exception of barbiturates and clonazepam) can be withdrawn over 6–8 weeks. There does not appear to be an advantage to slower withdrawal.

Recurrent seizures affect up to 25% of children who attempt withdrawal from medications. Recurrence of seizures is most likely within 6–12 months of discontinuing medications. Therefore, seizure safety precautions will need to be reinstituted, including driving restriction. If seizures recur during or after withdrawal, AED therapy should be reinstituted and maintained for at least another 1–2 years. The vast majority of children will again achieve remission of their seizures.

C. Alternative Treatments

1. Adrenocorticotropic hormone (ACTH) and corticosteroids—ACTH is indicated for treatment of infantile spasms. The utility of other immunotherapy is less clear. Duration of ACTH therapy is guided by cessation of clinical seizures and normalization of the EEG. Oral corticosteroids and intravenous immune globulin (IVIG) are occasionally used for pharmacoresistant epilepsy. However, dosing regimens and indications are not well established.

Landau-Kleffner syndrome (acquired epileptic aphasia) is reported to respond to oral steroid treatment. Anecdotal reports of use of immunosuppression in other patients have been published but no controlled clinical trials have been performed.

Precautions: Give additional potassium, guard against infections, provide GI prophylaxis, follow for possible hypertension, and discuss the cushingoid appearance and its disappearance. Do not withdraw oral corticosteroids suddenly. Side effects in some series occur in up to 40% of patients, In some regions of the country, prophylaxis against *Pneumocystis* infection may be required. Careful and frequent follow-up is necessary. Visiting nurse services can be very helpful in surveillance such as monitoring blood pressure, weight, and potential adverse effects.

2. Ketogenic diet—Fasting has been described to stop seizures for centuries and a diet high in fat and low in protein and carbohydrates will result in ketosis and simulate a fasting state. Fatty acids replace glucose as a source of energy for cellular metabolism. Such a diet has been observed to decrease and even control seizures in some children. A ketogenic diet should be considered for children with pharmacoresistant epilepsy. This diet should be monitored very carefully to ensure sufficient protein for body maintenance and growth as well as appropriate vitamin and mineral supplementation. Recent reports suggest efficacy with a modified Atkins diet or a low-glycemic index diet in older and higher functioning children who will not accept the ketogenic diet. A prepared commercial formula is available for children receiving tube feedings.

The mechanism for the anticonvulsant action of the ketogenic diet is not understood. The ketogenic diet requires close adherence full cooperation of all family members is required. However, when seizure control is achieved by this method, acceptance of the diet is usually excellent. Access to other families and patients via Internet has provided support and is particularly useful for providing increased variation of meals for families.

Table 25–9. Guide to AED use.

Medication/Target Dose in Adults [Pediatric Dose mg/kg/d]	Target Serum Levels (mcg/mL)	Idiosyncratic	Dose Related	Age Specific/Other
Carbamazepine 1000–2000 [10–30]	4–12	Dermatologic (rash, including Stevens-Johnson), rare, hematologic, hepatic	Vertigo, visual disturbance (diplopia), leukopenia	Hyponatremia in adults; leukopenia; liver induction; myoclonus in patients with general S/W
Clobazam 5–80 [2 y, 0.5–1; 2–16 y, 5–40]	—	Rash (rare), Stevens - Johnson reaction	Ataxia, sedation	Paradoxical reaction with aggressive behavior, withdrawal symptoms with abrupt cessation
Ethosuximide 1000 [15–40]	40–100	Leukopenia, SLE, nephrotic syndrome, rash	Sedation, GI upset	Behavioral
Ezogabine 600–1200		Urinary retention, prolonged QT	Dizziness, sedation	
Felbamate 2400–3600 [45–60]	30–100	Aplastic anemia, hepatic failure, rash (rare)	Anorexia, insomnia, headache, irritability	Aplastic anemia; drug interactions
Gabapentin 1800–3600 [30–100]	4–20	Rash (rare)	Somnolence, irritability, weight gain	Renal excretion, no drug interactions
Lacosamide 200–400 [8–12]	–	Prolonged PR interval, hypersensitivity reaction	Dizziness, ataxia, nausea, diplopia	? Interferes with neuronal plasticity
Lamotrigine 300–500 [1–15] (dose depends on concomitant medication)	3–20	Rash, hypersensitivity reaction	Ataxia, diplopia, GI, headache	Rash (1%–5% in children), Stevens-Johnson
Levetiracetam 1200–2400 [20–60]	5–50	None reported to date	Somnolence, ataxia	Agitation, aggression, depression
Oxcarbazepine 1200–2400 [15–45]	MHD–10–55	Rash (25% cross-reactivity with CBZ)	CNS, diplopia	Hyponatremia (3% of adults)
Phenytoin 200–600 [4–8]	10–20	Rash (5%–10%), hematologic, hepatic, lymphadenopathy others	Cosmetic, CNS, ataxia, nystagmus	Elevated LFTs, induction, reduced vitamin D, cerebellar degeneration?
Phenobarbital 60–120 [2–6]	15–40	Rash, Stevens-Johnson, SLE	Somnolence, irritability	Possible irreversible cognitive effects, liver induction
Rufinamide 400–3200 [10–45]	—	Hypersensitivity reaction	Sedation, headache, behavioral disturbance, shortened QT interval	
Tiagabine 32–56 [0.25–1.25]	5–70	Psychiatric	CNS, tremor, weakness, GE reflux, gait difficulty	
Topiramate 200–400 [5–25]	3–25	Rash (rare), acute glaucoma (rare)	Somnolence, memory disturbance, renal stones anorexia, paresthesia	Language and cognitive disturbance (especially polypharmacy); oligohidrosis
Valproic acid 750–1500 [20–60]	50–150	Hepatic failure; pancreatitis	Tremor, weight gain, alopecia, sedation and cognitive changes, thrombocytopenia, prolonged bleeding time	Hepatic failure (1/500 younger than age 2 on polypharmacy), elevated LFTs; GI upset with syrup; incidence of PCOS unknown, liver enzyme inhibition; teratogenicity

(Continued)

Table 25–9. Guide to AED use. (*Continued*)

Medication/Target Dose in Adults [Pediatric Dose mg/kg/d]	Target Serum Levels (mcg/mL)	Idiosyncratic	Dose Related	Age Specific/Other
Vigabatrin Max 3000 [40–100]	—	Visual field constriction, sedation, CNS	Psychiatric symptoms (rare), visual field constriction	Especially effective for infantile spasms and tuberous sclerosis
Zonisamide 200–600 [4–10]	10–30	Rash, hematologic, hepatic	Renal stones, anorexia, somnolence	Oligohidrosis in children; cross-sensitivity with sulfa drugs

CBZ, carbamazepine; CNS, central nervous system; GE, gastroesophageal; GI, gastrointestinal; LFT, liver function test; MHD, monohydroxy derivative; PCOS, polycystic ovary syndrome; SLE, systemic lupus erythematosus; S/W, spike and wave discharges.
Note: For newer drugs, doses, levels, and adverse effects are based on reported clinical experience and not on adequate scientific information from clinical trials in most cases. Some medications do not have FDA approval for children. The package insert for each medication lists potential adverse effects, warnings, and other important considerations.

As with all therapies, potential adverse effects can occur with the ketogenic diet. These include acidosis and hypoglycemia, particularly on initiation of the diet. Thus, it is prudent to admit the child for initiation of the diet after screening laboratory studies are performed to rule out underlying metabolic disorders. Renal stones, pancreatitis, and acidosis can occur. In addition, vitamin and minerals need to be followed carefully to avoid deficiencies especially carnitine, iron, and vitamin D.

3. Vagus nerve stimulator (VNS)—The VNS is a pace-maker-like device that is implanted below the clavicle on the left and attached to the left vagus nerve. A cycle of electrical stimulation of the nerve is established (typically 30 seconds of stimulation every 5 minutes), which has an antiepileptic effect, reducing seizures by at least 50% in over half the children so treated. In addition, an emergency mode that is activated by the use of a magnet may interrupt a seizure (ie, an anticonvulsant effect). For patients with sufficient warning of an impending seizure, the device can be activated with abortion of the seizure. Many patients also experience an improvement in learning and behavior with use of this device. With current technology, the battery in the stimulator will last 7 or more years in many patients.

D. Surgery

An evaluation for epilepsy surgery is indicated for all children with medically intractable partial epilepsy. The evaluation and surgery should be performed at a center with expertise in epilepsy surgery and which has a dedicated neurosurgeon, epileptologists, neuropsychologists, and physiatrists with experience in epilepsy surgery.

The first surgery for treatment of epilepsy took place over 100 years ago, and surgery is now established as an appropriate treatment option for adults and children with epilepsy refractory to medical treatment. Evaluation for possible surgical treatment should begin as soon as it is apparent that a child with focal onset seizures is not responding to standard therapy. Medication resistant ("refractory") epilepsy is usually defined as failure of two or three anti-epileptic drugs alone or as combination therapy to control seizures. Advances in technology allow for definition and removal of the epileptogenic focus even in young infants. Many centers now have access to video-EEG monitoring, positron emission tomography (PET), single photon emission computerized tomography (SPECT), and similar noninvasive techniques that can be used to identify the "ictal onset zone" for seizures such as a focal cortical dysplasia that may amenable to resection. Freedom from seizures is reported in as many as 80% who have been treated surgically. Some children without an identifiable onset to seizure may qualify for other types of surgery such as corpus callosotomy that aim to reduce seizure burden.

E. General Management of the Child with Epilepsy

1. Education—The initial diagnosis of epilepsy is often devastating for families. The patient and parents must be helped to understand the nature of epilepsy and its management, including etiology, prognosis, safety issues, and treatment options.

Excellent educational materials are available for families of a child with epilepsy, both in print and online. Two excellent web sites are http://www.epilepsyfoundation.org and http://www.epilepsy.com. Materials on epilepsy—including pamphlets, monographs, films, and videotapes suitable for children and teenagers, parents, teachers, and medical professionals—may be purchased through the Epilepsy Foundation: 8301 Professional Place, Landover, MD 20785; (800) 332–1000. The foundation's local chapter and other community

organizations are able to provide guidance and other services. Support groups exist in many cities for older children and adolescents and for their parents and others concerned.

2. Privileges and precautions in daily life—"*No seizures and no side effects*" is a motto established by the Epilepsy Foundation. The child should be encouraged to live as normal a life as possible. Children should engage in physical activities appropriate to their age and social group. After seizure control is established, swimming is generally permissible with a buddy system or adequate lifeguard coverage. Scuba diving and high climbing without safety harness is generally not allowed. There are no absolute contraindications to any other sports, although some physicians recommend against contact sports. Physical training and sports are usually to be welcomed rather than restricted. There is some literature that suggests that exercise decreases overall seizure burden. Driving is discussed in the next section.

Emotional disturbances, especially depression, are not uncommon, particularly in adolescents with epilepsy, and need to be treated. Loss of sleep should be avoided as sleep deprivation can be a trigger for seizures. Alcohol intake should be avoided because it may precipitate seizures. Prompt attention should be given to intercurrent illnesses as these can trigger seizures.

Although every effort should be made to control seizures, treatment must not interfere with a child's ability to function normally. A child may do better having an occasional mild seizure than being so heavily sedated that function at home, in school, or at play is impaired. Therapy and medication adjustment often require much art and fortitude on the physician's part. Some patients with infrequent seizures, especially if only nocturnal partial seizures (eg, Rolandic seizures) may not need treatment with AEDs.

3. Driving—Driving becomes important to most young people at age 15 or 16 years. Restrictions for persons with epilepsy and other disturbances of consciousness vary from state to state. In most states, a learner's permit or driver's license will be issued to an individual with epilepsy if he or she has been under a physician's care and free of seizures for at least 1 year provided that the treatment or basic neurologic problems do not interfere with the ability to drive. A guide to this and other legal matters pertaining to persons with epilepsy is published by the Epilepsy Foundation, and its legal department may be able to provide additional information.

4. Pregnancy—Contraception (especially interaction of oral contraceptive with some AEDs), childbearing, potential teratogenicity of AEDs, and the management of pregnancy should be discussed as soon as appropriate with the adolescent young woman with epilepsy. Daily use of vitamin preparations containing folic acid is recommended. For the pregnant teenager with epilepsy, management by an obstetrician conversant with the use of AEDs in pregnancy is appropriate. The patient should be cautioned against discontinuing her medications during pregnancy. The possibility of teratogenic effects of AEDs, such as facial clefts (two to three times increased risk), must be weighed against the risks from seizures. All AEDs appear to have some risk for teratogenicity, although valproate carries a particularly high risk for spinal dysraphism as well as being associated with cognitive issues in children exposed to valproate in utero. Dosing may need to be adjusted frequently during pregnancy as blood volume expands. Frequent AED blood levels may be helpful in making these adjustments.

5. School intervention and seizure response plans—Schools are required by federal law to work with parents to establish a seizure action plan for their child with epilepsy. A template for such a plan is available on the Epilepsy Foundation website at http://www.epilepsyfoundation.org/programs/upload/snactionplan.pdf. These plans usually require the approval of the child's physician. Schools are sometimes hesitant to administer rectal valium or to activate the vagal nerve stimulator. Often, information from the physician, especially that obtained from the Epilepsy Foundation website, will relieve anxieties. School authorities should be encouraged to avoid needless restrictions and to address the emotional and educational needs of all children with disabilities, including epilepsy. The local affiliates of the Epilepsy Foundation can often provide support for families in their interactions with the school.

2. Status Epilepticus

Status epilepticus is usually defined as a clinical or electrical seizure lasting at least 15 minutes, or a series of seizures without complete recovery over a 30-minute period. After 30 minutes of seizure activity, hypoxia and acidosis occur, with depletion of energy stores, cerebral edema, and structural damage. Eventually, high fever, hypotension, respiratory depression, and even death may occur. Status epilepticus is a medical emergency. Aggressive treatment of prolonged seizures may prevent development status epilepticus. It is generally recommended that treatment with benzodiazepines at home for prolonged seizures be initiated, 5 minutes after onset of a seizure. There are currently several forms of benzodiazepines that can be administered safely at home, rectal valium, intranasal midazolam, sublingual lorazepam, and intramuscular diazepam.

Status epilepticus is classified as (1) convulsive (the common tonic-clonic, or grand mal, status epilepticus) or (2) nonconvulsive (characterized by altered mental status or behavior with subtle or absent motor components). Absence status, or spike-wave stupor, and focal status epilepticus

are examples of the nonconvulsive type. An EEG may be necessary to aid in diagnosing nonconvulsive status because patients sometimes appear merely stuporous and lack typical convulsive movements.

▶ **Treatment**

For treatment options, see Table 25–10.

3. Febrile Seizures

Criteria for febrile seizures are (1) age 3 months to 6 years (most occur between ages 6 and 18 months), (2) fever of greater than 38.8°C, and (3) non-CNS infection. More than 90% of febrile seizures are generalized, last less than 5 minutes, and occur early in the illness causing the fever. Febrile seizures occur in 2%–3% of children. Acute respiratory illnesses are most commonly associated with febrile seizures. Gastroenteritis, especially when caused by *Shigella* or *Campylobacter,* and urinary tract infections are less common causes. Roseola infantum is a rare but classic cause. One study implicated viral causes in 86% of cases. Immunizations may be a cause. HHV-6 and HHV-7 is a common cause for febrile status epilepticus, accounting for 1/3 of cases. Febrile seizures rarely (1%–3%) lead to recurrent unprovoked seizures (epilepsy) in later childhood and adult life (risk is increased two- to fivefold compared with children who do not have febrile seizures). The chance of later epilepsy is higher if the febrile seizures have complex features, such as duration longer than 15 minutes, more than one seizure in the same day, or focal features. Other adverse factors are an abnormal neurologic status preceding the seizures (eg, cerebral palsy or mental retardation), early onset of febrile seizure (before age 1 year), and a family history of epilepsy. Even with adverse factors, the risk of epilepsy after febrile seizures is still only in the range of 15%–20%, although it is increased if more than one risk factor is present. Recurrent febrile seizures occur in 30%–50% of cases. Therefore, families should be prepared to expect more seizures. In general, recurrence of febrile seizures does not worsen the long-term outlook.

▶ **Clinical Findings**

A. Diagnostic Evaluation

The child with a febrile seizure must be evaluated for the source of the fever, in particular to exclude CNS infection. Routine studies such as serum electrolytes, glucose, calcium, skull radiographs, or brain imaging studies are seldom helpful unless warranted based on clinical history. A white count above 20,000/μL or an extreme left shift may correlate with bacteremia. Complete blood count and blood cultures may be appropriate. Serum sodium is often slightly low but not low enough to require treatment or to cause the seizure. Meningitis and encephalitis must be considered. Signs of meningitis

Table 25–10. Status epilepticus treatment.

1. ABCs
   a. Airway: maintain oral airway; intubation may be necessary.
   b. Breathing: oxygen.
   c. Circulation: assess pulse, blood pressure; support with IV fluids, drugs. Monitor vital signs.
2. Start glucose-containing IV (unless patient is on ketogenic diet); evaluate serum glucose; electrolytes, HCO_3^-, CBC, BUN, anticonvulsant levels.
3. Consider arterial blood gases, pH.
4. Give 50% glucose if serum glucose low (1–2 mL/kg).
5. Begin IV drug therapy; goal is to control status epilepticus in 20–60 min.
   a. Diazepam, 0.3–0.5 mg/kg over 1–5 min (20 mg max); may repeat in 5–20 min; or lorazepam, 0.05–0.2 mg/kg (less effective with repeated doses, longer-acting than diazepam); or midazolam: IV, 0.1–0.2 mg/kg; intranasally, 0.2 mg/kg.
   b. Phenytoin, 10–20 mg/kg IV (not IM) over 5–20 min; (1000 mg maximum); monitor with blood pressure and ECG. Fosphenytoin may be given more rapidly in the same dosage and can be given IM; order 10–20 mg/kg of "phenytoin equivalent" (PE).
   c. Phenobarbital, 5–20 mg/kg (sometimes higher in newborns or refractory status in intubated patients).
6. Correct metabolic perturbations (eg, low-sodium, acidosis). Administer fluids judiciously.
7. Other drug approaches in refractory status:
   a. Repeat phenytoin, phenobarbital (10 mg/kg). Monitor blood levels. Support respiration, blood pressure as necessary.
   b. Other medications: valproate sodium, available as 100 mg/mL for IV use; give 15–30 mg/kg over 5–20 min.
   c. Levetiracetam may be helpful (20–40 mg/kg/dose IV).
   d. For patients who fail initial intervention consider: midazolam drip: 1–5 mcg/kg/min (even to 20 kg/min); pentobarbital coma; propofol and general anesthetic.
8. Consider underlying causes:
   a. Structural disorders or trauma: MRI or CT scan.
   b. Infection: lumbar puncture, blood culture, antibiotics.
   c. Metabolic disorders: consider lactic acidosis, toxins, and uremia if child is being treated with chronic AEDs, obtain medication levels. Toxin screen.
9. Initiate maintenance drug treatment with IV medications: phenytoin (10 mg/kg); phenobarbital (5 mg/kg); valproate IV 30 mg/kg; levetiracetam 20–30 mg/kg. Transition to oral medication when patient can safely take them.

BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; ECG, electrocardiogram; IM, intramuscularly; IV, intravenously; MRI, magnetic resonance imaging.

(eg, bulging fontanelle, stiff neck, stupor, and irritability) may all be absent, especially in a child younger than age 18 months.

B. Lumbar Puncture

After controlling the fever and stopping an ongoing seizure, the physician must decide whether to do a lumbar puncture.

The fact that the child has had a previous febrile seizure does not rule out meningitis as the cause of the current episode. It is very important, especially in younger children, to exclude CNS infection as a source; these children are not classified as having a febrile seizure. A recent study demonstrated that 96% of children with febrile status epilepticus who received an LP had less than three WBC in the CSF. Therefore, seizure should not be acceptable explanation for elevated cells in the CSF. Although the yield is low, a lumbar puncture should probably be done if the child is younger than age 18 months, if recovery is slow, if no other cause for the fever is found, or if close follow-up will not be possible. Occasionally observation in the emergency department for several hours obviates the need for a lumbar puncture.

C. EEG

EEG is rarely useful. An EEG may be considered if the febrile seizure is complicated, focal, or otherwise unusual, but has little predictive value. In uncomplicated febrile seizures, the EEG is usually normal. If performed, the EEG should be done at least a week after the illness to avoid transient changes due to fever or the seizure itself. In older children, 3-Hz/s spike-wave discharges, suggestive of a genetic propensity to epilepsy, may occur. In the young infant, EEG findings seldom aid in assessing the chance of recurrence of febrile seizures or in long-term prognosis. Thus, EEG is not recommended for the child with simple febrile seizures.

▶ Treatment & Prognosis

Prophylactic anticonvulsants are not recommended after a febrile seizure. If febrile seizures are complicated or prolonged, or if medical reassurance fails to relieve family anxiety, anticonvulsant prophylaxis may be indicated and appropriately chosen medication may reduce the incidence of recurrent febrile seizures. Only phenobarbital and valproic acid have demonstrated efficacy in preventing febrile seizures; phenytoin and carbamazepine have been shown to be ineffective. Newer antiepileptic drugs have not been studied. Diazepam started at the first onset of fever for the duration of the febrile illness (0.5 mg/kg two or three times per day orally or rectally) may be effective but will sedate a child and possibly complicate the evaluation for a source of the fever. Prophylactic diazepam is also limited by the fact that a seizure is often the first evidence of fever associated with an acute illness. Diastat (rectal diazepam gel) can be used to prevent febrile status epilepticus in the child with a prolonged febrile seizure (one lasting over 5 minutes), often the greatest concern.

Measures to control fever such as sponging or tepid baths, antipyretics, and the administration of antibiotics for proven bacterial illness are reasonable but unproven to prevent recurrent febrile seizures.

Simple febrile seizures do not have any long-term adverse consequences. As noted earlier, there is only a small increase in the risk of developing epilepsy. Cognitive function is not significantly different from that of siblings without febrile seizures.

SLEEP DISORDERS

Sleep disorders can originate from abnormalities within the respiratory system, the neurologic system and as well as the coordination (or lack thereof) between the two systems. In order to understand abnormal sleep, one must understand normal sleep which changes as the child develops. Sleep and its development are reviewed in Chapter 3. Chapter 3 also discusses behavioral considerations in the treatment of sleep disorders. Respiratory abnormalities that are associated with sleep such as obstructive sleep apnea are described in Chapters 18 and 19. This discussion focuses on neurologic features of several sleep disorders affecting children.

1. Narcolepsy

Narcolepsy, a primary disorder of sleep, is characterized by chronic, inappropriate daytime sleep that occurs regardless of activity or surroundings and is not relieved by increased sleep at night. Onset can occur as early as age 3 years. One half of persons affected by narcolepsy have symptoms in childhood. Of children with narcolepsy, 18% are younger than age 10, and 60% are between puberty and their late teens.

Additional symptoms are cataplexy, hypnagogic and/or hypnopompic hallucinations (visual or auditory), and sleep paralysis. Cataplexy is a transient partial or total loss of muscle tone, often triggered by laughter, anger, or other emotional upsurge. Consciousness is preserved during these spells and they can last several minutes in duration. Hypnagogic hallucinations are intense dream-like states while falling asleep, whereas hypnopompic hallucinations occur while waking from sleep. Sleep paralysis is a brief loss of voluntary muscle control typically occurring at sleep-wake transitions.

Abnormally short latency to rapid eye movement (REM) sleep occurs in subjects with narcolepsy. REM usually occurs after 80–100 minutes or longer in normal subjects. Nocturnal polysomnography and Multiple Sleep Latency Testing (MSLT) demonstrate abnormal REM latency and are used to diagnose the disorder. HLA subtype DQB1*0602 and DRB1*1501 are associated with narcolepsy. Absence of a hypothalamic neuropeptide, hypocretin, is associated with the disorder. Low spinal fluid levels of hypocretin-1 are diagnostic.

Sleep hygiene and behavior modification are used to treat patients with narcolepsy. In general, medications

used for the treatment of narcolepsy in children are "off label." CNS stimulants such as amphetamine mixtures are typically used to treat excessive daytime somnolence. Modafinil is an effective treatment in adults and is used at times in children although controlled studies in children are lacking. Cataplexy responds to venlafaxine, fluoxetine, or clomipramine.

2. Benign Neonatal Sleep Myoclonus

Benign neonatal sleep myoclonus is characterized by myoclonic jerks, usually bilaterally synchronous, that occur only during sleep and stop abruptly when the infant is aroused. It is a benign condition that is frequently confused with epileptic seizures. Myoclonic jerks usually occur in the first 2 weeks of life, and resolve spontaneously in the first months of life although may occur as late as 10 months. Clusters of jerks may last from a few seconds up to 20 minutes.

3. Nocturnal Frontal Lobe Epilepsy

Nocturnal frontal lobe epilepsy is characterized by paroxysmal arousals from NREM sleep with hypermotor seizures with bizarre stereotyped motor movements with dystonic or hyperkinetic features lasting up to 5 minutes. NFLE is a heterogeneous disorder which includes both sporadic and familial forms, the latter related to a genetic abnormality affecting nicotinic receptors. Lack of definitive epileptiform abnormalities on EEG recordings may lead to misdiagnoses of nocturnal dystonia or a parasomnia, such as night terrors or somnambulism.

4. Parasomnias

Parasomnias are abnormal behavioral or physiologic events that occur in association with various sleep stages or the transition between sleeping and waking. The parasomnias of childhood are divided into those occurring in NREM and REM. The NREM parasomnias consist of partial arousals, disorientation, and motor disturbances and include sleep-walking/somnambulism and sleep terrors/pavor nocturnes among others. These are discussed in more detail in Chapter 3.

5. Restless Legs Syndrome

Restless legs syndrome refers to continuous, bothersome leg movements occurring at rest and producing unpleasant paresthesias (sensory symptoms) that often interfere with restful sleep. This disorder can be familial; therefore, a detailed family history may be helpful. Occasionally, anemia (low ferritin) has been noted in adults and children with the disorder; in these cases, improvement has occurred with ferrous sulfate treatment. These are discussed in more detail in Chapter 3.

HEADACHES

ESSENTIALS OF DIAGNOSIS

▶ The two most common causes of headaches in children are migraine and tension-type headache.

▶ Diagnosis is based upon a thorough history and physical, excluding secondary causes such as mass or idiopathic intracranial hypertension.

▶ Warning signs that require further investigation include headache in a young child, new onset and worsening headache, unexplained fever, awakening with headache or vomiting, headache worse with straining or position change, posterior headaches, neurological deficit, or neurocutaneous stigmata.

Headaches are common in children and adolescents and health providers need to recognize and differentiate the common from the more serious causes of headaches. Approximately 11% of children and 28% of adolescents experience recurrent headaches. First, the clinician must determine if the headache is primary or secondary. Symptoms and signs are the center of evaluation; however, red flags (Table 25–11) may prompt

Table 25–11. Red flags for children with headaches.

Headache in child less than 5 years
New ("explosive onset") and worsening headache in a previously healthy child
Worst headache of life
Unexplained fever
Night time or early morning awakenings with headache or vomiting
Headache worse with straining
Posterior headaches
Neurological deficit
Postural headache
Worse when lying
Worse when standing
Neurocutaneous stigmata (café au lait spots, hypopigmented macules)

further workup and evaluation. Correct diagnosis of headache disorders will guide treatment and management.

▶ Clinical Findings

A. Symptoms and Signs

Based on the 2004 International Classification of Headache Disorders-IIR (IHCD-IIR), primary headaches are divided into three major categories: migraine, tension-type, and trigeminal autonomic cephalgia. Clinical features of migraine without aura and tension-type headache are compared in Table 25–12. Migraine headaches are generally episodic unilateral (commonly bilateral in children), throbbing, severe headaches with a combination of photophobia, phonophobia, nausea, and or vomiting. Tension-type headaches (TTH) are a tight band dull sensation that can occur episodically or daily. TTH are not associated with nausea or vomiting

Table 25–12. Classification of TTH and migraine.

	Migraine Without Aura	Tension-Type Headache
Duration	1–72 h*	30 min to 7 days
Quality	Throbbing/pounding	Pressure tight band
Severity	Moderate to severe	Mild to moderate
Location	Unilateral/bilateral*	Bilateral
Physical activity	Worsens headache	No effect
Associated factors		
a. Nausea +/− vomiting	a or b	Not present
b. Photo + phonophobia		Photo or phonophobia but not both

*Modified for children based on the IHCD-IIR classification criteria.

but may have photophobia or phonophobia but not both. Individuals with greater than 15 headaches (migraine or tension-type) per month are considered chronic, and medication overuse must be excluded. Triggers of head pain can include stress, sleep deprivation, dehydration, skipped meals, caffeine, and possibly specific foods (eg, MSG or nitrites). Trigeminal autonomic cephalgia (or cluster headache) is rare in children, but presents as a unilateral severe headache and autonomic dysfunction (watery eye, congestion, facial sweating, miosis, and ptosis).

According to the IHCD-IIR, migraines include childhood pediatric syndromes such as cyclic vomiting, abdominal migraine, and benign paroxysmal vertigo of childhood. These are precursors to migraines and in an older child with new onset migraines; history of these periodic syndromes/symptoms may be discovered.

B. Laboratory Findings

Laboratory studies are not routinely needed in children presenting with recurrent headaches. History and examination may prompt basic screening studies for thyroid, anemia, or autoimmune disorders.

C. Imaging Studies

Routine neuroimaging is not indicated for children presenting with recurrent headaches unless Red Flags are present as noted in Table 25–11. A single red flag is less worrisome (except for abnormal neurological exam) and usually a combination of red flags will prompt neuroimaging evaluation. Imaging can also be considered for children with historical features that suggest recent onset of severe headache, change in headache, or features to suggest neurological dysfunction.

▶ Differential Diagnosis

Secondary causes of headache in children include broad categories such as head trauma, infection, vascular, intracranial pressure changes, structural, metabolic, toxic or substance related, and hematologic (Table 25–13). Headaches associated with head trauma are those that start within two weeks of closed head injury. They can have either features of migraines or tension-type headaches. Neck pain and headache after head trauma warrant evaluation for a dissection, especially if examination is suggestive for a connective tissue disorder such as Marfans or homocystinuria. Headaches that worsen with lying down or vomiting without nausea are concerning for increased intracranial hypertension such as IIH (IIH), sinus venous clot producing increased CSF pressure, hydrocephalus, or mass. Headaches that worsen with standing and improve with lying down are suggestive of low pressure headaches caused by a tear in the dura from a preceding LP, spontaneous leak, penetrating trauma, or surgery.

Medication and substance ingestion and withdrawal are both culprits to secondary headaches. Medications directly

Table 25–13. Differential diagnosis of headaches.

Primary Causes	Secondary Causes	
• Migraine without aura • Migraine with aura • Childhood pediatric syndromes • Tension-type headache • Trigeminal autonomic cephalgias including Cluster headaches	• Trauma • Hypertension • Arterial dissection • Medication overuse headache • Idiopathic intracranial hypertension • Intracranial hypotension • Chiari malformation • Seizure • Mass/Neoplasm • Sleep apnea	• Substance withdrawal • Infection • Sinusitis • Hypoxia • Hypercapnia • Mitochondrial disorders • Thyroid dysfunction • Anemia • Asthenopia (eye strain) • Tempomandibular joint dysfunction • Substance use

related to possible headaches include oral contraceptives, steroids, thyroid replacement, caffeine, cold medicines, ergotamines, vasodilators, overuse of vitamin A or D, sympathomimetics, bronchodilators, atypical antipsychotics, SSRIs, ethanol, antibiotics, and tetracycline. Steroids, vitamin A toxicity, oral contraceptives, and tetracycline are all associated with development of IIH. Medications that are commonly associated with medication overuse headache include aspirin, acetaminophen, NSAIDs, triptans, and combination analgesics such as acetaminophen, butalbital, and caffeine. Other toxins such as lead, carbon monoxide, or organic solvent poisoning cannot be overlooked.

Infections both of the CNS or systemically are associated with headaches. Meningitis and encephalitis will present with a combination of fever, seizures, altered mental status, stiff neck, and headache. However, common systemic or other focal infections may cause headaches such as viral upper respiratory infections, strep pharyngitis (especially in younger children), rhinosinusitis (sinus headache), influenza, and Lyme disease. Headaches are frequently misdiagnosed as sinus headaches and physicians should carefully obtain history of pain in the face, ears, or teeth and evaluate for signs of rhinosinusitis on either physical examination or imaging.

Any cause of hypoxia (eg, cardiac, respiratory, altitude, anemia) may cause a bifrontal throbbing headache that may be worsened with exertion, straining, or laying down. Hypercapnia causes a nonspecific headache and may be secondary to sleep apnea or other underlying metabolic or respiratory disorder. Hypothyroidism can cause bilateral nonpulsating continuous mild intensity pain that resolves after thyroid supplementation.

Although eye strain and temporal mandibular joint dysfunction are rare causes of recurrent headaches, they can be simply treated; therefore, when suspected, evaluation by ophthalmology or dentist, respectively, is indicated. Examination in TMJ dysfunction reveals a click on slow jaw opening and closing in addition to reduced angle of jaw opening.

A thorough history and physical examination helps diagnosing most of these conditions. Several common red flags associated with worrisome secondary causes are listed in Table 25–11. It is not one single symptom or red flag that usually points to a secondary cause; rather, it is a constellation of symptoms.

▶ **Complications**

Migraines and tension-type headaches are both episodic headache disorders but may transform into more frequent headaches. When a child has greater than 15 headaches per month for three or more months, the child has chronic headaches. Risk factors for chronicity include psychological comorbidity, excessive medication use leading to Medication Overuse Headache, and possibly signs of central sensitization. During migraines, central sensitization is indicated by presence of cutaneous allodynia (eg, pain with combing hair, wearing a pony tail, or touching the skin). These symptoms are currently being investigated and are thought to be associated with worsened prognosis with respect to treatment response and headache chronicity.

Depression and anxiety are both comorbid with headaches and are associated with increased headache burden and disability such as school absenteeism. Equally, children psychiatric disorders also have increased rates of primary headaches. School absenteeism and poor school performance appears to be one of the most challenging factors in children with recurrent headaches.

▶ **Treatment**

Treatment is divided into two categories: acute and preventative. Management of headaches should emphasize the necessity for early and adequate treatment during a headache, in addition to self-management skills to reduce frequency and disability such as life-style modification and headache diaries. Pharmacologic preventative treatment can be considered if frequency or disability is significant.

A. Acute Treatment

Acute treatment for pediatric migraine includes use of simple analgesics and migraine specific medications. Any abortive medication should be given as early as possible after the onset of headache. The United States FDA approved almotriptan for adolescents 12-17 and rizatriptan for 6-17 year olds. Simple analgesics include acetaminophen (15 mg/kg; max dose 1000 mg) and ibuprofen (10 mg/kg; max dose 800 mg). Studies showing significant benefit for pediatric migraine include rizatriptan, zolmitriptan nasal, sumatriptan nasal, and almotriptan. Occasionally home treatment fails and patients may need IV medications either in an emergency department or infusion center. When a patient fails emergency room treatments, IV dihydroergotamine can be effective with nausea as the most common side effect. All medications used for abortive treatment should be used cautiously to avoid medication overuse headache. Simple analgesics should be limited to 2–3 times per week and migraine-specific medications to approximately 1–2 times per month. During a headache biobehavioral techniques include rest and relaxation. Providing the child with a cool dark room in which to rest may provide added benefit.

B. Prevention

Any child with headaches should have biobehavioral management as a centerpoint to treatment. These include sleep hygiene; improved fluid intake and elimination of caffeine; nutritional meals; avoidance of skipping meals; regular exercise and stretching; and stress management. Preventative treatment can be considered in individuals with headache frequency of one or more per week. Treatments should be chosen by optimizing wanted side effects and minimizing unwanted side effects (eg, topiramate in an obese child given its side effect of weight loss).

Treatments are categorized into antiepileptic (eg, topiramate, valproic acid, levetiracetam), antihypertensive (eg, β-blockers, calcium channel blockers), antidepressants (eg, amitriptyline), antihistamine/antiserotonergic (eg, cyproheptadine), and nutraceuticals. Only small randomized double blinded or open label studies have tested these agents and there are no FDA-approved preventatives in the United States for the treatment of migraine or tension-type headache in children.

Topiramate, propranolol, amitriptyline, and cyproheptadine are the most commonly prescribed medications for pediatric headache. If topiramates started slowly and at low doses, cognitive side effects can be avoided. Peripheral tingling is uncommon and when present can be usually tolerated by most children. Decreased appetite and weight loss should be monitored at routine appointments. Amitriptyline is usually dosed at nighttime given its side effect of sedation, in addition to other common side effects including constipation, dry mouth, and prolonged QT. Cyproheptadine is a good medication to use in younger children given its small side effect profile of primary increased appetite and sedation. Divalproex sodium has not shown efficacy and side effects including weight gain, tremor, hair loss, and teratogenicity warrant caution in adolescent female patients.

Coenzyme q10, magnesium oxide, and riboflavin have shown some efficacy in childhood migraine. They may be a useful option for children with low frequency headache, low disability, or individuals who favor nonpharmaceutical options.

▶ Prognosis

From the few studies regarding long-term prognosis in adolescents presenting with migraines, approximately 25%–40% of adolescents will have remission of migraine symptoms, 40%–50% have persistence, and 20%–25% convert to tension-type headache. Of those with TTH, 20% convert to migraine. Headache severity at diagnosis is thought to be predictive of headache outcome in the long term.

PSEUDOTUMOR CEREBRI (IDIOPATHIC INTRACRANIAL HYPERTENSION)

ESSENTIALS OF DIAGNOSIS

▶ Signs and symptoms of increased intracranial pressure: chronic headache, tinnitus, cranial nerve VI palsy, papilledema, visual loss.

▶ Normal MRI/MRV of the head.

▶ Elevated opening pressure on lumbar puncture performed in the lateral decubitus position.

Pathogenesis

The pathogenesis of Idiopathic Intracranial Hypertension (IIH) is essentially unknown. Multiple risk factors have been identified, but obesity is the most common. Interestingly, multiple medications have been associated with IIH, including tetracycline, steroids, and retinol.

Clinical Findings

IIH is characterized by increased intracranial pressure as documented by a lumbar puncture performed in the lateral decubitus position in the absence of an identifiable intracranial mass, infection, metabolic derangement, or hydrocephalus. Symptoms include headache, tinnitus, and visual loss; signs of increased intracranial pressure are outlined in Table 25–14. Visual symptoms are commonly secondary to transient visual obscurations (TVOs), which are transient (less than 1 minute) and reversible alterations of vision in these patients. This must be distinguished from visual field anomalies, which can be permanent. Examine patient for papilledema, cranial nerve VI palsy, visual field deficit.

Differential Diagnosis

The cause of IIH is usually unknown, but it has been described in association with a variety of inflammatory, metabolic, toxic, and connective tissue disorders (Table 25–15). Assessing for alternative causes of increased intracranial pressure is essential to the diagnosis. MRI (or urgent CT for critically ill patients) may reveal hydrocephalus, tumor, or abscess. MRV may demonstrate a cerebral sinovenous thrombosis (CSVT),

Table 25–14. Signs of increased intracranial pressure.

Acute, subacute
Headache, vomiting
Excessive rate of head growth
Altered behavior
Decreased level of consciousness
Blurred or double vision; loss of vision
Optic disk swelling
Abducens nerve paresis
Chronic
Macrocephaly
Growth impairment
Developmental delay
Optic atrophy
Visual field loss

Table 25–15. Conditions associated with idiopathic intracranial hypertension and idiopathic intracranial hypertension mimickers.

Medications and metabolic-toxic disorders
Hypervitaminosis A, including use of retinoids
Obesity
Steroid therapy
Hormonal therapy
Steroid withdrawal
Tetracycline, minocycline toxicity
Nalidixic acid toxicity
Iron deficiency
Clotting disorders
Hypocalcemia
Hyperparathyroidism or hyperthyroidism
Adrenal insufficiency
Systemic lupus erythematosus
Chronic CO_2 retention
Infectious and parainfectious disorders
Chronic otitis media (lateral sinus thrombosis)
Guillain-Barré syndrome
Lyme disease
Dural sinus thrombosis
Minor head injury

requiring hematological evaluation and consideration of anticoagulation. As noted in Table 25–15, medications, endocrinologic disturbances, and rheumatologic anomalies may all predispose patients to IIH. Lumbar puncture is essential to the diagnosis, as it confirms the presence of increased pressure (above 180–250 mm H_2O depending on technique and anesthetic used), but also assesses for white blood cell count and protein (looking for an infectious mimicker, such as chronic meningitis). In some inflammatory and connective tissue diseases, the CSF protein concentration may be also be increased.

Complications

Vision loss is the main complication of IIH, as chronic papilledema may lead to permanent optic nerve damage. Vision loss usually occurs in the blind spot and/or nasal aspects of the visual field prior to affecting central vision. Headache, TVOs, cranial nerve VI palsy, and malaise are usually reversible.

Treatment

Treatment of IIH is aimed at correcting the identifiable predisposing condition and preventing vision loss. Sequential ophthalmologic evaluation to assess optic nerve swelling and visual fields is important. Obese patients will benefit significantly from weight loss. Some patients may benefit from the use of acetazolamide or topiramate to decrease the volume and pressure of CSF within the CNS. If a program of medical management and ophthalmologic surveillance fail,

lumboperitoneal shunt, ventriculoperitoneal shunt, or optic nerve fenestration may be necessary to prevent irreparable visual loss and damage to the optic nerves. Dural venous stenting has limited data in adults with no randomized studies in either adults or children.

▶ **Prognosis**

With appropriate workup and treatment, the majority of patients recover from IIH without long-term sequela including visual outcome. Reoccurrence risk is greatest within 18 months.

CEREBROVASCULAR DISEASE

Pediatric arterial ischemic stroke is subdivided into two categories: perinatal arterial ischemic stroke (perinatal ischemic stroke) and childhood arterial ischemic stroke (childhood ischemic stroke). Generally, perinatal ischemic stroke is defined as arterial ischemia occurring in a patient younger than age 28 days and older than 28 weeks' gestation. Childhood ischemic stroke is any ischemic stroke occurring in a patient between 28 days and 18 years old.

1. Childhood Arterial Ischemic Stroke

Childhood arterial ischemic stroke (AIS) is emerging as a serious and increasingly recognized disorder, affecting 2–8:100,000 children per year. There are numerous adverse outcomes, which include death in 10%, neurologic deficits or seizures in 70%–75%, and recurrent ischemic stroke in up to 20%. It is essential to recognize that childhood AIS represents a neurologic emergency, for which prompt diagnosis can affect treatment considerations and outcome. Unfortunately, most pediatric AIS is not recognized until 24–36 hours after onset; and treatment considerations matter most in the first hours after ischemic stroke onset. When possible, all children who present with ischemic stroke should be transferred to a tertiary care center that specializes in pediatric ischemic stroke management. The evaluation

should include a thorough history of prior illnesses, especially those associated with varicella (even in the prior 1–2 years) preceding viral infection, minor head or neck trauma, and familial clotting tendencies. A systematic search for evidence of cardiac, vascular, hematologic, or intracranial disorders should be undertaken (Table 25–16). Although many ischemic strokes are not associated with a single underlying systemic disorder, previously diagnosed congenital heart disease is the most common predisposing illness, followed by hematologic and neoplastic disorders. In many instances the origin is multifactorial, necessitating a thorough investigation even when the cause may seem obvious. Arteriopathy is seen in as many as 80% of "idiopathic" patients, and likely confers an increased recurrence risk.

▶ **Clinical Findings**

A. Symptoms and Signs

Manifestations of arterial ischemic stroke in childhood vary according to the vascular distribution to the brain structure that is involved. Because many conditions leading to childhood ischemic stroke result in emboli, multifocal neurologic involvement is common. Children may present with acute hemiplegia similarly to ischemic stroke in adults. Symptoms of unilateral weakness, sensory disturbance, dysarthria, and dysphagia may develop over a period of minutes, but at times progressive worsening of symptoms may evolve over several hours. Bilateral hemispheric involvement may lead to a depressed level of consciousness. The patient may also demonstrate disturbances of mood and behavior and experience focal or multifocal seizures. Physical examination of the patient is aimed not only at identifying the specific deficits related to impaired cerebral blood flow, but also at seeking evidence for any predisposing disorder. Retinal hemorrhages, splinter hemorrhages in the nail beds, cardiac murmurs, rash, fever, neurocutaneous stigmata, and signs of trauma are especially important findings.

B. Laboratory Findings and Ancillary Testing

In the acute phase, certain investigations should be carried out emergently with consideration of treatment options. This should include complete blood count, erythrocyte sedimentation rate, C-reactive protein, basic chemistries, blood urea nitrogen, creatinine, prothrombin time/partial thromboplastin time, chest radiography, ECG, urine toxicology, and imaging (see following section). Subsequent studies can be carried out systemically, with particular attention to disorders involving the heart, blood vessels, platelets, red cells, hemoglobin, and coagulation proteins. Twenty to fifty percent of pediatric ischemic stroke patients will have a prothrombotic state. Additional laboratory tests for systemic disorders such as vasculitis, mitochondrial disorders, and metabolic disorders are sometimes indicated.

Table 25–16. Etiologic risk factors for ischemic and/or hemorrhagic ischemic stroke.

Cardiac disorders
  Cyanotic heart disease
  Valvular disease
  Rheumatic
  Endocarditis
  Cardiomyopathy
  Cardiac dysrhythmia
Vascular occlusive disorders
  Cervical/cerebral arterial dissection
  Homocystinuria/homocystinemia
  Vasculitis
    Meningitis
    Polyarteritis nodosa
    Systemic lupus erythematosus
    Drug abuse (amphetamines)
  Varicella
  Mycoplasma
  Human immunodeficiency virus
  Fibromuscular dysplasia
  Moyamoya disease
  Diabetes
  Nephrotic syndrome
  Systemic hypertension
  Dural sinus and cerebral venous thrombosis
  Cortical venous thrombosis
Hematologic disorders
  Iron deficiency anemia
  Polycythemia
  Thrombotic thrombocytopenia
  Thrombocytopenic purpura
  Hemoglobinopathies
    Sickle cell disease
  Coagulation defects
    Hemophilia
    Vitamin K deficiency
  Hypercoagulable states
    Prothrombin gene mutation
    Methylenetetrahydrofolate reductase mutation
    Lipoprotein (a)
    Factor V Leiden deficiency
    Antiphospholipid antibodies
    Hypercholesterolemia
    Hypertriglyceridemia
    Factor VIII elevation
    Pregnancy
    Systemic lupus erythematosus
    Use of oral contraceptives
    Antithrombin III deficiency
    Protein C and S deficiencies
  Leukemia
Intracranial vascular anomalies
  Moyamoya
  Arteriovenous malformation
  Arterial aneurysm
  Carotid-cavernous fistula
  Focal cerebral arteriopathy

Examination of CSF is indicated in patients with fever, nuchal rigidity, or obtundation when the diagnosis of intracranial infection requires exclusion. Lumbar puncture may be deferred until a neuroimaging scan (excluding brain abscess or a space-occupying lesion that might contraindicate lumbar puncture) has been obtained. In the absence of infection, rheumatologic disease or intracranial subarachnoid hemorrhage, CSF examination is rarely helpful in defining the cause of the cerebrovascular disorder.

EEG may help in patients with severely depressed consciousness. ECG and echocardiography are useful both in the diagnostic approach to the patient and in ongoing monitoring and management, particularly when hypotension or cardiac arrhythmias complicate the clinical course.

C. Imaging

CT and MRI scans of the brain are helpful in defining the extent of cerebral involvement with ischemia or hemorrhage. CT scans may be normal within the first 12–24 hours of an ischemic stroke and are more useful to assess for hemorrhagic ischemic stroke. A CT scan performed early after the onset of neurologic deficits is valuable in excluding intracranial hemorrhage. This information may be helpful in the early stages of management and in the decision to treat with anticoagulants. Given the high incidence of ischemic stroke mimickers in the pediatric population (complicated migraine, Todd paralysis, encephalitis, etc.), urgent MRI with DWI is increasingly used in pediatric stroke centers.

Vascular imaging of the head and neck is an important part of pediatric ischemic stroke management and may include CTA, MRA, or conventional angiography. In studies in which both MRA and cerebral angiography have been used, up to 80% of patients with idiopathic childhood-onset arterial ischemic stroke have demonstrated a vascular abnormality. Vascular imaging is helpful in diagnosing disorders such as transient cerebral arteriopathy, arteriopathy associated with sickle cell disease, moyamoya disease, arterial dissection, aneurysm, fibromuscular dysplasia, and vasculitis. Recent studies have demonstrated that patients with vascular abnormalities on MRA or conventional angiography have a much greater recurrence risk than patients with normal vessels. When vessel imaging is performed, all major vessels should be studied from the aortic arch. With evidence of fibromuscular dysplasia in the intracranial or extracranial vessels, renal arteriography is indicated.

▶ Differential Diagnosis

Patients with an acute onset of neurologic deficits must be evaluated for other disorders that can cause focal neurologic deficits. Hypoglycemia, prolonged focal seizures, a prolonged postictal paresis (Todd paralysis), acute disseminated encephalomyelitis, meningitis, hemorrhagic stroke, encephalitis, hemiplegic migraine, ingestion, and brain abscess

should all be considered. Migraine with focal neurologic deficits may be difficult to differentiate initially from ischemic stroke. Occasionally the onset of a neurodegenerative disorder (eg, adrenoleukodystrophy or mitochondrial disorder) may begin with the abrupt onset of seizures and focal neurologic deficits. The possibility of drug abuse (particularly cocaine) and other toxic exposures must be investigated diligently in any patient with acute mental status changes.

▶ Treatment

The initial management of ischemic stroke in a child is aimed at providing support for pulmonary, cardiovascular, and renal function. Patients should be administered oxygen and are usually monitored in an intensive care setting. Typically, maintenance fluids without glucose are indicated to augment vascular volume. Pyrexia should be treated aggressively. Specific treatment of ischemic stroke, including blood pressure management, fluid management, and anticoagulation measures, depends partly on the underlying pathogenesis. Meningitis and other infections should be treated. Sickle cell patients require specialists in hematology to perform urgent exchange transfusion and most patients will require chronic transfusions after hospital discharge. Moyamoya is usually treated with surgical revascularization, while patients with vasculitis are often given anti-inflammatory therapy, such as steroids.

In most idiopathic cases of childhood ischemic stroke, anticoagulation or aspirin therapy is indicated. The Royal College of Physicians Pediatric Ischemic Stroke Working Group recommends aspirin, 5 mg/kg daily, as soon as the diagnosis is made. Aspirin use appears safe but the American Heart Association (AHA) recommends yearly flu-shots and close monitoring for Reye syndrome in pediatric ischemic stroke patients. Other groups, such as the American College of Chest Physicians, recommend initial treatment with anticoagulants, such as low-molecular-weight heparin or unfractionated heparin, for 5–7 days (while excluding cardiac sources and dissection) and then switching to aspirin (3–5 mg/d). Recent AHA guidelines support both of these approaches. In some situations, such as arterial dissection or cardio-embolic events, heparinization is usually considered. In adults with cerebrovascular thrombosis, thrombolytic agents (tissue plasminogen activator) used systemically or delivered directly to a vascular thrombotic lesion using interventional radiologic techniques has been shown to improve outcome in the appropriate patients. Although case reports exist, studies in children have not been completed. AHA guidelines recommend against the thrombolysis, outside of a clinical trial for children, while equivocating in the case of adolescents. Given the time-lag to diagnosis and the lack of evidence in children, tissue plasminogen activator is currently used in less than 2% of U.S. children with ischemic stroke. Cleary, the use of tPA should be limited to

practitioner who are familiar with cerebrovascular disease in children.

Long-term management requires intensive rehabilitation efforts and therapy aimed at improving the child's language, educational, and psychological performance. Length of treatment with antithrombotic agents, such as low-molecular-weight heparin and aspirin, is still being studied and depends on the etiology. Constraint therapy may be particularly helpful in cases of hemiparesis.

▶ Prognosis

The outcome of ischemic stroke in infants and children is variable. Roughly one-third may have minimal or no deficits, one-third are moderately affected, and one-third are severely affected. Underlying predisposing conditions and the vascular territory involved all play a role in dictating the outcome for an individual patient. When the ischemic stroke involves extremely large portions of one hemisphere or large portions of both hemispheres and cerebral edema develops, the patient's level of consciousness may deteriorate rapidly, and death may occur within the first few days. In contrast, some patients may achieve almost complete recovery of neurologic function within several days if the cerebral territory is small. Seizures, either focal or generalized, may occur in 30%–50% of patients at some point in the course of their cerebrovascular disorder. Recurrence is up to 20%, and is more prominent in some conditions, such as protein C deficiency, lipoprotein (a) abnormalities, and arteriopathies. Chronic problems with learning, behavior, and activity are common. Long-term follow-up with a pediatric neurologist is indicated and if possible a multidisciplinary ischemic stroke team.

2. Perinatal Arterial Ischemic Stroke

Perinatal arterial ischemic stroke is more common than childhood ischemic stroke, affecting 1:4000 children. Perinatal ischemic stroke has two distinct presentations: acute and delayed. Most patients with an acute presentation develop neonatal seizures during the first week of life, usually in association with a perinatal event. The seizures in acute perinatal ischemic stroke are often focal motor seizures of the contralateral arm and sometimes leg. The presentation is stereotypical because of the predilection of the ischemic stroke to occur in the middle cerebral artery. The presence of diffusion-weighted abnormalities on an MRI scan confirms an acute perinatal ischemic stroke during the first week of life. Other patients present with delayed symptoms, typically with an evolving hemiparesis at an average of 4–8 months. These patients are termed presumed perinatal arterial ischemic stroke.

Acute treatment of a perinatal ischemic stroke is usually limited to neonates with seizures. Unless an embolic source is identified, aspirin and anticoagulation are almost never prescribed. Management is based on supportive care, identification of comorbid conditions, and treatment of

seizures. In acute perinatal ischemic stroke, treatable causes such as infection, cardiac embolus, metabolic derangement, and inherited thrombophilia must be ruled out. In appropriate cases, echocardiography, thrombophilia evaluation, and lumbar puncture are indicated. Supportive management focuses on general measures, such as normalizing glucose levels, monitoring blood pressure, and optimizing oxygenation.

Long-term management of perinatal ischemic stroke usually starts with identifying risk factors, which might include prothrombotic states, cardiac disease, drugs, and dehydration. Although prothrombotic abnormalities with the best evidence of association are factor V Leiden, protein C deficiency, and high lipoprotein (a), many practitioners perform an extensive hematologic workup. Maternal risk factors such as infertility, antiphospholipid antibodies, placental infection, premature rupture of membranes, and cocaine exposure are all independently associated with perinatal ischemic stroke.

The prognosis for children who sustain perinatal ischemic strokes has been considered better than for children or adults with ischemic strokes, presumably because of the plasticity of the neonatal brain. Recent evidence, however, suggests that as patients progress into their school-age years, they may have previously unrecognized cognitive challenges, such as learning deficits or attention-deficit/hyperactivity disorder. Twenty to forty percent of patients who experience perinatal ischemic strokes are neurologically normal. Motor impairment affects about 40%–60% of patients and is predominantly hemiplegic cerebral palsy. In acute presentations, MRI can be predictive of motor impairment, as descending corticospinal tract diffusion-weighted MRI signal is associated with a higher incidence of hemiplegia. Language delays, behavioral abnormalities, and cognitive deficits are seen in 20%–40% of infants who experience perinatal ischemic strokes. Patients are also at an increased risk for seizures. Ischemic stroke recurs in 3% of neonates and is usually associated with a prothrombotic abnormality or an underlying illness, such as cardiac malformation or infection. Given the low incidence of recurrence, long-term management is largely rehabilitative, including constraint therapies.

CONGENITAL MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations of the nervous system occur in 1%–3% of living neonates and are present in 40% of infants who die. Developmental anomalies of the CNS may result from a variety of causes, including infectious, toxic, genetic, metabolic, and vascular insults that affect the fetus. The specific type of malformation that results from such insults, however, may depend more on the gestational period during which the insult occurs than on the specific cause. The period of induction, days 0–28 of gestation, is the period during which the neural plate appears and the neural tube forms and closes.

Insults during this phase can result in a major absence of neural structures, such as anencephaly, or in a defect of neural tube closure, such as spina bifida, meningomyelocele, or encephalocele. Cellular proliferation and migration characterize neural development that occurs after 28 days' gestation. During this period, lissencephaly, pachygyria, agyria, and agenesis of the corpus callosum may result from genetic, toxic, infectious, or metabolic disruptions.

1. Abnormalities of Neural Tube Closure

Defects of neural tube closure constitute some of the most common congenital malformations affecting the nervous system, occurring in 1:1000 live births. Spina bifida with associated meningomyelocele or meningocele is commonly found in the lumbar region. Depending on the extent and severity of the involvement of the spinal cord and peripheral nerves, lower extremity weakness, bowel and bladder dysfunction, and hip dislocation may be present. Delivery via cesarean section followed by early surgical closure of meningoceles and meningomyeloceles is usually indicated. Additional treatment is necessary to manage chronic abnormalities of the urinary tract, orthopedic abnormalities such as kyphosis and scoliosis, and paresis of the lower extremities. Hydrocephalus associated with meningomyelocele usually requires ventriculoperitoneal shunting.

▶ Diagnosis & Prevention

In general, the diagnosis of neural tube defects is obvious at the time of birth. The diagnosis may be strongly suspected prenatally on the basis of ultrasonographic findings and the presence of elevated α-fetoprotein in the amniotic fluid. All women of childbearing age should take prophylactic folate, which can prevent these defects and decrease the risk of recurrence by 70%.

2. Disorders of Cortical Development

Malformations of cortical development are increasingly recognized with the advent of MRI techniques and the explosion of newly identified genetic syndromes. They are subdivided into disorders based on (1) neuronal and glial proliferation or apoptosis dysfunction (2) abnormal migration or (3) abnormal post-migrational development. In this section, we provide some common examples of these subtypes.

A. Microcephaly and Megalencephaly

Common examples of neuronal and glial proliferation dysfunction are microcephalies and megalencephaly. Microcephaly is discussed below in abnormal head size section. Megalencephaly results in overdevelopment most commonly one hemisphere (hemimegalencephaly) and results in macrocephaly. Spectrum of clinical findings are broad and depend on the underlying etiology include developmental delay, seizures, and dysmorphisms.

B. Lissencephaly

Lissencephaly is the classic example of abnormal migration. This severe malformation of the brain is characterized by a smooth cortical surface with minimal sulcal and gyral development similar to a fetal brain at the end of the first trimester. Lissencephalic brains have a primitive cytoarchitectural construction with a four-layered cerebral mantle instead of the mature six-layered mantle. Quantities of pachygyria (thick gyri) and agyria (absence of gyri) may vary in an anterior to posterior gradient and help guide genetic diagnosis. Patients with lissencephaly usually have severe neurodevelopmental delay, microcephaly, and seizures (including infantile spasms); however, there is significant phenotypic heterogeneity. These disorders are autosomal recessive and X-linked disorders. *LIS1* mutations on chromosome 17 are associated with dysmorphic features (Miller-Dieker syndrome). Another autosomal recessive mutation, involving the *RELN* gene, results in a lissencephaly with severe hippocampal and cerebellar hypoplasia. X-linked syndromes involving mutations in *DCX* (double cortin) and *ARX* (associated with ambiguous genitalia) affect males with lissencephaly and females with band heterotopias or agenesis of the corpus callosum.

Lissencephaly with hydrocephalus, cerebellar malformations, or muscular dystrophy may occur in Walker-Warburg syndrome (*POMT1* mutation), Fukuyama muscular dystrophy (*fukutin* mutation), and muscle-eye-brain disease (*POMGnT1* mutation). It is particularly important to identify these syndromes not only because clinical tests are available, but also because of their genetic implications. Lissencephaly may be a component of Zellweger syndrome, a metabolic peroxisomal abnormality with the presence of elevated concentrations of very-long-chain fatty acids in plasma. No specific treatment for lissencephaly is available, and seizures are often difficult to control with standard medications.

C. Polymicrogyria

Polymicrogyria is a post-migrational disorder. Subcategories of polymicrogyria include those associated with schizencephaly and bilateral perisylvian polymicrogyria. Patients with bilateral perisylvian polymicrogyria pseudobulbar palsy, variable cognitive deficits, facial diplegia with dysarthria and drooling, developmental delay, and epilepsy. Seizures are often difficult to control with anti-epileptic drugs; some patients have benefited from corpus callosotomy. The cause of this syndrome is as yet unknown, although intrauterine cerebral ischemic injury has been postulated. Therapy is aimed at improving speech and oromotor functions and controlling seizures.

3. Disorders of Cerebellum Development

A. Arnold-Chiari Malformations

Arnold-Chiari malformation type I consists of elongation and displacement of the caudal end of the brainstem into the

spinal canal with protrusion of the cerebellar tonsils through the foramen magnum. In association with this hindbrain malformation, minor to moderate abnormalities of the base of the skull often occur, including basilar impression (platybasia) and small foramen magnum. Arnold-Chiari malformation type I may remain asymptomatic for years, but in older children and young adults it may cause progressive ataxia, paresis of the lower cranial nerves, and progressive vertigo; rarely may it present with apnea or disordered breathing. Posterior cervical laminectomy may be necessary to provide relief from cervical cord compression. Ventriculoperitoneal shunting may be required for associated hydrocephalus.

Arnold-Chiari malformation type II consists of the malformations found in Arnold-Chiari type I plus an associated lumbar meningomyelocele. Hydrocephalus develops in approximately 90% of children with Arnold-Chiari malformation type II. These patients may also have aqueductal stenosis, hydromyelia or syringomyelia, and cortical dysplasias. The clinical manifestations of Arnold-Chiari malformation type II are most commonly caused by the associated hydrocephalus and meningomyelocele. In addition, dysfunction of the lower cranial nerves may be present. Up to 25% of patients may have epilepsy, likely secondary to the cortical dysplasias. Higher lesions of the thoracic or upper lumbar cord are associated with mild mental retardation in about half of patients, while over 85% of patients with lower level lesions have normal intelligence quotients (IQs). Many patients will develop a latex sensitivity or allergy.

Arnold-Chiari malformation type III is characterized by occipital encephalocele, a closure defect of the rostral (upper) end of the neural tube. Hydrocephalus is extremely common with this malformation.

B. Dandy-Walker Syndrome

Despite being described nearly a century ago, the exact definition of the Dandy-Walker syndrome is still debated. Classically, it is characterized by aplasia of the vermis, cystic enlargement of the fourth ventricle, rostral displacement of the tentorium, and absence or atresia of the foramina of Magendie and Luschka. Although hydrocephalus is usually not present congenitally, it develops within the first few months of life. Ninety percent of patients who develop hydrocephalus do so by age 1 year.

On physical examination, a rounded protuberance or exaggeration of the cranial occiput often exists. In the absence of hydrocephalus and increased intracranial pressure, few physical findings may be present to suggest neurologic dysfunction. An ataxic syndrome occurs in fewer than 20% of patients and is usually late in appearing. Many long-term neurologic deficits result directly from hydrocephalus. Diagnosis of Dandy-Walker syndrome is confirmed by CT or MRI scanning of the head. Treatment is directed at the management of hydrocephalus.

4. Agenesis of the Corpus Callosum

Agenesis of the corpus callosum, once thought to be a rare cerebral malformation, is more frequently diagnosed with modern neuroimaging techniques; occurring in 1:4000 births. The cause of this malformation is unknown. Occasionally it appears to be inherited in either an autosomal dominant or recessive pattern. It has been associated with X-linked patterns (ARX as mentioned earlier). Most cases are sporadic. Maldevelopment of the corpus callosum may be partial or complete. No specific syndrome is typical of agenesis of the corpus callosum, although many patients have seizures, developmental delay, microcephaly, or mental retardation.

Neurologic abnormalities may be related to microscopic cytoarchitectural abnormalities of the brain that occur in association with agenesis of the corpus callosum. The malformation may be found coincidentally by neuroimaging studies in otherwise normal patients and has been described as a coincidental finding at autopsy in neurologically normal individuals. A special form of agenesis of the corpus callosum occurs in Aicardi syndrome. In this X-linked disorder, agenesis of the corpus callosum is associated with other cystic intracerebral abnormalities, early infantile spasms, mental retardation, lacunar chorioretinopathy, and vertebral body abnormalities.

5. Hydrocephalus

Hydrocephalus is an increased volume of CSF with progressive ventricular dilation. In communicating hydrocephalus, CSF circulates through the ventricular system and into the subarachnoid space without obstruction. In noncommunicating hydrocephalus, an obstruction blocks the flow of CSF within the ventricular system or blocks the egress of CSF from the ventricular system into the subarachnoid space. A wide variety of disorders, such as hemorrhage, infection, tumors, and congenital malformations, may play a causal role in the development of hydrocephalus. The presence of radialized thumbs and aqueductal stenosis is suggestive of X-linked hydrocephalus due to the clinically testable neural cell adhesion molecule-L1 deficiency.

Clinical features of hydrocephalus include macrocephaly, an excessive rate of head growth, irritability, bulging or full fontanelle, vomiting, loss of appetite, impaired upgaze, impaired extraocular movements, hypertonia of the lower extremities, and generalized hyperreflexia. Without treatment, optic atrophy may occur. In infants, papilledema may not be present, whereas older children with closed cranial sutures can eventually develop swelling of the optic disk. Hydrocephalus can be diagnosed on the basis of the clinical course, findings on physical examination, and CT or MRI scan.

Treatment of hydrocephalus is directed at providing an alternative outlet for CSF from the intracranial compartment. The most common method is ventriculoperitoneal shunting.

Other treatment should be directed, if possible, at the underlying cause of the hydrocephalus.

ABNORMAL HEAD SIZE

Bone plates of the skull have almost no intrinsic capacity to enlarge or grow. Unlike long bones, they depend on extrinsic forces to stimulate new bone formation at the suture lines. Although gravity and traction on bone by muscle and scalp probably stimulate some growth, the single most important stimulus for head growth during infancy and childhood is brain growth. Therefore, accurate assessment of head growth is one of the most important aspects of the neurologic examination of young children. A head circumference that is two standard deviations above or below the mean for age requires investigation and explanation.

1. Craniosynostosis

Craniosynostosis, or premature closure of cranial sutures, is usually sporadic and idiopathic. However, some patients have hereditary disorders, such as Apert syndrome and Crouzon disease that are associated with abnormalities of the digits, extremities, and heart. Craniosynostosis may be associated with an underlying metabolic disturbance such as hyperthyroidism and hypophosphatasia.

The most common form of craniosynostosis involves the sagittal suture and results in scaphocephaly, an elongation of the head in the anterior to posterior direction. Premature closure of the coronal sutures causes brachycephaly, an increase in cranial growth from left to right. Unless many or all cranial sutures close prematurely, intracranial volume will not be compromised, and the brain's growth will not be impaired. Closure of only one or a few sutures will not cause impaired brain growth or neurologic dysfunction.

A common complaint is abnormal head shape secondary to positional plagiocephaly due to supine sleep position ("positional"), not from occipital lambdoid suture craniosynostosis.

Repositioning the head during naps (eg, with a rolled towel under one shoulder), and "tummy time" when awake are remedies. Rarely is a skull film or consultation necessary to rule out craniosynostosis. Most positional nonsynostotic plagiocephaly resolves by age 2 years.

Management of craniosynostosis is directed at preserving normal skull shape and consists of excising the fused suture and applying material to the edge of the craniectomy to prevent reossification of the bone edges. The best cosmetic effect on the skull is achieved when surgery is performed during the first 6 months of life.

2. Microcephaly

A head circumference more than two standard deviations below the mean for age and sex is by definition microcephaly. More important than a single head circumference measurement is the rate or pattern of head growth over time. Head circumference measurements that progressively drop to lower percentiles with increasing age are indicative of a process or condition that has impaired the brain's capacity to grow. Primary microcephaly is present at birth and secondary microcephaly develops postnatally. The causes of microcephaly are numerous. Some examples are listed in Table 25–17.

Table 25–17. Causes of microcephaly.

Causes	Examples
Chromosomal	Trisomies 13, 18, 21
Malformation	Lissencephaly, schizencephaly
Syndromes	Rubenstein-Taybi, Cornelia de Lange, Angelman
Toxins	Alcohol, anticonvulsants (?), maternal phenylketonuria (PKU)
Infections (intrauterine)	TORCHS[a]
Radiation	Maternal pelvis, first and second trimester
Placental insufficiency	Toxemia, infection, small for gestational age
Familial	Autosomal dominant, autosomal recessive
Perinatal hypoxia, trauma	Birth asphyxia, injury
Infections (perinatal)	Bacterial meningitis (especially group B streptococci), Viral encephalitis (enterovirus, herpes simplex)
Metabolic	Glut-1 deficiency, PKU, maple syrup urine disease
Degenerative disease	Tay-Sachs, Krabbe

[a]TORCHS is a mnemonic for toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex, and syphilis.

▶ Clinical Findings

A. Symptoms and Signs

Microcephaly may be suspected in the full-term newborn and in infants up to age 6 months whose chest circumference exceeds the head circumference (unless the child is very obese). Microcephaly may be discovered when the child is examined because of delayed developmental milestones or neurologic problems, such as seizures or spasticity. There may be a marked backward slope of the forehead (as in familial microcephaly) with narrowing of the bitemporal diameter. The fontanelle may close earlier than expected, and sutures may be prominent. Abnormal dermatoglyphics (neurocutaneous marks) may be present when the injury occurred before 19 weeks' gestation. Parents' heads may need measurement to rule out a rare dominantly inherited familial microcephaly. Eye, cardiac, and bone abnormalities may also be clues to congenital infection.

B. Laboratory Findings

Laboratory findings vary with the cause. In the newborn, IgM antibody titers for toxoplasmosis, rubella, CMV, herpes simplex virus, and syphilis and urine culture for CMV may be assessed for sign of congenital infection. Genetic testing can be targeted based on history and physical examination. Genetic screening tests may be considered such as array Comparative Genomic Hybridization (CGH) or karyotyping. Most metabolic disorders present either as congenital syndromic microcephaly (ie, dysmorphisms present on examination) or with postnatal microcephaly and global developmental delay. Nonsyndromic microcephaly presenting at birth may be due to maternal PKU (maternal serum with elevated phenylalanine), phosphoglycerate dehydrogenase deficiency (disorder of L-serine biosynthesis), or Amish lethal microcephaly (elevated urine alpha-ketoglutaric acid).

C. Imaging Studies

CT or MRI scans may aid in diagnosis and prognosis. These studies may demonstrate calcifications, malformations, or atrophic patterns that suggest specific congenital infections or genetic syndromes. Plain skull radiographs are of limited value. MRI is most helpful in definitive diagnosis, prognosis, and genetic counseling.

▶ Differential Diagnosis

Common forms of craniosynostosis involving sagittal, coronal, and lambdoidal sutures are associated with abnormally shaped heads but do not cause microcephaly. Recognizing treatable causes of undergrowth of the brain such as hypopituitarism or hypothyroidism and severe protein-calorie undernutrition is critical so that therapy can be initiated as early as possible. Refer to Table 25–17 for examples of causes of microcephaly.

▶ Treatment & Prognosis

Genetic counseling should be offered to the family of any infant with significant microcephaly. Many children with microcephaly are developmentally delayed. The notable exceptions are found in cases of hypopituitarism (rare) or familial autosomal dominant microcephaly. Individuals may need screening for vision and hearing abnormalities as well as supportive therapies for developmental delay.

3. Macrocephaly

A head circumference more than two standard deviations above the mean for age and sex denotes macrocephaly. Rapid head growth rate suggests increased intracranial pressure, most likely caused by hydrocephalus, extra-axial fluid collections, or neoplasms. Macrocephaly with normal head growth rate suggests familial macrocephaly or true megalencephaly, as might occur in neurofibromatosis. Other causes and examples of macrocephaly are listed in Table 25–18.

▶ Differential Diagnosis

A. Catch-Up Growth

When a neurologically intact premature infant whose rapid head enlargement is most marked in the first weeks of life, or the infant in the early phase of recovery from

Table 25–18. Causes of macrocephaly.

Causes	Examples
Pseudomacrocephaly, pseudohydrocephalus, catch-up growth crossing percentiles	Growing premature infant; recovery from malnutrition, congenital heart disease, postsurgical correction

Increased intracranial pressure
    With dilated ventricles
    With other mass
	Progressive hydrocephalus, subdural effusion
	Arachnoid cyst, porencephalic cyst, brain tumor

Benign familial macrocephaly (idiopathic external hydrocephalus)	External hydrocephalus, benign enlargement of the subarachnoid spaces (synonyms)

Megalencephaly (large brain)
    With neurocutaneous disorder
 	
    With gigantism
    With dwarfism
    Metabolic
    Lysosomal
    Other leukodystrophy
	Neurofibromatosis, tuberous sclerosis, etc
	Sotos syndrome
	Achondroplasia
	Mucopolysaccharidoses
	Metachromatic leukodystrophy (late)
	Canavan spongy degeneration

Thickened skull	Fibrous dysplasia (bone), hemolytic anemia (marrow), sicklemia, thalassemia

deprivation dwarfism. As the expected normal size is reached, head growth slows and then resumes a normal growth pattern.

B. Familial Macrocephaly

This condition may exist when another family member has an unusually large head with no signs or symptoms referable to such disorders as neurocutaneous dysplasias (especially neurofibromatosis) or cerebral gigantism (Sotos syndrome), or when there are no significant mental or neurologic abnormalities in the child.

C. Hydrocephalus

See section Congenital Malformations of the Nervous System.

Other causes of macrocephaly are dependent on the etiology such as metabolic or genetic causes.

▶ Clinical Findings

Clinical and laboratory findings vary with the underlying process. In infants, transillumination of the skull with an intensely bright light in a completely darkened room may disclose subdural effusions, hydrocephalus, hydranencephaly, and cystic defects. A surgically or medically treatable condition must be ruled out. Thus, the first decision is whether and when to perform an imaging study.

A. Imaging Studies

An imaging study is necessary if signs or symptoms of increased intracranial pressure are present (see Table 25–14). If the fontanelle is open, cranial ultrasonography can assess ventricular size and diagnose or exclude hydrocephalus. CT or MRI scans are used to define any structural cause of macrocephaly and to identify an operable disorder. Even when the condition is untreatable (or does not require treatment), the information gained may permit more accurate diagnosis and prognosis, guide management and genetic counseling, and serve as a basis for comparison should future abnormal cranial growth or neurologic changes necessitate a repeat study.

NEUROCUTANEOUS DYSPLASIAS

Neurocutaneous dysplasias are diseases of the neuroectoderm and sometimes involve endoderm and mesoderm. Birthmarks and later appearing skin growths suggest a need to look for brain, spinal cord, and eye disease. Hamartomas (histologically normal tissue growing abnormally rapidly or in aberrant sites) are common. The most common dysplasias are dominantly inherited. Benign and even malignant tumors may develop in these conditions.

1. Neurofibromatosis Type 1 (Von Recklinghausen Disease)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- ▶ More than six café au lait spots 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals.
- ▶ Two or more neurofibromas of any type or one plexiform neurofibroma.
- ▶ Freckling in the axillary or inguinal regions.
- ▶ Optic glioma.
- ▶ Two or more Lisch nodules (iris hamartomas).
- ▶ Distinctive bony lesions, such as sphenoid dysplasia or thinning of long bone with or without pseudarthroses.
- ▶ First-degree relative (parent, sibling, offspring) with neurofibromatosis type 1 by above criteria.

Neurofibromatosis is a multisystem disorder with a prevalence of 1:3000. Fifty percent of cases are due to new mutations in the *NF1* gene. Forty percent of patients develop medical complications over their lifetime. Two or more positive criteria are diagnostic; others may appear over time. Children with six or more café au lait spots and no other positive criteria should be followed; 95% develop neurofibromatosis type 1.

Clinical Findings

A. Symptoms and Signs

The most common presenting symptoms are cognitive or psychomotor problems; 40% have learning disabilities, and 8% have mental retardation. The history should focus on lumps or masses causing disfigurement, functional problems, or pain. Café au lait spots are seen in most affected children by age 1 year. The typical skin lesion is 10–30 mm, ovoid, and smooth-bordered. Discrete well demarcated neurofibromas or lipomas can occur at any age. Plexiform neurofibromas are diffuse and can invade normal tissue. They are congenital and are frequently detected during periods of rapid growth. If the face or a limb is involved, there may be associated hypertrophy or overgrowth.

Clinicians should evaluate head circumference, blood pressure, vision, hearing, spine for scoliosis, and limbs for pseudarthroses. Strabismus or amblyopia dictates a search for optic glioma, a common tumor in neurofibromatosis. The eye examination should include a check for proptosis and iris Lisch nodules. The optic disk should be examined for atrophy or papilledema. Any progressive or new neurologic deficit calls for studies to rule out tumor of the spinal cord or CNS. Short stature and precocious puberty are occasional findings.

Parents should be examined in detail. Family history is important in identifying dominant gene manifestations.

B. Laboratory Findings

Laboratory tests are not likely to be of value in asymptomatic patients. Selected patients require brain MRI with special cuts through the optic nerves to rule out optic glioma. A common finding is hyperintense, nonmass lesions seen on T_2 weighted MRI images. These "unidentified bright objects" ("UBOs") often disappear with time. Hypertension necessitates evaluation of renal arteries for dysplasia and stenosis. Cognitive and school achievement testing may be indicated. Scoliosis or limb abnormalities should be studied by appropriate imaging.

Differential Diagnosis

Patients with McCune-Albright syndrome often have larger café au lait spots with precocious puberty, polyostotic fibrous dysplasia, and hyperfunctioning endocrinopathies. One or two café au lait spots are often seen in normal children. A large solitary café au lait spot is usually innocent.

Complications

Seizures, deafness, short stature, early puberty, and hypertension occur in less than 25% of patients with neurofibromatosis. Optic glioma occurs in about 15%. Although the tumor may be apparent at an early age, it rarely causes functional problems and is usually nonprogressive. Patients have a slightly increased risk (5% life risk) for various malignancies. Other tumors may be benign but may cause significant morbidity and mortality because of their size and location in a vital or enclosed space, for example, plexiform neurofibromas. These "benign" infiltrating tumors can disfigure facially, impair spinal cord, renal, or pelvic-leg function, and are often vexing to treat. PET scans are helpful to detect malignant transformations (to sarcoma). Experimental trials of interferons and mTOR inhibitors (rapamycin=sirolimus) are ongoing at many centers. Strokes from NF-1 cerebral arteriopathy are noteworthy; arteriopathy of renal arteries can cause reversible hypertension in childhood.

Treatment

Genetic counseling and screening is important and the risk to siblings is 50%. The disease may be progressive, with serious complications occasionally seen. Patients sometimes worsen during puberty or pregnancy. Annual or semiannual visits are important in the early detection of school problems, or bony or neurologic abnormalities. The following parameters should be recorded at each annual visit:

1. Child's development and progress at school
2. Visual symptoms, visual acuity, and funduscopy until age 7 years (to detect optic pathway glioma, glaucoma)
3. Head circumference (rapid increase might indicate tumor or hydrocephalus)
4. Height (to detect abnormal pubertal development)
5. Weight (to detect abnormal pubertal development)
6. Pubertal development (to detect delayed or precocious puberty due to pituitary or hypothalamic lesion)
7. Blood pressure (to detect renal artery stenosis or pheochromocytoma)
8. Cardiovascular examination (for congenital heart disease, especially pulmonary stenosis)
9. Evaluation of spine (for scoliosis and underlying plexiform neurofibromas)
10. Evaluation of the skin (for cutaneous, subcutaneous, and plexiform neurofibromas)
11. Examination of other systems, depending on specific symptoms

Multidisciplinary clinics at medical centers around the United States are excellent resources. Prenatal diagnosis is probably on the horizon, but the variability of manifestations (trivial to severe) will make therapeutic abortion an unlikely option. Chromosomal linkage studies are under way (chromosome 17q11.2). Information for lay people and physicians is available from the National Neurofibromatosis Foundation (http://www.nf.org).

2. Neurofibromatosis Type 2

NF-2 is a dominantly inherited neoplasia syndrome manifested as bilateral vestibular schwannomas (VIII nerve tumors) which may appear in childhood (with loss of hearing, etc). Café au lait spots are not part of NF-2. In 50% of patients the mutation occurs de novo (neither parent carrying the faulty gene). Tumors of cranial nerve VIII (Schwannomas) virtually never occur in neurofibromatosis type 1 but are the rule in neurofibromatosis type 2, a rare autosomal dominant disease. Café au lait spots are less common in neurofibromatosis type 2. Other tumors of the brain and spinal cord are common: meningiomas, other cranial nerve schwannomas, and ependymomas. Posterior lens cataracts are a third risk.

3. Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis (TS) is a dominantly inherited disease. Almost all individuals have deletions on chromosome 9 (*TSC1* gene) or 16 (*TSC2* gene). The gene products hamartin and tuberin have tumor-suppressing effects, therefore TS patients are more susceptible to hamartomas in many organs and brain tubers and tumors. A triad of seizures, mental retardation, and adenoma sebaceum occurs in only 33% of patients. Parents formerly thought not to harbor the gene are now being diagnosed as asymptomatic carriers.

▶ Clinical Findings

Tuberous sclerosis has a wide spectrum of disease: asymptomatic with only skin findings to severe infantile spasms and mental retardation. Seizures in early infancy correlate with later mental retardation.

A. Symptoms and Signs (Table 25–19)

1. Dermatologic features—Skin findings bring most patients to the physician's attention. Ninety-six percent of patients have one or more hypomelanotic macules, facial angiofibromas, ungual fibromas, or shagreen (leathery orange peel) patches. Adenoma sebaceum (facial skin hamartomas) may first appear in early childhood, often on the cheek, chin, and dry sites of the skin where acne is not usually seen. Ash-leaf spots are off-white hypomelanotic macules are often oval or "ash leaf" in shape and follow dermatomes. A Wood lamp (ultraviolet light) shows the macules more clearly. The equivalent to an ash leaf spot in the scalp is poliosis (whitened hair patch). Subungual or periungual fibromas are more common in the toes. Café au lait spots are occasionally seen. Fibrous or raised plaques may resemble coalescent angiofibromas.

2. Neurologic features—Seizures are the most common and up to 20% of patients with infantile spasms have TS. Thus, any patient presenting with infantile spasms (and the

Table 25–19. Major and minor criteria for tuberous sclerosis.

Major Features	Minor Features
Facial angiofibromas or forehead plaque	Multiple, randomly distributed pits in dental enamel
Nontraumatic ungula or periungual fibroma	Hamartomatous rectal polyps
Hypomelanotic macules (three or more)	Bone cysts
Shagreen patch (connective tissue nevus)	Cerebral white matter radial migration lines
Multiple retinal nodular hamartomas	Gingival fibromas
Glioneuronal hamartoma (cortical tuber)	Nonrenal hamartoma
Subependymal nodule	Retinal achromic patch
Subependymal giant cell astrocytoma	"Confetti" skin lesions
Cardiac rhabdomyoma, single or multiple	Multiple renal cysts
Lymphangiomyomatosis	
Renal angiomyolipoma	

Definite tuberous sclerosis complex: either two major features or one major feature plus two minor features

Probable tuberous sclerosis complex: one major plus one minor feature

Possible tuberous sclerosis complex: either one major feature or two or more minor features

parents as well) should be evaluated for this disorder. An imaging study of the CNS, such as a CT scan, may show calcified subependymal nodules; MRI may show dysmyelinating white matter lesions or cortical tubers. Virtually any kind of symptomatic seizure (eg, atypical absence, partial complex, and generalized tonic-clonic seizures) may occur. Mental retardation occurs in up to 50% of patients referred to tertiary care centers; the incidence is probably much lower in randomly selected patients. Patients with seizures are more prone to mental retardation or learning disabilities.

3. Renal lesions—Renal cysts or angiomyolipomas may be asymptomatic. Hematuria or obstruction of urine flow sometimes occurs; the latter requires operation. Ultrasonography of the kidneys should be done in any patient suspected of tuberous sclerosis, both to aid in diagnosis if lesions are found and to rule out renal obstructive disease.

4. Cardiopulmonary involvement—Rarely cystic lung disease may occur. Rhabdomyomas of the heart may be asymptomatic but can lead to outflow obstruction, conduction difficulties, and death. Chest radiographs and echocardiograms can detect these rare manifestations. Cardiac rhabdomyoma may be detected on prenatal ultrasound examination, rhabdomyomas typically regress with age, so

symptomatic presentations are typically in the perinatal period or infancy when rhabdomyomas are largest.

5. Eye involvement—Retinal hamartomas are often near the disk and usually asymptomatic.

6. Skeletal involvement—Cystic rarefactions can be found in the bones of the fingers or toes.

B. Imaging Studies and Special Tests

Plain radiographs may detect areas of thickening within the skull, spine, and pelvis, and cystic lesions in the hands and feet. Chest radiographs may show lung honeycombing. MR and CT imaging can show the virtually pathognomonic subependymal nodular calcifications, sometimes widened gyri or tubers, and brain tumors. Hypomyelinated lesions may be seen with MRI. EEG should be considered in any TS patient with new onset spells concerning for seizures.

▶ Treatment

Therapy is as indicated by underlying disease (eg, seizures and tumors of the brain, kidney, and heart). Skin lesions on the face may need dermabrasion or laser treatment. Genetic counseling emphasizes identification of the carrier. The risk of appearance in offspring if either parent is a carrier is 50%. The patient should be seen annually for counseling and reexamination in childhood. Identification of the chromosomes (9,16; *TSC1* and *TSC2* genes) may in the future make intrauterine diagnosis possible. Treatment of refractory epilepsy may lead to surgical extirpation of epileptiform tuber sites.

Recent research has suggested the "mammalian target of rapamycin" (mTOR) inhibitors (eg, rapamycin) may inhibit epilepsy in tuberous sclerosis, even shrink dysplasia/tubers, tumors, adenoma sebacea, and possibly improve learning.

4. Encephalofacial Angiomatosis (Sturge-Weber Disease)

Sturge-Weber disease is a sporadic disease which consists of a facial port wine nevus involving the upper part of the face (in the first division of cranial nerve V), a venous angioma of the meninges in the occipitoparietal regions, and choroidal angioma. The syndrome has been described without the facial nevus (rare, type III, exclusive leptomeningeal angioma).

▶ Clinical Findings

A. Symptoms and Signs

In infancy, the eye may show congenital glaucoma, or buphthalmos, with a cloudy, enlarged cornea. In early stages, the facial nevus may be the only indication, with no findings in the brain even on radiologic studies. The characteristic cortical atrophy, calcifications of the cortex, and meningeal angiomatosis may appear with time, solidifying the diagnosis.

Physical examination may show focal seizures or hemiparesis on the side contralateral to the cerebral lesion. The facial nevus may be much more extensive than the first division of cranial nerve V; it can involve the lower face, mouth, lip, neck, and even torso. Hemi-atrophy of the contralateral limbs may occur. Mental handicap may result from poorly controlled seizures. Late-appearing glaucoma and rarely CNS hemorrhage occur.

B. Imaging and Special Tests

Radiologic studies may show calcification of the cortex; CT scanning may show this much earlier than plain radiographic studies. MRI often shows underlying brain involvement.

The EEG often shows depression of voltage over the involved area in early stages; later, epileptiform abnormalities may be present focally.

▶ Differential Diagnosis

The differential diagnosis includes (rare) PHACES syndrome: **P**osterior fossa malformation, segmental (facial) **H**emangioma, **A**rterial abnormalities, **C**ardiac defects, **E**ye abnormalities, and **S**ternal (or ventral) defects; often, only portions of that list are present.

▶ Management & Treatment

Early control of seizures is important to avoid consequent developmental setback. If seizures do not occur, normal development can be anticipated. Careful examination of the newborn, with ophthalmologic assessment to detect early glaucoma, is indicated. Rarely, surgical removal of the involved meninges and the involved portion of the brain may be indicated, even hemispherectomy.

5. Von Hippel-Lindau Disease (Retrocerebellar Angiomatosis)

Von Hippel-Lindau disease is a rare, dominantly inherited condition with retinal and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and sometimes renal cancers. The patient may present with ataxia, slurred speech, and nystagmus due to a hemangioblastoma of the cerebellum or with a medullary spinal cord cystic hemangioblastoma. Retinal detachment may occur from hemorrhage or exudate in the retinal vascular malformation. Rarely a pancreatic cyst or renal tumor may be the presenting symptom.

The diagnostic criteria for the disease are a retinal or cerebellar hemangioblastoma with or without a positive family history, intra-abdominal cyst, or renal cancer.

CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS OF INFANCY & CHILDHOOD

The CNS degenerative disorders of infancy and childhood are characterized by arrest of psychomotor development and loss, usually progressive but at variable rates, of mental, motor, and visual functioning (Tables 25–20 and 25–21). Seizures are common especially in those with gray matter involvement. Symptoms and signs vary with age at onset and primary sites of involvement of specific types.

These disorders are fortunately rare. An early clinical pattern of decline often follows normal early development. Referral for sophisticated biochemical testing is usually necessary before a definitive diagnosis can be made. Patients with metachromatic leukodystrophy, Krabbe disease, and adrenoleukodystrophy are candidates for bone marrow transplantation. Treatment of some lysosomal storage diseases, such as Gaucher disease, with enzyme replacement therapy has shown promising results.

Table 25–20. Central nervous system degenerative disorders of infancy.

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings	Motor Findings	Seizures	Labs	Clinical Course
White matter									
Globoid (Krabbe) leukodystrophy	Recessive galactocerebroside β-galactosidase deficiency. Chromosome 14q21–14q31	Infantile form first 6 mo. Late-onset form 2–6 y. Adolescent and adult forms are rare	Feeding difficulties Shrill cry Irritability Arching of back	Optic atrophy Hyperacusis occasionally	Underweight Microcephaly	Spasticity Earlier hypotonia Decerebrate posturing	Myoclonic Generalized	Elevated CSF protein, prolonged sural nerve conduction, enzyme deficiency in leukocytes, cultured skin fibroblasts. Demyleination and gliosis on MRI and CT.	Rapid. Death usually by 1.5–2 y. Late-onset cases may live 5–10 y. Hematopoietic stem cell transplantation and enzyme replacement therapy is an experimental.
Metachromatic leukodystrophy	Recessive Arylsulfatase A (ASA) deficiency 22q13 Variant: Saposin B deficiency	Infantile form at 18–24 mo Juvenile and adult forms	Incoordination, gait disturbance, general regression.	Optic atrophy	Macrocephaly in infantile form	Upper and lower motor neuron signs Ataxia	Infrequent	CSF protein elevated. Urine sulfatide increased. Enzyme deficiency in leukocytes and fibroblasts. Imaging: diffuse white matter	Moderately slow. Infantile form death by 3–8 y. Juvenile form death by 10–15 y. Hematopoietic stem cell transplantation is an experimental treatment
Pantothenate kinase–associated neurodegeneration (Hallervorden-Spatz syndrome)	AR Most common chromosome 20 PANK2 gene	Age 10 y	Rigidity, dystonia, gait disturbance, tremor	Retinal degeneration.		Extrapyramidal signs, dysarthria, hyperreflexia	Variable	Axonal degeneration (spheroids). Iron deposits in basal ganglia on MRI: eye-of-the-tiger appearance	Progressive mental/motor deterioration

Table 25–20. Central nervous system degenerative disorders of infancy. (*Continued*)

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Somatic Findings	Motor Findings	Seizures	Labs	Clinical Course
Pelizaeus-Merzbacher disease	X-linked recessive; rare female. Proteolipid protein (myelin) decreased. Xq22.	Birth (perinatal) to 2 y.	Eye rolling often shortly after birth. Head bobbing. Slow loss of intellect.	Slowly developing optic atrophy. Hearing normal. Nystagmus.	Head and body normal.	Cerebellar signs Spasticity Hyperreflexia	Usually only late	None specific Point mutations or duplications of PLP gene account for 65%–90% of cases.	Very slow
Diffuse, but primarily gray matter									
Poliodystrophy (Alpers disease)	Recessive Metabolic forms	Infancy to adolescence	Variable: regression, seizures, incoordination, hepatic failure	Cortical blindness and deafness		Incoordination Spasticity	Myoclonic, akinetic, and generalized	*POLG1* and mitochondrial mutations Liver steatosis and cirrhosis Muscle and liver biopsy	Rapid with death within 1–3 y after onset Variants in older children, adults
Tay-Sachs disease and G$_{M2}$ gangliosidosis variants: Sandhoff disease; juvenile; chronic-adult	AR Hexosaminidase deficiencies caused by HEXA gene on chromosome 15q23–24.62,63. Sandhoff hexosaminidase A and B deficiency Juvenile partial hexosaminidase A.	Tay-Sachs and Sandhoff 3–6 mo Others 2 y or later.	Variable: shrill cry, vision loss, infantile spasms, developmental arrest. In juvenile and chronic forms: motor and mental difficulties	Cherry-red macula Blindness Hyperacusis Juvenile form: Strabismus and late blindness		Early hypotonia. Late decerebrate rigidity. Juvenile and chronic forms: dysarthria, ataxia, spasticity	Infantile spasms and generalized.	Blood smear: vacuolated lymphocytes; basophilic hypergranulation. Enzyme deficiencies in leukocytes and fibroblasts. Imaging: abnormal thalami and white matter	Moderately rapid. Death usually by 2–5 y. In juvenile form, 5–15 y.
Niemann-Pick disease and variants	AR Sphingomyelinase deficiency in types A and C	First 6 mo In variants onset later often non-Jewish.	Slow development Protruding belly	Cherry-red macula in 35%–50%. Blindness Deafness		Early hypotonia Late spasticity Extrapyramidal signs Ataxia	Rare and late	Vacuolated lymphocytes X-rays: "mottled" lungs, decalcified bones Leukocyte and fibroblast enzyme deficiency	Moderately slow Death usually by 3–5 y

Infantile Gaucher disease (glucosylceramide lipidosis)	AR	First 6 mo	Stridor or hoarse cry Feeding difficulties.	Cherry red macula. Convergent squint. Deafness		Early opisthotonos followed by decerebrate rigidity	Rare and late	Anemia X-rays: thinned cortex, trabeculation of bones. "Gaucher cells" in bone marrow. Leukocytes or fibroblasts enzyme deficiency	Rapid Experimental enzyme replacement therapy
Generalized gangliosidosis and juvenile type (G$_{M1}$ gangliosidoses)	AR β-galactosidase	Infantile: first 6 mo Late infantile: 7 mo to 3 y Juvenile onset	Developmental arrest Protruding belly Coarse facies Juvenile form: ataxia and dysarthria	50% "cherry-red spot." Corneal clouding Juvenile: retinitis pigmentosa	Macrocephaly Hepatosplenomegaly Gingival hypertrophy Cardiomyopathy	Early hypotonia Later spasticity	Late	Vacuolated lymphocytes. X-rays: dorsolumbar kyphosis, "breaking" of vertebrae.	Rapid within a few years Slower in juvenile type
Subacute necrotizing encephalomyelopathy (Leigh disease)	Variable: pyruvate carboxylase, pyruvate dehydrogenase, cytochrome enzymes, mitochondrial DNA.	Infancy to late childhood	Feeding difficulties Feeble or absent cry Hypotonia Apnea Developmental regression Ataxia	Optic atrophy Roving eye movements Ophthalmoplegia	Head usually normal. Cardiac and renal tubular dysfunction	Flaccid hypotonia Later spasticity Ataxia Myelopathy	Rare Tonic	Increased CSF and blood lactate and pyruvate. High-signal MRI T$_2$ foci in thalami and basal ganglia. DNA and enzyme tests on muscle	Usually rapid Central hypoventilation a frequent cause of death
Menkes disease (kinky hair disease)	X-linked Defect in copper absorption	Infancy	Peculiar facies White, twisted and split hair Hypothermia	Optic disk pallor and micro-cysts of pigment epithelium	Growth retardation	Variable: floppy to spastic	Myoclonic infantile spasms Status epilepticus	Cerebral angiography shows elongated arteries. Copper and ceruloplasmin low	Moderately rapid Death usually by 3–4 y
Carbohydrate-deficient glycoprotein syndrome	AR Glycoprotein abnormality	Infancy	Failure to thrive, retardation, protein-losing enteropathy	Strabismus Retinopathy	Dysmorphic facies Prominent fat pads Inverted nipples	Variable hypotonia Neuropathy	Rare	Normal transferrin decreased Carbohydrate-deficient transferrin increased Liver steatosis Cerebellar hypoplasia	Cardiomyopathy Thrombosis Hepatic fibrosis
Abetalipoproteinemia (Bassen-Kornzweig disease)	AR Microsomal triglyceride transfer protein (MTP) on chr 4q22–24	Early childhood	Diarrhea in infancy	Retinitis pigmentosa Ophthalmoplegia	None	Ataxia Movement disorder	None	Abetalipoproteinemia: acanthocytosis, low serum vitamin E Cerebellar atrophy	Progression arrested with vitamin E

AR, autosomal recessive; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; ERG, electroretinogram; MRI, magnetic resonance imaging; WBC, white blood cell.

Table 25–21. Central nervous system degenerative disorders of childhood.[a]

Disease	Enzyme Defect and Genetics	Onset	Early Manifestations	Vision and Hearing	Motor System	Seizures	Laboratory and Tissue Studies	Course
Adrenoleukodystrophy and variants (peroxisomal disease)	X-linked Xq28 Neonatal form: AR Acyl-CoA synthetase	5–10 y May also present as newborn, adolescent, or adult	Impaired intellect Behavioral problems	Cortical blindness Deafness	Ataxia Spasticity Motor deficits Adults: Adrenomyeloneuropathy	Occasionally	Hyperpigmentation and adrenocortical insufficiency ACTH elevated Very-long-chain fatty acids in plasma	Variable course, many mildly involved. Severe variant with death in 2–5 y.
Neuronal ceroid lipofuscinosis (NCL; cerebromacular degeneration); infantile NCL (INCL); late infantile (LINCL); juvenile NCL (JNCL; Batten disease)	AR Multiple gene mutations	INCL: 6–24 mo LINCL: 2–4 y JNCL: 4–8 y	Ataxia Visual difficulties Arrested intellectual development Seizures	Pigmentary degeneration of macula Optic atrophy	Ataxia Spasticity progressing to decerebrate rigidity	Myoclonus Generalized Refractory	Vacuolated lymphocytes. Biopsy, EM of skin, conjunctiva; WBC: "curvilinear bodies, fingerprint profiles." Molecular testing of *CLN1, CLN2, CLN3* genes. Protein gene product testing for CLN1 and CLN2.	Moderately slow Death in 3–8 y
Subacute sclerosing panencephalitis (Dawson disease)	None: measles infection. Also reported as result of rubella.	3–22 y	Impaired intellect Emotional lability Incoordination	Chorioretinitis Optic atrophy	Ataxia Dysarthria Involuntary movements Spasticity progressing to decerebrate rigidity	Myoclonic Akinetic Focal and generalized	CSF protein normal to moderately elevated. High CSF IgG,[b] oligoclonal bands. Elevated CSF and serum measles antibody titers. Characteristic EEG.	Variable: death in months to years Remissions occasional Treatment: INF-α
Megalencephalic leukodystrophy with subcortical cysts (MLC)	*MLC1* gene defect chr 22q	Infancy	Acquired macrocephaly		Ataxia Spasticity Dystonia	Varied	Characteristic MRI dysmyelination	Slowly progressive to adulthood; wheelchair bound by teens
Vanishing white matter/childhood ataxia with CNS hypomyelination	AR Chr 3q27	Infancy-fatal Variants: slower	Episodic deterioration with fever, head trauma, and fear.		Ataxia Spasticity	Varied	MRI: dramatic disappearance of white matter.	Infantile: fatal Variants are slowly progressive Adult variant (autosomal dominant) with ovarian dysgenesis

Alexander disease	AD *GFAP* gene	Infancy	Macrocephaly		Ataxia Spasticity		Demyelination; rosenthal fibers characteristic of biopsy.	Fatal infantile. Juvenile: bulbar signs, less retardation
Cerebrotendinous xanthomatosis	AR Abnormal accumulation of cholesterol	Late childhood to adolescence	Xanthomas Mental deterioration	Cataracts Xanthelasma	Cerebellar defects Bulbar paralysis	Myoclonus	Xanthomas in lungs and tendons	Slowly progressive into middle life. Replace deficient bile acid
Huntington disease	AD CAG repeat	10% childhood onset	Hypokinetic Dystonia Rigidity Dementia	Ophthalmoplegia	Rigidity Chorea frequently absent in children	50% motor seizures	CT scan: "butterfly" atrophy of caudate and putamen	Moderately rapid with death
Refsum disease (peroxisomal disease)	AR Phytanic acid oxidase deficiency	5–10 y	Ataxia Ichthyosis Cardiomyopathy	Retinitis pigmentosa Nystagmus	Ataxia Neuropathy Areflexia	None	Phytanic acid elevated Slow nerve conduction velocity Elevated CSF protein	Treat with low phytanic acid diet

ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; CHR, chromosome; CLN, ceroid lipofuscinosis; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EM, electron microscopy; ERG, electroretinogram; IFN-α, interferon-α; MRI, magnetic resonance imaging; VER, visual evoked response; WBC, white blood cell.

[a]For late infantile metachromatic leukodystrophy, Pelizaeus-Merzbacher disease, poliodystrophy, Gaucher disease of later onset, and subacute necrotizing encephalomyelopathy, see Table 25–22.

[b]CSF γ-globulin (IgG) is considered elevated in children when IgG is > 9% of total protein (possibly even > 8.3%); definitively elevated when > 14%.

ATAXIAS OF CHILDHOOD

ESSENTIALS FOR DIAGNOSIS

► Ataxia is most commonly due to cerebellar dysfunction but abnormalities at almost any level of the nervous system can result in motor incoordination.

► It is essential to distinguish between acquired and congenital ataxia as the evaluation, management and outcome is determined by etiology.

► A detailed history and evaluation of truncal vs limb ataxia, mental status, and eye movements can provide the most useful diagnostic points in the formulation of the differential diagnosis.

▶ Pathogenesis

In general, there are two major categories one should consider in the evaluation of ataxia. Acute acquired ataxia is a common reason for emergent neurological consultation. The best approach in the evaluation of these children is obtaining a detailed history of the antecedent events and current symptoms, as well as a detailed examination of associated neurological symptoms. Typically these patients develop symptoms within 72 hours prior to their presentation to medical care, and they have been previously healthy without developmental delay or neurological abnormalities.

In contrast, congenital ataxias may be associated with central nervous system abnormalities, genetic abnormalities, or metabolic disorders. In this section, a brief overview of will be provided of the most common causes of acute and congenital ataxia, and the evaluation and the management of each.

ACUTE ATAXIAS OF CHILDHOOD

ESSENTIALS FOR DIAGNOSIS

► Symptoms may include refusal to walk due to ataxia, in addition to sudden development of a wide-based, drunken gait.

► Families may not report unsteadiness of arm movements, ataxia of the trunk, or dysarthria, but these symptoms are essential to localization.

► Serious causes include CNS infections and intracranial mass lesions.

▶ Pathogenesis

Causes of acute ataxia that require emergent evaluation include increased intracranial pressure due to mass lesions. Therefore, any history suggestive of this should be elicited, such as persistent or recurrent headaches, or vision changes such as blurred or double vision. A history of head of neck trauma should prompt evaluation for vertebral artery dissection. Other common causes include accidental or purposeful ingestion. The evaluation of an acutely ataxic patient can be difficult as the patient may refuse to participate in the examination due to the discomfort of being ataxic, causing them to be irritable or hesitant. Therefore, distinguishing between weakness and ataxia can be difficult, but it is essential to making the correct diagnosis.

▶ Clinical Findings

A thorough examination should be performed, with attention to signs suggesting a serious central nervous system disorder, such as mass lesions or central nervous system infections. Changes in mental status are particularly important to observe, as this suggests an ingestion, stroke, acute disseminated encephalomyelitis, or opsoclonus-myoclonus syndrome. The presence of papilledema and cranial nerve palsies suggests an intracranial focal lesion or hydrocephalus. Asymmetry in the examination would be unusual for acute cerebellar ataxia.

Once signs of serious CNS disorders have been sought, localization of the cerebellar lesion should be made. A midline cerebellar lesion may present with dysarthria or truncal titubation. In contrast, a lesion of the cerebellar hemispheres

may present with sparse speech, dysmetria, tremor, or hypotonia. A patient with a hemispheric cerebellar lesion will tend to veer to the side of the lesion. A resting tremor, myoclonus, or opsoclonus will suggest a lesion affecting the deep cerebellar nuclei. Patient with cerebellar ataxia will not worsen with closed eyes, as a patient with sensory ataxia would.

A. Acute Cerebellar Ataxia

ESSENTIALS FOR DIAGNOSIS

▶ Symptoms may include refusal to walk due to ataxia, in addition to sudden development of a wide-based, drunken gait.

▶ Families may not report unsteadiness of arm movements, ataxia of the trunk, or dysarthria, but these symptoms are essential to localization.

▶ Serious causes include CNS infections and intracranial mass lesions.

This is the most common cause of acute childhood ataxia, accounting for about 40% of all cases. It occurs most commonly in children aged 2–6 years. The onset is abrupt, and the evolution of symptoms is rapid. In about 70% of patients, a prodromal illness occurs with fever, respiratory or gastrointestinal symptoms, or an exanthem within 3 weeks of onset. Associated viral infections include varicella, rubeola, mumps, echovirus infections, poliomyelitis, infectious mononucleosis, and influenza. Bacterial infections such as scarlet fever and salmonellosis have also been incriminated. Typically, the symptoms evolve rapidly, but the severity can vary between patients. Some patients have such severe ataxia that they cannot walk, and others have only mild unsteadiness. Usually the limbs are not as affected as the trunk. Mental status is normal in these patients, as is sensory and reflex testing.

1. Laboratory testing—CSF opening pressure, protein, and glucose levels are typically normal, though a mild pleocytosis with lymphocytic predominance can be seen. Any significant elevation in WBC and protein level should prompt an evaluation for meningitis or encephalitis. Autoantibodies against Purkinje cells and other cerebral and cerebellar tissue have been described, but typically are not clinically useful to obtain.

2. Imaging findings—CT scans are typically normal, as are MR images of the brain. Occasionally focal cerebellar or cerebellopontine demyelinating lesions or enhancement of the meninges can be seen. Decreased regional blood flow in the cerebellum on SPECT without abnormal foci on MRI of the brain has also been reported.

3. Treatment—Treatment for acute cerebellar ataxia is supportive. IVIg has been used. Steroid use does not result in any improvement. About 80%–90% of patients recover without sequelae within 6–8 weeks, though some may demonstrate residual behavioral changes, learning problems, eye movement abnormalities, and speech problems.

B. Toxic Cerebellar Syndrome

Ataxia due to toxins or medications accounts for as many as 32.5% of acute cases. Substances such as anticonvulsants, benzodiazepines, alcohol, and antihistamines, and less commonly organic chemicals and heavy metals can cause ataxia. In these cases, ataxia is usually accompanied by mental status changes, including lethargy, confusion, inappropriate speech and behavior, and in some cases, nystagmus or pupillary changes.

1. Laboratory testing—Urine toxicology screen may not detect specific medications, and therefore a detailed history is always helpful in guiding testing for specific medications. For phenytoin, the toxic level in serum is usually above 25 mcg/mL; for phenobarbital, above 50 mcg/mL; and for primidone, above 14 mcg/mL.

2. Imaging findings—Imaging is usually normal for patients with toxic cerebellar syndrome.

3. Treatment—Treatment is guided by the ingested agent, and requires toxicological consolation.

C. Acute Demyelinating Encephalomyelitis

Ataxia is a common feature of acute demyelinating encephalomyelitis (ADEM), and like acute cerebellar ataxia, can occur after a viral infection or vaccination. However, this entity may be distinguished from acute cerebellar ataxia by the accompanying change in mental status or other associated difficulties such as seizures, cranial nerve palsies, or hemiparesis. These clinical events arise from presumed immune-mediated demyelination of the central nervous system. Refer to later section (Noninfectious Inflammatory Disorders of the Central Nervous System) on ADEM in this chapter.

D. Posterior Circulation Stroke

Though rare, this should be considered as an etiology for ataxia if a history of neck trauma or family history of vascular abnormalities is present. Workup and management are discussed in the stroke section (Cerebrovascular Disorders) of this chapter.

E. Paraneoplastic Syndromes

Acute ataxia can occasionally be seen in the entity known as opsoclonus-myoclonus syndrome (OMS). In its classic form, patients will present with ataxia; rapid chaotic conjugate, multidirectional eye movements (opsoclonus); and nonepileptic jerking of the head, extremities, and face (myoclonus).

Some patients may additionally have sleep disturbance, cognitive dysfunction, and behavioral disruption. It is a rare disorder, with an incidence estimated to be 0.18 cases per million children per year in a prospective survey of United Kingdom pediatric neurology centers. Atypical presentations can result in initial erroneous diagnoses, such as of acute cerebellar ataxia, Guillain-Barre syndrome, and epileptic seizures. However, making the diagnosis has significant implications for treatment and prognosis. Forty-eight percent of patients with OMS have a neuroblastoma detected. Traditional methods to detect neuroblastoma with urine catecholamines or metaiodobenzylguanidine scans may be insensitive in patients with opsoclonus-myoclonus syndrome. Therefore, CT or MRI of the entire torso should be obtained in all patients with (OMS). Sometimes repeat testing is necessary to attain the diagnosis. In patients without a neuroblastoma, few will have an identifiable cause, though parainfectious or postinfectious processes have been implicated in some cases.

1. Laboratory testing—Readily available biomarkers would greatly facilitate the diagnosis of OMS. However, only in rare patients have autoantibodies against intracellular antigens been found, such as with anti-Hu or anti-*N*-methyl-D-aspartate receptor antibodies. None of these antibodies appear to be sensitive for the majority of patients. Relative CSF B-cell expansion has been proposed as a candidate biomarker for OMS, but more data need to be gathered regarding the sensitivity of this biomarker and its relationship to clinical severity. Laboratory evaluation for neuroblastoma or other malignancies should be pursued, with urine catecholamines.

2. Imaging—All patients with OMS should undergo CT or MRI of the entire torso to evaluate for occult malignancies.

3. Treatment—Gold standard treatment for OMS includes corticosteroids and adrenocorticotropic hormone, but no standard formulation or dosing is available, and the short-term benefits do not appear to predict a favorable long-term outcome. Additionally, relapses with dose tapering are common. Therefore, with the poor long-term outcome and the side effects of steroid use, new approaches have been used for treatment, including use of cyclophosphamide, chemotherapy to treat an identified neuroblastoma-associated OMS, and IVIG with ACTH and rituximab.

The long-term outcome for these patients is generally poor for patients both with and without neuroblastoma. From pooled data, 75%–80.6% of patients with OMS had abnormal neurological findings at follow-up, including eye movement abnormalities, dysarthria, ataxia, and myoclonus. In addition, all patients had cognitive impairment, including language, attention, memory, and intellectual disability.

F. Sensory Ataxia

Ataxia can result from loss of sensory input to the cerebellum due to posterior column of the spinal cord, nerve root, or peripheral nerve lesions. Etiologies may include Guillain-Barre syndrome (acute inflammatory demyelinating polyneuropathy) or its variant, Miller-Fisher syndrome; or toxins. These patients, in addition to ataxia, will demonstrate decreased reflexes, a Romberg sign, loss of proprioception and vibratory sensation, and a high steppage gait.

1. Laboratory testing—Testing for suspected Guillain-Barre syndrome should include a lumbar puncture. The CSF findings may show elevated protein with normal cells, known as albuminocytologic dissociation, but very early in the course can be normal in as many as 20% of children. Antibodies against GQ1b should be obtained if Miller-Fisher syndrome is suspected. Electrophysiologic testing with nerve conduction studies may also be helpful, though acutely there may be little in the way of abnormalities.

2. Imaging—MR imaging of the spine may show enhancement of the nerve roots in Guillain-Barre syndrome.

3. Special testing—Electromyography/nerve conduction study may be useful to identify a demyelinating polyneuropathy. Nerve conduction velocities will be slowed into the demyelinating range (motor conduction velocities in the upper extremities $\leq$ 38 m/s) in a patchy, nonuniform fashion. The sural sensory response is typically spared early in the disease. Conduction block and temporal dispersion are hallmarks of this acquired polyneuropathy.

4. Treatment—Both IVIg and plasmapheresis have been used in treatment of GBS. IVIg is typically used in a regimen of 0.4 g/kg daily for 5 days. The typical regimen for PE is a total exchange of about 5 plasma volumes over a 2 week time period. A Cochrane review of the use of IVIg and PE showed no significant difference between the two treatments with respect to disability after 4 weeks, duration of mechanical ventilation, mortality, or residual disability. Steroid treatment has not been showed to be beneficial in GBS.

G. Basilar Migraine

A basilar migraine may present with ataxia. Typically, other accompanying neurological signs are present, such as vertigo, nausea, vomiting, cranial nerve dysfunction, and headache. The patient's first episode may be concerning for a focal lesion and may prompt workup for a stroke. However, the description of positive visual phenomenon, such as flashing lights, suggests the migrainous nature of the episodes. Subsequent episodes, in the context of the history, are much easier to identify as basilar migraines.

H. Mass Lesions

Posterior fossa tumors arise from the cerebellum or the brainstem and typically present with slowly progressive ataxia and symptoms of increased intracranial pressure. About 45%–60% of all childhood brain tumors are posterior fossa tumors.

Therefore, any patient with a history of nocturnal headaches, chronic headaches, nocturnal emesis, focal neurological deficits, visual changes, or other signs concerning for mass lesion should have neuro-imaging performed immediately.

I. Functional Ataxia

In functional ataxia, the patient appears to lurch and stagger when walking, the gait is not wide-based, and falls are rare. The findings on the neurological examination do not indicate neuroanatomic localization, and therefore suggest a functional ataxia.

CONGENITAL CAUSES OF CHRONIC & EPISODIC ATAXIAS

ESSENTIALS OF DIAGNOSIS

▶ Establishing an inheritance pattern and temporal course is useful in determining the diagnosis.

▶ The findings of spasticity, ophthalmologic abnormalities, eye movement abnormalities, peripheral nervous system involvement, and seizures can be helpful in the evaluation of these patients.

▶ Pathogenesis

In considering congenital causes of ataxia, it is probably easiest for the general pediatrician to classify them by the disease progression, either progressive or intermittent/episodic. For instance, Friedreich's ataxia and ataxia-telangiectasia are both progressive ataxias, with worsening of the ataxia over years. In contrast, in metabolic disorders such as maple syrup urine disease and channelopathies such as episodic ataxia type 1, ataxia occurs episodically and occasionally in response to a trigger. Further defining the ataxias by inheritance pattern is also useful in determining an etiology.

▶ Clinical Findings

Similar to the evaluation of a patient with acute onset of ataxia, the examination of a patient with congenital causes of ataxia should include localization of signs to the cerebellum, either the hemispheres or the vermis. Therefore, the presence of ataxia in the trunk and limbs should be noted, of nystagmus, of the quality of eye movements, and of reflexes. Many of the patients may have multisystemic involvement, which may provide diagnostic clues to the etiology.

INTERMITTENT/EPISODIC ATAXIAS

1. Inborn Errors of Metabolism

Inborn errors of metabolism should be considered when ataxia is either intermittent or progressive. Acute exacerbation or worsening after high protein ingestion, a long period of fasting, febrile illness, or other physical stress is suggestive

of a metabolic disorder. Disorders in this category are broad and beyond the scope of this text, but may include amino-acidopathies such as maple syrup urine disease, urea cycle defects such as ornithine transcarbamylase deficiency, lactic acidosis such as in Leigh disease, leukodystrophies, lysosomal disorders such as metachromatic leukodystrophy, peroxisomal disorders, and disorders of glycosylation. Because some of these etiologies, such as maple syrup urine disease, can be treatable, diagnostic studies to consider include MRI of the brain, thyroid studies, vitamins E and B12, serum ammonia, ceruloplasmin, serum amino acids, urine organic acids, serum lactate and pyruvate, serum biotinidase, EMG/NCS, serum cholesterol, very long chain fatty acids, phytanic acid, transferring isoelectric focusing, and lysosomal enzyme profile on leukocytes.

2. Channelopathies

Channelopathies are a broad category of neurological disorders, and result from altered function of a voltage-gated ion channel which subsequently alters membrane excitability in neurons. This group includes the episodic ataxias and familial hemiplegic migraines. There are six recognized genetic forms of episodic ataxia (EA) at this time. They are generally inherited in an autosomal dominant fashion, with episodes of ataxia lasting from seconds to minutes. In some patients, the episodes of ataxia are precipitated by stress, exercise, startle, or fatigue. EA2 is the most common episodic ataxia. It is allelic with familial hemiplegic migraine and spinocerebellar ataxia 6, both of which can also result in ataxia. Typically the attacks in EA2 are more prolonged, lasting from hours to days.

PROGRESSIVE ATAXIAS

1. Autosomal Dominant Hereditary Ataxias

At this time, there are 29 described dominantly inherited spinocerebellar ataxias. The initial manifestation in infants can be hypotonia and delayed motor development, while in children the symptoms may include nystagmus, truncal and gait ataxia, spasticity, extensor plantar responses, and cognitive delay. Neurological symptoms are progressive, with wheelchair-dependence late in the disorder. In addition, in contrast to the autosomal recessive hereditary ataxias, they may exhibit diverse neurological symptoms, such as retinopathy, optic atrophy, extrapyramidal or pyramidal signs, peripheral neuropathy, cognitive impairment, or epilepsy. The neuroimaging findings can be relatively nonspecific for the various subtypes. However, three general patterns of atrophy on imaging have been described on brain MRI: pure cerebellar atrophy, olivopontocerebellar atrophy, and global brain atrophy. Because many of the spinocerebellar ataxias have overlapping clinical and radiographic phenotypes and there is significant intrafamilial and interfamilial variability

in the clinical presentation, confirmation by genetic testing of the subtype of spinocerebellar ataxia needs to be performed. Treatment in these patients is typically symptomatic, with use of acetazolamide for ataxia, and the use of baclofen for spasticity.

2. Autosomal Recessive Hereditary Ataxias

Most autosomal recessive ataxias are early onset, before 20 years of age. These patients, like those with autosomal dominant forms, also develop spinocerebellar ataxia, with poor balance with falls, difficulty with hand coordination, dysarthria, vertigo, and diplopia. In addition, they are generally associated with peripheral neuropathy, with loss of proprioception and vibratory sense. Areflexia is more commonly seen in autosomal recessive ataxias. Unlike the autosomal dominant inherited disorders, they typically do not exhibit other neurological symptoms, such as seizures, but they do tend to involve systems outside of the nervous system. The two most commonly encountered autosomal recessive hereditary ataxias that may be seen by the general pediatrician are Friedreich ataxia and ataxia-telangiectasia and will be discussed below.

A. Friedreich Ataxia

Friedreich ataxia is the most common of the autosomal recessive ataxias, with a prevalence of about 1 in 30,000–50,000, and a carrier rate of 1 in 85. Typically, patients present at the ages of 5–25 years, with progressive gait and limb ataxia, dysarthria, loss of proprioception and vibration, areflexia, abnormal eye movements, and pyramidal weakness of the feet with upgoing toes. In addition, patients develop systemic symptoms, and may have associated pes cavus, cardiomyopathy, diabetes, and scoliosis.

1. Laboratory testing—The diagnosis is made by performing genetic testing. Ninety eight percent of patients have a triplet GAA expansion in the frataxin gene on chromosome 9q13. In general, a greater number of repeats predicts an earlier onset of disease, more severe systemic manifestations, and more severe ataxia.

2. Imaging—Neuroimaging does not show progressive cerebellar degeneration, unlike the other inherited ataxias. Mild atrophy of the cervical spinal cord may be seen.

3. Treatment—Because of the multisystem involvement in Friedreich ataxia, yearly screening needs to be performed with an x-ray to track the scoliosis; serum glucose and hemoglobin A1C to monitor for the onset of diabetes, and echocardiogram to monitor for hypertrophic cardiomyopathy. Current evidence suggests that frataxin has a role in mitochondrial iron handling and respiratory chain function. Therefore, treatment trials have targeted antioxidant protection. Trials have demonstrated that coenzyme Q10 and

vitamin E can result in improvement in cardiac symptoms, and low dose idebenone can reduce cardiac hypertrophy. However, none of these have resulted in improvement in neurological symptoms, and therefore treatment of the progressive neurological symptoms remains symptomatic.

B. Ataxia-Telangiectasia

Ataxia-telangiectasia is a multisystem disorder arising from a defect in DNA repair. Patients with classic ataxia-telangiectasia present with slurred speech, truncal ataxia, and oculomotor apraxia between the ages of 1 and 4 years. Choreoathetosis is found in nearly all patients with ataxia-telangiectasia. Deep tendon reflexes are decreased or absent in older patients. Plantar reflexes are upgoing or absent. Nonneurologic manifestations include oculocutaneous telangiectasias, recurrent sinopulmonary infections, and hypersensitivity to ionizing radiation with increased susceptibility to cancers, usually leukemia or lymphoma. Premature aging with strands of gray hair and insulin-resistant diabetes mellitus may also be features. After Friedreich ataxia, this is the most common autosomal recessive ataxia, with an estimated prevalence of 1:40,000 to 1:100,000 live births. Greater than 99% of individuals with classic ataxia-telangiectasias have mutations in the ATM gene.

1. Laboratory testing—The serum alpha-fetoprotein level which is typically elevated in these patients to 10 ng/mL or higher, and can remain normal in unaffected children until age 24 months. Immunodeficiencies of IgA and IgE are common. To establish a diagnosis, an immunoblotting assay of the ATM protein level should be performed. Patients with absent or trace amounts of the ATM protein have a definitive diagnosis of ataxia-telangiectasia. Molecular genetic testing of the ATM gene can identify the disease-causing mutations.

2. Imaging—Though a small cerebellum can be seen in older patients on neuroimaging, it is typically not seen in children.

3. Treatment—To establish the extent of systemic involvement in ataxia-telangiectasia, screening should be performed at diagnosis. This should include screening for infectious and oncologic involvement with chest x-ray, pulmonary function testing, CBC with differential, immunoglobulin levels, B/T levels, and T-cell function. In addition, screening for diabetes should be performed with a urinalysis, fasting blood glucose, and hemoglobin A1C. Neurological evaluation should be performed regularly to monitor for disease progression, including ocular coordination, and MRI of the cerebellum. Patients should report any easy bruising, weight loss, or localized swelling to their physician as this may be an early manifestation of malignancy.

Treatment is symptomatic in these patients, though several compounds are under investigation in clinical trials.

IVIg replacement should be considered in patients with frequent and severe infections and very low IgG levels, as well as aggressive pulmonary toilet. The neurological manifestations are treated symptomatically, to minimize drooling and ataxia. Most patients will require a wheelchair by 10 years of age. Contractures and scoliosis can limit function, and physical therapy instituted early and continuously can minimize the development of both. Though steroids may decrease the neurological symptoms, discontinuation of steroids results in return of the neurological symptoms. Mutation-targeted therapy such as with antisense oligonucleotides appears promising.

3. X-Linked Cerebellar Ataxias

Fragile X tremor ataxia syndrome has not been documented to occur before 50 years of age, but will be included here as a rare cause of an X-linked inherited ataxia. Patients typically exhibit tremor or ataxia, in inverse relationship to the number of CGG triplet repeat expansions they harbor. In addition, they may also present with varying combinations of parkinsonism, autonomic dysfunction, polyneuropathy, and cognitive deficits.

EXTRAPYRAMIDAL DISORDERS

Extrapyramidal disorders are characterized by the presence in the waking state of one or more of the following features: dyskinesias, athetosis, ballismus, tremors, rigidity, and dystonias. For the most part, the precise pathologic and anatomic localization of these disorders is not understood. Motor pathways synapsing in the striatum (putamen and caudate nucleus), globus pallidus, red nucleus, substantia nigra, and the body of Luys are involved and this system is

modulated by pathways originating in the thalamus, cerebellum, and reticular formation.

1. Sydenham Post-Rheumatic Chorea

Sydenham chorea is characterized by an acute onset of choreiform movements, variable degrees of psychological disturbance, rheumatic endocarditis, and arthritis. Although the disorder follows infections with group A β-hemolytic streptococci, the interval between infection and chorea may be greatly prolonged; throat cultures may therefore be negative.

▶ Clinical Findings

A. Symptoms and Signs

Chorea is characterized by rapid involuntary discordinated movements of the limbs and face. Other symptoms and signs include emotional lability, waxing and waning ("milkmaid's") grip, darting tongue, "spooning" of the extended hands and their tendency to pronate, and knee jerks slow to return to their prestimulus position ("hung up" knee jerk). Hemichorea occurs in 20% of patients with Sydenham chorea.

B. Laboratory Findings and Special Tests

Anemia, leukocytosis, and an increased erythrocyte sedimentation rate and C-reactive protein may be present. The antistreptolysin O or anti-DNase titer (or both) are usually elevated, and C-reactive protein is present. Throat culture is sometimes positive for group A β-hemolytic streptococci.

ECG and echocardiography are often essential to detect cardiac involvement. If antineuronal antibodies (ANA) are present, chorea may be secondary to lupus. Similarly, antiphospholipid antibody (APA) may be elevated in autoimmune related chorea. Specialized radiologic procedures (MRI and SPECT) may show basal ganglia abnormalities.

▶ Differential Diagnosis

The diagnosis of Sydenham chorea is usually not difficult. Tics, drug-induced extrapyramidal syndromes, Huntington chorea, and hepatolenticular degeneration (Wilson disease), as well as other rare movement disorders, can usually be ruled out on historical and clinical grounds. Immunologic linkages among chorea, tics, and obsessive-compulsive disorder are being studied in pediatric patients. Thus, other causes of chorea in childhood include dyskinetic, "extrapyramidal" cerebral palsy, benign hereditary chorea, kernicterus, Lupus, postpump cardiac surgery, and, for unilateral chorea, stroke, and tumor. These other causes of chorea can often be ruled out by laboratory tests, such as antinuclear antibody for lupus, thyroid screening tests, serum calcium for hypocalcemia, and immunologic and virologic tests for (rare) HIV, parvovirus B19, and Epstein-Barr virus infection.

Relapse of herpes encephalitis rarely manifests as choreoathetosis. Anti-N-methyl-D-aspartate receptor (anti-NMDAR) encephalitis may cause chorea or other dyskinesias; detection of NMDAR antibodies is diagnostic. MRI and MRA can help to diagnose or exclude tumor or stroke causing hemichorea.

▶ Treatment

There is no specific treatment. Prednisone (high-dose IV or orally 0.5–2 mg/kg/d in divided doses) and in severe cases IVIG has been successful. Anticonvulsant sodium valproate (50–60 mg/kg/d in divided doses) and levetiracetam (20–60 mg/kg/d divided into twice a day dosing) is effective in reducing chorea symptoms. Dopaminergic blockers such as haloperidol (0.5 mg/d to 3–6 mg/d) and pimozide (2–10 mg/d) are rarely used because of other effective medications and possible parkinsonian side effects such as rigidity and masked facies, and tardive dyskinesia. Emotional lability and depression sometimes warrant administration of antidepressants. All patients should be given antistreptococcal rheumatic fever prophylaxis with either monthly benzylpenicillin injections or oral penicillin VK 250 mg twice a day.

▶ Prognosis

Sydenham chorea is a self-limited disease that may last from a few weeks to months. Relapse of chorea may occur with nonspecific stress or illness—or with breakthrough streptococcal infections (if penicillin prophylaxis is not done). One-third of patients relapse one or more times, but the ultimate outcome does not appear to be worse in those with recurrences. In adult longitudinal follow up studies, eventual valvular heart disease occurred in about one-third of patients, particularly if other rheumatic manifestations had been present as part of the childhood illness. Psychoneurotic disturbances were also present in a significant percentage of patients.

2. Tics (Habit Spasms)
▶ Clinical Findings
A. Symptoms and Signs

Tics, or habit spasms, are quick repetitive but irregular movements, often stereotyped, and briefly suppressible. Coordination and muscle tone are not affected. A premonitory urge ("I had to do it") is unique to tics. Transient tics of childhood (12%–24% incidence in school-aged children) last from 1 month to 1 year and seldom need treatment. Facial tics such as grimaces, twitches, and blinking predominate, but the trunk and extremities are often involved and twisting or flinging movements may be present. Vocal tics are less common; 90% of tics are "above the neck."

Tourette syndrome is characterized by multiple fluctuating motor and vocal tics with no obvious cause lasting more

than 1 year. Tics evolve slowly, new ones being added to or replacing old ones. Coprolalia and echolalia are relatively infrequent. Complex motor tics are coordinated sequenced movements mimicking normal motor acts or gestures for example ear scratching, head shaking, twisting, and "giving the finger." Self-injurious behavior is not uncommon in Tourette syndrome.

The usual age for all tic disorders at onset is 4–8 years (median age 6), and the familial incidence is 35%–50%. The disorder occurs in all ethnic groups. Tics may be triggered by stimulants such as methylphenidate and dextroamphetamine. An imbalance of or hypersensitivity to neurotransmitters, especially dopaminergic and adrenergic, has been hypothesized. No single chromosome/gene defect is causative; many "hot spots" have been identified. Either parent can transmit the disease.

In mild cases, tics are self-limited and wane with time. Most pediatric tic patients have transient tics of childhood (tics last less than 1 year), or chronic motor tics (> 1 year). When attention is paid to one tic, it may disappear only to be replaced by another that is often worse. If the tic and its underlying anxiety or compulsive neuroses are severe, psychiatric evaluation and treatment are needed.

Important comorbidities are attention-deficit/hyperactivity disorder and obsessive-compulsive disorder. Learning disabilities, migraine (25%), sleep difficulties, anxiety states, and mood swings are also common. REM sleep is decreased, arousals common. Tics may persist into sleep. Medications such as methylphenidate, amphetamines, and atomoxetine should be carefully titrated to treat attention-deficit/hyperactivity disorder and avoid worsening tics. Fluoxetine, clomipramine, or other selective serotonin reuptake inhibitors (SSRIs) may be useful for obsessive-compulsive disorder and rage episodes in patients with tics.

▶ Treatment

The most effective medications for treating Tourette syndrome are dopamine blockers; these drugs, however, have a small risk of tardive dyskinesia, and are thus reserved for use in difficult to control tic patients. Many pediatric patients can manage without drug treatment or with less hazardous medications. Medications are generally reserved for patients with disabling symptoms; treatment may be relaxed or discontinued when the symptoms abate (Table 25–22). Medications usually do not eradicate the tics. The goal of treatment should be to reduce the tics to tolerable levels without inducing undesirable side effects. Medication dosage should be increased at weekly intervals until a satisfactory response is obtained. Often a single dose at bedtime is sufficient. Clonidine, guanfacine (probably the two most safe drugs), and dopamine modulators have been used in individual patients with some success.

The two neuroleptic agents used most often are pimozide and risperidone. Sleepiness and weight gain are the most

Table 25–22. Medications for Tourette syndrome and tics.

Dopamine blockers (many are antipsychotics)[a]

[c]Useful for attention-deficit/hyperactivity disorder.
[d]Dopamine-modulating.

common side effects; rare are prolonged QT interval (ECG), akathisia, and tardive dyskinesia. Sometimes these agents are used in combination (eg, clonidine with pimozide). Clonazepam has the virtue of safety, but sleepiness and slowing of thinking are drawbacks. Topiramate has shown benefit in one controlled animal trial; human experience is limited. Levetiracetam failed in a controlled trial, but showed benefit in open trials. Tetrabenazine is being utilized for Tourette's syndrome in some university centers. IVIG has been unsuccessful.

Nonpharmacologic treatment of Tourette syndrome includes education of patients, family members, and school personnel. In some cases, restructuring the school environment to prevent tension and teasing may be necessary. Supportive counseling, either at or outside school, should be provided. Habit reversal therapy ("HRT") is controversial, very labor intensive, variably successful. More recently, comprehensive Behavioral Intervention for Tics (CBIT) is a new intensive (8 weekly visits) therapeutic approach; published results are favorable.

Sydenham chorea is a well-documented pediatric autoimmune disorder associated with streptococcal infections (pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection; PANDAS). Patients with tic disorders occasionally have obsessive-compulsive disorder precipitated or exacerbated by streptococcal infections. Less definite (much less frequent) are tic flare-ups with streptococcal infection. Active prospective antibody (antineuronal and antistreptococcal) and clinical studies are in progress.

Research centers have used experimental treatments (IVIG, plasmapheresis, and corticosteroids) in severe cases. At present, most patients with a tic do not worsen with group A streptococcal infections; with rare exceptions, penicillin prophylaxis is not necessary.

3. Paroxysmal Dyskinesias/Chronic Dystonia

Paroxysmal dyskinesias are sudden-onset, short-duration choreoathetosis or dystonia episodes (a sustained muscle contraction of limb or torso, frequently twisting or with abnormal posture). Most often these episodes are familial or genetic in origin. Episodes may occur spontaneously or be set off by actions ("kinesigenic," or movement-induced) such as rising from a chair, reaching for a glass, or walking. Sometimes only hard sustained exercise will induce the dyskinesia (Table 25–23). Nocturnal dyskinesia/dystonic episodes are currently thought to be frontal lobe seizures.

The diagnosis is clinical. Onset is usually in childhood; average age, 12 years. The patient is alert and often disconcerted during an episode. Episodes may last seconds to 5–20 minutes and occur several times daily or monthly. Laboratory work is normal. EEG is normal between or during an attack; brain imaging is normal. Inheritance is usually autosomal dominant. Anticonvulsants (eg, carbamazepine) usually prevent further attacks. Patients often grow out of this disease in one or two decades (Table 25–23).

Chronic non-kinesigenic dyskinesia is often secondary to an identifiable brain lesion, less responsive to medications, and may or may not have genetic underpinnings.

Disorders of ion channels underlie many of the genetic cases; some cases are linked to epilepsy and hemiplegic migraine. Chromosome loci are known for the latter. Chronic dystonia in childhood is often "cerebral palsy" a "secondarily caused" movement disorder often from perinatal vicissitudes.

Other chronic dystonias may have an unidentifiable genetic cause: autosomal dominant. DYT-1 is the most common. The diagnosis of chronic persistent dystonia may be aided by spinal fluid neurotransmitter (DYT5) and readily available genetic chromosome studies. Any child with dystonia of unknown cause should have a trial of low-dose L-dopa; a prompt improvement suggests DYT5—a genetic cause with favorable outcome. Long-term oral L-dopa is very effective. Rarely, transient dyskinesia (eg, dystonia) may be precipitated by fever. While the cause of persistent dystonia is often genetic, underlying biochemical and structural causes (eg, Wilson disease, basal ganglia tumor or other pathology, hypoxic ischemic encephalopathy (HIE), glutaric aciduria, etc) must be ruled out. Treatment for chronic dystonia may be specific if a syndrome cause is identified (eg, l-dopa for DYT5). Nonspecific treatment may be physical therapy (eg, for cerebral palsy) or medication trials with anticholinergics trihexyphenidyl (Artane), tetrabenazine, baclofen or botulism injections (eg, for a focal foot, or neck dystonia), or even chronic deep brain stimulation.

Persistent chorea (rarely) may be a benign lifelong genetic disease. Treatment is complex: L-dopa, anticholinergics (trihexyphenidyl, large doses), tetrabenazine, and baclofen are primary medications. A common cause of transient dystonia in childhood (adolescent) is a drug reaction to antipsychotic (eg, chlorpromazine) or antiemetics (phenothiazines, metoclopramide).

4. Tremor

The most common cause of persisting tremors in childhood is essential tremor; average age of onset is 12 years. Tremor is the third most common movement disorder, after restless legs and tics. Of those with this lifelong malady, 4.6% have onset in childhood (2–16 years). A genetic dominant inheritance is probable; 20%–80% afflicted report a relative with tremors. Tremor is worsened by anxiety, fatigue, stress, physical activity, and caffeine, and transiently improved by alcohol. Comorbidities include attention-deficit/hyperactivity disorder, dystonia, and possibly Tourette syndrome. Hand/arm tremor is the major manifestation; voice and head tremors are rare.

Laboratory studies are normal. No single chromosome/gene defect is known. Subtle abnormalities (eg, increased cerebellar blood flow) can be found in 25% in research studies. Progression is usually minimal; some patients develop other movement disorders over a lifetime. Helpful medications (rarely needed long term) include propranolol or primidone.

Differential diagnosis includes birth asphyxia, Wilson disease, hyperthyroidism, and hypocalcemia; history and laboratory tests rule out these rare possibilities.

Table 25–23. Paroxysmal movement disorders (genetics).

Name	PKD[a]	PNKD[b]	PED[c]

[a]Paroxysmal kinesigenic dyskinesia.
[b]Paroxysmal non-kinesigenic dyskinesia.
[c]Paroxysmal exercise-induced dyskinesia.

Recent research studies in adults utilizing proton MRS (magnetic resonance spectroscopy) suggest decreased nerve cells in the cerebellar cortex and increased harmane, a neurotoxin, at the same site. The latter suggests a possible environmental contribution to essential tremor.

5. Wilson Disease

(See also Chapter 22.) Wilson disease is a treatable and reversible genetic disease (AR). Half of patients with Wilson disease present with or have neuropsychiatric diseases; early symptoms may be as non-specific as school work deterioration or mild tremor. Wilson's should be ruled out in any child with any significant movement disorder or psychiatric disease in school-age children (adolescents, especially) with serum ceruloplasmin, liver function panel, and possibly 24-hour urine copper laboratory assessment. MRI may show hyperintense basal ganglia. Kayser-Fleischer rings seen with slit-lamp eye examination are virtually diagnostic in neurologically involved patients.

CEREBRAL PALSY

The term *cerebral palsy* is a nonspecific term used to describe a chronic, static impairment of muscle tone, strength, coordination, or movements. The term implies that the condition is nonprogressive and originated from some type of cerebral insult or injury before birth, during delivery, or in the perinatal period. Other neurologic deficits or disorders

(eg, blindness, deafness, or epilepsy) often coexist. Some form of cerebral palsy occurs in about 0.2% of neonatal survivors. The fundamental course, severity, precise manifestations, and prognosis vary widely.

▶ Clinical Findings

A. Symptoms and Signs

The most common forms of cerebral palsy (75% of cases) involve spasticity of the limbs. A variety of terms denote the specific limb or combination of limbs affected: monoplegia (one limb); hemiplegia (arm and leg on same side of body, but arm more affected than leg); paraplegia (both legs affected with arms unaffected); quadriplegia (all four limbs affected equally). Ataxia is the second most common form of cerebral palsy, accounting for about 15% of cases. The ataxia frequently affects fine coordinated movements of the upper extremities, but may also involve lower extremities and trunk. A dyskinetic movement disorder usually in the form of choreoathetosis or dystonia accounts for 5% of cases and persistent hypotonia without spasticity for 1%.

Depending on the type and severity of the motor deficits, associated neurologic deficits or disorders may occur: seizures in up to 50%, mild mental retardation in 26%, and severe retardation in up to 27%. Disorders of language, speech, vision, hearing, and sensory perception are found in varying degrees and combinations.

The findings on physical examination are variable and are predominantly those of spasticity, hyperreflexia, and, less often ataxia, and/or involuntary movements. Microcephaly is frequently present. In patients with hemiplegia, the affected arm and leg may be smaller and shorter than the unaffected limbs. Cataracts, retinopathy, and congenital heart defects may be indicative of congenital infections such as CMV and rubella.

B. Laboratory and Imaging Tests

Appropriate laboratory studies depend on the history and physical findings. MRI scans may be helpful in understanding the full extent of cerebral injury, and occasionally neuroimaging results suggest specific etiologies (eg, periventricular calcifications in congenital CMV infections or brain malformations such as pachygyri or lissencephaly). Genetic and metabolic testing should be targeted based on history or MRI findings.

▶ Differential Diagnosis

The cause is often obscure or multifactorial. No definite etiologic diagnosis is possible in 25% of cases. The incidence is high among infants small for gestational age or with extreme prematurity. Intrauterine hypoxia is a frequent cause. Other known causes are intrauterine bleeding, infections, toxins, congenital brain malformations, obstetric complications (including birth hypoxia), neonatal infections, kernicterus, neonatal hypoglycemia, metabolic disorders, and a small number of genetic syndromes.

▶ Treatment & Management

Treatment and management are directed at assisting the child to attain maximal neurological functioning with appropriate physical, occupational, and speech therapy. Orthopedic monitoring and intervention and special educational assistance may all contribute to an improved outcome. Treatment of spasticity (with medications or botulinum toxin) and seizures are needed in many children. Constraint-induced movement therapy is being studied in controlled trials. Also important is the general support of the parents and family with counseling, educational programs, and support groups.

▶ Prognosis

The prognosis for patients with cerebral palsy depends greatly on the child's IQ, severity of the motor deficits, etiology of CP, and degree of incapacity. In severely affected children, aspiration, pneumonia, or other intercurrent infections are the most common causes of death.

In contrast, patients with mild cerebral palsy may improve with age. Some patients experience resolution of their motor deficits by age 7 years. Many children may have normal intellect have normal life spans and are able to lead productive, satisfying lives.

▼ INFECTIONS & INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Infections of the CNS are among the most common neurologic disorders encountered by pediatricians. Although infections are among the CNS disorders most amenable to treatment, they also have a very high potential for causing catastrophic destruction of the nervous system. It is imperative for the clinician to recognize infections early in order to treat and prevent massive tissue destruction.

▶ Clinical Findings

A. Symptoms and Signs

Patients with CNS infections, whether caused by bacteria, viruses, or other microorganisms, present with similar manifestations. Systemic signs of infection include fever, malaise, and impaired heart, lung, liver, or kidney function. General features suggesting CNS infection include headache, stiff neck, fever or hypothermia, changes in mental status (including hyperirritability evolving into lethargy and coma), seizures, and focal sensory and motor deficits. Meningeal irritation is manifested by the presence of Kernig and Brudzinski signs. In very young infants, signs of meningeal irritation may be absent, and temperature instability and hypothermia are often more prominent than fever. In young infants, a bulging fontanelle and an increased head circumference are common. Papilledema may eventually develop, particularly in older children and adolescents. Cranial nerve palsies may develop acutely or gradually during the course of neurologic infections. No specific clinical sign or symptom is reliable in distinguishing bacterial infections from infections caused by other microbes.

During the initial clinical assessment, conditions that predispose the patient to infection of the CNS should be sought. Infections involving the sinuses or other structures in the head and neck region can result in direct extension of infection into the intracranial compartment. Open head injuries, recent neurosurgical procedures, immunodeficiency, and the presence of a mechanical shunt may predispose to intracranial infection.

B. Laboratory Findings

When CNS infections are suspected, blood should be obtained for a complete blood count, general chemistry panel, and culture. Most important, however, is obtaining CSF. In the absence of focal neurologic deficits or signs of brainstem herniation, CSF should be obtained immediately from any patient in whom serious CNS infection is suspected. When papilledema or focal motor signs are present, a lumbar puncture may be delayed until a neuroimaging procedure has been done to exclude space-occupying lesions. Treatment must be started even if lumbar puncture is delayed. It is generally safe to obtain spinal fluid from infants with nonfocal neurologic examination even if the fontanelle is bulging. Spinal fluid should be examined for the presence of red and white blood cells, protein concentration, glucose concentration, bacteria, and other microorganisms; a sample should be cultured. In addition, serologic, immunologic, and nucleic acid detection (PCR) tests may be performed on the spinal fluid in an attempt to identify the specific organism. Spinal fluid that contains a high proportion of polymorphonuclear leukocytes, a high protein concentration, and a low glucose concentration strongly suggests bacterial infection (see Chapter 42). CSF containing predominantly lymphocytes, a high protein concentration, and a low glucose concentration suggests infection with mycobacteria, fungi, uncommon bacteria, and some viruses such as lymphocytic choriomeningitis virus, herpes simplex virus, mumps virus, and arboviruses (see Chapters 40 and 43). CSF that contains a high proportion of lymphocytes, normal or only slightly elevated protein concentration, and a normal glucose concentration is suggestive of viral infections and CNS inflammatory disorders, although partially treated bacterial meningitis and parameningeal infections may also result in this CSF profile. Typical CSF findings in a variety of infectious and inflammatory disorders are shown in Table 25–2.

In some cases, brain biopsy may be needed to identify the presence of specific organisms and clarify the diagnosis. Herpes simplex virus infections can be confirmed using PCR to assay for herpes DNA in spinal fluid. This test has 95% sensitivity and 99% specificity. Brain biopsy may be needed to detect the rare PCR-negative case of herpes simplex, various parasitic infections, or in a suspected parainfectious or postinfectious cause with ambiguous spinal fluid findings (eg, vasculitis).

C. Imaging

Neuroimaging with CT and MRI scans may be helpful in demonstrating the presence of brain abscess, meningeal inflammation, or secondary problems such as venous and arterial infarctions, hemorrhages, and subdural effusions when these are suspected. In addition, these procedures may identify sinus or other focal infections in the head or neck region that are related to the CNS infection. CT bone windows may demonstrate bony abnormalities such as basilar fractures.

Although often nonspecific, EEGs may be helpful in the assessment of patients who have had seizures at the time of presentation. In some instances, such as herpes simplex virus or focal enterovirus infection, periodic lateralized epileptiform discharges (PLEDs) may be seen early in the course and may be one of the earliest study abnormalities to suggest the diagnosis. EEGs may also show focal slowing over regions of infarcts or (rare) abscesses.

BACTERIAL MENINGITIS

Bacterial infections of the CNS may present acutely (symptoms evolving rapidly over 1–24 hours), subacutely (symptoms evolving over 1–7 days), or chronically (symptoms evolving over more than 1 week). Diffuse bacterial infections involve the leptomeninges, superficial cortical structures, and blood vessels. Although the term *meningitis* is used to describe these infections, it should not be forgotten that the brain parenchyma is also inflamed and that blood vessel walls may be infiltrated by inflammatory cells that result in endothelial cell injury, vessel stenosis, and secondary ischemia and infarction. Overall clinical characteristics of bacterial meningitis (and viral meningoencephalitis) are outlined in Table 25–24.

Pathologically, the inflammatory process involves all intracranial structures to some degree. Acutely, this inflammatory process may result in cerebral edema or impaired CSF flow through and out of the ventricular system, resulting in hydrocephalus.

Table 25–24. Encephalitis.

Definition: Inflammation of brain parenchyma
Clinically characterized by: fever, headache, impaired consciousness, seizures, focal neurologic deficit
Laboratory features include: CSF pleocytosis, elevated protein. Evaluation should include: CSF culture/PCR; serology CSF/blood
Radiographic features: focal or diffuse edema, abnormal T2 signal on MRI, diffusion weighted abnormalities consistent with infarction
Pathologic features: perivascular cells, possible neuronophagia; edema, demyelination, gliosis
Infectious causes: (95%) enteroviruses, *Mycoplasma*, herpes, EBV, bacteria, fungi, protozoa
Some causes are mosquito- or tick-borne; seasonal
Para-/Postinfectious (ADEM): post vaccination (> 70%) or post viral (< 5%); no etiologic agent is identified (25%)
Treatment: supportive
Herpes: acyclovir
ADEM: high dose steroids, IVIG or plasma exchange
Broad Spectrum Antibiotics until cultures are negative

ADEM, acute disseminated encephalomyelitis; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; IVIG, intravenous immune globulin; PCR, polymerase chain reaction.
Data from Lewis P, Glaser CA: Encephalitis. Pediatr Rev 2005;26:347.

▶ Treatment

A. Specific Measures

(See also Chapters 39, 40, and the section on bacterial infections in Chapter 42.)

While awaiting the results of diagnostic tests, the physician should start broad-spectrum antibiotic coverage. The appropriate antimicrobial varies with age to match the likely pathogens encountered. After specific organisms are identified, antibiotic therapy can be tailored based on antibiotic sensitivity patterns.

Suspected bacterial meningitis in neonates is treated initially with ampicillin and aminoglycoside, usually gentamicin. Cefotaxime may be added if gram negative organisms are suspected. Ampicillin is used to treat *Listeria* and enterococci infections, which rarely affect older children. Thus, children older than 3 months are given ceftriaxone or cefotaxime *plus* vancomycin to empirically treat for the most common bacterial pathogens, penicillin-resistant *S pneumoniae* and *N meningitides*. Rifampin and dexamethasone use should be considered on a case by case basis. Therapy may be narrowed when organism sensitivity allows. Duration of therapy is 7 days for meningococcal infections, 10 days for *Haemophilus influenzae* or pneumococcal infection, and 14–21 days for other organisms. Slow clinical response or the occurrence of complications may prolong the need for therapy.

B. General and Supportive Measures

Children with bacterial meningitis are often systemically ill. The following complications should be looked for and treated aggressively: hypovolemia, hypoglycemia, hyponatremia, acidosis, septic shock, increased intracranial pressure, seizures, disseminated intravascular coagulation, and metastatic infection (eg, pericarditis, arthritis, or pneumonia). Children should initially be monitored closely (cardiorespiratory monitor, strict fluid balance and frequent urine specific gravity assessment, daily weights, and neurologic assessment every few hours), not fed until neurologically very stable, isolated until the organism is known, rehydrated with isotonic solutions until euvolemic, and then given intravenous fluids containing dextrose and sodium at no more than maintenance rate (assuming no unusual losses occur).

▶ Complications

Abnormalities of water and electrolyte balance result from either excessive or insufficient production of antidiuretic hormone and require careful monitoring and appropriate adjustments in fluid administration. Monitoring serum sodium every 8–12 hours during the first 1–2 days, and urine sodium if the inappropriate secretion of antidiuretic hormone is suspected, usually uncovers significant problems.

Seizures occur in 20%–30% of children with bacterial meningitis. Seizures tend to be most common in neonates

and less common in older children. Persistent focal seizures or focal seizures associated with focal neurologic deficits strongly suggest subdural effusion, abscess, or vascular lesions such as arterial infarct, cortical venous infarcts, or dural sinus thrombosis. Because generalized seizures in a metabolically compromised child may have severe sequelae, early recognition and therapy are critical

Subdural effusions occur in up to a third of young children with *S pneumoniae* meningitis. Subdural effusions are often seen on CT scans of the head during the course of meningitis. They do not require treatment unless they are producing increased intracranial pressure or progressive mass effect. Although subdural effusions may be detected in children who have persistent fever, such effusions do not usually have to be sampled or drained if the infecting organism is *H influenzae,* meningococcus, or pneumococcus. These are usually sterilized with the standard treatment duration, and slowly waning fever during an otherwise uncomplicated recovery may be followed clinically. Under any other circumstance, however, aspiration of the fluid for documentation of sterilization or for relief of pressure should be considered. Interestingly, prognosis is not worsened by subdural effusions.

Cerebral edema can participate in the production of increased intracranial pressure, requiring treatment with dexamethasone, osmotic agents, diuretics, or hyperventilation; continuous pressure monitoring may be needed.

Long-term sequelae of meningitis result from direct inflammatory destruction of brain cells, vascular injuries, or secondary gliosis. Focal motor and sensory deficits, visual impairment, hearing loss, seizures, hydrocephalus, and a variety of cranial nerve deficits can result from meningitis. Sensorineural hearing loss in *H influenzae* meningitis occurs in approximately 5%–10% of patients during long-term follow-up. Early addition of dexamethasone to the antibiotic regimen may modestly decrease the risk of hearing loss in some children with *bacterial* meningitis (see Chapter 42).

In addition to the disorders mentioned, some patients with meningitis develop mild to severe cognitive impairment and severe behavioral disorders that limit their function at school and later performance in life.

BRAIN ABSCESS

▶ Clinical Findings

Patients with brain abscess often appear to have systemic illness similar to patients with bacterial meningitis, but in addition they show signs of focal neurologic deficits, papilledema, and other evidence of increased intracranial pressure or a mass lesion. Symptoms may be present for a week or more; children with bacterial meningitis usually present within a few days. Conditions predisposing to development of brain abscess include penetrating head trauma; chronic infection of the middle ear, mastoid, or sinuses (especially the frontal sinus); chronic dental or pulmonary infection; cardiovascular lesions allowing right-to-left shunting of blood (including arteriovenous malformations); and endocarditis. Sinus infections more characteristically cause subdural-epidural, orbital and forehead abscesses or empyemas, or cellulitis rather than intrabrain abscesses.

When brain abscess is strongly suspected, a neuroimaging procedure such as CT or MRI scan with contrast enhancement should be done prior to lumbar puncture. If a brain abscess is identified, lumbar puncture may be dangerous and rarely alters the choice of antibiotic or clinical management since the CSF abnormalities usually reflect only parameningeal inflammation or are often normal. With spread from contiguous septic foci, streptococci and anaerobic bacteria are most common. Staphylococci most often enter from trauma or spread from distant or occult infections. Enteric organisms may form an abscess from chronic otitis. Unfortunately, cultures from a large number of brain abscesses remain negative.

The diagnosis of brain abscess is based primarily on a strong clinical suspicion and confirmed by a neuroimaging procedure. Strongly positive inflammatory markers (erythrocyte sedimentation rate, C-reactive protein) may be supportive as normal results would be unlikely in patients with brain abscess. EEG changes are nonspecific but frequently demonstrate focal slowing in the region of brain abscess.

▶ Differential Diagnosis

Differential diagnosis of brain abscess includes any condition that produces focal neurologic deficits and increased intracranial pressure, such as neoplasms, subdural effusions, cerebral infarctions, and CNS infections.

▶ Treatment

When a primary source or contiguous foci is suspected a 3rd generation cephalosporin (Cefotaxime or Ceftriaxone) plus metronidazole is recommended. Penicillin G is an alternative to a cephalosporin. In posttraumatic and postsurgical cases, nafcillin or oxacillin plus 3rd generation cephalosporin (cefotaxime or ceftriaxone) is recommended. Vancomycin should be considered as a substitute for nafcillin or oxacillin when methicillin-resistant *Staphylococcus aureus* is suspected. Treatment may include neurologic consultation and anticonvulsant and edema therapy if necessary. In their early stages, brain abscesses are areas of focal cerebritis and can be treated with antibiotic therapies alone. Encapsulated abscesses require surgical drainage.

▶ Prognosis

The surgical mortality rate in the treatment of brain abscess is lower than 5%. Untreated cerebral abscesses lead to irreversible tissue destruction and may rupture into the

ventricle, producing catastrophic deterioration in neurologic function and death. Because brain abscesses are often associated with systemic illness and systemic infections, the death rate is frequently high in these patients. Other poor prognostic indicators include rapid progression of disease and alteration of consciousness at the time of presentation.

VIRAL INFECTIONS

Viral infections of the CNS can involve primarily meninges (meningitis) (see Chapter 40) or cerebral parenchyma (encephalitis) (see Table 25–24). All patients, however, have some degree of involvement of both the meninges and cerebral parenchyma (meningoencephalitis). Many viral infections are generalized and diffuse, but some viruses, notably herpes simplex and some enteroviruses, characteristically cause prominent focal disease. Focal cerebral involvement is clearly evident on neuroimaging procedures. Some viruses have an affinity for specific CNS cell populations. Poliovirus and other enteroviruses can selectively infect anterior horn cells (poliomyelitis) and some intracranial motor neurons.

Although most viral infections of the nervous system have an acute or subacute course in childhood, chronic infections can occur. Subacute sclerosing panencephalitis, for example, represents a chronic indolent infection caused by altered measles virus and is characterized clinically by progressive neurodegeneration and seizures.

Treatment of CNS viral infections is usually limited to symptomatic and supportive measures, except for herpes simplex virus, and some cases of varicella zoster virus infections where acyclovir is used. West Nile virus is an arthropod-borne flavivirus. It is found in mosquitoes, thus the highest incidence of West Nile virus infections occurs from July to October. The infection is now endemic in United States. This disease is often asymptomatic or mild in pediatric patients; paralysis and death occur mostly in the elderly.

▼ ENCEPHALOPATHY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Neurologic syndromes associated directly with HIV infection include subacute encephalitis, meningitis, myelopathy, polyneuropathy, and myositis. In addition, secondary opportunistic infections of the CNS occur in patients with HIV-induced immunosuppression. *Pneumocystis, Toxoplasma,* and CMV infections are particularly common. Progressive multifocal leukoencephalopathy, a secondary papillomavirus infection, herpes simplex and varicella-zoster infections also occur frequently in patients with HIV infection. Various fungal (especially cryptococcal), mycobacterial, and bacterial infections have been described.

Neurologic abnormalities in these patients can also be the result of noninfectious neoplastic disorders. Primary CNS lymphoma and metastatic lymphoma to the nervous system are the most frequent neoplasms of the nervous system in these patients. See Chapters 33, 39, and 41 for diagnosis and management of HIV infection.

OTHER INFECTIONS

A wide variety of other microorganisms, including *Toxoplasma,* mycobacteria, spirochetes, rickettsiae, amoebae, and mycoplasma can cause CNS infections. CNS involvement in these infections is usually secondary to systemic infection or other predisposing factors. Appropriate cultures and serologic testing are required to confirm infections by these organisms. Parenteral antimicrobial treatment for these infections is discussed in Chapter 39.

NONINFECTIOUS INFLAMMATORY DISORDERS OF THE CENTRAL NERVOUS SYSTEM

The differential diagnosis of bacterial, viral, and other microbial infections of the CNS includes disorders that cause inflammation but for which no specific causal organism has been identified. Sarcoidosis, Behçet disease, systemic lupus erythematosus, and other collagen-vascular disorders are examples. In these disorders, CNS inflammation usually occurs in association with characteristic systemic manifestations that allow proper diagnosis. Some CNS inflammatory disorders lead to demyelination syndromes described in Table 25–25. Management of CNS involvement in these disorders is the same as the treatment of the systemic illness.

1. Acute Demyelinating Encephalomyelitis (ADEM)

Inflammatory reactions within the nervous system may occur during the convalescent stage of systemic viral infections. Parainfectious or postinfectious inflammation of the CNS results in several well-recognized disorders: acute

Table 25–25. Prominent features of CNS inflammatory demyelination syndromes.

ADEM	Encephalopathy and fever
CIS	Mono or multifocal lesions without encephalopathy
NMO	Longitudinally extensive transverse myelitis, optic neuritis, may or may not be NMO-IgG +
Relapsing ADEM	Exceedingly rare > 3 mo from onset of initial event; consider other etiologies
Pediatric MS	Relapsing and remitting, may be diagnosed after one attack if MRI criteria for separation in time and space are met

ADEM, acute disseminated encephalomyelitis; CIS, clinically isolated syndrome; MS, multiple sclerosis; NMO, neuromyelitis optica.

disseminated encephalomyelitis (ADEM; 25% of encephalitis), transverse myelitis, optic neuritis, polyneuritis, and Guillain-Barré syndrome.

A. Imaging

MRI findings in ADEM are distinctive: demyelinating lesions, seen on T_2 and FLAIR images, are key to the diagnosis. Small and large white matter lesions can mimic findings in multiple sclerosis (MS), but may also involve gray matter such as cortex, basal ganglia, and thalamus. Radiologic changes are usually florid when the patient is first seen but occasionally emerge only days to weeks later. Thus, serial or repeat scans may be necessary.

B. Laboratory Findings

Lumbar puncture findings may be normal or mildly abnormal, with mild pleocytosis and elevation of the CSF protein in 25%–50% of cases. Typically oligoclonal bands are not seen in clinically isolated syndromes, but elevated IgG indices and presence of oligoclonal bands are more often observed in children who subsequently develop multiple sclerosis.

▶ Treatment

In cases of ADEM, corticosteroids are beneficial. Current practice is to administer high dose therapy, followed by oral prednisone taper over 4–6 weeks. Most pediatric groups initially utilize intravenous methylprednisolone (10–30 mg/kg/d up to a maximum dose of 1 g/d) or dexamethasone (1 mg/kg/d) for 3–5 days (no comparative dose studies are available). In refractory patients, IVIG or plasmapheresis may be effective.

▶ Prognosis

Rarely, ADEM relapses within 3 months of onset. Recurrence more than 3 months after treatment should raise strong suspicion of MS, neuromyelitis optica (especially in cases of optic nerve or spinal cord involvement) or alternative cause. Congenital viral infections can also affect the CNS. CMV, herpes simplex virus, varicella, and (rare now, because of immunization) rubella virus are the most notable causes of viral brain injury in utero.

2. Paraneoplastic Syndromes

Paraneoplastic syndromes are increasingly recognized. These immune-mediated disorders are clinically heterogeneous with neurologic effects that can be both central and peripheral. The disorders are identified by autoantibodies to both intraneuronal and cell surface antigens. While the pathogenesis of these disorders is poorly understood, they are thought to result from misdirected immune response to shared epitopes between neuronal antigens and tumor antigens. Anti-NMDA receptor encephalitis is one example of a paraneoplastic syndrome that may precede detection of neoplasm, or result from post-viral immune dysregulation. Behavioral changes, autonomic instability, insomnia, aphasia, seizures, and movement disorders are prominent. Detection of the antibody is diagnostic. Immunotherapy, including glucocorticoids, intravenous immunoglobulin, and/or plasma exchange are shown to be beneficial. Second line therapies include rituximab and/or cyclophosphamide for refractory cases.

OTHER PARAINFECTIOUS ENCEPHALOPATHIES

In association with systemic infections or other illnesses, CNS dysfunction may occur in the absence of direct CNS inflammation or infection. Reye syndrome is a prominent example of this type of encephalopathy that often occurs in association with varicella virus or other respiratory or systemic viral infections. In Reye syndrome, cerebral edema and cerebral dysfunction occur, but there is no evidence of any direct involvement of the nervous system by the associated microorganism or inflammation. Cerebral edema in Reye syndrome is accompanied by liver dysfunction and fatty infiltration of the liver. As a result of efforts to discourage use of aspirin in childhood febrile illnesses, the number of patients with Reye syndrome has markedly decreased. The precise relationship, however, between aspirin and Reye syndrome is unclear.

MULTIPLE SCLEROSIS

Pediatric MS accounts for 5%–10% of all MS cases. Over the last 10 years, we have learned more about the epidemiology, pathophysiology, diagnosis, and treatment of multiple sclerosis in children. Several exciting discoveries have highlighted the importance of genetic and environmental factors alone and in combination. Notable examples include HLA subtypes and viral exposures, among others. Importantly, diagnostic criteria, including clinical, MRI, and laboratory studies are different among prepubertal patients when compared to postpubertal patients.

▶ Clinical Findings

The diagnosis of multiple sclerosis (MS) in a child remains challenging, given the limited diagnostic criteria and the somewhat poorly defined overlap with acute disseminated encephalomyelitis. Although there are many similarities between pediatric-onset and adult-onset MS, an earlier age at disease presentation seems to be associated with specific features such as more frequent encephalopathy, seizures, and brainstem and cerebellar symptoms during the first event.

A diagnosis of pediatric MS may be made after one episode of demyelination if the MRI scan meets criteria for dissemination in time and space. If these criteria are not met,

the child is diagnosed with clinically isolated syndrome, for example: optic neuritis; transverse myelitis; or brainstem, cerebellar, or hemispheric dysfunction. Atypical clinical features of pediatric MS include fever and involvement of the peripheral nervous system or other organ systems, elevated erythrocyte sedimentation rate or marked CSF pleocytosis. Encephalopathy is more commonly associated with ADEM. However, in young children, MS exacerbations may present with encephalopathy, making differentiation of the two disorders difficult.

In addition, the initial brain MRI scan of younger patients shows more frequent involvement of the posterior fossa and higher numbers of ovoid, ill-defined T2-bright foci that often partially resolve on the follow-up scan. At present, there are several sophisticated MRI criteria to separate pediatric MS diagnosis from alternatives (eg, ADEM).

Finally, the spinal fluid in younger patients may fail to reveal oligoclonal bands or elevated IgG index at disease onset. There is no FDA-approved therapy for MS in children. As a result physicians have started to use off-label drugs approved for adults. Retrospective data has shown them to be effective in children.

▶ Differential Diagnosis

Differential diagnosis includes ADEM, and neuromyelitis optica. Many other infections, metabolic disorders, and degenerative diseases can mimic MS.

▶ Treatment

Acute treatment (mainly corticosteroids; sometimes IVIg or plasmapheresis) and prevention or modulation of relapses is extrapolated from adult studies; pediatric trials are in their infancy. Immunomodulatory treatment to prevent relapses in children includes interferon-beta 1a or glatiramer acetate (injections); oral agents fingolimod, teriflunomide and dimethyl fumarate. Natalizumab, rituximab, or cyclophosphamide may be utilized in refractory patients.

SYNDROMES PRESENTING AS ACUTE FLACCID WEAKNESS

▶ Pathogenesis

Flaccid paralysis in a child can occur as a result of a lesion anywhere along the neuroaxis. The key to diagnosis is localizing the lesion. Associated changes in reflexes, sensory changes, abnormal reflexes such as a positive Babinski's sign, and bowel and bladder changes can help in localizing the lesion. Mass lesions, infectious or postinfectious causes, toxins (eg, from a tick or due to botulism), and metabolic causes, are only a few of the etiologies that can cause acute weakness. A review of some of the more common causes of acute weakness and their associated findings are listed in Table 25–26.

▶ Clinical Findings

A. Symptoms and Signs

Features assisting diagnosis are age, a history of preceding illness, rapidity of progression, cranial nerve findings, bowel and bladder changes, and sensory findings (Table 25–26). The finding of increased reflexes and upgoing toes suggests a CNS lesion. Fatigability in sucking on a bottle and constipation may be seen in patients with botulism. In Guillain-Barré syndrome (GBS, also known as acute inflammatory demyelinating polyneuropathy (AIDP)), patients may initially present with an ascending paresthesia and loss of reflexes before they develop overt weakness. Patients with the Miller Fisher variant of GBS may present with a classic constellation of symptoms including ophthalmoplegia, ataxia, and loss of reflexes. Back pain is suggestive of a spinal cord lesion, such as in transverse myelitis or a spinal cord mass.

B. Laboratory Findings

When a spinal cord or brain lesion is suspected, MRI imaging may be helpful, and in fact are essential if a mass lesion is suspected. Once a mass lesion is excluded by imaging, CSF studies, including opening pressure, can be obtained. Viral cultures (CSF, throat, and stool) and titers aid in diagnosing poliomyelitis. A high sedimentation rate may suggest tumor or abscess; the presence of antinuclear antibody may suggest lupus arteritis.

EMG and nerve conduction studies (NCSs) can be helpful in diagnosing polyneuropathy. In GBS, NCSs are particularly helpful after the first week when delayed or absent H or F reflexes are seen are the first changes. Later, motor NCS show prolonged distal latency, conduction block or temporal dispersion, with these changes seen in 50% of patients by 2 weeks and 85% by 3 weeks. EMG findings of fibrillation potentials and increased compound muscle action potential amplitudes with high-frequency stimulation are suggestive of botulism. Rarely, elevation of muscle enzymes or even myoglobinuria may aid in diagnosis of myopathic weakness.

▶ Differential Diagnosis

While the differential diagnosis for acute weakness is broad, a short list of common and potentially treatable causes of acute weakness is listed in Table 25–26. Atypical presentations of viral infections such as with influenza A and West Nile virus should be considered when a patient presents with symptoms of poliomyelitis. Ascending paresthesias and absent reflexes are often early signs of GBS. The weakness of the extremities, respiratory muscles and bulbar muscles can be followed rapidly thereafter. In previously healthy infants who presents with acute weakness, botulism should be considered, particularly in endemic areas or with a history of using honey or canned foods. Tick paralysis can be rapidly corrected with removal of the tick, but requires an index of suspicion and a careful search for the offending insect. Patients with transverse myelitis may present with acute weakness and absent reflexes, but in the ensuing weeks will develop hyperreflexia and increased tone in the regions below the area of the lesion.

Table 25–26. Acute flaccid paralysis in children.

	Poliomyelitis (Paralytic, Spinal, and Bulbar), With or Without Encephalitis	Guillain-Barré Syndrome (AIDP)	Botulism	Tick-Bite Paralysis	Transverse Myelitis and Neuromyelitis Optica (NMO)
Etiology	Poliovirus types I, II, and III; other enteroviruses, eg, EV-71; vaccine strain poliovirus (rare); West Nile virus: epidemic in birds; mosquitoes infect horses, humans. EV-71 is hand-foot-mouth disease, rarely paralytic.	Likely delayed hypersensitivity—with T-cell–mediated antiganglioside antibodies. Mycoplasmal and viral infections (EBV, CMV), *Campylobacter jejuni*, hepatitis B.	*Clostridium botulinum* toxin. Block at neuromuscular junction. Under age 1, toxin synthesized in bowel by organisms in ingested spores or honey. At older ages toxin ingested in food. Rarely from wound infection.	Probable interference with transmission of nerve impulse caused by toxin in tick saliva.	Usually unknown; often postviral. Antibodies to aquaporin in NMO.
History	None, or inadequate polio immunization. Upper respiratory or GI symptoms followed by brief respite. Bulbar paralysis more frequent after tonsillectomy. Often in epidemics, in summer and early fall.	Nonspecific respiratory or GI symptoms in preceding 5–14 d common. Any season, though slightly lower incidence in summer.	Infancy: dusty environment (eg, construction area), honey. Older: food poisoning. Multiple cases hours to days after ingesting contaminated food.	Exposure to ticks (dog tick in eastern United States; wood ticks). Irritability 12–24 h before onset of a rapidly progressive ascending paralysis.	Rarely symptoms compatible with multiple sclerosis or optic neuritis. Progression from onset to paraplegia often rapid, usually without a history of bacterial infection.
Presenting complaints	Febrile at time of paralysis. Meningeal signs, muscle tenderness, and spasm. Asymmetrical weakness widespread or segmental (cervical, thoracic, lumbar). Bulbar symptoms early or before extremity weakness; anxiety; delirium.	Symmetrical weakness of lower extremities, which may ascend rapidly to arms, trunk, and face. Verbal child may complain of paresthesias. Fever uncommon. Facial weakness early. Miller-Fisher variant presents as areflexia, ataxia, and ophthalmoplegia.	Infancy: constipation, poor suck and cry. "Floppy." Apnea. Lethargy. Choking. Bulbar palsy. Older: blurred vision, diplopia, ptosis, choking, and weakness.	Rapid onset and progression of ascending flaccid paralysis; often accompanied by pain and paresthesias. Paralysis of upper extremities 2nd day after onset. Sometimes acute ataxia presentation.	Root and back pain in about 30%–50% of cases. Sensory loss below level of lesion accompanying rapidly developing paralysis. Sphincter difficulties common. Fever (58%).
Findings	Flaccid weakness, usually asymmetrical. Cord level: Lumbar: legs, lower abdomen. Cervical: shoulder, arm, neck, diaphragm. Bulbar: respiratory, lower cranial nerves. Encephalopathy accompanies paralysis in West Nile.	Flaccid usually symmetric weakness of the extremities, with variable respiratory and bulbar weakness in severe cases. Miller-Fisher variant: ophthalmoplegia, ataxia. Bulbar involvement may occur.	Infants: flaccid weakness. Alert. Ophthalmoparesis and facial weakness. Lack of papillary responses. Deep tendon reflexes decreased. Absent suck, gag. Constipation. Older: paralysis accommodation, eye movements. Weak swallow. Respiratory paralysis.	Flaccid, symmetrical paralysis. Cranial nerve and bulbar (respiratory) paralysis, ataxia, sphincter disturbances, and sensory deficits may occur. Some fever. Diagnosis rests on finding tick, which is especially likely to be on occipital scalp.	Paraplegia with areflexia below level of lesion early; later, may have hyperreflexia. Sensory loss below and hyperesthesia or normal sensation above level of lesion. Paralysis of bladder and rectum. Optic neuritis is present in NMO.

CSF	Pleocytosis (20–500 + cells) with PMN predominance in 1st few days, later monocytic preponderance. Protein frequently elevated (50–150 mg/dL). CSF IgM-positive in West Nile.	Cytoalbuminologic dissociation; 10 or fewer mononuclear cells with high protein after 1st week. Normal glucose. IgG may be elevated. West Nile will have cells; nerves can be involved in a myeloradiculitis.	Normal.	Normal.	Usually normal opening pressure; CSF may show increased protein, pleocytosis with predominantly mononuclear cells, increased IgG.
EMG/NCS	EMG shows denervation after 10–21 d. Nerve conduction normal. Amplitude reduced in West Nile.	NCSs may be normal early (within 1st week). Earliest changes slowed to absent F or H reflexes. Demyelinating changes are typically seen 7–10 d after onset of symptoms.	EMG distinctive: BSAP (brief small abundant potentials). High-frequency stimulation may increase in CMAP amplitude but is painful to perform in awake infant.	Nerve conduction slowed; returns rapidly to normal after removal of tick.	Normal early. Denervation at level of lesion after 10–21 d.
Other studies	Virus in stool and throat. Serial serologic titers IgG, IgM in West Nile. Hyponatremia 30% in West Nile.	Search for specific cause such as infection, intoxication, autoimmune disease. Anti GM$_1$ antibodies seen in AMAN[a]. Anti-GQ1b antibodies seen in Miller-Fisher syndrome.	Infancy: stool culture, toxin. Rare serum toxin positive. Older: serum (or wound) toxin.	Leukocytosis, often with moderate eosinophilia.	Normal spine x-rays do not exclude spinal epidural abscess. MRI to rule out cord-compressive lesions. Cord usually swollen and distorted in myelitis.
Course and prognosis	Paralysis usually maximal 3–5 d after onset. Transient bladder paralysis may occur. Outlook varies with extent and severity of involvement.	Course progressive over a few days to about 2 wk.	Infancy: supportive.	Total removal of tick is followed by rapid improvement and recovery. Otherwise, mortality rate due to respiratory paralysis is very high.	Large degree of functional recovery possible. Corticosteroids are of controversial benefit in shortening duration of acute attack or altering the overall course. Plasmapheresis, IVIG: anecdotal benefit.
	Note: Mortality greatest from respiratory failure and superinfection. West Nile paralysis may be permanent.	**Note:** Threat greatest from respiratory failure (10%), autonomic crises (eg, widely variable blood pressure, arrhythmia), and superinfection. Majority recover completely. Plasmapheresis may have a role. IVIG. Relapses occasionally occur.	Penicillin. Botulism immune globulin intravenous (BIGIV). Respiratory support, gavage feeding. Avoid aminoglycosides. Older: penicillin, antitoxin, prolonged respiratory support. Prognosis: excellent. Fatality 3%.		

AIDP, acute inflammatory demyelinating neuropathy; CMAP, compound muscle action potentials; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Ebstein–Barr virus; EMG, electromyogram; EV-71, enterovirus 71; GI, gastrointestinal; IVIG, intravenous immune globulin; MRI, magnetic resonance imaging; NCS, nerve conduction studies; PMN, poly-morphonuclear neutrophil; SIDS, sudden infant death syndrome.
[a]AMAN is acute motor axonal neuropathy (uncommon variant in the United States).

▶ Complications

A. Respiratory Weakness and Failure

Early and careful attention to ventilation is essential, especially in those patients with bulbar weakness and early signs of respiratory failure. Administration of oxygen, intubation, mechanical respiratory assistance, and careful suctioning of secretions may be required. Increasing anxiety and a rise in diastolic and systolic blood pressures are early signs of hypoxia. Cyanosis is a late sign. Deteriorating spirometric findings (forced expiratory volume in 1 second and total vital capacity) may indicate the need for controlled intubation and respiratory support and is an important mode of monitoring as blood gases may be normal even in late stages of respiratory failure.

B. Infections

Pneumonia is common, especially in patients with respiratory weakness. Antibiotic therapy is best guided by results of cultures. Bladder infections occur when an indwelling catheter is required because of bladder paralysis. Recovery from myelitis may be delayed by urinary tract infection.

C. Autonomic Crisis

This may be a cause of death in Guillain-Barré syndrome. Strict attention to vital signs to detect and treat hypotension or hypertension and cardiac arrhythmias in an intensive care setting is advisable, at least early in the course and in severely ill patients.

▶ Treatment

Most of these syndromes have no specific treatment, and therefore, supportive treatment is of the essence. Ticks causing paralysis must be removed. Other therapies include the use of erythromycin in *Mycoplasma* infections and botulism immune globulin in infant botulism. Recognized associated disorders (eg, endocrine, neoplastic, or toxic) should be treated by appropriate means. Supportive care also involves pulmonary toilet, adequate fluids and nutrition, bladder and bowel care, prevention of decubitus ulcers, and in many cases, psychiatric support.

DISORDERS OF CHILDHOOD AFFECTING MUSCLES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Usually painless, symmetric proximal more than distal muscle weakness (positive Gowers sign, excessive lordosis with walking, waddling gait).

▶ Preserved deep tendon reflexes compared with muscle weakness.

▶ Normal to elevated serum creatine kinase (CK) levels.

▶ Generally normal NCSs; myopathic findings on EMG.

▶ Clinical Findings

A. Laboratory Findings and Special Tests

1. Serum enzymes—Serum creatine kinase (CK) levels reflect muscle damage or "leaks" from muscle into plasma.

Generally, CK levels are normal to mildly elevated in myopathies, and markedly elevated in muscular dystrophies, up to 50–100 times, as in Duchenne muscular dystrophy. Medications and activity level may affect CK levels, for instance after an EMG or muscle biopsy procedure. Corticosteroids may suppress levels despite very active muscle disease, for example, as in polymyositis.

2. Electrophysiologic studies—Nerve conduction study (NCS) and needle electromyography (EMG) are often helpful in grossly differentiating myopathic from neurogenic processes. Generally, NCSs are normal in muscle disorders. In demyelinating polyneuropathies, NCSs may show slowing of conduction velocities or conduction block. EMG involves inserting a needle electrode into muscle to record muscle electrical potentials. The examination includes assessment of abnormal spontaneous activity (eg, fibrillation and fasciculation potentials, myotonic discharges, myokymic discharges, and complex repetitive discharges) and motor unit action potentials (MUAPs). In the myopathies, MUAPs during contraction characteristically are of short duration, polyphasic, and increased in number for the strength of the contraction (increased interference pattern). In neuropathic processes, MUAPs are polyphasic, are of large amplitude, and show decreased recruitment.

3. Muscle biopsy—A muscle biopsy can be helpful in the diagnosis of a muscle disorder, if properly executed. It is important to consider the timing of the biopsy and the biopsied muscle should be chosen based upon the degree of weakness (ie, weaker muscles will show more pathology than strong muscles). Imaging with MRI or ultrasound may guide the choice of an appropriate site. Biopsies performed in the newborn period may be of limited utility as pathologic changes may not be evident in immature muscle. Care should be taken to avoid sites of prior needle EMG examinations or injections as this may cause spurious areas of focal inflammation pathologically. Findings common to the muscular dystrophies include variation in the size and shape of muscle fibers, increase in connective tissue, interstitial infiltration of fatty tissue, areas of degeneration and regeneration, focal areas of inflammatory changes, and centralized nuclei. Myopathies typically do not have the vigorous cycles of degeneration/regeneration and inflammation is seen in dystrophies.

Immunostaining for proteins of the sarcolemmal membrane, surrounding collagen matrix, and intracellular components of the myofiber is a valuable tool. For instance, demonstration of absent collagen VI is virtually diagnostic of Ullrich congenital muscular dystrophy. In the past, absent dystrophin staining at the sarcolemmal membrane on muscle biopsy was diagnostic of Duchenne muscular dystrophy, but mutation analysis of the dystrophin gene is the preferred initial step given the ready availability of commercial testing.

4. Genetic testing and carrier detection—Mutation analysis for Duchenne and Becker muscular dystrophy is considered the initial step in diagnosis, though it should be noted that readily available commercial testing is not exhaustive, and an initial negative result does not exclude the diagnosis. Full characterization of the mutation is critical, as newer treatments targeting specific mutations are emerging. Carrier testing should be offered to all mothers, not only for genetic counseling purposes but also because carriers are at increased risk for developing cardiomyopathy.

Genetic testing for other myopathies and muscular dystrophies should be guided by the clinical findings, serum CK levels, and muscle biopsy results. Commercially available tests are available for many of these disorders (see Table 25–27).

Genetic counseling is particularly important for families of patients with spinal muscular atrophy. Testing for the survival motor neuron (SMN)1 gene deletion has a sensitivity of 95% and a specificity of 100%. Carrier testing, along with genetic counseling, should also be offered, as the carrier rate is 1 in 25 to 1 in 50, depending upon ethnicity.

▶ **Complications**

Though skeletal muscle weakness may be profound in muscle disorders, the greatest morbidity and mortality arises from cardiorespiratory complications. Advances in supportive care, especially in critical care management of these patients, have had a tremendous impact in the care of these patients. Noninvasive ventilation, better management of secretions, and generation of effective cough are a few examples. Other complications include delayed gastrointestinal motility which can lead to debilitating constipation or pseudo-obstruction. Contractures are a particularly frustrating complication which can limit mobility of these patients, cause pain, and affect quality of life. Some DMD patients may have a nonprogressive mental retardation with IQ scores one standard deviation below normal means.

▶ **Treatment**

Treatment for patients with muscle disorders is predominantly supportive, and medications altering disease progression is, at this time, limited. Patients with Duchenne muscular dystrophy (DMD)/Becker muscular dystrophy (BMD) should be offered treatment with corticosteroids (prednisone/prednisolone and deflazacort) which have been shown to extend the period of independent ambulation by approximately 2.5 years, and to preserve respiratory strength and cardiac function into the second decade. Instituting steroid treatment between 4 and 8 years, when motor function plateaus or is in decline, appears to have the greatest impact on muscle strength and cardiorespiratory function, according to recent practice parameter guidelines. Additional promising treatments targeting the mutation more specifically have been developed over the last decade

Table 25–27. Muscular dystrophies, myopathies, myotonias, and anterior horn diseases of childhood.

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes	Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Muscular dystrophies									
Duchenne muscular dystrophy (pseudohypertrophic infantile)	X-linked recessive; Xp21; 30%–50% have no family history and are spontaneous mutations.	2–6 y; rarely in infancy.	Clumsiness, easy fatigability on walking, running, and climbing stairs. Walking on toes; waddling gait with excessive lumbar lordosis. Motor delays. Positive Gowers maneuver.	Proximal (pelvic and shoulder girdle) muscles; pseudohypertrophy of gastrocnemius, triceps brachii, and vastus lateralis. Second decade, progressive scoliosis, cardiomyopathy and respiratory weakness develop.	Knee jerks +/− or 0; ankle jerks + to ++	Areas of degeneration and regeneration, variation in fiber size, inflammatory changes, proliferation of connective tissue. Immunostaining for dystrophin absent.	Myopathic EMG. CK levels can be up to 50-100× normal, but decrease with increasing disease severity, reflecting replacement of muscle with fat/connective tissue. Genetic testing will show deletion 60% of time, while 5%–15% are duplications, and 20%–30% are point mutations, intronic deletions, or repeats.	Corticosteroids may prolong extend independent ambulation by 2.5 y if started between age 4 and 8 y; management is largely supportive. Close pulmonary and cardiac follow-up should be maintained due to risk of cardio-respiratory failure in 2nd–3rd decade of life. Osteoporosis should be treated with calcium and vitamin D.	Patients are wheelchair-bound by ~12 y old. Death from cardiorespiratory causes usually occurs by the early 20s.
Becker muscular dystrophy (late onset)	X-linked recessive; Xp21.	Variable: childhood to adulthood.	Similar to Duchenne.	Similar to Duchenne.	Similar to Duchenne	Same as above except dystrophin immunostaining is reduced, not absent.	As above.	As above.	Variable. Patients may remain ambulant 15–20 y after 1st symptoms. Near-normal life expectancies.
Limb-girdle muscular dystrophy	Autosomal dominant, autosomal recessive, and X-linked forms.	Variable; early childhood to adulthood.	Weakness, with distribution according to type. Waddling gait, difficulty climbing stairs. Excessive lumbar lordosis.	Slowly progressive, symmetric proximal muscle involvement; characteristically involves shoulder and pelvic muscles.	Usually present	Necrosis and fiber splitting, increased endomysial connective tissue and inflammation, absent immunostaining for various DGC proteins by subtype.	Myopathic EMG. CK often > 5000 IU/L. MRI of the legs may show selective involvement (eg, peroneal muscles in Miyoshi myopathy).	Physical therapy. Echocardiogram to screen for cardiomyopathy. PFTs to screen to respiratory weakness. No curative treatment available.	Variable by subtype.

Facioscapulohumeral muscular dystrophy (Landouzy-Déjérine)	Most are autosomal dominant inherited deletions of D4Z4 on 4q35; sporadic cases in 10%–30% cases.	Usually late in 1st–5th decade depending on size of deletion.	Diminished facial movements with inability to close eyes, smile, or whistle. Difficulty in raising arms over heard.	Face, shoulder girdle muscles (biceps, triceps), often asymmetric. Deltoid and forearm spared. 75% have sensorineural hearing loss; 60% Coats disease; 89% mental retardation.	Present	Nonspecific myopathic changes: variation in fiber size, moderate increased endomysial connective tissue, mild inflammatory changes.	Nonspecific chronic myopathic changes. CK mild to moderately elevated (< 1500 IU/L).	No curative treatments available. Management of pain important. Identify and treat hearing loss, retinal telangiectasias, respiratory insufficiency (1% cases). Ongoing clinical trials with β_2-agonists. Studies show possible benefit with creatine monohydrate and exercise.	Variable and inversely related to age at symptom onset. Life-threatening bulbar, respiratory and cardiac problems rare, so life expectancy normal.
Congenital myopathies									
Myotubular myopathy	X-linked recessive; Xq27.	Neonatal period.	Floppy infant; severe hypotonia and respiratory insufficiency.	Ptosis, ophthalmoplegia; severe symmetric distal and proximal weakness.	+ to −	Small rounded myotube-like myofibers. Patchy central clearing with radial spokes.	Normal to mildly elevated CK. Myopathic EMG with fibrillations and complex repetitive discharges.	No curative treatment. Respiratory, nutritional support. Liver and peritoneal hemorrhage reported in cases.	Generally death before 5 mo of age.
Central core myopathy	Most autosomal dominant, some autosomal recessive, 19q13, RYR1.	Infancy to adulthood.	Reduced fetal movements; hypotonia; ankle contractures.	Nonprogressive proximal weakness of legs more than arms, mild facial weakness, normal eye movements.	+ to −	Variable myofiber size; oxidative staining shows central cores absent of mitochondrial activity.	High CK, mild myopathic changes on EMG, muscle MRI shows increased T1 signal.	Physical therapy. Respiratory follow-up required. Avoid inhalational anesthetics and succinylcholine due to risk of malignancy hyperthermia.	Weakness is nonprogressive. Life expectancy normal.

Table 25–27. Muscular dystrophies, myopathies, myotonias, and anterior horn diseases of childhood. (*Continued*)

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes	Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
Metabolic myopathies									
Pompe disease	Autosomal recessive; 17q23.	Classic infantile presentation: present by 6 mo of age. Juvenile: 2–18 y.	Severe hypotonia, hepatomegaly, cardiomyopathy, hypoventilation. Proximal muscle weakness.	Proximal more than distal muscles, bulbar and respiratory muscles. Recurrent respiratory infections; nocturnal hypoventilation.	0	Cytoplasmic lysosomal vacuoles stain positive with acid phosphatase.	High CK in infants (< 10 × normal). Mildly high CK in teens.	Enzyme replacement therapy with alglucosidase alfa (Myozyme). Respiratory and nutritional support. Monitor cardiomyopathy. As above.	Significant but variable with treatment, with improved survival, cardiorespiratory status and motor skills. Variable, some become nonambulatory and most require ventilatory support.
Ion channel disorders									
Hyperkalemic periodic paralysis	Autosomal dominant 17q35.	Childhood, usually by 1st decade.	Episodic flaccid weakness, precipitated by rest after exercise, stress, fasting or cold.	Proximal and symmetric muscles, distal muscles may be involved if exercised.	Normal, may be 0 with episode	Hyperkalemic periodic paralysis.	CK normal to 300 IU/L; attacks associated with high serum K^+; NCS show increased CMAP amplitude after 5 min exercise.	Many attacks are brief and do not need treatment; treat acute attack with carbohydrates; if needed, chronic treatment with acetazolamide.	Attacks may be more frequent with increasing age.
Congenital muscular dystrophies (CMD)									
CMD with CNS involvement: includes laminin α_2 (merosin) deficiency, Ullrich CMD	Autosomal recessive, autosomal dominant.	Birth to 1st mo.	Hypotonia, generalized weakness. Contractures proximally and lax hypermobility distally.	Generalized and respiratory muscle weakness.	0 to +	Laminin α_2 deficiency: absent/reduced laminin α_2 staining. Ullrich CMD: reduced/absent COLVI.	CK normal to 10 × normal. Laminin α_2 deficiency: mild neuropathy. Skin changes in Ullrich CMD: follicular hyperkeratosis.	Most never walk or lose ability to walk early. Respiratory support required early.	Variable: death by 1st–2nd decade secondary to respiratory failure.

CMD with CNS involvement: Fukayama (FCMD), Walker-Warburg (WW), Muscle-eye-brain (MEB)	Recessive; 6 genes identified (including *POMT*). Associated with abnormalities of glycosylation of α-dystroglycan.	Birth to 9 mo.	Severe weakness; profound motor delay; severe mental. retardation. MEB with severe congenital myopia, retinal hypoplasia.	Severe generalized weakness.	Variable	Variability in fiber size, internalized nuclei, decreased immunostaining of α-dystroglycan.	CK 400–4000 IU/L, myopathic EMG, small evoked response on electroretinogram, MRI shows white matter changes, migrational abnormalities, lissencephaly, cerebellar hypoplasia.	No curative treatment. Respiratory and nutritional support. Treatment of seizures.	Variable, but generally poor with death by 2nd decade secondary to respiratory failure.
Myotonic disorders									
Myotonic dystrophy type 1 (DM1)	Autosomal dominant, expanded CTG triple repeat on chromosome 19q13.	Congenital presentation.	Decreased fetal movement, respiratory insufficiency, difficulties in feeding, sucking, and swallowing.	Generalized weakness; facial and pharyngeal involvement prominent; mental retardation.	Decreased to 0	Mild myopathic changes, centralized nuclei, variation in fiber size, ring fibers.	Usually normal CK. Electrical myotonia on EMG. Cataracts on slit lamp exam. Reduced testosterone levels. ECG shows conduction defects, like ventricular arrhythmias. Insulin resistance. Sleep study shows hypercapnia and hypoventilation.	No curative treatment. Patients should avoid medications that predispose to arrhythmia such as quinine, amitriptyline, and digoxin. Should be closely followed by pulmonologist with sleep studies, by cardiologist for risk of arrhythmia, by endocrinologist for insulin resistance, and by ophthalmologist for cataracts. May have GI hypomotility with constipation and pseudoobstruction.	Reduced survival to age 65; mean survival to 60 y. 50% patients are wheelchair bound before death.

(Continued)

Table 25–27. Muscular dystrophies, myopathies, myotonias, and anterior horn diseases of childhood. (*Continued*)

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes	Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
		Typical teen to adult onset (2nd–4th decade).	Complaints of difficulty opening jars, releasing objects, manipulating small objects.	Distal more than proximal weakness; involved hands and feet. Slow release of hand grip or eyelid closure (myotonia); cataracts; insulin resistance, cardiac conduction defects.	+ to ++	Mild myopathic changes: variability in fiber size, centralized nuclei.	Mildly elevated CK. Electrical myotonia on EMG. Cataracts seen in 100%, cardiac arrhythmias in 20% (less than DM1), insulin resistance in 20%, hearing loss 20%.	No curative treatment. Supportive are same as DM1.	More benign prognosis than DM1.
Myotonic dystrophy type 2 (DM2)	Autosomal dominant expanded CCTG repeat on chromosome 3q21.	~8–60 y old.	Complaints of difficult climbing stairs, arising from stairs.	Mild facial weakness, with proximal > distal and legs > arms (usually hip flexors and leg extensors); grip myotonia.	+ to ++	Usually normal, though there may be absence of 2B fibers.	Myotonia and mild myopathic changes on EMG; CK may be slightly elevated 3-4× normal.	Symptomatic treatment with quinine, mexiletine, dilantin, carbamazepine. May improve with exercise. Worsened with β$_2$-agonists, monocarboxylic amino acids, depolarizing muscle relaxants.	Normal life expectancy; muscle stiffness may interfere with activity but improves with exercise.
Myotonia congenita (Thomsen)	Autosomal dominant on chromosome 7q35 on CLCN1 gene.	Early infancy to adulthood.	Muscle hypertrophy. Difficulty in relaxing muscles after contracting them, especially with cold or stress.	Mild fixed proximal muscle weakness or mild functional difficulties (like climbing stairs).	Normal	Same as above.	Same as above.	Same as above.	Same as above. .

Myotonia congenital (Becker)	Autosomal recessive on chromosome 7q35 on CLCN1 gene.	4–12 y	Myotonia, relaxes with exercise. Muscle hypertrophy of legs and gluteals.	Mild distal muscle weakness; limitations from myotonia (inability to voluntarily relax muscle).	Normal	Large areas of grouped muscle fiber atrophy, most larger fibers are type I.	EMG shows fibrillation and fasciculation potentials, large amplitude motor unit potentials. Normal to mildly elevated CK.	No curative treatments. Respiratory and nutritional support. Clinical trials underway with sodium phenylbutyrate, valproic acid, and riluzole.	No independent sitting or standing. Life expectancy < 2 y without respiratory or nutritional support
Spinal muscular atrophy									
SMA type 1 (Werdnig-Hoffman)	Autosomal recessive, rare cohorts with autosomal dominant or X-linked inheritance, 5q.	1st 6 mo of life.	Hypotonia, "floppy" infant, with alert look, fasciculations may be noted of tongue.	Severe progressive, symmetric proximal and respiratory muscle weakness; face spared.	0				
SMA type 2		1st 18 mo.	Motor delays.	Progressive symmetric proximal muscles, mild to moderate respiratory weakness, limited cough and secretion control.	0 to +	As above.	EMG also shows fibrillation potentials and large amplitude motor unit potentials, but fasciculations not as common as in SMA type 1; tremor of fingers.	No curative treatments. Mild to moderate respiratory weakness, sleep-disordered breathing, and limited cough and secretion control require close follow-up with pulmonologist.	Will achieve independent sitting but not standing. 75% alive at 25 y old.

(*Continued*)

Table 25–27. Muscular dystrophies, myopathies, myotonias, and anterior horn diseases of childhood. (*Continued*)

Disease	Genetic Pattern	Age at Onset	Early Manifestation	Involved Muscles	Reflexes	Muscle Biopsy Findings	Other Diagnostic Tests	Treatment	Prognosis
SMA type 3 (Kugelberg-Welander)		Recognized after 18 mo of age.	Motor delays, difficulty with climbing stairs, may achieve independent walking but may lose this.	Progressive symmetric proximal muscle weakness, +/– tremor of hands.	0 to +	As above.	EMG similar to SMA type 2.	No curative treatments.	Independent ambulation may be achieved, but this skill may be lost. Normal life expectancy.
SMA type 4		Adulthood.	Clumsy gait.	Mild progressive proximal muscle weakness.	0 to ++	As above.	EMG similar to SMA type 2; tremor of hands often noted.	No curative treatment. Physical therapy and assistive devices. No pulmonary issues.	Slow progression of muscle weakness. Normal life expectancy.

ASA, acetylsalicylic acid; CK, creatine kinase; CPT, carnitine palmityl transferase; CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; EMG, electromyogram; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; SIDS, sudden infant death syndrome.

and are currently in clinical trials, including exon-skipping and read-through strategies that target specific mutations.

In the past, the prognosis for infantile Pompe disease was uniformly grim, with death by age 1 year, but enzyme replacement therapy with recombinant alglucosidase alpha has changed the outlook for many of these patients. Published short-term studies of infants with Pompe disease show significant improvement after treatment with alglucosidase alpha; with improved survival, respiratory performance, cardiomyopathy, and attainment of motor skills.

Until curative treatments for muscle diseases are available, the emphasis on management ought to be on slowing the progressive deterioration in muscle strength and cardiorespiratory function, and to improve quality of life.

BENIGN ACUTE CHILDHOOD MYOSITIS

Benign acute childhood myositis (myalgia cruris epidemica) is characterized by transient severe muscle pain and weakness affecting mainly the calves and occurring 1–2 days following an upper respiratory tract infection. Although symptoms involve mainly the gastrocnemius muscles, all skeletal muscles appear to be invaded directly by virus; recurrent episodes are due to different viral types. By seroconversion or isolation of the virus, acute myositis has been shown to be largely due to influenza types B and A and occasionally due to parainfluenza and adenovirus.

Agyeman P et al: Influenza-associated myositis in children. Infection 2004;32:199 [PMID: 15293074].

MYASTHENIC SYNDROMES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Asymmetric, variable weakness, usually coming on or increasing with use (fatigue).
▶ Involves extraocular, bulbar, and respiratory muscles.
▶ Positive response to neostigmine and edrophonium.

▶ General Considerations

Myasthenic syndromes are characterized by easy fatigability of muscles, particularly the extraocular, bulbar, and respiratory muscles. In the neonatal period, however, or in early infancy, the weakness may be so constant and general that an affected infant may present nonspecifically as a "floppy infant." Three general categories of myasthenic syndromes are recognized: transient neonatal myasthenia, autoimmune myasthenia gravis, and congenital myasthenia.

▶ Clinical Findings

A. Symptoms and Signs

1. Neonatal (transient) myasthenia—This disorder occurs in 12%–19% of infants born to myasthenic mothers as a result of passive transfer of maternal acetylcholine receptor antibody across the placenta. Neonates present before the third day of life with bulbar weakness, difficulty feeding, weak cry, and hypotonia.

2. Juvenile myasthenia gravis—Like the adult form of myasthenia gravis, juvenile myasthenia gravis is characterized by fatigable and asymmetric weakness. However, more than half of patients present with ocular symptoms (ptosis

or ophthalmoplegia), unlike adult patients who typically present with limb weakness. Weakness may remain limited to the extraocular muscles in 10%–15% of patients, but approximately half of children develop systemic or bulbar symptoms within 2 years and 75% within 4 years. Symptoms of weakness tend to recur and remit, and can be precipitate by illness or medications such as aminoglycoside antibiotics. Typical signs include difficulty chewing foods like meat, dysphagia, nasal voice, ptosis, ophthalmoplegia, and proximal limb weakness. Other autoimmune disorders such as rheumatoid arthritis and thyroid disease may be associated findings.

3. Congenital myasthenic syndromes—These syndromes are a heterogenous group of hereditary, nonimmune disorders of presynaptic, synaptic, or postsynaptic neuromuscular transmission. Patients present with symptoms similar to that of myasthenia gravis, but onset is earlier, before the age of 2 years, and can vary from mild motor delay to dramatic episodic apnea. Serum acetylcholine receptor antibody testing is negative. Response to anticholinesterases is variable, depending on the type of congenital myasthenic syndrome, and some forms may paradoxically worsen. The distinction between this group of disorders and myasthenia gravis is important, as these patients will not benefit from a thymectomy, steroids, or immunosuppressants, but it may be clinically difficult to distinguish between the two.

B. Laboratory Findings

1. Anticholinesterase inhibitor testing

a. Neostigmine test—In newborns and very young infants, the neostigmine test may be preferable to the edrophonium (Tensilon) test because the longer duration of its response permits better observation, especially of sucking and swallowing movements. There is a delay of about 10 minutes before the effect may be manifest. The physician should be prepared to suction secretions, and administer atropine if necessary.

b. Edrophonium test—Testing with edrophonium is used in older children who are capable of cooperating in certain tasks and who exhibit easily observable clinical signs, such as ptosis, ophthalmoplegia, or dysarthria. Maximum improvement occurs within 2 minutes. Both cholinesterase inhibitor tests can be limited by patient cooperation and lack of an easily observable clinical sign.

2. Antibody testing—Serum acetylcholine receptor binding, blocking, and modulating antibodies typically, though not always, are found in autoimmune juvenile myasthenia gravis. Though not specifically studied in the pediatric population, in the general myasthenia gravis population at large, about 40% of the seronegative patients have muscle-specific receptor tyrosine kinase (MuSK) antibodies.

Serum acetylcholine receptor antibodies or MuSK antibodies are often found in the neonatal and juvenile forms. In juveniles, thyroid studies are appropriate.

3. Genetic testing—Commercially available genetic testing is limited for patients with congenital myasthenic syndromes.

C. Electrophysiologic Studies

Electrophysiologic studies may be helpful when myasthenic syndromes are considered. Repetitive stimulation of a motor nerve at slow rates of 2–3 Hz with recording over an appropriately chosen muscle reveals a progressive fall in compound muscle action potentials by the fourth to fifth repetition in myasthenic patients. At higher rates of stimulation of 50 Hz, there may be a transient repair of this defect before the progressive decline is seen. Both studies may be technically difficult to perform in infants and younger children as repetitive stimulation can be painful and requires cooperation. If this study is negative, single-fiber EMG in older cooperative children may be helpful diagnostically, but it is technically challenging and time intensive, and requires concentration on the part of the child. Stimulated single-fiber EMG may be performed by trained electromyographers.

D. Imaging

Chest radiograph and CT scanning in older children may show thymic hyperplasia. Thymomas are rare in children.

▶ **Treatment**

A. General and Supportive Measures

In the newborn or in a child in myasthenic or cholinergic crisis (see the following section Complications), supportive care is essential and the child should be monitored in a critical care setting. A careful search for signs of respiratory failure is crucial: simple bedside tests include evaluation of cough and counting to 20 in a single breath. An inability to do either signals respiratory failure. Neck flexion weakness, nasal speech, and drooling are other important signs to observe. Management of secretions and respiratory assistance should be monitored by trained critical care staff.

B. Anticholinesterase Inhibitors

1. Pyridostigmine bromide—Pyridostigmine is the first-line treatment in patients with juvenile myasthenia gravis and mild weakness. Anticholinesterase inhibitors do not modify disease progression but transiently improve muscle strength. For younger children, the starting dose is 0.5–1 mg/kg every 4–6 hours. In older children, the initial dose is 30–60 mg every 4–6 hours. The maximal daily dose is 7 mg/kg/d with an absolute maximum dose of 300 mg/d.

The dosage must be adjusted for each patient based on clinical symptoms and side effects.

2. Neostigmine—Fifteen milligrams of neostigmine are roughly equivalent to 60 mg of pyridostigmine bromide. Neostigmine often causes gastric hypermotility with diarrhea, but it is the drug of choice in newborns, in whom prompt treatment may be lifesaving. It may be given parenterally.

C. Immunomodulatory Treatment

Patients with more severe weakness not responding to cholinesterase inhibitors alone require long-term treatment with immunomodulation. There are four therapeutic options in this category: (1) plasmapheresis, (2) intravenous immunoglobulins (IVIg), (3) steroids, and (4) immunosuppressants. The mainstay of treatment is steroids, but some patients who either cannot tolerate or do not respond to steroids require treatment with other immunosuppressants such as azathioprine, cyclosporine, or mycophenolate mofetil. Both plasmapheresis and IVIg may be given on a long-term basis, depending on the severity of symptoms, as well as in the acute setting, with myasthenic crises. Special note must be made to the use of steroids, which can transiently worsen symptoms before any benefit is noted, particularly with large starting doses.

▶ Complications

A. Myasthenic Crisis

Respiratory failure can develop swiftly due to critical weakness of respiratory muscle, bulbar muscles or both, resulting in a myasthenic crisis. Crises are generally not fatal as long as patients receive timely respiratory support and appropriate immunotherapy. Particular vigilance, however, needs to be maintained as crises can occur in the setting of medical illnesses or surgical procedures. Patients and their caregivers should also be alerted that certain medications can exacerbate myasthenia gravis, including aminoglycoside antibiotics, muscle relaxants, and anesthetics.

B. Cholinergic Crisis

Cholinergic crisis may result from overmedication with anticholinesterase drugs. The resulting weakness may be similar to that of myasthenic crises, and the muscarinic side effects (diarrhea, sweating, lacrimation, miosis, bradycardia, and hypotension) are often absent or difficult to evaluate. If suspected, cholinesterase inhibitors should be discontinued immediately, and improvement afterward suggests cholinergic crisis. As in myasthenic crisis, supportive respiratory care and appropriate immunotherapy should be given.

C. Surgical Measures

Data for efficacy of thymectomy in the pediatric population are few. Some studies suggest that thymectomy within 2 years of diagnosis results in a higher rate of remission in Caucasian children. Experienced surgical and postsurgical care are prerequisites.

▶ Prognosis

Prognosis for neonatal (transient) myasthenia is generally good, with complete resolution of symptoms in 2–3 weeks. However, immediate treatment with appropriate respiratory support in the acute presentation period is crucial, primarily because of the risk of secretion aspiration. No further treatment is required thereafter. The prognosis for congenital myasthenic syndromes is variable by subtype. Some subtypes show improvement in weakness with age. Others demonstrate life-threatening episodic apnea, including those with rapsyn mutations, fast-channel mutations, and choline acetyltransferase mutations. Patients with juvenile myasthenia gravis generally do well, with greater spontaneous remission rates than adult patients. Improvements in respiratory and critical care support has improved prognosis for these patients.

PERIPHERAL NERVE PALSIES

▶ Facial Weakness

ESSENTIALS OF DIAGNOSIS

▶ Central vs peripheral facial nerve lesions need to be distinguished in order to determine workup, treatment, and prognosis. The inability to raise the eyebrows indicates peripheral involvement of the facial nerve.

▶ Pathogenesis

The most common cranial mononeuropathy is facial nerve palsy. Cranial nerve VII is a complex nerve that carries several different nerve fibers, including motor fibers to all muscles of facial expression, parasympathetic motor fibers supplying the mucosa of the soft palate and the salivary and lacrimal glands, taste fibers to the anterior 2/3 of the tongue, parasympathetic sensory fibers for visceral sensation from the salivary glands and the nasal and pharyngeal mucosa, and somatic sensory fibers supplying a small part of the external auditory meatus and the skin of the ear. Facial weakness can occur as the result of a lesion anywhere along the path of the nerve. A central lesion, proximal to the facial nerve nuclei, causes contralateral weakness of the lower face, sparing the forehead and orbicularis oculi muscles which are bilaterally innervated. Peripheral lesions, at or distal to the facial nerve nuclei, cause ipsilateral facial weakness that affects both the upper and lower facial muscles, resulting in an inability to wrinkle the forehead, close the eye or smile. In addition, there may be dysfunction in the ability of tearing and saliva production, hyperacusis, and absent taste sensation over the anterior two-thirds of the tongue.

▶ Clinical Findings

The inability to wrinkle the forehead may be demonstrated in infants and young children by getting them to follow a light moved vertically above the forehead. Loss of taste of the anterior two-thirds of the tongue on the involved side may be demonstrated in cooperative children by age 4 or 5 years. Playing with a younger child and the judicious use of a tongue blade may enable the physician to note whether the child's face puckers up when something sour (eg, lemon juice) is applied with a swab to the anterior tongue.

▶ Differential Diagnosis

Injuries to the facial nerve at birth occur in 0.25%–6.5% of consecutive live births. Forceps delivery is the cause in some cases; in others, the side of the face affected may have abutted in utero against the sacral prominence. Often, no cause can be established.

Acquired peripheral facial weakness (Bell palsy) is common in children. Some cases are postinfectious, although an increasing body of evidence suggests that Bell palsy is a viral-induced cranial neuritis caused by herpes virus. It may be a presenting sign of Lyme disease, infectious mononucleosis, herpes simplex, or Guillain-Barré syndrome and is usually diagnosable by the history, physical examination, and appropriate laboratory tests. Chronic cranial nerve VII palsy may be a sign of brainstem tumor.

Bilateral facial weakness in early life may be due to agenesis of the facial nerve nuclei or muscles (part of Möbius syndrome) or may even be familial. Myasthenia gravis, polyneuritis (Miller-Fisher syndrome), fascioscapulohumeral muscular dystrophy, and myotonic dystrophy must be considered.

Asymmetrical crying facies, in which one side of the lower lip depresses with crying (ie, the normal side) and the other does not, is usually an innocent form of autosomal dominant inherited congenital malformation. The defect in the parent (the asymmetry often improves with age) may be almost inapparent. EMG suggests congenital absence of the depressor angularis muscle of the lower lip. Forceps pressure is often erroneously incriminated as a cause of this innocent congenital anomaly. Occasionally other major (eg, cardiac septal defects) congenital defects accompany the palsy. Congenital unilateral lower lip paralysis with asymmetric crying facies, most often attributed to congenital absence of the depressor anguli oris, is associated with major malformations, most commonly heart defects, in 10% of cases.

▶ Treatment & Prognosis

In the vast majority of cases of isolated peripheral facial palsy—both those due to birth trauma and those acquired later—improvement begins within 1–2 weeks, and near or total recovery of function is observed within 2 months. In severe palsy with inefficient blinking, methylcellulose drops, 1%, should be instilled into the eyes to protect the cornea during the day; at night the lid should be taped down with cellophane tape. Upward massage of the face for 5–10 minutes three or four times a day may help maintain muscle tone. Prednisone therapy (2–4 mg/kg orally for 5–7 days) likely does not aid recovery. In the older child, acyclovir or valacyclovir (herpes antiviral agent) therapy or antibiotics (Lyme disease) may have a role in Bell palsy.

In the few children with permanent and cosmetically disfiguring facial weakness, plastic surgical intervention at age 6 years or older may be of benefit. New procedures, such as attachment of facial muscles to the temporal muscle and transplantation of cranial nerve XI, are being developed.

CHRONIC POLYNEUROPATHY

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Insidious onset of weakness and fatigability of the limbs, sometimes with pain or numbness; decreased strength and reflexes.

▶ General Considerations

Polyneuropathy is usually insidious in onset and slowly progressive. Children present with disturbances of gait and easy fatigability in walking or running, and slightly less often, weakness or clumsiness of the hands. Pain, tenderness, or paresthesias are mentioned less frequently. Neurologic examination discloses muscular weakness, greatest in the distal portions of the extremities, with steppage gait and depressed or absent deep tendon reflexes. Cranial nerves are sometimes affected. Sensory deficits occur in a stocking-and-glove distribution. The muscles may be tender, and trophic changes such as glassy or parchment skin and absent sweating may occur. Rarely, thickening of the ulnar and peroneal nerves may be felt. In sensory neuropathy, the patient may not feel minor trauma or burns, and thus allows trauma to occur.

Known causes include (1) toxins (lead, arsenic, mercurials, vincristine, and benzene); (2) systemic disorders (diabetes mellitus, chronic uremia, recurrent hypoglycemia, porphyria, polyarteritis nodosa, and lupus erythematosus); (3) inflammatory states (chronic inflammatory demyelinating polyneuropathy and neuritis associated with mumps or diphtheria); (4) hereditary, often degenerative conditions, which in some classifications include certain storage diseases, leukodystrophies, spinocerebellar degenerations with neurogenic components, and Bassen-Kornzweig syndrome; and (5) hereditary sensory or combined motor and sensory neuropathies. Polyneuropathies associated with malignancies, vitamin deficiencies, or excessive vitamin B_6 intake are not reported or are exceedingly rare in children.

The most common chronic motor neuropathy of insidious onset often has no identifiable cause. This chronic inflammatory demyelinating neuropathy (CIDP) is assumed to be immunologically mediated and may have a relapsing course. Sometimes facial weakness occurs. CSF protein levels are elevated. Nerve conduction velocity is slowed, and findings on nerve biopsy are abnormal. Immunologic abnormalities are seldom demonstrated, although nerve biopsy findings may show round cell infiltration. Corticosteroids, repeated IVIG, and, occasionally, immunosuppressants may give long-term benefit.

▶ Clinical Findings

Hereditary neuropathy is the most common documented cause of chronic neuropathy in childhood. A careful genetic history (pedigree) and examination and electrical testing (motor and sensory nerve conduction and EMG) of patient and relatives are keys to diagnosis. Genetic tests are available for many of the variants. Nerve biopsy is rarely necessary.

Other hereditary neuropathies may have ataxia as a prominent finding, often overshadowing the neuropathy. Examples are Friedreich ataxia, dominant cerebellar ataxia, and Marinesco-Sjögren syndrome. Finally, some hereditary neuropathies are associated with identifiable and occasionally treatable metabolic errors (see Tables 25–20 and 25–21). These disorders are described in more detail in Chapter 36.

Laboratory diagnosis of chronic polyneuropathy is made by measurement of motor and sensory nerve conduction velocities. EMG may show a neurogenic pattern. CSF protein levels are often elevated, sometimes with an increased IgG index. Nerve biopsy, with teasing of the fibers and staining for metachromasia, may demonstrate loss of myelin, and to a lesser degree, loss of axons and increased connective tissue or concentric lamellas (so-called onion-skin appearance) around the nerve fiber. Muscle biopsy may show the pattern associated with denervation. Other laboratory studies directed toward specific causes mentioned above include screening for heavy metals and for metabolic, renal, or vascular disorders.

▶ Treatment & Prognosis

Therapy is directed at specific disorders whenever possible. Corticosteroid therapy is used first when the cause is unknown or neuropathy is considered to be due to chronic inflammation (this is not the case in acute Guillain-Barré syndrome [AIDP; acute inflammatory demyelinating neuropathy]). Prednisone is initiated at 2–4 mg/kg/d orally, with tapering to the lowest effective dose; it may need to be reinstituted when symptoms recur. (Prednisone should probably not be used for treatment of hereditary neuropathy.) Immunomodulating therapy may be safer or "steroid-sparing"; IVIG, plasmapheresis, mycophenolate mofetil, and rituximab are choices.

The long-term prognosis varies with the cause and the ability to offer specific therapy. In the corticosteroid-dependent group, residual deficits are more frequent.

MISCELLANEOUS NEUROMUSCULAR DISORDERS

FLOPPY INFANT SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

▶ Classic maneuvers to evaluate a floppy infant include checking vertical suspension, horizontal suspension, and traction response.

▶ Correct interpretation of neurological findings in a hypotonic infant is dependent on a thorough knowledge of normal childhood development.

▶ Pathogenesis

An infant may present with hypotonia due to dysfunction at any place along the neuroaxis, from the brain, spinal cord, nerve, neuromuscular junction, and muscle. Additionally, systemic disorders, metabolic disease and genetic disorders may cause an infant to appear "floppy." The evaluation of the hypotonic infant is therefore one of the most challenging diagnostic problems that a pediatrician is often faced with.

The diagnostic workup requires a thorough knowledge of normal developmental milestones at each stage of a developing infant and child, and careful assessment of the pre- and perinatal history, family history, developmental history, and presence of other systemic involvement (see Table 25–28).

▶ Clinical Findings

A. Signs and Symptoms

In the young infant, horizontal suspension (ie, supporting the infant with a hand under the chest) normally results in the infant's holding its head slightly up (45 degrees or less), the back straight or nearly so, the arms flexed at the elbows and slightly abducted, and the knees partly flexed. The "floppy" infant droops over the hand like an inverted U. The normal newborn attempts to keep the head in the same plane as the body when pulled up from supine to sitting by the hands (traction response). Marked head lag is characteristic of the floppy infant. In vertical suspension, the hypotonic infant will slip through the examiner's hands when held under the armpits. Hyperextensibility of the joints is not a dependable criterion.

B. Laboratory Findings

A general rule for laboratory testing is to localize the etiology of the hypotonia. For instance, if a lower motor neuron etiology is suspected, a serum CK, EMG/NCS, and/or muscle biopsy may be appropriate as first tier testing. Many neuromuscular disorders may be diagnosed by clinical findings alone, as is often the case with spinal muscular atrophy and congenital myotonic dystrophy, and in those cases, genetic testing is often the first testing warranted. If the hypotonic is accompanied by language or cognitive delay, a CNS or genetic disorder is most likely, and MR imaging of the brain may be the most useful diagnostic test.

▶ Differential Diagnosis

The most common etiology of hypotonia in the neonate is hypoxic ischemic encephalopathy. Dysmorphic features may suggest a genetic etiology such as Down syndrome and Prader-Willi syndrome. Abnormalities of the hair or skin, which form from the neuroectoderm in development with the brain, may prompt an evaluation for brain malformations. Often seizures or language or cognitive delay may be accompanying features. Regression in development is often a clue for mitochondrial or metabolic disorders. Neuromuscular disorders including congenital myotonic dystrophy and spinal muscular atrophy can present as hypotonic in the infant. While the list of differential diagnosis in Table 25–28 is not complete, it describes the clinical features of some of the more common causes of hypotonia in infants and children.

Table 25–28. Floppy infant.

	LOWER MOTOR NEURON CAUSES	
Disease	**Genetic/Causes**	**Early Manifestations**
Spinal muscular atrophy (SMA)	Autosomal recessive; diagnose by deletion exons 7 and 8 in the SMN gene (98% of cases).	In-utero movements decreased in one-third. Gradual weakness, delay in gross motor milestones. Weak cry. Abdominal breathing. few spontaneous movements except of the distal extremities. No deep tendon reflexes. Fasciculations of tongue. Normal personal-social behavior.
Infantile botulism	Acquired, younger than age 1 y (mostly before age 6 mo); botulism spore in stool makes toxin.	Poor feeding. Constipation. Weak cry. Failure to thrive. Lethargy. Facial weakness, ptosis, ocular muscle palsy. Inability to suck, swallow. Apnea. Source: soil dust, honey. EMG may be helpful.

Myasthenia gravis
    Neonatal transient
 	
    Congenital
	12% of infants born from a myasthenic mother.
	
	Mother normal. Rare inherited disorder
		Floppiness. Poor sucking and feeding; choking. Respiratory distress. Weak cry. Autoimmune antibodies from mother.
		As above; may improve and later exacerbate.

Myotonic dystrophy type 1	Autosomal dominant: in 99% mother transmits gene. DNA testing 98% accurate.	Polyhydramnios; failure of suck, respirations. Facial diplegia. Ptosis. Arthrogryposis. Thin ribs. Later, developmental delay. Examine mother for myotonia, physiognomy. EMG variable in infant.
Neonatal congenital myopathy		Virtually all of the rare myopathies may have a severe (even fatal) neonatal or early infant form.
Nemaline, central core, myotubular myopathy, etc	Autosomal recessive or dominant.	Clinical features often include respiratory failure. Muscle biopsy for definitive diagnosis.
Congenital muscular dystrophy Fukayama (FCMD)	Autosomal recessive.	Early onset. Facial weakness. Joint contractures. Severe mental retardation. Seizures. Brain structural abnormalities; MRI helpful.

Infantile neuropathy
    Hypomyelinating (rare)
 	
    Benign congenital hypotonia
	HSMN most common cause.
	
	Unknown cause.
		Demyelinating or axonal; a rare cause. Rule out mimicking SMA (deletion study). EMG, NCV are key studies. Nerve biopsy.
		Diagnosis of exclusion. Family history variable. Mild to moderate hypotonia with weakness. (This term being used less with increasing genetic, microscopy advances.) Improves with time.

(*Continued*)

Table 25–28. Floppy infant. (*Continued*)

CENTRAL CAUSES		
Causes		**Manifestations**
Structural CNS causes		
Hypoxic ischemic encephalopathy	Multiple causes, detailed prenatal and perinatal history crucial	Limpness, stupor; poor suck, cry, Moro reflex, and grasp; later, irritability, increased tone and reflexes.
Brain malformations	Multiple causes, including genetic, exposures, infections	Seizures may be seen. Cognitive and language delay when older.
Syndromes with hypotonia (CNS origin)		
Trisomy 21	Genetic	All have hypotonia early.
Prader-Willi syndrome	Genetic deletion 15q11.	Hypotonia, hypomentia, hypogonadism, obesity
Marfan syndrome	Autosomal dominant.	Arachnodactyly.
Dysautonomia	Autosomal recessive.	Respiratory infections, corneal anesthesia.
Turner syndrome	45X, or mosaic.	Somatic stigmata (see Chapter 36).
Degenerative disorders		
Tay-Sachs disease	Autosomal recessive.	Cherry-red spot on macula.
Metachromatic leukodystrophy	Autosomal recessive.	Deep tendon reflexes increased early, polyneuropathy late; mental retardation.
Systemic diseases[a]		
Malnutrition	Deprivation, cystic fibrosis	
Chronic illness	Congenital heart disease; chronic pulmonary disease (eg, bronchopulmonary dysplasia); uremia, renal acidosis.	
Metabolic disease	Mitochondrial; Lowe, Pompe, Leigh disease; hypercalcemia.	
Endocrinopathy	Hypothyroid.	

[a]See elsewhere in text for manifestations.
AD, autosomal dominant; AR, autosomal recessive; EMG, electromyogram; HSMN, hereditary sensory motor neuropathy; MRI, magnetic resonance imaging; NCV, nerve conduction velocity; SMN, survival motor neuron.

▶ Treatment

Treatment for many of these disorders is supportive. Physical and occupational therapy can facilitate some progress to a varying degree. Accompanying seizures and other systemic manifestations should be controlled to optimize development.

Orthopedics

Mark A. Erickson, MD, MMM
Brendan Caprio, BS

Orthopedics is the medical discipline that deals with disorders of the musculoskeletal system. Patients with orthopedic problems generally present with one or more of the following complaints: pain, swelling, loss of function, or deformity. While the history reveals the patient's expectation, physical examination and radiographic imaging are vitally important features of orthopedic diagnosis.

▼ DISTURBANCES OF PRENATAL ORIGIN

ESSENTIALS OF DIAGNOSIS & TREATMENT

▶ Conditions are present at birth.
▶ Multiple organ systems may be involved.
▶ Treatment is aimed at maximizing function.

CONGENITAL AMPUTATIONS & LIMB DEFICIENCIES

Congenital amputations may be due to teratogens (eg, drugs or viruses), amniotic bands, or metabolic diseases (eg, maternal diabetes). Limb deficiencies are rare with an overall prevalence for all types of limb deficiencies of 0.79 per 1000. The most common cause of limb deficiencies is vascular disruption defects (prevalence of 0.22 per 1000). As a group, upper limb deficiencies occur more frequently than lower limb deficiencies, but the single most frequent form of limb deficiency is congenital longitudinal deficiency of the fibula. Children with congenital limb deficiencies, such as absence of the femur, tibia, or fibula, have a high incidence of other congenital anomalies, including genitourinary, cardiac, and palatal defects. Deficiencies usually consist of a partial absence of structures in the extremity along one side. For example, in radial club hand, the entire radius is absent, but the thumb may be either hypoplastic or completely absent. The effect on structures distal to the deficiency varies. Complex tissue defects are virtually always associated with longitudinal bone deficiency since associated nerves and muscles are not completely represented when a bone is absent.

▶ Treatment

Limb lengthening and/or contralateral limb shortening can be used to treat less severe deficiencies. More severe deficiencies are treated with a prosthesis to compensate for the length discrepancy. For certain severe anomalies, operative treatment to remove a portion of the malformed extremity (eg, foot) is indicated to allow for early prosthetic fitting. In these instances, early prosthetic fitting allows for maximization of function.

Typically, a lower extremity prosthesis would be fit at about 1 year of age allowing the child to begin ambulation at an appropriate developmental age. The prosthesis is well accepted since it becomes necessary for balancing and walking. In unilateral upper extremity amputation, the child benefits from the use of a passive mitten type prosthesis starting as early as 6 months of age. Early fitting has the advantage of instilling an accustomed pattern of proper length and bimanual manipulation. Although myoelectric prostheses have a technologic appeal, the majority of patients find the simplest construct to be the most functional. Children quickly learn how to function with their prostheses and can lead active lives.

DEFORMITIES OF THE EXTREMITIES

Metatarsus Adductus

Metatarsus adductus, a common congenital foot deformity, is characterized by inward deviation of the forefoot. When the deformity is more rigid, it is characterized by a vertical crease in the medial aspect of the arch. Angulation occurs at the base of the fifth metatarsal causing prominence of this bone. Most flexible deformities are secondary to intrauterine positioning and usually resolve spontaneously. Several investigators have noticed that 10%–15% of children with metatarsus adductus have hip dysplasia; therefore, a careful hip examination is necessary. The etiology of rigid deformities is unknown. If the deformity is rigid and cannot be manipulated past the midline, it is worthwhile to perform serial casting, with cast changes in 1–2-week intervals, to correct the deformity. Corrective shoes do not live up to their name; however, they can be used to maintain the correction obtained by casting.

Sankar WN, Weiss J, Skaggs DL: Orthopedic conditions in the newborn. J Am Acad Orthop Surg 2009;17(2):112–122 [PMID: 19202124].

Clubfoot (Talipes Equinovarus)

Classic talipes equinovarus, or clubfoot, requires three features for diagnosis: (1) plantar flexion of the foot at the ankle joint (equinus), (2) inversion deformity of the heel (varus), and (3) medial deviation of the forefoot (adductus). Clubfoot occurs in approximately 1 per 1000 live births. The three major categories of clubfoot are idiopathic, neurogenic, and those associated with syndromes such as arthrogryposis and Larsen syndrome. Infants with a clubfoot should be examined carefully for associated anomalies, especially of the spine. Idiopathic club feet may be hereditary.

▶ Treatment

Manipulation of the foot to stretch the contracted tissues on the medial and posterior aspects, followed by casting to hold the correction is the preferred treatment. Serial castings are typically performed on a weekly basis for 6–8 weeks. When instituted shortly after birth, correction is rapid. If treatment is delayed, the foot tends to become more rigid within a matter of days. Casting treatment requires patience and experience, but fewer patients require surgery when attention is paid to details of the Ponseti technique. After full correction

is obtained, a night brace is necessary for long-term maintenance of correction. Recent studies indicate that there is poor compliance with brace use following intervention with the Ponseti technique. If the foot is rigid and resistant to cast treatment, surgical release and correction are appropriate. Approximately 15%–50% of patients require a surgical release.

Ramirez N, Flynn JM, Fernandez S, Seda W, Macchiavelli RE: Orthosis noncompliance after the Ponseti method for the treatment of idiopathic clubfeet: a relevant problem that needs reevaluation. J Pediatr Orthop 2011;31(6):710–715 [PMID: 21841450].

Developmental Dysplasia of the Hip Joint

Dysplasia is the term used to describe abnormal growth or development. Dysplasia of the hip encompasses a spectrum of conditions where an abnormal relationship exists between the proximal femur and the acetabulum. In the most severe condition, the femoral head is not in contact with the acetabulum and is classified as a *dislocated hip*. In a *dislocatable hip,* the femoral head is within the acetabulum but can be dislocated with a provocative maneuver. A *subluxatable hip* is one in which the femoral head comes partially out of the joint with a provocative maneuver. *Acetabular dysplasia* is used to denote insufficient acetabular development and is a radiographic diagnosis.

Congenital dislocation of the hip more commonly affects the left hip, occurring in approximately 1%–3% of newborns. At birth, both the acetabulum and femur are underdeveloped. Dysplasia is progressive with growth unless the instability is corrected. If the dislocation is corrected in the first few weeks of life, the dysplasia can be completely reversible and a normal hip will more likely develop. If the dislocation or subluxation persists with age, the deformity will worsen until it is not completely reversible, especially after the walking age. For this reason, it is important to diagnose the deformity and institute treatment early.

▶ Clinical Findings

Clinical diagnosis of dislocations in newborns is dependent on demonstrating the instability of the joint by placing the infant on his or her back and obtaining complete relaxation. As these clinical signs can be subtle, with a crying or upset infant they can be easily missed. The examiner's long finger is then placed over the greater trochanter and the thumb over the inner side of the thigh. Both hips are flexed 90 degrees and then slowly abducted from the midline, one hip at a time. With gentle pressure, an attempt is made to lift the greater

trochanter forward. A feeling of slipping as the head relocates is a sign of instability (Ortolani sign). When the joint is more stable, the deformity must be provoked by applying slight pressure with the thumb on the medial side of the thigh as the thigh is adducted, thus slipping the hip posteriorly and eliciting a palpable clunk as the hip dislocates (Barlow sign). Limited hip abduction of less than 60 degrees while the knee is in 90 degrees of flexion is believed to be the most sensitive sign for detecting a dysplastic hip. Clinical signs of instability are more reliable than radiographs for diagnosing developmental dislocation of the hip in the newborn. Ultrasonography is most useful in newborns, and can be helpful for screening high-risk infants, such as those with breech presentation or positive family history. Asymmetrical skin folds are present in about 25% of normal newborns and therefore are not particularly helpful to diagnosing hip dislocation.

The signs of instability become less evident after the first month of life. Contractures begin to develop about the hip joint, limiting abduction to less than 90 degrees. It is important to hold the pelvis level to detect asymmetry of abduction. If the knees are at unequal heights when the hips and knees are flexed, the dislocated hip will be on the side with the lower knee. Radiological examination becomes more valuable after the first 6 weeks of life, with lateral displacement of the femoral head being the most reliable sign. An acetabular index or angle can be measured on pelvis radiographs by drawing one line horizontally through the triradiate cartilage and another line starting at the triradiate cartilage and extending to the outer edge of the acetabulum. A normal angle would be less than 30 degrees. In mild cases, increased steepness of acetabular alignment (acetabular angle > 35 degrees) may be the only abnormality.

If dysplasia of the hip has not been diagnosed before the child begins to walk, there will be a painless limp and/or a lurch to the affected side. When the child stands on the affected leg, a dip of the pelvis will be evident on the opposite side, due to weakness of the gluteus medius muscle. This is called the Trendelenburg sign and accounts for the unusual swaying gait. In children with bilateral dislocations, the loss of abduction is almost symmetrical and may be deceiving. In children with incomplete abduction during the first few months of life, a radiograph of the pelvis is indicated. As a child with bilateral dislocation of the hips begins to walk, the gait is waddling. The perineum is widened as a result of lateral displacement of the hips, and there is flexion contracture as a result of posterior displacement of the hips. This flexion contracture contributes to marked lumbar lordosis, causing the greater trochanters to be easily palpable in their elevated position. Treatment is still possible in the first 2 years of life, but the results are not as good as with early treatment. In patients older than 2 years, more aggressive procedures like osteotomies are often necessary to create a more normal orientation and shape of the hip joint.

▶ Treatment

Most unstable hips undergo spontaneous correction by 2–6 weeks of age. A Pavlik harness, which maintains reduction by placing the hip in a flexed and abducted position, can be easily used to treat dislocation or dysplasia diagnosed in the first few weeks or months of life. In order to be safely treated in a Pavlik harness, hips must be manually reducible with only gentle manipulation. Forced abduction, or reduction requiring extremes of motion for stability, can lead to avascular necrosis of the femoral head and is contraindicated. The use of double or triple diapers is ineffective. An orthopedic surgeon with experience managing the problem is best to supervise treatment.

In the first 4 months of life, reduction can be obtained by simply flexing and abducting the hip with a Pavlik harness; no other manipulation is usually necessary. In late cases, preoperative traction for 2–3 weeks may assist by relaxing soft tissues about the hip. Following traction, in which the femur is brought down opposite the acetabulum, reduction can typically be achieved, without force, under general anesthesia. A hip spica cast is used for 3 months after reduction. If the hip is not stable within a reasonable range of motion after closed reduction, open reduction is indicated. If reduction is done at an older age, operations to correct the deformities of the acetabulum and femur, as well as open reduction, may be necessary. Older children are more likely to experience complications from more extensive procedures.

Delaney LR, Karmazyn B: Developmental dysplasia of the hip: background and the utility of ultrasound. Semin Ultrasound CT MR 2011;32:151–156 [PMID: 21414550]

Sewell MD, Roendah K, Eastwood DM: Developental dysplasia of the hip. BMJ 2009;339:b4454. Doi: 10.1136/bmj.b4454 [PMID: 19934187].

Torticollis

Injury to the sternocleidomastoid muscle during delivery or disease affecting the cervical spine in infancy, such as congenital vertebral anomalies, may cause torticollis. When contracture of the sternocleidomastoid muscle causes torticollis, the chin is rotated to the side opposite of the affected muscle, causing the head to tilt toward the side of the contracture. A mass felt in the midportion of the sternocleidomastoid muscle in a newborn is likely a hematoma or developmental fibroma, rather than a true tumor.

If the deformity is left untreated, a striking facial asymmetry can persist. Passive stretching is an effective treatment in up to 97% of all cases. If the deformity does not correct with passive stretching during the first year of life, surgical release of the muscle origin and insertion can be an effective treatment option. Excising the "tumor" of the sternocleidomastoid muscle is unnecessary and creates an unsightly scar.

Torticollis is occasionally associated with congenital deformities of the cervical spine. Radiographs of the spine are indicated in most cases where such anomalies are suspected. In addition, there is a 15%–20% incidence of associated hip dysplasia.

Acute torticollis may follow upper respiratory infection or mild trauma in children. Upper respiratory infections may lead to swelling in the upper cervical spine, particularly at the C1-C2 region. This swelling renders the C1-C2 articulation susceptible to rotatory subluxation, which commonly presents as a clinical picture of torticollis. Rotatory subluxation of the upper cervical spine requires computed tomography for accurate assessment. Traction or a cervical collar usually results in resolution of the symptoms within 1 or 2 days. Other causes of torticollis include spinal cord and cerebellar tumors, syringomyelia, and rheumatoid arthritis.

GENERALIZED DISORDERS OF SKELETAL OR MESODERMAL TISSUES

Arthrogryposis Multiplex Congenita (Amyoplasia Congenita)

▶ Clinical Findings & Diagnosis

Arthrogryposis multiplex congenita (AMC) consists of incomplete fibrous ankylosis (usually bilateral) of many or all joints of the body. AMC affects both genders equally and occurs in approximately 1 in 2–3000 live births. Upper extremity contractures usually consist of adduction of the shoulders; extension of the elbows; flexion of the wrists; and stiff, straight fingers with poor muscle control of the thumbs. Common deformities of the lower extremities include dislocation of the hips, extension contractures of the knees, and severe club feet. The joints are fusiform and the joint capsules decreased in volume due to lack of movement during fetal development. Muscle development is poor, and may be represented only by fibrous bands. Various investigations have attributed the basic defect to an abnormality of muscle or lower motor neurons.

It is possible to diagnose AMC during routine fetal ultrasound scanning. The fetus will be in an abnormal position or lack mobility. Early diagnosis helps the family and provider with delivery planning and counseling.

▶ Treatment

Passive mobilization of joints is the early treatment. Prolonged casting results in further stiffness and is not indicated. Removable splints combined with vigorous therapy are the most effective conservative treatment; however, surgical release of the affected joints is often necessary. Clubfoot associated with arthrogryposis is very stiff and nearly always requires surgical correction. Knee surgery, including capsulotomy, osteotomy, and tendon lengthening, is used to correct deformities. In young children, a dislocated hip may be reduced operatively by a medial approach. Multiple operative hip procedures are contraindicated, as they may further stiffen the hip dislocation with consequent impairment of motion. Affected children are often able to walk if the dislocations and contractures are reduced surgically. The long-term prognosis for physical and vocational independence is guarded. These patients have normal intelligence, but they have such severe physical restrictions that gainful employment is hard to find.

Marfan Syndrome

Marfan syndrome is a connective tissue disorder characterized by unusually long fingers and toes (arachnodactyly); hypermobility of the joints; subluxation of the ocular lenses; other eye abnormalities, including cataract, coloboma, megalocornea, strabismus, and nystagmus; a high-arched palate; a strong tendency to scoliosis (60% of all those diagnosed); pectus carinatum (an outward protrusion of the sternum); and thoracic aortic aneurysms due to weakness of the media of the vessels (see Chapter 37). Fibrillin-1 gene mutations are commonly associated with Marfan syndrome. Serum mucoproteins may be decreased, and urinary excretion of hydroxyproline increased. The condition is easily confused with homocystinuria, because the phenotypic presentation is nearly identical. The two diseases are differentiated by detecting homocystine in the urine of patients with homocystinuria.

Treatment is usually supportive and includes management of blood pressure and restriction of physical activity. Scoliosis may involve more vigorous treatment by bracing or spine fusion. The long-term prognosis has improved for patients since the development of better treatment of their aortic aneurysms.

Yuan SM, Jing H: Marfan syndrome: an overview. San Paulo Med J 2010;128(6):360–366 [PMID: 21308160].

Klippel-Feil Syndrome

Klippel-Feil syndrome is characterized by failure of segmentation of some or all of the cervical vertebrae. Multiple congenital spinal anomalies may be present, with hemivertebrae and scoliosis. The neck is short and stiff, the hairline is low, and the ears are low-set. Congenital scoliosis, cervical rib, spina bifida, torticollis, web neck, high scapula, renal anomalies, and deafness are commonly associated defects. Renal ultrasound as well as a hearing test are indicated if there is evidence of abnormal renal function. Surgical intervention is necessary to prevent neurologic injury in symptomatic patients who present with unstable spinal anomalies. If asymptomatic, a spine surgeon will determine if surgical intervention is warranted after review of patient's age, history, and activity level. Spinal arthrodesis is indicated if progressive scoliotic deformities develop.

Kim HJ: Cervical spine anomalies in children and adolescents. Curr Opin Pediatr 2013;25(1):72–77 [PMID: 23263023].

Sprengel Deformity

Sprengel deformity is a congenital condition where one or both scapulas are elevated and hypoplastic. The deformity prevents the arm from raising completely on the affected side, and torticollis may be an associated finding. The deformity occurs alone or in association with Klippel-Feil syndrome or scoliosis and rib abnormalities. If the deformity is functionally limiting, the scapula may be surgically relocated closer to the normal anatomic position. Surgical intervention improves cosmetic appearance and function.

Mooney JF 3rd, White DR, Glazier S: Previously unreported structure in Sprengel deformity. J Pediatr Orthop 2009;29(1):26–28 [PMID: 19098640].

Osteogenesis Imperfecta

Osteogenesis imperfecta is a rare genetic connective tissue disease characterized by multiple and recurrent fractures. The incidence is 1 in 15,000–20,000. Clinical features of the disease lead to diagnosis in the majority of cases. The severe fetal type (osteogenesis imperfecta congenita) is distinguished by multiple intrauterine or perinatal fractures. Moderately affected children have numerous fractures and exhibit dwarfism as a result of their acquired bone deformities and growth retardation. Fractures begin to occur at different times and in variable patterns after the perinatal period, resulting in fewer fractures and deformities relative to severe cases. Cortical thickness is reduced in the shafts of the long bones, and accessory skull bones that are completely surrounded by cranial sutures (wormian bones) are present in the skull. Blue sclerae, thin skin, hyperextensibility of ligaments, otosclerosis with significant hearing loss, and hypoplastic and deformed teeth are characteristic of osteogenesis imperfecta. Cardiovascular and respiratory problems are the most common causes of morbidity and mortality in adulthood. Intelligence is not affected. Affected patients are sometimes suspected of having suffered abuse. Osteogenesis imperfecta should be ruled out in any case of potential non-accidental trauma.

Molecular genetic studies have identified more than 150 mutations of the *COL1A1* and *COL1A2* genes, which encode for type I procollagen. Ninety percent of cases occur as the result of a spontaneous mutation; in these families the likelihood of a second affected child is negligible. Among the other 10%, a recessive mode of inheritance has been identified in 2%–5%.

Bisphosphonates have been shown to decrease the incidence of fractures. Surgical treatment involves deformity correction of the long bones. Multiple intramedullary rods have been used to prevent deformity from fracture malunion. Patients are often confined to wheelchairs during adulthood.

Osteopetrosis (Osteitis Condensans Generalisata, Marble Bone Disease, Albers-Schönberg Disease)

Osteopetrosis is a rare disorder of osteoclastic resorption of bone, resulting in abnormally dense bones. The reduced marrow spaces result in anemia. There are two types: a milder autosomal dominant type and a more malignant autosomal recessive type. The findings may appear at any age. Radiologic examination shows increased bone density and transverse bands in the shafts, clubbing of ends, and vertical striations of long bones. Thickening about the cranial foramina is present, and heterotopic calcification of soft tissues is possible. Diminished life expectancy is seen in severe infantile forms.

Treatment is largely symptomatic. The most severe autosomal recessive forms of osteopetrosis can be treated successfully by hematopoietic stem cell transplantation.

Michou L, Brown JP: Genetics of bone diseases Paget's disease, fibrous dysplasia, osteopetrosis, and osteogenesis imperfecta. Joint Bone Spine 2011;(78):252–258 [PMID: 20855225].

Achondroplasia (Classic Chondrodystrophy)

Achondroplasia is the most common form of short-limbed dwarfism. The upper arms and thighs are proportionately shorter than the forearms and legs. Skeletal dysplasia is suspected based on abnormal stature, disproportion, dysmorphism, or deformity. Measurement of height is an excellent clinical screening tool. Findings frequently include bowing of the extremities, a waddling gait, limitation of motion of major joints, relaxation of the ligaments, short stubby fingers of almost equal length, frontal bossing, midface hypoplasia, otolaryngeal system dysfunction, moderate hydrocephalus, depressed nasal bridge, and lumbar lordosis. Intelligence and sexual function are normal. While this disorder has an autosomal dominant transmission pattern, 80% of cases result from a random mutation in the fibroblast growth factor receptor-3 (*FGFR3*) gene. Radiographs demonstrate short, thick tubular bones and irregular epiphysial plates. The ends of the bones are thick, with broadening and cupping. Epiphysial ossification may be delayed. Due to diminished growth in the spinal pedicles, the spinal canal is narrowed (congenital stenosis), and a herniated disk in adulthood may lead to acute paraplegia. Growth hormone is given to some children with bone dysplasia. Limb lengthening is possible, but controversial.

Shirley ED, Ain MC: Achondroplasia: manifestations and treatment. J Am Acad Orthop Surg 2009;(17):231–241 [PMID: 19307672].

Osteochondrodystrophy (Morquio Disease)

Morquio disease is an autosomal recessive disorder affecting mucopolysaccharide storage. Skeletal abnormalities include shortening of the spine, kyphosis, scoliosis, shortened extremities, pectus carinatum, genu valgum or "knock knees," and a hypoplastic odontoid with atlantoaxial instability. Appearance is generally normal at birth, with deformities developing between ages 1 and 4 years as a result of abnormal deposition of mucopolysaccharides. Increased urinary glycosaminoglycan levels are associated with increased severity.

Radiographs demonstrate wedge-shaped flattened vertebrae and irregular, malformed epiphyses. The ribs are broad and have been likened to canoe paddles. The lower extremities are more severely involved than the upper extremities. Progressive hip subluxation, genu valgum, and ankle valgus often require surgical intervention.

The major treatment issue revolves around prevention of cervical myelopathy. Bone marrow transplantation has been successful in alleviating some symptoms. Enzyme replacement therapy has emerged as another possible treatment option for afflicted patients. Prognosis depends on age of onset.

Valayannopoulos V et al: Mucopolysaccharidosis VI. Orphanet J Rare Dis. 2010 Apr 12;5:5. doi: 10.1186/1750-1172-5-5. Review [PMID: 20385007].

▼ GROWTH DISTURBANCES OF THE MUSCULOSKELETAL SYSTEM

SCOLIOSIS

Scoliosis is characterized by lateral curvature of the spine associated with rotation of the involved vertebrae and classified by its anatomic location, in either the thoracic or lumbar spine, with rare involvement of the cervical spine. The convexity of the curve is designated right or left. A right thoracic scoliosis would denote a thoracic curve with convexity to the right. This is the most common type of idiopathic curve. Kyphosis or posterior curvature of the spine is normal in the thoracic area, although excessive curvature is pathologic. Anterior curvature of the spine, or lordosis, is normal in the lumbar and cervical spine regions.

Eighty percent of cases of scoliosis are idiopathic. Idiopathic scoliosis typically develops around age 8–10 years, with progression occurring during periods of rapid skeletal growth. In rare instances, infantile scoliosis may be seen in children age 3 years or younger; idiopathic infantile scoliosis is much more common in Great Britain than in the United States. In infantile scoliosis, if the rib-vertebral angle of Mehta is less than 20 degrees, the curve will likely resolve spontaneously. If the angle is greater, the curve will likely progress.

Idiopathic scoliosis is about four or five times more common in girls. The disorder is usually asymptomatic in the adolescent years, but severe curvature can progress during adulthood causing pain or, in extreme cases, diminished pulmonary function as a result of reduced lung volumes due to deformity of the rib cage. The screening examination for scoliosis is performed by having the patient bend forward 90 degrees with the hands joined in the midline. Asymmetry of the height of the ribs or paravertebral muscles on one side indicates rotation of the trunk associated with lateral curvature. Because 30% of family members are also affected, siblings of an affected child should be examined.

Neurofibromatosis, Marfan syndrome, cerebral palsy, muscular dystrophy, poliomyelitis, and myelodysplasia are among several diseases that may be present with an associated scoliosis.

Congenital vertebral anomalies such as hemivertebra or unilateral vertebral bar account for 5%–7% of all scoliosis. These curves are more rigid than the more common idiopathic curve and will often increase with skeletal growth, especially during adolescence.

Olisthetic scoliosis may result from pressure on the spinal cord or roots by infectious processes or herniation of the nucleus pulposus; the underlying cause must be sought. Secondary curvature will resolve as the primary problem is treated.

▶ Clinical Findings

A. Symptoms and Signs

Scoliosis in adolescents does not typically cause significant pain. If a patient has significant pain, then the source of the pain should be sought in order to rule out the possibility of some other disorder such as infection or tumor. Deformity of the rib cage and asymmetry of the waistline are clinically evident for curvatures of 30 degrees or more. Lesser curves may be detected through the forward bending test, which is designed to detect early abnormalities of rotation that may not be apparent when the patient is standing erect.

B. Imaging

Radiographs taken of the entire spine in the standing position in both the anteroposterior and lateral planes are the most valuable for diagnosis. Usually a primary curve is evident with compensatory curvature to balance the body. At times two primary curvatures may be seen (usually in the right thoracic and left lumbar regions). A left thoracic curvature should be suspected of being secondary to neurologic disease and prompt a more meticulous neurologic examination. If the curvatures of the spine are balanced (compensated), the head is centered over the center of the pelvis. If the spinal alignment is uncompensated, the head will be displaced to one side, which produces an unsightly deformity. Rotation of the spine may be measured with a scoliometer. Rotation is associated with a marked rib hump as the lateral curvature increases in severity.

▶ Treatment

Treatment of scoliosis depends on the curve magnitude, skeletal maturity, and risk of progression. Treatment is indicated for any curvature that demonstrates progression on serial radiologic examination. Definitive spinal fusions should be delayed as long as possible in young children through the use of casting, bracing, and growth modulating surgeries such as growing rods or vertical expandable prosthetic titanium ribs (VEPTR).
